Proceedings of the 36th ASMS Conference on Mass Spectrometry and Allied Topics

June 5 - 10, 1988
San Francisco, California

THE 36th ASMS CONFERENCE ON MASS SPECTROMETRY AND ALLIED TOPICS
June 5-10, 1988

TABLE OF CONTENTS

INTRODUCTION iv

ASMS BOARD OF DIRECTORS v

ASMS COMMITTEES v

CORPORATE MEMBERS vi

ASMS INTEREST GROUPS viii

LISTING OF EXTENDED ABSTRACTS ix

Monday Morning
- Symposium: Elemental and Isotopic Analysis by Mass Spectrometry 1
- Ion Molecule Reactions. Chemical and Atmospheric Ionization 11
- Environmental Mass Spectrometry 29
- Cluster Ions. Ion Activation. Biomedical Mass Spectrometry 49

Monday Afternoon
- Symposium: Mass Spectrometry and Complex Lipids 198
- Isotopic and Elemental Analysis 202
- Symposium: Cluster Ion Mass Spectrometry 224
- Environmental. Fuels and Geoscience. SIMS and Surface Analysis 230

Tuesday Morning
- Plenary Lecture 363
- Symposium: Mass Education 365
- Cluster Ions. Ion Activation 367
- Lipid Biochemistry 385
- Peptides. Polymers. Nucleic Acids. Isotopic, Inorganic and Elemental 405

Tuesday Afternoon
- Symposium: Measurement of Peptides 549
- Reaction Mechanisms I 557
- Symposium: Environmental Fate of Organo-Chlorine Cmpds. in the Atmosphere 575
- Ion Traps and FT-ICR. Ion Molecule Reactions. Chem. and Atmospheric Inztn 586

Wednesday
- Plenary Lecture 727
- Symposium: Applications of Continuous-Flow FAB 729
- Reaction Mechanisms II 741
- Ionization Methods 763
- Instrumentation. Lipids. Environmental Applications of LC/MS 783

Thursday Morning
Oligosaccharides, Nucleic Acids, and General Biochemistry 921
Symposium: Crossing the Solution-Vacuum Barrier 939
Instrumentation 948
Pharmacology and Drugs. LC/MS Applications 970

Thursday Afternoon
Ion Traps and FT-ICR 1106
Symposium: The Drug Industry in Japan 1130
Peptides 1136
Ionization Methods. LC/MS Instrumentation and Techniques. Oligosaccharides 1156

Friday Morning
Plenary Lecture 1299
Symposium: Ion Trapping - Methods and Applications 1302
Liquid Introduction Mass Spectrometry 1308
A Mass Spectral Potpourri 1326

INDEX OF AUTHORS 1427

MINUTES OF THE ASMS BUSINESS MEETING 1440

MEMORIAL PAGE 1443

Terms to Use in Your Research Presentation 1444

COMMITTEE, INTEREST GROUP AND WORKSHOP REPORTS
Academic Laboratory Managers Interest Group 1445
Biomedical Interest Group 1446
Analysis of Drugs and Drug Metabolites by Tandem MS 1447
Education Committee 1448
Ethics in the Workplace 1449
Environmental Interest Group 1450
New Ionization Techniques for Environmental MS 1451
Fundamentals Interest Group 1452
Making Metal Ions 1453
History of Mass Spectrometry Interest Group 1455
Instrumentation and Ion Physics Interest Group 1457
Isotope Ratio Interest Group 1458
Isotope Ratio Mass Spectrometry - A look to the Future 1459
Measurement and Standards Committee 1460
Quantitative Analysis of Peptides 1462
Solids and Surface Analysis Interest Group 1464
Use of Mass Spectrometry in Space 1466
Young Mass Spectrometrists Interest Group 1468

1988 ASMS MEMBERS AND CONFERENCE ATTENDEES 1469

INTRODUCTION

By action of the ASMS Board of Directors, this official record of the annual meeting will henceforth be known as the Proceedings instead of the more informal term "bound volume". Thus, the 1988 designation is Proceedings of the 36th ASMS Conference on Mass Spectrometry and Allied Topics.

The extended abstracts that comprise the bulk of the Proceedings provide a valuable and timely view of the most current research in this very dynamic field. A large number (more than 90 %) of those presenting papers and posters at the conference contribute extended abstracts to the Proceedings. Also included in the Proceedings are workshop and interest group reports and a directory of names, addresses, and telephone numbers of members and conference attendees.

The efforts of Judith A. Watson and her staff of Professional Association Management, Inc. in compiling the Proceedings and arranging for timely printing and distribution in a cost effective manner are gratefully acknowledged. The work presented here also reflects the hard work and creativity of the Vice-President for Programs, Ronald A. Hites, in arranging the technical program.

The Proceedings find a greater audience each year and form a valuable asset to the members of the Society. No doubt there are ways it could be improved, and suggestions or comments directed toward making this a more useful resource are appreciated.

Willard W. Harrison
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

Author(s); title; Proceedings of the 36th ASMS Conference on Mass Spectrometry and Allied Topics, San Francisco, California, June 5-10, 1988.

BOARD OF DIRECTORS

President	Gerry G. Meisels 1223 Old Father Hall Univeristy of Nebraska Lincoln, NE 68588
Vice President for Programs	Ronald A. Hites SPEA 410H Indiana University Bloomington, IN 47405
Vice President for Arrangements	Gary L. Glish Oak Ridge National Laboratory Analytical Chemistry Division Oak Ridge, TN 37831
Secretary	Susan T. Weintraub University of Texas Health Science Center San Antonio, TX 78284
Treasurer	Kelsey D. Cook Department of Chemistry University of Tennessee Knoxville, TN 37996
Member-at-Large (Publications)	Willard W. Harrison Department of Chemistry University of Virginia Charlottesville, VA 22901
Member-at-Large Education	Christie G. Enke Department of Chemistry Michigan State University East Lansing, MI 48824
Member-at-Large (Measurements and Standards)	Paul C. Goodley Hewlett-Packard Co. 1601 California Avenue Palo Alto, CA 94304
Past President	R. Graham Cooks Department of Chemistry Purdue University West Lafayette, IN 47907

SOCIETY OFFICE

Post Office Box 1508
East Lansing, MI 48826-1508

Courier address
750 Audubon Road
East Lansing, MI 48823

ASMS COMMITTEES

Nominating	P. Jane Gale, Chair Lazlo Tokes Klaus Biemann James A. McCloskey Marvin Vestal
Education	Harry S. Hertz, Chair Paul C. Goodley Ann G. Goetz Alfred Yergey
Measurements and Standards	Henry M. Fales, Chair Ronald Grigsby William Budde Douglas Cameron

ASMS INTEREST GROUPS

The following is a brief decription of the role of each interest group as provided by their coordinators.

Academic Laboratory Managers, *Richard W. Kondrat*
The problems encountered by those responsible for academic service mass spectrometry facilities.

Biomedical Applications, *Richard M. Caprioli*
Mass spectrometric relevance to biological and medical systems, including areas such as enzymology, macromolecular sequencing, metabolic screening, natural products, etc.

Computer Applications, *Jon D. Onstot*
Enhancement of the science of mass spectrometry by exploitation of computer technology either through electronic data acquisition, data processing, artificial intelligence or other technologies.

Environmental Applications, *Michelle V. Buchanan*
The development and application of mass spectrometry and related techniques to the qualitative and quantitative analysis of chemicals in environmental systems.

Fundamentals, *Keith R. Jennings*
The chemistry of gas phase ions including structural, spectroscopic, thermodynamic and kinetic properties and their influence on other areas of mass spectrometry.

History of Mass Spectrometry, *Robert W. Kiser*

Instrumentation and Ion Physics, *Scott A. McLuckey*
Techniques for forming, transporting, analyzing, and detecting charged particles with the goal of improving mass spectrometry as a research tool.

Isotope Ratio Measurements, *Philip H. Hemberger*
The application and development of isotope ratio mass spectrometry in all areas of science, including but not limited to archeology, atmospheric science, geology, medicinal chemistry, and nuclear science.

Physical Organic Mass Spectrometry, *John L. Holmes*
The physiochemical processes taking place among organic ions in the gas phase.

Pharmacology, *James Vrbanac*
The structural and quantitative analysis of drugs and their metabolites, and of endogenous bioactive compounds and their metabolites.

Solids, Surface Analysis and Inorganic Materials, *Peter J. Todd*
The application of mass spectrometry to the study of solid-state materials and processes, including the determination of the elemental and chemical composition and structure of bulk solids or solid surfaces and the characterization of atomic and molecular adsorbates.

Young Mass Spectrometrists, *Mark M. Ross*
The support and advancement of mass spectrometrists in the early stages of their careers.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Symposium: Elemental and Isotopic Analysis by Mass Spectrometry.

ELEMENTAL AND ISOTOPIC ANALYSIS BY SECONDARY ION MASS SPECTROMETRY 1
*MAGEE, C W

NONRESONANT MULTIPHOTON IONIZATION FOR SENSITIVE ELEMENTAL ANALYSIS 3
*BECKER, C H AND PALLIX, J B

SOLIDS ELEMENTAL ANALYSIS BY GLOW DISCHARGE MASS SPECTROMETRY 5
*HARRISON, W W

THE DEVELOPMENT OF HIGH PRECISION MASS SPECTROMETRY 7
*BARNES, I L

ADVANCES IN THERMAL IONIZATION MASS SPECTROMETRY 9
*PAPANASTASSIOU, D A

Ion Molecule Reactions. Chemical and Atmospheric Ionization.

LIGAND SUBSTITUTION REACTION OF 17 ELECTRON METAL CARBONYL RADICAL ANIONS IN GAS PHASE 11
*PAN, Y AND RIDGE, D P

A FTMS STUDY OF METAL-CATALYZED OLIGOMER FORMATION IN THE GAS PHASE 13
*BJARNASON, A AND TAYLOR, J W

EXPERIMENTAL EVIDENCE FOR THE FORMATION OF H*3 BY H+5/e DISSOCIATIVE RECOMBINATION 15
MIDERSKI, C A AND *GELLENE, G I

KINETIC ENERGY RELEASE DISTRIBUTIONS IN THE DISSOCIATION OF ION-DIPOLE COMPLEXES 17
*BASS, L M,ROEHL, C AND BOWERS, M T

A MASS SPECTROMETRIC AND AB INITIO CALCULATION STUDY OF THE POTENTIAL ENERGY SURFACE FOR REACTIONS OF CARBENE-LIKE CATIONS 19
*FISHER, J J AND MCMAHON, T B

AN INVESTIGATION OF THE GAS PHASE BASE CATALYZED ALDOL REACTION: COLLISION INDUCED DISSOCIATION OF -HYDROXY-CARBONYL NEGATIVE IONS 21
*HAYES, R N,GRESE, R P AND GROSS, M L

GAS-PHASE ELECTROPHILIC SUBSTITUTION REACTIONS OF ORGANOSILANES 23
HAJDASZ, D J AND *SQUIRES, R R

TEMPERATURE DEPENDENCE OF API SENSITIVITY 25
IKONOMOU, M,KEBARLE, P AND *SUNNER, J

ON THE REACTIVITY OF NO+ TO LOCATE CC DOUBLE BONDS IN ALIPHATIC COMPOUNDS USING A QUADRUPOLE TRIPLE ANALYZER INSTRUMENT 27
*EINHORN, J,ROLONDO, C AND MALOSSE, C

Environmental Mass Spectrometry

QUANTITATIVE DETERMINATION OF SELECTED COMPOUNDS IN CIGARETTE MAINSTREAM SMOKE USING MULTI-DIMENSIONAL GAS CHROMATOGRAPHY AND SELECTED-ION-MONITORING MASS SPECTROMETRY 29
*WHITE, E L,UHRIG, M S,GORDON, B M,NANNI, E J,BORGERDING, M F AND HICKS, R D

ANALYSIS OF ETHYL DIMETHYLPHOSPHORAMIDOCYANIDATE (TABUN) BY CAPILLARY COLUMN GAS CHROMATOGRAPHY-MASS SPECTROMETRY 30
*D'AGOSTINO, P A,PROVOST, L R AND LOOYE, K M

HPLC/MS AND HPLC/MS/MS ANALYSIS OF WASTE SAMPLES FOR ORGANOPHOSPHOROUS PESTICIDES 32
*BETOWSKI, L D AND JONES, T L

ON-COLUMN GC/MS OF NON-IONIC DYES 34
*ROSEN, R T,ROVIN, L H,HARTMAN, T G,OXENFORD, J,HO, C T AND ROSEN, J D

THE APPLICATION OF A HIGH RESOLUTION MASS SPECTROMETRIC METHOD FOR MEASURING 2,3,7,8-TCDD IN HUMAN ADIPOSE TISSUE AND SERUM 36
*PATTERSON, D G,ALEXANDER, L R,TURNER, W E,NEEDHAM, L L,ANDREWS, J S, PIRKLE, J L AND SAMPSON, E J

DETECTION OF POLYCHLORINATED TERPHENYLS BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY WITH NEGATIVE CHEMICAL IONIZATION 38
*GREAVES, J AND HALE, R

LASER DESORPTION MASS SPECTROMETRY OF HIGH MOLECULAR WEIGHT PAH FROM HYDROCARBON SOOTS 39
*SO, H Y AND WILKINS, C L

CAD ANALYSIS OF METHYL PAH: FUSED-RING TROPYLIUM ION FORMATION AND FRAGMENTATION 41
*STANDLEY, L J AND HITES, R A

THE ANALYSIS OF ORGANIC COMPOUNDS IN DRINKING WATERS BY MASS SPECTROMETRY: SOME REMAINING PROBLEMS 43
*JAMES, H A,GIBSON, T M AND HAMMOND, I

VOLATILE ORGANIC ANALYZER FOR SPACECRAFT AIR QUIALITY MONITORING 45
*GALEN, T J AND PIERSON, D L

TRACE ANALYSIS FOR ORGANICS IN AIR USING AN ATMOSPHERIC SAMPLING GLOW DISCHARGE IONIZATION SOURCE 47
GRANT, B C,*ASANO, K G,GLISH, G L AND MCLUCKEY, S A

Cluster Ions. Ion Activation. Biomedical Mass Spectrometry

MIXED CLUSTER ION FORMATION BETWEEN SMALL MOLECULES AND H2SO4 49
*SHARP, T R

LARGE CARBON CLUSTER FORMATION BY LASER ABLATION OF POLYIMIDE 51
*CREASY, W R AND BRENNA, J T

LITHIUM AND SODIUM CLUSTERS EMITTED FROM LIQUID METAL ION SOURCE 53
SAITO, Y,MINAMI, K,ISHIDA, T,INOUE, M,NISHIGAKI, S AND *NODA, T

FORMATION, FRAGMENTATION, AND REACTIONS OF TRANSITION-METAL/OXYGEN CLUSTERS 55
*YU, W AND FREAS, R B

HCN REACTIONS REVEAL NEW CARBON CLUSTER ION ISOMERS 57
*PARENT, D C AND MCELVANY, S W

A STUDY OF THE MASS SPECTRA OF COBALT(II) SALTS OF ORGANIC ACIDS 59
SUN, Z L,DONG, Z W,LIN, C H AND *CAO, Z M

SIGNIFICANCE OF CLUSTER IONS IN THE GENERATION OF FAST ATOM BOMBARDMENT MASS SPECTRA 61
*PERREAULT, H AND BERTRAND, M J

MEASUREMENTS OF ION DISSOCIATION IN A REFLECTING TIME-OF-FLIGHT MASS SPECTROMETER 63
*MAYER, F,ENS, W,SCHUELER, B,STANDING, K G,TANG, X AND WESTMORE, J B

TANDEM MASS SPECTROMETRIC ANALYSIS OF THE FIRST PERFLUORINATED CRYPTAND: 4,7,13,21, 24-HEXAOXA-1,10-BIAZABICYCLO[8.8.8]HEXACOSANE 65
*MALEKNIA, S,CLARK, W D AND LAGOW, R J

REACTIVE AND DISSOCIATIVE COLLISIONS AT A METAL SURFACE IN A TANDEM TIME-OF-FLIGHT INSTRUMENT 67
*SCHEY, K L,COOKS, R G,KRAFT, A,GRIX, R AND WOLLNIK, H

FRAGMENTATION OF THE [M-H]- IONS OF SOME SULFOXIDES AND SULFONES 69
*CHOWDHURY, S AND HARRISON, A G

ISOMER IDENTIFICATION BY METASTABLE DECAY RATES OF LASER PRODUCED IONS 71
*KINSEL, G R AND JOHNSTON, M V

A NEW METHOD OF SURFACE INDUCED DISSOCIATION FOR MASS SPECTROMETRY 73
*ABERTH, W

APPEARANCE POTENTIAL MEASURMEMENTS ON SULFURIC ACID VAPOR 75
SNOW, K B AND *THOMAS, T F

CID OF ISOTOPICALLY LABELLED SURFACTANTS 77
*TUINMAN, A AND COOK, K

ION KINETICS IN THE ACCELERATION REGION 79
*MARCH, R E,HUGHES, R J,KOYANAGI, G K AND MCMAHON, A W

DYNAMICS OF COLLISION-INDUCED DISSOCIATION OF ACETONE IONS 81
*SHUKLA, A,SOHLBERG, K AND FUTRELL, J H

ENERGY UPTAKE IN COLLISIONAL ACTIVATION 83
*GIBLIN, D E AND GROSS, M L

PHOTODISSOCIATION OF 2-METHYL-1-PENTEN-3-YNE 85
*FAULK, J AND DUNBAR, R C

CHOPPED-LASER TWO-PHOTON PHOTODISSOCIATION MEASUREMENT OF COLLISIONAL RELAXATION IN EXCITED BENZENE IONS 87
*AHMED, M S AND DUNBAR, R C

INTERNAL ENERGY DISTRIBUTIONS DETERMINED FOR COLLISIONALLY SCATTERED Fe(CO)5 IONS USING ANGLE RESOLVED TECHNIQUES 89
*HORNING, S R,VINCENTI, M AND COOKS, R G

LASER INDUCED PHOTODISSOCIATION OF C5H5+ IONS DERIVED FROM DIFFERENT NEUTRALS 91
*MOINI, M,OZTURK, F AND EYLER, J R

HIGH RESOLUTION LASER-ION BEAM PHOTODISSOCIATION STUDIES OF THE CLUSTER FRAGMENTS OF IRON CARBONYLS 93
*TECKLENBURG, R E AND RUSSELL, D H

STUDIES OF THE ACTIVATION AND DISSOCIATION OF DANSYL AND DINITROPHENYL DERIVATIZED PEPTIDES 95
*TECKLENBURG, R E AND RUSSELL, D H

LASER-ION BEAM PHOTODISSOCIATION UTILIZING A BIASED ACTIVATION CELL 97
SELLERS-HANN, L,*TECKLENBURG, R E AND RUSSELL, D H

COLLISION-INDUCED DISSOCIATION REACTIONS OF DOUBLY-CHARGED MOLECULAR IONS OF POLYCYCLIC AROMATIC HYDROCARBONS 99
*BOYD, R K,JAMIESON, W D AND SIM, P G

THE DISSOCIATION DYNAMICS OF ION-DIPOLE COMPLEXES: HCL LOSS FROM ETHYL CHLORIDE 101
*MORROW, J C,BAER, T AND SHAO, J D

SOLID FAB MS AND FAB MS/MS FOR THE GENERATION AND STUDY OF SOME UNUSUAL SPECIES 103
*CALDWELL, K,DAVOLI, E AND GROSS, M L

A GEOMETRIC MODEL FOR SIMULATING THE SHAPES OF ION KINETIC ENERGY RELEASE SIGNALS 105
*KOYANAGI, G K AND MARCH, R E

DIRECTIONAL PROPERTIES IN PHOTODISSOCIATION STUDIED IN A LASER-TOF-MS SYSTEM 107
*MARCUS, P,PLATZNER, I,BAR, I AND ROSENWAKS, S

REACTION-INDUCED MASS DISCRIMINATION IN XQQ INSTRUMENTS: ABSOLUTE CROSS SECTIONS FOR N+2* + SF6 -- N2 + SF+X (X=1-5) 109
*MARTINEZ, R I AND GANGULI, B

A COMPARISON OF DAUGHTER ION SPECTRA OBTAINED USING HYBRID AND 4-SECTOR TANDEM MASS SPECTROMETERS 111
*GASKELL, S J,REILLY, M H,CARR, S A,ROBERTS, G D AND VICKERS, R

THE EFFECT OF CHEMICAL IONIZATION ON COLLISION INDUCED FRAGMENTATION IN THE THERMOSPRAY SOURCE 113
*BENCSATH, F A

THE MS/MS OF DOUBLY CHARGED IONS 115
BARBER, M,*BELL, D J,MORRIS, M,TETLER, L W,WOODS, M,MONAGHAN, J J AND MORDEN, W E

ELEMENTAL AND ISOTOPIC ANALYSIS BY SECONDARY ION MASS SPECTROMETRY

Charles W. Magee
Evans East, Inc.
666 Plainsboro Road, Suite 1236
Plainsboro, New Jersey 08536

Secondary ion mass spectrometry has been used for elemental and isotopic analysis for over 20 years. Yet, contrary to what one might expect, the technique is not a mature one by almost any measure one would like to make. Instrumentation is still evolving. The theory of ion production is still not understood. Most importantly, however, as the materials research community develops new technologies and continues to shrink the dimensions of current technology, SIMS analysts and instrument developers are forced to push the technique to its limits in order to provide answers to questions which continue to get more difficult. The current state of SIMS as applied to elemental and isotopic analysis will be reviewed, with emphasis on the following areas:

Bulk elemental detection limits
Bulk elemental precision and accuracy
Depth profiling detection limits
Depth profiling precision and accuracy
Depth resolution
X Y Spatial resolution

A central theme common to all these topics will become apparent, and that is the fact that elemental and isotopic analysis by secondary ion mass spectrometry is a science of numbers. It is not and "observational" technique where questions can be answered by the presence or absence of a peak(s) in a mass spectrum. Rather, one must measure elemental concentra-tions or isotopic ratios with great precision and accuracy, at very low concentrations and often with very good depth resolution. These are the challenges which continue to make SIMS such an interesting field.

Bulk Detection Limits

SIMS is not often thought of as a bulk analysis technique because of its unparalleled sensitivity as a depth profiling tool for thin films. This same high sensitivity can be further exploited in a bulk analysis mode where one is not limited by the amount of sample which may be consumed in order to make a measurement. This has been demonstrated recently [1] by using SIMS for the ultra trace detection of uranium and thorium in aluminum used in integrated circuit manufacturing. These elements have been measured (not just detected) at the 0.02 part per billion level, or 20 parts per trillion, or approximately 10^{-20} moles of U and Th detected per measurement point. This is a truly impressive analysis.

Bulk Precision and Accuracy

SIMS, when used for bulk analysis, is also capable of very impressive performance in terms of precision and accuracy. Again, the inherent high sensitivity of the technique makes it possible to obtain high countrates for even trace impurities thus making it possible to obtain high precision analyses. The technique has been used for detection of oxygen in single crystal silicon at the 10 ppm level with precisions and accuracies considerably better than +/ 10% [2].

Depth Profiling Detection Limits

As stated above, SIMS is best known as a depth profiling technique, and as such, it is capable of obtaining exceptionally low detection limits for elements in thin films while maintaining depth resolutions of better than 500 Angstroms. SIMS has been shown by at least one laboratory [3] to be capable of routine detection of trace impurities in III-V materials at the mid 10^{13} atom/cc range, with demonstrated detection limits of some elements down to 10^{12} atoms/cc, or 0.02 ppb atomic. At this level of performance, one is detecting the presence of only several hundred atoms within the analyzed volume of the sample.

Depth Profiling Precision and Accuracy

Not only must one be able to obtain high sensitivity in SIMS depth profiling, but the analyses must be precise and accurate. One particularly exacting requirement for such analyses is in the determination of the total dose of ions which are implanted into semiconductors in integrated circuit fabrication. SIMS has been shown [4] to be able to measure doses of the order of 10^{15} atoms/cm^2 (equivalent to approximately one monolayer of atoms) with precisions and accuracies of better than 2%. This is approaching the accuracy obtainable with more conventional techniques such as electron probe microanalysis, but the concentrations of elements being measured using SIMS are several orders of magnitude lower than those detectable by the electron probe.

Depth Resolution

As stated in the preamble of this work, materials researchers are continuing to develop fabrication technologies which push the state of SIMS to its limits. This is especially true in IC processing where the trend is to smaller and smaller dimensions, not only across the surface of the chip, but also in depth. SIMS is now being called on to measure accurately changes in elemental concentrations over depths of as little as several tens of Angstroms. An example of such an analysis is the determination of in-depth profiles of dopants which are implanted into semiconductors to exceedingly shallow depths, typically less than 100 Angstroms. It has been shown that SIMS can determine such profiles (arsenic implanted into silicon, for example) with depth resolutions of better than 15 Angstroms [5]. But in the future, we will be called upon to analyze even thinner layers as the use of strained layer superlattices becomes more widespread. In that technology, layers are grown which are only several atoms thick. This will certainly provide a formidable challenge to the SIMS analyst in the coming years.

X - Y Spatial Resolution

SIMS has also advanced to an unprecedented level in the area of spatial resolution across the sample surface, and in the area of image processing. Mass resolved elemental images can now be obtained with resolutions of better than 200 Angstroms [6]. This is approaching the lateral extent of an individual collision cascade induced in a sample by the primary ion. This level of achievement is one of the few examples in analytical chemistry where instrumentation has approached ultimate limit of a measurement imposed by the physics of the measurement itself; the analytical chemist's version of the Heisenberg Uncertainty Principle.

However, not only can we obtain very high resolution ion images of surfaces using SIMS, but we have advanced in our use of the image data. Hardware and computer techniques have been developed [7] which enable the analyst to keep track of the total number of secondary ions detected in each pixel of and image, and to store a succession of images in memory such that one can reconstruct the entire three-dimensional concentration distribution of one or several elements within a given analyzed volume. And in keeping with the theme of quantitative analyses, these 3-D data can be converted into quantitative depth profiles, line scans and x - y maps which are quantitative in concentration.

Nonresonant Multiphoton Ionization for Sensitive Elemental Analysis

C. H. Becker and J. B. Pallix
Chemical Physics Laboratory
SRI International
Menlo Park, California 94025

High detection efficiency and quantitation are necessary for measurements of small amounts of solid sample requiring high spatial resolution. When examining non-uniform materials, especially interfacial regions, matrix effects associated with SIMS make this technique unreliable. Because most sputtered atoms and molecules are neutral in charge, detection of the sputtered neutral fraction by nonselective postionization is a much more stable and reliable approach. A high sensitivity like SIMS enjoys is desirable because high dynamic range measurements can be made with high lateral and depth spatial resolutions. For general (nonselective) analysis, to date only the surface analysis by laser ionization (SALI) method[1,2] has a high efficiency comparable to but more uniform than SIMS (useful yield $\sim 10^{-3}$). For comparison, overall system useful yields are lower by 4-5 orders of magnitude using other nonselective postionization approaches (electron impact and RF low pressure plasma).

The SALI method uses nonselective photoionization of desorbed atoms and molecules by an untuned laser source followed by reflecting time-of-flight mass spectrometry (TOF-MS). For elemental analysis, nonresonant multiphoton ionization (MPI) by a very intense, pulsed, focused, UV laser beam is used. This nonlinear photoionization typically requires laser beam intensities $>10^9$ W/cm^2 for efficient and uniform ionization due to saturation. The intensity required to reach saturation depends to a large extent on the number of photons required, especially for small numbers of photons (say 1-4). Most species can be efficiently ionized by 2 photons with wavelengths such as 193, 248, and 266 nm. Just a few atoms require more than 2 photons at 193 nm (6.42 eV/photon), and are generally not efficiently ionized with common lasers. Common lasers for ionization are a single-cavity excimer or frequency-quadrupoled Nd:YAG laser. More powerful lasers such as chirped-pulse amplified solid-state lasers[3] could routinely saturate even He photoionization.

Material removal is usually by ion beam sputtering though electron-stimulated, laser-induced, and thermal desorptions are used in some instances. Ion beam sputtering is a very convenient spatially resolved surface probe.

An example of a sputter depth profile through an interface is shown in Fig. 1. The sample was a 2000 Å thick polycrystalline Si sample on a thin SiO_2 layer on crystalline Si implanted with 10^{15} F atoms/cm^2 at 93 keV. The mobility of F under annealing conditions was the processing issue highlighted in this work. But in Fig. 1, the F depth distributions are shown of unannealed samples where a smooth F distribution is expected. A comparison is made of SALI and a SIMS profile, the latter taken on a Cameca instrument. The SIMS data shows the common influence of matrix effects at an interface. Using a standard excimer laser focused to about 10^{10} W/cm^2 the atomic F ionization efficiency at 193 nm (3 photons to ionize) is low, but the neutral sputtered diatomic molecule SiF still provides a sensitive and useful monitor of the F concentration.

Another study involved thin anodic oxide layer growth on alloys for corrosion prevention. For the dilute alloys based on Ni (6% of Al, Ti, or Mo), an enhancement effect in the amount of dilute metal incorporated into the oxide is seen to be in the order Mo>Ti>Al in agreement with the prediction of a theory of solute segregation which says the dominating effect is the difference in valency between the solute metal and the base metal vacancy. Furthermore, the compensating depletion of this minor alloy component is clearly seen; these data will determine diffusion coefficients for the solute metals in the base metal. Though O atoms are not efficiently detected, note the direct O atom signal marks the oxide layer. Note also the H detection. The nonzero H signal at longer sputter times is from H_2 gas phase background.

The authors thank Peter Wright and Mordehai Ben-Haim for providing the F/Si and Ni alloy samples, respectively.

SOLIDS ELEMENTAL ANALYSIS BY GLOW DISCHARGE MASS SPECTROMETRY: W. W. Harrison, Department of Chemistry, University of Virginia, Charlottesville, VA 22901.

Introduction

Glow discharge mass spectrometry (GDMS) is a technique generating increasing interest (1) in elemental analysis circles. A key factor is its ability to perform direct analysis of solids, obviating the need to carry out tedious, time consuming, and at times incomplete dissolutions. GDMS has several analytical advantages that make it increasingly attractive: low to sub-ppb detection limits; relatively uniform elemental response (3X); minimal matrix effects; isotopic information; simple spectra; rapid qualitative and quantitative results. Figure 1 shows a simplified drawing of a glow discharge ion source.

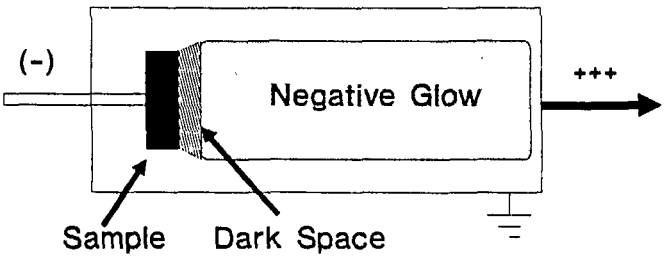

Figure 1. Representation of a glow discharge ion source.

Gas discharges have been studied for many years by both optical and mass spectrometry. Emphasis has been on gaining better insight into the species formed, the reactions they undergo, and other fundamental aspects of discharges. Only more recently, however, has attention turned to analytical details and the role of sputtered species (the analytical sample) in these rich and efficient plasma interactions. As this area becomes more fully developed, GDMS will operate from a better foundation so that theory enhances practice.

GDMS Instrumentation

The glow discharge source lends itself to various types of mass analysis apparatus. Quadrupole units have found the greatest application in research, although the only present commercial instrument is a magnetic sector type (2). The latter approach provides sufficient mass resolution to separate many spectral interferences, but certainly not all. Quadrupole based instruments have a significant price advantage and are easily interfaced to the glow discharge; the analyst must, however, be alert to potential unresolved interferences at high sensitivity conditions. New approaches are being studied in which collision induced dissociation (CID) is used to break up polyatomic ions in a glow discharge effluent, thus permitting in principle the broader use of quadrupole analyzers.

Relevance of GDMS in Elemental Analysis

The major use of GDMS has been in the elemental analysis of metals and alloys, in many cases replacing spark source mass spectrometry as the technique of choice. Metal samples require little or no pretreatment, other than cutting to fit the sample holder. The glow discharge serves to perform a final cleaning of the surface in the initial sputter process. Nonconducting samples must be mixed with a conducting matrix and compacted into a form suitable for source mounting. Selection of matrix is important; the material must be of high purity, have good compacting characteristics, and contribute minimal background. The opportunity exists to select chemically reactive matrices, such as getters, that can produce favorable plasma conditions for complex samples. Earth materials are particularly difficult given their strong bond energies and built-in oxygen environment, but the glow discharge has been effective in breaking down such samples into atomic components.

The nature of glow discharge sputtering suggests the possibility of surface analysis, applications of which have been reported. The low energy ions in a glow discharge do not penetrate far into the surface, minimizing atomic mixing. However, sharp transitions between films can be broadened by redeposition effects. RF discharges, operating at lower pressures than do DC discharges, may be useful in reducing these redeposition problems. In addition to thin film analysis, similar methodology can be applied to the residue analysis of solutions dried onto a conducting support. Some utility can be realized for small solution samples, particularly considering the concentration effect produced by the evaporation step.

At present, the more rapid spread of GDMS is limited by the high cost of commercial instrumentation. The availability of less expensive alternatives could make it much more accessible to a wide variety of laboratories where it would seem logically to have potential application.

The Development of High Precision Mass Spectrometry

I. Lynus Barnes
National Bureau of Standards
Center for Analytical Chemistry
A-23 Physics Building
Gaithersburg, MD 20899

The search for high precision in mass spectrometric measurements has been fundamental since the invention of the instrument even though it was most difficult to obtain in the early spectrometers. Most of them used photographic plates as detectors, small "furnaces" as sources for solids and stabilized power supplies were still to be discovered. Aston, for example, analyzed a number of elements[1] and with improved versions of his instrument measured both concentration and composition of a number of different elements. High precision only as a relative term was obtained from the blackening of the photographic plates.

The invention (or discovery) of the electrometer tube in the 1930s however meant that truly high precision measurements were possible, but the most important development came in 1940 with the construction by A.O. Nier of the first successful sector mass spectrometer[2] This meant that instruments with lighter magnets (with the corresponding lower power requirements) but with adequate resolution and sensitivity could be used for isotopic measurements. During the following few years many sector mass spectrometers were constructed for measurements of the enrichment of uranium isotopes in separation facilities and for controlling the process stream in the gas diffusion plant[3]. As a natural part of this, many improvements were made in the instruments and in the associated electrical and electronic circuitry. Of developments during this period that were important to later general use, the author counts the development of the "gaussmeter", early "electrometer amplifiers", and the refinement of the electron impact ion source (discovered earlier by Bleakney[4]) as of particular interest. Because of the use of these instruments for the measurements of small isotopic differences, high precision became an important concept.

With the end of the War there was renewed interest in the use of mass spectrometers in solving problems in physics, chemistry and geology, many new instruments were constructed and commercial instruments became available with the result that vast amounts of very high quality data became available. A few examples of this are the work done by Wasserburg and his colleagues on the returned Lunar samples[5] and on many other materials, that done by Tatsumoto and co-workers[6] also on the returned Lunar materials, the work on the redetermination of the atomic weights of the elements done at the National Bureau of Standards[7] and that done by Lugmair and co-workers[8] on the development of the Nd-Sm dating system. Limited space forces the omission of many, many others with significant contributions to the very high precision data obtained within the past decade.

Although steady improvement continues on these spectrometers, recent advances in high precision mass spectrometry have come with the development of a new group of instruments based on multiple collection of several (3 or more) beams at the same time. These are the result of work published many years ago by Cross[9] that showed that if ion beams were allowed to enter a magnetic field at an angle (selected) other than normal increased dispersion resulted. While this increased dispersion permitted the use of multiple collectors with the advantageous of time, an at least equal benefit is that focussing in the "Z" direction is achieved and greatly improved ion beam throughput results. Several commercial instruments are now available and data is becoming available to demonstrate that the predicted improvements are obtained. In fact, precision obtained indicate that the limit of error in many analyses come from the inability to prepare samples sufficiently well in the laboratory and research effort in the chemical manipulation will be required before further advances will be realized.

ADVANCES IN THERMAL IONIZATION MASS SPECTROMETRY

D. A. Papanastassiou, Division of Geological and Planetary Sciences, California Institute of Technology, Mail Code 170-25, Pasadena, CA 91125.

During the last decade it has been possible to demonstrate that thermal ionization mass spectrometry can yield high sensitivity and high precision isotopic analyses. The major advances for high precision have involved improvements in the duty cycle for the measurement of isotopic ratios and in the ionization efficiency for a substantial number of elements. Improvements in the duty cycle were provided by a new generation of mass spectrometers which included: a) the ability to control precisely the magnetic field (2ppm under static conditions); b) the ability to step the magnetic field at a fast rate (2kgauss/sec slewing rate; 0.3sec lock-in time; 10ppm reproducibility under these dynamic conditions); c) fast response electrometers, coupled with digitization of the ion beam measurement (Wasserburg, Papanastassiou, Nenow, and Bauman, 1968). These improvements can, for the last ten years be found also in commercially available mass spectrometers. In addition, recent advances include the introduction of multiple Faraday cup detectors for the simultaneous measurement of ion beams. The use of these systems on relatively low dispersion instruments has resulted in delicate, low mechanical tolerance collector assemblies which depend on continued manufacturer support and development. With care, high precision data can be obtained by the use of simultaneous ion beam detector systems. The obvious advantages are increased duty cycle (by the inverse of the number of isotopes that are measured) and less dependence on the ion beam stability in the source. The disadvantages include the need for calibration of multiple electrometer systems, and the need to ascertain that the ion transmission and detection are independent of the source parameters and beam shape, at the level of the quoted precision. More experience with multiple collector systems is required before these issues can be resolved. Care will be required to establish that reproducibility ("external precision") is consistent with error estimates from individual analyses ("internal precision"). It is also important to consider that a substantial improvement in multiple collector systems can be obtained by their introduction to higher dispersion instruments.

For improvement in sensitivity for thermal ionization sources, extensive work has been devoted to improvements in ionization efficiency for various elements. Since ionization efficiency ($f_N = N^+/N^o$) is an exponential function of the ionization potential, the filament work function, and the temperature, substantial improvements have been possible. Specific cases include: a) f_{Mg} up to 10%, using as an emitter colloidal SiO_2 (Si-gel; typically obtained by hydrolysis of $SiCl_4$) and phosphoric acid; b) f_{Cr} of about 10^{-3}, using Si-gel and boric acid; c) f_{Pb} of 15% using Si-gel and phosphoric acid; d) NdO^+/Nd of up to 50%, with a slight increase of the oxygen partial pressure in the filament region, without adverse effects in mass resolution; f_{NdO^+} on a single filament assembly is at least a factor of 100 higher than f_{Nd^+} from a double filament source assembly; e) f_{TiO^+} of 0.01%; TiO^+ is typically a factor of 20 more efficiently ionized than Ti^+; control of the oxygen isotopic composition in TiO^+ is critical and requires the use of a slurry of fine grained Ta_2O_5 on Ta filaments which themselves have been oxidized at a partial pressure of oxygen of 0.2 torr; f) for U and Th ionization efficiencies of 0.5% and 0.1%, respectively, are obtained by the loading of these elements in a colloidal graphite matrix, which enhances the formation of U^+ and Th^+ at high filament temperatures. This list provides an indication of substantial improvements, sometimes by many orders of magnitude (e. g., 10^5 for Mg) which have been possible by a careful consideration of matrix effects and of the species that are emitted from a heated filament in a vacuum. An important and general observation has also been that the ionization efficiency is not a linear function of the amount of an element loaded on a source filament. For example, f_{NdO^+} of 2% to 4% and of 25% to 50% are obtained for amounts of 5 x 10^{-8}g and 5 x 10^{-10}g of Nd, respectively, loaded on a filament. Similarly, Edwards, Chen, and Wasserburg (1986) have documented a precipitous drop of ionization efficiency for Th, from a high value of 0.1%, as the amount of Th loaded on the filament was increased. This has important implications for the measurement of ^{230}Th and for the use of the U-series for dating, based on disequilibrium effects.

The improvement in ionization efficiency appears to have had as an important and beneficial side-effect a substantial reduction in the range of instrumental isotope fractionation. This is important for elements with only two isotopes (e. g., Rb, Tl, Ag) and for elements with only three isotopes (e. g., Mg) for which a double spike technique is not possible, in the absence of longlived radioactive isotopes (e. g., the case of U using a double tracer enriched in $^{233,236}U$). The observed narrow range of instrumental isotope fractionation is most probably attributable to the depletion of the emitter (e.

g., Si-gel) well before the element of interest on the filament has been depleted. The measurement of intrinsic isotope fractionation has been important for the investigation of substantial kinetic isotope fractionation effects in refractory inclusions in primitive meteorites. These effects are attributed to kinetic isotope fractionation during condensation and/or evaporation in the early solar nebula.

It has also been established that it is possible to obtain isotope data for a variety of major and trace elements on micro-samples without the need of chemical separation of the element of interest, e.g., Mg, Ca, Cr, Rb, Sr. This technique has been labelled the direct loading technique (Lee, Papanastassiou, and Wasserburg, 1977). It has permitted isotopic analyses with a substantial reduction in the amount of laboratory introduced contamination; these types of analyses have also taken advantage of the sharp increase in ionization efficiency for micro-samples. Applications of these techniques can be found in the literature. Examples include a) analyses of interplanetary dust particles, less than 10 micrometers in size, as well as deep sea spherules of extraterrestrial origin; b) the study of correlated isotopic anomalies in meteorites which resulted in the identification of exotic components from specific nucleosynthetic processes; c) Rb-Sr and Sm-Nd studies of microtektites and the identification of the characteristics and mean age of the impact source materials; d) the study by mass spectrometry of U and Th for the purpose of disequilibrium series dating of corals with a sensitivity a factor of 10^4 better than obtained by alpha counting.

It is now possible to consider the types of problems worthy of investigation without the common restriction on sensitivity based on the limitation of terrestrial contamination and of ionization efficiency. It is now possible to consider also a much greater overlap between thermal ionization mass spectrometry and other complementary techniques, e.g., resonance photon ionization, nonresonance photoionization, and ionization by ion sputtering.

LIGAND SUBSTITUTION REACTION OF 17 ELECTRON METAL CARBONYL RADICAL ANIONS IN THE GAS PHASE

Y. Pan, D. P. Ridge

Department of Chemistry and Center for Catalytic Science and Technology, Univ. of Delaware, Newark, DE 19716

Ligand substitution reactions of the 17 electron species, $Cr(CO)_5^-$, $Fe(CO)_4^-$, and $Ni(CO)_3^-$, with activated olefins and aromatic compounds have been examined. 17 electron species are usually less reactive than corresponding 16 and 15 electron species because of their lower electron deficiency. However the 17e species do react with various ligands with activated double bonds. The reaction rates measured indicate that the reactions are sometimes highly efficient. The number of carbonyls replaced in each metal-ligand reaction varies from one to three. It is found that ligands with low electron affinity, for example 2,3-cyclohexene-1-one and succinic anhydride, tend to be less reactive or not reactive at all. By contrast ligands with high electron affinity, for example p-quinone and maleic anhydride, are very reactive. The correlation of electron affinity and reactivity suggests that the reaction involves incipient electron transfer between ligand compounds and metal carbonyls.

To measure the reaction rates the metal carbonyl was admitted to the source of a Nicolet FTMS 2000 through the batch inlet and the anion formed by electron attachment. The ligand was admitted through the batch inlet or on the probe. The ligand pressure was deduced from a positive ion mass spectrum. The sum of the peak intensities in the spectrum was taken to be proportional to the product of the pressure and the ionization cross section of the ligand. The ionization cross sections were taken from a formula given by Bartmess. The absolute pressure scale was determined by using reactions of known rate constants.

The results of the rate constant measurements for a large set of ligands and the three seventeen electron metal carbonyl anions are summarized in Fig. 1. As outlined above the reaction rate increases dramatically with electron affinity of the ligand. Note also that $Ni(CO)_3^-$ is substantially more reactive than the other ions. This corresponds with the lower electron affinity of $Ni(CO)_3$ (1.08 eV) relative to that of $Fe(CO)_4$ (2.4 eV). The behaviour of $Cr(CO)_5^-$ suggests that $Cr(CO)_5$ has an electron affinity between 1.08 eV and 2.4 eV. These correlations with electron affinity substantiate the postulated electron transfer mechanism for the ligand substitution.

Another observation supports the electron transfer mechanism. Two products are observed for reaction of bromonitrobenzene with $Cr(CO)_5^-$: ligand substitution (rate constant = k_1) and $Cr(CO)_5Br^-$ (rate constant = k_2). It is found that for the ortho compound $k_2/k_1 = 0.5$, while for the para compound $k_2/k_1 = 0.1$. This is consistent with the electrochemistry of the two isomers which shows that on reduction the ortho compound readily loses Br^- ($k = 110s^{-1}$) while the para compound does not ($k = .004s^{-1}$).

This suggests that the metal carbonyl radical anion behaves towards the bromobenzenes much as an electrode. It transfers an electron. The resulting anion then attaches itself to the metal.

AN FTMS STUDY OF METAL-CATALYZED OLIGOMER FORMATION IN THE GAS PHASE.

Asgeir Bjarhason
Science Institute, University of Iceland, Dunhaga 3, 107 Reykjavik, Iceland.
James W. Taylor
University of Wisconsin-Madison, Madison, WI 53705.

INTRODUCTION

Polymerization via metal catalyzed synthesis is a well known technique. The details of the mechanisms are in many cases understood to a lesser extent. Polyphenylenes and related compounds have received considerable interest in recent years due to their unique electrical conductive properties. Various synthetic routes have been investigated for the production of polymers with specific properties, and Brown and coworkers[1)] have developed a technique to analyze the products using laser desorption in a FTMS. A decade ago, Dietz et al.[2)] reported a study of the reactions of iron ions with phenyl halides in the gas phase using an ion cyclotron resonance spectrometer. Several interesting reaction products were observed, including $Fe(C_6H_4)_n^+$ (n=1-3). Instrumental advances have allowed us to probe these reactions in more detail, and we wish to report a number of additional reactions for these systems, including the direct observation of iron-catalyzed phenylene oligomer formation.

EXPERIMENTAL

A Nicolet FTMS-2000 Fourier transform mass spectrometer equipped with a 3.0 T superconducting magnet was used for these experiments. Iron ions were generated using the laser ionization technique developed by Freiser and coworkers[3)], using here a stainless steel target on the direct insertion probe and a pulsed CO_2 laser. Iron(I) ions were isolated using double ejection pulses, stored in the cell, and allowed to react with the sample during a delay event, which was varied from 0.003 to 25.6 seconds. All reaction paths were established using double resonance techniques.

RESULTS AND DISCUSSION

Dietz et al.[2)] report the following reaction for fluorobenzene, chlorobenzene, and bromobenzene:

$$Fe^+ + C_6H_5X \text{ --------> } Fe(C_6H_4)^+ + HX \qquad (1)$$

In the case of chlorobenzene, two more steps of dehydrohalogenation were observed to form $Fe(C_{12}H_8)^+$ and $Fe(C_{18}H_{12})^+$. Iodobenzene, however, was found to react differently.

We have observed a number of additional steps of

dehydrohalogenation. Fluorobenzene was found to yield $Fe(C_6H_4)_n^+$ with n=1,2, chlorobenzene with n=1-7, and bromobenzene with n=1-6. Chlorobenzene was the most reactive of the three. These reactions all proceed according to:

$$Fe(C_6H_4)_n^+ + C_6H_5X \text{ -----> } Fe(C_6H_4)_{n+1}^+ + HX \qquad (2)$$

Another reaction channel competes with (2) for certain values of n:

$$Fe(C_6H_4)_n^+ + C_6H_5X \text{ -----> } (C_6H_4)_n^+ + Fe(C_6H_5X) \qquad (3)$$

The phenylene oligomers are observed for fluorobenzene with n=2 and, in the case of chlorobenzene and bromobenzene, for n=2-4. To the best of our knowledge, these are the first direct observations of metal-catalyzed oligomer formation in the gas phase.

Iron ions also react to form molecular ion clusters of the type $Fe(C_6H_5X)_n^+$, which are observed for fluorobenzene (n=1,2), chlorobenzene (n=1), and bromobenzene (n=1,2). Ions of the form $Fe(C_6H_5X)(C_6H_4)_n^+$ were also detected for fluorobenzene (n=1,2) and chlorobenzene (n=2-6). No ions of this type were observed for bromobenzene or iodobenzene.

At longest reaction times the dominant ions become $(C_6H_4)_3^+$ and $Fe(C_6H_4)_5^+$, suggesting that they have the most stable configuration.

The results presented here were obtained with instrument access provided through the courtesy of the Nicolet Instrument Corporation, which is gratefully acknowledged. Studies are continuing using other transition metal ions and a wider variety of arenes to gain a more complete understanding of these processes.

Experimental Evidence for the Formation of H_3^* by H_5^*/e^- Dissociative Recombination

C. A. Miderski and Gregory I. Gellene
Department of Chemistry
University of Notre Dame
Notre Dame, IN 46556

In the early 1980's, Herzberg and co-workers observed and analyzed several electronic emission band systems of H_3^* in hydrogen discharges. In that work the localization of the spectra to the hollow cathode region and its enhancement with low discharge temperature suggested a role for hydrogen cluster ion/e^- dissociative recombination in the formation of H_3^*. This hypothesis was investigated by determining the effect of discharge temperature and hydrogen density on the intensity of H_3^* emission and comparing the results with the predictions of a kinetic model (Fig. 1) which incorporates known rates for relevant diffusional, clustering, and recombination processes.

The 6025 Å band ($3s^2A'_1 \rightarrow 2p^2A''_2$) of H_3 was monitored optically with nine lines being observed giving the relative population for seven individual upper state rotational levels (Fig. 2) which collectively provides a measure of the efficiency of production of H_3^* in the discharge (points plotted in Fig. 3). Comparing these results with those of the kinetic model it is found that the observed discharge pressure and temperature dependence on H_3^* spectral intensity can be adequately accounted for (curve in Fig. 3) if the reaction sequence:

$$H_5^+ + e^- \rightarrow H_5^{**} \rightarrow H_3^* + H_2 + KE \rightarrow h\nu \qquad (1)$$

is assumed to be the primary process leading to H_3^* in the discharge.

In the context of this mechanism, the kinetic energy released in the unimolecular dissociation of H_5^{**} would be expected to give rise to spectral line broadening. The analysis of the observed spectral line shape was simplified by assuming that the dissociative kinetic energy release gives rise to an isotropic single valued velocity distribution which combines with the original thermalized H_5^+ velocity distribution. The normalized emission line intensity contour, G, as a function of wave number shift $\tilde{\nu}$ is then given by:

$$G(\tilde{\nu}) = (a/4b)\ [\mathrm{erf}(a\tilde{\nu}+b) - \mathrm{erf}(a\tilde{\nu}-b)] \qquad (2)$$

where $a = (Mc^2/2kT)^{1/2}/\nu_o$ and $b = (m_2E_D/m_1kT)^{1/2}$. ν_o is the wave number of the line center, M is the total mass (m_1+m_2), m_1 is the mass of the observed fragment, and E_D is the dissociation energy. An optimized fit of Eq. (2) convolved with a gaussian instrumental line shape function to the $R_0(0)$ line (Fig. 4) resulted in a value of $E_D = 0.7 \pm 0.1$ eV. With this result conservation of energy consideration applied to reaction 1 indicates that the initial products of recombination are either $H_3^*(3s^2A'_1) + H_2(v=1)$ or $H_3^*(4p^2E'$ or $4p^2A''_2) + H_2(v=0)$.

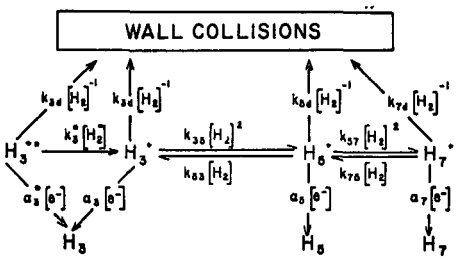

Fig. 1. Reaction scheme employed in the kinetic modeling of the hydrogen discharge.

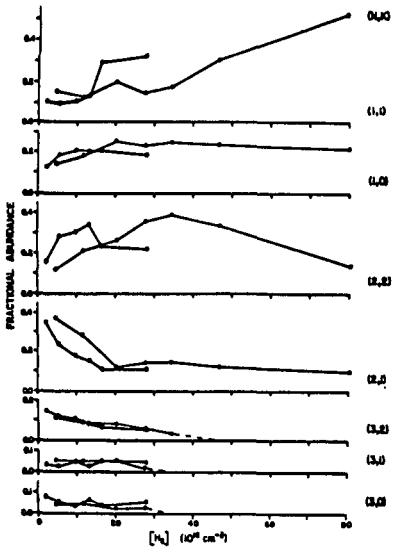

Fig. 2. Relative population of the observed rotational levels of the $3s^2A_1'$ Rydberg state of H_3 as a function of discharge temperature and density. Open and closed circles correspond to discharge bath temperatures of 195 K and 77 K respectively. The rotational levels are denoted by (N,K) where N and K are the rotational quantum numbers of a symmetric top.

Fig. 3. Relative total population observed for the $3s^2A_1'$ Rydberg state of H_3 (plotted points in a) and relative optical intensity of the undispersed cathode glow between 4000 A and 8000 A (plotted points in b) as a function of discharge temperature and density. The curves in (a) represent the results of the kinetic calculations for the relative production of H_5^{**} scaled as described in the text. In both plots, open and closed circles corresponded to discharge bath temperatures of 195 K and 77 K respectively.

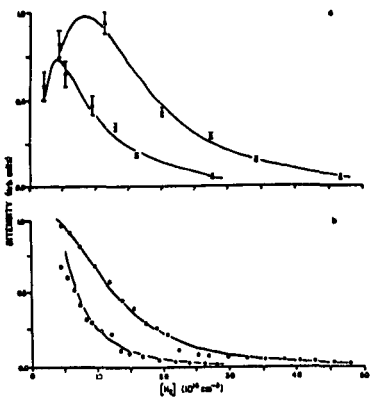

Fig. 4. Photodensitometer trace (solid curve) of the $R_0(0)$ line of the 6025 A band of H_3 obtained at a hollow cathode pressure and bath temperature of 0.5 Torr and 77 K respectively. The dotted curve represents an optimized fit of Eq. 2 to the observed lineshape as described in the text.

KINETIC ENERGY RELEASE DISTRIBUTIONS IN THE DISSOCIATION OF ION-DIPOLE COMPLEXES

Lewis M. Bass
Millersville University, Millersville, PA 17551

Coleen Roehl and Michael T. Bowers
University of California, Santa Barbara, CA 93106

We have undertaken a study aimed at determining the effect of the charge-dipole interaction on the kinetic energy release distribution (KERD) produced in the dissociation of ion-dipolar molecule complexes. Two systems were chosen for initial experiments: (1) cis- and trans- difluoroethylene, and (2) meta- and para- difluorobenzene. In each case, one isomer has a non-zero permanent dipole moment while the other isomer is nonpolar. Other parameters, such as reduced mass, polarizability, and internal vibrational modes are essentially the same for the two isomers. Hence, differences in the KERD's can be attributed entirely to the difference in dipole moments between the two isomers.

Measurements were carried out using a ZAB-2F mass spectrometer. The reaction sequences are as follows:

$$AH^+ + A \longrightarrow (A_2H^+)^* \quad (1A)$$

$$(A_2H^+)^* \longrightarrow AH^+ + A \quad (1B)$$

A = cis- or trans- difluoroethylene,

and

$$B^+ + B \longrightarrow (B_2{}^+)^* \quad (2A)$$

$$(B_2{}^+)^* \longrightarrow B^+ + B \quad (2B)$$

B = meta- or para- difluorobenzene.

In each case, the excited ion-molecule complex is formed in the ion source and then mass-selected through the magnetic sector. Fragment ions (AH^+ in reaction 1B or B^+ in reaction 2B) produced in the second field-free region are energy-analyzed by scanning the voltage on the electric sector. The plot of ion intensity vs. electric sector voltage is then analyzed to determine the KERD.

Results are shown in Figures 1 and 2 below. In both cases the KERD is shifted to lower values for the polar isomer. This is consistent with the

general predictions of statistical phase space theory [see L. M. Bass and M. T. Bowers, J. Chem. Phys., 86, 2611 (1987)], although detailed calculations on these systems have not yet been completed.

A MASS SPECTROMETRIC AND *AB INITIO* CALCULATION STUDY OF THE POTENTIAL ENERGY SURFACE FOR REACTIONS OF CARBENE-LIKE CATIONS

J.J. Fisher and T.B. McMahon

Department of Chemistry and Guelph-Waterloo Centre
for Graduate Work in Chemistry
University of Waterloo
Waterloo, Ontario, N2L 3G1
CANADA

The potential energy surface for the reaction of difluoronitrenium ion (NF_2^+) with methane (CH_4) has been explored experimentally using ion cyclotron resonance spectroscopy (ICR), high pressure mass spectrometer (HPMS) and CID/MIKES technquies, as well as an extensive *ab initio* calculation study. Preliminary high pressure mass spectrometric (HPMS) studies of NF_3 and CH_4 showed that the major product ion formed was an ion of m/z 28. It was concluded that the only feasible structure of m/z 28 was $HCNH^+$. Examination of mixtures of various compositions established that NF_2^+ is by far the most probable source of m/z 28 species and that a single step reaction must occur with CH_4 in which a C-N bond is formed and at least one new N-H bond is made.

NF_2^+ is isoelectronic and isolobal with difluorocarbene and it is therefore tempting to propose that the first step in the formation of $HCNH^+$ may be the result of the insertion of NF_2^+ into the carbon-hydrogen bond of methane. It has been proposed that NF_2^+ can insert into C-H bonds by a direct (3-centered transition state) insertion mechanism or abstraction-recombination mechanism (Figure 1.) analogous to that of neutral carbenes. The *ab initio* calculations yield a transition structure which resembles a $[NF_2H + CH_3^+]$ ion molecule complex. Since a stable minimum and/or saddle point was not located for this complex, the abstraction-recombination mechanism for the insertion of NF_2^+ into C-H bond of methane is the preferred mechanism. This process leaves the newly formed $CH_3NF_2H^+$ with a significicant extent of internal excitation which can then promote unimolecular decomposition of this ion. Figure 2 shows the probable subsequent steps in the production of $HCNH^+$. The protonated N,N-difluoromethylamine eliminates an HF to yield protonated N,N-difluoromethylenimine which also subsequently eliminates HF to give the final product, $HCNH^+$, protonated HCN.

ICR double resonance experiments also established that NF_3H^+ reacts with CH_4 to produce m/z 28. In devising a reaction mechanism for NF_3H^+ and CH_4, two possible structures of NF_3H^+ must be considered; one involving protonation of NF_3 on the nitrogen site and the second involving protonation on a fluorine site. ICR and CID/MIKES experiments as well as *ab initio* calculations support protonation of NF_3 on the fluorine site. There CH_4 reacting with NF_3H^+ undergoes a nucleophilic displacement forming a $[NF_2 \cdots CH_4]^+$ ion molecule complex. This complex then forms a protonated N,N-difluoromethylamine intermediate which undergoes sequential loss of two HF.

AN INVESTIGATION OF THE GAS PHASE BASE-INITIATED ALDOL REACTION: COLLISION INDUCED DISSOCIATIONS OF β-HYDROXY-CARBONYL NEGATIVE IONS.

R.N. Hayes, R.P. Grese, and M.L. Gross, Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE 68588.

The aldol condensation is an important class of organic reactions. The generally accepted mechanism for the base-catalyzed aldol reaction in the condensed phase invokes the intermediacy of an β-hydroxy-carbonyl species (Scheme 1).[1] In contrast, gas-phase aldol condensations are not well understood; in particular, the structures of stable adducts so formed have not been fully characterized.

We have employed tandem mass spectrometry (MS/MS) techniques to isolate and characterize representative adducts produced by reactions between simple enolate anions with carbonyl compounds in a chemical ionization source. Enolate negative ions were easily produced by deprotonation of alkyl carbonyl compounds by using MeO- [produced by dissociative secondary electron capture of methyl nitrite[2]]. Adducts from subsequent reactions of the enolate anions with neutral aldehyde or ketone were mass selected by using the first stage of the tandem mass spectrometer, and then collisionally activated (CA) by collision with He gas. The CA mass spectra of these adducts were compared with those of appropriate deprotonated β-hydroxy-carbonyl model compounds. The structures of the condensation products were then assigned on the basis of these comparisons.

In common with the model compounds, the gas-phase adducts upon collisional activation decompose by elimination of neutral aldehyde (ketone), H·, CH_4 and H_2O (see Figures 1A and 1B); kinetic energy releases for each loss are nearly identical for adduct and model compound. The eliminations of H·, CH_4 and H_2O are representative of a species of tetrahedral geometry (Equations 1-3).

A comparison of the CA mass spectra indicate that there are, however, differences in the relative abundances of ions corresponding to loss of neutral aldehyde (ketone) between adduct and model compound. These differences are rationalized in terms of at least three adducts being formed; viz, an ion-dipole complex, a proton-bound dimer and a species of tetrahedral geometry. A hypothetical reaction coordinate diagram for a reaction between acetaldehyde enolate ion and acetaldehyde (Figure 2) shows all three possible species as stable intermediates. The energy barrier between the ion-dipole complex and the proton-bound dimer is more likely entropic in nature rather than enthalpic because of the losses of rotational and vibrational degrees of freedom as the ion-dipole complex evolves into the proton-bound dimer. The energy barriers for the losses of H_2O and CH_4 through the tetrahedral species are unknown but can be expected to be of higher energy than reactants because of the absence of these losses in the metastable spectra.

The charge reversal (positive ion) spectra[3] of the adducts and model compounds are also very similar; thus indicating a high probability that a fraction of the original negatively charged species each had a common structure. However, little evidence of the more loosely bound species (i.e., ion-dipole and proton-bound dimer) can be obtained from the charge reversal mass spectra. One reason that the cross section for charge stripping of

these loosely bound species is appreciably lower than that of the tetrahedral adducts is that the favored process for the ion-dipole and hydrogen-bonded complexes is to revert to starting materials; that is, these species never survive a charge stripping collision.

The conclusion then, is that adducts of tetrahedral geometry are formed in base-initiated gas phase aldol condensations. These adducts undergo fragmentation in a characteristic and novel manner upon collisional activation. However, a significantly higher proportion of at least two more species of adduct are formed; namely, an ion-dipole complex and a proton-bound dimer.

GAS-PHASE ELECTROPHILIC SUBSTITUTION REACTIONS OF ORGANOSILANES

David J. Hajdasz and Robert R. Squires
Department of Chemistry, Purdue University, West Lafayette, IN 47907

Electrophilic substitution represents an important class of organic reaction commonly used in synthesis.[1] The wide availability of trimethylsilyl-substituted organic compounds and the desirable characteristics of the Me_3Si^+ ion as a cationic "leaving group" make organosilanes excellent substrates for studies of bimolecular electrophilic substitution reactions in the gas phase (eq 1). We have undertaken a

(1) $$R^+ + X\text{-}SiMe_3 \longrightarrow RX + Me_3Si^+$$

$$X = Me,\ Cl,\ Ph,\ CH_2CH,\ CH_2CHCH_2$$

program of study of this type of reaction with use of a flowing afterglow-triple quadrupole instrument. Electrophilic cations are chosen such that protolytic cleavage of the substrate which would also produce Me_3Si^+ as a product (eq 2) is endothermic.[2]

(2) $$RH^+ + X\text{-}SiMe_3 \longrightarrow R + HX + Me_3Si^+$$

A wide range of reactivity is found that depends on the nature of the attacking electrophile and the type of reactive site in $X\text{-}SiMe_3$. The tertiary butyl cation does not react with Me_4Si at room temperature in the 0.4 torr helium flow reactor, despite the mild exothermicity computed for methyl anion transfer. Reaction does occur in the triple quadrupole (Q2) when the Me_3C^+ reactant ion is translationally excited; the observed kinetic energy dependence of the rate is typical of an exothermic reaction (eq 3). Acetyl cation reacts with Me_4Si in the flow reactor (P = 0 4 torr)

(3) $$Me_3C^+(KE) + Me_4Si \xrightarrow{\Delta H = -2\ kcal/mol} Me_4C + Me_3Si^+$$

exclusively by addition, and reacts by (exothermic) methyl anion transfer in Q2 (eq 4). The stabilized adduct undergoes CID by loss of both

(4) $$CH_3CO^+ + Me_4Si \longrightarrow (CH_3)_2CO + Me_3Si^+$$

$(CH_3CO^+ + Me_4Si)$ and $((CH_3)_2CO + Me_3Si^+)$, while an authentic $Me_3Si^+/(CH_3)_2CO$ adduct fragments to produce <u>only</u> Me_3Si^+. Thus, the CH_3CO^+/Me_4Si adduct represents a mixture of structures <u>A</u> and <u>B</u>.

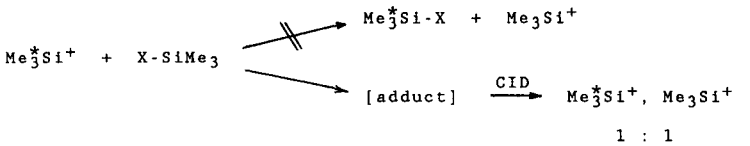
$$[CH_3CO^+ \cdot \cdot Me_4Si] \qquad\qquad [(CH_3)_2\overset{+}{C}O\text{-}SiMe_3]$$

<u>A</u> <u>B</u>

Thermoneutral, symmetric exchange reactions in which the electrophile is $Me_3^{29}Si^+$ or $Me_2(CH_2D)Si^+$ (= $Me_3^*Si^+$) have been examined in order to obtain information about the shapes of the potential energy profiles for electrophilic substitution reactions. Bimolecular Me_3Si-group exchange does not occur in reactions of $Me_3^*Si^+$ with $X\text{-}SiMe_3$ where X = CH_3, Ph, Cl, vinyl, allyl. However, each of the stabilized $Me_3^*Si^+/X\text{-}SiMe_3$ adducts

formed in the flow tube undergoes CID to produce equal amounts of $Me_3^*Si^+$ and Me_3Si^+ daughter ions (eq 5). Thus, the Me_3Si^+ groups become equivalent

(5)



in the long-lived adducts, or as a result of collisional activation. The mechanistic implications of these results are discussed in terms of double- or triple-minimum potential energy profiles for Me_3Si^+ exchange.

TEMPERATURE DEPENDENCE OF API SENSITIVITY

Ikonomou, M., Kebarle, P., Department of Chemistry
University of Alberta, Edmonton, AB; Canada T6G 2G2.
Sunner, J., Department of Chemistry
Montana State University, Bozeman, MT 59717.

In ambient air Atmospheric Pressure Ionization (API) Mass Spectrometry, analyte molecules (B) are ionized by proton hydrates,

$$H_3O^+(H_2O)_n + B = BH^+(H_2O)_b + (n+1-b)\ H_2O \qquad (1)$$

With API many compounds in air can be detected at sub-ppb levels. Previously, we found that a combination of thermo-dynamic and kinetic factors determines the relative sensitivities for analytes in ambient air API (1). Thus, the sensitivities for compounds belonging to the "T-group", Figure 1, are thermodynamically controlled, i.e. determined by the equilibrium constants, $K_{eq}(1)$ for reaction 1. These compounds are mostly oxygen bases with gas-phase basicities (GB) < ca. 200 kcal/mol, and the sensitivities tend to increase with increasing GB. A second group of compounds, the "K-group" shows high and uniform sensitivities that do not vary with GB, Figure 1. These sensitivities are kinetically controlled and determined by the nearly Langevin rate of reaction 1 for these mostly nitrogen bases with GB > ca. 200 kcal/mol. The compounds belonging to the third group, the "L-group", have much lower sensitivities than expected from their GB's alone. The ion intensities for these mostly carbon and sulfur bases are thermodynamically controlled, i.e. determined by $K_{eq}(1)$. However, the equilibrium is pushed very far to the left because of very weak gas-phase solvation interactions of these BH^+ ions with water molecules. By varying the conditions in the API source, for example the water pressure or ion residence time, specific compounds may change from thermodynamic control to kinetic control or vice versa.

In the present work, the sensitivities for a range of analytes were studied as a function of ion source temperature from 30°C to 400°C. The experimental arrangement is shown in Figure 2. The most noteworthy finding is that the sensitivities of the sulfur and carbon bases in group L, that are very low at 30°C, increase by many orders of magnitude as the temperature is increased, Figure 3. These large temperature effects can be explained as follows: For the sulfur and carbon bases, the equilibrium constant, $K_{eq}(1)$ is small due to the very unfavorable hydration of the BH^+-ions relative to the hydronium ion, H_3O^+. At high temperature, the extent of hydration is low, however. This results in an increase in $K_{eq}(1)$ and thus an increase in sensitivity.

The equilibrium constant for reaction 1 can be calculated from the GB of B and from the thermodynamic data for the step-wise gas-phase solvation of H_3O^+ and BH^+, respectively. Thus, when the solvation data is available, the temperature dependence of the sensitivity of a thermodynamically controlled analyte B can be calculated. Such calculations show good agreement with experimental sensitivities. The calculations also reveal that all analytes with GB>210 kcal/mol should have high, kinetically controlled sensitivities at 25°C and at a water pressure of a few torr.

On the Reactivity of NO^+ to Locate CC Double Bonds in Long Chain Aliphatic Compounds Using a Multiquadrupole Triple Analyzer Instrument

Jacques Einhorn (1), Christian Rolando (2) and Christian Malosse (1)
(1) INRA-CNRS
Laboratoire des Médiateurs Chimiques
Magny-les-Hameaux, 78470 St-Rémy-Les-Chevreuse, France

(2) Ecole Normale Supérieure
UA1110, Laboratoire de l'Activation Moléculaire
24 rue Lhomond, 75231 Paris cedex 05, France

It has been shown recently that the characteristic odd-mass fragment ions observed (1) in the CI-NO^+ mass spectra of long chain mono-unsaturated alcohols, acetates and aldehydes can also be formed for alkenes and alkenoic acid esters in certain conditions (2). For the latter compounds, these acylium type ions might then, in principle, be used for structural assignment together with ions of other origins (3,4).

In order to optimize the production of the acylium ions, we have investigated the role of various experimental factors. The observed strong influence of the sample pressure as well as that of the reagent gas (5) might explain the origin of the acylium ions as follows:

$$R_1CH{=}CHR_2 \xrightarrow[\text{or } N_2O_2^+]{NO^+} (R_1CH{=}CHR_2)^+ \xrightarrow{NO^{\cdot}} R_1CO^+ \text{ and/or } R_2CO^+$$

R_1, R_2 = alkyl

According to this hypothesis, the diagnostic products would result from an adduct ion $(M+NO)^+$ after a secondary ion-molecule reaction. The purpose of the present study is to verify this assumption using a multiquadrupole triple analyzer instrument (6) which allows: (i) a primary reaction to be performed in the first collision cell after selection of the cation NO^+ or its dimer $N_2O_2^+$ by the first analyzer. (ii) Selection of the adduct ion by the second analyzer, (iii) a secondary ion-molecule reaction in the second collision cell between the adduct ion and neutral NO·.

Another strategy consists of introducing the alkene with or without NO· in the first collision cell and studying the structure of any of the produced ions by CAD (Ar used as collision gas in the second collision cell). In this case, conventional spectra may be recorded by maintaining the second analyzer transparent.

Ion confinement can also be achieved in either RF-only collision cell using the entrance and exit lenses as electrostatic mirrors (7) to examine the influence of residence time(s).

According to our experiments (Table 1), the only way to produce an acylium ion was to select NO^+ (of various origins) as reactive species from the reagent plasma and allow it to react with both the sample (E-4-nonene) and NO· in the same collision cell (Figure 1, cf. ion at m/z 85). Any attempt to generate an acylium ion through introduction of the alkene alone, even with ion confinement, failed, generating only alkyl ions (cf. CAD or typical profile in the conventional spectrum).

On the other hand, the adduct ion formed using $N_2O_2^+$ is only responsible for the formation of alkyl ions or NO-containing ions (i.e. m/z 114, see Figure 2).

All these results suggest the diagnostic acylium ion(s) produced from alkenes under CI-NO^+ conditions, to originate from an excited adduct ion after stabilization to the required energy by neutral NO·. Further studies are necessary to define the nature (collisional or reactive) of this interaction.

QUANTITATIVE DETERMINATION OF SELECTED COMPOUNDS IN CIGARETTE MAINSTREAM SMOKE USING MULTI-DIMENSIONAL GAS CHROMATOGRAPHY AND SELECTED-ION-MONITORING MASS SPECTROMETRY.

Earl L. White, Mary S. Uhrig, Bert Gordon, Ed J. Nanni, Jr.
Mike F. Borgerding and Richard D. Hicks

R. J. Reynolds Tobacco Company
Bowman Gray Technical Center
Winston-Salem, NC 27102

An automated multidimensional gas chromatographic (MDGC) technique has been developed and optimized for use as an analytical tool for complex mixture analyses. This system utilizes the precolumn of the MDGC system to effectively replace the chemical fractionations employed in more classical sample preparation schemes. MDGC systems interfaced to a mass spectrometer and to a matrix isolation/Fourier Transform-infrared spectrometer were used to identify components of a flue-cured tobacco essential oil sample.[1] Eight (8) compounds from a Kentucky 1R4F reference cigarette smoke condensate were selected for determination by selected-ion-monitoring mass spectrometry to confirm the validity of MDGC as a quantitative tool in complex mixture analyses.

Four (4) electrostatically precipitated smoke condensates from 100 cigarettes were each reconstituted in 60 ml of 2-propanol containing 2 esters (C_8 and C_{14}) used as internal standards (IS) and a second set of samples reconstituted in 60 ml of 2-propanol containing 5 deuterium-labeled compounds. A 5 ul aliquot of each sample was injected onto a precolumn using cool on-column injection. At pre-selected times, the eluant of the first column was transferred (heartcut) to a second (analytical) column via a multidimensional capillary switching device (SGE) modified for use in two separate standard chromatograph ovens.

A series of solutions containing authentic compounds of interest was prepared and subjected to identical analyses as the samples to obtain standard dilution curves. Analysis of the compounds of interest, pyridine, acetamide, acrylamide, phenol, o-, m-, p-cresol, and quinoline was accomplished using two heartcuts and two of the three IS selected for injection volume and heartcut-corrections in analyses similar to the essential oil analyses. Three heartcuts were made in the portion of this study employing deuterium-labeled internal standards. The result of this study showed that the MDGC technique developed could be used for quantitative analyses. The precision of the technique using esters as internal standards was determined by injecting a single sample eight (8) times and determining the mean $\pm$ std. dev. for each compound. These values were 1.96 $\pm$ 0.08, 11.30 $\pm$ 0.09, 2.27 $\pm$ 0.09, 12.22 $\pm$ 0.19, 3.29 $\pm$ 0.08, 6.92 $\pm$ 0.10, 0.99 $\pm$ 0.05 and 0.30 $\pm$ 0.01 for pyridine, acetamide, acrylamide, phenol, o-cresol, p-cresol, m-cresol and quinoline, respectively. Mean values $\pm$ std. dev. for a different sample injected seven (7) times using deuterium-labeled internal standards were 2.27 $\pm$ 0.04, 5.56 $\pm$ 0.08, 1.43 $\pm$ 0.12, 7.71 $\pm$ 0.03, 2.51 $\pm$ 0.24, 5.48 $\pm$ 0.15, 2.16 $\pm$ 0.11 and 0.23 $\pm$ 0.01 for pyridine, acetamide, acrylamide, phenol, o-cresol, p-cresol, m-cresol and quinoline, respectively. These results showed that the precision of the technique using methyl esters as internal standards was comparable to that using deuterium-labeled compounds as internal standards.

ANALYSIS OF ETHYL DIMETHYLPHOSPHORAMIDOCYANIDATE (TABUN) BY CAPILLARY COLUMN GAS CHROMATOGRAPHY-MASS SPECTROMETRY, Paul A. D'Agostino, Lionel R. Provost and Karen M. Looye, Defence Research Establishment Suffield, Ralston, Alberta, Canada, TOJ 2NO.

The alleged use of the nerve agent ethyl dimethylphosphoramidocyanidate (tabun) in the Iran-Iraq war emphasizes the need for specific detection and identification procedures for the verification of this and other chemical warfare agents (1). Gas chromatographic-mass spectrometric (GC-MS) techniques have been used extensively for the analysis of organophosphorus compounds. Electron impact (EI) ionization of organophosphorus compounds provides valuable structural information, but the presence of little or no molecular ion data often hinders the identification of unknowns. Chemical ionization (CI) has been used with increasing frequency to provide the molecular ion information necessary for the identification of these organophosphorus compounds (2-4).

Previous GC-MS analysis of tabun samples by several laboratories has resulted in the detection of several tabun related impurities including diethyl dimethylphosphoramidate, ethyl isopropyl dimethylphosphoramidate, triethyl phosphate, ethyl tetramethylphosphorodiamidate, tetramethylphosphorodiamidic cyanide and two pyrophosphates (3, 5, 6). Recent analysis of a munitions grade tabun sample by our laboratory indicated the presence of all of the above compounds and a number of other impurities. The primary objective of this GC-MS study was the identification of these unknown sample components, as this information may aid future chemical event verification.

Capillary column GC-MS analyses were performed with a VG 70/70E mass spectrometer equipped with a Varian 3700 gas chromatograph under the following conditions: (GC column: 15 m x 0.32 mm ID J+W DBWAX or DB-1701; Temperature program: 50°C (2 min) 10°/min 230°C (DBWAX) or 280°C (DB-1701) (5 min); Injector: cold on-column at 50°C; EI: 200°C, 100 µA; 70 eV; 2 x 10^{-6} torr; Ammonia CI: 120-140°C; 500 µA; 50 eV; 5-6 x 10^{-5} torr; Scan rate and function: 500 to 35 u, 1 sec/decade).

Figure 1 illustrates a typical capillary column GC-MS total-ion-current chromatogram for about 1 µg of munitions grade tabun. Tabun and nineteen sample components, listed in Table I, were identified (or tentatively identified) based on the acquired mass spectral data. Figures 2 to 4 illustrate the EI, NH_3-CI and ND_3-CI mass spectra acquired for tabun, the isopropyl analogue of tabun, isopropyl dimethylphosphoramidocyanidate and diisopropyl ethyl phosphate. Characteristic fragmentation ions, and in some cases molecular ions, were obtained for these and the other organophosphorus sample components during EI operation. Complementary pseudo-molecular $(M+X)^+$ and/or $(M+NX_4)^+$ (where X=H during NH_3-CI and X=D during ND_3-CI) ions, along with a limited number of CI fragmentation ions, were observed for all the tabun related impurities. ND_3-CI data was also valuable for the identification of previously unreported compounds such as diisopropyl ethyl phosphate, since the CI fragmentation ions contained active hydrogens which underwent isotopic exchange (H/D ex.) with deuterium during CI analysis. Successive losses of C_3H_6 from the pseudo-molecular ions, illustrated below, suggested this was a compound with two isopropoxy substituents (Figure 4).

NH$_3$-CI:	$(M+H)^+$	$\xrightarrow{-C_3H_6}$	m/z 169	$\xrightarrow{-C_3H_6}$	m/z 127
	$(M+NH_4)^+$		m/z 186		m/z 144
ND$_3$-CI:	$(M+D)^+$	$\xrightarrow{-C_3H_6}$	m/z 171	$\xrightarrow{-C_3H_6}$	m/z 130
	$(M+ND_4)^+$	H/D ex.	m/z 191	H/D ex.	m/z 150

Interpretation of the EI, NH_3-CI and ND_3-CI data enabled the identification of nineteen tabun related impurities, including twelve new monophosphorus and pyrophosphate compounds previously unreported or unassociated with tabun. Application of the methodology and reported findings is anticipated since characteristic sample components may provide analysts with sample origin, synthetic method or munitions type information.

HPLC/MS AND HPLC/MS/MS ANALYSIS OF WASTE SAMPLES FOR ORGANOPHOSPHORUS PESTICIDES

L.D. Betowski and T.L. Jones, U.S.
Environmental Protection Agency, Las Vegas,
Nevada 89193-3478

INTRODUCTION

The U.S. Environmental Protection Agency recently conducted a single laboratory validation of SW-846 Method 8140, Organophosphorus Pesticide Parameters[1]. This procedure is a gas chromatographic method for the analysis of organophosphorus pesticides in water, soil, and hazardous waste. In addition to the presentation of data on precision and accuracy, the validation report provided findings on analytical difficulties encountered with specific organophosphorus pesticides. The purpose of this present work is to investigate the use of high performance liquid chromatography/mass spectrometry (HPLC/MS) and HPLC/MS/MS for the analysis of problem compounds.

EXPERIMENTAL

A Finnigan TSQ®45 was operated with a Vestec Thermospray LC/MS interface and a Spectra-Physics SP8700XR pump to generate the HPLC/MS and HPLC/MS/MS data. An Isco LC-5000 syringe pump was used o deliver a ostcolumn flow of ammonium acetate. A 10cm x 2mm ODS Hypersil 5um PN-Special analytical column from Keystone Scientific was the chromatographic element.

The CAD experiments were conducted at a collision energy of 20eV with argon at a pressure of 1 mTorr.

RESULTS AND DISCUSSION

Ten organophosphorus pesticides were chosen to be studied by HPLC/MS because of their poor recoveries under Method 8140. Thermospray ionization generated mainly the protonated molecule at $(M + 1)^+$ and the ammoniated adduct ion at $(M + 18)^+$ in the single quadrupole mass spectra of these compounds. Methyl parathion showed a 30 amu loss from these ions which can be attributed to either a loss of NO_2 or the reduction to the corresponding amine. Trichlorfon and, to a lesser extent, naled show evidence of degradation to dichlorvos. Merphos showed a large contamination of merphos oxide which eluted 2.5 minutes before the merphos peak.

While most of the ion current remains in the protonated molecules and adduct ions upon thermospray introduction, CAD daughter ion spectra show ions characteristic of the structure of the molecule or class of compound. For example, the organophosphates show a significant m/z 127 ion while for the phosphorothionates and the phosphorodithioates, the O,O-dimethyl compounds show a strong m/z 125 ion. These are also characteristic ions formed under electron impact mass spectrometry conditions[2].

The CAD daughter ion spectra were useful in identifying the organophorphorus pesticides in soil samples. For example, one large and one smaller peak at m/z 275 eluted in the retention window for disulfoton (molecular weight, 274). Only by subjecting the m/z 275 ions to the CAD process were we able to identify the smaller peak as disulfoton.

The limits of detection for these organophosphorus pesticides ranged from 200pg injected in the full scan mode for naled to 30ng for methyl parathion. Precision results from triplicate injections on standards for these compounds gave a grand mean of 7.1%.

Four soil samples that were known by GC/MS to contain organophosphorus pesticides were chosen for analysis by LC/MS. The results from these analysis along with the amounts from GC/MS are listed on Table 1. Qualitatively, the results show good agreement. Only in sample 1 is there some doubt about the presence of compounds. The same compounds were detected by both techniques in the rest of the samples. In some cases the results are quantitatively very close as for phorate and methyl parathion in sample 2 and disulfoton in sample 3. The amounts calculated for dimethoate and phorate are higher under LC/MS analysis for all occurrences of these compounds. Since these compounds have shown difficulties under GC analysis, it is possible that some of these compounds were degraded or irreversibly bonded on the GC.

ON-COLUMN CAPILLARY GC/MS OF NON-IONIC DYES, **Robert T. Rosen**[1], Lise H. Royin[2], Thomas G. Hartman[1], Linda B. Clark[2], Jeffrey Oxenford[3], Chi-Tang Ho[2] and Joseph D. Rosen[2]. Center for Advanced Food Technology[1] and Food Science Department[2], Cook College, New Jersey Agricultural Experiment Station, Rutgers University, New Brunswick, New Jersey 08903, and New Jersey Department of Environmental Protection[3], Trenton, New Jersey 08625.

Dyes derived from coal tar and from synthetic sources are important because some of them are known mutagens. Examples include aminobiphenyl and naphthylamine which have been identified as bladder carcinogens.

On-column capillary GC/MS has, for the first time, been used to determine the presence of non-ionic dyes in plant waste streams. This includes those compounds containing an azo functionality. Previous methodology[1,2] has required LC/MS accompanied by MS/MS to identify these species.

On-column capillary GC/MS using electron ionization is a technique whose simplicity makes analysis applicable to any environmental laboratory, even when using automatic injectors. Using an on-column injector of our own design[3] EI spectra were obtained for a series of compounds including Disperse Orange 3 (MW 242), Solvent Red 3 (MW 292), Pigment Red 3 (MW 307), Solvent Red 23 (MW 352), and Sudan Red 7B (MW 379). Although hundreds of azo dyes are utilized by the dye industry, this analysis was limited by the lack of their commercial availability.

Samples from an industrial dye facility were screened using on-column capillary GC/MS. While most of the compounds identified were precursors such as substituted anilines and nitrogen heterocycles, several dyes were identified. These include methoxynitroaminobiphenyl and its azo analog, as well as two analogs also containing an acid moiety. An isolated fraction containing these four species was active in the Ames test. The Spectra and Structures of the two major dyes are shown below.

THE APPLICATION OF A HIGH RESOLUTION MASS SPECTROMETRIC METHOD FOR MEASURING 2,3,7,8-TCDD IN HUMAN ADIPOSE TISSUE AND SERUM: THE VIETNAM VETERAN AGENT ORANGE AND RANCH HAND VALIDATION STUDIES; 2,3,7,8-TCDD HUMAN HALF-LIFE STUDY; MISSOURI RESIDENTS CASE/CONTROL STUDY; AND OCCUPATIONALLY EXPOSED WORKERS.

D.G. Patterson, Jr., L.R. Alexander, W.E. Turner, L.L. Needham, J.S. Andrews, Jr., J.L. Pirkle, and E.J. Sampson

Division of Environmental Health Laboratory Sciences, Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services, Atlanta, GA 30333

Introduction

Intense public health interest continues to focus on the polychlorinated dibenzo p-dioxins and related compounds. Humans are exposed to many of these compounds from such sources as municipal incinerators and automobile exhausts; other sources, such as the manufacture and use of compounds for which 2,4,5 trichlorophenol is a synthetic intermediate, give rise primarily to 2,3,7,8-TCDD. A number of recent studies have shown that the level of 2,3,7,8-TCDD in the adipose tissue of individuals from several industrialized countries is about 6-7 parts per-trillion. Over the past two years we have analyzed more than 2,000 adipose tissue and serum sample and over 800 quality control samples in five different studies.

The Vietnam Veteran Agent Orange Validation Study

Purpose of the Study: To determine whether military records can be used to identify veterans likely to have been exposed to Herbicide Agent Orange.

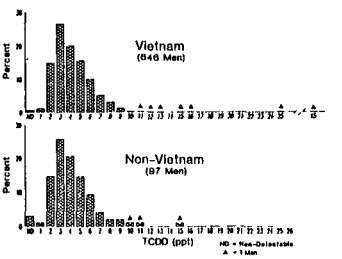
Indirect Exposure Measures: 1) "Hits": Weighted number of days within 2 km of an Agent Orange spray, within 6 days after the spray; 2) Slow decay: Weighted number of days within 2 km of a previous Agent Orange Spray; 3) the same scores for sprays with agent unknown; 4) the number of days in 5 heavily sprayed areas; and 5) Two self-reported measures of exposure.

Summary of Results: 1) No association between current serum TCDD levels and any indirect measure of exposure; and 2) Serum TCDD distribution in these Vietnam veterans is the same as in unexposed veterans (see Table 1 and Figure 1).

Table 1. TCDD Levels by Place of Service

Place of Service	Mean I s.d. (ppt)
Non-Vietnam (n = 97)	4.1 ± 2.3
Vietnam (n = 646)	4.2 ± 2.6

Figure 1. TCDD Distribution in Vietnam and Non-Vietnam Ground Troop Veterans



Ranch Hand Vietnam Veterans Pilot Study

Purpose of the Study: To assess the validity of the study design and exposure index for evaluating the possible exposure of Ranch Hand veterans to Agent Orange.

Summary of Results: 39% of Ranch Hand Veterans had TCDD < 20 ppt, while 98% of the comparisons had TCDD < 20 ppt (see Table 2 and Figure 2).

Table 2. Current TCDD Levels by Group (ppt)

2378-TCDD	Ranch Hand (n = 147)	Comparison (n = 49)
Mean	49.4	5.2
Median	26.5	4.7
Range	3.2-313	2.0-21.3

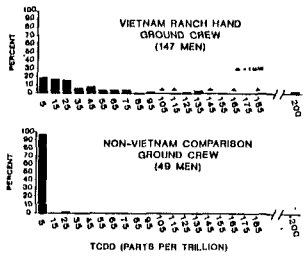


Figure 2. TCDD Distribution in Vietnam and Non-Vietnam Ground Crew Veterans

Conclusions: 1) Some Ranch Hand Veterans have had unusual TCDD exposure; 2) Since 39% of exposed group had TCDD < 20 ppt, an actual body burden measurement is necessary.

2,3,7,8-TCDD Half-Life in Humans

Purpose of the study: To better estimate the half-life of 2,3,7,8-TCDD in humans.

Summary of Results: The half-life of 2,3,7,8-TCDD in serum has been measured in 36 Air Force Vietnam veterans of Operation Ranch Hand. From serum samples taken in 1982 and 1987, the median half life of 2,3,7,8-TCDD in these Ranch Hand veterans was found to be 7.1 years (95% confidence internal about the median of 5.8 to 9.6 years). Levels of 2,3,7,8-TCDD in the 1982 serum samples ranged from 16.9 to 423 ppt.

Missouri Residents Case/Control Study

Purpose of the study: To compare 2,3,7,8-TCDD levels in persons from Missouri with exposure to waste oils and Missouri residents with no known exposure.

Summary of Results: 1) Participants from each of the four exposed groups (TCP production; horse arena riding; residential; waste hauling) had adipose tissue TCDD levels that exceeded 20.2 ppt, the highest level measured in persons with no known exposure (see Table 3 and Figures 3 and 4); 2) Twenty-two (43%) of the 51 exposed participants had TCDD levels of 20.2 ppt or less.

Conclusion: An objective measure of adipose tissue 2,3,7,8-TCDD makes it possible to minimize misclassification when studying the association of TCDD exposure and health effects.

Table 3. Adipose Tissue Levels (Whole-Weight Basis) in ppt in 51 Exposed Participants, Missouri 1986.

Exposure Status	n	Range	Mean	s.d.	Median
TCP Production	9	41.9-750	245	287	122
Horse Arena	16	5.0-577	145	202	24.1
Residential	16	5.2-59.1	26.8	18.9	19.5
Waste Handling	10	3.7-25.8	12.4	8.3	9.0

Detection of polychlorinated terphenyls by gas chromatography mass spectrometry with negative chemical ionisation

J. Greaves and R. C. Hale
Virginia Institute of Marine Science
College of William and Mary
Gloucester Point, Virginia 23062

Polychlorinated terphenyls (PCT) are a group of compounds that were recommended as alternatives to polychlorinated biphenyls (PCB) for certain industrial applications. Although not used to the same extent as PCB, production was of the order of 10% that of PCB. PCT have been used in a wide variety of applications which included: waxes for investment casting, printers ink, sealants, adhesives, resins and lubricants. PCT manufactured in the United States were marketed as components of the Aroclor 25, 44, 50, 54 and 60 series, with the 54 series being the only formulation consisting purely of PCT. The 25, 44 and 60 series were mixtures of PCT and PCB and the 50 series formulations were unpurified versions of the 54 series. The two major members of the 54 series were 5432 and 5460, where the 32 and 60 in the nomenclature designated the percentage chlorine by weight. There have been few reports published on the analysis of these compounds, due in part to their relatively high molecular weight, the large number of isomers making chromatographic separation difficult, and the fact that U.S. manufacture ceased in 1972. PCT are, however, both highly persistent and toxic and, in addition, since the toxicity of this type of compound is related to isomeric structure and degree of chlorination, a more detailed study of them may be important. The first stages of this research are reported here.

Late eluting peaks detected on a GC with a Hall detector were identified as PCT using an Extrel ELQ 400-2 GC-MS with negative chemical ionisation. Methane was the moderator gas. The spectra obtained were typical of chlorinated hydrocarbons when negative chemical ionisation is used and showed $[M]^-$, $[M + O - Cl]^-$, $[M - Cl]^-$ ions and sequential losses of chlorine. The extent of fragmentation was positively correlated with increasing degree of chlorination. Aroclor 5432 consisted of terphenyl substituted with 2-5 chlorine atoms. In Aroclor 5460 the predominant congeners contained from 7-10 chlorine atoms, though as many as 12 chlorine atoms were seen. A 25 m fused silica GC column, coated with SE-54, was used. The column was run directly to the ionisation volume of the MS. The Aroclor 5432 and 5460 components eluted before and after decachlorobiphenyl, respectively. Some minor overlap between Aroclor 5432 and highly chlorinated PCB formulations (eg. Aroclor 1254), was observed.

Freeze-dried sediment samples, dry weight approximately 70 g, were soxhlet extracted with dichloromethane and cleaned up by gel permeation and Florisil chromatography. Decachlorobiphenyl was used as the internal standard. The sediment samples were obtained near effluent outfalls at a wide variety of sites, including ship repair and building facilities, military installations and research centers. Both mass spectral and GC peak patterns matched those obtained for standard mixtures, confirming the presence of PCT. Mass spectra and GC peak patterns matched those obtained for both Aroclor 5432 and 5460. Concentrations detected were in the 0.6 to 30 ppm range, based on response factors calculated for the Aroclors against decachlorobiphenyl. In certain samples the PCT concentration exceeded that for PCB. Initial work has been carried out to examine biota from these sites and there is some preliminary evidence that selective accumulation of the lower chlorinated PCT may be occurring.

LASER DESORPTION FOURIER TRANSFORM MASS SPECTROMETRY OF HYDROCARBON SOOT

Hun Young So and Charles L. Wilkins
Department of Chemistry
University of California, Riverside
Riverside, CA 92521

Laser desorption Fourier Transform mass spectrometry (LD/FT/MS) (1) is applied to characterize molecular weight distribution of benzene soot. Soot is chosen as an example of a complicated sample matrix. It is well known that soot contains a variety of polycyclic aromatic hydrocarbons (PAH) and large size spherical carbonaceous material. Most of PAH analysis of environmental samples have been limited to lower molecular weight PAH, due to their low volatility and lack of standard materials (2). The LD technique is used to investigate the distribution of higher molecular weight (>400 amu) PAH in soot. The spherical structure of soot was discussed in relation to the carbon clusters (3). We investigated soot as a possible source of carbon clusters.

A Nicolet FT-2000 equipped with an autoprobe and a CO_2 laser was used in this experiment. Soot was collected directly on the stainless steel probe tip. A typical LD/FT/MS spectrum of benzene soot is shown in Fig. 1. The empirical formulas of high intensity peaks are assigned by comparing with spectra given by deuterated benzene soot (Fig. 2b). Most of the high intensity peaks of each peak groups are characterized as PAH. It is interesting to observe that PAH with even numbers of carbons (lettered in Fig 2) show higher intensities than those with odd numbers of carbons (numbered in Fig. 2). Detection of PAH with higher molecular weight than the previously reported is shown in Fig. 1. Similar distributions of PAH are also observed with soot from other hydrocarbon fuels.

A series of peaks 24 amu apart are observed in the high mass region of the LD/FT/MS spectrum of benzene soot , and are appeared to be carbon clusters. In a spectrum acquired with 131K data points, carbon clusters with up to 120 carbons could be detected with reasonable resolution, in addition to PAH components.

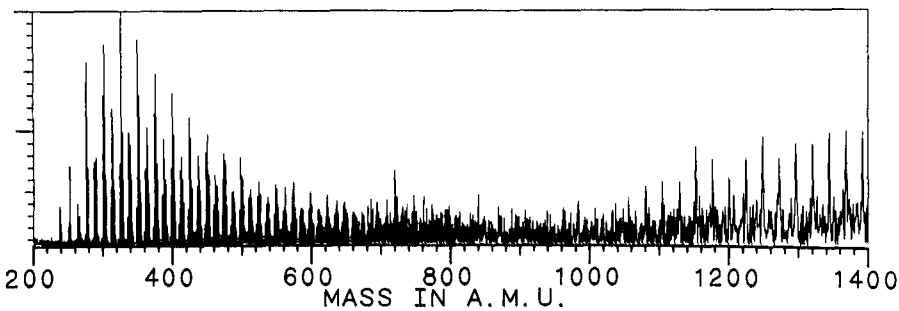

Fig. 1 LD/FT/MS spectrum of benzene soot, 50 time domain signals were coadded, band width-2.6 MHz, data points-131K

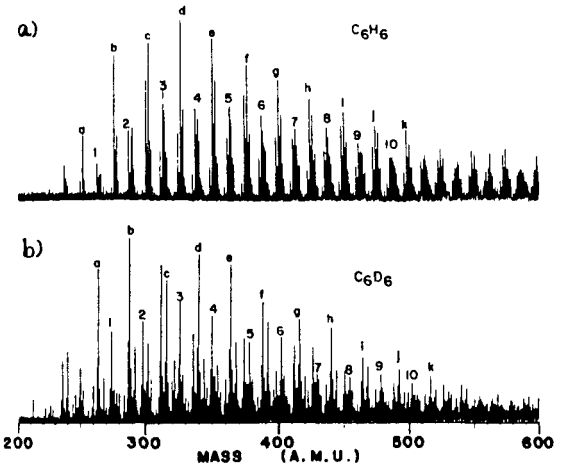

Fig 2. Comparison of the two spectra to assign empirical formulas of the peaks.

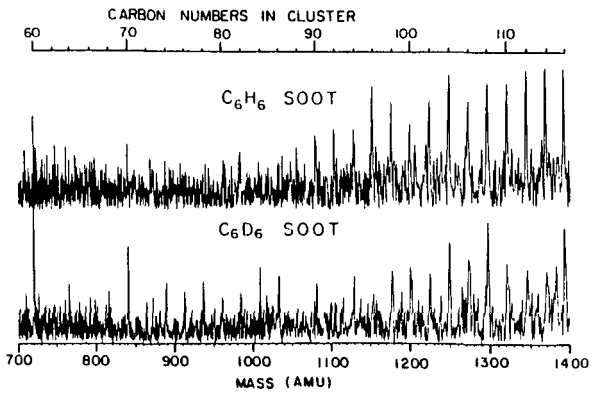

Fig 3. Carbon clusters observed in LD/FT/MS of soot samples.

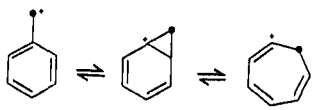
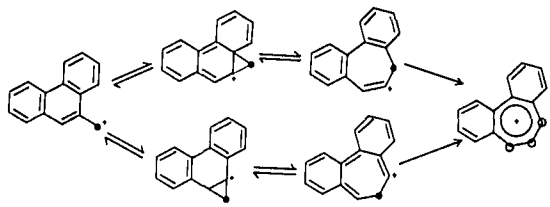
CAD Analysis of Methyl PAH: Fused-ring Tropylium Ion Formation and Fragmentation:

Laurel L. Standley and Ronald A. Hites; School of Public and Environmental Affairs and Department of Chemistry, Indiana University, Bloomington, IN, 47405.

The formation of tropylium ions by the rearrangement of alkyl benzenes is well documented in mass spectrometric studies[1]. The most likely mechanism for the formation of these ions is through a cyclopropyl intermediate as shown below[2,3]. Early research also demonstrated that the carbons in the tropylium ion are scrambled[4]. An equilibrium between the benzylium and tropylium ions through the cyclopropyl intermediate was considered to be the mechanism for carbon atom scrambling[2,3]. The question arises as to whether alkyl polycyclic aromatic hydrocarbons (PAH) also rearrange to form a tropylium-type ion. They might form and scramble by the same mechanism:





Note the large $(M-1)^+$ ion (m/z 191) in the mass spectrum of 9-methyl phenanthrene shown in Figure 1. The structure of this ion parallels the $(M-1)^+$ ion in methyl benzene, which corresponds to the tropylium ion rearrangement product. In this study, we demonstrate the formation of fused-ring tropylium ions from methyl phenanthrenes and anthracenes. Four possible fused-ring tropylium structures can be formed from these compounds, depending on whether the methyl group is on the center or terminal ring.

The fragmentation patterns of the methyl phenanthrenes and anthracenes were studied using MS/MS on a VG 30-250 triple quadrupole instrument. The major fragmentation route, after loss of a hydrogen to form the $(M-1)^+$ (m/z 191) ion, was a sequential loss of several neutral acetylene molecules (see Figure 2). A minor amount of CH_3 was also lost from the m/z 191 ion forming an ion which subsequently lost an acetylene group. However, the predominant fragment formed from the m/z 191 ion was the m/z 165 ion. This is the fragmentation which proved most useful as an indicator of structure as will be discussed below. No statistically significant differences were found between the methyl phenanthrene and anthracene isomers in the MS/MS results with respect to either the fragmentation pathway or the intensity of fragments formed.

To prove whether the structures of these m/z 191 ions were in the form of fused-ring tropylium ions, we studied labeled compounds. We synthesized ^{13}C-labeled methyl phenanthrenes and anthracenes and then monitored the loss of that label during fragmentation of the m/z 192 (the labeled ion equivalent to m/z 191) ion to the m/z 165 and 166 fragment ions. Two mechanisms can affect the loss of the label (see Figure 3): (a) whether or not the methyl carbon scrambles after incorporation into the tropylium ring; and (b) from where in the structure the acetylene group is lost.

The C_2H_2 group could either be lost from the seven membered tropylium ring (losses 1 and 2 as shown in Figure 3) and/or from either of the six membered rings (losses 3 through 8 as shown in Figure 3). In order to determine which loss would be more likely, if either, we calculated the heats of formation of the various structures using the semi-empirical model MNDO. The heats of formation give a relative measure of the stability of structures, i.e.- the more stable a structure the lower its heat of formation. Two of the fused-ring tropylium structures and the possible fragmentation products are shown in Figure 4. The calculated heats of formation in kcal/mole are listed below the structures. In the first example, the structure with the tropylium ring in the center of the molecule (formed from 9-methyl anthracene) could fragment by losing the acetylene molecule either from the six membered ring or from the seven membered ring to form structures with heats of formation of 280 and 240 kcal/mole, respectively. The structure resulting from fragmentation of the seven-membered ring is clearly more stable, as reflected in its heat of formation being 40 kcal/mole less than that of the other fragmentation product; it is thus more likely to form. Fragmentation products of the fused-ring tropylium ion formed from 1, 2, 3, or 4-methyl phenanthrene can be compared in a similar fashion. Again note that the product resulting from the loss of the acetylene molecule from the seven-membered

ring is more stable than the product forming from a loss from the six-membered ring, this time by 11 kcal/mole.

Thus far our results have documented that fragmentation of these $(M-1)^+$ ions occurs predominantly by losing an acetylene molecule from the seven-membered ring. Whether or not the labeled carbon scrambles in the structure, as has been shown to occur in the tropylium ion, will also affect whether or not it will be lost upon fragmentation. Based on the mechanism proposed earlier (i.e.- the cyclopropyl intermediate), the methyl carbon should be scrambled in the tropylium ring only. Experimental results for the methyl phenanthrenes support the two predictions discussed above (i.e.- loss of the acetylene molecule from and scrambling in the seven-membered ring only). The methyl anthracenes, however, did not match the theoretical predictions as well as the phenanthrenes. The only mechanism which explained the results was an equilibrium between the two fused-ring anthracene tropylium ions (i.e. - one with the tropylium ring in the center of the three rings and the other in the terminal position). We calculated the heats of formation (as described earlier) for the most likely transition states to see if an equilibrium between the two ions would be energetically feasible. There was no additional energy barrier beyond those necessary to form and equilibrate the fused-ring tropylium ions in the first place. The phenanthrene ions may not equilibrate to the extent of the anthracene ions due to a rate limiting step or a high energy intermediate which we have not yet considered. Formation of the benzylium ion with no rearrangement to the fused-ring tropylium ion was ruled out with these results.

THE ANALYSIS OF ORGANIC COMPOUNDS IN DRINKING WATERS BY MASS SPECTROMETRY: SOME REMAINING PROBLEMS

H A James, T M Gibson and I Hammond, Water Research Centre, Medmenham Laboratory, PO Box 16 Marlow, Bucks SL7 2HD, UK

Mass spectrometry has been applied to the identification and quantification of organic compounds in drinking waters for over 20 years. Examination of published data indicates that there are some areas in which MS has yet to be totally successful and where effort needs to be directed. Experience in our laboratory over the last fifteen years suggests that three such areas are the identification of unknowns detected by GCMS, the identification of non-volatile compounds (ie compounds not amenable to analysis by GCMS), and quantification.

We find that unknowns (compounds not immediately identifiable by comparison with reference data or by manual interpretation) are regularly detected during general-survey GCMS examination of extracts from drinking waters. It has been noted (1) that due to the effort and expense arising from the application of non-routine MS and other techniques, it is not practical to attempt to identify most of these unknowns. However, in certain instances, eg when a sample is being analysed because of customer complaints, there may be an urgent requirement to identify an unknown. The identification of 2-t-butyl-5-methyl-p-benzoquinone is one such instance. We found that this compound was responsible for a "graphitic" taste in some drinking waters. Its electron impact spectrum, which as far as is known is not present in any reference collections is shown in Figure 1.

It is difficult to form a scientifically credible view of the correct reaction following the detection of an unknown in a sample of water examined during routine monitoring activities. Even if identification is possible, because of insufficient toxicological data, the implications of the findings are usually not clear. Frequently unknown spectra are added to a library of unknowns, but this is only of value if some positive action is taken in the event of regular and frequent detection of a particular unknown.

A related problem which has recently been noted (2), concerns mis-identification. This is particularly likely to occur when automated spectral interpretation techniques are employed, and the only remedy appears to be expert scrutiny of results.

The identification of non-volatile compounds (ie compounds not amenable to analysis by GCMS) is an area which seems to be developing very slowly at present. There are many possible reasons for this.

We have found that a target compound approach has been more productive than a general-survey approach for non-volatiles. Compound classes successfully analysed at WRc in drinking waters using off-line LC - "soft-ionisation" MS include epoxy resin components (3), surfactants and pharmaceuticals (4). Initial experience with thermospray LCMS suggests that, as for LC combined with FD or FAB, its main utility at present lies in its use in a target compound mode, as the spectra produced from some compounds can be difficult to predict.

Quantification, even following well documented methodology, is often not an easy task (5). We have found, along with others, that for general survey analysis, the use of deuterated internal standards can assist in the provision of preliminary quantitative information (6), which is often useful in deciding whether further (better) quantification is necessary. Normally, this latter data would be

produced using selected ion monitoring, which is a widely used and fairly routine technique. However, we encountered problems with the quantification of 3-chloro-4-(dichloromethyl)-5-hydroxy -2(3H)-furanone, a potent mutagen which may be present in some drinking waters (7). Its analysis as the methyl ether had been previously described (8), but we found that initially the response on GCMS was non-linear. Following the inclusion of a combined oxygen/water trap in the carrier gas line (rather than just an oxygen trap) it gave a linear response, which improved the detection limit.

Some of the problems mentioned above, particularly those related to GCMS, will undoubtedly be alleviated by improvements and advances in instrumentation (eg the more widespread availability and use of triple quadrupole mass spectrometers). However, at present it appears unlikely that there will be similar progress in the identification of non-volatiles, unless many more laboratories show an interest in this type of work.

A VOLATILE ORGANIC ANALYZER FOR SPACECRAFT AIR QUALITY MONITORING

*Theodore J. Galen, Duane L. Pierson, Biomedical Laboratories,
NASA Johnson Space Center, *KRUG International, Houston, TX 77058

In manned space exploration, maintaining the quality of the air which the astronauts breathe in the spacecraft is extremely critical. Sources of air contaminants can include materials offgassing, utility chemicals, thermal degradation, inflight scientific experiments, and human metabolites. Analogous to the Environmental Protection Agency's air quality standards here on Earth, NASA has established spacecraft maximum allowable concentration limits for many volatile compounds. The environmental control and life support system on board the spacecraft is equipped with various technologies (e.g. scrubbers containing lithium hydroxide and charcoal and active catalytic processes) to remove contaminants such as carbon dioxide, carbon monoxide, and volatile organics. The environmental control system maintains a constant level of oxygen, supplementing the oxygen consumed by respiration; it is a partially closed-loop system supplying only make-up oxygen and nitrogen and removing only selected contaminants. In the Space Shuttle Program, the operational efficiency of the system has been assessed by collecting samples during each mission and performing postflight analysis for trace-level contaminants using gas chromatography/mass spectrometry. For long-term shuttle missions, planetary missions, or missions on board the permanently manned space station, monitoring the levels of potentially harmful volatile compounds in the spacecraft atmosphere in flight, on a real-time basis will be essential.

To verify that the air in the spacecraft is safe and that the purification system is operating effectively, particularly on long-term missions, a Volatile Organic Analyzer system is being developed in the Toxicology Laboratory of the Biomedical Laboratories Branch at the Johnson Space Center in Houston. The Volatile Organic Analyzer is being developed to unequivocally identify all the known potentially harmful volatile compounds and to quantitatively determine that these compounds are not exceeding the predetermined maximum allowable limits. In addition, this system will be used to characterize volatile organics which have not been previously identified in the spacecraft atmosphere. The following is a list of the primary design considerations: the system must be space-flight compatible with respect to size, weight, and power requirements; it must be capable of withstanding the launch- and boost-vibration profile; it must be able to function in microgravity; and it must be as fully automated as possible, providing ease of operation and requiring minimum crew/operator time.

The Volatile Organic Analyzer prototype system is composed of a combination of four subsystems: a sample inlet, a gas chromatograph, a mass detector, and a computer. The sample inlet subsystem contains a sampling pump and solenoid valve, a series of Tenax traps to concentrate the volatile organics, and a 10-port micro switching valve. The gas chromatograph subsystem utilizes a temperature-programmable oven containing a state-of-the-art fused-silica capillary column. A commercially available ion trap detector functions as the mass analyzer. The computer subsystem operates using a standard lap-top IBM-compatible computer.

The sample inlet and gas chromatograph subsystems are only available commercially as large standard laboratory equipment. After extensive evaluation and modification of various candidate technologies, a flight-prototype of these subsystems has been developed. In designing the gas chromatograph subsystem, significant reductions were made in the size, weight, and power required to operate the subsystem. The gas chromatograph was integrated with an automatic sampling system for preconcentration of the trace-level contaminants present in an air sample. This integration required requiring isolation and precise control of five independent temperature zones: the sample inlet, the two Tenax traps, the micro switching valve, and the analytical column oven. To maximize the analytical performance, the inlet and the gas chromatograph were designed to be compatible with the fused-silica capillary columns. With accurate helium carrier gas control, the analytical column was directly coupled to the ion trap detector without the need for an open/split interface. To control the Volatile Organic Analyzer, integrated software was developed for the lap-top computer. The computer subsystem controls the overall system sequence timing; the sample inlet functions, including the operation of the sample pump and solenoid valve; the position and timing of the 10-port valve driver; and the four thermal zones. The computer also controls and monitors the analytical column temperature in both isothermal and temperature-programming modes. It functions as the operational computer

for the ion trap detector, controlling the temperature and performing data acquisition and analysis.

Over the past year, the major progress in this development effort has been the reduction in the size and weight of the inlet and gas chromatograph subsystems. The operation of these subsystems can be described as follows: in valve position "A," an air sample is drawn into the first Tenax trap by the sampling pump. The solenoid vent valve is closed at this time. The switching valve then rotates to position "B," and the compounds collected on the first Tenax trap are thermally desorbed and transferred to the second and smaller Tenax trap. The switching valve then rotates back to position "A," and the smaller trap is ballistically heated to desorb the organics as a narrow band onto the fused-silica analytical column. Separation of the mixture of organic compounds present in the sample occurs by temperature-programmed capillary gas chromatography. The ion trap is used to detect and identify the compounds as they elute from the analytical column. Finally, the valve rotates to position "B," where both Tenax traps are thermally cleaned and the sample inlet is purged in preparation for the next sample.

The overall system has been operated both with non-polar and polar capillary columns. Typical operational parameters for the ion trap detector are scanning from 35 to 300 AMU at one scan per second with a trap temperature of 150 degrees and a multiplier setting of 1550 volts. Utilizing version 3 software, the trap is run with the AGC on. Checks are performed of the total system background by introducing zero air samples as blanks into the analyzer system. Overall system sensitivity has been measured by sampling a 1 ppm standard of fluorobenzene at various times, ranging from 2 to 20 seconds and equivalent to 12 to 120 pg on column. To test the overall performance of the system, 2 test mixtures composed of 10 and 25 selected volatile organics were blended as standards. The concentration of the the individual components ranged from 70 to 150 ppb or 70 to 150 ng of each compound on column. The analysis of these standards demonstrated that the system could automatically sample an atmosphere, concentrate the organic components, and subsequently separate and identify individual compounds based on their mass fragmentation. In addition, all operations were performed in an automated manner, including sequence timing, temperature and valve control, data acquisition and analysis.

The goal of this NASA development effort has been to maintain or enhance the Volatile Organic Analyzer's analytical performance, while combining the four subsystems into an integrated package. A source has been identified for mechanical and electrical integration of the four subsystems into a single package. This effort will include further significant reductions in total system size and weight and will entail converting the system to spacecraft power sources. To date, engineering drawings have been prepared, and a one- to-one scale model system has been fabricated. Future work on the Volatile Organic Analyzer will include system integration of the mechanical and electronic components into a flight-qualified package. A series of laboratory-verification tests will then be performed, followed by flight- verification evaluations in NASA aircraft and on the shuttle. The system is currently targeted as a primary component of the space station Environmental Health Subsystem. When in operation, the Volatile Organic Analyzer will be a vital instrument in verifying that the air inside a spacecraft is safe for the crewmembers to breathe.

TRACE ANALYSIS FOR ORGANICS IN AIR USING AN ATMOSPHERIC SAMPLING GLOW DISCHARGE IONIZATION SOURCE

Barry C. Grant, Keiji G. Asano, Gary L. Glish,
and Scott A. McLuckey
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN

We have developed an ion source for the real-time analysis of trace organics in ambient air.[1] The ion source is based on the establishment of a glow discharge in a region of reduced pressure sustained by air drawn into an interelectrode region. Figure 1 shows a schematic of the ion source attached to a quadrupole mass filter. The discharge is established either by using the plate containing aperture A1 as the cathode and the plate containing the aperture A2 as the anode or by establishing the discharge between the half-plates labelled P1 and P2. A voltage difference of 400 V between the electrodes is sufficient for establishing a stable discharge under the normal pressure conditions of 0.2-0.8 torr.

Features of this ion source include, briefly, a high sampling rate (5 ml/s), short memory, a degree of flexibility in ionization, minimal clustering, simplicity, and ruggedness. A degree of flexibility in ionization in the positive ion mode is afforded via the discharge voltage. The relative abundance of proton hydrates, the major proton transfer reagent ions, is maximized at low discharge voltages whereas at higher discharge voltages (>450 V) reagent ions that undergo charge transfer, such as $O_2^{+\cdot}$, are by far most abundant. Conditions can be established where some clustering of water molecules is observed but this can be avoided by operating at slightly higher discharge voltages. The relative lack of clustering is largely due to the fact that cooling by expansion from one pressure region to the next is minimized by use of relatively large aperture sizes (A1=200 μm, A2=800 μm) and two stages of pressure reduction. A significant advantage of the ion source is its relative simplicity and ruggedness. Since the source relies on no materials that are rapidly oxidized or pitted it can operate for long periods of time without maintenance. We have operated this ion source 24 hours a day for months at a time without maintenance and have noted no noticeable loss in performance.

The ion source was developed for the analysis of trace quantities of explosives in ambient air. These compounds typically contain several NO_2 or NO_3 groups and are therefore readily detected in the negative ion mode. We find that we can detect such species with high electron affinities at the parts per trillion level. For example, Figure 2 shows the response curve obtained for 2,4,6-trinitrotoluene (TNT) by monitoring the molecular anion. The concentration of TNT that enters the ion source at the point where the signal is three times the standard deviation of the noise is about 1 ppt.

Recently we have measured detection limits for members of several other compound classes choosing to monitor one relatively intense ion at or near the molecular weight. For example, in the positive ion mode detection limits have been measured for anthracene ($M^{+\cdot}$, 5 ppb), butanol ((MH^+-H_2O), 1 ppb), propionic acid ($M^{+\cdot}$, 2 ppb), and trichloroethylene ($(M-Cl)^+$, 3

ppt). In the negative ion mode detection limits have been measured for anthracene ($(M+O-H)^-$, 1 ppb), butanol ($(M-H^+)^-$, 10 ppb), and propionic acid ($(M-H^+)^-$, 2 ppb). The detection limit is, of course, a reflection of the performance of the entire system and is determined by, in addition to the performance of the ion source, ion transport through the system, detection efficiency, and background noise. Considering the limitations of the mass spectrometers used to acquire these data, the reported detection limits are deemed to be conservative estimates. Furthermore, in some cases in the positive ion mode, significant chemical noise was present at the mass used to measure the detection limit. In these cases, a lower detection limit should be attainable using MS/MS.

MIXED CLUSTER ION FORMATION BETWEEN SMALL MOLECULES AND H_2SO_4 CLUSTERS FORMED WITH WATER

Thomas R. Sharp
Mass Spectrometry Applications Laboratory
Center for Chemical Characterization and Analysis
Department of Chemistry, Texas A&M University, College Station, Texas 77843 U.S.A.

Previous reports [1,2] describe observation of both positively charged and negatively charged cluster ions from concentrated mineral acids -- H_2SO_4 and H_3PO_4 -- produced by fast atom bombardment. In marked contrast to the behavior of H_3PO_4 [3], certain small molecules can be mixed with H_2SO_4, with the resulting mixture yielding mixed cluster ions. The results of further investigations into the nature of these mixed molecule clusters are reported here.

Observation of the FAB mass spectrum of concentrated H_2SO_4 showed the production of cluster ions of the formula $(H_2SO_4)_nH^+$, n=1,2,3..., with n as high as 15 being easily seen. In addition, the small H_2O content of reagent H_2SO_4 contributed to the occurrence of an additional cluster ion series of formula $(H_2SO_4)_nH_3O^+$, n=1,2,3..., with high n clusters being as easily observed, if not moreso, than for $(H_2SO_4)_nH^+$. Figure 1 shows the positive ion FAB spectrum of H_2SO_4 over the mass range m/z 10-300. Upon absorption of H_2O from the atmosphere due to the hydroscopic nature of concentrated H_2SO_4, the intensities of $(H_2SO_4)_nH_3O^+$ increase with respect to $(H_2SO_4)_nH^+$ for a given n.

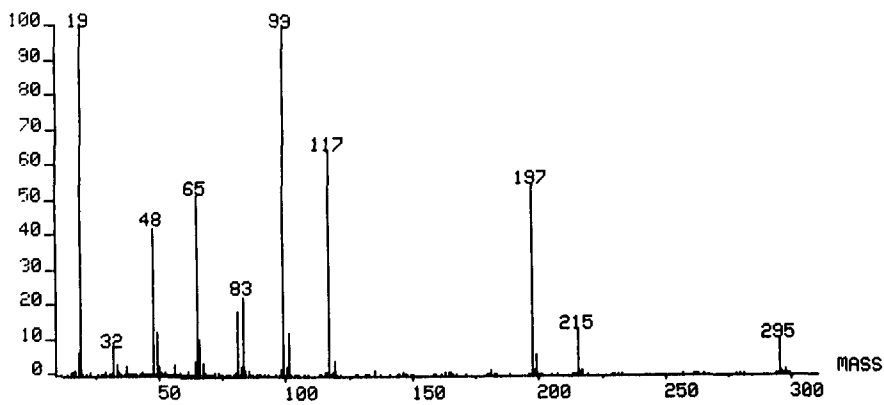

Figure 1: Positive ion FAB mass spectrum of H_2SO_4, illustrating the $(H_2SO_4)_nH^+$ series (m/z 99, 197, 295) and $(H_2SO_4)_nH_3O^+$ series (m/z 117, 215) as well as the fragments of H_2SO_4 below the protonated molecular ion. Note that m/z 19 (H_3O^+) and m/z 99 are off scale.

To investigate the formation of hydrated clusters further, mixtures of H_2SO_4 and H_2O were prepared gravimetrically to give varying mole ratios spanning the range from "100%" H_2SO_4 to 1:11 H_2SO_4:H_2O. Positive ion FAB-MS spectra were recorded on these mixtures to monitor changes in intensity ratios and appearance of new cluster ions. Comments made here pertain to positively charged ions only. The negative ion spectrum of conc. H_2SO_4 consists exclusively of clusters of formula $(H_2SO_4)_nHSO_4^-$, n=0,1,2,3..., regardless of the amount of H_2O added to the acid.

Figure 2 plots the relative intensities of the two cluster ion series as a function of cluster number, showing that no apparent "magic number" phenomena exist in this system. This is consistent with the "amorphous" nature of the liquid droplet from which the cluster ions are being formed, as opposed to the presence of such magic number clusters in the alkali metal halides being attributed to stable crystal lattice arrangements [4]. Comparison of the slopes of the lines in Figure 2 indicates that the $(H_2SO_4)_nH_3O^+$ series is slightly more stable than the $(H_2SO_4)_nH^+$ series. At a given H_2O content, the hydrated clusters are more intense than the protonated clusters, especially above n=3. Cluster series intensities were plotted for all of the different acid:water mixtures. Slopes of the lines stayed remarkably constant for all mixtures. The only noticeable change was that the point where the two lines crossed changed from slightly above n=3 for low H_2O concentrations to slightly below n=3 for high H_2O content. With increasing H_2O concentration, no new cluster ions or series appear. In spite of acid:water mole ratios as high as 1:11, the $(H_2SO_4)_nH^+$ and $(H_2SO_4)_nH_3O^+$ clusters are the only series present.

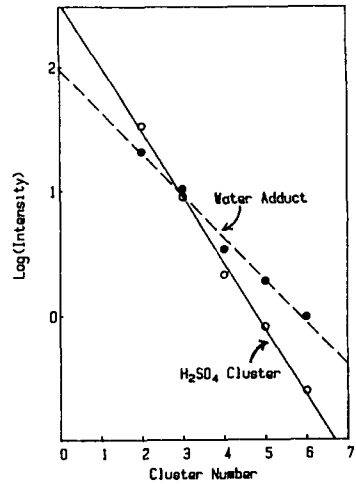

Figure 2: Log relative intensity vs. cluster number for $(H_2SO_4)_nH^+$ and $(H_2SO_4)_nH_3O^+$ cluster ions.

The results of B/E linked scan experiments are summarized in the accompanying table. Fragmentations of H_2SO_4 itself were relatively unaffected, while certain decomposition reactions of the larger clusters could be enhanced by collisional activation.

Parent	Daughter Ions			
m/z	m/z	ion yield - CID	ion yield + CID	fragmentation
99	81	50%	53%	$HSO_3^+ + H_2O$
	65	16%	17%	$HSO_2^+ + H_2O_2$ (?)
	48	8%	10%	$SO^+ + H_2O + OH$ (?)
117	99	75%	75%	$H_2SO_4H^+ + H_2O$
	81	10%	8%	
	65	4%	3%	
	48	2%	2%	
197	117	85%	21%	$H_2SO_4H_3O^+ + SO_3$
	99	15%	63%	$H_2SO_4H^+ + H_2SO_4$
	81	0%	8%	$HSO_3^+ + H_2SO_4 + H_2O$
215	197	77%	41%	$(H_2SO_4)_2H^+ + H_2O$
	117	23%	33%	$H_2SO_4H_3O^+ + H_2SO_4$
	99	0%	20%	$H_2SO_4H^+ + H_2SO_4 + H_2O$

The acid:water observations were made on a VG Analytical 70-E instrument with DS2000 datasystem, operated at +5KV. The linked scan experiments were performed on a VG 70-S with 11/250J datasystem, operated at +8KV. The Ion Tech fast atom gun produced a 6-8 KeV neutral argon beam. Sufficient helium target gas was introduced into an electrically grounded first field-free region collision cell to attenuate the parent ion intensities by appx. 50%. B/E linked scans were performed under datasystem control, after mass calibration against H_2SO_4 [2]. Daughter ion yields are expressed as a percentage of total daughter ion intensity. Funds from NSF Grants CHE-8310031 for the 70-E and CHE-8705697 for the 70-S are gratefully acknowledged.

LARGE CARBON CLUSTER FORMATION BY LASER ABLATION OF POLYIMIDE

William R. Creasy and J. T. Brenna
IBM Corp. (T43), 1701 North St., Endicott, NY 13760

Polyimide (Dupont Kapton®) is an important polymer for electronics packaging applications. We have studied it using a laser microprobe/ Fourier Transform Mass Spectrometer (FTMS) apparatus in order to analytically identify small areas of the polymer. The polymer is ablated and ionized by the 266 nm pulsed laser radiation, and the ions are mass analyzed by FTMS. Laser ablation is found to form a positive ion distribution of high mass carbon cluster ions. A more detailed discussion of the laser ablation, and of the carbon cluster ion distribution, has been submitted for publication.[1]

Laser ablation of polyimide was studied using a laser microprobe/ FTMS system which has been described in detail elsewhere.[2] A Nicolet FTMS/2000 was used for the ion detection, and a Quantel Nd:YAG laser (fourth harmonic at 266 nm) was used for the laser ablation/ionization. The polyimide samples were 15 um films which are chemically identical to Dupont Kapton.

A sample mass spectrum is shown in Figures 1, 2A, and 3A. The single spectrum is divided into three distributions. All three distributions can be observed in the same experiment, but the relative intensities depend strongly on the incident laser power and focussing conditions.

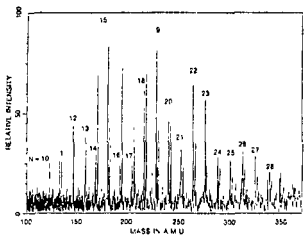

Figure 1 Low Mass Distribution

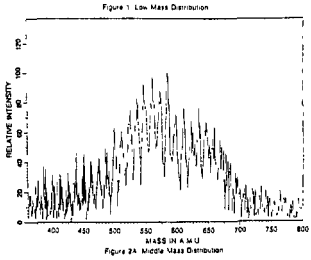

Figure 2A Middle Mass Distribution

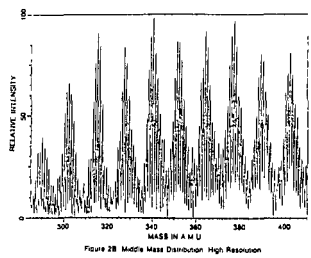

Figure 2B Middle Mass Distribution High Resolution

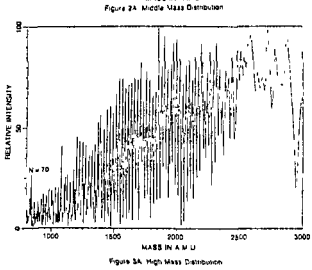

Figure 3A High Mass Distribution

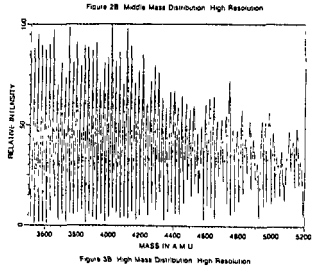

Figure 3B High Mass Distribution High Resolution

At the lowest fluence (approximately 200-500 mJ/cm^2, which is near threshold for positive ion formation), the distribution in Figure 3A has the largest relative intensity by at least a factor of 10. A higher resolution expansion of another spectrum is shown in Figure 3B. All of the ions which are observed correspond to even carbon cluster ions up to mass 5000. For calibration, the distribution was compared to a similar carbon cluster ion distribution formed from laser ablation of graphite with 532 nm radiation. Using the same FTMS conditions, the corresponding peaks of the graphite and polyimide spectra have the same masses, within the resolution of the spectrum.

The middle mass distribution is shown in Figure 2A, and an expanded section is in Figure 2B. This distribution has a peak at nearly every mass unit, and has a periodic oscillation over 12 amu. The maxima of the oscillations corresponds to carbon cluster ions with 6 to 8 H atoms. The low mass distribution in Figure 1 consists of carbon cluster ions with 0, 1, 2, and 3 H atoms. Both of these distributions are only formed with higher than threshold laser fluence on the sample. This observation suggests that photodissociation in the laser generated plasma may be responsible for the formation of the smaller ions.

In order to determine the mechanism of formation of the high mass carbon cluster ions, it is helpful to estimate of the gas phase particle density of the laser generated plasma which is formed during the laser pulse. This can be done[1] by measuring the depth of the crater which is ablated per laser pulse[2]. Previous work in the literature by Srinivasan, Dreyfus, and co-workers[3] provides estimates for the laser plasma temperature, compostion, and bulk expansion velocity. These results can be used to estimate the plasma density, which is about 10^{19} molecules/cm^3, giving a pressure on the order of 10 atm. This estimate is similar to the plasma density found by the same method for the laser ablation of graphite using 532 nm radiation. A density of this magnitude is consistent with the formation of large carbon cluster ions by gas phase condensation reactions. These ions are therefore probably not desorbed directly from the surface for these systems.

The negative ion mass spectrum of polyimide was also measured. Negative ions can be formed at lower laser fluence, and for lower values of etch depth/pulse, than positive ions. At the lowest fluence, the ions CN^-, OCN^-, and C_3N^- are observed. Increasing the fluence slightly produces other ions which can be assigned to structural fragments of polyimide.

Further study of the laser ablation of polymers is in progress. A study is being done to determine the fingerprint spectra of other high molecular weight polymers. It is also interesting to examine the feasibility of depth profiling and surface analysis of polymers by laser ablation, and to analyze the mechanisms of ion formation from laser ablation.

Studying metal clusters by mass spectrometric technique has been developing rapidly. For many metals, mass spectra often display ion abundance anomalies where the intensity of a cluster with specific size(magic number) is more abundant than its neighbors. The magic number is related with stability of the clusters. The relative stability of atomic clusters depends strongly on their size. For mass spectra obtained by ionization of neutral cluster beam, the interpretation of the relative ion intensities is followed by a severe problem where the size-dependent ionization cross section and fragmentation play a role. On the other hand, for mass spectra of ions produced by a secondary cluster ion source or liquid metal ion source, it is usually accepted that the ion abundance reflects the relative stability of the ionic clusters under an assumption that they have been born in the ion production process. Therefore, detailed investigations of the "born ionized" clusters are fundamentally important for understanding the electronic and geometric structures of neutral clusters. In the field of atomic cluster studies, alkali metals have attracted considerable attention because of their character as a typical metal. The purpose of the present study is to produce "born ionized" alkali metal clusters by a liquid metal ion source(LMIS), and to investigate the origin of the magic numbers.

The LMIS used in the present experiment is equipped with a closed-type reservoir of source material and with an emitter tip, which are heated by electron bombardment. The detailed structure of the LMIS has been described elsewhere.[1)] Pure metals(99.99 % for Li, 99.5% for Na) were used as the source material. The needle emitters were made of a piece of tungsten wire for Li, and iron for Na. The needle emitters were sharpened to a tip radius of several um by electrochemical etching. The mass distribution of cluster ions was measured with a single focusing magnetic analyzer.

Figures 1 and 2 show relative ion intensities of Li_n^+ and Na_n^+, respectively. For Li, singly charged clusters containing up to 19 atoms were distinctly detected, but multiply charged ones were not observed. Ion intensity as a function of cluster size showed peaks or steps at n = 3, 7, 9, 13 and 19. For Na, on the other hand, singly charged clusters up to 25 atoms were observed, and n = 3, 5, 11, 13, 19 and 21 were found as magic numbers. As for multiply charged clusters, only Na_7^{2+} was identified. In either metal, a sharp decline in the ion signal is observed after n = 19. The odd-

even alternation in the intensity variation is prominently found for Na in a region from n = 5 up to 19, where clusters with an odd number of atoms show higher intensity. This alternation shows a significant contribution of the spin-pairing energy to the total energy of these cluster cations.

The magic numbers observed for singly charged Li and Na clusters are summarized below, together with those predicted from the electronic shell model.[2)]

Li_n^+	3,	7, 9,		13,	19
Na_n^+	3, 5,		11, 13,		19, 21
Shell Model	3,	9,			19, 21, 35

For Li, n = 3, 9 and 19 coincide with the magic numbers predicted from the model, whereas the others(n = 7 and 13) can not be explained. It is interesting that the latter magic numbers(n = 7 and 13) coincide with those derived from sphere packing consideration: a pentagonal bipyramid for 7 atoms, and an icosahedron for 13 atoms. For Na, more serious discrepancy between the observation and the model is found: (1) a predicted magic number n = 9 does not show distinct feature in mass spectra, (2) the model can not explain the observed magic numbers n = 5, 11 and 13. This unsatisfactory agreement indicates the importance of considering geometric structure in predicting stability and other physical properties of metallic clusters.

FORMATION, FRAGMENTATION, AND REACTIONS OF METAL/OXYGEN CLUSTER IONS

WEN YU AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TX 77204-5641

INTRODUCTION: Transition-metals and their oxides are widely used as catalysts. Metal clusters serve as an useful model for studying catalysis. We have used mass spectrometry to study the structure and reactivity of first-row transition-metal/oxygen cluster ions. Titanium/oxygen and vanadium/oxygen cluster ions have been produced using high-pressure, fast-atom bombardment desorption ionization and collision-induced dissociation. We have used an elementary, pair-potential ionic model to calculate the geometrical structures of titanium/oxygen cluster ions based on observed stoichiometries and fragmentations.

EXPERIMENTAL: Metal/oxygen cluster ions were produced by sputtering metal foils or metal oxides (TiO_2 or V_2O_5) with an energetic (8 KeV) beam of fast Xenon atoms. In the high-pressure fast-atom bombardment (HPFAB) ionization technique[1], a reactant gas (O_2) is added to the ion source at a pressure ranging from 0.1 to 0.5 torr, as measured using a thermocouple gauge. Low kinetic energy (10 to 50 eV) collision-induced dissociation (CID) studies were performed using a VG 70-SEQ (EBQQ) instrument with argon as the collision gas. The pressure of the collision gas was adjusted to reduce the intensity of the main beam by 50-70%. The collision energy ranged from 10 to 50 eV, and was adjusted to optimize fragmentation.

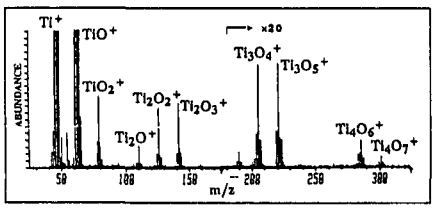

Figure 1. FAB Mass Spectrum of TiO_2

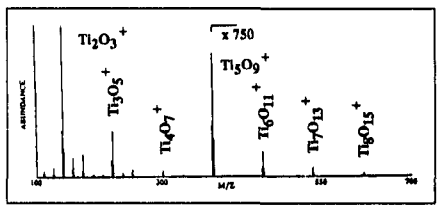

Figure 2. HPFAB Mass Spectrum of Ti Foil and O_2

RESULTS: Two major classes of $[Ti(TiO_2)_x]^+$ and $[TiO(TiO_2)_x]^+$ cluster ions were seen (Figure 1) when sputtering TiO_2 powder and Ti foil in the FAB source. Reactions between titanium/oxygen cluster ions and O_2 were observed in the HPFAB ion source . As the O_2 pressure increased, $[TiO(TiO_2)_x]^+$ (Figure 2) became the dominant type of clusters, while other types of cluster ions decreased in relative intensity.

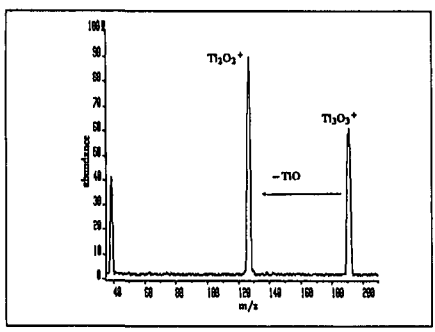

Figure 3. Collision-induced dissociation of $Ti_3O_3^+$

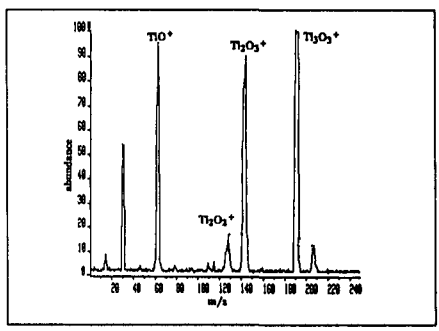

Figure 4. Hyperthermic Reaction of $Ti_3O_3^+$ and O_2

Hyperthermic reactions were studied in the collision cell (RF-only quadrupole) of the EBQQ instrument. Reactant gas (O_2) pressure ranged from $8x10^{-4}$ to $1x10^{-5}$ mbar in the cell housing. The exact pressure in the cell can not yet be determined. The collision energy ranged from 1 to 10 eV. Mass-selected titanium/oxygen cluster ions were injected into the collision cell where they react with O_2. Reactions

were examined as a function of reaction gas pressure and collision energy. Cluster ions with the formula $[TiO(TiO_2)_x]^+$ also were the major products (Figures 3 & 4).

VANADIUM/OXYGEN CLUSTER IONS: Vanadium/oxygen cluster ions have been formed by sputtering V_2O_5 powder. Figure 5 shows the FAB mass spectrum of V_2O_5. Three abundant classes of cluster ions were seen: $[V_2O(VO_2)_x]^+$, $[V(VO_2)_x]^+$, and $[VO(VO_2)_x]^+$.

The relative intensity of $V_nO_m^+$ clusters sputtered from foil were fitted (Figure 6) to the empirical formula of Kloppel and Jegers[2]:

$$I = I_o \cdot \exp[-(K - K_o)^2 / 2r^2]$$

$$K = (2m + 1) / n$$

where I = rel.abundance, K = modified fragment valence, and I_o, K_o, and r are constants.

n	I_o	K_o	r
2	5.900	0.585	0.972
3	0.386	1.576	0.682
4	0.109	1.491	0.589
5	2.00×10^{-2}	1.470	0.610
6	8.45×10^{-3}	1.516	0.470
7	1.21×10^{-3}	1.587	0.458

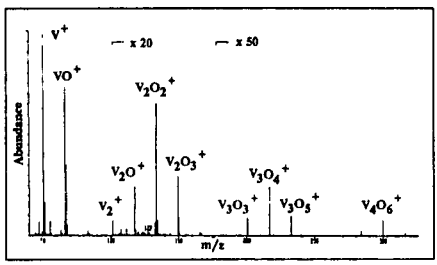

Figure 5. FAB Mass Spectrum of V_2O_5

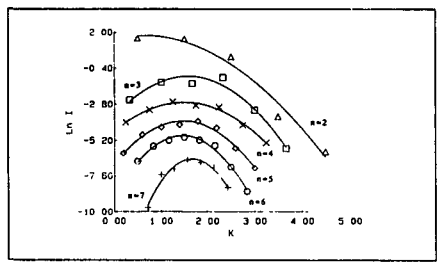

Figure 6. Distribution of vanadium/oxygen cluster ions

CLUSTER STRUCTURES: Titanium/oxygen and vanadium/oxygen cluster ions consisted of multiples of MO_2 units. This contrasts with iron/oxygen and cobalt/oxygen cluster ions, which consist of MO units[3]. The cluster ions were collisionally dissociated to produce fragments indicative of their structure. The observed fragmentations (loss of MO or MO_2) were used to confirm the stoichiometries of the cluster ions.

An elementary pair-potential ionic model[3] was used to calculate structures of metal/oxygen clusters. The observed stoichiometries of the clusters provided the basis for calculating the geometric structures. Calculated structures correlate with observed fragmentations of the metal/oxygen cluster ions. Several low-energy isomeric structures were found for each cluster suggesting that a single "magic" structure for each cluster is not likely.

$$V_T(r) = V_{MO}(r) + V_{MM}(r) + V_{OO}(r)$$

$$V(r) = Q_iQ_j/R_{ij} + A \cdot \exp(R_{ij}/P)$$

R_{ij} = the internuclear distance; Q_M,Q_O are the atomic charges ; A,P are adjustable parameters obtained by requiring them to give the nearest-neighbor distance for the monomer and for the bulk solid.

ACKNOWLEDGEMENTS: The Robert A. Welch Foundation is acknowledged for support of this work. The computer programs that were used to calculate the structures of the clusters were written by Dr. Brett I. Dunlap (Naval Research Laboratory).

HCN REACTIONS REVEAL NEW CARBON CLUSTER ION ISOMERS

Denise C. Parent and Stephen W. McElvany

Chemistry Division/Code 6110
Naval Research Laboratory, Washington, D.C. 20375-5000

In a previous study on the reactivity of positive carbon cluster ions with D_2 and O_2 [Ref. 1] an abrupt decrease in the reaction rate constant between n=9 and 10 was observed. This correlates with theoretical predictions of a change in structure from linear to monocyclic at n=10 [Ref. 2]. (A large decrease in photodissociation cross-section between n=9 and 10 has also been reported [Ref. 3].) The proposed structures for carbon clusters have reactive carbene sites (a pair of nonbonding electrons) at the end of the linear chains, which are missing in the cyclic structures. Thus the clusters with $n < 10$ are expected to be more reactive than the larger clusters. The reactivity studies also revealed that C_7^+ is present as two structural isomers when formed by direct laser vaporization. It was postulated that one isomer is linear (high reactivity) while the other isomer is cyclic (much lower reactivity) [Ref 1].

For the present work, we chose HCN as the neutral reactant so as to compare the reactivity of carbon cluster ions with polar HCN and the nonpolar molecules used previously [Ref. 1]. Also, HCN is an abundant species in the interstellar medium (ISM) and its reactions with other ISM species such as carbon chains are of interest for chemical modelling.

We studied the primary and secondary reactions of C_n^+ ($3 \leq n \leq 20$) with HCN and used collision-induced dissociation (CID) to investigate the structure (bonding) of the product ions. Experiments were performed in a Fourier-transform (ICR) mass spectrometer (FTMS) . The frequency-doubled output of a Nd:YAG laser was focused onto a graphite sample to produce cluster ions by direct laser vaporization. Reaction rate constants were determined by varying the reaction time at a constant HCN pressure.

In agreement with previous results, a large decrease in reactivity between n=9 (linear) and 10 (cyclic) was observed, as shown in Figure 1. A new result is that both the n=8 and 9 clusters, as well as n=7, have two components of differing reactivity with HCN. The parameters characterizing the two component decay are listed below.

n	fraction slow	K_{fast}/K_{slow}
7	0.7	35
8	0.3	300
9	0.2	43

The only products formed by the primary reactions are addition of H, CN or HCN to the cluster ion, as shown in Figure 2 for the linear isomers. (The cyclic isomers' only reaction pathway was radiative association.) No products involving breakup of the cluster are observed and a significant fraction of radiative association occurs. Both observations are in contrast to previous work [Ref. 1], indicating that the HCN reactions are lower energy processes. Most of the product ions formed from linear clusters subsequently react by adding HCN once. No further reactions were observed. This appears to agree with the proposed mechanism, whereby reactions occur at the two carbene sites of the linear cluster ions.

The CID results partially contradict this mechanism. The bonding of HCN to the cluster ions in the primary reaction is covalent (ie. at the carbene site), but the secondary product ions (C_nXHCN^+, X=H, CN or HCN) lose HCN at very low CID excitation energies. This suggests that the bonding does not occur at the second carbene site. Instead, H-bonding to the "X" end of the cluster ion is proposed to be the favored pathway. The cyclic cluster ions also bond only very weakly to HCN, with the exception of C_7^+, which forms a strong (covalent) bond with HCN.

The seven-carbon cluster ion exhibits anomalous behavior in other ways (ie. the decay curve is not a simple biexponential, the primary association product is reactive (for n <> 7 it is not reactive), and the fraction of the "cyclic" form is high). From these observations, we suggest that the cyclic C_7^+ isomerizes to the linear form during the reaction with HCN. Thus the seven-carbon ring appears to be less stable than the eight- or nine-carbon ring, yet it has a relatively high abundance, which we are unable to explain.

A STUDY OF THE MASS SPECTRA OF COBALT(II) SALTS OF ORGANIC ACIDS

Z. L. Sun, Z. W. Dong, C. H. Lin and Z. M. Cao

Dalian Institute of Technology, Dalian, CHINA

INTRODUCTION

Metal carboxylates have long been known, but their mass spectrometry has not been much investigated until recent fifteen years. Cobalt carboxylates are now widely used in different fields of industries. While the mass spectrometry of only those of lower fatty acids was studied (1-3). In this work the following cobalt salts: acetate, propionate, n-butyrate, isovalerate, n-hexanoate, 2-ethylbutyrate, n-heptanoate, n-octanoate, 2-ethylhexanoate, n-decanoate, n-dodecanoate and n-tetradecanoate are studied. Due to the limitation of our machine, high mass cluster ions in the spectra are neglected.

EXPERIMENTAL

Cobalt acetate was GR chemical purchased from Beijing Chemicals Co., and was used without further purification. The other 11 kinds of carboxylates were synthesized in our laboratory by either fusion or precipitation method (4). The former method was used in preparing salts of C_3-C_8 acids while those of C_9-C_{14} acids were prepared by the latter method. The purity of the prepared salts was checked by elemental analysis, and IR and UV spectra.

All spectra were recorded on a Finnigan MAT 312 mass spectrometer. Isobutane was used as the reacting gas in the CI mode.

RESULTS AND DISCUSSION

EI spectra

It has been shown that EI spectra of neutral cobalt carboxylates do not show molecular ion peak, $[Co(OCOR)_2]^{+\cdot}$, but that of basic salt, $[Co_4O(OCOR)_6]^{+\cdot}$ instead (2). It is supposed that neutral cobalt carboxylate converts, during vaporizing, into its basic form which is more stable in the vapor phase. Just as mentioned in the literature (2), the initial fragmentation involves in the loss of a ligand radical to give $[Co_4O(OCOR)_5]^+$ which further loses a neutral salt molecule forming $[Co_3O(OCOR)_3]^+$. The molecular ion and the above-mentioned two fragment ions form the three most intense peaks in all the spectra of cobalt carboxylates (Table). Due to the ability of Co atom to change oxidation state, the molecular ion can act as an even electron ion. So do the two even electron fragment ions can behave as odd electron ions. Thus two modes of fragmentation of losing radicals and neutral molecules can take place at the same time with the same parent ion. The molecular ion and the two abundant fragment ions all lose anhydride molecule giving fragment ions whose abundance changes with the length of the acid chain (Table). The longer the acid chain of the carboxylate, the less intense the anhydride abstracted ion peak. Three doubly charged ions $[Co_4O(OCOR)_5]^{+2}$, $[Co_4O(OCOR)_4]^{+2}$ and $[Co_4O_2(OCOR)_3]^{+2}$ are observed.

CI (isobutane) spectra

There is only one report in the literature (3) on the CIMS (methane) of cobalt carboxylates. The CI spectrum of cobalt acetate (i-C_4H_{10}) in this paper differs from that reported in the literature in the intensity of the protonated molecular ion. In their work the protonated molecular ion was observed only with 14% relative abundance of the base peak, while in our work the protonated molecular ion is the base peak. This might be due to the fact that in our work isobutane is used as the reacting gas instead of methane which forms a stronger Bronsted acid and leads to more fragmentation of the protonated molecular ions. The three most abundant ions in EI spectra also appear in CI spectra, but with less intensity.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Negative ion (electron capture) spectra

The negative ion mass spectra of cobalt carboxylates have not been reported previously. Due to the 3d electron configuration of $3d^7$, the neutral molecule, $Co_4O(OCOR)_6$, readily captures a thermal electron to form a stable anion. The negative ion spectra of cobalt carboxylates are unique in that they consist of nearly the molecular ion $[Co_4O(OCOR)_6]^-$, which forms the base peak, and $[Co_4O(OCOR)_6 \pm n14]^-$ peaks on both sides of it, where n is a small whole number.

CONCLUSION

1. Negative ion spectra (electron capture) of cobalt carboxylates have been recorded for the first time. These spectra are unique in that they are dominated by the molecular ion peak, which is the base peak, and peaks of ± n14 amu on either side of the base peak.
2. The phenomenon of ± n14 amu on either side of a peak of high intensity can also be observed in both EI and CI spectra, but not so typical as in negative ion spectra.
3. $[Co_4O(OCOR)_6]^{+\cdot}$, $[Co_4O(OCOR)_5]^+$ and $[Co_3O(OCOR)_3]^+$ form the three most abundant peaks in all EI spectra of the carboxylates. They lose acid anhydride molecule forming fragment ions whose intensities depend on the length of the chain of the acid redical in the salt. The longer the chain of the acid radical, the less abundant the anhydride abstracted fragment peak.
4. The change of valence in Co atom makes it possible to convert an odd electron ion to an even one and vice versa. Thus two sets of fragmentation of losing both radical and neutral molecule from the same parent ion occur.
5. Doubly charged ions are observed.

SIGNIFICANCE OF CLUSTER IONS IN THE GENERATION OF FAST ATOM BOMBARDMENT MASS SPECTRA

H. Perreault and M.J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, P.O. Box 6128, Station A,
Montreal, Quebec, Canada H3C 3J7

In recent years, fast atom bombardment has been widely used as a desorption-ionization technique for the mass spectral analysis of polar and high molecular weight compounds. However, the processes responsible for ionization and generation of the mass spectrum are still not fully understood and several models have been proposed in the literature. Three of the models that have received special attention are:

i) The precursor model: Molecular ions are preformed in solution and directly ejected upon impact of the atom beam.

ii) The gas phase model: Ions are mostly formed by gas phase collisons in a microplasma generated by the atom beam in the selvedge region of the impact.

iii) Charged aerosol droplets: Ions solvated by matrix molecules are desorbed from the solution and these charged droplets further dissociate to yield ions observed in the resulting spectrum.

An important feature of the FAB spectra of polar analytes dissolved in glycerol is the presence of cluster ions composed of molecules of the matrix G_nH^+, of the analyte M_mH^+ or both $G_nM_mH^+$. These clusters can be observed in figure 1a that shows the FAB spectrum of the dipeptide glycylphenylalanine obtained in glycerol. In order to investigate the origin of these clusters, experiments in the present work were conducted in the gas phase using CI and in solution using FAB. In the gas phase experiments, the dipeptide was vaporized in a chemical ionization source using a direct insertion probe and glycerol was used as a reagent gas in order to simulate the gas phase reactions that may occur in FAB. In the solution experiments using FAB, the concentration of the dipeptide glycylglycine was varied in glycerol and the internal energy of the mixted clusters $(MG\pm H)^{\pm}$ and $(MG_2\pm H)^{\pm}$ was monitored by measuring the ratios of ion intensities $(M\pm H)/(MG\pm H)$ and $(MG\pm H)/(MG_2\pm H)$ in the unimolecular MIKE spectrum of the corresponding species.

The spectrum of the dipeptide obtained under conditions of chemical ionization is shown in figure 1b and even though dimers are observed at m/z 185 (G_2H^+), 315 (MGH^+) and 445 (M_2H^+), polymolecular clusters of higher masses are absent and could not be observed under the range of temperatures and pressures used in these experiments. Another difference that is observed when comparing the CI and FAB spectra resides in the loss from the MH^+ of water (m/z 205) which is present in CI and absent in FAB, indicating that the two processes may be different. Other results obtained in the solution experiment show a clear dependance of the internal energies of the $(MG_2\pm H)$ and $(MG\pm H)$ ions on concentration. As the concentration is increased the $MG\pm H/MG_2\pm H$ and $M\pm H/MG\pm H$ ratios measured in the unimolecular MIKE spectrum of the corresponding ions increase accordingly, indicating a dependance of the internal energy of the clusters with concentration. This phenomena which is hard to explain by the gas phase model, but in agreement with the desorption of charged aerosol droplets, seems to indicate that the latter would be responsible for the generation of the cluster ions observed in FAB.

Since the results obtained indicate that the ejection of charged droplets might play an important role in the generation of a FAB spectrum, the unimolecular and collison activated spectra of G_nH^+, M_mH^+ and $G_nM_mH^+$ clusters were recorded to verify that ions observed in

the FAB spectrum could be rationalized by the decomposition of clusters of different sizes and different internal energies. Figures 2a and 2b show the unimolecular and CA spectra of the MG_3H^+ cluster of glycyl-phenylalanine at m/z 499. It can be observed that relatively low energy clusters decompose mainly by loss of glycerol and water and that hot clusters decompose by loosing one, two or several molecules of glycerol and can also generate fragments of the peptide.

The results presented can be used to rationalize the ions observed in a FAB spectrum of a polar analyte in glycerol in terms of fragmentation of analyte and matrix molecules around the point of impact, with the desorption of clusters of different sizes and internal energies as the distance from impact increases. The fragments produced on impact and the decomposition products of the clusters are in agreement with the ions observed in the spectrum. This rationalization is also consistent with the intensities of parent-molecular ions of labile compounds that are observed in FAB since the MH^+ ions are stabilized by the evaporating of matrix molecules from the clusters.

Measurement of the Ion Dissociation in a Reflecting Time-of-Flight Mass Spectrometer

Franz J. Mayer, W, Ens, B. Schueler, K. G. Standing, X. Tang and J.B. Westmore,
Physics and Chemistry Departments, University of Manitoba, Winnipeg, Canada R3T 2N2

Installation of a single-stage ion mirror in a time-of flight mass spectrometer enables measurements of daughter ion masses from parents that decay in the first leg of the flight path. Measurements of the unimolecular decay of several small peptides with a reflecting TOF spectrometer (Manitoba TOF II) have been reported [1]. Some further progress is described below.

^{18}O-Labelling Studies: The C-terminal of gly-gly-phe was labelled with ~50% incorporation of ^{18}O into the carbonyl group. The resulting $(M+Na)^+$ doublet was partially resolved in the neutral spectrum, so time windows could be chosen to select parent ions with and without ^{18}O. The resulting daughter ion spectra confirmed that $(M+Na)^+$ parent ion decomposed into a B_2+OH+Na daughter, with the addition of OH from the C-terminal group. [1].

Analysis of Metastable Ions from a Mixture of Three Peptides: An equimolar mixture of the peptides gly-gly-phe, leu-enkephalin and met-enkephalin, has been examined. Fig.1 shows the "direct" spectrum, i.e. the normal TOF spectrum observed in detector #1 behind the mirror with the mirror voltage off. Parent and daughter ions as well as neutral fragments are recorded.

With the mirror voltage on, the parent and daughter ions are measured in a second detector #2 at ~177 degrees (fig.2), while the neutral fragments appear in detector #1(fig.3) as before. The TOF of the neutral fragment identifies its parent ion.

Decay of a given parent ion may be examined by selecting the daughter ions correlated with neutral fragments having the correct flight time. The daughter ion spectra of some of the parent ions in the peptide mixture are shown in fig. 4. These spectra are much simpler than the overall reflected spectra, so unambiguous assignments of decay pathways can be made. Thus the technique has advantages similar to those of conventional tandem mass spectrometry.

Tandem Mass Spectrometric Analysis of The First Perfluorinated cryptand: 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane

S. D. Maleknia, W. D. Clark, and R. J. Lagow, UT of Austin, Austin, TX 78712.

INTRODUCTION: The most important unique properties of perfluorinated compounds are their biological compatibility and high oxgygen carrying capacity. Recently, human clinical trials on Fluosol-DA, a patented emulsion of perfluorodecalin and perfluorotripropylamine, a major component of "artificial blood" have been started (1), and the rapid developement of this technology perpetuates the need for analytical techniques, especially MS, developed specifically to provide identification and limited structural characterization of perfluorinated compounds (2). The chemistry of perfluorinated compounds is as diverse as it is interesting. Presently the only facile route to syntheses of sterically hindered macrocyles is by the LaMar direct fluorination process of hydrocarbon analogues, which has in the past decade successfully introduced new perfluorocyclic and branched molecules (3), and was recently applied to the synthesis of the first perfluorinated cryptand, 1. Perfluorinated compounds differ from their hydrocarbon analogues by the special properties that fluorines confer upon the molecule. Properties which favor MS analysis are high volatility and thermal stability. The high electronegativity of fluorine causes strong inductive effects which significantly alter the stability and lability of chemical bonds, and such perturbations are expected to influence the mass spectral fragmentation pathway. Electron capture negative ion (ECNI) mass spectrometry combined with collision induced dissociation were used to determine the fragmentation characteristics of the title compound.

EXPERIMENTAL: A Finnigan MAT(TSQ-70) triple stage quadrupole was operated in negative chemical ionization mode at source pressure of 1.2 T of methane, and temperature of 80°C. A Varian GC model 3400 equipped with a 15m, BP5 capillary column with 5% methyl phenyl silicone coating was temperature programmed to 220°C at 25°C/min. A solution of 1 in Freon was injected into the column, and the perfluorinated cryptand eluted at 100°C. For CID analyses the sample was coated on a rhenium filament of the direct exposure probe, and further heating was not required. Argon was used as the collision gas at 1.2 mT. All MS/MS tuning parameters were software controlled.

RESULTS & CONCLUSION: A GC/ECNI spectrum of 1, is shown in Figure 1. The base peak is attributed to the molecular ion at M/Z 1024, and reagent gas adduct ions were not observed under any of the investigated CI conditions; this points to the high electron affinity of the title compound. Ions observed at M/Z 986, 908, 792 are attributed to losses of F_2, C_2F_4O, and $C_4F_8O_2$, respectively. Other ions in the spectrum at M/Z 496, 346, and 296 are the result of further ionization in the CI source and are not major features in the CID spectra . The stepwise or concerted multiple extrusion of neutral perfluoro ethylene oxide is observed by the ions at M/Z 908, 792, and 560 in Figures 2 and 3. Further loss of C_2F_4O or C_3F_6N fragments results production of ions at M/Z 428, 444, and 676. CID studies suggest that the cyclic structure of the perfluorinated cryptand is preserved as the fragmentation proceeds. The structural validity of these ring contracted homologs may be tested in future studies by the synthesis of molecules similar to the M/Z 792 ion.

REACTIVE AND DISSOCIATIVE COLLISIONS AT A METAL SURFACE IN A TANDEM TIME-OF-FLIGHT INSTRUMENT

K.L. Schey and R.G. Cooks

Ion/surface collisions are examined in a tandem time-of-flight (TOF/TOF) mass spectrometer. An earlier TOF/TOF instrument[1] has been modified to improve mass resolution by adding an electrostatic mirror to the second time-of-flight analysis stage (Fig. 1). In addition, improvements in source electronics allow collision energies of up to 750 eV to be achieved, over seven times the capabilities of existing instruments which examine inelastic ion/surface collisions.

The addition of the electrostatic mirror improved the mass resolution by one order of magnitude as seen in the surface induced dissociation (SID) daughter spectra of the phenetole molecular ion at 40 ev collisions (Fig. 2).

Surface induced dissociation of relatively stable molecular ions of polynuclear aromatic hydrocarbons (PAH) show increased fragmentation as the collision energy is increased providing mainly two and three carbon containing fragments at high collision energies. The SID daughter spectra of the anthracene molecular ion at 100 eV and 150 eV (Fig. 3) are indicative of the large amount of internal energy being deposited in inelastic ion/surface collisions. The internal energy deposition characteristics of the surface induced dissociation method are valuable in ion structural analysis of stable ions.

The improved mass resolution reveals the occurence ion/surface reactive collisions whereby one, two, and three carbon groups are abstracted from the surface by incident PAH ions. As seen in Fig. 4, the pyrene molecular ion abstracts one, two, and three carboon groups from the surface. Ion/surface reactions are competitive with SID at collision energies between 50 and 150 eV. and these processes provide information on ion reactivity and on the nature of surface adsorbates.

As the collision energy is raised above 100 eV, efficient sputtering of surface adsorbates is observed to compete with SID. The sputtering spectra (Fig. 5) are similar to the spectra of hydrocarbon background observed in high energy secondary ion mass spectrometry (SIMS), but here occur at relatively low kinetic energies. This low energy sputtering has been observed previously at very low kinetic energy for fluorocarbon ions[2] and is indicative of a different mechanism than momentum transfer operative in SIMS. The sputtering spectra provide information on the nature of surface adsorbates.

In summary. a simple tandem time-of-flight mass spectrometer is capable of examining a variety of ion/surface collision phenomena at larger collision energies and with comparable resolution to existing, more complex, instruments. The ion/surface collision phenomena observed in the TOF/TOF instrument provide valuable information on the nature and reactivity of the parent ions, on the nature of the surface, as well as fundamental information on inelastic ion/surface collisions.

FRAGMENTATION OF SOME DEPROTONATED SULFOXIDES AND SULFONES

S. Chowdhury and A. G. Harrison
Department of Chemistry
University of Toronto
Toronto, Canada M5S 1A1

Fragmentation of enolate ions of the formula $RCOCH_2^-$ is known(1) to proceed through formation of an intermediate ion/dipole complex as shown by Scheme 1.

$$RCOCH_2^- \longrightarrow [R\text{—}CH_2CO]^- \begin{cases} \nearrow R^- + CH_2CO \\ \searrow RH + HCCO^- \end{cases}$$

SCHEME 1

The present work was undertaken, in part, to explore the effect of replacing the carbonyl group by the sulfoxyl (SO) or sulfonyl (SO_2) group on the fragmentation of the ions $RSOCH_2$ and $RSO_2CH_2^-$, analagous to the enolate ions. The $(M - H)^-$ ions were prepared by reaction of $RSOCH_3$ or RSO_2CH_3 with OH^- in a chemical ionization source. High energy (8 keV) and low energy (5—100 eV) collision–induced dissociation mass spectra, as well as unimolecular metastable ion mass spectra, were studied using a hybrid BEQQ mass spectrometer(2).

Although the major metastable ion fragmentation reaction of the $(M - H)^-$ ion of methyl phenyl sulfoxide involves elimination of H_2O, over much of the breakdown graph (Fig. 1) the $C_6H_5^-$ and $HCSO^-$ ions dominate, indicating a fragmentation sequence analagous to enolate ions

$$C_6H_5SOCH_2^- \rightarrow [C_6H_5\text{—}CH_2SO]^- \begin{cases} \nearrow C_6H_5^- + CH_2SO \\ \searrow C_6H_6 + HCSO^- \end{cases}$$

The metastable ion mass spectrum of $CH_3SOCH_2^-$ shows predominate formation of SO^-, obviously requiring rearrangement of the molecular framework. In the breakdown graph (Fig. 2) $HCSO^-$ and H_2CSO^- are the two most important products indicating the reaction channels.

$$CH_3SOCH_2^- \rightarrow [CH_3\text{—}CH_2SO]^- \begin{cases} \nearrow CH_4 + HCSO^- \\ \searrow CH_3 + H_2CSO^- \end{cases}$$

The latter reaction channel is not observed for enolate ions, but the analagous reaction becomes even more important (Fig. 3) for $CH_3SO_2CH_2^-$ where no $HCSO_2^-$ formation is observed

$$CH_3SO_2CH_2^- \rightarrow [CH_3\text{—}CH_2SO_2]^- \begin{cases} \nearrow\!\!\!\times\ CH_4 + HCSO_2^- \\ \searrow CH_3 + H_2C\text{–}SO_2^- \end{cases}$$

The opening of this new reaction channel for deprotonated sulfoxides and sulfones presumably is related to the stability of the radical anions CH_2SO^- and $CH_2SO_2^-$ compared to CH_2CO^-. The electron affinity of CH_2S is 10.7 kcal mol^{-1}(3) and the oxygens bonded to sulphur should increase this electron affinity. The electron affinity of CH_2CO does not appear to have been measured but would be expected to be quite low.

The full paper, to be submitted, will extend the work to a greater variety of compounds, including cyclic sulfones, and will include a comparison of high energy and low energy collisional activation.

ISOMER IDENTIFICATION BY METASTABLE DECAY RATES OF LASER PRODUCED IONS: G.R. Kinsel and M.V. Johnston; Dept. of Chemistry and Biochemistry, CIRES, University of Colorado, Boulder, CO 80309-0215.

The narrow internal energy (E_{INT}) distributions created during Resonance Enhanced Multiphoton Ionization / Dissociation (REMPI/D) mass spectrometry make this technique uniquely sensitive to small changes in molecular energetics. This unique sensitivity can be exploited to identify isomer configuration from metastable tailing of daughter ion signals. Calculated rates for metastable decompositions also yield information about the fragmentation mechanism for the molecule.

A program has been developed which emulates a mass spectrometer and produces a theoretical mass spectrum across the m/z region of metastable ion production for a given set of rate constants. A simplex routine varies the set of rate constants until a best fit with the experimental mass spectrum is obtained. The program offers several advantages in that it can be applied to spectra with overlapping metastable ion signals, can account for isotopic contributions to metastable ion production, and yields a high level of precision as a result of requiring a fit to both the individual and total decay rates simultaneously. The program was tested by calculating a decay rate for the production of M^+-Cl (m/z 77) in the 271.5 nm REMPI/D mass spectrum of chlorobenzene. An example of the experimental and calculated data is shown in Fig. 1. When the proper set of fitting parameters is chosen the program correctly discriminates against the non-metastable contribution at the daughter ion peak position which arises from a two-photon dissociation of the parent ion. The calculated rate is in good agreement with previously reported values for this process.

The program was used to calculate decay rates for the metastable production of M^+-HCl (m/z 91), M^+-Cl (m/z 90), and M^+-HNC (m/z 100,102) from the three isomers of the chloroanilines at 266 nm. Examples of experimental and calculated spectra are shown in Figs. 2, 3, and 4. Note that regions of the experimental spectra containing non-metastable ion signals have been omitted for clarity. The tabulated results for the calculated rates are shown in Fig. 5. The uncertainties reflect the precision of fits of 5 separate spectra.

The calculated rates show that the o-, m-, and p- isomers can easily be distinguished on the basis of their individual or total decay rates. Evidence of the "ortho" affect resulting in an increase in rate for loss of HCl and a decrease in rate for loss of HNC as substituent positions move together is also observed. An intriguing isomer dependent isotope affect also seems to exist, although this may be an artifact of the assumptions made in applying the calculational program. Interpretation of the rates also supports minimal isomerization of the parent ions prior to dissociation as evidenced by the fact that individual and total rates will never converge simultaneously.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

The narrow E_{INT} created during REMPI/D can be exploited as a tool for isomer identification. Improvements to the experimental setup used here to further refine the E_{INT} (PES, Jet Spectroscopy) and addition of second laser to extend the applicability of the technique to molecules having higher and lower A.E.'s would enhance this method dramatically. Nevertheless, successful isomer distinction with this simple one-color experiment has been demonstrated. REMPI/D with calculation of decay rates from metastable decompositions shows promise as a useful method for isomer identification.

Use of a Microchannel Plate for Surface Induced Dissociation (McSID)

William Aberth
Mass Spectrometry Facility
Department of Pharmaceutical Chemistry
University of California, San Francisco, CA 94143-0446

The technique of collision-induced dissociation (CID), as applied to mass spectrometry, typically uses a gas target to fragment mass-selected energetic molecular ions The use of a gas for CID has several drawbacks 1) Large energy spreads occur in the fragment ions resulting in reduced resolution and sensitivity, 2) The efficiency of collisional fragmentation decreases with increasing molecular size due to a reduction in translational energy available for internal energy conversion and a lower primary ion velocity; 3) The introduction of a collision gas raises the background pressure resulting in poorer resolution and transmission of the high mass compounds.

The technique of surface induced dissociation (SID) was introduced to overcome some of these difficulties [1-4] The use of a surface to collisionally fragment molecules does not degrade the instrument vacuum and offers the possibility of large amounts of internal energy conversion for effective high-mass fragmentation. The SID technique typically involves collisions of parent molecules with energies below 300eV on a metallic surface at an incident angle of about 45 degrees Encouraging results have been achieved with this technique, using a variety of instrumental arrangements, for compounds below about 250d [1-4]

A new SID method has been developed which utilizes the channel surfaces of a microchannel plate (McSID) In this arrangement energetic (100-1,000eV) parent ions undergo grazing (1-5 degrees) collisions on a surface of very high surface resistance (about 10^{13} ohms) (see Fig 1) The in-line nature of the McSID geometry should facilitate its adaptation to magnet sector, quadrupole and TOF type instruments. Several surface bounces of each molecular ion passing through the channel are likely since the ratio of channel length to diameter is about 50 The high surface resistance greatly reduces the probability of ion neutralization. The average amount of internal energy absorbed by the parent ion is proportional to its translational energy and to the square of its grazing angle θ (see Fig. 1). By varying these two parameters a broad range of fragmentation quality control is possible A tandem Wien MS [5] was used to demonstrate the McSID technique. The instrument operated at 25keV beam energy for mass separation and is provided with a floatable microchannel plate target to permit lower collision energies. The resolution of Wien MS-1 was set at 500 while that of Wien MS-2 was 80. The microchannel plate contained an array of channels 9.6 microns in diameter and 432 microns long with an open area ratio of 59% The plate was aligned so that the channel axis differed by about 3 degrees from the beam axis. Figure 2 shows a positive McSID spectrum of the peptide leu-enkephlin (Tyr-Gly-Gly-Phe-Leu, 555d) obtained at 250eV collision energy showing good sequence structure. Figure 3 is the McSID spectrum of negative leu-enkephalin obtained at 1,000eV, and yielding complimentary structural information. In all McSID spectra the dominant peak is the parent molecular ion and fragmentation efficiencies are typically 10-20%. Figure 4 shows the McSID spectrum of $(CsI)_{23}Cs^+$ (6113d) showing all $(CsI)_nCs^+$ fragments from n=0 to 23, and demonstrates the high-mass capability of the McSID technique Because of the distinct advantages provided by the McSID techniq;ue it should become an important addition to the MS/MS methodology

APPEARANCE POTENTIAL MEASUREMENTS ON SULFURIC ACID VAPOR

K.B. Snow and T.F. Thomas, Dept. of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110

After a long effort to develop a suitable inlet system, mass spectra of $H_2SO_4(g)$ have been obtained which-for the first time, to our knowledge-show a significant parent peak. Key details include using a helium carrier gas flowing over $H_2SO_4(l)$ at 75°C and exposing the entrained vapor only to quartz, teflon and gold-plated surfaces (including the ion source). A mass spectrum obtained from vapor at the azeotropic composition (∿98.3%, by weight, is shown in Figure 1 for an ion source temperature of 108°C and an electron impact energy of 50ev. The intensity of the $H_2SO_4^+$ peak was found to be strongly dependent on the temperature of the ion source, declining from 28% to 0.79%, relative to the base peak (SO_3^+), as T_{source} was raised from 92 to 152°C. This effect appears to be due to the temperature dependence of the equilibrium constant for

$$H_2SO_4(g) \rightarrow SO_3(g) + H_2O(g).$$

The ionization potential of H_2SO_4 and the appearance potentials of its fragment ions were determined using a previously-described Fox-type RPD ion source,[1,2] modified for computer-controlled data acquisition and using ion-counting in place of analog detection. Ionization efficiency curves for $H_2SO_4^+$, several fragment ions, and one of the gases (Xe) used to calibrate the electron energy scale, are shown in Figure 2. Experimental results for the ions derived from H_2SO_4 are presented in Table II.

Table I. Appearance Potentials from $H_2SO_4(g)$
T_{source} = 108°C

No.	Reaction	A.P.(ev)
1.	$H_2SO_4^+ \rightarrow H_2SO_4^+ + e^-$	12.40 ± .05
2.	$H_2SO_4 \rightarrow H_2O^+ + SO_3 + e^-$	13.2 ± .2
3.	$H_2SO_4 \rightarrow SO_3^+ + H_2O + e^-$	13.8 ± .2
4.	$H_2SO_4 \rightarrow HSO_3^+ + OH + e^-$	13.9 ± .1
5.	$H_2SO_4 \rightarrow SO_2^+ + H_2O_2 + e^-$	16.0 ± .15

In the cases of H_2O^+, SO_3^+, and SO_2^+ it was necessary to subtract a contribution by direct EI ionization of the small amounts of H_2O, SO_3 and SO_2 present in the sample stream from the total ionization efficiency curves obtained. Thus the uncertainties indicated for the results are larger in those cases.

CID OF ISOTOPICALLY LABELLED SURFACTANTS:

Albert Tuinman and Kelsey Cook
University of Tennessee, Knoxville, TN 37996

Three synthetic surfactants (1-3) were examined by FAB and collision induced decomposition (CID), with the object of determining the extent and positional integrity of their deuterium isotope labelling.

	Structures	El.-Comp.	Cation Mass
1	Br^- $(CH_3)_3N^+(C_{13}H_{26}\text{-}CH_3)$	$C_{17}H_{38}D_{00}NBr$	256
2	Br^- $(CH_3)_3N^+(C_{13}D_{26}\text{-}CD_3)$	$C_{17}H_{09}D_{29}NBr$	285
3	Br^- $(CD_3)_3N^+(C_{13}D_{26}\text{-}CH_3)$	$C_{17}H_{03}D_{35}NBr$	291

The FAB spectrum of 1 at 20000 resolution in the multi-channel acquisition mode over a small mass range (around m/z = 256), demonstrated that the "M-1" peak consisted of one elementary composition only, $C_{16}C^{*}H_{36}N$. No loss of a single H from the ammonium cation could be detected. It follows that all "M-1" ions recorded for 2 and 3 must be caused by incomplete deuterium labelling. Relative abundances of peaks in the cation mass region of 2 and 3 are given in Table 1.

Table 1. Relative Ion Abundances of 2 and 3.

Cmpd.	M-4	M-3	M-2	M-1	M	M+1
2 (M=285)	11.5	3.2	13.6	56.2	100	18.3
3 (M=291)	10.2	3.0	8.9	36.6	100	17.0

From the data in Table 1, the specific isotope incorporation can be calculated at 98.2% for 2 and 98.8% for 3.

Determination of the positions at which deuterium incorporation was incomplete ("mislabelling") was achieved using MS/MS. The experiment requires at least unit resolution of the parent ion (total separation of the mislabelled parent from the isotopically pure parent) as well as unit resolution of the daughters (to quantify the isotope distribution between neutral and ionic daughters).

Neither B/E linked scans or the MIKES experiment meet both of these requirements, and are therefore unsuited to the experiment. Quadrupole

scanning in the hybrid ZAB-EQ does meet the criteria, and this method was employed.

Energy resolved CID spectra of 2 and 3 displayed a maximum of remote site fragmentation intensity with collision energies between 200V and 400V when the collision quadrupole was flushed with Argon to a reading of $2x10^{-5}$ Torr.

Daughter scans of the "isotopically pure" parent ion of 2 (m/z=285.5) displayed i.a. unit resolved singlets at intervals of 14 Dalton, from mass m/z=124 to 268, representing remote site fragmentation.[1] The equivalent ions in the daughter scan of the "mislabelled" parent (m/z=284.5) appeared as doublets differing by one Dalton. The relative intensities within each doublet varied, with the lighter of the two gaining intensity at higher mass. Relative intensities within these daughter pairs closely matched those calculated for random distribution of the errant atom in the mislabelled parent. It is thus indicated that incomplete isotopic labelling of 2 is random, rather than concentrated on any one carbon atom.

Exactly the same situation was found to apply to 3.

Ion Kinetics in the Acceleration Region

Raymond E. March, Richard J. Hughes*,
Gregory K. Koyanagi* and Adam W. McMahon
Department of Chemistry, Trent University
Peterborough, ON, Canada K9J 7B8
*Registered at Queen's University, Kingston, ON, Canada

A method is presented for the investigation of unimolecular reactions which occur during the first 10^{-9} to 10^{-7}s in the acceleration region of a double-focussing mass spectrometer equipped with a standard Nier-type source. This method, which is described as Acceleration Region Kinetics (ARK), has been applied initially to an investigation of unimolecular fragmentation of molecular ions of nitrous oxide, n-butylbenzene and nitrobenzene-d_5. Studies which have been conducted with xenon and with n-butylbenzene have been applied to the determination of ionization cross-section by charge exchange as a function of collision energy and the effects of pressure in the acceleration region on charge transfer.

The position of ion formation in the acceleration region may be determined to within 0.02mm, in favourable cases, due to the relatively high resolving power of the electric sector of the ZAB 2FQ mass spectrometer. The ARK technique is similar to that of Field Ionization Kinetics (FIK) and has the advantage that it may be used with a standard Nier-type source.

Dissociation of ions in a non field-free region was first discussed by Hipple *et al.* [1] who considered the reaction

$$m_1^{x+\bullet} \longrightarrow m_2^{y+}\, m_3^{z+} \tag{1}$$

where unimolecular dissociation occurs as the ion is being accelerated following emergence from the source. This fragmentation occurs when $m_1^{x+\bullet}$ has fallen through a fraction b of the accelerating potential V_o. After fragmentation, the nascent daughter ion , m_2^{y+} , has kinetic a energy of $m_2\, bexV_o/m_1$. It is assumed here that there is zero kinetic energy release; the argument for fragmentation with release of kinetic energy is presented elsewhere [2]. The daughter ion falls through the remaining fraction, $(1-b)$, of the accelerating potential. The apparent mass/charge ratio, m_b^*, at which m_2^+ is transmitted through the magnetic sector is given by

$$m_b^* = \frac{m_2^2}{m_1}\left[\frac{m_2\, xb + m_1\,(1-b)y}{m_2\, y^2}\right] \tag{2}$$

as discussed by Cooks *et al.* [3]. From eqn.(2), the point of fragmentation, b, may be calculated as

$$b = \frac{m_1\, y - m_b^*\, m_1\,/m_2\, y^2}{m_1\, y - m_2\, x} \tag{3}$$

When $b = 0$, m_2^{y+} is formed in the source; when $b = 0$, m_2^{y+} is formed in the 1ST FFR and $m^* = m_2^2\, x/m_1\, y^2$. The voltage required for transmission of the daughter ion is E_b where

$$E_b = \left[\frac{m_2\, bx}{m_1} + y(1-b)\right] E_o \tag{4}$$

Rearrangement of eqn.(4) yields

$$b = \left[\frac{y - E_b/E_o}{y - m_2 x/m_1} \right] \tag{5}$$

Equations (2) and (4) relate the operating conditions for the magnetic sector and ESA, respectively, to the transmission through both sectors of a fragment ion formed at a given point in the acceleration region. Elimination of b gives

$$E_b = m_b^{\cdot} E_o y^2 / m_2 \tag{6}$$

thus for a given value of b, E_b is proportional to $m_b^{\cdot}$ and thus to B^2; therefore, for a specific m_2, a linked scan at constant B^2/E will reveal the metastable decomposition to $m_2^{\cdot +}$ throughout the range of b.

Investigation of unimolecular reactions must be conducted in a pressure regime where collisional processes may be neglected. A study of the dissociation of n-butylbenzene (m/z 134) via scission to form m/z 91 and rearrangement to form m/z 92 as a function of pressure has been conducted. As shown in Figure 1, the scission process is the more sensitive to collisional activation but the intensities due to both processes vary linearly with indiated pressure below 2×10^{-6} mbar.

Figure 1: Intensities of two competing reactions of n-butylbenzene as a function of pressure

DYNAMICS OF COLLISION-INDUCED DISSOCIATION OF ACETONE IONS

A. Shukla, S. Howard, S. Anderson, and J. Futrell
Department of Chemistry, University of Delaware, Newark, DE 19716.

Interest in the detailed dynamics of collision-induced dissociation (CID) of polyatomic ions has grown since the technique has become well established in organic and analytical mass spectrometry. A recent publication by van der Zande et al. [1] showed that in 5 keV acetone ion CID the fragment ion (CH3CO+) intensity is maximum at non-zero scattering angle. It was suggested that excitation takes place in close collisions with momentum transfer rather than by electronic excitation at such high energies. With these results in mind we initiated a study of CID of acetone ions at low energies where momentum transfer is suggested to be the dominant channel for ion excitation.

Experiments were performed on a tandem hybrid mass spectrometer-supersonic beam instrument which has been described in detail earlier [2]; only sailent features are mentioned here. A high energy (3keV) beam of acetone ions generated by electron impact ionization from a double focussing mass spectrometer was decelerated to the desired final energy via a series of cylindrical and rectangular tube lenses and focussed at the collision region where it collides with a supersonic beam of argon neutrals at right angles. Fragment ions were energy and mass analyzed at a series of angles using a hemispherical energy analyzer and a quadrupole mass filter. Laboratory angular and energy distributions were taken at angles up to 22 deg for the fragment ions. The data were collected on an IBM PC, smoothed and tranformed into Cartesian probabilities. Details of the transformation specific to our instrument configuration are described elsewhere [3].

Scattering contour diagrams for the CID of acetone ion into acetyl ion at 4.5, 14, and 25 eV (laboratory energy) are shown in Figures 1, 2, and 3 respectively. Considerable scattering is observed in these experiments and the intensity maximum in each case is at a non-zero angle. This is consistent with high energy observations [1]. It is therefore obvious that the excitation of acetone ions proceeds via strong collisions with momentum transfer at both low and high energy.

The most interesting new observation in the present study is the evidence for a complex formation (Figure 1) at 4.5 eV laboratory energy (1.9 eV center-of-mass). Besides intensity maximum near the center-of-mass there are intensity maxima suggesting forward-backward scattering in the process. At this energy therefore the colliding acetone ion forms a complex with neutral argon with an appreciable amount of internal excitation which then fragments after a lifetime longer compared to usual collision time. Since almost all the kinetic energy is transferred into internal modes and the dissociation process requires only 0.6 eV it is quite likely that substantial energy is transferred to the neutral CH_3 (internal and translational) and argon (translational only) in the dissociation process.

ENERGY UPTAKE IN COLLISIONAL ACTIVATION

D.E. Giblin and M.L. Gross
Midwest Center for Mass Spectrometry
Dept. of Chemistry, University of Nebraska,
Lincoln, NE 68588-0304.

INTRODUCTION

During collisional activation (CA), some of the translational kinetic energy is converted to internal energy of the incident ion. In recent years, the internal energy required to induce fragmentation has been studied primarily by the appearance energy method in conjunction with low-energy collisions (<100eV) with massive target gases or surfaces[1]. The amount of energy deposited in the internal modes of the incident ion is estimated indirectly. There are several critical assumptions of this approach. First, that the fractional conversion of kinetic energy (T) to internal energy (Q) as a function of available kinetic energy is the same for all ionic species including a well-characterized calibrant. Second, that all internal energy is partitioned to the incident ion in collisions with quite polarizable target gas molecules.

Particularly troublesome has been the difficulty of estimating the internal energy requirements for charge-remote fragmentation by he low-energy approach. Reported energetics for such fragmentations indicate widely different energy requirements for similar ionic species. Also different mechanisms are implied for an apparently homologous set of fragmentations from the same parent ionic species.

To circumvent such problems, a high-energy method which measures the kinetic energy loss due to CA of a parent ionic species as manifest in the kinetic energy shift of a daughter species. The internal energy again is then calculated from the kinetic energy loss by using a basic physical relationship[2]. The energetics of high-energy CA and fragmentation with regard to charge-remote fragmentation has been investigated by using this approach.

EXPERIMENTAL PROCEDURE

This study of the energy requirements of CA was performed on a Kratos MS-50TA. CA took place in the 2nd collision cell located between MS-I and MS-II. The potential of the 2nd ESA (MS-II) was controlled by a custom MID which produced a centered sweep of preset width (ppm) of that potential and also performed a precision, programmable division of that potential. Sweeps over parent and daughter masses thus have the same proportional width in ppm about the central energy (mass). Signals were collected and averaged by a Nicolet 1170 signal averager. Data was then transferred to a Data General Nova 4X computer for smoothing, peak centroiding by fitting to Gaussian peaks, and the calculation of the kinetic energy loss and internal energy uptake.

In practice, the parent ionic mass, m_1, is selected by MS-I. The daughter ionic mass, m_2, is selected by setting the voltage divider in the MID to the exact ratio of m_2/m_1. The 2nd beta slits are closed down until the peak shape of m_1 in energy space becomes Gaussian (~0.005"). Scans are collected over m_1 and m_2 by the Nicolet signal averager. From the displacement of the centroid of m_2 from its unshifted position is derived a proportional kinetic energy displacement, ΔW. The kinetic energy loss of the parent species which fragment to the selected daughter species is given by: $\Delta T = T\Delta W$. The internal energy gain, Q, is then calculated using an approximation derived from the basic relationship[2]:

$$Q = \Delta T[1-0.25(m_1/m_T)(\Delta T/T)] = Q_a+(m_1/m_T)T \sin^2(\theta_s/2)$$

where Q_a is the actual internal energy uptake, m_T is the mass of the target gas, and θ_s is the scattering angle of m_1 by collision. In practice, θ_s is usually considered to be negligible.

RESULTS AND DISCUSSION

To check the consistency of this high-energy approach, the internal energy gain was determined for several fragmentations by both CA and metastable decomposition. (The latter should give Q=0.) It was found necessary to improve the high-vacuum pumping efficiency on the MS-50TA to

eliminate the residual CA. After the modifications were made, values of Q=0 were found for the chosen fragmentations. A particularly striking example was the loss of NO· from the anion formed by electron attachment to 1-nitro-2-naphthol. This fragmentation had a Q=7.9eV for 30% He CA (by beam reduction). The large value of Q=7.9eV probably reflects a large kinetic shift for this fragmentation. (Most fragmentations we have studied have Q=1.0 to 5.0eV except for charge-remote fragmentations for which Q>12eV). The certainty of kinetic shifts means that the values obtained for Q by this method are therefore upper limits to the energetic requirements for CA. In addition, the information from peak broadening due to kinetic energy release upon fragmentation is preserved in at least some cases, as in the previous example.

The energy gain requirements of CA for charge-remote decompositions of some fatty acid anions were studied at 8kV. The energy gain, Q, was determined for the losses of CH_4, C_2H_6, C_3H_8, C_4H_{10}, and C_6H_{14} from palmitate, oleate, elaidate, and linoleate and for the loss of $C_{11}H_{20}$ from linoleate and $C_{11}H_{22}$ from oleate and elaidate. The values of Q appear to be the same within statistical variation with no apparent function related parent or loss. The average values for Q are 12.7, 13.3, 12.5, and 12.8eV for palmitate, oleate, elaidate, and linoleate, respectively. Such results are consistent with the same mechanism for the homologous series of fragmentations. In addition, the energy widths of the peaks corresponding to these losses are all about 60eV which indicate that scattering due to CA dominates over kinetic energy release as the primary cause of peak broadening for this class of fragmentations.

A further study of the energetics of CA leading to charge-remote fragmentation was conducted on the putative alkane losses from dodecyl sulfate anion as a function of incident ion kinetic energy. The energy gain was determined for the losses of CH_4, C_2H_6, C_3H_8, C_4H_{10}, C_6H_{14}, and C_7H_{16} at an incident ion kinetic energy of 8 and 4kV and for the losses of methane through butane at 2kV. Again, no significant variation of Q as a function of loss was found. However, a significant variation in the average values of Q as a function of kinetic energy was discovered. The average values of Q are 13.9, 16.3, and 20eV for kinetic energies of 8, 4, and 2kV, respectively. The corresponding available energies are 119, 59, and 30eV, respectively. Likely, the increasing Q values reflect increased scattering at lower kinetic energies associated with the production of that population of parent ions that undergo the alkane-loss fragmentations. If scattering is assumed negligible for the 8kV parent ions, then the increases in Q correspond to mean scattering angles of .12 and .19° for 4 and 2kV parent ions, respectively. Thus the mean Q=13.9eV associated with the 8kV parent ions probably has a scattering component and is therefore an upper limit. Since the envelope of the intensities of the alkane-loss series is unchanged with respect to this range of kinetic energies the result constitutes an additional piece of evidence along with similar Q values at a given kinetic energy for a common mechanism. As in the previous example, the energy widths of the peaks at a given kinetic energy are the same which indicates the dominance of scattering over kinetic energy release as the primary cause of peak broadening. Finally, the much lesser fragmentation probabilities at 2kV and the Q value that approaches the maximum available energy indicate that double-collision processes may be important at this kinetic energy.

PHOTODISSOCIATION OF 2-METHYL-1-PENTN-3-YNE CATION.

J. Faulk and R.C. Dunbar; Chemistry Dept., Case Western Reserve University
Cleveland, Ohio 44106.

OBJECTIVES

The objectives of this study were to compare the changes in geometry that accompany the electronic transitions in the phtodissociation and photoelectron experiments, to compare the resolution of a photoelectron spectrum with that available from a photodissociation spectrum and to determine if the two spectra agree as expected from the known electronic transitions.

INTRODUCTION

The high resolution photodissociation spectrum of gas phase 2-methyl-1-penten-3-yne cation was measured from 600nm to 540nm. The photodissociation at 5 Ar ion laser lines (514.5, 501, 497, 488 and 476nm) was also measured

EXPERIMENTAL

The ions were trapped in an icr spectrometer with capacitance bridge detection. The light source was a dye laser pumped with the 514.5nm line of an Ar ion laser The dissociation products were determined using an Ion Spec FTICR spectrometer.

RESULTS

Hydrogen loss is the primary photoprocess:

The photodissociation data points are compared in figure 1 with the He I photoelectron spectrum (solid black line) taken from reference 1 The energy scale is adjusted so that the photoelectron band of the ground state ion appears at 0eV on the left hand side of the figure The π electronic transitions appear above the corresponding photoelectron bands The red line drawn through the photodissociation data points is not fitted to the data points but is only intended to guide the eye

DISCUSSION

Vibrational fine structure:

It is suggested that the vibrational progression shown in figure 2 (with a peak spacing of 1310cm^{-1}; 0 16eV) is due to a stretching mode involving the double bond and probably the central single bond (ref 1).The shoulders on the lower energy photoelectron peak indicate underlying vibrational fine structure with a spacing on the order of 230cm^{-1}. We are not able to assign this frequency to a vibrational mode at this time.

Comparison of spectra:

The photodissociation spectrum is shifted by about 250cm-1 to the high energy side of the photoelectron peak. This is probably due to a difference in the Franck-Condon factors for the two spectra Since the electronic transitions that occur in the photoelectron and photodissociation experiments are different it is not unreasonable to expect them to be accompanied by different changes in the equilibrium geometry and therefore to have different Franck-Condon factors

The small amount of photodissociation occuring in the hot band region (to the low energy side of the photoelectron peak) is probably due to dissociation of vibrationally excited electronic ground state ions At 370K (a reasonable temperature for ions in our instrument) the occupation of the v=1 level of a 250cm-1 vibrational mode is about 35% of the v=0 level Ions with this much internal energy can reasonably be expected to give a significant 1,0 peak

CONCLUSIONS

It appears that the electronic transitions occuring in the photodissociation and photoelectron experiments are accompanied by significantly different changes in cation equilibrium geometry

The vibrational fine structure in the photoelectron spectrum is resolved in the photodissociation spectrum, however hot band absorption and rotational broadening broaden the photodissociation peaks

When compared as in figure 1(where the ground state neutral to ground state ion transition energy is set equal to zero) the two spectra are in good agreement.

Chopped-Laser Two-photon Photodissociation Measurement of Collisional Relaxation in Benzene Ion

Mohammed S. Ahmed and R C Dunbar
Case Western Reserve Univertsity, Cleveland, OH 44106

INTRODUCTION

One of the principal motivations of the present study was to compare the quenching of benzene ion with that of bromobenzene ions, which we have reported in detail[1]. Collisional quenching of bromobenzene ion showed several trends A number of small closed-shell molecules and saturated hydrocarbons had quenching efficiencies which correlated in a very regular way with the quenching molecule and its number of internal degrees of freedom. A number of quenchers with open-shell or unsaturated electronic structures had quenching efficiencies substantially enhanced above this normal rate. This enhanced quenching probably reflects some specific chemical interaction between the bromobenzene ion and the odd electrons or the p electrons of the unsaturated quench molecule. It was speculated that this interaction might involve the lone-pair electrons of the bromine atom of bromobenzene. To clarify this possibility, it seemed interesting to measure the quenching effiency of some of the same neutral molecules with benzene ion: any dramatic difference in the pattern of quenching effiencies could be attributed to effects specific to the presence or absence of the bromine substituent.

TECHNIQUE

The sequential two-photon absorption model is given by the kinetic scheme:

$$C_6H_6^{+\cdot} \xrightarrow{\sigma_1 I} C_6H_6^{+\cdot *} \xrightarrow{\sigma_2 I} C_6H_5^{+} + H \qquad K_cP + K_r$$

$$1/D = \frac{K_cP + K_r}{I^2\sigma_1\sigma_2 t} + \frac{\sigma_1 + \sigma_2}{I^2\sigma_1\sigma_2 t} \quad . \quad . \quad (1)$$

where, D is the dissociation defined by $-\ln\left(\frac{S_{on}}{S_{off}}\right)$, S_{on} and S_{off} are the signal intensities at light on and light off conditions repectively P is the pressure of quench gas

EXPERIMENTAL

The chopped-laser two photon technique in the ICR spectrometer has been described in previous reports[2]. In this study, using the pulsed ICR spectrometer with bridge detection, benzene ions were formed by electron impact with an electron beam pulse of 10-200 ms duration at a nominal electron energy of 11-12 eV. Ions were trapped and irradiated for 3 s Illumination at 488 nm was with the Coherent Radiation I -12 argon ion laser.. The data were analyzed by the usual procedure of fitting to a numerical simulation of the dissociation kinetics, to find the actual relaxation rate at the given pressure.

RESULTS

Table I displays the results for the quench gases used. The number of collisions , Z required for quenching of the photo-excited ion is defined as(K_{orb}/ K_q), where K_{orb} and K_q are the orbiting rate constant and observed collisional quenching rate constant respectively. Z is the inverse of the collisional efficiency for quenching In order to make comparisons among different systems, it is convenient to reduce the observed quenching rates to a calculated energy lost on the first collision[2]. This is readily calculated assuming that collisional energy loss is exponential. This assumption gives the expression

$$\Delta E = E_{\emptyset}(\,(1-(E_T/E_o)^{1/Z})$$

where $E_{\emptyset}$ is the photon energy, E_T is the one-photon threshold energy and E_o is the internal energy above one-photon threshold. These values are compared for benzene and bromobenzene in the last columns of Table II

C_6H_6	8400	--

CONCLUSIONS

1 The quenching efficiency for benzene ion follows the expected trends, increases with increasing size and complexity of the neutral partners.

2 The quenching efficiency for bromobenzene ion is 2.5 times higher than that for benzene ion

3 The quenching efficiency for bromobenzene ion could be a result of the dipole moment or the extended lone-pair electrons of the bromine atom, or the longer duration of collisions in the heavier system or some combination of these factors.

4. The presence of bromine atom appears not to have a specific effect on quenching by a particular gas

5. The chopped-laser two-photon technique is an excellent method in measuring the efficiency of even inefficient quench gas

Internal Energy Distributions Determined For Scattered $Fe(CO)_5^+$ Ions Using Angle Resolved Techniques

S.R. Horning, R.G. Cooks
Department of Chemistry
Purdue University
West Lafayette IN 47904 USA

M. Vincenti
Istituto Guido Donegani
Via Fauser 4, 28100 Novara, Italy.

Internal energy distributions for polyatomic ions collected through scattering angles increasing from 0 - 2.5°, following high energy (keV) collision activation, afford explicit confirmation that the average internal energy ($\Delta\epsilon$) of the excited ion increases with the scattering angle. In addition, the $P(\epsilon)$ curves show a marked dependence on the collision energy (E) and the angle (θ) through which the scattered ions are collected, the data suggesting that ions which are scattered through small angles in high energy collisions are excited through vibrational, as well as through electronic, excitation channels.

Angle resolved experiments were performed on a Finnigan MAT 8200 mass spectrometer. Argon was introduced into the first field-free region of the instrument and the daughter ions were recorded through a linked (B/E) scan of the sector fields. The scattering angle was varied by electrical deflection of the ion beam in the x-z plane as it left the ion source before entering the collision region (1,2). Effects due to multiple collisions were examined by performing the experiments over a wide range of sample and collision gas pressures. No changes which could be attributed to multiple collisions could be detected. In addition contributions to scattering through isotropic kinetic energy release (3) were shown to be small by measuring kinetic energy releases for the contributing reactions.

Internal energy distributions are approximated using known activation energies for each successive decarbonylation process, in conjunction with fragment ion abundances observed in the angle resolved daughter ion spectra (4). Several $P(\epsilon)$ curves obtained at laboratory scattering angles increasing from 0°to 2.5° at 3 keV collision energy are shown in Fig. 1. These curves establish that the average energy deposited during collisional activation increases as the scattering angle is raised. Similar data were obtained at collision energies of 2.25 and 1.5 keV. A plot of the reduced parameter (θE), see Fig. 2, demonstrates that the average energy of the activated ion ($\bar{\epsilon}$) increases approximately linearly with θ, in parallel with earlier studies at much lower collision energies (5).

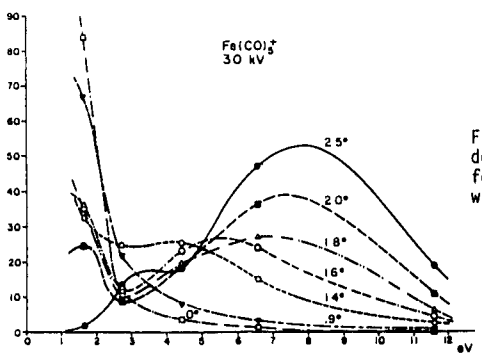

Figure 1. Internal energy distributions determined at several scattering angles for $Fe(CO)_5^+$ upon activation by collision with argon at 3 keV.

Further insight into the nature of these highly structured $P(\epsilon)$ curves for scattered ions can be made by considering the internal energy distributions associated with other methods of activation (see Fig. 3). Under electron impact (EI) conditions, where strict Franck-Condon factors control the formation and internal energy of the ionic species, the region between 2 and 5 eV ion internal energy remains unpopulated. This is in contrast to the distributions found in Fig. 1, and suggests that a mechanism besides electronic excitation may be contributing to the formation of these excited ions. A possible contributor is vibrational excitation or an oblique transition process as proposed by Russek (6). Evidence for participation of vibrational excitation in small angle keV collisions is found in the following observations. First, excitation of $Fe(CO)_5^+$ at a solid surface in the SID experiment, presumably a vibrational process, readily populates the region between 2 and 5 eV in the $P(\epsilon)$ curve (Fig. 2). Second, at low collision energies, where vibrational modes predominate, a linear relationship between the internal energy deposited ($\Delta\epsilon$) during the collision and reduced parameter ($E\theta$) is found (5), resembling the data shown in Fig. 2. These results support the role of both electronic and vibrational excitation processes in keV collisions leading to laboratory scattering angles of a few degrees.

These data hold the promise that with more precise definition of the scattering angle it should be possible to acquire a much more detailed description of the mechanism of collision activated dissociation. It is of interest to note that both $W(CO)_6^+$ and $Cr(CO)_6^+$ show similar structured internal energy distributions with strong angular dependence.

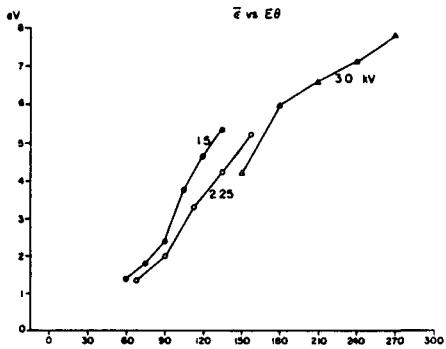

Figure 2. Plot of average $Fe(CO)_5^+$ internal energy ($\bar{\epsilon}$) vs. the reduced parameter ($E\theta$).

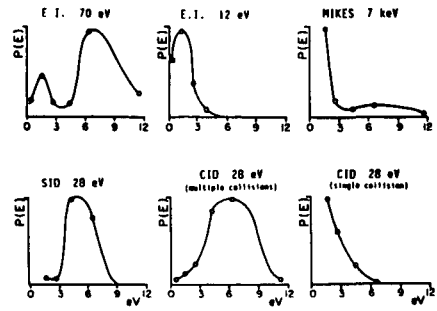

Figure 3. Internal energy distributions for $Fe(CO)_5^+$ activated by various methods.

LASER INDUCED PHOTOFRAGMENTATION OF C5H5+ IONS DERIVED FROM DIFFERENT PRECURSORS

Mehdi Moini
Department of Pharmacology, The George Washington University, Washington DC
Feza Ozturk and John R. Eyler
Department of Chemistry, University of Florida, Gainesville FL

In order to identify different isomeric forms of the $C_5H_5^+$ ion, laser induced photodissociation (PD) of $C_5H_5^+$ ions derived from five different precursors was studied. Photodissociation thresholds, photofragmentation pathways and reactivities of the photofragment ions were then used as a probe of the $C_5H_5^+$ isomeric forms. Reactions of $C_5H_5^+$ produced from these five precursors with diacetylene have also been compared to the PD study of $C_5H_5^+$.

Fourier transform ion cyclotron resonance mass spectrometry (Nicolet FT/MS-1000) was utilized for these studies in conjunction with a pulsed Nd:YAG pumped dye laser (Quantel International). Two different magnets and laser beam configurations were used. The first was a superconducting magnet with a magnetic field of 3 Tesla (Figure 1). The second was an electromagnet which was operated at 1 Tesla (Figure 2).

Photodissociation and reactivity of photofragment ions of $C_5H_5^+$ derived from dicyclopentadiene, norbornadiene, cycloheptatriene, 1-penten-3-yne, and cyclopentadiene were studied according to:

$$\text{precursor} + e \rightarrow C_5H_5^+ + \text{neutral(s)} + 2e \quad (1)$$

$$C_5H_5^+ + h\nu \rightarrow C_3H_3^+ + (C_2H_2) \quad (2)$$

$$\text{precursor} + C_3H_3^+ \rightarrow \text{product(s)} \quad (3)$$

The results of PD of $C_5H_5^+$ at a wavelength of 355 nm show that $C_5H_5^+$ ions produced from dicyclopentadiene, 1-penten-3-yne, norbornadiene, and cycloheptatriene dissociate according to Reaction (2). Within the range of the laser pulse energy used and the signal to noise ratio obtained in these experiments no photodissociation were observed for $C_5H_5^+$ ions produced from cyclopentadiene. $C_3H_3^+$ ions produced in Reaction (2) were >90% reactive for norbornadiene, cycloheptatriene, and dicyclopentadiene while only 50% reactive for 1-pentene-3-yne. The spectra showing the photodissociation of $C_5H_5^+$ ions derived from cycloheptatriene and the reactivity of the photofragment ion ($C_3H_3^+$) are given in Figure 3.

The main reaction of $C_5H_5^+$ produced following charge transfer chemical ionization of a mixture of diacetylene and a precursor compound was:

$$C_5H_5^+ + C_4H_2 \longrightarrow C_9H_7^+ \quad (4)$$

A minor reaction

$$C_5H_5^+ + C_4H_2 \longrightarrow C_7H_5^+ + (C_2H_2) \quad (5)$$

was also observed for all precursors <u>except for cyclopentadiene</u>.

To compare the behavior of ions produced from cycloheptatriene and norbornadiene precursors, relative abundances as a function of electron energy were obtained. Based on the higher relative intensity of $C_5H_6^+$ for norbornadiene, there exists the possibility of formation of $C_5H_5^+$ ions from the $C_5H_6^+$ channel too. In fact, $C_5H_5^+$ ions formed from cycloheptatriene in the energy range of 12-50 eV show similar behavior in reactivity, i.e., the percent of unreactive $C_5H_5^+$ remains constant at 5% while in the norbornadiene case, the amount of unreactive ions increases to 20%,

indicating that $C_5H_5^+$ formed from the $C_5H_6^+$ channel has a higher percent of unreactive isomer.

The results of photodissociation of $C_5H_5^+$ ions using 6 different wavelengths (532 nm, 460 nm, 420 nm, 365 nm, 355 nm, and 266 nm) indicate that the dissociation energy of Reaction (2) is in the range of 420 - 365 nm (2.8 - 3.4 eV). This is in agreement with the calculated energy of dissociation based on thermochemical information. A schematic potential energy surface for the $C_5H_5^+$ system is shown in Figure 4.

$C_5H_5^+$ produced from different precursors exhibit two populations, reactive isomers and unreactive isomers. Photodissociation and chemistry of $C_5H_5^+$ and its photofragment, $C_3H_3^+$, implies that at least two different isomers of $C_5H_5^+$ exist within the pool of the "reactive isomers". Heat of formation of one isomer is estimated to be 255 kcal/mol with the activation energy for dissociation of about 3.4 eV. This isomer also reacts with diacethylene according to Reaction (5). The heat of formation of the other isomer is less than 255 kcal/mol and does not react according to Reaction (5). There may exist a third isomeric form of $C_5H_5^+$ which dissociates according to Reaction (2), but it produces a photofragment, $C_3H_3^+$, with different percentages of the reactive and unreactive isomers.

HIGH RESOLUTION LASER-ION BEAM PHOTODISSOCIATION STUDIES OF IONIC CLUSTER FRAGMENTS OF IRON CARBONYLS.

R.E. Tecklenburg, Jr., and D.H. Russell

Texas A & M University
Department of Chemistry
College Station, Texas 77843

The chemical and physical properties of ionic transition-metal species, e.g., monatomic bare and ligated metals, as well as dimer, trimer, and small metal clusters, have been the subject of intense research over the past decade.[a,b] There have been numerous recent studies that demonstrate the change in chemical reactivities as a function of cluster size and the dependence of the chemical reactions on the electron environment.[c,d] Recent studies also clearly indicate the existence of long-lived electronic states of metal ions and the importance of these species on chemical reactivities.[e,f] These studies demonstrate the need for additional information on the physical properties of transition-metal species, and how such properties influence the chemical reactivities of these species.

Previous work from this laboratory described various aspects of the production of ionic cluster fragments by ion-molecule reactions within an ICR cell.[g] A specific outgrowth of this work is the structure-reactivity relationships of ionic cluster fragments as a function of cluster size and metal-to-ligand ratios (M/L). The reactivities of some clusters were much less than expected based purely on M/L ratio considerations. Photodissociation is potentially useful for characterization of ionic cluster fragments, specifically metal-metal and metal-ligand binding energies, as a function of M/L ratios.[h] Thus, photodissociation provides an additional method for understanding the structure/reactivity relationships of ionic cluster fragments.

The results from laser-ion beam photodissociation studies of ionic cluster fragments of iron carbonyls are presented. Ionic cluster fragments of the type $Fe_x(CO)_y^+$ (x=1-3; y=0-6) are mass resolved by high resolution (R= 7500) prior to photodissociation in the third field-free region of an EBE tandem mass spectrometer. The ions studied are formed by the direct 70 eV electron impact of $Fe_3(CO)_{12}$. Relative photodissociation cross-sections and upper and lower limits to the bond dissociation energies for both Fe-CO and Fe-Fe bonds are reported.

Table I compares the average metal-ligand and metal-metal bond dissociation energies for the various $Fe_x(CO)_y^+$ ions (x=1-3; y=0-6). The metal-metal bond for Fe_3^+ is estimated to be <27.8 kcal/mol. The Fe_2^+ ion does not photodissociate over the wavelength range (458-514.5 nm), placing the lower limit for the bond dissociation energy

at <62.4 kcal/mol. These metal-metal bond energies determined are in agreement with those reported by Smalley.[i] Binding energies in the range 19.5-58.6 kcal/mol are found for metal-ligand bonds. In general, the metal-ligand bond energies for the $Fe_x(CO)_y^+$ species follow the same general trend as observed for $Mn_x(CO)_y^+$ and $Co_x(CO)_y^+$ systems also studied in this laboratory. That is, low metal-ligand bond energies of *ca.* 20 kcal/mol for small x/y ratios, and metal-ligand bond energies which increase to as much as 58 kcal/mol for $x/y \geq 1$. Note from Table I that the $Fe_3(CO)_4^+$ ion has as surprisingly large bond dissociation energy for the loss of one carbonyl ligand. The stability of the $Fe_3(CO)_4^+$ ion relative to other $Fe_3(CO)_y^+$ ions is supported by complimentary information derived from the high resolution collision-induced dissociation (CID) data of the same ions. For example, Figure 1 contains the CID spectra for the $Fe_3(CO)_{10}^+$ ion. Note the unusually large CID signal corresponding to the production of the $Fe_3(CO)_4^+$ daughter ion. Collision-induced dissociation of other $Fe_3(CO)_y^+$ ions (y=5-12) also reveal anonymously large $Fe_3(CO)_4^+$ daughter ion intensities suggesting the $Fe_3(CO)_4^+$ ion has an uncommon stability. This stability may be rationalized in terms of a different type of iron metal center-to-ligand bonding. For example, the carbonyl ligands in the $Fe_3(CO)_4^+$ ion may bind to the metal center through both the carbon and oxygen end of the carbonyl ligands (e.g., four electron donating ligands rather than two electron donating terminal and/or bridging ligands), thus increasing the Fe-CO binding energies.

Table XII. Bond dissociation energies measured from the crossed laser-ion beam photodissociation thresholds for $Fe_3(CO)_y^+$ ions.

TRANSITION	THRESHOLD		THRESHOLD ENERGY • BONDS BROKEN
	(nm)	(kcal/mole)	(kcal/mole)
$Fe_3(CO)_4^+ \longrightarrow Fe_3(CO)_3^+$	502	56.9	56.9
$Fe_3^+ \longrightarrow Fe_2^+$	>514.5	<55.6	<27.8[a]
$Fe_3^+ \longrightarrow Fe_2^+$	>514.5	<55.6	<55.6[b]
$Fe_3^+ \longrightarrow Fe^+$	<458	>62.4	>62.4

STUDIES OF THE ACTIVATION AND DISSOCIATION OF DANSYL AND DINITROPHENYL DERIVATIZED PEPTIDES

R.E. Tecklenburg, Jr., and D.H. Russell

Texas A & M University
Department of Chemistry
College Station, Texas 77843

Tandem mass spectrometry has become an important analytical tool for identification and structural characterization of complex molecules. The use of tandem mass spectrometry in conjunction with fast atom bombardment (FAB) ionization[a] has many advantages for structural characterization of large biomolecules (m/z=1,000-2,000 amu), especially problems related to sensitivity and sample purification.[b,c] The intrinsic advantages for the combined use of FAB and tandem mass spectrometry is that the molecular ion, e.g., $[M+H]^+$, $[M-H]^-$, etc., of a thermally labile, polar molecule can be formed, and the mass-selected $[M+H]^+$ or $[M-H]^-$ ion can be subjected to collision-induced dissociation (CID). Structural information for the $[M-H]^+$ or $[M-H]^-$ ion can then be inferred from the collision-induced dissociation spectrum. However, the factors that control and influence the dissociation of large molecular weight species are not easily probed by CID. For example, the ion internal energy distributions and energy transfer accompanying CID of high molecular weight species are ill-defined and not well understood. Photodissociation offers an alternative to CID for the study of ion activation/dissociation, and the determination of ion structures.[d,e] Although photodissociation may develop as a method for structurally characterizing complex molecules,[f] our studies are designed to understand the underlying factors that influence dissociation.

The results of the laser-ion beam photodissociation studies for a series of derivatized amino acids and di- and tri-peptides are presented herein. The protonated molecular peptide ions are formed by fast-atom bombardment and photodissociated in the third field-free region of a EBE tandem mass spectrometer. Photoexcitation is performed using the visible (514.5 nm - 458 nm) and ultraviolet (385 nm - 333 nm) lines of a CW argon ion laser. Because peptides do not absorb at the visible and uv lines of the argon-ion laser, suitable chromophores (either the dansyl (uv chromophore) or dinitrophenyl group (uv and visible chromophore)) are attached to the N-terminus of the peptide. The times required for ions to undergo photodissociation are measured in the present study using a biased activation cell.[g]

The relative photofragment ion yields and rates of photodissociation for individual reaction channels are reported for the DNP amino acids in Table I. The column labeled prompt (%) lists the percentage of the incident ions that undergo prompt dissociation following photoexcitation (dissociate entirely within the activation cell). The results of these studies can be generalized in the following manner: i) photoexcitation of the dinitrophenyl group by a visible photon results in cleavages within the peptide chain, with little cleavage within the chromophore (e.g. loss of DNP, NO_2, or NO); ii) photoexcitation of the dinitrophenyl group with uv radiation results in both cleavages within the chromophore as well as cleavages within the peptide chain, (but loss of NO, or NO_2 dominant the photofragment ion spectrum); and iii) the percentage of ions that undergo prompt photodissociation decreases in going from uv to visible wavelengths and as the mass of the incident ion increases. These results are rationalized by an "energy selective"[h] model for the dissociation of large ionic systems.

Table XVI. Photodissociation kinetic data, normalized metastable, CID, and photofragment ion yields for the $[M+H]^+$ ions of DNP amino acids.

Laser-Ion Beam Photodissociation Utilizing A Biased Activation Cell

L. Sellers-Hann, R. E. Tecklenburg, and D. H. Russell

Texas A&M University
Department of Chemistry
College Station, TX 77843

Although the sensitivity and dynamic range of photodissociation measurements performed on an ion-beam apparatus are much better than for ion cyclotron resonance, photofragment ion yields are low and long data acquisition times are required. The laser-ion beam photodissociation experiment is complicated by the presence of background signals from metastable and/or collision-induced dissociation reactions. In order to study a photodissociation process free from metastable and/or collision-induced dissociation background, the photon source must be modulated by a mechanical chopper and the photofragment ion signal is monitored in phase with the laser modulation. In cases where the photofragment ion signals are weak and the background signal is large, long data acquisition times are necessary to achieve adequate signal-to-noise ratios (i.e. >10). An objective of this paper is to show a method that can help reduce the background signal associated with metastable background.

The laser-ion beam photodissociation experiment has been modified to utilize a biased activation cell (Fig. 1) for signal-to-noise enhancements. The biased activation cell acts as a symmetrical einsel lens and decelerates the ions as they enter the cell and then accelerates them as they exit the cell. The net effect is a change in the kinetic energy of the ions that dissociate with in the activation cell , thus product ions formed in the activation cell are separated from ions which dissociate in the field-free region. For example, ions which undergo photodissociation within the biased activation cell (B^*) have a kinetic energy defined by $[(m_2/m_1)V + (1-(m_2/m_1))V']$,[1] while ions dissociating outside the cell (A^*) have a kinetic energy defined by $[(m_2/m_1)V]$, where V is the main beam accelerating voltage, and V' the biased cell voltage. The principle advantage of the biased activation cell for photodissociation studies is the separation of the metastable ion dissociation signal (noise) from the photodissociation signal. This gives an overall reduction in the metastable ion signal by *ca.* a factor of 20.

Signal-to-noise enhancements are most realized for transition metal compounds as they dissociate promptly (<≈50 ns). As an example, a S/N enhancement from 2.3 to 44 is achieved for the photofragment ion yields for cleavage of the Mn-Mn bond of $Mn_2(CO)_{10}^+$ and data collection times are reduced from 6.7 minutes to 1.7 minutes for this system using the biased activation cell. This example shows that the poor signal-to-noise ratios for the photofragment ion signal obtained without biasing the activation cell is a result of the metastable background rather than instrument noise. The utility of the biased activation cell technique is the increased sensitivity for weak photofragment ion signals. Thus, improvements in peak heights/peak areas measurements (used in the calculation of photodissociation cross-sections) as well as photodissociation threshold measurements (used to determine bond dissociation energies) can be obtained.

The biased activation cell also provides a means of distinguishing between ions that dissociate promptly (within the biased activation cell) and those which are longer lived (dissociate outside the biased activation cell). This allows for the measurement of the fraction of prompt/slow photofragmenting ions thus, providing dissociation rates to be estimated. For example, photodissociation rates of $>5.6\times10^6\ s^{-1}$ and $5.6\text{-}0.29\times10^6\ s^{-1}$ can be specified for a 500 amu ion (V=8 kV, V'≈1 kV) photodissociating within the activation cell (length=1.9 cm) and between the exit of the activation cell and entrance to the second electrostatic analyzer (length=19.4 cm), respectively. Slow dissociation reactions occur most often for hydrocarbons that have excited states lying close to the dissociation threshold or for ions that undergo isomerization prior to dissociation. An example of such an ion is the 1,3-butadiene ion that has its first excited state *ca.* 0.1 eV below the dissociation threshold for loss of the methyl radical and this ion shows both prompt (64%) and slow (36%) dissociation.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

It is interesting to compare the ratio of prompt to slow photodissociation reactions (Table I). For example, trans,trans-2,4-hexadiene, cis,trans-2,4-hexadiene, and cis,cis-2,4-hexadiene ions photodissociate to form $C_5H_7^+$ and $C_4H_6^{+\cdot}$. For the $C_6H_{10}^{+\cdot}$ isomers the prompt/slow photodissociation ratios give an indication for isomer differentiation. For example the trans,trans-2,4-hexadiene prompt/slow ratios ($C_5H_7^+$, 51/49; and $C_4H_6^{+\cdot}$, 79/21) differ significantly from the cis,trans-2,4-hexadiene ($C_5H_7^+$, >95/<5; and $C_4H_6^{+\cdot}$, 65/35), and cis,cis-2,4-hexadiene ($C_5H_7^+$, >95/<5; and $C_4H_6^{+\cdot}$, 69/31). In an earlier paper these $C_6H_{10}^+$ isomers were differentiated on the basis of kinetic energy release data for the photofragment ions.[2] The isomer dependent kinetic energy release values were interpreted in terms of the photoexcited trans,trans-2,4-hexadiene ions undergoing a slow rearrangement reaction prior to dissociation. The prompt/slow photodissociation ratio data for the $C_6H_{10}^{+\cdot}$ isomers is also consistent with the previous explanation.

The biased activation cell has utility for the laser-ion beam photodissociation experiment especially in the area of signal-to-noise enhancement. The signal-to-noise enhancement is realized most for those ions that dissociate promptly. Also, the kinetics data for photodissociation may be of considerable interest from a fundamental point-of-view and may have analytical utility as well.

---

COLLISION-INDUCED DISSOCIATION REACTIONS OF DOUBLY-CHARGED IONS OF POLYCYCLIC AROMATIC HYDROCARBONS#

R.K. Boyd, W.D. Jamieson and P.G. Sim

Atlantic Research Laboratory
National Research Council of Canada
1411 Oxford St., Halifax, Nova Scotia, CANADA B3H 3Z1.

In a largely unsuccessful attempt to achieve isomer distinction for PAHs via tandem mass spectrometry of their molecular dications, a striking difference was noted between these spectra for "large" and "small" PAHs. Small PAH dications undergo charge separation reactions and (for collisionally activated spectra) electron capture (both dissociative and non-dissociative). Large PAH dications, however, preferentially expel small neutral molecules such as C_2H_2, C_4H_2 and, at higher collision energies, even free radicals such as $CH_3\cdot$ and $C_2H_5\cdot$. These trends are illustrated by Fig. 1, which compares MIKE spectra for benzo[b]fluoranthene as a typical large PAH and for furan as a small PAH (benzene is not suitable for this comparison since the $C_6H_6^{2+}$ ion is dominated by the $C_3H_3^+$ fragment ion).

These trends have been studied using a tandem hybrid instrument of BEqQ configuration (VG Analytical ZAB-EQ) at both high collision energies MIKES and in the range 50 - 400 eV (qQ). Though this work will be reported separately, the following trends can be summarized here:

(a) The dominant unimolecular reaction of dications of large PAHs is expulsion of neutral acetylene; this reaction is the most sensitive to isomeric structural differences.
(b) Below about m/z 70 the fragment spectra are essentially identical for all large PAHs studied (anthracene, phenanthrene and larger); this suggests some common intermediate(s) in the fragmentation pathways (see Pachuta et al., J. Am Chem. Soc. 110, 657 (1988), for similar discussion of the monocations) leading to the ion series $C_nH_m^{2+}$ for m = 2, 4, 6 and n even.
(c) The qualitative difference between large and small PAHs can be rationalized in terms of different means of avoiding anti-aromaticity (4n pi-electrons, see Moran et al., Org. Mass Spectrom. 16, 92 (1981)) in the dications. Small PAHs, e.g. benzene, form aromatic cyclopropenium structures amenable to charge separation reactions (Lammertsmaa et al., J. Am. Chem. Soc. 105, 1049 (1983)). Larger aromatic systems can form diradical dication structures (McLafferty et al., Chem. Commun. 533 (1967)) from which radical site initiated reactions (including radical loss) can occur.
(d) The monoradical fragment dications observed in this work all contain odd numbers of carbon atoms, in agreement with previous work on ion-source reactions (2E mass spectra, Ast et al., Org. Mass Spectrom. 6, 749 (1972)); it seems likely that a similar interpretation applies here.

Although necessarily speculative these mechanistic proposals can rationalize the present observations. A more complete account will be published elsewhere.

THE DISSOCIATION DYNAMICS OF ION-DIPOLE COMPLEXES: HCL LOSS FROM ETHYL CHLORIDE

J.C.Morrow, Tomas Baer, and Jian-Dong Shao

Department of Chemistry
University of North Carolina, Chapel Hill, N.C. 27599-3290

The dissociation rates of energy selected ethyl chloride ions are known from the measurements made by Tsai, Werner, and Baer (1) using the technique of photoelectron photoion coincidence (PEPICO). The present experimental investigation of CH_3CH_2Cl and CD_3CH_2Cl has shown that the activation energy for the loss of DCl from the deuterated parent ion is 0.13 eV higher than the activation energy for the non-deuterated ion. This difference, which is three times the shift arising from the difference in the zero point energies, is probably a result of the H atom transfer in a tunneling mechanism. Thus the tunneling is inhibited in the case of the deuterated compound. The dissociation rates, which are measured as a function of the ion internal energy, have two components, with the slower component in the 10^6 sec^{-1} range near the dissociation threshold. This rate is orders of magnitude less than that expected on the basis of the statistical theory (Rice-Marcus/quasiequilibrium theory).

The dissociation mechanism has been investigated by ab initio calculations at the MP2/6-31G* level. These results show that the ethyl chloride ion rearranges to a more stable ion-dipole complex configuration which is 0.27 eV (when zero point energies are used) more stable than the dissociation products HCl and $C_2H_4^{+\cdot}$. It is thus more stable than the ethyl chloride ion itself by about 0.19 eV. Calculations also show that the ethyl chloride molecule experiences a considerable change in geometry upon ionization. As discussed previously (2) for the case of the n-propanol ion dissociation, the dissociation from the ion-dipole complex is slow because of the long range interaction potential between the ion and the dipole.

This work was supported by the National Science Foundation, the Pittsburgh Supercomputing Center, and the Computation Center of the Technical University of Berlin.

SOLID FAB MS AND FAB MS/MS FOR THE GENERATION AND STUDY OF SOME UNUSUAL SPECIES

K. Caldwell[2], E. Davoli[1], and M.L. Gross[2].

(1) "Mario Negri" Pharmacological Research Institute, Via Eritrea 62, Milano, Italy; (2) Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE 68588.

Fast Atom Bombardment (FAB) is a technique generally used for the desorption of large organic molecules. A liquid matrix is used in order to, at least in part, prevent the extensive radiolytic damage produced by the atom beam. To study extremely nonvolatile inorganic species we have used matrixless FAB conditions and MS/MS along with high resolution peak matching. Under these conditions (solid FAB) it is also possible to detect, isolate, and study ions that are normally suppressed or that readily react with the matrix.

Spectroscopic studies of extremely nonvolatile materials are generally done by heating the sample to obtain a sufficient vapor pressure. Mass spectrometry may be performed with subsequent ionization of these neutrals. However, for metal alloys composed of metals with differing vapor pressures, as well as for salts, practical difficulties exist for obtaining gas phase ions. Under solid FAB conditions we have observed the species listed in Table 1.

Experiments were carried out on a Kratos Triple Analyzer. The instrument is equipped with an Ion Tech FAB gun operated normally at 6 kV with a discharge current of 6 mA. The MS/MS spectra are MIKES CAD spectra obtained scanning ESA 2. The pressure in the collision cell was raised until the main beam was suppressed by 30%. The target gas was Helium.

Aqueous solutions of alkali halides are deposited on the probe tip and dried in vacuo. Generally low resolution is sufficient in MS1 to produce a clear, interference free spectra. All spectra are MIKES spectra and parent ions are collisionally activated since these species do not decay metastably. For certain species, such as F^+, it is necessary to remove completely the water of hydration in an oven in order to have a sufficiently intense ion. Less than a milligram of salt on the probe will produce a steady current for several hours.

The CAD spectra (Fig. 1 and 2) of these molecular radical ions confirms their compositions. The high precision of the ESA scans allows measurements of the products with a precision sufficient to show a logarithmic trend (Fig. 3). It is shown that solid FAB offers a means for producing ions of unusual species from refractory precursors. FAB MS/MS can be used to characterize and study these ions. CAD MIKES spectra, as well as energetic measurements, provide information on the mechanism of the dissociation. Experiments are currently under way.

A GEOMETRIC MODEL FOR THE DECONVOLUTION OF ION KINETIC ENERGY SIGNALS

G.K. Koyanagi† and R.E. March, Trent University, Peterborough, ON, Canada, K9J 7B8
† Registered at Queen's University, Kingston, ON, Canada, K7L 3N6

Much kinetic and energetic data have been extracted from generalized examinations of the shape of Mass-analysed Ion Kinetic Energy (MIKE) signals. There exist several approximate formulae to determine the mean kinetic energy, <T>, released in a unimolecular fragmentation reaction from a measure of the width of the MIKE signal [1]. The deconvolution of MIKE signals to the associated Kinetic Energy Release Distribution (KERD) is a more complex process which can yield more descriptive kinetic and energetic data.

In 1974 Terwilliger *et al.* [2] produced an excellent model for describing the trajectory of ions through the electric sector of a reversed geometry mass spectrometer. In the above work several extensions were discussed which could increase the accuracy of the geometric model and extend the applicability of the deconvolution process. Recently, Rumpf and Derrick [3] have examined some of the extensions discussed by Terwilliger *et al.* and have produced an improved model. Since the deconvolution process is iterative; where the KERD is slowly refined to reproduce the experimentally observed peak shape, minimized computational time is paramount. Rumpf and Derrick reduced computational time by utilizing an approximated 'basis set' description of variables intermediate in the calculation. Also, the model by Rumpf and Derrick accounted for fragmentation reactions occurring before the intermediate slit in the second field free region, a necessary extension to the original model by Terwilliger *et al.*

A major failure of the original model by Terwilliger *et al.* was the prediction that the peak should be symmetric about the mean electric sector potential. The model produced by Rumpf and Derrick predicts that the high energy side of a dish-topped peak is slightly more intense than the low energy side. Rumpf and Derrick attributed this to decompositions occurring within the electric sector.

In the model presented, briefly here and in detail in reference [4], the major extensions consider: (i) fragmentations occurring along the entire length of the 2ndFFR, (ii) the difference in ion beam intensity before and after the intermediate slit, and (iii) the slight difference in angular acceptance between forward scattered and backward scattered product ions. In addition, several mathematical approximations have been introduced which speed, greatly, the computation of a theoretical peak shape. In all cases the accuracy of each approximation was found to be better than 1 part in 10^6.

To calculate contributions to the MIKE signal for fragmentation reactions occurring before the intermediate slit of the 2ndFFR, the angular acceptance, (in the x-y plane) of the intermediate slit must be considered simultaneosly with the angular acceptance of the electric sector collector slit. Figure 1 is a schematic representation of the determination of $\Delta\varsigma$, the angular acceptance of the intermediate slit, here u_2 is the velocity of the product ion relative to the centre-of-mass and v_1, the initial velocity of the reactant ion. In Figure 1 the magnitude of v_1 has been reduced to accentuate the difference in angular acceptance for forward and backward projected fragment ions. It should be noted that the model presented here also correctly predicts that the high energy horn of a dished peak is of greater intensity than the low energy horn, based solely on the difference in angular acceptance at the intermediate slit.

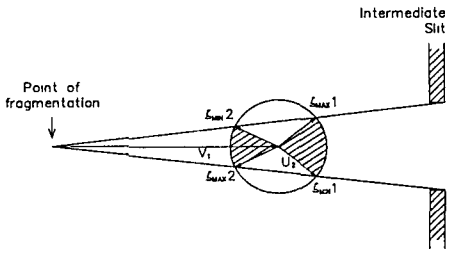

Figure 1. Schematic representation for the determination of $\Delta\varsigma$. The magnitude of v_1 has been reduced to accentuate the difference in $\Delta\varsigma$ between forward and backward fragmentations.

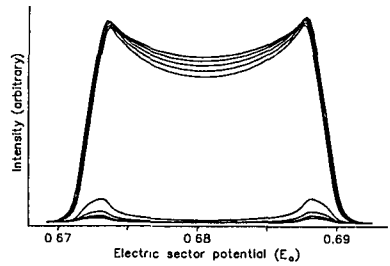

Figure 2. Plots of intermediate peak shapes for the nine selected points of fragmentation along the second field free region.

Logically, from Figure 1, there will also exist a difference in angular acceptance between forward and backward fragmentations in the z-direction, which also contributes to the asymmetry of the MIKE signal. All three models discussed here do not account for this as it would increase the computational time required by at least ten-fold. Fortunately, however, owing to the typically large height of z-direction restrictions to the ion beam the relative difference in angular acceptance is small, and therefore adds little to the asymmetry of the MIKE peak.

In practice it was found that a numerical integration of nine theoretical peak shapes calculated along the length of the 2ndFFR gave satisfactory results. Increasing the numerical integration to fifteen points along the 2ndFFR gave similar results and almost doubled the computational time required. In Figure 2 are presented plots of the intensity profiles of nine typical intermediately calculated peak shapes, the ordering is from magnet exit to electric sector enterance in ascending intensity. In the numerical integration of the intermediate peaks along the 2ndFFR a weighting factor must be applied to peaks originating before the intermediate slit to account for the removal of ions from the main beam at the intermediate slit.

Also, the algorithm allows for the expression of the KERD as either a step function in T, or as a polynomial function of T. If the KERD can be described sufficiently well by a polynomial the calculation time can be reduced by up to half.

Directional Properties in Photodissociation Studied in a Laser TOF-MS System

P.Marcus, I.Platzner, N.R.C.Negev, Div. of Chemistry,
I.Bar & S.Rosenwaks;Dept. of Physics, Ben-Gurion Univ. of the Negev,
Beer-Sheva Israel.

Introduction: Any initial velocity and spatial distribution of ions in a time of flight mass spectrometer source will be reflected in the ion peak profile, unless a compensation method like "time delay"[1] or "reflectron technique" [2,3] is used. These profile changes can be monitored if a recording system of sufficiently high time resolution is used. The photofragment spectroscopy with mass spectrometric detection has the advantage of not being restricted to small photofragments with accurately known spectroscopic properties, as laser induced fluorescence (LIF) requires, and hence such studies have aroused a growing interest[4]. In view of the recent application of TOF-MS in this field, experiments have mainly been involved in verifying and complementing the results obtained thus far by the LIF method[5-9].
NO produced following the photodissociation of tert-Butylnitrite (TBN) by a pulsed polarized laser at 266, 355 and 532 nm in a time-of-flight mass spectrometer[10,11] showed an anisotropic spatial velocity distribution. The dynamics of the photodissociation process and, in particular, its directional properties are discussed in view of these experimental results.
Experimental: The laser beam was focused into the center of the mass spectrometer ionization cell by a 20 cm focal length, plano-convex quartz lens. The laser energy varied between 5-85, 1-19, and 0.15-6.5 mJ, for 532, 355 and 266 nm, respectively. Mass spectra of TBN were obtained at 266, 355 and 532 nm as a function of sample pressure and laser power at two perpendicular laser polarization directions, one parallel and one perpendicular to the ions' flight direction (hereafter referred to as parallel and perpendicular polarization, respectively). For more details see Ref.10&11.
Results and discussion: A splitting of the NO fragment ion peak profile depending on the polarization direction of the laser beam was observed . The split peak has a trough coinciding with the apex of the NO ion peak originating from pure NO. At 532 nm and 266 nm with parallel laser polarization the peak is split, while at 355 nm the same effects are observed with perpendicular laser polarization (see figs.1&2). The kinetic energy of the NO fragment formed in the laser source was evaluated by comparing the pure NO and the fragment NO kinetic energy obtained for the same laser flux (10^{10} W/cm^2) at 532nm, 355nm, and 266nm. From energy balance calculations we conclude that at 532nm , the fragmentation takes place as a result of a two photon resonant absorption process, although one photon is enough to cause dissociation (~1.7eV[12]). The NO fragment peak profile dependence on the laser polarization direction is attributed to the vector correlation between the transition dipole moment of TBN and the NO fragment velocity direction. It indicates, that the CONO skeleton of the excited TBN is planar, and its life time is shorter than the rotation period. At both 532 and 266 nm the transition dipole moment is parallel to the CONO skeleton, while at 355 nm the transition dipole moment is perpendicular to the CONO skeleton. These findings are similar to the results obtained for methylnitrite in the same wavelength region[6,9] and also correspond to the LIF results[13,14] obtained in our laboratory at 250, 351.8 and 363.5 nm.

Conclusion: Using a TOF-MS in conjunction with a laser, vector correlation measurements and kinetic energy balance are relatively easy to perform. The results provide information about the excited parent molecule symmetry properties and its lifetime and about the mechanism by which it fragments.

REACTION-INDUCED MASS DISCRIMINATION IN XQQ INSTRUMENTS: Absolute Cross Sections for $N_2^+ + SF_6 \rightarrow N_2 + SF_x^+$ (x=1-5)

Richard I. Martinez

Washington, DC 20057

ABSTRACT

Dynamically-correct branching ratios can be measured in a XQQ tandem mass spectrometer (MS/MS) under single-collision conditions when the key MS/MS parameters are properly selected to correct for reaction-induced mass discrimination within the rf-only quadrupole mass filter (Q2). The energy dependence of the cross section, $\sigma(E)$, for the reaction $N_2^+ + SF_6 \rightarrow N_2 + SF_x^+$ (x=1-5) was measured in the NBS triple quadrupole (QQQ) tandem mass spectrometer. Identical $\sigma(E)$ were measured from both the rate of reactant ion decay and the rate of product ion formation. Therefore, these σ values are substantially free from kinetic interferences (i.e., no back reactions, no impurity reactions, no scattering losses, minimal fringing fields, no mass discrimination, well-defined gas target, etc.). Moreover, there is probably no significant systematic error in our measurements of the absolute σ values for $N_2^+ + SF_6 \rightarrow N_2 + SF_x^+$ (x=1-5) because the σ values we measured with this same technique for $Ne^+ + Ne \rightarrow Ne + Ne^+$, $Ar^+ + Ar \rightarrow Ar + Ar^+$, and $Ar^+ + N_2 \rightarrow Ar + N_2^+$ agreed well with literature values obtained with several well-established techniques.

INTRODUCTION

XQQ instruments (QQQ, BEQQ hybrid, etc.) are complex ion-optical devices.[1-7] Instrument parameters affect the observed ion distribution. Therefore, the observed ion abundances may not accurately reflect the molecular dynamics of a reaction occurring within Q2. That is, instrument-dependent spectra will be observed [8].

To develop an instrument-independent MS/MS database (library) for XQQ instruments one must obtain an undistorted (dynamically-correct) representation of any reaction studied within such instruments [8]. The prerequisites for obtaining dynamically-correct branching ratios within XQQ instruments have been detailed elsewhere [8].

Of special concern is the reaction-induced "mass discrimination" which is intrinsic to XQQ instruments [8]. When reaction occurs within Q2, the mass changes from that of the reactant (projectile) ion, m_{react}, to that of the product ion, m_{prod}. Any ion will follow an unstable trajectory when its Mathieu parameter q exceeds 0.908 (the stable-trajectory limit) [4]. Thus, when CAD experiments are carried out in XQQ instruments, low-mass daughters are not detected when $m_{prod} < m_{react} \cdot q_{react}/0.908$ within Q2. However, $q_{prod} < q_{react}$ when $m_{prod} > m_{react}$. Then, product ions will always follow stable trajectories within the Q2Q3 structure (so long as $q_{react} < 0.908$).

In this study of the dissociative charge-transfer reaction $N_2^+ + SF_6 \rightarrow N_2 + SF_x^+$ (x=1-5) we assess the complex interplay among the key MS/MS parameters [8] under optimum dynamical conditions (i.e., when $m_{prod} > m_{react}$). Note that SF_6^+ product ion is never observed; it always predissociates to SF_5^+.

EXPERIMENTAL

All experiments were carried out in the NBS QQQ instrument.[9] Briefly, the instrument consists of (i) a standard electron impact ionizer, (ii) three standard quadrupole rod assemblies (Q1, Q2, Q3) operated in phase at 1.2 MHz and mounted in tandem on a special multipurpose track, and (iii) a continuous-dynode electron multiplier which incorporates a conversion dynode. Q2 is surrounded by a collision chamber enclosure.

Reaction cross sections σ were derived by using equations (1)-(3), etc. with reference to the following reaction sequence.

$$A^+ + B \rightarrow C^+ + S \qquad [\alpha\sigma]$$
$$\rightarrow D^+ + T \qquad [\beta\sigma]$$
$$\text{etc.}$$

$$\text{Ln } Y \equiv \text{Ln } \{[A^+]_o/[A^+]\} = \sigma[B]L \quad (1)$$

and

$$\text{Ln } W_\alpha \equiv \text{Ln } \{\alpha[A^+]_o/(\alpha[A^+]_o - [C^+])\} = \sigma[B]L \quad (2)$$
$$\text{Ln } W_\beta \equiv \text{Ln } \{\beta[A^+]_o/(\beta[A^+]_o - [D^+])\} = \sigma[B]L \quad (3)$$

etc.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Equations (1)-(3) are applicable under pseudo-first order $\{[B]_o >> [A^+]_o\}$, single-collision conditions for a reaction zone of length L wherein the number density of the target gas is [B] and the "target thickness" is [B]L. Here σ $(=\alpha\sigma+\beta\sigma+...)$ is the total cross section for the A^++B interaction, and the sum of the branching ratios $\alpha+\beta+...$ is equal to 1. Also, A^+, B, α, β, γ, δ, and ϵ correspond, respectively, to N_2^+, SF_6, SF_5^+, SF_4^+, SF_3^+, SF_2^+, and SF^+.

N_2^+ ions were generated by 70 eV electron impact, and the N_2^+ projectiles were selected by Q1. The collision energy E_{coll} was selected by setting the Q2 pole bias = $E_{50\%} - E_{coll}$. $E_{50\%}$ corresponds to the Q2 potential required to stop 50% of the projectile ions entering Q2.

RESULTS

Plots of Ln Y vs. P [based on equation (1)] and of Ln W_{α}, etc. vs. P [based on equations (2), (3), etc.] were linear. Table 1. summarizes the branching ratios ($\alpha-\epsilon$) and the σ at E_{cm}= 4.3 and 34 eV. For comparison, the table includes the characteristic branching ratios $\alpha-\epsilon$ observed during the electron ionization of SF_6 with 70 eV electrons.

Table 1. Branching Ratios ($\alpha-\epsilon$)

		Branching Ratio Value		
Product	Symbol	at E_{cm}= 34 eV	at E_{cm}= 4.3 eV	Electron Ionization E_e= 70 eV
SF_5^+	α	0.89±0.08	1.01±0.08	0.68
SF_4^+	β	0.007±0.0006	0.01	0.06
SF_3^+	γ	0.04±0.004	0.02	0.18
SF_2^+	δ	0.005±0.0004	<0.002	0.036
SF^+	ϵ	<0.0006	--	0.051
$\alpha+\beta+\gamma+\delta+\epsilon$	$\longrightarrow$	0.94±0.08	1.04±0.08	1.0
σ	$\longrightarrow$	56 Å^2 (±10%)	61 Å^2 (±10%)	

DISCUSSION

The results show that $\alpha+\beta+\gamma+\delta+\epsilon$ = 1.0. That is, there is no mass discrimination. Under all conditions $\Sigma[SF_x^+] = [N_2^+]_o - [N_2^+]$. Therefore, when $m_{prod} > m_{react}$, careful control of the key MS/MS parameters makes it possible to account properly for reaction-induced mass discrimination within Q2 over a four-fold change in mass (SF_5^+/N_2^+).

CONCLUSIONS

The observation of the SF_x^+ (x=1-4) product ions under single-collision conditions suggests that a large fraction of the center-of-mass kinetic energy of some ($\lesssim$10%) of the N_2^++SF_6 interactions is efficiently converted to internal excitation of the SF_6^+.

Dynamically-correct branching ratios can be measured under single-collision conditions when the key MS/MS parameters [8] are properly selected to compensate for reaction-induced mass discrimination.

A COMPARISON OF DAUGHTER ION SPECTRA OBTAINED USING HYBRID AND 4-SECTOR TANDEM MASS SPECTROMETERS.

Simon J. Gaskell and Marc H. Reilly, Center for Experimental Therapeutics, Baylor College of Medicine, Houston, Texas 77030

Steven A. Carr, Mark Bean and Richard Vickers, Mass Spectrometry Facility, Smith Kline and French Laboratories, King of Prussia, Pennsylvania 19406.

The theoretical relative advantages of tandem mass spectrometers of hybrid sector/quadrupole (specifically BEqQ)and 4-sector (BEEB) design may be summarized as follows: (i) The hybrid design provides greater facility for the performance of parent and neutral loss, as well as daughter, scans; (ii) The advantages of the 4-sector design lie in the double-focusing of daughter ions, with expected benefits with respect to both transmission and resolution, particularly at higher masses.

The principal tandem MS operating modes for the two instruments are distinct. Collisionally-activated decomposition (CAD) usually occurs in an RF-only quadrupole (q) in the BEqQ instrument and in a collision cell in the third field-free region in the BEEB instrument. Experimental conditions for CAD differ in the following respects: (a) collision energy (laboratory frame-of-reference) - KeV for the BEEB instrument, eV for BEqQ; (b) multiplicity of collisions - generally higher in the quadrupole collision region; (c) residence time in the decomposition region: longer for the BEqQ instrument. The analytical implications of these differences are poorly understood. We have therefore compared data for a series of peptides and oligosaccharides obtained by tandem MS using hybrid and 4-sector instruments.

Analyses were performed on VG ZAB SEQ (BEqQ) and ZAB 4SE (BEEB) instruments. Ionization was by xenon atom and cesium ion bombardment on the BEqQ and BEEB instruments, respectively. For both instruments, parent ion resolution was unit. Daughter ion resolution was set to 1000 for the BEEB instrument and generally 1-2u (though poorer for analytes with M_r > 2000) for the BEqQ instrument.

The conclusions may be summarized as follows: (1) For lower molecular weight analytes (M_r < 1000), daughter ion spectra were obtained from both instruments which included excellent structural information. The spectra obtained for the pentapeptide, methionine-enkephalin, for example, were similar from the two instruments. Daughter ion spectra for maltopentaose MH^+ ions are shown in Figure 1. (2) For the peptides in this study with M_r > 1000, determinations of complete sequence were more readily made from spectra obtained on the BEEB instrument. Thus, for Substance P (Figure 2), the predominance of the A and D ion series facilitated the "reading" of the sequence. The daughter ion spectrum obtained using the BEqQ instrument included C- and N-terminal ions, together with "internal" fragments, which provided confirmatory evidence for structure. The daughter ion spectrum recorded on the 4-sector instrument for ACTH (18-39) was clearly superior to that obtained on the hybrid. (3) The yield of daughter ions from low mass (M_r < 1000) analytes appeared to be superior with the hybrid instrument; this advantage was not apparent at higher masses. A rigorous quantitative comparison, however, is complicated by the several factors influencing transmission of the parent ion through the quadrupole collision region. A detailed investigation of this aspect of the comparative study is the subject of continuing research.

THE EFFECT OF CHEMICAL IONIZATION ON COLLISION-INDUCED FRAGMENTATION IN THE THERMOSPRAY SOURCE.

F. Aladar Bencsath
University of South Alabama, College of Medicine
Department of Biochemistry, Mobile, Alabama 36688

Lewis, Smith and Veares found [1] that a positively biased electrode placed downstream from the ion exit hole influenced remarkably the thermospray spectra. Beside meaningful intensity enhancement, they observed definite qualitative changes in the spectral pattern that occurred at higher electrode potentials. Using an electrode with proper shape and in proper position in the source, we were able to confirm their results as reported recently [2], and we also could provide evidences that all those changes observed were the results of collisionally activated reactions with useful analytical information.

The addition of the Chemical Ionization (=CI) to the Thermospray (=TS) process in form of external electron beam [3] or internal glow discharge [4] opened a wider field of applications for this valuable LC/MS interface. It is desirable, therefore, to explore the retarder's influence on the CI spectra and assess its analytical use under CI conditions in the TS source.

Experiments.

As in our earlier studies, a modified Vestal-type TS source and interface was used with a BIOSPECT quadrupole mass spectrometer. We studied the spectra obtained with pure methanol as LC solvent under CI conditions, compaired the TS and CI spectra of ammonium acetate solution in 95% methanol / 5% water, and we also recorded CI spectra of several solutes (oligopeptides, organic acids, nucleosides) observing in all experiments the effect of the retarder potential between 0 and 500 V. Negative spectra with negatively biased retarder electrode were also studied.

Results.

1. Interesting changes appear in the pure methanol spectra as the retarding potential increases. At zero volt, the protonated methanol dominates; at 100 V, the cluster ions are the chief charge carriers indicating a collision induced addition

$$MeOH + MeOH \rightarrow (MeOH)\,H \text{ and}$$
$$(MeOH)\,H + MeOH \rightarrow (MeOH)\,H\ .$$

The further increase of the retarding potential (i.e., the collision energy) results in the decrease of the trimer's (200 V) then the dimer's (250 V) intensity with the consecutive rise of the protonated methanol m/z 33 and the daughters CH OCH H m/z 47, CH O m/z 31 and CH m/z 15.

2. The retarding field in the source has a stronger effect under CI conditions than under TS conditions as the comparative experiments with ammonium acetate/methanol/water solvent showed. The fragmentation is more extensive in CI mode; the CI spectra obtained at 200 V exhibited a pattern that was observable in the TS spectra only above 300 V. As for the ionization efficiency, the TIC in the CI spectra was larger by one order of magnitude than it was in the corresponding TS spectra. The useful range of retarder potential, however, proved to be narrower in CI mode by about 150-200 V; its upper limit was determined by the onset of electric breakdown in the source. This limit appeared to be 500 V in TS mode.

3. Negative spectra obtained with negatively biased retarder electrode exhibited analogous changes upon the increase of the retarding potential, both in TS and CI mode. The symmetrical behaviour of the + and - charges indicates that mainly ion retardation and collision induced decomposition processes are responsible for the retarder-caused spectral changes.
4. Ions in solute spectra undergo the same changes that was described for the solvent ions: intensity enhancement at moderate retarder potentials, fragmentation and intesity enhancement at higher potencials. These changes are well demonstrated on the positive and negative spectra of homovanillic acid in CI mode, at 0 V and 250 V. At 0 V, only the ammoniated molecular ion at m/z 200 appears in the positive, and the de-protonated molecular anion at m/z 181 appears in the negative spectra. At 250 V, both spectra exhibit several intense ions, each of them can be associated with a well defined fragment structure.

Conclusion.

The retarder electrode in the TS source if properly shaped, positioned and biased, reproducibly increases the total ion current and induces, also reproducibly, collisionally activated decompositions both in TS and in CI mode. This simple electrode thus promises to become a useful analytical tool.

MASS SPECTRA OF DOUBLY CHARGED IONS

M.Barber, D.J.Bell, M.R.Morris, L.W.Tetler, M.D.Woods, UMIST, PO Box 88, Manchester M60 1QD, UK.
J.J.Monaghan, W.E.Morden, ICI C&P Group, Runcorn Heath, Cheshire.

Previously reported studies of peptides have concentrated on the generation of the singly charged pseudo-molecular ion, such as $(M+H)^+$. An alternative approach to the study of high mass samples is to consider the multiply charged ions and the resulting fragments. Indeed, it has been observed that the mass spectra of small proteins (r.m.m. 10-25000 daltons) contain multiply charged molecular ion species of considerable intensity, with the doubly charged ion often being the most intense ion in the spectrum representative of the molecular mass (1)

Spectra consisting of ions originating from a doubly charged parent can be acquired using a hybrid or triple quadrupole mass spectrometer with selection of the doubly charged ion in MS1 and MS2, i.e. the quadrupole analyser, scanned in the normal way as it is not energy focusing.

Results of the study of ions in sector instruments show that the instrument should be set up with the parent ion at H and E and scanned with B/E constant from 2H and 2E downwards. To scan in this way, assuming the singly charged species is within the mass range of the instrument, the instrument is operated at half the full accelerating voltage to enable 2E to set on the ESA.

Although intense multiply charged ions are usually observed with peptides of r.m.m. greater than 5000 daltons it was considered more appropriate to initially study smaller compounds as the resulting spectra are less complex and fragmentation pathways are more readily determined.

Doubly protonated Gramicidin S was studied by B/E scans, from 2E downwards, on a two sector instrument. The observation of sequence ions of greater m/z ratio than the parent illustrate that the instrument is being scanned in the correct fashion and that the doubly charged ions are fragmenting in the first field free region to form singly charged ions.

Sequence ions found in the singly charged spectra were also observed in the spectra, but some of these were of reduced intensity. Overall, the prominent sequence ions observed above the parent ion m/z value are different to those observed from the singly charged parent due to the loss charged rather than neutral residues. Only the ions above the parent ion m\z were considered as this sample, being symmetrical, can produce an ion at m/z=571 corresponding to $(M/2+H)^+$ and hence the ions below this may originate from the singly charged species. To avoid the interference of the singly charged ion the $(^{13}C_1.M+2H)^{2+}$ isotope was studied. The instrument used was a hybrid of BEQQ geometry allowing the CID spectra of $(M+2H)^{2+}$ and its ^{13}C isotope to be compared. The spectrum from the monoisotopic species (fig. 1) was

quite similar to that from the B/E scan focusing on m/z=571, although an additional ion was detected at m/z=441 which corresponds to $(M+2H-PheLeu)^{2+}$. In comparison the $^{13}C_1$ doubly charged parent produced noticeably fewer ions of m/z less than 571 suggesting that daughters of the singly charged parent did contribute to the previous spectra. Sequence ions were observed both above and below the parent m/z value with the expected 1 a.m.u shift of singly charged daughters compared with the daughters of the monoisotopic parent. It was also observed that the ion at m/z=441 shifted by only 0.5 a.m.u. when the the $^{13}C_1$ parent was selected. Another doubly charged daughter was observed in the spectrum corresponding to $(M+2H-Phe)^{2+}$.

The CID spectrum of doubly protonated Angiotensin I, obtained on the hybrid instrument, produced sequence ions both above and below the parent ion. (fig. 2) It is interesting to note that complimentary ions are observed in the spectrum i.e. those that produce the molecular mass when combined.

In order to confirm the proposed fragmentation the mono- and di-methyl esters of Angiotensin were studied. The daughter ion spectrum of the mono-methyl ester is a combination of the diacid and dimethyl ester spectrum indicating that esterification occurs at both acid sites as both methylated and non-methylated fragments are observed.

Daughter ion spectra of doubly charged ions provided structural information often in excess of that provided by the spectra of singly charged ions as a doubly charged ion can form two singly charged daughters and, additionally, doubly charged daughters may be collected. The fragmentation observed for the peptides studied is generally similar to the fragmentation of singly protonated ions although the fact that both fragments remain charged affects the intensity of some sequence ions.

This successful study of multiply charged ions presents the possibility that such ions generated from high mass samples bombarded with liquid metal ions may be analysed using extended mass range tandem mass spectrometers.

COLLISIONAL ACTIVATION SPECTRA OF BISBENZYLISOQUINOLINE ALKALOIDS

K.P. Madhusudanan+, P.R. Das and B.N. Pramanik
Schering-Plough Corporation, Bloomfield, N.J. 07003.
Sudha Jain and D.S. Bhakuni
Central Drug Research Institute, Lucknow 226001, India.

Bisbenzylisoquinoline alkaloids are characterized by the number and type of linkages between the two benzylisoquinoline moieties and the nature of the substituents. Mass spectrometry has been one of the analytical tools successfully used for the structure elucidation of bisbenzylisoquinoline alkaloids (1). Recently, there has been a report of the evaluation of FAB/MS and FAB/MS/MS for the structure elucidation of a few of these alkaloids (2). The results indicate that FAB/MS is a less useful technique than EIMS for the structural studies of bisbenzylisoquinolines containing two ether linkages. However, the EI spectra of these alkaloids are often complicated by the presence of very abundant doubly charged ions (1,3). It was therefore decided to investigate the collisional activation (CA) spectra of the $[M]^+$ of a few bisbenzylisoquinolines having 1-3 ether linkages and/or a C-C linkage. The results of this investigation are described here.

The bisbenzylisoquinolines studied have been isolated from natural sources (4). The collisionally activated mass analyzed ion kinetic energy spectra (CA MIKES) were recorded on a VG-ZAB-SE instrument using a VG 11-250 data system. The ion source conditions were : electron energy, 70 eV and temperature, 200°C. Helium was used as the collision gas . The pressure of helium in the collision cell was adjusted so that there was a 70-80% suppression of the main beam. Samples were introduced through the direct inlet system and heated to 200°C.

The compounds studied and the collision induced fragmentation of their molecular ions are indicated in Figure 1-6. The bisisoquinoline ions $[BIQ]^+$, arising out of double benzylic cleavage give rise to the most intense peak in the CA MIKE spectra of these compounds. Loss of Me and OMe are the other two fragmentation pathways observed. $[M-Me]^+$ ion is more abundant (>50%) in compounds having no 1,4-dioxine bridge (compounds 1-5) than in bisbenzylisoquinolines with 1,4-dioxine bridge (compounds 6-16).
The bisbenzylisoquinolines 1-5 are further characterized by the presence of ions corresponding to loss of isoquinoline and benzyl moieties. Because of the proximal benzyl group only C(8)-O ether linkage is cleaved, followed by rupture of C(1')-C(α') bond resulting in [M-IQ]+ ions. This cleavage is not observed in bisbenzylisoquinolines having 1,4-dioxine bridge. For the formation of $[M\text{-benzyl}]^+$ ion, cleavage occurs at either side of the diaryl ether oxygen leading to either $[M\text{-benzyl}_1]^+$ or $[M\text{-benzyl}_2]^+$ ions.

FAB-MS-MS OF PEPTIDES : UNAMBIGUOUS RECOGNITION OF SEQUENCE PEAKS IN THE CAD SPECTRA.

Bhupesh C. DAS
Institut de Chimie des Substances Naturelles, CNRS
91190 Gif-sur-Yvette, France.

Frédéric de Maack, Gérard Devant
S.N. NERMAG 49 quai du Halage, 92500 Rueil, France

Recent reports from several laboratories have suggested that FAB-MS in combination with MS-MS can provide the amino acid sequences of peptides (R.S. Johnson et al., Anal. Chem. 1987, 59, 2621-2625 and references cited therein). In contrast to the normal FAB spectra, the Collision Activated Decomposition (CAD) mass spectra of peptides often exhibit extensive series of peaks due to different types of fragment ions. However, recognition of the sequence determining peaks in these spectra can be a difficult task particularly when one is confronted with a completely unknown peptide.
The problem can be clearly appreciated from the FAB-MS/MS spectrum of the underivatized pentapeptide H-TYR-GLY-GLY-PHE-LEU-OH presented in Figure 1.

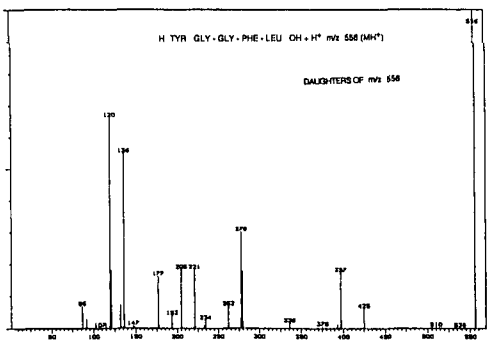

Figure 1

Our objective was to explore simple means for unambiguous recognition of sequence determining peaks. For this purpose, we investigated the FAB-MS/MS spectra of peptides whose amino terminals were acetylated (CH_3CO/CD_3CO) with an equimolecular mixture of acetic anhydride and deuterated acetic anhydride, a reaction which can be easily performed with sub nanomolar quantities.

When only one acetyl group is introduced, the protonated molecular ions in the FAB spectra appeared as two peaks of equal intensity separated by 3 amu, representing the acetylated CH_3CO and trideutero acetylated CD_3CO- species.

Thus, after N-acetylation of the above pentapeptide with the mixture of anhydrides, the protonated molecules in the FAB spectrum appeared at m/z 598 and 601. Comparison of the CAD spectra (Figures 2 and 3) produced selectively from each of these two parent ion species readily differentiated the N-terminal sequence peaks which are shifted 3 amu higher in the deuterated acetyl-bearing fragments. Also, all other fragment ions could be assigned with certainty as a result of this study with deuterium label.

FAB/MS/MS of CH_3CO-TYR-GLY-GLY-PHE-LEU-OH
DAUGHTERS of MH^+ 598

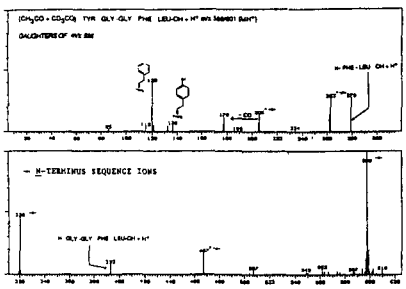

Figure 2

FAB/MS/MS of CD_3CO-TYR-GLY-GLY-PHE-LEU-OH
DAUGHTERS of MH^+ 601

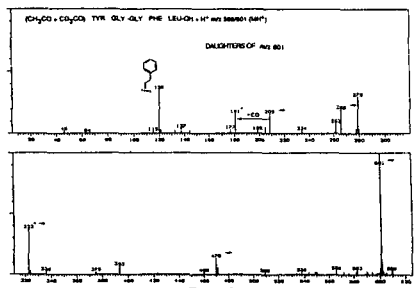

Figure 3

Experiments conducted with several other peptides of both synthetic and natural origin gave similar results. It is expected that this simple methodology, when applied to unknown peptides, should provide unambiguous sequence information. Further work is in progress to extend this method to poly-functionnalized amino acid containing peptides.

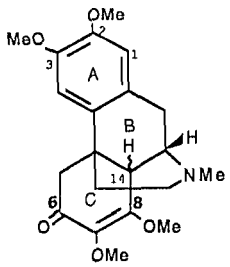
INFLUENCE OF REAGENT GAS PROTON AFFINITY ON COLLISIONALLY-ACTIVATED DECOMPOSITIONS OF ISOMERIC PROTONATED MORPHINANS

B. CHARLES[1], R.B. COLE[2], J. BRUNETON[1] and J.C. TABET[2]*

[1]UER des Sciences Medicales et Pharmaceutiques, ANGERS, FRANCE

[2]Laboratoire de Chimie Organique Structurale, UA 455, Université Pierre et Marie CURIE, Place Jussieu, PARIS Cedex 05, FRANCE

The possibility to differentiate isomeric and stereoisomeric compounds using MS/MS techniques is now well documented. Often, CAD spectra are not dependent upon the mode of protonated molecule preparation in the ion source because the initial internal energy of source ions is low in comparison to the excitation energy transferred during the collision process (case of keV collisions, lab. frame of reference). In this report, we use a triple quadrupole (Nermag R30-10) to investigate some unusual behavior observed in the decompositions of protonated isomeric morphinans characterized by a ketone group in one of two positions on the C-ring, and either cis or trans B/C ring junction stereochemistry:



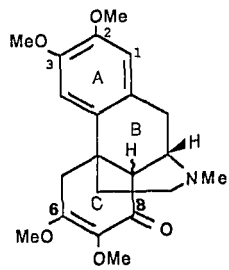
1c $H_{14\,eq}$

1t $H_{14\,ax}$

B/C ring junction

cis

trans



2c $H_{14\,eq}$

2t $H_{14\,ax}$

B/C ring junction

cis

trans

CAD spectra of CI/NH_3 generated MH^+ ions (Fig. 2) are characterized by an unusual "silhouette" as primarily low mass daughter ions predominate for the four isomers. Among these lower mass daughters, even mass nitrogen-containing ions are detected in high yields. The abundance ratios of m/z 44 : m/z 58 immonium or aziridinium species are almost identical for both cis and trans isomers, thus stereochemical effects are not linked to their forma-

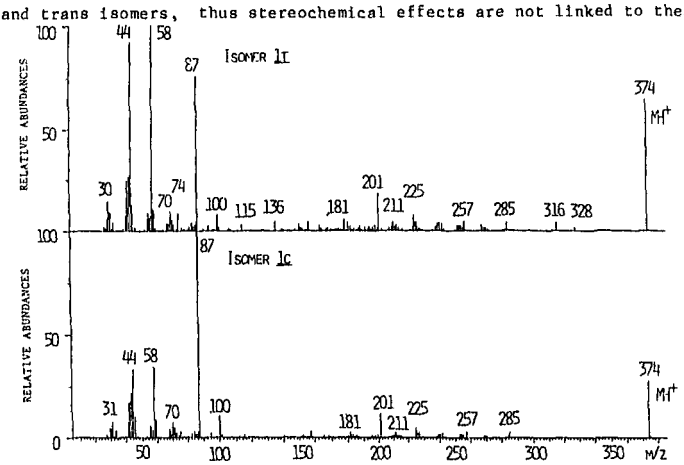


Figure 2

tion. Furthermore, the relative abundances of these ions remain constant even when the collision energy is varied from 10 to 80 eV (laboratory frame of reference). This constancy may indicate that these even-mass ions are produced as a result of the decomposition of a common intermediate ion (D-ring open) formed prior to CAD in the ion source (or in flight). This resultant intermediate ion, common to both cis and trans configurations, could decompose via competitive pathways to yield the even-mass daughter ion fragments, plus highly conjugated (stable) neutrals. To activate opening of the D-ring, attachment of the ionizing proton must be localized to one of two nucleophilic sites: either the $-NCH_3$ group (favored) or the keto-enonic system of the C-ring.

In sharp contrast to the results above, when switching CI reagent gas from NH_3 to CH_4, CAD spectra of MH^+ ions (Fig. 3) obtained using identical collision conditions present mainly higher mass daughter ions (above m/z 200); the low mass nitrogen-containing ions are detected in far lower abundances. The distinct behavior of each of the two reactive plasma systems towards the analyte morphinans can be explained by two interralated phenomona: (i) the average internal energy of MH^+ ions prepared by CI/CH_4 is very much higher than that of MH^+ ions prepared by CI/NH_4^+, and (ii) in contrast to the latter conditions where mainly the $N-CH_3$ group was protonated, for the CI/CH_4 system significant protonation takes place at other nucleophilic sites (i.e., methoxy and carbonyl groups, and the aromatic ring). The losses of low mass neutrals (species having relatively low proton affinities, e.g., $H_2C=O$, H_3C-OH, $H_3C-O-CH_3$) yielding daughter ions at m/z 344, 342, 328, respectively, and m/z 310 (by consecutive losses of two CH_3OH molecules), are consequently favored over formation of low-mass nitrogen containing ions.

The finding that reagent gas (protonating agent) composition exerts a tremendous effect upon the profile of daughter ions observed in the CAD spectrum of protonated molecules of a given isomer is attributed to a higher regioselectivity of protonation for the NH_3 reagent gas which possesses a higher proton affinity than methane. Relative to the methane reagent, ammonia plasma protons may thus be transferred to a smaller number of sites, and product molecules protonated at a given site contain lower internal energies, hence, possess more limited possibilities for internal proton transfer prior to collisional activation.

INFLUENCE OF CATIONIZING ALKALI METALS ON THE STABILITY OF FAB DESORBED PYRIMIDINE DERIVATIVES

Richard B. Cole and Jean-Claude Tabet
Laboratoire de Chimie Organique Structurale, UA 455,
Université Pierre et Marie Curie (Paris VI), 4 Place Jussieu, 75230 Paris Cedex 05, FRANCE

Jean-Claude Blais
Laboratoire de Physique et Chimie Biomoléculaire, CNRS, UA 198, Institut Curie and
Université Pierre et Marie Curie, 11 Rue Pierre et Marie Curie, 75231 Paris Cedex 05, FRANCE

The presence of alkali cations is known to affect the distribution of organic molecular adducts desorbed from surfaces undergoing particle bombardment in secondary ion mass spectrometric analysis. Using various pyrimidines (e.g. 4(2'-hydroxyphenyl)-5-methyl-2-hydrazinopyrimidine, Fig. 2a) as model compounds for studying the cationization phenomenon, we have investigated the stability of alkali metal adduct molecules (i.e., MH^+, $(M+Li)^+$, $(M+Na)^+$) as a function of cation size. Such cationized molecules were desorbed from a thioglycerol matrix using 8 keV Ar bombardment; decompositions were monitored using a Triple Quadrupole (Nermag R30-10) under conditions of collisional activation (CAD), as well as in the metastable mode. Metastable decompositions are generally more sensitive probes of ion internal energy than high pressure CAD's because subtle differences in the intensities of daughter ions arising from low-energy decompositions may be lost if a huge excess of internal energy is acquired by the molecule (i.e., CAD).

MH^+ ions were observed to undergo metastable decompositions via competitive pathways (Fig. 1a) resulting in the losses of neutrals at 16 amu (postulated to be a rearrangement loss of CH_4) and 17 amu (NH_3), plus consecutive losses of 27 amu (HCN) or 28 amu following NH_3 loss (verified by constant daughter scans). In contrast, $(M+Li)^+$ ions exhibited metastable decomposition solely via loss of 16 amu neutrals (Fig. 1b). Incorporation of a second

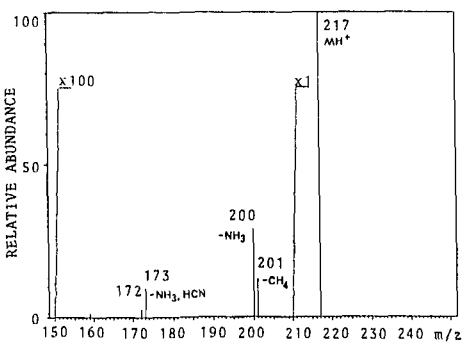

Figure 1A

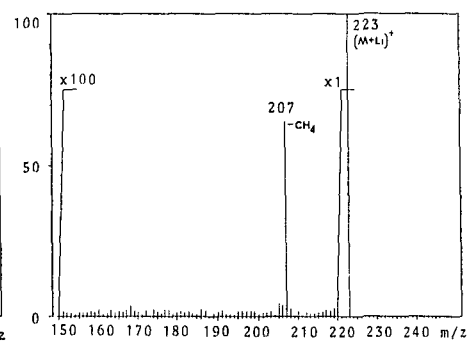

Figure 1B

lithium atom into the pyrimidine structure by Li^+/H^+ substitution, however, blocked even this process. With an even larger cation, Na^+, metastable decompositions of $(M+Na)^+$ ions were also suppressed entirely. These results indicate an augmented stability of molecular ion adducts with increasing cation size, and number of incorporated metal atoms. Thermodynamic and kinetic factors involved in this stabilization may include processes such as increased ground state stability of the precursor adduct ion, increased decompositional activation barriers, and/or reduced internal energy of the cation-molecule complex.

Li^+ adduct molecules thus decompose by a single metastable process (loss of 16 amu), whereas protonated molecules decompose by competitive pathways (e.g., losses of 16 or 17 amu). Under CAD conditions, however, the 17 amu loss from the $(M+Li)^+$ adduct appears. Collisional activation also promotes loss of 17 amu (relative to 16 amu) for MH^+ molecules. The loss of 17 amu must then be regarded as a process requiring a relatively higher internal energy content. An internal energy vs. log k(E) scheme describing the competition between these two processes which conforms to the classic Wahrhaftig diagram is offered in Fig. 2b.

In comparing relative intensities of MH^+ metastable daughter ion peaks over the course of FAB sputtering, the 17 amu loss was observed to increase relative to the 16 amu loss, with disappearance of the matrix. In combination with the scheme below, this finding supports the contention that evaporation of the matrix results in a slight increase in the internal energy of desorbed molecules.

INFRARED MULTIPHOTON DISSOCIATION OF SMALL PEPTIDE IONS FORMED BY LASER DESORPTION

Clifford H. Watson and John R. Eyler
Department of Chemistry, University of Florida
Gainesville, FL 32611

Pseudo-molecular ions ($M+H^+$, $M+Na^+$, $M+K^+$, and $M-H^-$) of selected peptides were formed by laser desorption with a pulsed carbon dioxide laser. The desorbed ions were trapped within the analyzer cell of a Fourier Transform Ion Cyclotron Resonance (FTICR) mass spectrometer where they could be irradiated by the output from a grating-tuned continuous wave (cw) carbon dioxide laser. Fragment ions potentially useful for elucidation of peptide sequence were observed after irradiation for 0.5 to 5 s with the cw laser.

Irradiation of the ions was facilitated by replacing the rear trap plate of the analyzer cell with one containing a 1.5 cm hole covered by a fine stainless steel mesh. The normal laser desorption optics (as supplied by the manufacturer) were used to obtain the ions in the gas phase, and light from the cw laser irradiated the ions by passing through a salt window mounted on the hollow solids probe as illustrated in Figure 1. The estimated power density from the cw laser inside the FTICR cell was about 4.3 to 17.1 Watts/cm^2. The peptides were mixed with methanol and deposited on a hollow solids probe with a micropipette, allowed to dry, then inserted into the FTICR vacuum chamber and evacuated to ca. 2×10^{-8} torr.

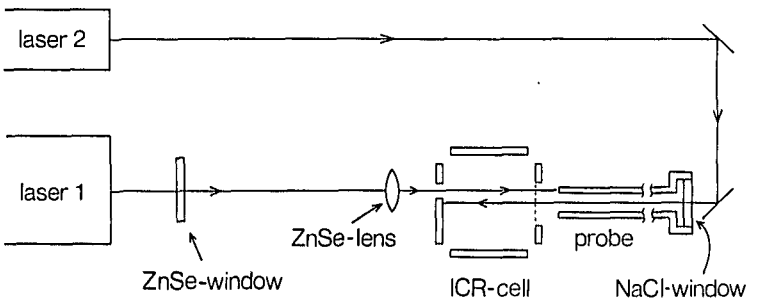

Figure 1.
Light from a pulsed CO_2 laser (1) is used to desorb the peptide sample.

The negative ion laser desorption mass spectrum often contained much less chemical noise than the positive ion spectrum, greatly simplifying interpretation. Typically, only the pseudo-parent ion $(M-H)^-$ or $(M-OH)^-$ was observed in the negative ion laser desorption mass spectra. For example, the parent ion $(M-H)^-$ of L-arginyl-L-lysine dissociated upon irradiation with cw laser producing the Lys^- ion (see Table 1).

The positive ion spectrum, on the other hand, was often complicated by the excessive amounts of Na^+, K^+, and contaminant hydrocarbon ions. For most peptides studied to date, the positive ion mass spectrum was often dominated by the presence of $(M+K)^+$ which fragmented upon irradiation to yield K^+. However, exceptions to this behavior were found. *Protonated L-arginyl-L-phenylalaninyl-L-alanine produced structurally useful fragment ions* upon irradiation. The fragment ions produced by this peptide are listed in Table 1.

Doping with a 4:1 mole ratio of LiCl to peptide resulted in the production of the $(M+2Li-H)^+$ ion which was more stable than the $(M+K)^+$ cation. The photodissocation pathways of two peptides with Li attachment are listed in Table 1. For example, the dipeptide L-arginyl-L-phenylalanine dissociates to produce the $(Phe+2Li)^+$ ion as the major fragmentation pathway. *Thus, with lithium cation attachment the pathway of lowest activation energy is cleavage of the* peptide rather than loss of the alkali cation.

All of the peptides that were observed to photodissociate contained an arginine unit, and no photodissociation was observed when arginine was absent. For example, the dipeptides Trp-Gly and Pro-Phe did not photodissociate under identical conditions to the compounds listed in Table 1. The presence of more than one fragmentation pathway for several of the peptide ions *suggests that vibrational energy is completely randomized throughout the ion prior to* dissociation.

Table 1

Infrared Multiphoton Dissociation of Peptide Ions

Peptide	Ion Studied	Fragment Observed
Arg-Glu	$(M-H)^-$	Arg^- (A_1)
		Phe^- (X_1)
Arg-Lys	$(M-H)^-$	Lys^- (Y_1)
	$(M+2Li)^+$	$(Lys+2Li)^+$ (Y_1)
		$(Arg+2Li)^+$ (A_1)
	$(M+K+Li)^+$	$(Lys+K+Li)^+$ (Y_1)
Arg-Phe	$(M-H)^-$	Phe^- (Y_1)
	$(M+2Li)^+$	$(Phe+2Li)^+$ (Y_1)
		$(Arg+2Li)^+$ (A_1)
Arg-Trp	$(M-H)^-$	Trp^- (Y_1)
		Arg^- (B_1)
Arg-Phe-Ala	$(M-H)^-$	$Phe\text{-}Ala^-$ (X_2)
		Phe^- (B_2Y_2)
	$(M+H)^+$	$Arg\text{-}Phe^+$ (B_2)
		Arg^+ (B_1)
Leu-Tyr-Met-Arg-Phe-Ala	$(M+H)^+$	$Leu\text{-}Tyr^-$ (B_2)
		Leu^- (B_1)
		$Leu\text{-}Tyr\text{-}Met^-$ (C_3)
		$Phe\text{-}Ala^-$ (Z_2)

The major fragmentation pathway is listed first when more than one dissociation pathway was observed.

COLLISIONALLY-ACTIVATED DISSOCIATION (CAD) STUDIES IN THE OPTIMIZATION OF MS/MS FOR THE TRACE DETERMINATION OF PROSTAGLANDINS

Todd A. Gillespie and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611

The pentafluorobenzyl (PFB) ester trimethyl silyl (TMS) derivative or the methoxime (MO)-PFB-TMS derivative used in electron-capture negative chemical ionization (EC-NCI) are the most sensitive and specific means for the trace determination of prostaglandins (PGs). Although these studies were first initiated to optimize the MS/MS conditions for trace determination of PGs, some rather intriguing discoveries were made concerning the CAD fragmentation behavior of derivatized PGs.

For example, it was discovered that the carboxylate anion $(M-PFB)^-$ formed from electron-capture negative chemical ionization (EC-NCI) of $PGF_{2\alpha}$-PFB-TMS showed little fragmentation under typical (collision gas pressure < 2.0 mTorr N_2 and collision energy < 30 eV) CAD conditions. In contrast, the daughter spectra of the carboxylate anion of PGE_2-MO-PFB-TMS produced many intense fragments under the same conditions. The fragmentation efficiency (E_f) of the PGs (Figure 1) may be compared by examining the differences in fragmentation behavior of their respective carboxylate anions. Various PGs were then studied to determine the reason the two derivatized PGs, which are similar in structure (Figure 2), behave differently during CAD experiments. The E_f of PGD_2 and $DHKF_{2\alpha}$ provided no useful information to explain the differences in fragmentation behavior.

It was first believed that the additional TMS group on $PGF_{2\alpha}$-PFB-TMS would add to the ion's stability during CAD experiments. In order to test this hypothesis, the $PGF_{2\alpha}$-PFB and PGE_2-PFB derivatives were examined. A conventional solids probe was used to introduce the derivatized PGs, since with only PFB derivatization the PGs were no longer amenable to GC. The E_f data from this study is shown in Figure 3. The fragmentation behavior of the $PGF_{2\alpha}$- and PGE_2-PFB derivatives are similar to those found with the fully derivatized PGs (Figure 1). The $PGF_{2\alpha}$-PFB derivative appears to be more stable than the PFB-TMS derivative at collision gas pressures > 2.0 mTorr N_2. This suggests the additional TMS group found on $PGF_{2\alpha}$-PFB-TMS has little or no effect on the observed differences in the fragmentation behavior of $PGF_{2\alpha}$ and PGE_2.

The original purpose of the efficiency studies was to optimize the MS/MS conditions for trace analysis of PGs by GC/MS/MS. General information can be obtained from the overall efficiency (E_O) graph of the MO-PFB-TMS derivatives in Figure 4. The graph shows that $PGF_{2\alpha}$ and $DHKF_{2\alpha}$ exhibit low E_O which will lead to difficulties when performing selected-reaction monitoring (SRM) experiments. A pressure resolved breakdown curve for selected fragment ions of $PGF_{2\alpha}$ is shown in Figure 5. This type of information is useful in determining the optimum conditions for obtaining qualitative daughter spectra. The parent-to-daughter selected reaction (Figure 6) with the highest collection efficiency should be selected to yield the highest sensitivity for SRM determination of trace PGs. Similar curves can be obtained for all PGs for both energy and pressure. Table 1 lists the optimum conditions which should be used to obtain qualitative daughter spectra, as well as conditions for SRM analysis for $PGF_{2\alpha}$ and PGE_2.

In summary, the difference in the MS/MS fragmentation behavior between $PGF2_\alpha$ (-OH) and PGE_2 (=O) appears to be due to the difference in functional groups. We have hypothesized that the 3-D conformation of the PG anion permits interaction of the carboxylate group with the -OH groups. The additional -OH group on $PGF_{2\alpha}$ and $DHKF_{2\alpha}$ could account for the added stability of the PG anions. PGE_2 and PGD_2 are less stable due to the =O group. Thus, lower collision pressure and energy is required to fragment the 3-D conformation of the PGE_2 and PGD_2 anion. The above studies demonstrate the utility of efficiency curves in the optimization of MS/MS conditions for trace determinations.

FRAGMENTATION AND SEQUENCING OF PEPTIDES INVESTIGATED BY MULTIPHOTON IONIZATION MASS SPECTROMETRY.

J. Grotemeyer, R.C. Beavis, J. Lindner, C. Köster, E.W. Schlag

Institut für Physikalische und Theoretische Chemie, TU München
Lichtenbergstr. 4, D-8046 Garching, Germany.

Investigations of peptides by well established mass spectrometric methods, such as electron impact, are often disturbed by several features. First, the intensities of sequence ions as well as the stability of the molecular ion usually decrease considerably with increase in the number of amino acid residues, because sequence ions of higher order decompose to those of lower order. This fact is due to the broad energy distribution in the ions by the ionization procedure. Secondly, other ions beside sequence ions are also formed from the peptide molecular ion. These additional fragmentations occur by reactions in the functional groups of the peptide chain.

It has been demonstrated [1] that multiphoton ionization (MUPI) with its intrinsic features, the real soft ionization and the tuneable fragmentation, allow to overcome these shortcomings of conventional methods. The soft ionization at laser powers between 10^5 and 10^6 W/cm^2 produces mainly the molecular ion. By increasing the laser intensity to roughly 10^7 W/cm^2 fragmentation reactions beside the formation of the molecular ion occur.

Figure 1 displays the EI mass spectrum and the metastable ion decomposition (MIKE) spectrum from the molecular ion as well as the soft and hard MUPI mass spectra of the protected tripeptide BzO-Val-Leu-Asp-(O-Bz)$_2$. A comparison of the mass spectra show that the MIKE and the partial hard MUPI mass spectrum show some similarities in their fragmentation behaviour. In both cases mostly sequence specific fragment ions of the A- and B-type are formed, while the EI mass spectrum shows a extense fragmentation especially in the low mass region. This behaviour can be understood by the fact of the broad energy distribution in EI contrary to MUPI. While electron ionization yield in energy distribution of 5-15 eV, MUPI has a typical distribution of a few 100 meV.

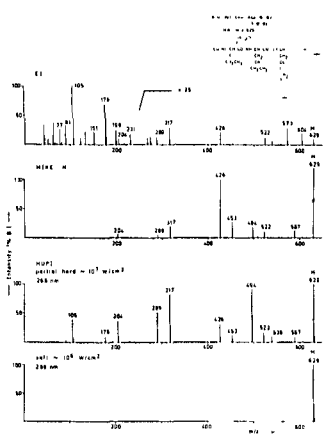

Fig.1 EI, MIKE, MUPI (hard) and MUPI MUPI (soft) mass spectrum of the protected Tripeptide Val-Leu-Asp.

The preferred formation of the A- and B-ions can be explained comparing quantum mechanical calculations and MUPI investigations of phenylalanyl-glycine. It could be shown that the formation of the N-terminal sequence ions is energetically favored over other cleavage reactions. The calculation predicts that these reactions should have transition energies close to the three photon level of the multiphoton absorption. The results of the calculations fits very close to the experimental findings. Because of the different energy distributions in the ionization methods MUPI mass spectra display only fragments which have appearence energies very close to or lower than the total energy accumulated in the molecule. Therefore a direct comparison of EI and MUPI mass spectra is often difficult.

A further example of the possibilities of MUPI in peptide investigations is shown in figure 2. Here the partial hard ionization mass spectrum of substance P is shown.

Clearly the complete series of fragment ions containing the N-terminal end of the peptide chain can be identified. This series starts with the formation of the A_9, B_9 ion and goes down to the formation of even the A_1, B_1 ion. But also some fragmentations containing the C-terminal end are observed. These ions yield in the signals at masses 465, 612 and 868. These ions are of type Y'. Note also the high intensity of the fragment ions close to the aromatic residues.

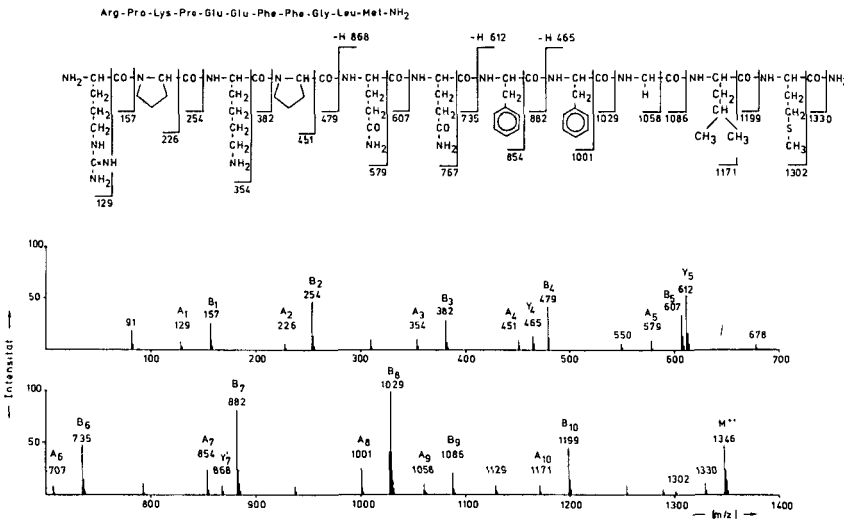

Fig.2 MUPI mass spectrum of substance P.

The table below shows a comparison of peptide investigations by various ionization methods. As can be seen, MUPI gives an intermediate number of fragment ions that is well sufficient to deduce the structure of any peptide.

Ionization Method	Typical Sequence Ions
Electron Ionization (metastable Ions)	$(A_n)^+$, $(B_n)^+$
Multiphoton Ionization	$(A_n)^+$, $(B_n)^+$, $(Y'_n)^+$
Fast Atom Bombardment	$(A_n)^+$, $(B_n)^+$, $(C_n)^+$ $(Y_n)^+$, $(Z_n)^+$

MS-MS IN A FOUR SECTOR MASS SPECTROMETER: PARAMETERS AFFECTING THE MS-II LINKED SCAN

K.B. Tomer and S. Verma

Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709

FAB in conjunction with MS-MS is rapidly becoming the method of choice for the structure determination of peptides and other biomolecules. The major advantages of MS-MS are that components of mixtures can be analyzed without prior separation and, with collisional-activation, fragments are produced that give the complete sequence of many biopolymers. Several groups have pointed out that with increasing mass of the parent ion, daughter ions produced by high energy collisional activation undergo peak broadening and exhibit an increasing kinetic energy loss, E. In an MS-MS instrument in which MS-II is an electrostatic analyzer, these phenomena translate into broad peaks whose apparent mass has shifted significantly.

The B/E ratio of the daughter ions is proportional to $(E- E)^{-1/2}$ where E is the energy loss experienced by the parent ion during collisional excitation. E varies from ~5 eV for a small molecule (<200 amu) to 40 eV for a peptide of molecular mass 1500 (1). When E is negligible, the B/E ratio for daughter ions is identical to that of the parent. However, for large E, the B/E ratio of daughter ions is higher than that of the parent. Table 1 shows the effect of E on the B/E ratio of fragments by defining a daughter ion mass that should have the same B/E ratio as the parent.

Increasingly four sector tandem instruments have come into use for MS-MS studies in which the daughter ions are analyzed via a linked (B/E) scan of MS-II. In the B/E scan based on negligible E and an exponential scan law for B_2 there are no mass shifts observed since the daughter ions that have significant E are not passed to the detector. Thus the effects of E are "hidden".

The experimental results reported here are the outcome of a study aimed at investigating the effect of energy loss on the relative abundances of daughter ions observed during a B/E linked scan. The experiments were performed on a VG ZAB-4F of BEEB geometry. CA spectra were recorded at the 3rd and 4th sector. The collisional excitation conditions were varied by changing the nature of the target gas (eg. He vs Xe) and the pressure of the target gas. Unimolecular dissociation spectra at the 3rd sector were compared to corresponding CAD spectra to determine the energy loss E. Data were acquired by either scanning MS-II manually across the desired mass window or by computer generated scans of MS-II after calibration of MS-II by using the second source located between MS-I and MS-II immediately before the 3rd collision cell.

The results of our experiments are presented in Table 2 and Figures 1-3. One thus concludes:

i) conditions used to obtain optimum fragmentation may not correspond to single collision experiments.

ii) a single scan law may not be possible for a substance and/or the scan laws may differ for different compounds depending on whether a given fragment occurs under single collision or multiple collision conditions.

iii) a scan law generated for He may not yield good data for Xe.

iv) Although the position of the peaks do not change at the 4th sector, the relative abundances may be significantly affected due to energy loss.

COMPARISON OF THE COLLISIONAL ACTIVATION DECOMPOSITION SPECTRA OF PEPTIDES CONTAINING BACKBONE MODIFICATIONS

L. J. Deterding[1], K. B. Tomer[1], and A. F. Spatola[2]

[1]Laboratory of Molecular Biophysics, N.I.E.H.S.,
P.O. Box 12233, Research Triangle Park, NC 27709

[2]Department of Chemistry
University of Louisville, Louisville, KY 40292

Fast atom bombardment (FAB) in conjunction with tandem mass spectrometry (MS/MS) has become a useful approach for the determination and confirmation of the structures of peptides. Upon collisional activation (CA), peptides readily decompose into fragment ions. These fragment ions can be assigned structures which usually are the result of cleavages of the backbone and/or side chain cleavages of the amino acids. Therefore, collisionally activated decomposition (CAD) is very useful for the structural elucidation and amino acid sequencing of peptides.

Recently, Spatola et al. (1) have shown that variations in the backbone elements in peptides have assisted in determining the functional role of the normal -CONH- peptide linkage. These variations include the replacement of -CONH- bonds with such groups as thiomethylene ether (CH_2S), thiomethylene sulfoxide (CH_2SO), thioamide (CSNH), and methylene amine (CH_2NH) moieties. Among the benefits of such modifications can be: 1) enhanced receptor selectivity; 2) increased resistance to enzymatic degradation; and 3) altered solubility properties. The CAD spectra of these backbone modified peptides are compared in order to determine the effect of the modification on the daughter ion spectra.

Upon collisional activation, the $(M+H)^+$ ions of straight-chain and cyclic peptides, which have been modified by substitution of a [CH_2NH] moiety for a [CONH] group in the backbone chain, fragment to give typical amino acid sequence ions (Fig. 1). However, internal fragment ions are also observed which are the result of a cleavage alpha to the substituted methylene group (Fragment F).

Substitution of a [CSNH] group into the backbone chain of peptides does not seem to have a large effect on the fragmentation of the peptide (Fig. 2). Cleavages around the thioamide are of relatively low abundance if present at all. Amino acid sequence fragmentations are observed and are of relatively high abundance.

In comparing the CAD spectra of straight chain peptides which have been modified by thiomethylene ether vs thiomethylene sulfoxide moieties (Fig. 3), the presence of the [CH_2SO] group leads to much more abundant N-terminal fragment ions than does the presence of the [CH_2S] group. The major difference observed in the CAD spectra is the relative abundance of fragmentations resulting from cleavages alpha to the thiopeptide linkages (Fragments B_3 and C_3). For the [CH_2SO] modified peptide of Tyr-Ala-Gly-Phe-Leu, the B_3 and C_3 fragment ions are relatively abundant (i.e. approximately 72% and 95%, respectively), whereas, with the [CH_2S] substitution, these same fragment ions are of relatively low abundance (i.e. <5%). In addition, it should be noted that these modified peptides tend to decompose into C-terminal fragment ions whereas the unmodified peptides tend to fragment into N-terminal ions.

The MS/MS spectra of cyclic peptides containing thioether/sulfoxide linkages have also been compared (Fig. 4). The C-terminal ions of X_4 and Y_4 are major fragmentations observed in the CAD spectra of these modified peptides. However, both the [CH_2S] and [CH_2SO] substituted peptide of Tyr-c(Lys-Gly-Phe-Leu) fragments to give the ion of m/z 420, which corresponds to the loss of $-CH_2CH_2SCH(CHC_6H_5)CO$ and $-CH_2CH_2SOCH(CHC_6H_5)CO$, respectively, from the $(M+H)^+$ ions.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Upon collisional activation, peptides containing modifications in the backbone chain undergo amino acid sequence fragmentations and side-chain fragmentations. Straight-chain peptides containing [CH_2S] and [CH_2SO] groups decompose to give daughter ions indicating the presence of a sulfur in the backbone chain. However, the presence of a [CSNH] group has little effect on the fragmentation of the peptide. In comparison, the backbone modified peptides tend to give relatively more abundant C-terminal fragment ions than the normal unmodified peptides. However, the daughter ion spectra vary with the presence of the amide bond replacement. Therefore, useful structural information may be obtained. In addition, these peptide backbone modifications have been recognized as having the potential for yielding structures with biological selectivity and increased resistance to enzymatic degradation.

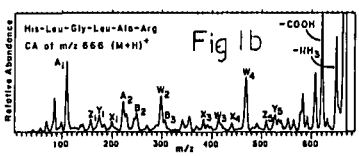
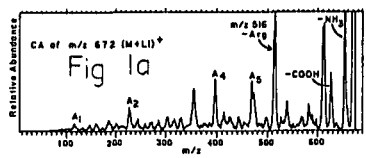
COLLISIONAL ACTIVATION TANDEM MASS SPECTROMETRY OF LITHIUM-CATIONIZED PEPTIDES

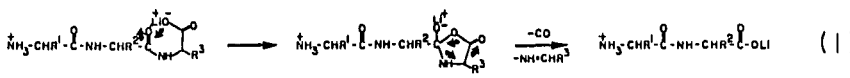
R.P. Grese and M.L. Gross
Midwest Center for Mass Spectrometry
Dept. of Chem., U. of Nebraska, Lincoln, NE 68588-0304.

Complexes of metal ions and peptides can be produced in the gas phase by FAB and the site of interaction determined by using collisional activation (CA) and tandem mass spectrometry (MS/MS). This methodology gives complementary information to CA of protonated peptides and may be useful in understanding interactions of peptides and biologically important metals.

Generally, monovalent metal ions interact with the C-terminus of a peptide in the gas phase. Both the metastable and CA decompositions of [peptide + Li]$^+$ ions produce an abundant fragment ion by loss of the C-terminal amino acid residue. The [M + Li]$^+$ ion of HisLeuGlyLeuAlaArg (Figure 1a) fragments upon CA to give an abundant ion of m/z 516 formed by loss of an arginine residue. Also in the spectrum are sequence ions which provide complementary information to that from the CA mass spectrum of the protonated species (Figure 1b). We have observed that this process occurs for sixty peptides, from tri- to nonapeptides, for all common amino acids at the C-terminus, and for N-terminally blocked peptides. The structural utility of the method is clearly seen -- the C-terminus is rapidly verified.

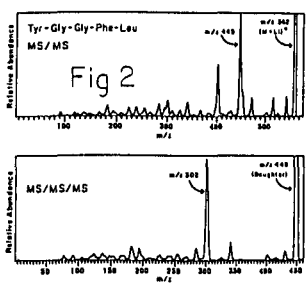






(1)

Recently, Renner and Spiteller[1] suggested, with little experimental support, a mechanism (Equation 1) for the C-terminus elimination. We report three substantial pieces of experimental evidence that the process occurs as per Equation 1: (1) The fragment ion, a smaller peptide, decomposes in manner identical to a metal-peptide complex. This is illustrated in the MS/MS/MS spectrum of the m/z 449 ion from CA of leu-enkephalin (Figure 2). (2) CA of ^{18}O and ^{15}N labelled peptides give neutral losses consisent with the losses of CO and an imine. (3) CA of [M + Li]$^+$ ions of various model compounds (Table 1) reveal that a free C-terminal and a carbonyl on the amino acid next to the C-terminus are necessary for this fragmentation.



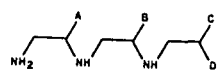


Table 1 "Glycine-Glycine-Glycine" Model Compounds

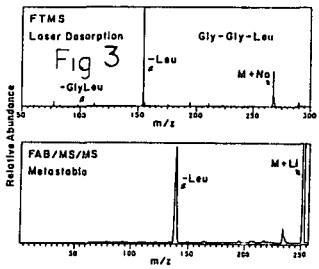
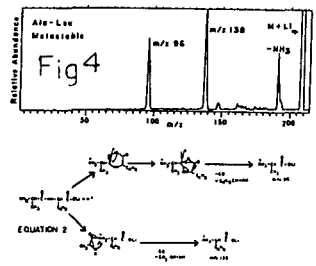
Compounds	A	B	C	D	Loss of C-terminus from (M + Li)+
I	O	O	O	OH	Yes
II	NH_2	NH_2	NH_2	OH	No
III	NH_2	NH_2	O	OH	No
IV	O	NH_2	O	OH	No
V	O	O	NH_2	CH_3	No
VI	O	O	O	OCH_3	No
VII	O	O	O	NH_2	No

1 Renner, D.; Spiteller, G. Biomed. Mass Spectrom. **1988**, 15, 75-77.

The loss of the C-terminus has also been observed for peptides complexed with Na^+, Ag^+, and Cu^+, but not with K^+. Presumably the K^+-peptide interaction is weaker and is released upon CA. Elimination of the C-terminus also occurs upon IR laser desorption of cationized-peptide in a Fourier transform mass spectrometer (Figure 3) suggesting that this process is thermally allowed. The use of laser desorption-FTMS is attractive because with multiple resonance techniques it may be possible to sequence small peptides by sequentially eliminating the C-terminus.





Loss of the C-terminus residue occurs also with $[M + Li]^+$ of dipeptides; however, the most abundant fragment ion in the metastable (and CA) mass spectrum is $[Y + H + Li]^+$ (Figure 4). Preliminary MS/MS/MS and deuterium labelling experiments are consistent with the proposed mechanism (Equation 2).

The decomposition of metal-cationized peptides containing histidyl residues are exceptions to the general fragmentation described above. The most abundant fragment ion is cleavage at the histidyl residue indicating that the Li^+ preferentially chelates to the imidazole nitrogens of histidine (see Figure 5 for proposed structure). This underscores the potential of this research for establishing solution analogies because histidine has been shown to be a prinicipal binding site for transition metals in metalloproteins.

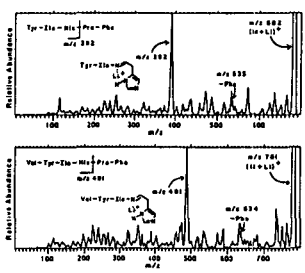


Fig 5

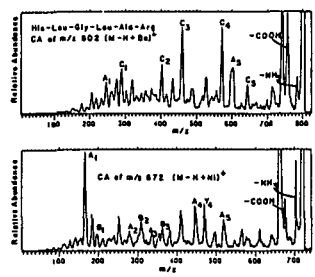

Fig 6

One area of future research will be the study of the intrinsic reactivities of divalent metal ions with peptides in the gas phase. Divalent transition metal ions are important biologically in many metalloenzyme systems. Comparison of the CA mass spectra of the $[M - H + Ba]^+$ and $[M - H + Ni]^+$ ions of HisLeuGlyLeuAlaArg (Figures 6 a and b) point to differences in the gas phase reactivities of these two metal ions with the same peptide which may be useful in understanding the reactivities is solution.

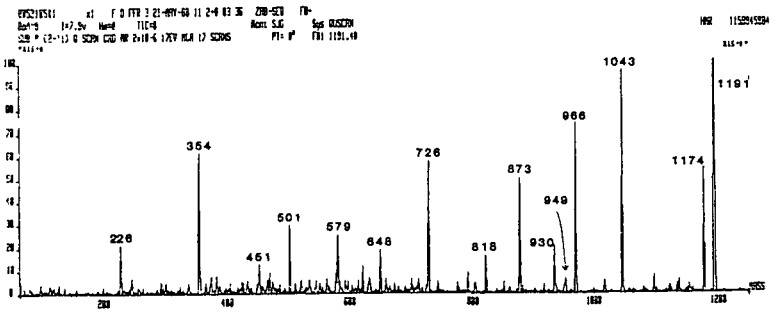
TANDEM MASS SPECTROMETRIC ANALYSIS OF PEPTIDES ON A HYBRID INSTRUMENT.

Marc H. Reilly and Simon J. Gaskell, Center for Experimental Therapeutics, Baylor College of Medicine, Houston, Texas 77030

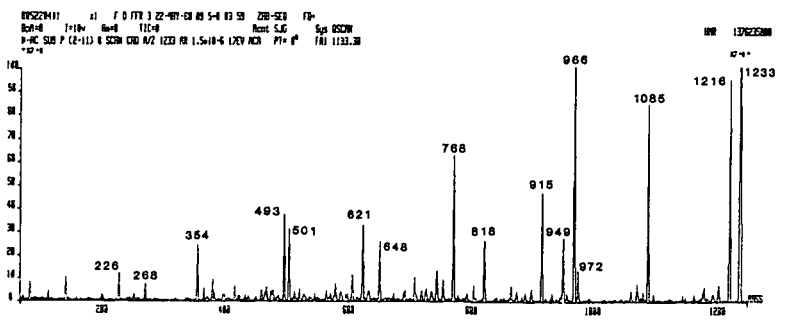
Tandem MS with collisionally activated decomposition (CAD) of peptide $[M+H]^+$ ions can provide improved mixture analysis capabilities and increased structural information. Though comparisons between multiple analyzer configurations for tandem MS may be made on the basis of mass range and ultimate resolution capabilities, these appear not to be the critical issues at present. Decreasing parent ion yield during FAB and decreasing conversion to daughter ions both occur as the mass of the analyte increases, generally limiting to 3-4000 the mass range currently accessible in tandem MS experiments and dictating that analyses be operated at close to maximum transmission, corresponding to low resolution of both parents and daughters. More important considerations in the comparison of instrument configurations are the conditions under which decompositions of selected parent ions are allowed or induced to occur. These conditions are markedly different when decompositions occur in a quadrupole region (as in the triple quadrupole or hybrid configurations) and in a field-free region of a multi-sector instrument. Thus, for the example of hybrid instruments (combining double focusing and quadrupole components) parent ions are selected using the double-focusing section and decelerated to kinetic energies of (usually) <100eV before introduction into the RF-only quadrupole collision region. Collision energies (in the laboratory frame-of-reference) are therefore <100eV and, importantly, residence times in the decomposition region are of the order of milliseconds. The collimating properties of the RF-only quadrupole facilitate the use of heavy collision gases (increasing the center-of-mass collision energy) at pressures favoring multiple collisions, conditions which might otherwise lead to excessive scattering losses. There is a growing body of data derived from FAB/tandem MS of peptides on four sector instruments and some data obtained using a triple quadrupole. Analytical data for peptides obtained with hybrid sector/quadrupole instruments are few.

We have analyzed a number of peptides in the 1000-1500 mass range using a hybrid instrument of BEqQ design (VG ZAB SEQ). Sample introduction used a conventional FAB probe with the liquid matrix thioglycerol/2,2'-dithiodiethanol (1/1). The primary FAB beam was xenon atoms. Argon was the collision gas. As an example, we present data for the decapeptide Substance P, fragment 2-11 (Pro-Lys-Pro-Glu-Glu-Phe-Phe-Gly-Leu-Met $[NH_2]$). Figure 1a shows the daughter ion spectrum of MH^+ ions, m/z 1191. Very clear fragmentation information is apparent but interpretation is ambiguous without consideration of complementary data obtained by CAD of MH^+ ions of the terminal N-acetyl derivative. These data are shown in Figure 1b. Mass shifts of 42u, observed for a number of the major fragments, are consistent with assignments as B-series ions (Figure 1). Daughters with m/z 966 and 949 are not shifted and are assigned Y_8'' and Z_8 structures. They are the only prominent representatives of C-terminal ions in the spectrum. A further series of ions is attributed to $(B_nY_8)'_{n-2}$ structures. The prominence of these fragments is similar to that of the B-series. The ion of m/z 226 in the spectrum of the underivatized peptide is shown by N-acetylation to have a dual origin. A pair of ions of m/z 226 and 268 are observed in the spectrum of the derivatized peptide (Figure 1b), attributable to B_2 and $(B_4Y_8)'_2$ fragments (which are isobaric for the native peptide).

(a) Daughters of m/z 1191



(b) N-acetyl derivative : daughters of m/z 1233



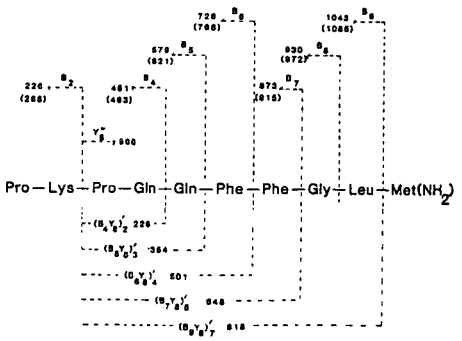


Fig. 1. CAD of MH^+ ions derived from Substance P, fragment 2-11 (m/z 1191) and the N-acetyl derivative (m/z 1233). The pressure of argon collision gas was calculated to be 0.3 mtorr in the collision region. The collision energy was 17eV.

FAB MASS SPECTRA AND CAD SPECTRA OF GLYCEROL AND AMINO ACIDS WITH SEVERAL CHLORIDES.

Kimio ISA and Yasuhiko TERAI
Department of Chemistry, Faculty of Education, Fului University;
Bunkyo 3-9-1, Fukui-shi, 910, JAPAN

I.

The relation between metal ion (alkali or alkaline earth metals) with amino acid is an important problem in biophysics. Soft ionization methods makes easily to get the cationized ions of biomolecular substances, especially amino acids, peptides and sugars. Relation between alkali ion affinity and ionic radius ratio in the case of glycerol (G) by means of fast atom bombardment tandem mass spectrometry (FABTMS) has been already published (1). This report explains the relation between the alklai and alkaline earth metals (Li,Na, K, Rb, Cs and Mg, Ca) with L-α-amino acids by FABTMS.

II.

Collisionally activated decomposition (CAD) and metastable ion (MI) decomposition spectra of the pre-selected ions which are seperated by a high resolution mass spectrometer (JEOL DX303, EBE type), operating an ion accelerating voltage of 3 kV and a mass resolution of approximately 1000 (10 % valley definition) are studied by a tandem mass spectrometer (2). Post acceleration high sensitive detector (conversion dynode) was set up to increase the sensitivity. The gases for the fast atom gun and collision are both Ar. The energy of this fast Ar atom beam was 6 keV and tube current was 20 mA. The pressure of collision gas was increased until the precursor ion signal was reduced to about 1/3 of it soriginal value and CAD spectrum was obtained by a scan of the second electric sector analyzer. The mass spectra were processed with a JEOL DA-5000 data system. Commercial Glycerol, alklai halide(AX), alkaline earth halide (BX_2) and 20 L-α-amino acids are used with no further purification.

III.

1) FABMS spectra of mixtures of amino acids, glycerol and AX showed that typical four ions, $(M+H)^+$, $(M+A)^+$, $(M+G+H)^+$, and $(M+G+A)^+$ were identified. In the case of using only glycerol, $(M+A)^+$ is dominantly appeared, but in the case of the mixture of amino acids and glycerol, $(M+H)^+$ was the dominant peak. Therefore, alkali halide as additive to sample of FABMS did not help to increase the signal.

2) Affinity of various metal ions (Li to Cs) with amino acids with alkyl side chain, Gly (R=H), Ala (R=CH_3), Val (R=C_3H_7), Leu (R=C_4H_9), Ile (R=C_4H_9), and glycerol was studied. The CAD spectra of precursor ion , $(M+G+A)^+$ was measured, and the results were listed below (where M=

amino acid, A=alkali metal),

Gly	all A	M<G
Ala	Li, Na, K, Rb,	M<G
	Cs	M>G
Val, Leu	Li, Na, K,	M<G
	Rb, Cs	M>G
Ile	Li,Na,	M<G
	K, Rb, Cs	M>G.

3) The fragment ion A^+ from the CAD spectra of $(M+A)^+$ decreases with alkyl side chain's length was considered to be complex in three dimension.
4) The mixtures of the glycerol, 20 amino acids, and three chlorides, Mg, Ca, and Al were measured by FABMS. Six characteristic ions, $(M+Mg-H)^+$, $(M+MgCl)^+$, $(M+Ca-H)^+$, $(M+CaCl)^+$, $(M+Al-2H)^+$, $(M+AlCl_2)^+$, were identified (where M=glycerol and amino acids). The CAD spectra from $(M+Mg-H)^+$, $(M+Ca-H)^+$, $(M+Al-2H)^+$, showed the typical dehydration ($-H_2O$, -18) and the intensities of these ions decrease in order of Al, Ca, Mg. The ionic radii of these ions reflects the intensity of dehydration has already been established (2 or 3). But the disorder of Ca and Mg was not been understood until now.
5) Almost all amino acids can combine the $(Ca-H)^+$ easily, but $(M+AlCl_2)^+$ ion can not be obtained in almost all amino acids except Glu and Trp.
6) The precursor ion $(M+A)^+$ and $(M+B-H)^+$ were measured and discused in the form of gaseous structures, where M represents Gly, Ala, Val, Leu, and Ile. The alklai ion, A^+, was placed between two oxygens of carboxylate and the alklaine earth metal ion, B^{2+}, was placed between nitrogen of amide and oxygen of carboxylate.
7) The precursor ion, $(M+BX)^+$ was mainly decomposed to $(M+B-H)^+$ with elimination of HCl.

This work was partly supported by the Grant-in-Aid for Scientific Research (6254032) from the Ministry of Education , Science and Culture.

TANDEM MASS SPECTROMETRY INVESTIGATIONS ON LICHEN'S METABOLITES

P. Allemand, G. Tsoupras and R. Tabacchi

Institute of Chemistry, University of Neuchâtel,
Av. de Bellevaux 51, CH-2007 Neuchâtel, Switzerland

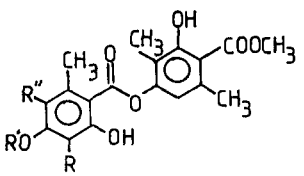
INTRODUCTION

Lichens are organisms of very slow growth. In spite of being widely distributed, for certain species it is difficult, if not impossible, to obtain sufficient quantities of material to carry out an investigation on their composition by classical methods (i.e. extraction, isolation and identification). We have undertaken a study to assertain whether direct analysis of lichens by MS-MS offers a rapid and sure alternative.
The presence of a few compounds in large quantities and many others in small, even trace quantities, in lichens means that any method of direct analysis is difficult.
Depsides and depsidones are the most abundant metabolites in lichens. In spite of their chemical structure, depsides rarely show a molecular peak and consequently are difficult to identify by mass spectrometry.
We investigated first a series of typical compound: Atranorine (1), Chroratranorine (2) and Methyl-barbatate (3). Using different ionisation methods and CAD spectra of molecular, quasimolecular, isotopic and fragment ions.

(1) R = CHO R' = H R" = H

(2) R = CHO R' = H R" = Cl

(3) R = CH_3 R' = CH_3 R" = H



RESULTS

Under E.I. conditions depsides gave a number of small fragments of large intensity and very weak parent ions which were lost in the spectral noise. Under positive CI conditions quasimolecular ions were observed but the CAD spectra gave no useful fragmentation information. In our study negative CI gave the best results. These results have been used in the direct study of very small quantities of crude samples of *Pseudevernia Furfuracea* and *Lobaria Pulmonaria*.

NCI/MS STUDY OF ATRANORIN AND SOME OTHER DEPSIDES

When a depside is analysed by NCI/MS, two ions are formed : $M^{-\cdot}$ and $(M-H)^-$. An MS-MS study of these two ions shows that their fragments give ions containing either the A or the S ring. m/z 373 gives two fragments (m/z 195 and 177) from S and A rings respectively. m/z 374 has two possible origins, $M^{-\cdot}$ or $(M-H)^-$-^{13}C. Four fragments are observed from this peak, m/z 177, 195 and m/z 178, 196 which correspond either to the same fragments containing ^{13}C, or to $S^{-\cdot}$ and $A^{-\cdot}$ (cf scheme).

NCI/MS with thermalyse electrons (CH_4) gives only $M^{-\cdot}$ and leads mainly to m/z 178. A new ion (m/z 552 is formed by combination of an atranorin molecule with an S unit. This spectrum confirms that the other peaks in NCI-NH_3/CAD-spectra are due mainly to the fragmentation of $(M-H)^-$-^{13}C.

The fragmentation pathways of Cl-atranorin are similar to those of atranorin. However, ionization by loss of a hydroxyl proton is favoured by their greater lability. Consequently, in this case m/z 408 is principaly due to $(M-H)^-$-^{13}C. The spectrum of the daughter ions confirm this through the relative intensities of the ions compared with the one of the spectrum of daughter ions on m/z 374 from atranorin.

Daughter ions of m/z 407 (^{35}Cl-atranorin) compared to daughter ions of m/z 409 (^{37}Cl-atranorin) confirm that m/z 195 corresponds to cycle A and m/z 211 (m/z 213) to cycle S.

Comparison of the MS-MS spectra of atranorin and methyl-barbatate gives useful information. Both compounds have the same molecular weight, but substitution of ring S is different.
The substituents in methyl-barbatate are less electrophilic than those of atranorin. Thus, fragmentation of $M^{-\cdot}$ (m/z 374 / CH_4) leads mainly to m/z 195.
In the collision spectrum of m/z 373 ($(M-H)^-$ / CH_4), no fragment from ring S is observed, because there is only one hydroxyl on this ring. For fragmentation, two are necessary, one for ionization $(M-H)^-$, and the other for the fragmentation transfer mechanism.

DIRECT NCI/MS-MS STUDY OF *LICHENS*

NCI/MS-MS has been used to characterise compounds directly from lichens without prior extraction.
Pseudevernia Furfuracea has been investigated in our laboratories in a previous study. Several compounds have been isolated and identified. Through direct NCI/MS-MS on a piece of lichen we were able to identify five of these metabolites.

The NCI/MS-MS spectra obtained directly from the lichen *Lobaria Pulmonaria* and those from the isolated compounds show that this technique gives results reproducible enough to allow the comparison of data from different sources.
The peak at m/z 368 in the spectrum of 8'O-methyl stitic acid obtained directly for the lichen is probably due to the presence of a compound of the same molecular weight or a compound which gives a fragment at m/z 400. This illustrates one of the problems encountered in using MS-MS when substances have common ions.

CONCLUSION

Our results show that direct study of lichens by negative CI/MS-MS is rapid and can be carried out on very small samples. The obtention of meaningfull results is dependent on many factors, above all the composition of the mixture under study. The thermal instability and low volatility of the depsides and depsidones are the major problems. Use of chromatographic methods (TLC and HPLC) in parallel with MS-MS can be a very powerfull tool for investigations on lichens.

FABMS AND FAB MS/MS INVESTIGATIONS OF TECHNETIUM AND RHENIUM COMPLEXES

C. E. Costello[1], C-H. Zeng[1], N. H. de Vries[1], L. A. O'Connell[1], R. M. Pearlstein[1], A. Davison[1] and A. G. Jones[2]

[1]Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139 and [2]Dept. of Radiology, Harvard Medical School, Boston, MA 02115

Technetium-based radioimaging agents are very important for clinical diagnosis. A thorough understanding of the structure and chemistry of Tc complexes is essential for rational design and efficient synthesis of new agents targeted to specific organs or tissues. Fragmentation pathways of technetium and rhenium complexes have been explored by recording the metastable (MS/MS) and collision induced decomposition (CID MS/MS) spectra of molecular ions, cluster ions and fragment ions that appear in the fast atom bombardment mass spectra (FABMS) of three series of related compounds. This information should provide insight into the effects that variations in the ligands, the metal core and the oxidation state of the metal have upon ion structure and chemistry. The three series for which data are reported are chloro(1,2-dioxolato)oxo-(1,10-phenanthroline)technetium(V) complexes, sterically hindered arene thiolates of the general structure $Tc(III)(SAr)_3L_2$, and hexakis aryl isonitrile technetium(I) cations.

FABMS and MS/MS spectra of the three classes of technetium complexes, obtained with or without the use of a collision gas, exhibit quite unique and informative characteristics. The mass spectral behavior of these complexes seems to be an accurate reflection of the changes in properties that accompany modifications of ligand, oxidation states and the metal core itself. Because the MS/MS spectra are free of matrix-related ions, they are simpler to interpret than the FABMS spectra. The MS/MS spectra are useful to clarify the many fragmentation pathways because they permit observation of products originating from individual species.

Chloro(1,2-dioxolato)oxo-(1,10-phenanthroline)technetium(V) complexes have proven to be a useful source of the TcO^{3+} core for ligand exchange reactions. $TcOCl_3$(phen) reacts with olefins to produce *cis*-diols. The fragmentation pattern shown below was deduced on the basis of MS/MS spectra obtained for six members of the series, chosen as representative of the structural variations among more than ten 1,10-phenanthroline analogs and many more analogs containing other aromatic ligands for which two-sector spectra had been recorded. Facile chlorine loss is always observed, but there is a minor pathway which retains the chlorine atom while the ethanedioxolate ligand is lost. Fragmentation may occur within the ethanedioxolate ligand or it may be lost completely. Only after loss of the other ligands is bond-breaking within the phenanthroline ligand observed, and then it may be fragmented or stripped away entirely to leave Tc(I).

Complexes of technetium with sterically hindered arene thioxolates, $Tc(III)(SAr)_3(L)_2$, can exchange their ligands without disturbing the $Tc(SAr)_3$ core. The MS/MS spectra of common ions, obtained with or without the presence of collision gas, derived from complexes that vary in the axial ligand, are indistinguishable, suggesting the formation of identical intermediates. The spectra obtained from analogs that contain Re instead of Tc show quite different fragmentation patterns that reflect the difference in the oxidation potentials of the two metals. Like the first group of compounds, the Tc arene thioxolates form dimers in their FAB mass spectra. However, while the CID MS/MS spectrum of $(2M-Cl)^+$ Tc(V)dioxolato species indicates that the dimer most readily collapses back to the monomer, the $(2M-L_n)^+$ ions of the $Tc(III)(SAr)_3L_2$ complex form a variety of product ions by sequential loss of ligands but with retention of both Tc atoms.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

The hexakis Tc(I) alkyl isonitrile cations generally produce FABMS and MS/MS spectra that are characterized by multiple alkyl or alkene losses to form $Tc(CN[H])_n(CNR)_{6-n}$ species. The spectrum of the hexakis aryl isonitrile cation is quite simple, dominated by CNAr losses. Upon CID, the doubly-charged ion is formed from the singly-charged ion by two routes, apparently equally probable: loss of a second electron and loss of a proton. CID of the doubly charged cation leads predominantly to $(M-CNAr_n)^{++}$ species; the few singly-charged ions formed show loss of Ar and/or CNAr. The substitution of aryl for alkyl groups affects both the spectra and the chemistry of these complexes.

TANDEM MASS SPECTROMETRY OF NUCLEIC ACID HYDROLYSATES

C.C. Nelson and J.A. McCloskey.
Department of Medicinal Chemistry, University of Utah, Salt Lake City, Utah 84112

The combination of FAB and tandem mass spectrometry has been shown to provide useful structural information about nucleosides and nucleotides[1,2]. Modified nucleosides, such as nucleoside antibiotics and constituents of nucleic acids, frequently occur as minor components in complex biological mixtures and are often difficult to isolate and characterize[3]. The present study demonstrates the utility of tandem mass spectrometry with FAB ionization as a method for identification and structure analysis of minor component modified nucleosides in enzymatic digests of transfer ribonucleic acid (tRNA) without prior sample purification.

Experiments were carried out on a VG 70 - SEQ mass spectrometer (EBQQ geometry). A series of low-energy collision-induced dissociation (CID) reactions of the molecular ions (MH^+) were first examined for two model nucleosides 2'-O-methylcytidine (Cm) and threonyladenosine (t^6A), which are sugar modified and base modified nucleosides, respectively. Relative fragment ion intensities were determined as a function of incident ion (MH^+) translational energy and pressure in the rf-only quadrupole using helium, argon, krypton, and xenon collision gases. Optimum energies and MH^+ transmissions for the model nucleosides were then used for tRNA hydrolysate mixtures assuming general applicability to other modified nucleosides.

For low-energy collisions of the model nucleosides, Ar and Kr collision gases provided more efficient fragmentation of MH^+ within the rf-only quadrupole than He or Xe. This was determined by comparing relative fragment ion intensities and collision losses after normalization of MH^+. Kr yielded more total fragment ion current, however, compared to Ar when the transmission through the entire QQ system was determined at the same transmission of MH^+ through the rf-only quadrupole. It is possible that collision losses outside the rf-only quadrupole are greater for Ar than Kr at the 20% transmission used. Subsequent low-energy CID of tRNA hydrolysates were therefore analyzed using Kr as collision gas.

Full scan CID daughter spectra were acquired on preselected parent ions (MH^+) of nucleosides from E. coli tRNA - Phe and E. coli B tRNA - Tyr. The collision gas pressure used corresponded to an MH^+ transmission of approximately 20% as determined at 50 eV energy through the rf only quadrupole. Daughter scans and neutral loss spectra were acquired on hydrolysates corresponding to 5 μg of tRNA. Daughter ion spectra taken on about 70 ng of the highly modified nucleosides queuosine (Q) (fig. 1) and methylthioisopentenyladenosine (ms^2i^6A) (fig. 2) from tRNA - Tyr were acquired directly in the crude hydrolysate mixture. Structurally informative fragment ions were obtained as indicated by intense protonated base (BH_2^+) ions as well as characteristic side chain fragment ions m/z 295, 312 and 182, 194, 314 for Q and ms^2i^6A, respectively.

The presence of minor component nucleosides in complex mixtures such as enzymatic digests are not always evident from primary FAB mass spectra (fig. 3) because of varying ionization efficiencies and / or matrix effects. However, with a suitably designed neutral loss scan, such as loss of 132 amu

(ribose) to produce BH_2^+ ions, the majority of nucleoside molecular ions can by rapidly identified in 1 - 5 μg of crude tRNA hydrolysate (10 - 100 ng of individual nucleosides) (fig. 4). Subsequently, daughter ion spectra of these molecular ions can provide significant leads toward structural characterization for known nucleosides or unknown nucleosides of undetermined modification.

THE EFFECT OF COLLISION GAS AND GAS MIXTURES ON DAUGHTER ION SPECTRA OF PEPTIDES USING A TANDEM DOUBLE-FOCUSING MASS SPECTROMETER

J.M.Curtis, L.S.Rong, R.M.Milberg, and K.L.Rinehart
School of Chemical Sciences, Univ. of Illinois, Urbana, IL 61801

Introduction

A new tandem double-focusing mass spectrometer of EB-EB geometry (VG Analytical 70-4SE) has recently been installed in our laboratory. One of the principal uses of the machine is to run MS/MS spectra of peptide ions produced by FAB. Since typical sample sizes are in the 0.2-10 microgramme range, it is essential that the optimum conditions for the production of structurally significant daughter ions are known prior to analysis. The aim of this study is to identify collision regimes which give daughter ions in high intensity throughout their possible mass range, and hence to provide the best possible sequence information.

Results and Discussion For Peptides of Mass 500-1500 Daltons

Previous studies [1] on the CID of peptide ions demonstrated the existence of an optimum collision gas pressure (the pressure giving the maximum abundance of fragment ions) which corresponds to a beam attenuation of 60-70% and is mass dependent. In order to investigate this, a test compound, the undecapeptide physalaemin (MH+ = 1265.59) was selected and the intensity of four fragment ions were recorded for different beam attenuations using H_2, He, N_2, Ar, and Xe collision gases (Figure 1). In general, light target gases (H_2, He) produce abundant high mass fragments at all pressures but less abundant low mass fragments except at high pressures. In contrast, the heavy target gases (Xe, Ar, N_2) produce low mass fragments in the greatest intensity corresponding to a greater conversion of translational energy into internal energy.

The optimum spectrum is defined here as one in which fragment ions are observed in good intensity throughout their possible mass range. This corresponds to a beam attenuation of 70% for the heavy target gases which is below that giving the maximum total daughter ion current. For light target gases the optimum beam attenuation is 90%.

A more detailed comparison of spectra produced using either heavy or light collision gases reveals that some fragment ions may be weak or missing in either case. An excellent compromise is to use as collision gas a mixture of a light gas with a heavy gas e.g., using a 1:1 mixture of H_2 and Xe, all the fragment ions are observed with good intensity at high and low masses.

CID of Peptides of Mass >1500 Daltons

The above results for physalaemin appear to apply well for parent ions of mass 500-1500 daltons. At higher masses, parent ions are produced in lower intensity by FAB so it becomes essential to maximize the intensity of daughter ions. A study of the effect of collision gas on the spectra of peptides in the 1500-2500 dalton range showed that light target gases become very much less efficient than heavy ones (Ar and Xe) at inducing fragmentation, and that some fragments (especially low mass) are completely absent from their spectra. Hence only heavy target gases are useful for this mass range.

Peptide ions of mass >2500 daltons readily undergo unimolecular decomposition, but the daughter ion spectra are usually missing important ions for structure determination. However, even moderate pressures of collision gas tend to drastically reduce the daughter ion currents. Thus, only low beam attenuations (<30%) using a heavy target gas can be used.

EI AND COLLISIONAL ACTIVATION MASS SPECTROMETRY OF BHT AND CERTAIN ALTERATION PRODUCTS:

William C. Brumley; U.S. Environmental Protection Agency,
EMSL-LV, Las Vegas, NV 89193-3478

BHT (2,6-di-t-butyl-4-methylpheonol) is a widely used antioxidant that has applications in food, cosmetics, medicines, and feeds. This paper describes the EI mass spectra of BHT and many of its alteration products. The alteration products arise from the study of BHT in a food simulating solvent of water/ethanol and in the pyrolysis study of hydroperoxy BHT. Hydroperoxy BHT is a plausible intermediate in the antioxidant role of BHT. The EI mass spectra are studied using accurate mass measurements and collisional activation of selected ions on a triple quadrupole instrument at -10eV energy. Compounds characterized include BHT (RMM=220) and BHT derived hydroperoxy (RMM=252), quinone (RMM=220), aldehyde (RMM=234), alcohol (RMM=236), acid (RMM=250), epoxide (RMM=252), dimer (RMM=438), ethyl ether (RMM=264), and butyl derivatives (RMM=276).

Fragmentation involves pure hydrocarbon losses and losses including oxygen, as revealed by high resolution MS. The elemental compositions of selected fragment ions are given in the EI spectra of Fig. 1. For example in the spectrum of BHT it is of interest to note that $(M-31)^+$ results from loss of $CH_3\cdot$ and CH_4. The ion corresponding to $(M-59)^+$ is also the result of pure hydrocarbon losses. Ions represented as $(M-57)^+$ and $(M-75)^+$ each consist of two different elemental compositions.

The CA spectra of the $(M-CH_3\cdot)^+$ ion of BHT and similar compounds exhibit an abundant ion at m/z 57 correlated with the presence of the second tert butyl group in the molecule. This provides a convenient tool for examining whether alterations have occurred at the tert-butyl moieties.

Distinguishing between the benzoid and cyclohexadienone structure is apparent in the CA spectra of the $(M-15)^+$ ions. The cyclohexadiene and quinone structures exhibit specific framentations with rearrangement. The CA mass spectrum of m/z 219 afforded by some of the compounds provides a fingerprint to verify this moiety in various alteration products; an ethyl ether and butyl derivative attached at the 4-methyl position are examples. (Fig. 2)

Two cases for the application of CA spectra to analogous structures are obvious. In one, different compounds fragment to the same ion structure. For example, m/z 161 of BHT, the ethyl ether derivative and the butyl derivative are probably the same; m/z 219 of Fig. 2 is also illustrated and is the same or similar for other compounds fragmenting at this position. The fragmentations leading to these ions involve the site of structural difference. In the second case, different compounds show parallel fragmentations but the ions are separated by a constant mass difference (e.g., 14 u); fragmentations resulting in these ions do not involve the site of structural difference.

Figure 1. EI mass spectrum of BHT.

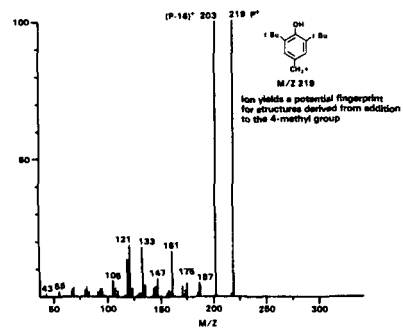

Figure 2. CA mass spectrum of m/z 219 from the ethyl ether derivative.

These studies provide a basis for the identification of many alteration products of BHT, the correlation of structure to the spectra, and the recognition of common ion structures as an aid to structure elucidation.

APPLICATIONS OF CONTINUOUS FLOW FAB MASS SPECTROMETRY FOR THE STUDY OF DRUG METABOLISM

Ralf Schubert*, **Ernst Schroeder***, Peter Jacobs**

*Finnigan MAT GmbH, Barkhausenstraße 2, D-2800 Bremen, FRG
**Organon Int. B.V., Scientific Development Group, Oss, The Netherlands

Introduction

Since its introduction in 1986 (1), continuous flow FAB (CFF) has been applied to various mass spectrometric problems. In this paper, we report on a new CFF development that we have used for quantitative determination of vecuronium bromide (figure 1) in plasma.
Vecuronium bromide is a clinically effective non-depolarizing neuromuscular blocking agent that has a wide margin of cardiovascular safety (2-4). Published assay methods have not been sensitive enough to monitor vecuronium in all clinical situations (5). Sensitivity could be improved using CFF.

Results

The conventional FAB mass spectrum of vecuronium bromide is shown in figures 2 and 3. The detection limit with FAB is 10 ng. The ion at m/z 553 is from the glycerol matrix. On the other hand, the CFF mass spectrum (figure 4) shows a signal-to-noise ratio that is 50 times higher than seen in the conventional FAB spectrum.
This increase in detection limit, along with improved reproducibility (figure 5), makes CFF better suited for the assay of vecuronium bromide in plasma than conventional FAB. With CFF, the linear response of the drug is approximately 3 orders of magnitude (figure 6).
Sensitivity can be enhanced further by multiple ion detection (MID) of selected ions. We have used an internal standard with stable isotopes for quantitative measurements (figure 7, Table 1), specifically, vecuronium bromide with a CD_3-group at the quaternary nitrogen (figure 1).

Experimental

All measurements were performed on a Finnigan MAT 90 sector-field mass spectrometer. BioProbe™ was used for introduction and ionization of the samples. The eluent was a solution of 20 % glycerol in water, and the samples were injected through a loop.
MID experiments used m/z 553, from the glycerol background, as a lock mass, with electrostatic peak jumping. Resolution was set at 2 000 (10 % valley definition). Sample preparation has been described in detail elsewhere (5).

Conclusion

Continuous flow FAB is a sensitive ionization method for the identification and quantification of vecuronium bromide in plasma. Concentrations in the low picogram range can be detected and quantified. Matrix effects from the plasma have been observed and need further investigation. The on-line coupling of LC, with CFF as the LC/MS interface, may be a solution for this problem.

ACCUMULATION OF FURANCARBOXYLIC ACIDS AND INDOXYL SULFATE IN UREMIC SERUM AS INHIBITORS OF DRUG-BINDING

T. Niwa, N. Takeda*, H. Yoshizumi*, A. Tatematsu*

Nagoya University Branch Hospital, Nagoya 461, Japan
*Meijyo University, Nagoya 468, Japan

Introduction The albumin binding of many drugs and endogenous metabolites is well known to be reduced in uremic serum. The reduction of albumin binding of drugs is considered to be due to the accumulation of endogenous protein-bound metabolites in uremic serum. To detect the protein-bound metabolites accumulated in uremic serum, we analyzed the organic acid fraction extracted from isopropanol-deproteinized uremic serum using GC/MS, and also analized the protein-bound metabolites in uremic serum using HPLC (1,2).

Experimental Serum samples were obtained from uremic patients before and after hemodialysis, and healthy subjects. For GC/MS analysis, serum was deproteinized with isopropanol. After centrifugation the supernate was collected. After evaporation the extract was dissolved with water. To extract the organic acids, the solution was acidified to pH 1 with HCl, saturated with NaCl, and extracted three times with ethyl acetate. The organic phase was collected after centrifugation, dehydrated over anhydrous sodium salfate and evaporated with a nitrogen stream. The extract was methylated with diazomethane. After evaporation with a nitrogen stream, the sample was dissolved with methanol/ethyl acetate, and then analyzed by GC/MS.

For quantitation of 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid, serum was deproteinized by boiling at 100 °C for 5 min, and centrifuged to remove protein. The supernate filtered through a filter was subjected to ODS-HPLC with an eluate of acetonitrile/water/trifluoroacetic acid (40/60/0.08, by vol).

For quantitation of indoxyl sulfate, serum was filtered through a filter and then subjected to internal-surface reversed-phase (ISRP) HPLC with an eluate of 0.2M acetic acid/triethylamine (pH 7)-isopropanol-tetrahydrofuran (84/10/6). The identification of indoxyl sulfate was carried out using liquid secondary ion mass spectrometry (SIMS).

Results and Discussion Figure 1 shows the EI mass spectra of 3-carboxy-4-methyl-5-ethyl-2-furanpropionic acid (a), 3-carboxy-5-propyl-2-furanpropionic acid (b), 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid (c), 3-carboxy-4-methyl-5-pentyl-2-furanpropionic acid (d), which were detected in the organic acid fraction from uremic serum. Mass chromatography revealed that the serum levels of the furancarboxylic acids were increased in the chronic hemodialysis patients, and that the acids were not detected in the uemic serum ultrafiltrate. Scince the furancarboxylic acids were strongly albumin-bound, the acids could not be removed from blood by hemodialysis.

3-Carboxy-4-methyl-5-propyl-2-furanpropionic acid was also quantitated by HPLC. Serum levels of the acid showed significant but weak correlation with serum levels of urea and duration on hemodialysis.

Indoxyl sulfate was detected and quantitated in uremic serum by ISRP-HPLC. Identification of indoxyl sulfate was performed only by use of liquid SIMS. Serum level of indoxyl sulfate was markedly increased in chronic hemodialysis patients, and its removal by hemodialysis was not enough due to its binding to serum albumin.

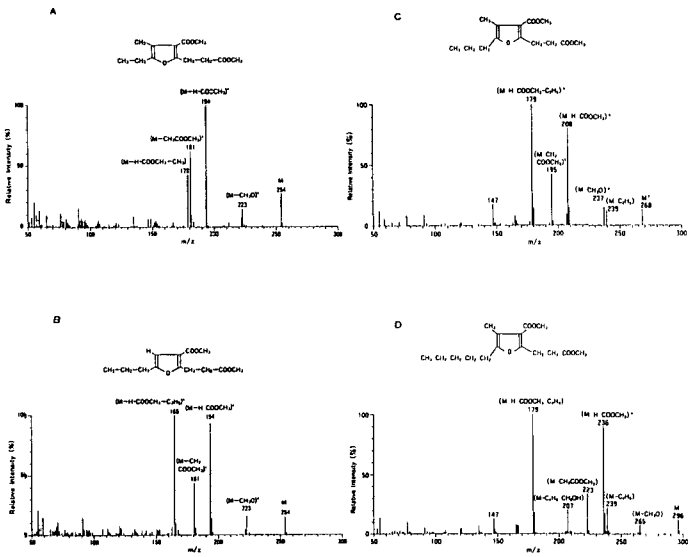

Figure 1 EI mass spectra of 3-carboxy-4-methyl-5-ethyl-2-furanpropionic acid dimethyl ester (a), 3-carboxy-5-propyl-2-furanpropionic acid dimethyl ester (b), 3-carboxy-4-methyl-5-propyl-2-furanpropionic acid dimethyl ester (c), 3-carboxy-4-methyl-5-pentyl-2-furanpropionic acid dimethyl ester(d).

Equilibrium dialysis demonstrated that 3-carboxy -4-methyl-5-propyl-2-furanpropionic acid, 3-carboxy-4-methyl-5-pentyl-2-furanpropionic acid, and indoxyl sulfate inhibited the binding of salicylate to albumin.

The urinary excretion of the furancarboxylic acis and indoxyl sulfate seems to be performed by renal tubular secretory function in healthy subjects. Since the conventional hemodialysis method cannot remove the protein-bound metabolites, a novel hemodialysis method which can remove these strongly protein-bound metabolites, should be developed to prevent possible complications of uremic patients on long-term hemodialysis due to accumulation of the furancarboxylic acids and indoxyl sulfate.

EFFECT OF EXTENDED USE OF SINGLE ANABOLIC STEROIDS ON URINARY STEROID EXCRETION AND METABOLISM,

LM Harrison, D Martin, RW Gotlin, PV Fennessey,
University of Colorado Health Sciences Center, Denver, CO 80262 USA

The use of anabolic steroids in athletes who compete in strength and body fitness events is widespread. In the past, research has centered on those endocrine effects that are associated with reproductive organs and regulation. As a results of this research anabolic steroids have been shown to: reduce endogenous serum testosterone production; lead to testicular hypoplasia after long term use; and to inhibit gonadotrophin release. Desirable effects such as weight gain, increased muscle mass and strength increase have been more difficult to demonstrate (1). In spite of the lack of solid data, anabolic steroids are used solely for these desired results. Known effects, such as testicular hypoplasia, are circumvented by taking the steroids in high doses for a limited period of time (4-6 weeks) and then remaining steroid free for an equal or longer period of time.

In our initial study, where athletes were taking multiple steroids (stacking) in order to be able to attain very high levels of anabolic agents, we found a reduction in endogenous adrenal steroid production (2). Because of the mixture of steroid being used there was a question about whether this was a general effect of anabolic steroids, a result of the combined high doses, or caused by one or two of the steroids being used.

Male body builders were asked to collect 24h urine samples at each of the following intervals: 1) at least 3 weeks subsequent to any prior steroid use; 2) after using a single anabolic steroid (nandrolone decanoate, methandrostenolone, oxandrolone or oxymetholone) at dosages >25 mg/d for at least three weeks; 3) following at least 3 weeks recovery after last using the anabolic steroid. The volume of each sample was measured and recorded and an aliquot was frozen at -70C until analysis.

Samples were processed using a standard technique (3) and the concentration (mg/24h) of each steroid was determined.

For the evaluation of adrenal function, we compared the concentration of androsterone (A), etiocholanolone (E), tetrahydrocortisone (THE), tetrahydrocortisol (THF), and allo-tetrahydrocortisol (aTHF) before, during and after a steroid cycle. These compounds were selected because together they make up the bulk of the urinary steroids. For all subjects where the five test compounds were in the normal range at the beginning of the test (before sample), we found suppression of adrenal output while they were taking anabolics. Some patients had abnormally low levels of some or all of the test compounds in their before sample. In this group, the effect on adrenal output was difficult to assess. All four of the anabolic agents studied showed apparent reduction in adrenal function indicating that this may be a general effect of anabolic steroids.

Metabolism in man is often times completely different from the animal models that have been used to study these compounds. Of the four compounds in this study oxandrolone was the only compound excreted in the urine without major metabolism. The other three compounds underwent substantiated biotransformation before excretion. A further interesting observation was that, regardless of the agent used, only 10-20% of the anabolic agent (2-5 mg) were excreted each day.

NEGATIVE ION CI ISOTOPE DILUTION GC/MS ASSAY FOR PUTRESCINE IN BIOLOGICAL FLUIDS

Daniel L. Norwood and David S. Millington
Duke University Medical Center, Division of Pediatric Genetics and Metabolism, Box 3028, Durham, NC 27710

Putrescine (1,4-butanediamine) is a low molecular weight polyamine produced during cell growth and proliferation. Increased levels of putrescine in biological fluids and tissues are associated with increased rates of cell division, as occurs during the the proliferation of malignant tumors. For example, elevated levels of putrescine in cerebrospinal fluid (CSF) correlate with active medulloblastoma, a malignant brain tumor that affects young children. The objective of this research was to develop a definitive assay for putrescine, based on electron-capture NICI isotope-dilution GC/MS, applicable to CSF, urine and other biological fluids. Two different derivatives of putrescine were evaluated.

Methods

The bis-pentafluorobenzyl (PFB) imine derivative of putrescine was prepared using pentafluorobenzaldehyde according to the method of Avery and Junk (J. Chromatogr. Biomed. Appl. 420:379-384, 1987). The bis-pentafluoropropionyl (PFP) amide derivative was prepared with pentafluoropropionic anhydride according to the method of Rattenburg, et al. (Clin. Chim. Acta 95:61-67, 1979).

Aliquots of normal urine (1 mL) were spiked with putrescine and the internal standard, $^{15}N_2$-putrescine, at the nmol/mL level. In-situ derivatization and recovery were accomplished by Avery and Junk's procedure. Normal CSF (1 mL) was treated in a similar manner.

Analyses were performed on a TRIO-2 quadrupole mass spectrometer (VG Masslab) operated in NCI mode with argon as buffer gas. Separations were performed on a non-polar fused-silica capillary column (DB-1, 30m).

Results

The electron-capture NCI spectra of the PFP (amide) and PFB (imine) derivatives of putrescine are shown in Figures 1 and 2 respectively. The amide shows less fragmentation and therefore potentially better sensitivity than the imine. However, the PFB derivative is prepared in aqueous solution, i.e. directly in the urine or CSF and recovered by solid-phase extraction, whereas the PFP derivative is formed after recovery of the putrescine by an ion-exchange procedure. In our hands, the former procedure was more efficient and successful.

The results of a standard addition experiment in which putrescine was added to normal urine at levels of 10-400 nmol/mL and the internal standard was added at 100 nmol/mL are shown in Figure 3. Selected-ion monitoring was carried out on the molecular anions (m/z 444, 446) of the corrresponding imine derivatives. Excellent sensitivity and linearity were observed at these concentrations.

The endogenous putrescine was also easily detected in unhydrolyzed normal CSF (extract of 1 mL) by SIM after formation and extraction of the PFB derivative, indicating the potential of the method for application to the diagnosis and management of patients with medulloblastoma.

Study on Mass Spectra of New Sesquiterpene

Quan-Long Pu*[1], Linxing He[2] and Ju Zhang[2]

[1]Guangxi Institute of Traditional, Medical and Pharmaceutical Sciences, Nanning, P.R. China (present address: NIDDK, NIH, Bethesda, MD 20892).
[2]Nanjing Institute of Wild Plants, Nanjing, P.R. China

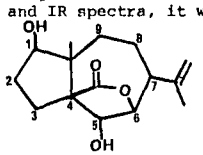
AIM: The plant species Aristalochia versicolar S.M. Hwang has been used as a traditional Chinese medicine in the cure of problems including sore throat/laryngitis, angina and breast abscesses. As part of an investigation of the compounds present in such species which may account for their activities, we isolated two new sesquiterpene lactones with structures different from any previously reported. The structures of these compounds were obtained by a combination of mass spectrometry, NMR and IR techniques and were subsequently confirmed by X-ray crystal diffraction methods.

ISOLATION: The dried powder of the plant root was extracted with hot ethanol three times. After evaporating to dryness, the residue was extracted with petroleum ether, shaken with water and the aqueous portion extracted with ethyl acetate. The ethyl acetate was concentrated and chromatographed on a silica column. The first lactone eluted with petroleum ether/ ethyl acetate (8:2) and the second one with petroleum ether/ethyl acetate (5:5). The following paper describes the mass spectral fragmentation of the compounds.

INSTRUMENTATION: All mass spectra were recorded on a MAT-311A mass spectrometer connected to a MAT-200 data system located at the Guangxi Institute of Traditional, Medical and Pharmaceutical Sciences. The EI source was operated at 70ev with an accelerating voltage of 3kv. Samples were desorbed from the solids probe at approximately 120°C.

VERSICOLACTONE C: This compound crystallized to give a compound with a melting point of 181-182°C and a high resolution measured formula of $C_{15}H_{22}O_4$. On the basis of its mass spectra, NMR and IR spectra, it was assigned the structure in Figure 1.

Figure 1.



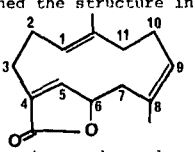


Figure 2.

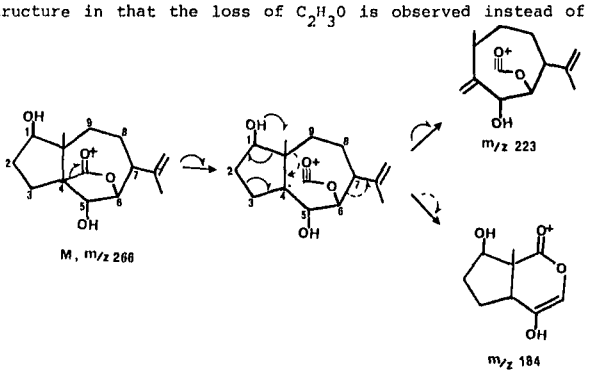
High resolution measurements were made on the major peaks and metastable ion peaks were mapped using a computer B^2/E scanning function.

The skeleton has three possible modes of fragmentation:

A: Ring A fragmentation: The ion m/z 223 ($C_{13}H_{19}O_3$) results from bond cleavage as shown in Figure 3. This fragmentation is characteristic of this new sesquiterpene lactone structure in that the loss of C_2H_3O is observed instead of the more usual C_3H_6O.



Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

B: Ring B fragmentation: The ion at m/z 184 ($C_9H_{12}O_4$) results from cleavage at bonds C(9)-C(10) and C(6)-C(7).

C: Figure 4 shows the fragmentations observed following cleavage of the lactone ring. It results in the formation of intense ions at m/z 95, 109, 151, 191, etc. as in A, and these fragmentations are again characteristic of this sesquiterpene skeleton and are absent in the mass spectra of the more common azulene-lactone structures.

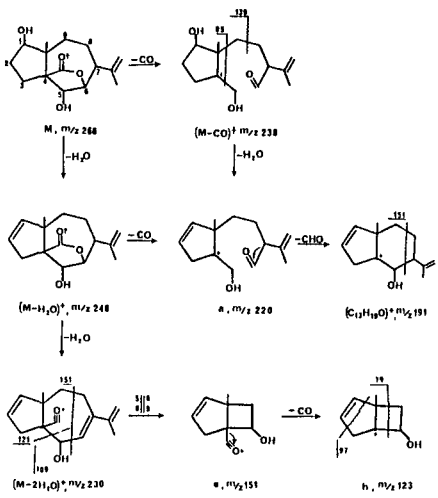


Figure 4

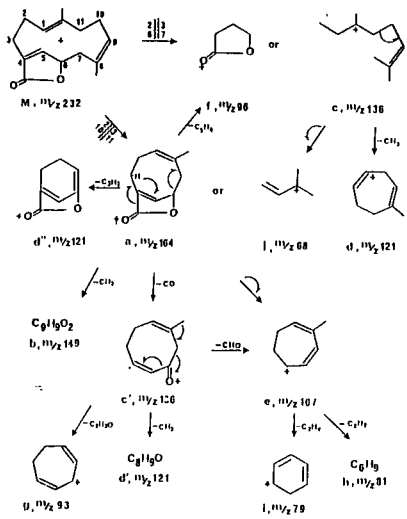

Figure 5

Versicolactone M: This compound had a melting point of 132-134°C and a molecular formula of $C_{15}H_{20}O_2$. Its structure is shown in Figure 2.

High resolution mass measurements were made on the major ions and the metastable ion transition recorded.

Fragmentations at the C(2)-C(3), C(6)-C(7) and C(10)-C(11) bonds are predominant. The intense ions at m/Z 164 ($C_{10}H_{12}O_2$) and m/z 68 (C_5H_8) indicate that the two double bonds in the twelve membered ring are located at C(8) and C(12). Another strong ion at m/z 96 ($C_5H_4O_2$) confirms that there are no other functional groups in the lactone ring. A weak ion and m/z 217 ($C_{14}H_{17}O_2$) was found to fragment to the m/z 81 (C_6H_9) and this allowed the placement of the two methyl groups at C(8) and C(12). Figure 5 shows the fragmentation pathways determined.

SUMMARY: The mass spectra of these two sesquiterpene lactones are consistent with the structures which have since been confirmed by X-ray crystallography. Investigations into the biological effects of these compounds is continuing.

INVESTIGATION OF NONCOVALENT INTERACTIONS BY FAB-MASS SPECTROMETRY

Dennis P. Michaud, Thomas F. Brennan and Paul Vouros
Barnett Institute of Chemical Analysis and
Department of Chemistry, Northeastern University,
Boston, MA 02115

Noncovalent interactions involving ligands, receptors, and enzymes are extremely important in biological systems. A number of methods are available for studying these interactions but until recently there has been no mass spectrometric technique capable of addressing the problem. The introduction of FAB methodology has renewed interest in the mass spectrometry of larger biological molecules.

Information about noncovalent interactions can be obtained by analyzing the formation of clusters. Cluster ion formation involving the matrix is a prominent feature in FAB mass spectra, but analyte-analyte clusters have also been detected. Since FAB/MS has been used successfully by many (1,2,3) for the study of liquid phase chemistry, the examination of analyte-analyte clusters should yield information about the association of biomolecules in solution.

Molecular association is evidenced by the formation of peaks above the molecular ion peak of the monomeric species in the mass spectrum. For solutions containing more than one component, complexes due to mixed-association as well as self-association are observed. When a mixture of kyotorphin (MW=337) and leu-enkephalin (MW=555) is examined by FAB, a protonated complex at m/z 893 (337+555+1) is observed along with the protonated dimer of kyotorphin at m/z 675 (Figure 1). Examination of a possible structure of the kyotorphin/leu-enkephalin complex reveals that such a structure can be stabilized by several hydrogen bonds, an electrostatic attraction , and a pi-stacking interaction. Kyotorphin also forms a mixed-associated complex with phe-enkephalin at m/z 926 (337+588+1). When a ternary mixture of kyotorphin (MW=337), leu-enkephalin (MW=555) and TRH (MW=362) was examined by FAB, all possible binary mixtures were present but apparently greater preference was observed for the complex between TRH and leu-enkephalin.

Recently it was reported (4) that the gas phase basicity rather than the solution phase basicity is what determines which protonated species is preferentially expressed. In order to distinguish the formation of complexes in FAB as solution or vapor phase phenomena, we utilized a probe tip that was divided horizontally by a paraffin barrier. If two different analytes of sufficient concentration are placed on opposite sides of the barrier, then the formation of a complex of the two analytes would suggest that the complex is formed in the vapor phase. Figure 2 shows a mixture of arginine (A) and leu-enkephalin (L) placed on both sides of the paraffin barrier. The mixed-associated as well as the self-associated complexes are observed. When arginine (A) is placed on one side of the barrier and leu-enkephalin (L) on the other the resulting spectrum (Figure 3) is similar to that in Figure 2 except that the ion of the mixed complex is absent. This suggests that the formation of complexes of biomolecules in FAB is a solution phenomenon.

We are continuing our investigation of structural and solution effects on the complex formation of biomolecules in FAB.

Reaction of Mass Spectrometry

—— An Approach to Stereochemical Analysis of Organic Compounds

Yao-Zu Chen Suming Hua Honng Li Houjun Yang
(Chemistry Department, Lanzhou University, Lanzhou, China)

Reaction mass spectrometry (RMS) is a technique in which a stereospecific reagent is introduced into the ion source (EI, CI or FAB), where the reagent may react as ions or molecule with the sample molecule to form some characteristic ions. From the relative abundances of these characteristic ions, the stereochemical information about the sample molecule may be obtained. The work done along this line in our lab in recent years are summarized in Table 1. The experimental results showed that the RMS proved to be a promising tool for differentiation of diastereoisomers and conformers, detection of chirality and determination of absolute configuration of some organic compounds.

In continuing our work on RMS for stereochemical analysis, the negative ion fast atom bombardment mass spectra (NIFAB-MS) of mono-, disaccharides and glycosides with phenylboronic acid(PBA) as reagent have been studied. In the ion source, PBA react stereoselectively with cis-vicinal Hydroxyl groups to form characteristic ions $(M_s+M_r - H - 2H_2O)^-$ and $(M_s+2\ M_r - H - 4H_2O)^-$, from relative abundances of which the stereoisomers of saccharides and glycosides can be definitely distinguished. The structures of these characteristic ions have been elucidated by means of MS/MS technique.

Table 1 in situ Reactions of Stereospecific Reagents

Reagent	Ionization	Information
Trimethylborate	DCI	diastereoisomerism of saccharides
l-Amyl alcohol	CI, in beam	chirality of amino acids
Me_3SiNEt_2	EI, CI	conformation of steroidols
D- & L-Mandelic acid D- & L-Methylbutyric acid D- & L-Phenylethylamine	CI	detection of enantiomers of amino acids
R- & S-Phenylbutyric anhydride	CI	determination of absolute configuration of alkaloids, etc.
Phenyl boronic acid	NIFAB	differentiation of epimers of saccharides and glycosides

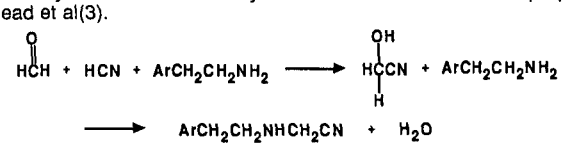
Reaction of Cyanide and Formaldehyde with Neurotransmitter Amines: Formation of New Compounds from Cigarette Smoke

D.A. Durden, B.A. Davis, P.H. Yu and A.A. Boulton
Neuropsychiatric Research Unit, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.

Introduction

When aqueous solutions of cigarette smoke are mixed with solutions of biogenic neurotransmitter amines or when smoke is passed over rat lung tissue slices, the concentrations of the neurotransmitters are reduced and new compounds appear (1). Initial experiments with phenylethylamine lead to the identification of N-cyanomethyl-phenylethylamine (2).Although cigarette smoke contains a large number of reactive combustion products it appears that the new compounds are formed by reaction with a mixture of cyanide and formaldehyde in a manner similar to that proposed by Winstead et al(3).



With 5-hydroxytryptamine the major organically extractable product was not N-cyanomethyl-5-hydroxytryptamine but 2-cyanomethyl-6-hydroxy-1,2,3,4-tetrahydro-beta-carboline Thus the indolylalkylamines, histamines and some of the ring substituted phenylethylamines may be expected to undergo cyclization with additional formaldehyde via the Pictet-Spengler reaction.

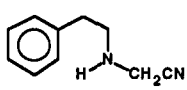
We wished to investigate the products of the following putative neurotransmitter amines: phenylethylamine (PE), p-tyramine (pTA), m-tyramine (mTA), p-octopamine (pOct), m-octopamine (mOct), dopamine (DA), noradrenaline (NA), 3-methoxytyramine (3-MT), 3,4-dimethoxyphenyl-ethylamine (DMPEA), tryptamine (T), 5-hydroxy-tryptamine (5-HT) and histamine with mixtures of cyanide and formaldehyde and to develop derivatives suitable for their detection in physiological fluids and tissues.

Methods

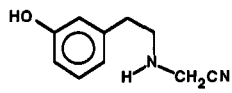
A solution of 37% formaldehyde (1.5 eq), sodium cyanide (1.0 eq) and sodium bisulphite (1.5 eq) was added to the amine free base or hydrochloride salt in 2 to 5 ml water (3). After one hour the products were extracted with ether and examined by GC-MS. Pentafluoropropionyl derivatives were made with pentafluoropropionic anhydride (1-2 mg product + 50 µl PFPA reacted at 80c, 1h) and t-butyldimethylsilyl (TBDS) derivatives using N-Methyl-N-(t-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA, 80C,1h with 50µl acetonitrile or dimethylformamide solvent). The derivatives were analysed by GC-MS using capillary columns: DB-1, 1.5 µm, 30m x 0.5 mm id , and BP-5, 1.0 µm, 60m x 0.32 mm id, at low resolution using a VG 7070F mass spectrometer.

Results and Discussion

When reacted with approximately equal amounts of formaldehyde and cyanide phenylethylamine and p-tyramine, as predicted, produce simple cyanomethylamine products that have been confirmed by spectra of several derivatives.

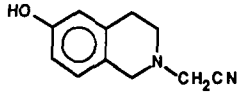


N-cyanomethylphenylethylamine

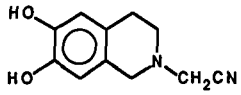


N-cyanomethyl-p-tyramine

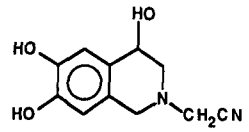
It appears that p-Oct, however, cyclises to form 2-cyanomethyl-4,7-dihydroxy-tetra-hydroisoquinoline. The meta substituted phenylethylamines: m-tyramine, dopamine, noradrenaline and dimethoxyphenylethyl-amine all produce several products mainly substituted tetrahydroisoquinolines (THIQs)



2-cyanomethyl-6-hydroxy-1,2,3,4-tetrahydroisoquinoline

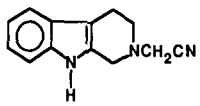


2-cyanomethyl-6,7-dihydroxy-1,2,3,4-tetrahydroisoquinoline

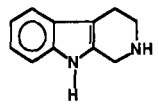


2-cyanomethyl-4,6,7-trihydroxy-1,2,3,4-THIQ

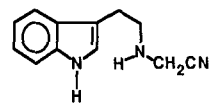
This is followed by the cyanomethyl derivative of the amine and in some cases by the tetrahydroisoquinoline. The indolylethylamines, tryptamine and 5-hydroxytryptamine similarly react to form primarily the 2-cyanomethyl-beta-carbolines followed by the N-cyanomethyl amines and the beta carbolines.Truptamine produced



2-cyanomethyl-1,2,3,4-tetrahydro-beta-carboline



1,2,3,4-tetrahydro-beta-carboline



N-cyanomethyl-tryptamine

Although a large number of products were predicted for histamine the major product was 6-cyanomethyl-4,5,6,7-tetrahydro-aza-benzimidazole with a small amount of the unsubstituted alkaloid 4,5,6,7-tetrahydro-aza-benzimidazole also observed.

PFPA and MTBSTFA both react with the cyanomethyl products to give derivatives suitable for GC-MS. PFPA appears to cause additional reactions and may indicate the presence of compounds that were not in the original product mixture. For example PFPA produced about 6 derivatives from the products of a m-tyramine/ HCHO/ KCN mixture wheras there were only 3 TBDS derivatives. When PFPA was reacted with purified N-cyanomethyl-phenylethylamine the PFP derivative of tetrahydroisoquinoline was found wheras with MTBSTFA only the TBDS derivative of N-cyanomethylphenylethylamine was observed. Thus it appears that PFPA will cause cyclization of the cyanomethyl group (with loss of the cyanide) in a manner similar to the Pictet-Spengler cyclization of formaldehyde Schiff bases. This has important implications for the identification of THIQ in tissues as almost all of the published reports used PFPA or one of its analogs and the THIQ could be formed from the Schiff base itself

Many of the alkaloid products are similar to compounds known to have physiological activity. For example the THIQs and THBCs are similar to methylated alkaloids associated with alcohol addiction and may contribute to the addictive properties of smoking and some appear to have enzyme inhibiting properties(1), and will be investigated further.

Conclusion

The major products of reaction of formaldehyde and cyanide in aqueous solution are the cyanomethyl derivatives of the amines in the case of the simple phenylalkylamines and the cyanomethyl derivatives of the tetrahydroisoquinolines (THIQs) and beta carbolines (THBCs) in the case of the meta substituted phenylethylamines and indolylethylamines. Derivatization with PFPA is not suitable due to the possibility of formation of unwanted cyclized derivatives. The use of the TBDS derivative or other mild reagent appears to be more approprate.

A Micromethod For The Derivatization Of Organic Compounds Using Reagent Vapor

J.E. Vath and K. Biemann
Department of Chemistry
MIT, Cambridge, MA 02139

Many analytical measurements require an organic compound to be converted into a derivative. In mass spectrometry this is commonly done either to make a compound more volatile for introduction into a GCMS, to enhance sensitivity or to change the fragmentation to obtain more structural information. Often the need to react sample becomes a problem when there is only a very small amount of material available. Because it is hard to perform reactions with solvent volumes less than 50 µl, one is forced to use a very large excess of reagent when reacting less than a microgram. In this case impurities in reagents and multistep reactions make the situation difficult. Another consideration is how one is going to introduce the small amount of derivative into the mass spectrometer.

We have, therefore, extended a technique that was presented last year to analyze peptide derivatives by GCMS[1] to one that is useful for a broader range of reactions that are applied to mass spectrometry. The strategy is one where the sample, present as a solid, is exposed to an environment of reagent vapor in a form which is well suited for both GC and FAB MS. The sample is deposited by placing 1-2 µl of a sample solution into a capillary which contains an indentation to hold the sample in place (Fig. 1, top). The tube is then placed in a vacuum causing the solvent to evaporate leaving the sample as a thin band of solid on the inner wall of the tube (Fig. 1, bottom). The tube is then placed into a reaction vessel which contains 200 µl of the proper reagent or reagent mixture in a vertical side arm well (Fig. 2). After cooling the well the vessel is briefly evacuated to remove air, sealed and heated in an oven to the required temperature for a period of time. After that, the reagent well is cooled again and excess reagent and volatile products are removed by evacuation at room temperature. The tube is then removed for transfer into the instrument or into another reaction vessel for a subsequent reaction step. For GCMS the sample is placed directly into a solid sample GC injector[2]. For FAB the derivative is washed out of the tube directly onto the FAB probe with a 2 µl plug of matrix in a suitable solvent, manipulated by a micrometer controlled piston attached to the sample tube by a short piece of rubber tubing.

Examples of some applications we have found for the technique are: 1) the derivatization of peptides at their C-terminus using an ammonium ethyl ester derivative[3] for FAB analysis, 2) hydroboration and silylation of unsaturated fatty acids for double bond location using GCMS, 3) reduction and hydroboration of ceramides and cerebrosides to increase sensivity and structural information in their FABMS and CID spectra respectively. The reaction sequence in the latter example is detailed with reaction conditions in Scheme I. The dramatic increase in sensitivity can be noted by comparison of Figs. 3 and 4. Fig. 3 is the spectrum of 1 µg of underivatized palmitoyl-sphingosine while that in Fig. 4 was obtained with 10 ng of the derivatized material directly from the sample tube.

Our experience with this technique has led us to believe that it has many useful applications. The most imporatant aspects of the method are its ability to convert a very small sample into a derivative which is not contaminated from large amounts of solvent or reagent, the minimization of losses due to sample handling and contact with large surfaces and the ability to tranfer the entire product to the instrument for measurement.

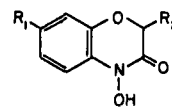
INVESTIGATION OF THE TEMPERATURE DEPENDENCE IN THE MASS SPECTRUM OF HYDROXAMIC ACIDS.

Kelly R. Stringham, Phil C. Lyons, Ralph L. Nicholson, and Karl V. Wood; Department of Biochemistry, Department of Botany and Plant Pathology, and Campus-Wide Mass Spectrometry Center, Purdue University, West Lafayette, IN 47907.

Cyclic hydroxamic acids found in plant tissues are believed to have a role in disease and insect resistance.[1] 2-(2,4-dihydroxy-7-methoxy-2H-1,4-benzoxazin-3(4H)-one)β-D-glucopyranoside (DIMBOA-glc) is the major hydroxamic acid in corn and wheat with the demethoxy analog (DIBOA-glc) being a minor component. Both glucosides may be enzymatically converted *in vivo* to the corresponding aglycones DIMBOA and DIBOA, respectively. The reported electron impact mass spectra of DIMBOA and DIBOA showed molecular ions whereas the highest mass peak observed for the glucosides was $(M-O)^{+\cdot}$.[2] Low abundance ions were observed for the loss of O, $OH^{\cdot}$, and H_2O in the aglycones with the base peak corresponding to the loss of CO from the $M-H_2O$ ion.



DIMBOA-glc:	$R_1 = OCH_3$	R_2 = O-glucosyl
DIMBOA:	$R_1 = OCH_3$	$R_2 = OH$
DIBOA-glc:	$R_1 = H$	R_2 = O-glucosyl
DIBOA:	$R_1 = H$	$R_2 = OH$

The loss of O from N-oxides is a known thermal decomposition[3] that at sufficiently high ion source temperatures, can direct the majority of the ion abundance of the EI spectra. Hydroxamic acids form N-oxides in the gas phase by keto-enol tautomerization and so can readily lose O. The loss of H_2O from many compounds is also a known thermal decomposition that can dominate the mass spectrum. Since DIMBOA and DIBOA lose both O and H_2O their EI spectra would be expected to be a combination of these two competing thermal decompositions along with unimolecular fragmentation. In this study, DIMBOA was analyzed at various ion source temperatures to evaluate the effect of temperature on the two decompositions, and EI/MS/MS daughter spectra were utilized to ascertain the origin of the major fragment ions.

The daughter spectrum of the molecular ion of DIMBOA, m/z 211, differs from the EI spectrum of DIMBOA (Figure 1). Not only is the base peak different in the two spectra but the fragment ions $(M-O)^{+\cdot}$ and $(M-H_2O)^{+\cdot}$ are absent in the daughter spectrum. This demonstrates that these ions, unlike $(M-OH)^+$, are due to thermal decomposition and not unimolecular fragmentation. The daughter spectra of the thermal decomposition products, $(M-O)^{+\cdot}$ and $(M-H_2O)^{+\cdot}$, were also obtained (Figure 2). They differ from each other and from that of $M^{+\cdot}$, indicating the existence of a different fragmentation scheme for each of the three ions. The ions which dominate the EI spectrum of DIMBOA, however, are associated with the daughter spectra of the $(M-O)^{+\cdot}$ and $(M-H_2O)^{+\cdot}$ ions, demonstrating the effect of thermal decomposition on the observed EI spectrum.

The ion source temperature was varied from 150°C to 350°C to investigate the effect of temperature on the relative abundances of the thermal decomposition products $(M-O)^{+\cdot}$ and $(M-H_2O)^{+\cdot}$. Since a change in either of the thermal decompositions would affect both of the ratios to the molecular ion, *i.e.*, $(M-O)^{+\cdot}/M^{+\cdot}$ and $(M-H_2O)^{+\cdot}/M^{+\cdot}$, by reducing the abundance of the molecular ion, these ratios could not be used to assess the effect of temperature on the individual decompositions. The range of m/z 190-215 amu was scanned and ratios of $(M-O)^{+\cdot}$, $(M-OH)^+$, and $(M-H_2O)^{+\cdot}$ to the total ion count (essentially m/z 193, 194, 195, 211, and their ^{13}C isotopes) were plotted as a function of increasing source temperature (Figure 3). Both

the $(M-O)^{+\cdot}$ and $(M-H_2O)^{+\cdot}$ ratios increased while the $(M-OH)^+$ ratio decreased slightly. The increase in relative abundances of $(M-O)^{+\cdot}$, a 60% increase, and $(M-H_2O)^{+\cdot}$, a 120% increase, demonstrates the degree to which these thermal decompositions are affected by ion source temperature.

From these results and the EI/MS/MS results, it can be concluded that the major part of the EI spectra of DIMBOA and probably DIBOA results from thermal decomposition and not unimolecular fragmentation from the molecular ion. Even at fairly low ion source temperatures these decompositions dominate the spectrum.

In DIMBOA-glc and DIBOA-glc the hydroxyl group responsible for the loss of H_2O in the aglycones is replaced by a glucosyl group. The EI mass spectrum of DIMBOA-glc matches the daughter spectrum of the $(M-O)^{+\cdot}$ ion of DIMBOA except for small peaks at m/z 357 $(M-O)^{+\cdot}$, m/z 178, and m/z 179. Thus, despite the absence of the thermal loss of H_2O, thermal decomposition dominates the EI mass spectra of these glycosylated compounds also, and to a degree that a molecular ion is not obtained.

SYNTHESIS AND ANALYTIC UTILITY OF DEUTERIUM LABELED 3-NITROBENZYLALCOHOL

Victoria V. Mykytyn, A. Mahendar Reddy and Karl H. Schram
Department of Pharmaceutical Sciences
College of Pharmacy
University of Arizona
Tucson, AZ 85721

There are various organic liquids available for use as matricies in Fast Atom Bombardment (FAB) mass spectrometry. Criteria for determining the utility of these liquids as matrix compounds for FAB include 1) the ability to solubilize compounds of interest 2) minimal background contribution to sample spectrum and the absence of high mass ions 3) a suitable viscosity and boiling point to permit convenient handeling 4) and the absence of any chemical reaction with the compound of interest. A widely used sample matrix for FABMS is glycerol. However, a significant disadvantage of glycerol is that it has been found to participate in redox reactions of some sample molecules prior to particle bombardment. This concern is exemplified by Callahan and co-workers who used proton nuclear magnetic resonance to quantitatively confirm the reduction of m-phenylenebis (trimethylammonium iodide) in a solution with glycerol as observed by electrohydrodynamic mass spectrometry.[1] As a result, other organic liquids were evaluated for their usefulness as FAB matricies.[2] For example, Meili and Seihl found that o-nitrophenyloctylether (NPOE) was useful as a matrix for corrin- and porphyrin type esters.[3] Another alternative matrix to glycerol is m-nitrobenzylalcohol (m-NBA). Barber et al,[4] have sucessfully used m-NBA to obtain FAB mass spectra from a variety of compounds, including cholesterol and chlorophyll which have previously been difficult to run by FAB using gylcerol.

A particular advantage of glycerol, however, is the utility of [hydroxy-$^2H_3$]glycerol-^2H_2O in establishing the number of active hydrogens in molecules with complex structures.[5] In determining the overall structure of an unknown molecule, its exact active hydrogen content is useful in identifying and determining the structure and arrangement of structural subunits and/or functional groups. The number of active hydrogens in a molecule can be determined from the magnitude of the mass shift of the M+H/M+^{2}H ion following hydrogen-deuterium exchange and correction for the contribution of natural heavy isotopes.[6,7]

We have expanded the analytical utility of m-NBA by preparing [hydroxy-^{2}H]m-NBA (^{2}H-NBA) which was used to establish the active hydrogen content of the anti-tumor agents **Mitomycin-C, Tetrocarcin-A, Tricyclonucleoside, Streptonigrin,** and **Mitoxantrone.** Deuterated m-NBA was prepared by vigorously shaking a 1:1 mixture of m-NBA and D_2O, allowing the bilayers of the mixture to separate, removing the aqueous layer, and repeating this procedure two additional times with a final ratio of m-NBA to D_2O of 1:3. Anti-tumor agents were labeled by preparing solutions in deuterated m-NBA at a concentration of 1ug per 1ul. In some cases, a solvent was used to increase sample solubility in m-NBA. The following precautions were taken in order to avoid re-exchange of deuterium by absorbed moisture: 1) Prior to the application of samples to the FAB probe tip, the tip was rinsed with deuterated water and bombarded with argon atoms 2) 1ul of each sample solution was transfered to the tip of the probe using a 10ul glass syringe that had been previously rinsed with deuterated water 3) The probe was then transfered quickly to the vacuum lock of the instrument. Positive ion FAB mass spectra were acquired using a Varian MAT 311A instrument equiped with an SS 300 data system. Magnetic scanning was done at an accelerating potential of 3kV. An Ion Tech saddle field gun producing a neutral argon beam at a potential of 9 kV was used for ion desorption. The ion source temperature was maintained at 30°C. Resolution was 1000.

2 Deuterated methanol.
3 Tricyclonucleoside.

In general, m-NBA proves to be a valuable alternative to the conventional glycerol matrix. Both polar and non-polar compounds can be solubilized in m-NBA with the addition of cosolvents such as water or methanol. The selection of a particular cosolvent depends on the exact nature of the compounds under investigation. Specifically, combinations of deuterated m-NBA/D_2O or deuterated m-NBA/MeOD are shown to be acceptable matrices for the FAB MS analysis of selected anti-tumor agents in hydrogen-deuterium experiments. From such experiments, the exact number of active hydrogens in complex molecules can be easily determined. Deuterated m-NBA is easy to prepare, offers minimal background interference by exhibiting low mass ions that are relatively few in number, and does not appear to react chemically with sample compounds.

IDENTIFICATION OF THE SEX ATTRACTANT PHEROMONE IN THE RED-SIDED GARTER SNAKE BY GC/MS AND GC/MS/MS or "CAN A SEX-STARVED CANADIAN GARTER SNAKE FIND HAPPINESS WITH A PAPER TOWEL IN AUSTIN, TEXAS?"

J. W. Chinn, Jr.*, E. Holly*, R. T. Mason† and D. Crews†
Departments of Chemistry* and Zoology†
The University of Texas at Austin, Austin, Texas 78712

The red-sided garter snake, *Thamnophis sirtalis parietalis*, breeds in large aggregations (mating balls) consisting of hundreds of individuals. The females produce a sex attractant pheromone which serves to elicit courtship behavior from conspecific males during the spring breeding season. The pheromone is expressed along the dorsal surface of the female's body, but unlike nearly all insect pheromones, which are volatile, this pheromone is nonvolatile at ambient temperatures found in the field (southern Manitoba, Canada). Males detect and begin to court sexually active females when rapid tongue-flicks deliver the pheromone from the female's dorsal surface to the male's vomeronasal system. We have found that the pheromone is soluble in nonpolar solvents, since hexane washes of the female's back will elicit stereotyped courtship behavior from sexually active males when the solution is applied to moist paper towels. In contrast, garter snake males express on their skin surface a pheromone which will mask the female sex attractant pheromone, thereby inhibiting courtship behavior.

Hexane washes of dead snakes were first filtered and then fractionated on a Cellite column with hexane/ethylacetate, incrementing in 5% steps from 100% hexane to 100% ethylacetate. Each fraction was subjected to both analytical thin-layer chromatography (TLC) [hexane : diethylether : ethylacetate = 125 : 5 : 3] and capillary column [12m BP1 (0.1u film)] GC/MS [Finnigan MAT 4023/4500; 70 eV ionization; 150°C source setting; 250° C injector temp.; 60°C(1min) to 290°C(@10°/min)] and correlated against field behavior trials.

Only one fraction of the female skin lipids (fraction 5) elicited any courtship behavior. That fraction produced a single spot via TLC but at least 12 peaks with GC/MS [**Figure 1A**], encompassing three homologous series of compounds (two major, one minor). Based on the E.I. and C.I. (methane, 0.4mm) spectra [shown for one pair of peaks in **Figure 2**], the compounds were initially determined to be sets of unsaturated wax esters, having chain lengths varying from 26 to 36 carbons. However, high field NMR studies on the mixture and MS studies on synthetic standards proved this incorrect and indicated that the compounds were long chain saturated and unsaturated methyl ketones. Analysis of the male fraction 5 showed the dramatic absence of the major unsaturated series found in the female fraction 5 [**Figure 1B**]. Peaks in **Figure 1** are labeled by the chain length of the hydrocarbon side chain.

It is suggested by the E.I. spectrum of **C31'** that the double bond is located between carbons 5 and 6 (read from the carbonyl). MS/MS studies were thus conducted using a Finnigan MAT TSQ-70 on the protonated molecular ion of **C31'** to verify the double bond site. However, no additional information resulted from the C.I.D. experiments, even though the collision energy was varied from 0 to 200 eV.

With regard to the male inhibitory pheromone, analysis of the other male skin lipid fractions revealed that fraction 2 contained one major component, identified as squalene by the NBS library. Coinjection of an authentic standard with the male fraction 2 confirmed the

identity of this peak as squalene. In field trials squalene was found to inhibit courtship, but only half as well as whole male skin lipid.

We conclude, therefore, that the sex attractiveness pheromone produced by the female is a series of unsaturated methyl ketones ranging from **C29'** to **C35'**. The male red-sided garter snake recognizes this fingerprint pattern is different from the pattern borne by other males. We also conclude that squalene is one of the chemicals produced by the male which inhibits courtship behavior, but it is not the only one.

APPLICATION OF GC/MS IN MONITORING THE ISOLATION AND PURIFICATION OF AN IMMUNOREACTIVE PATHOGENIC FUNGAL PRODUCT.

J.W. Chinn, Jr.*, D. Kruse† and G.T. Cole†
Departments of Chemistry* and Botany†
The University of Texas at Austin, Austin, Texas 78713.

Our earlier investigations have suggested that 3-*O*-methylmannose (3-*O*-MM) is unique to *Coccidioides* among the fungal respiratory pathogens. This methylated sugar has been identified in several immunoreactive wall fractions of *C. immitis*, including an alkali-soluble, water-soluble (ASWS) extract of the conidial wall. The purpose of this study was to determine whether 3-*O*-MM represents the reactive epitope of the diagnostic tube precipitin (TP) antigen of this pathogen.

Crude mycelial culture filtrates of *C. immitis* contain 3-*O*-MM but only in easily detected amounts after 10-20 days growth, at which stage the cells have begun to autolyse. The ASWS fractions of the conidial wall, which contains relatively abundant amounts of 3-*O*-MM, has been shown to consist of three antigenic components, identified by SDS-PAGE as 66kD, 31kD and 19kD polypeptides. One of these fractions has been shown to be the immunoreactive component responsible for human tube precipitin (TP) antibody reactivity, An important reagent used for immunodiagnosis of this respiratory disease. It seemed likely that a correlation may exist between the immunoreactivity of at least one of these components and the presence of 3-*O*-MM.

In this study, we have reexamined the antigenic, carbohydrate, and protein composition of ASWS wall extracts of *C. immitis*. After dialysis, the ASWS product fractionated by solid phase immunoadsorption (SPIA) using a monoclonal antibody to the 66kD component. The unbound fraction of the ASWS extract was further purified by Con A-Sepharose 4B affinity chromatography which binds a 31kD component. The Con A bound fraction was shown to be reactive with human anti-*Coccidioides* tube precipitin (TP) antibody in the standardized immunodiffusion (ID) assay and was further fractionated by HPLC. The 66kD component showed no IDTP reactivity but did contain 3-*O*-MM as shown by gas chromatography/mass spectrometry (GC/MS) using a synthetic methylated sugar standard, while the 31kD component showed only a trace of 3-*O*-MM. The same Con A bound fraction (31kD glycoprotein) was also isolated from the 3-day mycelial culture filtrate, shown to be reactive in the IDTP assay, but lacked 3-*O*-MM, as did the 66kD component isolated form mycelial culture filtrate. Figure 1 summarizes our isolation and analytical procedure.

GC/MS comparison of xylose and 3-*O*-MM standard revealed two peaks for each, with the second peak (in terms of retention time) of xylose overlapping with the first peak of 3-*O*-MM. Since all of the glycoproteins isolated contained xylose, confirmation of the presence of 3-*O*-MM depended upon the use of mass spectrometry to distinguish the two sugars in the chromatograms. Figure 2 shows the mass spectra of xylose and 3-*O*-MM.

We conclude that the methylated mannose-containing poly-saccharide appears to be a structural component of the cell wall of *Coccidioides*. The polysaccharide can be extracted from the walls using 1N NaOH. This same polysaccharide is released naturally from cell walls during autolysis in stationary phase cultures. However, the immunoreactive 66kD, 31kD and 19kD glycoproteins can be isolated from filtrates of logarithmic phase cultures in the absence of 3-*O*-MM. The methylated polysaccharide is not responsible for the specific immunoreactivity demonstrated by the three glycoproteins examined in this study. Instead, we suggest that this unusual polysaccharide mediates natural release of immunoreactive components from the cell wall of *C. immitis* both *in vitro* and *in vivo*.

MASS SPECTROMETRY AS A TOOL FOR THE STUDY OF CHEMICAL REACTIVITY OF PAH RADICAL CATIONS WITH CELLULAR NUCLEOPHILES

E. Davoli[1], R.L. Cerny[2], M.P. Chiarelli[2], and M.L. Gross[2].

(1) "Mario Negri" Pharmacological Research Institute, Via Eritrea 62, Milano, Italy. (2) Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE 68588.

The first step in the carcinogenicity of the stable polynuclear aromatic hydrocarbons (PAHs) is their activation to chemically reactive metabolites. The formation of active arene oxides by the oxigenase enzymes, that occurs principally on the microsomes of the endoplasmic reticulum, is generally accepted. More recently a different pathway in the activation of the PAHs has been proposed. It involves a one-electron oxidation, catalized by peroxidases enzymes, to an active radical cation. There is evidence now for a covalent binding of benzo[a]pyrene (BP) to DNA via a one-electron oxidation during in vitro studies[1]. Chemical reactivity of BP radical cation toward nucleic acids has been proven in solution. The BP radical cation is generally induced electrochemically, by UV irradiation or by one-electron oxidants such as I_2.

We have evidences for their reactivity with nucleophiles in the gas phase: benzene, anthracene and BP readily react with pyridine in a CI source to give a covalently bound adduct (Fig. 1). On the basis of these results the mechanism in Fig. 2 is proposed.

Most of the biochemically important nucleophiles (nucleosides, nucleotides, peptides, etc.) are nonvolatile, therefore research was focussed on 3 different instrumental approaches for studying nonvolatile nucleophiles and/or nonvolatile radical cation sources: FAB, LD FTMS and high pressure FAB.

FAB gave no adducts even if PAH and nucleophiles+H are desorbed together on the same matrix. The presence of the $PAH^{+\cdot}$ and the nucleophile+H^+ indicate that, although both are codesorbed, they do not react together in the FAB selvedge.

LD FTMS: thermal desorption of guanosine (1064 nm laser) and ionization of PAH with a 8 eV electron beam seems to give an adduct formation. When anthracene and pyridine are studied, it seems that the adduct formation is enhanced at high electron energies (35-70 eV).

High pressure FAB: we developed a gas tight FAB source (Fig. 3) in order to increase the number of collisions and/or the collision stabilization of the eventually formed products. The high pressure capabilities have been tested with isobutane (measuring the ratio of *m/z* 57 over 43). Results indicate that the source is even suitable for chemical ionization. However, even at these pressures, no adduct was detected.

Interestingly, the system anthracene/imidazole, which has been shown to be a facile reaction in the CI source, under these conditions forms an ion dipole product, easily identified in the MS/MS spectra by the low energy spread of the peaks.

These results and the FT MS experiments, seem to indicate that the excess internal energy is insufficient to affect covalent bonding.

Future developments might consider the design of a high pressure FAB source with a filament option to raise the internal energies of the reagents.

LSIMS INVESTIGATION OF MAGNETIC RESONANCE IMAGING (MRI) CONTRAST AGENTS: [Gd-EDTA], [Gd-CDTA], [Gd-HEDTA], and [Gd-DTPA].

James L. Grant, D.L. White, and Robert C. Brasch
Contrast Media Laboratory, University of California
San Francisco, CA, 94143

Mass Spectrometry Facility, University of California
San Francisco, CA, 94143

Introduction

The development of Magnetic Resonance Imaging (MRI) as a clinical modality has brought about the need for new, biocompatible drugs, which are used to enhance the image contrast between normal and diseased tissue.[1] Relaxation rates of in vivo water can be affected by stable complexes containing paramagnetic metals, with Gd-complexes being especially effective as image enhancers.[2,3] [Gd-DTPA] is the only contrast agent presently being considered in clinical trials.[4] To improve the efficacy of these monomeric contrast agents, considerable research effort is underway to synthesize a large variety of $[Gd\text{-}DTPA]_n$ (n = 1-50) macromolecular contrast agents (2000-90000 daltons) which would increase the number of [Gd-DTPA] units per dose of agent as well as influence the extracellular or intravascular distribution of the agents due to increasing molecular size.[5],

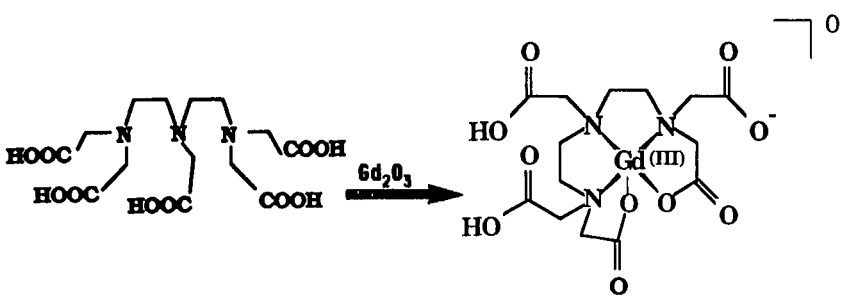
Methods

All Gd-complexes were prepared from commercially available complexing ligands (Aldrich) and Gd_2O_3 (Aldrich) by methods described in the literature.[2] Mass spectra were obtained with a Kratos MS-50S Double Focusing Mass Spectrometer equiped with post-acceleration detection and a Cs^+ ion LSIMS ion source designed in this laboratory.[6] The Cs^+ primary beam energy was approximately 8 keV. A scan rate of 300 s/decade was used, and the resulting spectra were recorded on a Gould ES-1000 electrostatic recorder. The LSIMS matrix was glycerol/diethanolamine in negative mode.

Results and Discussion

LSIMS has proven to be an effective mass spectral technique in obtaining information concerning the identity and purity of these nonvolatile, highly charged monomeric contrast agents: [Gd-EDTA], [Gd-CDTA], [Gd-HEDTA], and [Gd-DTPA]. Dimers (MW 800-1100 daltons) of monomeric contrast agents were also observed in all LSIMS spectra. LSIMS spectra of the starting complexing ligands EDTA, CDTA, HEDTA, and DTPA were also obtained (See Ref. 7 for molecular structures of all complexing ligands), and all spectra correspond to calculated isotope distribution patterns (Fig. 1).

All complexes are structurally related; therefore, only the synthetic route to the [Gd-DTPA] contrast agent, currently undergoing clincal trials, is shown schematically.



DTPA MW 393

$[Gd\text{-}DTPA]^0$ MW 548

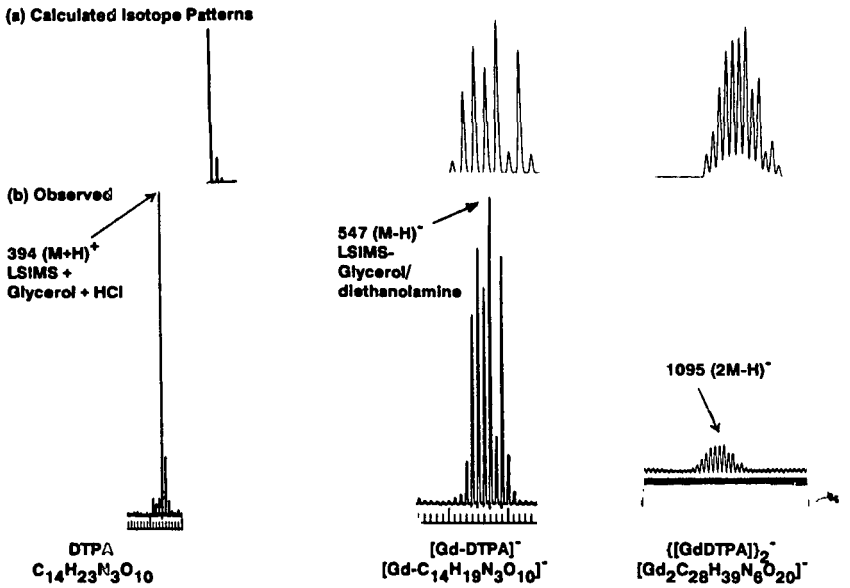


Fig. 1 Calculated (a) and observed (b) mass spectra for complexing ligand DTPA and monomeric [Gd-DTPA] and dimeric $\{[Gd\text{-}DTPA]\}_2$ products (not according to scale).

Works In Progress

Synthetic modification of suitable organic hosts [Cluster contrast agents, e.g.,quinones (1), porphyrins, or Starburst oligomers[8] (2)] permit the covalent attachment of the [Gd-DTPA] moiety at multiple sites on these molecules to produce a large range of $[Gd\text{-}DTPA]_n$-macromolecular contrast agents.

Liquid-Ionization Mass Spectorometry of Bioorganic Compounds Abiotically Synthesized from Simulated Primitive Earth Atmosphers

Kensei Kobayashi, Takeo Kaneko and Masahiko Tsuchiya
Department of Physical Chemistry, Faculty of Engineering
Yokohama National University, Hodogaya-ku, Yokohama 240, Japan

Numerous studies have been reported on abiotic syntheses of compounds of biological importance such as amino acids from simulated primitive earth atmospheres since 1950's. From the mixtures of methane, ammonia (or nitrogen) and water , various amino acids and nucleic acid bases have been reported to be synthesized with such energy sources as spark discharges (1,2). They have been analyzed mainly by chromatography and EI mass spectrometry. The products of abiotic syntheses have, however, so many kinds of components that it is very difficult to detect and to identify trace amount of compounds in them.

Liquid ionization (LI) mass spectrometry is a promising technique to analyze compounds of low volatility in aqueous solution only with simple pretreatments (3). We performed proton irradiation of mixtures of carbon monoxide (or methane), nitrogen and water, simulating an action of cosmic rays, and analyzed the products by LI-MS, and compared the results with those by conventional techniques.

Forty mL of water with some kinds of ions and nitrogen gas mixed with carbon monoxide or methane were introduced into a 420mL Pyrex glass tube (Fig.1). The gas mixture was irradiated with high energy protons (4.0 MeV, 0.8-1.0 μA) generated by a Van de Graaff accelerator at room temperature. After 2.5-5.0 hours' irradiation, the resulting aqueous solution was filtered through membrane filter and concentrated. It was separated into several fractions (reffered as "AA", "NB" and "SG") by adsorption technique with charcoal-celite and/or a cation-exchange resin (Bio-rad AG-50) as shown in Fig. 2. Each fraction was analyzed by LI-MS (JEOL JMS-QH100 with the LI source). Mass spectra were scanned over the range of m/z= 10-400 in 1 second. The scan was repeated 100 times in 5 minutes, while heater current was linearly increased from 0 to 0.75 A. It was also analyzed by ion-exchange chromatography (Irica Automated Amino Acid Analyzer Model A-5500), gas chromatography (Shimadzu Model GC-9A) and gas chromatography combined with mass spectrometry (GC/MS; Shimadzu Model GCMS-QP1000).

An LI mass spectrum of "AA" fraction of the product after 5 hour's irradiation of methane, nitrogen and water is shown in Fig. 3. Peaks at m/z= 76 + 14n (n=0, 1,2,..) were observed to indicate such aliphatic amino acids as glycine (MW=75), alanines (MW=89), aminobutylic acids (MW=103) and so on. Among them, the peak at m/z=118 is predominent. Amino acids in the same fraction were determined by ion-exchange chromatography, and the results are summarized in Table 1. Glycine was the most abundant amino acid product, followed by alanine. The yield of amino acids with 5 carbons (such as valine; MW=117) was far less than that of glycine. Under the present conditions, aliphatic amino acids with higher molecular weights are detected more sensitively than those with lower molecular weights because of their proton affinity. The higher molecular weight an amino acid has, the more isomers there are. They are the reasons why the peak of m/z=118 was higher than m/z=76 or 90.

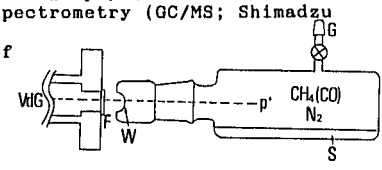

Fig.1. Proton irradiation apparatus. VdG: Van de Graaff accelerator; F: Havar foil; W: concave end window; p^+: proton; G: gas inlet; S: water.

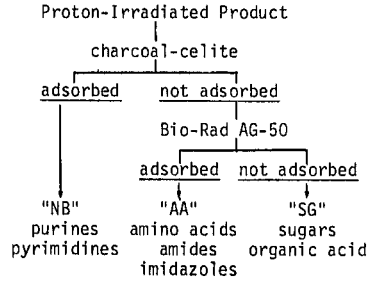

Fig.2. Fractionation of Proton-Irradiated Products.

The peak at m/z=69 was often observed in mass spectra of the "AA" fractions, suggesting some cationic compounds of mass 68, which was plausibly $C_3H_4N_2$. The "AA" fraction was fractionated by HPLC. The fraction with the same retention time as imidazole gave a strong peak at m/z=69 in LI mass spectrum, which fact showed imidazole, a component of histidine, is likely to be abiotically synthesized in the present reactions.

LI mass spectra of the "NB" fraction and the "SG" fraction of the proton-irradiated product are shown in Figs. 4 and 5. The "SG" fraction gave peaks at m/z=(99 + 18n), while the "NB" fraction at m/z= (113 +14n). These compounds have not identified yet, but some of them may be the peaks of nucleic acid components; e.g., uracil gives the peak at m/z=113, and deoxyribose at m/z=99 + 18n. Some nucleic acid bases including uracil have been detected by HPLC. Further identification of these compounds by the combination of HPLC and LI-MS is in progress.

Major amino acids in simulated primitive earth atmosphere experiments have been analyzed chromatography and conventional mass spectrometry. Some bioorganic compounds, which had not been detected by conventional methods, were detected by LI-MS technique. LI-MS can be a useful tool to find new pathways in abiotic syntheses.

SURFACE-ACTIVE REAGENTS FOR INCREASED SPUTTERED ION YIELDS IN BIOMOLECULAR ANALYSIS. Stephen M. Brown and Kenneth L. Busch, Department of Chemistry, Indiana University, Bloomington, IN 47405.

The development of fast atom bombardment in 1981 greatly increased the number of compounds that could be analyzed by mass spectrometry. This "soft" ionization technique made it possible to analyze involatile, thermally labile biological compounds such as steroids, peptides, and proteins.

The usual procedure in FAB is dissolution of the sample in a suitable matrix, ususally glycerol, followed by bombardment with a 2-7 keV beam of energetic atoms. The ions sputtered from the solution into the gas phase are mass-analyzed to produce the SIMS spectrum. One mechanistic model suggests that ionization takes place in a two-step process, (i) the transfer of the sample from the solution into the gas phase, and (ii) ionization of the sample molecules by various reactions, such as protonation to form $(M+H)^+$ or cationization to form, for example, $(M+Na)^+$. FAB mass spectra usually contain a lower abundance of ions such as $(M+H)^+$ and $(M+Na)^+$ relative to intact cations of ammonium, sulfonium, iodonium and other onium salts that exist in the glycerol solution as preformed ions. Therefore, it is usually advantageous to convert the sample molecules to an ionic form prior to FAB analysis. The desorption/ ionization process then takes place in a single step (the sputtering of a preformed ion). This single-step process can be shown to be much more efficient than the two-step process. Also, if the preformed ionic species is present predominantly at the surface of the liquid matrix, i.e. they are surface-active, these species are almost invariably sputtered with even higher efficiency. Therefore, derivatization of neutral molecules to form surface-active, ionic compounds should increase sensitivity by at least an order of magnitude over that of the neutral molecule.

2-Fluoro-N-substituted-pyridinium salts have been shown to derivatize hydroxyl (1), sulfhydryl (2), and primary amino (3) functionalities. Scheme 1 shows the pathway for the derivatization of cysteine with 2-fluoro-N-methyl pyridinium. Figure 1 is the positive ion FAB mass spectrum of that very compound, derivatized cysteine. Cysteine was chosen as a model compound because it possesses both a primary amino and a sulfhydryl group. Not surprisingly, the derivatized intact cation, m/z 213, and its fragments are very abundant. Also, note the two different functionalities were derivatized, evidenced by the ion at m/z 304. This doubly-derivatized ion exists, however, as a singly-charged species.

This derivatization procedure is not only viable for single amino acids, but also for peptide chains. Figure 2 shows the FAB spectrum for Ala-Gly-Ser-Glu derivatized with 2-fluoro-N-methyl pyridinium. Again, two functionalities are able to be derivatized in this molecule.

Although the reagent used, 2-fluoro-N-methyl-pyridinium, imparts a positive charge on the analyte, it shows only a slight increase in surface-activity. Similar derivatizing agents that are specific for the above mentioned functionalities that impart both a charge and surface-activity to the analyte are being developed in this laboratory. The reagents differ from the commercially available methyl pyridinium in the substituent on the N position. The substituents are an octyl group, and a pentafluorobenzyl group. These three pyridinium compounds exhibit varying degrees of reactivity with the molecules of interest, as well as differing amounts of surface-activity in a number of commonly used SIMS matrices. Figure 3 is the positive-ion FAB mass spectra of an equimolar mixture of the methyl- and pentafluorobenzyl-substituted pyridinium salts in glycerol. Notice that the pentafluorobenzyl pyridinium is preferentially sputtered from the matrix. As expected, preliminary results suggest that the octyl substituted pyridinium will be even more surface-active than both the methyl and pentafluorobenzyl substituted salts.

RAPID ANALYSIS OF BIOMOLECULES USING LASER VAPORIZATION, MULTIPHOTON IONIZATION AND TIME-OF-FLIGHT MASS DETECTION

R.Frey, A.Holle, H.Kaminski, G.Weiss, J.Franzen and D.Koch
Bruker-Franzen Analytik GmbH,
Kattenturmer Heerstr. 122, D-2800 Bremen, FRG

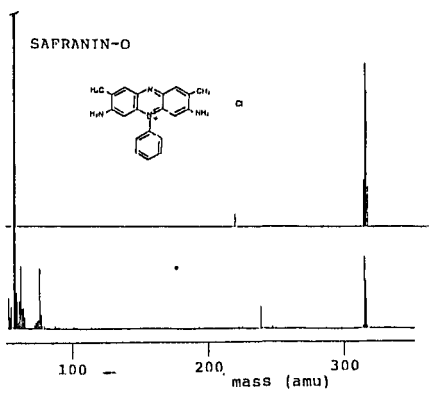
The Bruker TOF 1 Photon Resonance Mass Spectrometer has been used to obtain mass spectra of peptides and other molecules of biological interest. Due to the particular properties of this system the mass spectra of the biomolecules are simple and very easy to interprete.

The system consists of a high resolution time-of-flight mass spectrometer, a new multistage ion source based on resonance-enhanced multiphoton ionization, and an appropriate fast data system (1),(2).
A mass resolution of 10 000 at mass 106 (50 % definition) has been achieved (3) using very short laser pulse duration. Typically, using 5 ns laser pulses a mass resolution of higher than 5 000 holds for the full mass range up to 10 000. This mass range is only limited by the efficiency of the ion detector.

The multistage ion source is characterized by the following steps:

a. desorption of neutral molecules by short IR-laser pulses.
b. cooling of the desorbed molecules and transfer into the ionization region with a cold supersonic jet.
c. resonance-enhanced multiphoton ionization with tunable pulsed laser radiation

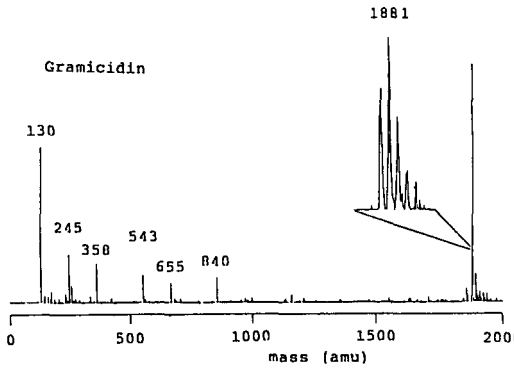
This ionization method provides the possibility to control the degree of the fragmentation which simplifies greatly the molecular weight determination and structure analysis. In the soft ionization mode at moderate laser power, almost only molecular ions are produced. This is illustrated by the mass spectrum of the organic salt safranin-O, see fig. 1 upper curve.

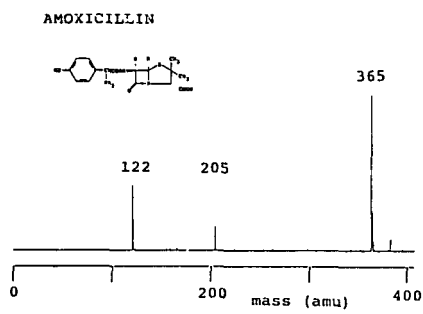


In the hard ionization mode at increased laser power, structure significant fragment masses appear in the spectrum, see fig.1, lower curve. Another example is the spectrum of gramicidin, seen in fig. 2.
In particular these modes of operation represent a unique methode of rapid sequence analysis of peptides (4).

The ability of selective ionization of a single compound of a mixture is another important property of the ion source. This is accomplished

by tuning the laser wavelength to spectral regions where efficient absorption and thus ionization only of this compound occurs. This is illustrated by the spectrum of a methyl-chlorophyllide complex which was taken from a methanol extract of a plant leaf sample.
Further mass spectra are shown covering a broad range of applications: Mass spectra of amoxicillin (see fig. 3), of the steroid testosterone, of clusters of mesoporphyrine dimethyl ester with masses up to 4800 and of the polymer p-polyphenylene.





It is important to note that the method described above involves the desorption and ionization as separated steps with respect to time and space. Each step can singly controlled and adjusted to the substance to be analyzed. In particular the resonance-enhanced multiphoton can thus be applied on those large, nonvolatile and thermally labile molecules, for which its unique features are most valuable.

**Nagoya University School of Medicine, Nagoya 466, Japan

Introduction Since a highly selective, irreversible neurotoxin, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) that induces parkinsonian state in humans, monkeys and mice, was discovered, extensive studies on the search for endogenous or exogenous compounds which induce parkinsonism have been elaborated by many researchers. We screened for the neurotoxicity of various compounds structually related to MPTP by assaying the inhibition of tyrosine hydroxylase system in tissue slices of the mouse striatum (1-3). After screening 1,2,3,4-tetrahydroisoquinoline (TIQ) and N-methyl-1,2,3,4-tetrahydroisoquinoline were proposed as candidates for the possible endogenous neurotoxins. We detected TIQ in parkinsonian and normal human brains as an endogenous compound (4). Repeated administration of TIQ to marmosets produced parkinsonian symptoms with reduction in tyrosine hydroxylase, dopamine and total biopterin concentrations in the substantia nigra (5). To determine if subcutaneously administered TIQ can pass through the blood-brain barrier, and if TIQ can be metabolized in the brain and liver, we analyzed the brains and livers of the TIQ-treated marmosets.

Experimental The parkinsonian human brain was obtained from a patient with Parkinson's disease, and a normal human brain was obtained from a patient with stomach cancer. The brain samples were prepared for GC/MS. The brain was homogenized in perchloric acid containing EDTA and ascorbic acid. The supernatant was transfered to a glass test tube, and the pellet was vortexed with perchloric acid containing EDTA and ascorbic acid, and centrifuged again. The combined supernatant was extracted with diethyl ether. The aqueous phase was adjusted to pH 11 with NaOH and extracted twice with dichloromethane. The organic phase was extracted with HCl solution containing EDTA and ascorbic acid. The aqueous phase was dehydrated over anhydrous sodium sulfate and the filtrate evaporated to dryness with nitrogen stream. The residue was derivatized in ethyl acetate/heptafluorobutyric anhydride (HFBA).

Brains and livers were obtained from 2 saline-treated marmosets and 2 TIQ-treated marmosets. TIQ was injected subcutaneously at a dose of 50 mg/kg for 16 days. TIQ concentration was quantitated in the brains and livers of saline-treated marmosets and TIQ-treated marmosets using d3-/d4-TIQ as an internal standard by GC/MS.

Results and Discussion Figure 1a shows the EI mass spectrum of HFB derivatized TIQ. Figure 1b shows EI mass spectrum of a peak in the gas chromatogram of the HFB derivatized extracts from the parkinsonian human brain. Since figure 1b compound showed identical EI mass spectrum and identical retention time on the gas chromatogram with those of TIQ,figure 1b compound was identified as TIQ. TIQ was also detected in the normal human brain. The identification of TIQ in the parkinsonian and normal human brains was also confirmed by using PFP derivatization.

The concentration of TIQ in the brains of TIQ-treated marmosets, 201 and 149 µg/g wet tissue, were highly increased to the same degree as in the livers of the TIQ-treated marmosets, 296 and 142 µg/g wet tissue, respectively. This suggest that TIQ can pass easily through the blood-brain barrier. Any metabolite of TIQ, such as 1,2-dihydroisoquinoline, could not be detected in the brains and livers of TIQ-treated marmosets.

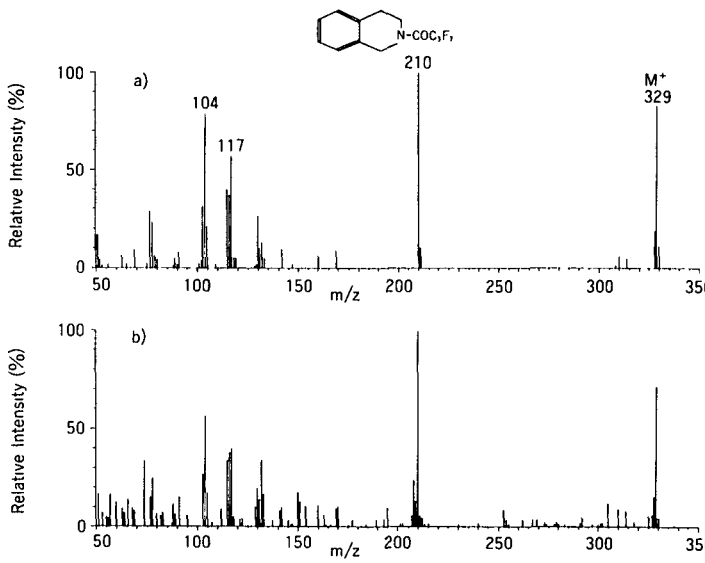

Figure 1 EI mass spectra of the HFB derivative of TIQ (a), and a peak in the gas chromatogram of the HFB derivatized extract from parkinsonian human brain (b).

This suggests that TIQ is not a substrate of monoamine oxidase. TIQ was also detected as an endogenous compound in the brains (0.149 and 0.193 ug/g wet tissues) and livers (0.193 and 0.180 ug /g wet tissue) of saline-treated marmosets at low concentrations.

TIQ injected to marmosets could not be metabolized in the liver and brain, passed easily through the blood-brain barrier, then accumulated in the brain, and produced parkinsonian symptoms with reductions of dopamine and biopterin concentrations, and tyrosine hydroxylase activity. Thus, TIQ may be an important endogenous compound that was demonstrated for the first time to produce an experimental parkinson's disease in monkey.

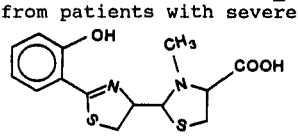
FAST ATOM BOMBARDMENT OF PYOCHELIN COMPLEXES OF IRON AND ZINC: BEHAVIOR OF FE(III) IN FAB MS. Ross C. Beier and Robert D. Stipanovic, Veterinary Toxicology and Entomology Research Laboratory and Southern Crops Research Laboratory, ARS, U.S. Department of Agriculture, College Station, TX 77841-5125.

Introduction. Pyochelin (1) is an iron binding compound, which can be isolated from culture media of *Pseudomonas aeruginosa*.[1] *P. aeruginosa* can cause infections which may be fatal in immunocompromised, cystic fibrosis, and burn patients.[2] Pyochelin increases the lethality of virulent bacteria. Eighteen of 21 isolates of *P. cepacia* which produce pyochelin were obtained from patients with severe infections resulting in 11 deaths.[3]



1

Pyochelin also complexes very well with the Zn(II) ion.[4] The ability of pyochelin to complex so well with Fe^{+3} and Zn^{+2} is intriguing.

Objective. The objectives of this study were three-fold: 1) obtain the FAB MS of the suspect zinc pyochelin complex, and verify the presence of zinc and determine the number of pyochelin molecules in the complex, 2) obtain the FAB MS of the iron pyochelin complex, and determine the oxidation state of the iron, if possible, and determine the number of pyochelin molecules in the complex, and 3) study ion formation, in the FAB mode, of various iron compounds using different matrices, to evaluate the oxidation state of iron in these different complexes and matrices.

Instrumentation. The mass spectrometer used for these FAB measurements was a double-focusing VG 70-250 EHF spectrometer. The instrument is equipped with a saddle-field cold cathode ion gun and used stainless steel targets (6 x 1.5mm). Xenon gas was used as the particle source and the ion gun was adjusted to 8 kV and 1 ma current. Each sample (0.1-1 μg solid) and HOAc was added to 1-2 μl of glycerol on the target. Data was recorded by a VG 11-250 data system.

Results and Discussion. The positive ion FAB mass spectrum of ferripyochelin is shown in Fig. 1. The intense parent ion at m/z 379 contains one molecule of pyochelin and one iron plus a proton (i.e., $[322+Fe+H]^+$).

Fig. 2 shows the positive ion FAB mass spectrum of zinc-pyochelin in HOAc. The parent ion and base peak at m/z 387 contains one molecule of pyochelin and one zinc plus a proton (i.e., $[322+Zn+H]^+$).

The positive ion FAB mass spectra of ferric chloride and ferrous chloride are essentially identical. The only observable iron ion species in both spectra is Fe(II). This result was the same in every matrix or condition attempted.

Results in Table 1 show the major ion produced from FAB ionization of ferric chloride, ferric nitrate, and ferric sulfate in glycerol, thioglycerol or the magic bullet matrix was the Fe(II) ion. In fact, no Fe(III) ions were observed in any attempted conditions, with or without acetic acid.

Iron-pyochelin was determined to contain Fe(III) and not Fe(II) by wet chemical methods.[5]

Conclusion. The FAB mass spectra clearly show that both iron and zinc appear to complex with pyochelin in a 1:1 relationship. It has been earlier indicated from NMR studies that pyochelin exists as two species in solution when complexed with zinc.[4]

FAB mass spectrometry can not be used to determine the presence of Fe(III) ions with typical conditions as used in this study. Every Fe(III) compound ionized by FAB gave rise only to Fe(II) ions. Iron-pyochelin was determined to contain Fe(III) and not Fe(II) by wet chemical methods. However, FAB mass spectra indicated that iron-pyochelin contained Fe(II) ions.

APPLICATION OF MS/MS TO THE ANALYSIS OF BIOLOGICAL MIXTURES

M.Barber, D.J.Bell, M.Morris, L.W.Tetler, M.Woods, UMIST, Sackville St., Manchester, UK. B.W.Bycroft, University of Nottingham, UK. J.J.Monaghan, W E.Morden, ICI C&P Group, Runcorn, UK. B.N.Green, VG Analytical, Manchester, UK.

INTRODUCTION

Many antimicrobial agents produced by bacterial metabolism contain a multiplicity of closely related components.
FABMS often allows identification of the components of such complex mixtures(although one must be aware of suppression effects).We have previously shown [1] that application of MS/MS techniques enables "facile separation" of such mixtures and subsequent structural analysis of the components.

We have applied such techniques to an unknown actinomycin complex [2], the bacitracin complex and nisin [3].

EXPERIMENTAL

Low energy CID was carried out on a VG ZAB-HSQ. High energy CID employed a VG ZAB-4F and a VG 70/70-4SE. MIKES results were obtained on a VG ZAB-SE.

RESULTS AND DISCUSSION

a) Actinomycin (fig.1)
The molecular ion region (fig 2) of a previously unidentified streptomyces strain was shown to exhibit a number of components. Actinomycin D was chosen as the model for fragmentation pathways. Both high and low energy CID were performed, providing complementary information The structures elucidated are shown in table 1. Furthermore, it was found that the cationised species exhibited very different fragmentation patterns.

b) Bacitracin (fig 3)
It was found that the high and low energy CID spectra showed significant differences These differences are energy dependent (fig 4) The significant daughter ions formed at high energy CID are of the W_n type [4], whereas at low energy, the ions are of type Y_n.

Interpretation of the MS/MS spectra for Bacitracin B indicate that each Ile may be replaced by a Val, i.e. there are at least three different, isomeric structures for Bacitracin B.

SUMMARY

(1) A previously unidentified streptomyces strain was characterised employing MS/MS methodology
(2) Ideally, both high and low energy CID spectra are required to enable full structural analysis.
(3) Daughter ion spectra for Bacitracin produced by high energy CID were found to be energy related.

CONSTANT NEUTRAL LOSS SPECTRA OF PEPTIDES

DE PAUW E.*, NASAR K. **, FACCHETTI S. *
* Commission of the European Communities, Joint Research Center, 21020 ISPRA (Varese) ITALY
** Physical Chemistry Department, Liege University, 4000-LIEGE BELGIUM

Secondary ion mass spectrometry of liquids (LSIMS) and fast atom bombardment (FAB) are successfully used for peptide sequencing. However fragmentation patterns are often difficult to interprete in terms of sequence owing to the mixing of both C- and N- terminal specific ions. Daughter ion spectra can help to obtain unambigous information as well as chemical modifications of the sample (matrix doping or derivatization).
In this paper, a strategy is presented, which is designed to monitor specifically C- and N- terminal fragment ions using the so called constant neutral loss scans.

EXPERIMENTAL TECHNIQUE

Peptides are dissolved in glycerol (2 nm/ul) acidified with a slightly surfactant acid.
Two microliters of the solution are deposited on the FAB target and are bombarded by 8 KeV Xe. The spectra are recorded on a VG 70 - 250 SE as well as on a VG 70 - 250 SEQ for comparison.
First field free region linked scans are monitored in the absence of collision gas either as single scans followed by averaging, if needed, or in a *multichannel mode to monitor resolution and peak shape.*
Low mass calibration is performed using a LiCl/glycerol mixture. No difference has been noticed between 1 FFR and 3 FFR spectra.

RESULTS

According to the peptide structure, several specific losses can be foreseen:
a) the loss of H_2O, H_2CO_2 from the carboxylic end
b) the loss of NH_3 from the amino end
c) the loss of CO already detected in normal spectra and occuring from the $B_n \longrightarrow A_n$ transition.

For each peptide, the following set of seven scans is recorded :
a) the normal spectrum
b) the daughter ion spectrum
c) the CNL spectra monitoring the above losses, as well as in addition, the CO_2 scan in negative ion mode.

From this set of spectra, a table including all the major ions is constructed. Structurally significant ions can be identified taking into account rules deduced from the spectra of known peptides.
B_n as well as Y_n ions can be readily identified with the help of the low mass part of the normal spectrum containing iminium ions indicators for the residue composition and after comparison with the daughter ion spectrum.
Two examples of tetrapeptide analysis are given below.
In the first example, the residue composition is known from the iminium ions. The CNL 28 spectrum allows to place GLU and SER in Ct position, GLY being the next suspected one (Fig. 1). The identification of Y" in the CNL 17 spectrum allows full sequence determination, confirmed by the analysis of the normal and daughter ion spectrum.

The same analysis applies in the case of another tetrapeptide analysed as a blind test with the help of VG Manchester Mass Lab. The results were communicated in the following form.

Table 1. Major peaks in the unknown peptide spectra [a,b]

FAB	Daughter ions	CNL 28	CNL 46	CNL 18	CNL 17
427(70)	409(25)	409(15)	427(60)	427(100)	426(82)
217(20)	382(15)	262(13)	318(45)	336(40)	279(55)
197(15)	280(35)	233(17)	223(77)	280(70)	222(60)
181(18)	262(40)	205(100)	178(15)	223(68)	178(50)
120(80)	223(55)	189(13)	166(100)	149(42)	120(100)
91(100)	205(20)	161(12)		121(70)	
	177 *	131(12)			
	166 *	119(15)			
	120 *				

a Peaks originated from the matrix have to be omitted.
b Intensities in brackets (% relative to the base peak).
* Appearing only with collision gas.

The m/3 427 is identified as MH^+. It can lose H_2O and H_2CO_2. The CNL 28 allows to identify the -GLY-PHE CT structure as followed:

427 - 18 = 409 - H_2O
409 - 262 = 147 - Phe
262 - 205 = 57 -GLY

From CNL 18 and 17, M/3 280 and 279 are Y''_3 and Y''_3 candidates. The structure should then be - GLY - GLY - PHE, the last PHE-residue is identified by difference.

CONCLUSIONS

The above results show how the monitoring of neutral losses can help to solve sequencing problems for small peptides. Larger size peptides are currently under study.

For this purpose, an interactive computer program including all the above features has been developed and is actually under testing.

MASS SPECTROMETRY AND HERBAL MEDICINE

LIANG, XIAO-TIAN

Institute of Materia Medica, Nan-wei Road, Beijing 100050, China

Mass spectrometry is well suited for the examination of minute amounts of isolates from natural sources, e.g., herbal drugs of traditional Chinese medicine. In our institute, we have had occasion to make heavy use of this tool in the course of structural elucidation of these isolates.

In this paper, we will give three examples. The last one is actually a toxin, not exactly belonging to herbal medicine.

The relative disposition of the methylenedioxy grouping and the hydroxy group in 1 was determined by close scrutiny of very weak peaks amidst the background continuum (1). Dehydration of 1 gave the expected mixture of three isomeric alkenes. One of the oxidation products thereof is an acid which can be readily separated from the other two ketones. A closely similar natural product with six methoxy groups (identical oxygenation pattern as 1) was treated in the same manner. Subtle but definitive differences of the two acids in fragment ions involving the cleavage of the biphenyl linkage, all with relative intensities below 1%, were invoked to establish the structure of 1.

Recently a series of triterpenoid glycosides (2) were isolated from Stauntonia chinensis DC, a herb prescribed for analgesic purposes (2). The sequencing of the sugar residues was mainly solved by negative FAB MS, coupled with partial alkaline hydrolysis to remove R^2.

The Ke-shan disease is a serious heart disease in a number of rural districts, with the exact causative factor still not fully known. Deficiency of Se in the diet is now considered by many specialists to be of minor importance only. We have suspected toxin(s) in the food and small amounts of moniliformin (3) were actually detected in the grains of the inflicted areas (2). It is of interest to note that p-toluenesulfonylhydrazone (4) displayed the M+2 peak in the EI mode.

SCANNING TLC/SIMS

Yuzo Nakagawa and Kouji Iwatani
Shionogi Research Laboratories
Fukushima-ku, Osaka 553, Japan

The scanning thin-layer chromatography/secondary ion mass spectrometry system (Scanning TLC/SIMS) was newly devised to obtain good separation and good mass spectra of thermally unstable and nonvolatile mixtures [1-4]. The new method was successfully used to analyze drug metabolites and other organic compound mixtures.

EXPERIMENTAL

A sintered glass thin-layer chromatography plate was prepared by heating a mixture of silica gel, fluorescent powder and glass powder on a glass plate which is one of our inventions[3,5,6].

A Hitachi M-68 Mass Spectrometer (equivalent to an M-80 Mass Spectrometer) was used for mass spectrometry measurement. The probe of Scanning TLC/SIMS was designed and constructed by ourselves. A special holder for a thicker plate, such as a glass plate, can be used to retain the plate surface in a suitable position. Driving of the probe is controlled by electric motor.

RESULTS AND DISCUSSION

1. TLC/SIMS (batch process)

The new technique TLC/SIMS enables very simple yet precise measurement of thermally unstable mixture sample [2,3,4].

This technique uses a small strip of TLC plate taken from conventionally developed TLC plate which is TLC aluminum sheet coated with silica gel or our new sintered TLC/MS plate described above, as the primary ion target instead of the usual silver plate. The plate are held by the primary ion target holder of the Liq. SIMS ion source. The sample that collides with the primary ion should be at the same electric voltage as the ionization chamber wall because this electric condition is essential for the ion optics. Chang et al [7] and Iwabuchi et al. [8] also reported the almost same method except the consideration of this electric condition.

Three different target plates, namely a small piece of aluminum sheet, which is the support of the "TLC aluminum sheet silica gel", a small sheet of "TLC aluminum sheet silica gel 60 F_{254}", and a small piece of our sintered glass TLC plate were compared with the usual silver plate as to the sensitivity of the secondary ion. All three targets gave sensitivity of more than 80% sensitivity of that of the silver plate.

The reproducibility and stability of the secondary ion current from the TLC plate gave almost the same results as these from the conventional silver plate, showing that TLC/SIMS can be applied to quantitative analysis using stable isotope labeled internal standard.

No back ground spectra which might interfere with the spectra were found in the mass spectra of TLC/SIMS using silica gel, alumina and cellulose as adsorbent. Reversed phase adsorbent also gave no back ground spectra.

2. Scanning TLC/SIMS

Successive ionization along the chromatogram in TLC/SIMS is very important and was achieved by reconstructing the sample introduction probe, part of the ion source housing and part of the ionization chamber. Movement of the TLC plate, mounted on the TLC/SIMS probe, led to successive collision of the primary ion with the spots to generate secondary ions. The plate drive could be controlled to move at a constant or variable-programmed speed and even to hold at the same position. Schematic diagram of the system is shown in the Fig. 1. Independently of our work, Kushi et al. [9] reported a similar method using the small piece of TLC plate attached to the SIMS target.

A mixture of a new sleep inducer rilmazafone and its metabolites, aminoglycosides in a mixture and many other mixture were also analyzed by Scanning TLC/SIMS, which provided a good chromatogram and mass spectra. A TLC

sintered glass plate also gave good results.

We prepared the reversed phase chromatography plate by processing the normal phase chromatography plate coated on an aluminum sheet, and our sintered TLC plate. Scanning TLC/SIMS of steroids and cephalosporins using reversed phase (RP-8) plate gave good chromatograms with excellent resolutions and mass spectra. In the examples of steroids and cephalosporins, less than 1 ug of sample can give good mass spectra for identification. The spectra from reversed phase TLC plate were more sensitive than those from normal phase TLC plate and, sometimes, from conventional silver plate SIMS. In many drug metabolism experiments, this method was successfully applied.

The limitation of the TLC/SIMS, including batch processing TLC/SIMS, and Scanning TLC/SIMS, are only the cases when the TLC can not separate the mixture and when the conventional SIMS measurement of the pure component sample can not provide the SIMS spectrum. In case sodium ion adducts $[M + Na]^+$ of small amount of sample which can interfere with spectrum analysis, it can be diminished by using our new TLC sintered glass plate.

CONCLUSION

The Scanning TLC/SIMS system can be used to analyze nonvolatile and thermally unstable mixtures in biomedical studies. The chromatograms and mass spectra observed by this system are of excellent quality like those of authentic compounds examined individually observed by the conventional methods. The Scanning TLC/SIMS system is especially excellent for analyzing mixtures of drug metabolites. The handling simplicity and versatility of the systems should make them widely accepted in the biomedical studies, and may even replace GC/MS and LC/MS as powerful tools in life science research.

FAST ATOM BOMBARDMENT MASS SPECTROMETRY OF GLYCOSPHINGOLIPIDS

Charles C. Sweeley[1], Douglas A. Gage[1], Heber Becker[2] and Stephen Ladisch[2]

[1]Department of Biochemistry, Michigan State University, East Lansing, Michigan 48824

[2]Department of Pediatrics and Oncology, UCLA School of Medicine, Los Angeles, California 90024

Mass spectral analysis has long been important in the structural elucidation of derivatized glycosphingolipids using trimethylsilylation, acetylation or permethylation to decrease hydrogen bonding and increase volatility. The development of fast atom bombardment (FAB) techniques for the analysis of underivatized polar molecules has enabled small amounts of glycolipids to be studied, opening up a previously difficult area, the study of tumor cell gangliosides.

Two examples are presented. The first involves the use of this technique to characterize (or to distinguish among) several gangliosides isomeric in their oligosaccharide component. In this study negative FAB MS was used to identify the two major components of the total gangliosides shed from highly tumorigenic murine lymphoma cell lines. The purified total gangliosides from these lines when coinjected with poorly tumorigenic lymphoma cells dramatically increase the amount of tumor formation observed (1). The FAB MS spectrum showed one of the two major components was $GD_{1\alpha}$, NeuAc (α2-3) Gal (β1-3) Neu Ac (α2-6) Gal NAc (β1-4) Gal (β1-4) Glc Cer, with fragments clearly distinguishing it from alternative isomers, GD_{1a} and GD_{1b}. The second major component of the shed gangliosides was the monosialo compound GM_{1b}, Neu Ac (α2-3) Gal (β1-3) Gal NAc (β1-4) Gal (β1-4) Glc Cer. Again, several key fragments indicated the terminal position of the sialic acid residue rather than attachment to the internal galactose as in the isomer GM_1. Examination of the molecular ion region of the negative FAB spectra of these two major components $GD_{1\alpha}$ and GM_{1b}, indicates both are quite heterogeneous in their ceramide composition. Note that the ion at m/z 1735 does not represent an unusually large fatty acyl group-containing ceramide, but rather a thioglycerol adduct to the 24 1 fatty acid-containing species at m/z 1627 (figure 1)

The second example concerns the identification of multiple lipid (ceramide) isomers of GM_2 from human neuroblastoma tumor The ceramide composition of GM_2 from tumor cells differs from that of normal human brain GM_2. In the positive FAB CAD MS/MS spectra of gangliosides, fragments containing the sphingosine moeity (W") are observed which allow the entire ceramide composition to be determined by difference from the ceramide ion (Y_0 or Y_0') (2, 3, 4) The W" sphingosine ion is particularly prominent when the ceramide ion (Y_0 or Y_0') is selected as the parent in the MS/MS experiment. It is also possible to directly determine the acyl group in the ceramide by a negative FAB CAD MS/MS experiment (4). Two fatty acyl group containing fragments (S and T) are produced by CAD of the total ceramide fragment (see figure 2).

A combination of positive and negative FAB CAD MS/MS was used to identify a number of the GM_2 components occurring in neuroblastoma tissue.

EXPERIMENTAL

Gangliosides were isolated and purified by diisoproplyl ether/butanol/water partition and gel filtration, followed by normal phase HPLC and either HPTLC (lymphoma cells) or reverse phase HPLC (neuroblastoma and normal brain GM_2).

Approximately one µl of ganglioside solution in MeOH (1-5nmol/µl) was mixed with 2 µl of matrix (thioglycerol or triethanolamine for negative mode, glycerol/thioglycerol (1:1) for positive mode) on the FAB probe tip. Ions were formed by bombardment with a 6 keV beam of Xe atoms in a JEOL HX-110 double focussing mass spectrometer The accelerating voltage was 10 kV and the resolution was 3000. For CAD MS/MS helium was used the collision gas in a cell located in the first field-free region. The helium pressure was adjusted to reduce the abundance of the precursor ion by 75%. A JEOL DA-5000 data system generated linked scans at constant B/E.

Immunoaffinity Purification - Gas Chromatography - Mass Spectrometric Analysis of Prostaglandins and Thromboxanes

D.R. Knapp and J.J. Vrbanac

Department of Pharmacology, Medical University of South Carolina
Charleston, S.C. 29425

Prostaglandins and thromboxanes play an important role in regulating vascular tone and platelet aggregation and appear to be important in the pathophysiology of cardiovascular diseases and shock. Much of the biological work in this area relies upon radioimmunoassay analyses, but GC-MS is regarded as the benchmark method for analysis of these lipids. Although the application of GC-MS to prostaglandin quantitation dates back nearly 20 years, the methods are still not widely utilized by biological investigators, due partly to the technological barrier of mass spectrometry and partly to the difficulties of sample preparation. We have sought to enable wider utilization of GM-MS methods in this field of biology via simplification of the methodology and utilization of simpler, less expensive GC-MS instrumentation. In efforts to simplify sample preparation we have employed immobilized antibodies to isolate these lipids from biological samples. The first reported application of immunoaffinity extraction in conjunction with mass spectrometric analysis employed a batch extraction of estradiol-17β by antibodies bound to cyanogen bromide activated microcellulose (1). Krause, et al. (2) utilized cyanogen bromide activated Sepharose 4B in a column procedure to extract Iloprost®, a stable prostaglandin analog. We have employed antibodies immobilized on silica gel and on agarose in the GC-MS analysis of thrombaxane B_2 (TXB_2)(3), 6-keto-prostaglandin $F_{1\alpha}$ (6K-$PGF_{1\alpha}$)(4), and prostaglandin E_2 (5). Cross reactivity of the antibodies to TXB_2 and 6K-$PGF_{1\alpha}$ to their respective dinor metabolites has been exploited to quantitate the parent compounds and dinor metabolites in the same procedure (6,7).

The technological barrier to employing a biological tool such as immobilized antibodies should not deter the mass spectrometrist. Numerous books on immunoassay methods (e.g. 8) are available as information sources on antibody production. Most institutions have scientists experienced in antibody production who could give advice, and animal care personnel can provide all aspects of dealing with the antibody producing animals. The essentials of antibody production, immobilization, and application are given below.

Small molecules such as prostaglandins must be conjugated to a larger molecule to elicit an immune response. The prostaglandin carboxyl group can be activated as a mixed anhydride with isobutyl chloroformate to couple to free amino groups on a carrier protein such as bovine serum albumin or keyhole limpet hemocyanin. The resulting conjugated antigen is emulsified with Freund's adjuvant and used to immunize rabbits at monthly intervals. Blood collected from the rabbits a week following immunization is allowed to clot at 4°C to yield antiserum. Antisera must be "titred" to determine the amount of antibody present. This is most simply done by adding radiolabeled analyte to series of dilutious of the serum followed by separation of the free analyte from that bound to the antibodies using dextran coated charcoal. Scintillation counting of the separated forms of the analyte is used to determine the percent bound and therefrom the serum dilution which binds 50% of a standard amount added (the "titre"). A titre of at least 1:1000 is generally needed for production of immobilized antibodies. The antibodies are isolated from the antiserum using an affinity column of commerically available immobilized protein-A. The serum is diluted with buffer and applied to the protein-A column, the column is washed with buffer, and the immunoglobulin G fraction eluted with acetic acid. The eluate is lyophilized and the antibodies coupled to a commercially available N-hydroxysuccinimyl activated carboxy substituted agarose (Affi-Gel 10®). The immobilized antibodies are then packed into columns with 1-2 ml of the gel per column.

Although biological samples can be applied directly to the columns, for prostaglandin analysis, we have found it advantageous to precede the immunoaffinity extraction with an ODS cartridge extraction. After washing, the ODS cartridge is eluted with ethyl acetate, and eluent dried, dissolved in buffer,

and applied to the immunoaffinity column. After washing the column with buffer and water, the analytes are eluted with 95% acetonitrile in water. The extracted prostaglandins are derivatized as the methoxime, pentafluorobenzyl ester, silyl ether derivatives and analyzed by gas chromatography-negative ion chemical ionization spectrometry-selected ion monitoring. Although TMS ethers are most commonly used, we have found the TBDMS ether useful to resolve 6-keto-$PGF_{1\alpha}$ from a commonly encountered interference. The figure below shows a typical urine analysis using this procedure.

The work on prostaglandins and thromboxanes as endogenous signal molecules is now evolving to study of the receptors for these signals. In collaboration with P.V. Halushka who is isolating and purifying thromboxane receptors, we are working toward the application of mass spectrometry to study of the receptor structure. Since the thromboxane receptor is believed to be of the rhodopsin class, we are beginning this work, with S. Martin and R. Crouch, with studies on the rhodopsin receptor model protein bacteriorhodopsin. Using photoaffinity labeled retinal analogs we are seeking to learn about the movements in bacteriorhodopsin associated with signal tranduction and lay the groundwork for the study of the thromboxane receptor as well as other receptors of the thromboxane class.

Supported in part by N.I.H. grants RR 01239 and HL 29566.

The Importance of High Abundance Sensitivity in Thermal Ionisation Mass Spectrometry used for the Measurement of very low abundance Isotopes.

P J Turner VG Isotopes, Winsford, UK

It is necessary in some isotope systems to be able to measure as accurately as possible the abundance of certain minor isotopes which may be in close proximity to major components in the system. Examples of this are the measurement of the thorium 230/232 ratio in uranium-thorium disequilibrium studies where the ^{230}Th ion beam is typically a few ppm of the ^{232}Th beam or the measurement of 234/238 and 236/238 ratios in uranium samples. The thorium data is used for dating oceanic processes whilst the uranium data is used for monitoring burn-up history of fuel in the nuclear power industry.

The ability of the mass spectrometer to make these measurements depends not only on the abundance sensitivity of the instrument but also on the dynamic range of the measuring system. The abundance sensitivity of a mass spectrometer is usually defined as the ratio of the height of the tail of the peak at unit mass separation from the peak to the height of the peak itself. In a thermal ionisation isotope mass spectrometer with a 30cm radius analyser magnet the abundance sensitivity will typically be a few ppm.Tailing is symmetric on both high mass and low mass sides of the peak and is found to be directly proportional to analyser residual pressure.

Measurements are conveniently carried out using the NBS U005 or U010 uranium isotope standards and figure 1 shows a scan of the uranium spectrum from 233 to 237.5 with a mass spectrometer abundance sensitivity of approx 2ppm. Measurement was carried out on a Daly Multiplier system operating in analogue mode on a VG354 mass spectrometer.

The main mechanism contributing to tailing is inelastic scattering of ions by collision with residual gas atoms in the analyser, although there may also be a small contribution from scattering processes in the ion source.

The abundance sensitivity may be very substantially improved by adding an electrostatic analyser to the ion optical system in a double focussing configuration. This has been done in the VG54-38 mass spectrometer (fig 3) where the parameters have been chosen such that not only is the system double focussing (in terms of angle and energy) but is also close to stigmatic. The intermediate slit is 0.7mm wide, the final slit is 0.9mm wide which provides a flat topped peak mode of operation at approx 400 resolving power in mass and 240 resolving power in energy.

Transmission in the two-sector instrument is the same as that in the single focussing instrument, and the abundance sensitivity is improved to better than 0.1ppm. With this level of performance low levels of hydrocarbons (mass positive wrt the metal ion) and low

levels of K_6^+ ions (mass negative wrt the metal ion) can be readily detected. This emphasises the importance of clean preparation methods if reliable results are to be obtained.

With the 54-38 mass spectrometer in its basic form it is only possible to analyse one ion beam at any given time so that isotope ratio measurements may only be carried out in the single collector peak hopping mode. There is not enough physical space to transmit more than one ion beam through the electrostatic sector, but it is possible to add additional Faraday collectors at the intermediate focal point. This arrangement is shown in figure 6. Since the dispersion length is only 325mm it is not possible to have collectors operating at unit mass separation at uranium. It is however possible to operate at two unit mass separation so that, for example, the ratio 236/238 may be measured in the static (non-peak-hopping) mode.

With this arrangement it is possible to measure very large dynamic range isotope ratios without the necessity of having an intermediate abundance isotope available. Calibration is carried out by peak switching a beam of appropriate size between the Faraday collector at the intermediate focus and the multiplier collector at the final focal point. The dynamic range of the measuring system in this mode may be in excess of 10 orders of magnitude depending on the value of the measuring resistor which is chosen for the intermediate Faraday collectors.

Results from a direct 236/238 ratio measurement are shown in figure 8. Reproducibility is better than +/- 1% using the analogue system, and better than +/- 0.3% if a pulse counting system is used.

For full multiple collection in the double focussing mode, it is necessary to use a forward geometry Nier-Johnson configuration, and this has now been constructed and designated ISOLAB 54. The dispersion length with this arrangement of components is 540mm, so that the established VG Multicollector system may be used, providing unit mass separation at uranium. This system is shown in figure 9. It is particularly suitable for measuring ratios on ion beams produced from an energetic ion source which may also be temporally unstable. However since the magnetic sector is now the second stage of the mass spectrometer, there is no filtering against scattered particles. The abundance sensitivity follows the same analyser pressure dependency as it does for the single focussing analyser, but an overall substantial improvement is still possible since the electrostatic sector can be used as an additional differential pumping stage between the source and the magnetic analyser.

The final magnetic stage can be operated in the 10^{-10} torr range resulting in an abundance sensitivity better than 0.5ppm. This is shown in figure 10.
It would be possible to add a second 38cm radius filter to this system on the axial collector position to further improve the abundance sensitivity while retaining full multiple collector operation.

ISOTOPE RATIO MEASUREMENTS BY TOTAL SAMPLE VOLATILIZATION AND SIGNAL INTEGRATION UTILIZING A MULTICOLLECTOR SYSTEM

E. L. Callis and Robert M. Abernathey
Los Alamos National Laboratory
Los Alamos, NM 87545

In thermal ionization mass spectrometry, observed ratios must normally be corrected for fractionation introduced by the evaporation process. Because the composition of the sample remaining on the filament, and hence the observed ratios, is constantly changing throughout the analysis, carefully controlled and reproducible conditions must be applied to both sample and standard to achieve accurate results. Typically, only a small fraction, 10% to 50%, of the sample is volatilized.

It has long been theorized that the effects of fractionation should be virtually eliminated by evaporation of the entire sample while integrating the signal from each isotope over the life of the sample. The availability of commercial multicollector instrumentation now makes this an attractive alternative to conventional techniques.

Experimental: A VG-354 mass spectrometer, equipped with five Faraday collectors and a Daly detector ion-counting system was employed in this work. All analyses were performed using multiple-filament geometry in which sample evaporation and ionization can be controlled independently. The instrument software was modified to perform the analyses in the following manner. While holding the sample filament current at zero, the ionizing filament is brought to operating temperature by monitoring the ^{187}Re intensity. The element peaks are next located and the total beam intensity is set to 10^{-14} A using the ion-counting system. Use of the ion-counting system at this stage, while not essential, minimizes the consumption of sample before initiation of the integration. After the peaks have been located and focusing has been completed, the Daly system is turned off, Faraday amplifier zeroes are measured, and the integration/current ramp is started. Before each 5-second integration period, the sample filament current is incremented in steps of 20 to 100 mA, depending on the present beam intensity. The maximum beam intensity is controlled roughly between 6×10^{-11} and 7×10^{-11} A by suspending the current ramp when the intensity is within these limits. Because all isotopes are collected simultaneously, no attempt is made to obtain a stable beam. The integration/current ramp continues until sample exhaustion ($<10^{-13}$ A intensity). A second set of amplifier zeroes is measured at the end of the analysis.

Results and Discussion: Results obtained on uranium and plutonium standards are shown in Table 1. These data have been corrected only for relative collector efficiencies, which are determined in a separate experiment by cycling a single ion beam, ^{238}U for example, onto each collector in turn. These data indicate that within the uncertainty limits of the standards, "true" or unfractionated ratios are obtained. In addition, the between-run precision using the total integration technique is typically <0.02% RSD, which represents an improvement over all but the most carefully made nonnormalized measurements using conventional techniques.

The amount of sample loaded in these experiments was typically 10 ng plutonium and 100 ng uranium. With 10^{11} Ω input resistors, these sample sizes yield integrated intensities of approximately 10 V-min for plutonium and 50 V-min for uranium. Although much smaller samples can be analyzed, some degradation of the minor isotope measurement should be expected.

The results on uranium and plutonium are very encouraging. However, much work remains in evaluating various effects of the vaporization and ionization processes, especially for elements not so well behaved as uranium and plutonium, to determine the degree to which absolute measurements can be approached by this technique.

Acknowledgment: Work performed under the auspices of the U.S. Department of Energy.

The users of thermal ionization mass spectrometry are increasingly concentrating on higher accuracy and, at the same time, on smaller and smaller sample loads. Stringent transportation regulations combined with increasing levels of radioactivity in reprocessed fuels demand that nuclear analysts be able to accurately analyze sub nanoCurie samples of uranium and plutonium (i.e.<10 ng U and <1 ng Pu). Similarly, geochronologists and geochemists now require Pb measurements from single zircon crystals that contain less than 1 ng total lead (1,2) and Sr measurements from small crystalline domains or from fluid inclusions (less than 1 ng of total strontium). Isotope ratios of greater than 150,000 for $^{232}Th/^{230}Th$ and greater than 20,000 for $^{238}U/^{234}U$ need to be accurately measured by simultaneous SEM ion counting/Faraday multiple ion collection to apply the uranium/thorium disequilibrium method for precise measurement of time over the past million of years,

In nuclear applications, simultaneous Faraday cup ion multicollection, combined with flash evaporation of <1 ng Pu or <5 ng U, samples produce accuracies comparable to previous techniques requiring a factor of 100 larger samples. Sample fractionation can be neglected as all ions from a totally consumed sample are integrated simultaneously, Additionally, sample throughput can be drastically increased, as a single sample can be measured in 10 to 12 minutes, to a rate of 5 to 6 per hour.

Ion counting a minor isotope peak simultaneously with Faraday cup measurement of the major isotope(s), further improves the precision that can be obtained with small samples. The ionization efficiency for uranium is about a factor of 10 less than that of plutonium. Thus, ion counting employed on small uranium samples (less than 2 ng) provides the same precision that multiple Faraday ion collection achieves for similar size plutonium samples (Fig. 1 and Fig. 2).

Advances in geochronology and geochemistry have traditionally driven and have been driven by advances in instrumentation. Thermal ionization mass spectrometry, employing simultaneous multiple collection of several ion beams has not only changed the "state-of-the-art" in terms of sample size and data precision. The simultaneous use of SEM (analog detection) or SEM (ion counting) with multiple Faraday collection has dramatically improved the capabilities for precise measurement of extremely large

isotope ratios, even when measured on small samples. Radiogenic lead samples, with $^{206}Pb/^{204}Pb$ ratios ranging from 250 to 30,000, have been accurately measured on samples containing less than 1 ng total Pb and less than 0.1 pg ^{204}Pb (3). Geochronologists employing the uranium/thorium disequilibrium method require the measurement of extreme isotope ratios on small samples. Less than 1 ng of thorium having a $^{232}Th/^{230}Th$ isotope ratio of >150,000 has been measured to better than ± 0.5 % relative, in "mixed multicollection mode" with a SEM (ion counting) registering the minor isotope beam.

NEUTRON ACTIVATION AND MASS SPECTROMETRIC MEASUREMENT OF IODINE-129

R. S. Strebin, Jr., F. P. Brauer, J. H. Kaye,
M. S. Rapids and J. J. Stoffel(s)

Pacific Northwest Laboratory*
Richland, Washington 99352

An integrated procedure has been developed at our laboratory for measure -ment of iodine-129 by neutron activation analysis and mass spectrometry. Work has been completed on procedures for extracting iodine from environmental materials in a form and purity suitable for analysis by both methods. Steps in the sample processing include spiking with iodine-125 for yield and isotope dilution measurements; combustion in oxygen; adsorption on charcoal; iodine separation by either CCl_4 extraction or gas-phase hydrated manganese dioxide separation; and precipitation as silver iodide for filament loading.

Negative surface ionization is used in a triple filament arrangement to produce I^- ions with high efficiency. At an ionizer brightness temperature of 1000 C, stable nanoampere currents of mass analyzed iodine ions are consistently produced from 100-ng samples of silver iodide. The overall sample efficiency averages 1%; that is, 1% of the iodine atoms loaded are measured as I^- ions.

Mass spectrometric analysis is performed with a computer-controlled, three-stage mass spectrometer (see figure), which provides an abundance sensitivity better than 10^{-12} for the measurement of I-129 relative to natural I-127. The spectrometer is equipped with a dual detector system to measure the large isotope ratios encountered in environmental samples. An electron multiplier operated in the pulse-counting mode measures the I-129 signal at the exit of the third stage. A Faraday collector located in the focal plane of the first stage simultaneously determines the I-127 intensity by direct-current measurement. The I-125 spike is measured by the electron multiplier as are adjacent masses used to check for interferences and impurities. The sample solution remaining is processed further for neutron activation analysis.

A variety of reference standards and environmental sample materials have been analyzed in replicate by the integrated procedure. Agreement has been achieved down to the measurement limit of about 10^7 atoms or 2×10^{-15} g of I-129. For neutron activation analysis, this value defines the inherent limit of the measurement method. For mass spectrometry, however, this value defines only the current state-of-the-art. Continued development may extend this limit by one or more orders of magnitude.

RESONANCE IONIZATION MASS SPECTROMETRY OF PROMETHIUM

D. H. Smith, R. W. Shaw, and J. P. Young
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

Promethium is difficult to analyze mass spectrometrically because of isobaric interferences from neodymium and samarium. This situation arises because promethium, unique among the lanthanides, has no naturally occurring isotopes. It is synthesized in a reactor by neutron capture from samarium starting material. The longest lived promethium isotope is 145, which has a 17.7-year half-life. All of the promethium isotopes whose half-lives are long enough to allow measurement of the properties of the element decay in one of two ways, both of which give rise to isobaric interference. Some decay via beta emission to produce the samarium isotope of the same mass as the promethium. Others decay via electron capture or positron emission to produce the neodymium isotope of the same mass as the original promethium. Efforts to analyze promethium using thermal ionization have failed to achieve adequate separation of the three elements,[1] and it was decided to investigate resonance ionization mass spectrometry (RIMS) for this purpose.

A tunable, flashlamp-pumped dye laser was interfaced to a mass spectrometer comprised of a single magnetic 90-degree sector of 30 cm. radius.[2] Rhodamine 6G dye was used, and pulses with energies of about 2 mJ were produced. The laser was focused so that ion formation occurred at the object focal point of the mass spectrometer's ion source. A neutral plume of atoms was obtained from a heated rhenium filament to which had been added a small chip of charcoal; temperatures of this filament were about 1400 degrees C. The charcoal provided a reducing atmosphere that encouraged evaporation of the analytes as neutral atoms. Much care was expended to achieve maximum overlap of the neutral analyte plume and the ionizing laser beam. Samarium and promethium were loaded onto the charcoal as dilute nitric acid solutions. Optical spectra were obtained by focusing on one isotope and scanning over the range of the dye, using the mass spectrometer as the detector. Each element was ionized by a single-color, three-photon process: successive resonant absorption of two photons of essentially the same wavelength brings the atom close enough to the ionization limit that non-resonant absorption of a third photon causes ionization.

The resonance ionization spectra for a limited region are shown in the figure. Trace A was acquired from a loading of 600 ng of samarium of natural isotopic abundance; the most abundant samarium isotope (152) was monitored. It is extremely unlikely promethium was present as the half-life of 152-Pm is 18 minutes. The lines at 587.55 and 587.8 are among the strongest samarium transitions in the range of R6G dye. Wavelength was calibrated using mercury emission lines; accuracy is better than 0.1 nm. Trace B (shaded) was obtained after adding 100 ng of promethium to the filament and is thus comprised of contributions from both elements. Note the strong doublet at 584.6 and 585.0; these are the strongest promethium transitions within the dye range. Note, too, that both the promethium and samarium transitions are entirely free of interference from contributions from the other element. We measured an elemental selectivity of 1000:1 for Pm/Sm at the 584.6 transition. The actual selectivity is undoubtedly greater as the number quoted is limited by counting statistics.

Earlier work has shown that the nearest neodymium transitions lie 0.7 nm on either side of the 584.6 transition.[3] It will thus be possible to analyze any one of the three elements from any combination of them. The only question that remains unresolved is that of isotopic bias in isotope ratio measurements using resonant three-photon ionization processes. This is an important issue that transcends this particular application.

FOURIER TRANSFORM MASS SPECTROMETRY FOR ELEMENTAL ISOTOPE RATIO DETERMINATION AND QUANTITATIVE ANALYSIS

J. T. Brenna and W. R. Creasy
IBM Corporation, D/T43
1701 North Street
Endicott, New York 13760

Quantitative isotopic and elemental analysis is a common goal for microprobe analyses. Though quantitative analysis is routinely achieved by microprobe mass spectrometers based on conventional mass dispersion systems (quad, TOF, magnetic sector), there is a wide variety of specimen types which do not easily lend themselves to quantitative analysis. Often selectivity, in the form of mass resolution or the inability to perform multiple stage MS, is inadequate to remove interferences from the peaks of interest.

FTMS has established itself as capable of selectivity unparalleled by other mass spec techniques. Recently we have assembled a laser microprobe system for FTMS (1). We report here some of our investigations of the instrument's capabilities as a quantitative tool. The goal for this work is to identify optimum analysis conditions and experimental parameters while establishing practical limits for critical figures-of-merit such as precision and accuracy. Our strategy is to work from simplest analysis to most complex systems. These studies serve as a benchmark toward an eventual goal of quantitative molecular microprobe analysis.

All analyses were performed with a Nicolet FTMS-2000 system, with a home built laser microprobe interfaced to the mass spectrometer. The laser was operated at 266 nm, and fluence at the surface is estimated to 10^8 J/cm^2. All analyses, including ultra-high mass resolution studies, were performed in the source cell, with no ion transfer to the analyzer cell.

Repetitive gas phase spectra of $Mo(CO)_6$ and $Cr(CO)_6$ were acquired and analyzed for reproducibility of isotopes ratios in the elemental sections of the spectra. Reproducibility of 1% (rel. std. dev.(RSD)) for Mo and 5% for Cr, representative of major and minor isotopes respectively, were obtained for single EI scans. RSD's of a factor of 8 smaller than these values were obtained for spectra of 200 co-added scans.

The effect of apodization function on RSD's of identical transients was determined. The following functions were evaluated for their effect on RSD's: No apodization, Hanning, Kaiser-Bessel, Kaiser-Bessel 4-term, Blackman-Harris 3-term and 4-term, and Noest-Kort. A series of transients was acquired, apodized by each function, Fourier transformed, and evaluated for RSD. For both major and minor isotopes, the Noest-Kort function provides superior reproducibility to the other functions studied. For minor isotopes, RSD's are smaller by 30%.

We have previously observed fast damping of transients acquired from specimens of polymers analyzed under ablative conditions. This phenomenon has precluded ultra-high mass resolution analysis of these specimens. However, we have been able to generate long-lived transients from Pb wire, and ultra-high mass resolution is demonstrated for laser ablated Pb metal. Transients lasting in excess of 10 s were acquired in the source cell of the instrument. Mass resolution of 4×10^5 was acquired from apodized, Fourier transform transients.

Reproducibility of isotopic and elemental ratios from ablated species was examined with NBS isotopic standards. NBS lead standard yields reproducibility in the 10% range (single shot). NBS microprobe standard glasses yield reproducibility in the 30-40% range for certified major elements. These values are in the range of published values for quantitative analysis of similar specimens by commercial TOF-based laser microprobe mass spectrometers. In addition, the spectra show similarities to published spectra acquired on TOF systems.

STUDIES OF SPUTTERING IN GLOW DISCHARGE MASS SPECTROMETRY: C.M. Barshick and W.W. Harrison, University of Virginia, Charlottesville, Va. 22901. USA.

INTRODUCTION

The continued growth of glow discharge mass spectrometry (GDMS) has required a reevaluation of the fundamentals of the glow discharge with regard to the optimization of analytical results. The glow discharge is comprised of a multistep process of sputter-atomization, thermalization, and ionization. While these have been reviewed in some detail, little has been done to characterize the role of sputtering in GDMS. The sputter process is critical, since it is this initial step whereby target atoms are ejected from the cathode surface before being ionized and eventually detected by the mass spectrometer.

While sputter yields are known to vary by a factor of 2-3 across the periodic table, it is still unclear how they vary overall as a function of ion energy, and pressure. In addition, previous investigations have shown that the sputter rate varies with the mass and energy of the bombarding ion, but the exact manner in which it varies is still unclear. The present investigations center on the correlation between sputtering of an atomic population and subsequent detection of an ionic population as a function of (a) the mass and energy of the incident ions and (b) the pressure of the discharge. The results of these investigations are the basis of this paper.

EXPERIMENTAL

The glow discharge mass spectrometer system used for these studies is quadrupole based. The glow discharge ion source takes the form of a 1.0 mm diameter iron coaxial cathode fitted on the end of a direct insertion probe. Ions are sampled from the negative glow region through a 0.5 mm orifice into an einzel lens system that focuses the ion beam into a Bessel-box energy analyzer mounted on the quadrupole mass filter. A DEC-MINC-11/23 microcomputer controls mass scanning and data acquisition, and the ion signal is collected and converted into a form suitable for computer processing by a Princeton Applied Research Model #112 ion counter/processor.

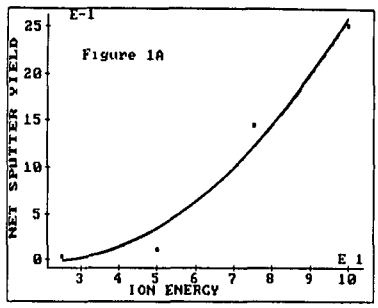
Subsequent net sputter yield data were obtained by sputter weight loss measurements. Samples were weighed on a Sartorius-Werke microanalytical balance, sputtered for one hour and then reweighed. The following expressions were used to calculate the net sputter yield (atoms/ion):

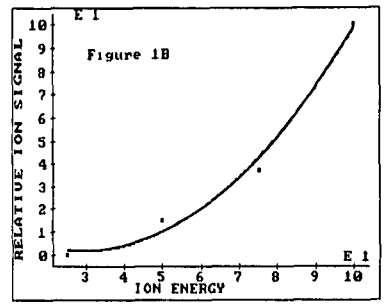
$$Y = 10^5 \, [W/ \, (M \, i^+ \, t)]$$
$$i^+ = i/(1 + \gamma)$$

where W is weight loss in grams, M is atomic weight, i^+ is ion current in amperes, t is sputter time in seconds, i is total current in amperes, and γ is the secondary electron fraction.

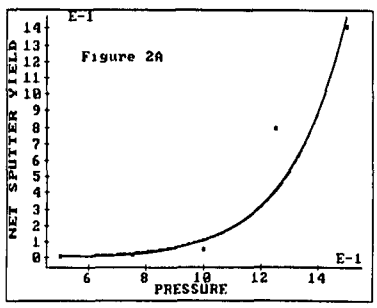
RESULTS AND DISCUSSION

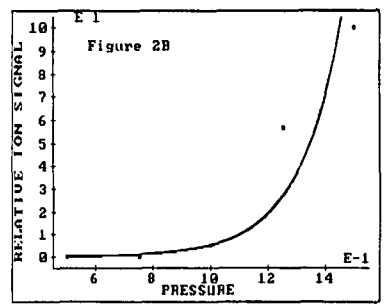
Ion energy. The effect of ion energy was studied using an argon discharge run at a constant pressure of 1.0 torr. The voltage was varied to obtain the desired energy of incident ions, as per Davis and Vanderslice (1). Results of net sputter yield vs ion energy are illustrated in Figure 1A. The sharp increase in slope at 50 eV is attributed to a pressure dependent threshold for sputtering, and is similar to results seen in high vacuum ion beam studies. Similarly, Figure 1B is a plot of relative ion signal vs ion energy. The fact that the two curves mimic one another shows that the ion signal detected is directly affected by the sputtered atomic population. The small range of ion energies studied in this investigation is the result of the inability of the instrument to detect ion signals when the incident sputtering energies are below 25 eV, and overheating of the cathode material when the energies are above 100 eV.





Pressure. The effect of pressure was studied using an argon discharge run at a constant 50 eV ion energy. In this manner, the pressure dependent nature of the threshold energy could be determined. Figure 2A and 2B show the effect of pressure on the net sputter yield and relative ion signals, respectively. The curves increase over the entire range investigated with a threshold at a pressure of 1.0 torr. While larger ion signals appear to be obtainable beyond the range of pressures investigated, limitations in the ability to differentially-pump the ion source preclude operating beyond 1.5 torr.





Discharge gas. The effect of varying discharge gas species was studied at a constant pressure of 1.0 torr and bombarding ion energy of 50 eV. Figure 3A and 3B are plots of net sputter yield vs projectile mass, and relative ion signal vs projectile mass, respectively. The data show a maximum at a target-projectile mass ratio of $M_2/M_1 \simeq 1$, a result similar to those observed in ion beam studies.

COLLISION-INDUCED DISSOCIATION OF MOLECULAR IONS IN GLOW DISCHARGE MASS SPECTROMETRY (CID-GDMS).

F. L. King and W. W. Harrison, University of Virginia, Charlottesville, VA 22901.

INTRODUCTION

Glow discharge mass spectrometry (GDMS) is gaining wide acceptance as a viable technique for the direct elemental analysis of solids and is perceived as having certain advantages over competing techniques. The problem of isobaric interferences due to polyatomic ions has evolved as the principle hindrance to quadrupole based GDMS. Common approaches taken in the circumvention of this problem in elemental MS are the utilization of high resolution instrumentation, the selection of alternative isotopes for analysis, and the implementation of an expert data system to correct for the interferences. The latter two solutions are employed with varying degrees of success in inductively coupled plasma mass spectrometry (ICP-MS) utilizing quadrupole mass analyzers exclusively. Recently, this laboratory has undertaken investigations aimed at the elimination of polyatomic interferences, rather than simply their compensation.

A glow discharge ion source was installed on a triple quadrupole mass spectrometer to facilitate the investigation of collision-induced dissociation (CID) for the removal of polyatomic ions from the ion beam prior to mass analysis. Additionally, the application of various tandem mass spectrometry (MS/MS) techniques to GDMS permitted investigations of the isobaric interferences not previously possible. Such investigations are shown to provide results of fundamental as well as analytical interest. The investigations reported on here show the removal of molecular interferences by CID, the identification of ion composition from daughter spectra, and the prediction of interfered m/z from parent spectra.

RESULTS AND DISCUSSION

Analytical Response. A concern in employing CID was the effect on ion transmission efficiency due to increases in scattering in the collision cell at higher pressures. Table I demonstrates the effect of scattering on the sensitivities of selected species as a function of collision cell pressure. One compensating feature is that the noise level is also reduced by the collision cell, so that although the sensitivity worsens by an average factor of 7 at the highest pressure of 2.4 mtorr, the detection limits only suffer by an average factor of 3. The negative influence on sensitivity and detection limit observed in the CID attack on polyatomic interferences has its counterpart in the high resolution approach, in that the cost of increased mass resolution is reduced ion transmission.

CID of Interferences. The main thrust of this study was an examination of the polyatomic ion problem in GDMS. Figure 1 shows spectra acquired for a 1264a steel sample. In Spectrum A an interference due to $^{56}Fe^{40}Ar^{+}$ prevents the analytical use of $^{96}Mo^{+}$. Spectrum B shows the effect of CID indicating that at this level of sensitivity the isobaric interference due to the iron argide is effectively eliminated. Also the contribution of iron dimers is seen to be eliminated. While some of these interferences can be mass resolved with commercial GDMS equipment, metal argides and numerous oxides require higher resolution than is presently available, making the CID approach especially attractive.

TABLE I

CELL PRESSURE milliTorr	Sensitivity (Counts/ppm) ^{100}Mo	^{121}Sb	^{181}Ta	^{186}W	^{208}Pb	Isotope Ratio 96/100*
0.0	704	389	148	231	717	2.5
0.7	514	276	105	199	366	2.0
1.4	306	155	65	126	222	1.8
2.4	106	79	27	58	50	1.7

* The natural ratio for $^{96}Mo/^{100}Mo$ is 1.716

Collision Energy Effect. The effect of collision energy on the dissociation of a potentially interfering species was undertaken to evaluate the correspondence of dissociation threshold with bond energy, and to determine the ability of increased collision energy to increase dissociation. Figure 2 is a plot of Ta^+/TaO^+ as a function of the center-of-mass collision energy. The vertical line drawn on the plot in Figure 2 corresponds to the reported bond energy of TaO^+; this differs from the threshold value by ca. 6 eV. The observed results indicate that species produced in the discharge have appreciable internal energy complicating attempts at bond strength measurement by CID. Figure 2 also demonstrates that once the threshold energy for dissociation is reached the percent dissociation increases rapidly with increasing energy, but the slope of the curve can already be seen to indicate the approach of a maximum for dissociation. It does not appear that this maximum will correspond to 100% dissociation.

Daughter Spectra. A well known molecular ion observed in GDMS is the Ar_2H^+ species at m/z = 81. Utilizing a brass sample the daughter spectrum of m/z = 81 was acquired. The daughter spectrum shows the expected signal at m/z = 41 due to the fragmentation of the Ar_2H^+ yielding ArH^+. An unexpected contribution attributed to CuH_2O^+ at m/z = 81 is identified from the fragment appearing at m/z = 63. This demonstrates the ability to evaluate any m/z for the presence of isobaric interferences and to identify the interfering species.

Parent Spectra. The utilization of parent spectra to identify spectral regions of potential interference were investigated employing a stainless steel cathode. The observed signals correspond to parent ions which upon CID yield fragment ions of m/z = 56. In addition to the expected indication of FeAr at m/z 96 there is also signal at m/z 73 which is attributable to $FeOH^+$. Thus the parent scan was shown to predict interfered mass values in a spectrum.

CONCLUSIONS

These initial investigations into the application of tandem mass spectrometry techniques to trace elemental analysis have yielded promising results. CID is effective in eliminating certain isobaric interferences due to polyatomic ions, enhancing the ability to pursue GDMS with quadrupole-based mass spectrometry systems. The technique is not limited by resolution or the lack of alternative isotopes. The ability to obtain daughter and parent spectra permits the identification of interfered species and the prediction of interferences in the spectrum. Before the full potential of CID GDMS can be assessed, however, additional development and exploration are required.

ION ASSOCIATION BY TIME-OF-FLIGHT MASS SPECTROMETRY

L. Q. Huang[a], R. J. Conzemius, G. A Junk and R. S. Houk
Ames Laboratory-U.S. Department of Energy and Department of Chemistry
Iowa State University, Ames, Iowa 50010 (USA)

Time-of-flight (TOF) mass spectra are normally obtained by averaging repetitive mass scans of ions accelerated from a pulsed source. In the present work, individual mass scans from each pulse were tested for probable associations between ions of different m/z, i.e., was the presence of one ion contingent upon the presence of the other in the same scan? The tendency for ions to be associated was evaluated statistically by testing data obtained from solid specimens of cesium iodide and the superconductor, $YBa_2Cu_3O_7$. A low power, short duration laser (300 ps, 10 uJ) was used to produce ions at only a few masses per laser pulse. With few ions produced per pulse, ion associations could be observed which might otherwise be masked when the number of ions per pulse was very high as in most ion sources. A data acquisition system was developed (Fig. 1) to allow convenient recording and study of the information in the individual scans and two classical statistical methods were used to identify associations.

The results of ion association tests for the CsI sample indicate that Cs^+ and $[(CsI)Cs]^+$ are associated. Both statistical treatments for the $YBa_2Cu_3O_7$ sample show association between the pairs Ba^+ and BaO^+, BaO^+ and $BaCuO^+$, BaO^+ and $YBaCuO^+$ (or $Ba_2O_2^+$), and $BaCuO^+$ and $YBaCuO^+$ (or $Ba_2O_2^+$). These associations infer some commonality in their formation by laser desorption (LD).

The preliminary ion association data show promise for providing information about structure and ion formation mechanisms that cannot be obtained from interpretation of conventional (i.e., averaged) LD mass spectra. The instrumentation stores each scan separately from each ionization event so all of the possible associations can be tested in retrospect by simply examining the data already collected; no instrument modification is needed and the experiment need not be repeated. Also, statistical tests could be applied for other criteria such as association and unassociation of three or more ions. Naturally, the general concept of ion association need not be limited to LD or even condensed phase samples. Further experiments with various sample types and operating conditions are warranted to delineate the value of the information provided by ion association.

SUPERCONDUCTOR ANALYSIS BY GLOW DISCHARGE MASS SPECTROMETRY

J Clark, D J Kirby, N E Sanderson
VG Elemental Ltd, Ion Path, Road Three, Winsford, Cheshire, CW7 3BX, UK

Introduction

High resolution Glow Discharge Mass Spectrometry is routinely used in the analysis of a wide range of bulk solid samples, including metals, semiconductors and insulators. (1)

Recent work on the VG 9000 has demonstrated the extension of this technique to the exciting area of high temperature superconductors. Pin samples of the type $YBa_2Cu_3O_x$ have been analysed whilst maintained at temperatures near liquid nitrogen using standard cell cryo cooling.

The absence of standards for these new materials highlights the importance of the matrix independance of the GDMS technique. Results for the oxygen stoichiometry and impuriy concentration are particularly interesting.

Analytical Protocol

Four different samples of $YBa_2Cu_3O_x$ were analysed on the VG 9000 Glow Discharge Mass Spectrometer. The samples had been processed differently to induce different oxygen contents. Samples A, B and C are from three stages of preparation method 1 and sample D from method 2.

Sample A: An 'as prepared' powder using standard preparation techniques. This sample is superconducting at 90K.
Sample B: Prepared as sample A and subjected to hot pressing - this reduces oxygen content compared to sample A. This sample is not superconducting.
Sample C: A sample of 'B' re-annealed in oxygen - this should increase the oxygen content. This sample is superconducting at 60K.
Sample D: Prepared by a different method to the above samples and expected to be the purest sample. This sample is superconducting at 90K.

Analysis

The samples were received in powder form. They were compressed into pins and immediately loaded into the VG 9000 plasma cell (2), which with the sample is cooled to near liquid nitrogen temperatures. The sample forms the cathode of a DC discharge within the plasma cell. Neutral atoms are sputtered from the sample and subsequently ionized in the plasma. Ions are accelerated through 8KV into a high resolution double focussing mass spectrometer and are collected by a dual Faraday/Daly detector system linear over 11 orders of magnitude. This enables majors (100%-1%), minors (1%-1ppm) and traces (1ppm - 10ppt) to be analysed during one analysis cycle. The majors, (termed matrices) are used as an internal standard against which the minors and traces are ratioed.

Results

Table 1 shows the uncorrected ion beam ratio data for the matrix elements. The internal precision achieved over 5 consecutive analyses is significantly less than 1% of the measured values.

Table 1 - Matrix concentration (wt %)

Element	Sample A	Sample B	Sample C	Sample D
Y	11.74	15.98	11.12	15.22
Ba	56.20	55.57	57.73	53.57
Cu	11.00	9.84	9.94	9.65
O	21.10	18.12	21.20	21.56

Correction factors were derived using the formula $YBa_2Cu_3O_{6.89}$ *to describe* the previously characterised sample D and used to correct the raw data for samples A, B and C. Table 2 shows the corrected results.

Table 2 - Corrected Matrix concentration (wt %)

Element	Sample A	Sample B	Sample C	Sample D
Y	10.1	14.1	9.9	13.38
Ba	42.2	42.6	44.4	41.35
Cu	31.8	29.0	29.4	28.69
O	15.8	13.9	16.3	16.57

Table 3 shows the uncorrected ion beam ratio data for a comprehensive list of impurity elements found in the superconductive ceramics. These values, obtained in one minute/element, reflect sub-ppb limits of detection and are typically within a factor of 3 of the absolute values without standards.

Table 3 - Minor and Trace concentration (ppm wt)

Element	Sample A	Sample B	Sample C	Sample D
F	34	6	12	3
Na	73	85	101	27
Mg	2	5	5	3
Al	878	2083	1780	1526
Si	6	79	48	9
S	19	65	41	13
Cl	905	221	264	78
K	21	2170	1914	20
Ca	57	58	86	86
Sc	0.5	2	0.6	0.8
Cr	6	4	25	5
Fe	12	24	247	8
Mn	1	1	3	1
Co	1	1	2	3
Ni	1	2	3	2
Pb	2	77	3	1
Bi	2	3	3	5
Total Impurities	2020.5	4886	4537.6	1790.8

Discussion

The results clearly demonstrate some important differences between the samples, the most important being the difference in oxygen concentration of the superconductive samples (A, C, D) and the non superconductive sample (B).

From Table 3 is seen that sample D is indeed the purest. Samples A (Tc 90K) and D (Tc 90K) have less than half the total impurities of sample C (Tc 60K) with sample B being of the lowest purity.

The two 90K superconductive samples have significantly lower levels of Si, S and K than the 60K sample, with the non superconductor having the highest levels of these elements. Sample C (Tc 60K) has 247 ppm of iron, approximately 10 times that of the other three samples. Sample B has significanly higher levels of Pb and Al than the other samples.

Conclusion

$YBa_2Cu_3O_x$ samples have been successfully analysed by GDMS. This preliminary data shows differences in oxygen content between superconductive and non superconductive ceramics. Significant levels of impurities have been found in all samples, with the highest temperature superconductors being the samples with the lowest total impurities. Differences in specific element levels between samples have been demonstrated and it may be postulated that these affect the Tc of the ceramic.

ENHANCEMENT OF SPARK SOURCE MASS SPECTROGRAPHIC DATA USING STATISTICAL CLUSTER ANALYSIS

Charles R. Wilson, M. Le Roy Jacobs
WAL Inc., 6385 W 52nd Ave., Arvada, CO 80002
and R. M. Hutchinson, Dept. of Geol. Eng.,
Colo. School of Mines, 250 Berthoud Hall,
Golden, CO 80401

Stibnite (antimony sulfide) crystal specimens were analyzed by spark source mass spectrography (SSMS) for trace element content to establish a "trace element fingerprint" for judicative purposes. Removal of many crystal specimens from an antimony mine for surreptitious sale over an extended period of time was suspected. A method was sought for a establishment of the source of certain stibnite crystals and if possible spatial orentiation of crystal specimens in the identified mine.

SSMS was used in this investigation since the technique will give a trace element determination of all elemental constituents from lithium to uranium in as little time as one hour. The SSMS sample preparation involves the grinding of the sample to -200 mesh, mixing with graphite and the addition of an known amount of indium as an internal standard.

It is well known that the absolute concentration of a given trace element can change in similar types of samples matrices on a sample to sample basis. It is also true that elements tend to occur in association with other complimentary elements, i.e., elements which are alike in chemical nature. Even though the absolute concentrations change the inter-element ratios tend to remain constant. Similarities of samples can be established through the use of trace elements, by measuring total concentration of a given trace element in a sample and measuring the same element concentration in a different sample and attempting to correlate the two concentrations. However, if the two absolute concentation levels are different (a frequent occurrence) very little, if any correlation, may be found. Therefore; conversion of absolute element concentrations to inter-element ratios may provide a "finger print" independent of concentration.

Over fifty stibnite crystal samples were examined for trace element ratios or "fingerprints". Direct sample to sample comparison of trace element concentrations was inconclusive. To enhance the similarities and differences between the stibnite specimens, a statistical method was indicated. The determined concentrations of twenty-eight trace elements were converted to inter-element ratios and compared to the same element ratios from reference stibnite samples. The trace elemental ratios derived in this manner gave the sought for unique identifying features, since dependence on absolute trace element concentrations has been mathamatically limited. Further, if one measures many trace element ratios which are characteristic of the sample, a trace element ratio pattern will quickly develop which will be specific to a given sample.

This ratio pattern will uniquely identify a sample much as a fingerprint identifies an individual human. Samples of common origin will have similar trace element ratio patterns. These trace element ratio patterns can then be compared with other ratio patterns to determine any similarities between samples. This process is called clustering and can produce correlation (distance) coefficients which can be used to group samples into similar families.

Graphical representation of this clustering is termed a dendrogram or "tree like" graph. For the stibnite crystals examined, the dendrogram was constructed by grouping together samples that had inter-element ratio similarities. Then by averaging the "distance coefficients" new groupings were constructed until all sample had been grouped into a related branch of the "family tree".

The use of statistical cluster analysis as applied to the elemental ratios of the in-common trace elements of the stibnite crystals allowed the SSMS to differentiate the originating mine from several other known stibnite mines and indeed, to identify the crystal specimens as to specific locations within the mine.

In other words, a very specific "trace element fingerprint" was established for each crystal specimen, which allowed spatial location of individual samples to be correlated with mining production records to establish a probable time-span in which the crystals may have been removed from the mine.

MASS SPECTROMETRIC PROBES OF METAL CLUSTER DISTRIBUTIONS AND METASTABLE ION DECAY*

E. K. Parks, K. Liu, S. K. Cole, and S. J. Riley

Chemistry Division, Argonne National Laboratory, Argonne, IL 60439

The study of metal clusters has provided both an opportunity and a challenge to the application of mass spectrometry. These days the most often-used technique for cluster generation - laser vaporization - leads to extensive distributions of cluster sizes, from one to perhaps thousands of atoms, and most studies reported to date use excimer laser ionization and time-of-flight mass spectrometry for cluster detection. Our apparatus is a simple one-stage TOF design employing Wiley-McLauren spatial focussing and a one-meter drift tube. The double extraction grid (to minimize penetration of the high tube voltage into the extraction region) consists of two 85% transmission molybdenum meshes separated by 0.6 mm. The tube is oriented perpendicularly to the cluster beam, so that deflection plates are needed to direct cluster ions to the detector. Typically, a 20 μsec section of TOF time can be imaged onto the detector for a given set of plate voltages. Our plates are curved to match the round drift tube, and are offset downstream so that larger clusters can be directed to the detector. Even so, for the heaviest masses we see a breakdown of the usual $(\text{mass})^{1/2}$ - time relationship across the 20 μsec window because the ions do not all pass through the center of the plates. The heaviest cluster clearly resolved in this apparatus has been Ni_{366}.

The presence of a nearly continuous distribution of masses has revealed an interesting instrumental effect. The upper panel of Fig. 1 shows a composite (constructed from successive 20 μsec sections) distribution of nickel clusters measured in an earlier version of the apparatus. The undulations in intensity are not a result of the composite construction, but instead are due to interference of some ion trajectories through the double extraction grid (an effect akin to Moiré fringes). The lower panel in Fig. 1 shows a nickel cluster distribution measured in a more recent version of the apparatus (which obviously has higher resolution) in which the double mesh extraction grid is replaced by a double parallel wire grid having the wires parallel to the cluster beam. The interference effects are clearly no longer present.

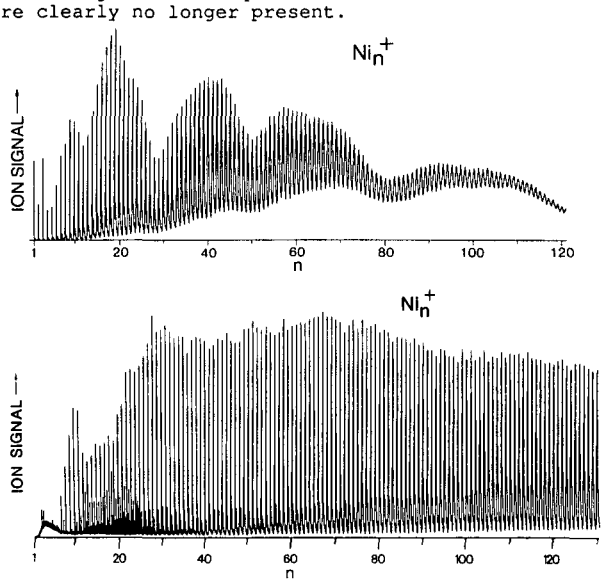

Fig. 1. Upper panel: Spectrum of nickel clusters taken with a double-mesh extraction grid in the TOF mass spectrometer. The small substructure around n = 20 is due to oxide impurities.
Lower panel: Nickel cluster spectrum that is seen when the extraction grid is of parallel-wire type. The mass spectrometer resolution is considerably improved over that in the upper panel. More oxide impurities are evident. Laser ionization conditions were such that only one-photon ionization processes were possible, so the small clusters below n = 7 were not detected.

In a second apparatus employing a pulsed valve in the cluster source, we see asymmetric broadening of niobium cluster mass peaks under multiphoton ionization conditions, indicating metastable decay of parent cluster ions. An example, for Nb_7^+, is shown in the first panel of Fig. 2. Other studies of niobium clusters have shown no such asymmetric peaks. Normally one would fit the peak tail and, using calculated relationships between parent and daughter ion extraction and flight times, determine the decay rates for the parents. In this case, having a continuous distribution of neutral cluster sizes, we do not *a priori* know the parent. Instead, the parent metastable decay can be probed directly by delaying the ion extraction in the TOF spectrometer, allowing the parents to convert to daughters before extraction. The other panels in Fig. 2 show such data. From the disappearance of the tail, the parent decay rate can be determined. Now, from the calculated decay time - TOF relationship, which depends on the parent/daughter mass ratio, the parent mass can be determined.

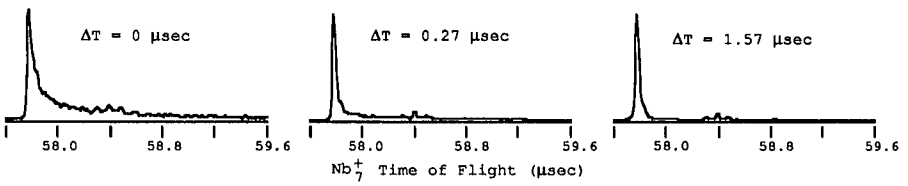

Fig. 2. First panel: The TOF peak for Nb_7^+ with no ion extraction delay. Next two panels: The peaks when extraction is delayed by the times shown.

The results of this procedure are quite surprising. First, fitting the TOF peak tails shows that there are at least two decay pathways. The identification of parents shows that one pathway corresponds to evaporation of one or two atoms, the usual fragmentation process for metal clusters. The other pathway is fission of a larger cluster, a process more characteristic of semiconductor clusters, and suggests there is something unusual indeed about the niobium clusters that are made in this particular cluster source.

Since these are multiphoton ionization/fragmentation processes, there are presumably intermediate neutral electronically excited states involved. We can probe these using a two-color scheme. Following the excimer laser pulse a dye laser at 2 eV photon energy is fired at the clusters. By itself, the dye laser produces no ions, but after the excimer laser pulse it produces a second mass peak arising from excited neutral species. By varying the delay between laser pulses, we find the lifetime of the intermediate neutral is 3.15 μsec, in sharp contrast to the usual picture of transition metal clusters having a "vibronic soup" showing near-instantaneous internal conversion. "Normal" transition metal clusters cannot retain electronic excitation for even picoseconds, yet here are clusters doing so for microseconds.

We believe these unusual clusters result from the pulsed valve used in this source. It opens faster and farther than most, resulting in unusually high carrier gas pressure in the cluster formation area. Under these conditions the metal will be tightly confined, since diffusional loss will be small. The metal is transported out of the growth channel very quickly, so clusters do not grow very large. At the nozzle, we then have a high density of small clusters and a strong expansion because the gas pressure is so high. Thus we have rapid cooling, and many cluster-cluster collisions leading to the formation of unannealed species that might be likened to van der Waals clusters of clusters. Now cluster fission fragmentation can be understood. It represents a decomposition of the "super cluster" into its constituent parts. Also, a mechanism for long-lived storage of electronic excitation is suggested. It could be that the agglomeration leads to isolated electronic bands in a chromophore analogous to typical van der Waals clusters.

GUIDED ION BEAM STUDIES OF TRANSITION METAL CLUSTER ION CHEMISTRY:

S. K. Loh, Lian Li, D. A. Hales, and P. B. Armentrout;
Chemistry Department, University of Utah, Salt Lake City, Utah, 84112.

Reactions of size-specific metal cluster ions are examined using guided ion beam tandem mass spectrometry. A continuous beam of cold cluster ions is generated by vaporizing the metal sample with a high repetition rate (6 kHz) Cu vapor laser in a fast flow of helium. Sufficient ions are produced in the laser vaporization step that there is no need for a separate ionization step. Measurement of reaction cross sections and branching ratios characterize the interactions of the clusters with a variety of neutral gases. By examining the variation of these quantities with the kinetic energy of the cluster ions, thermochemical data for both ionic and neutral cluster species can be determined.

In one series of studies, we have examined the collision-induced dissociation (CID) of gas-phase iron cluster ions, Fe_x^+, with Xe. For the dimer ion, the energy dependence of the cross section is consistent with theoretical models and gives $D^o(Fe_2^+) = 2.72 \pm 0.07$ eV,[1] in good agreement with previous studies.[2,3] Combined with the known ionization potentials[4] and electron affinities[5] of Fe and Fe_2, this bond energy also provides $D^o(Fe_2) = 1.15 \pm 0.09$ eV and $D^o(Fe_2^-) = 1.90 \pm 0.09$ eV. For larger cluster ions, up to the decamer, the lowest energy decomposition channel is always loss of an Fe atom. Indeed, our data offers no indication that any molecularly bound neutral products are formed in the dissociation of these cluster ions. Dissociation occurs exclusively by sequential Fe atom loss. This has also been concluded for photodissociation of Fe_x^+ clusters.[3]

This CID behavior contrasts with that of V_x^+ and Nb_x^+. This is most dramatically seen in the CID behavior of the tetramers of these ions.[6] Here, the lowest energy pathway for fragmentation is fission of the molecule into an ionic and neutral dimer. Atom loss does not occur until higher energies, but is the dominant channel at elevated kinetic energies. Thus, the "most probable" process is highly energy dependent, i.e. the relative thermodynamic stability of the dimer and trimer ions is not reflected by the branching ratio at elevated kinetic energies.

These experimental techniques can also be applied to the reactive chemistry of the cluster ions. For example, we have studied the endothermic reactions of D_2 with the monomer, dimer, and trimer ions of iron. The thresholds for production of Fe_x^+-D, the only product observed, differ with cluster size. Analysis of the reaction thresholds lead to bond energies of $D^o(Fe_2^+\text{-D}) = 1.5$ eV and $D^o(Fe_3^+\text{-D}) = 1.8$ eV, which can be compared to $D^o(Fe^+\text{-D}) = 2.2$ eV.[7] These values are very similar to $D^o(Fe_2^+\text{-Fe})$ and $D^o(Fe_3^+\text{-Fe})$, which may imply that the bonding

in Fe^{2+} and Fe^{3+} is largely single σ bonds.

STRUCTURE AND REACTIVITY OF CLUSTER IONS

A.P. Baronavski, J.H. Callahan, S.W. McElvany and M.M. Ross
Chemistry Division/Code 6110, Naval Research Laboratory
Washington, D.C. 20375.

Clusters are of great scientific interest because they might bridge the gap between the solid- and gas-phase forms of matter. In order to understand how the transition from atoms to the condensed phase is made, studies have been directed at the determination of the structure and reactivity of clusters as a function of size. The objective of this work is to compare different methods of cluster ion production and to characterize the clusters ions using ion/molecule reactions and collision-induced dissociation (CID).

Cluster ion distributions of bismuth and antimony have been produced by a variety of methods. Direct laser vaporization (DLV) at 532 nm yields distributions which truncate at Sb_5^+ and Bi_5^+. These distributions are strikingly similar to those observed by Duncan [1] using a molecular beam and photoionization of the neutral species. However, Duncan's data for ions from the supersonic expansion extend to Bi_{11}^+. In our work, we have attempted to explain the similarities and differences between (1) Duncan's data and our DLV data, and (2) the distributions of cluster ions of bismuth and antimony produced by particle bombardment (SIMS) and DLV [2], and by condensation from ovens [3].

We have found that the DLV of bismuth depends upon the wavelength of the laser used in vaporization. However, only one additional cluster ion, Bi_7^+, is observed when 1064 nm light is used rather than 532 nm. On the other hand, SIMS produces Bi_x^+ up to x=31. This is dramatically different than the data for DLV or Duncan's data. In Figure 1 we compare the Bi_x^+ distribution observed using SIMS with that observed by Sattler [3] using an oven/ condensation source with electron ionization. The agreement, considering the radically different methods, is remarkable. The enhancements observed for smaller cluster ions (x<=8) can be attributed to dissociations of larger species. This interpretation is borne out by both collision-induced dissociation (CID) experiments in our lab and by photodissociation conducted by Geusic et al. [4] The differences between our DLV data and the SIMS data is believed to be due to dissociations of the larger cluster ions in the plasma produced by the laser.

Similar studies have been carried out for antimony and lead (not Pb) to the conclusion that, unlike larger bismuth cluster ions, the larger antimony cluster ions are produced (using SIMS, DLV, molecular beam) with enough internal energy to unimolecularly dissociate. In high-pressure/SIMS experiments, cluster ions up to Sb_7^+ are collisionally stabilized and observed.

One of the unique aspects of DLV is the ability to induce chemistry in the laser plasma. An example of this is shown in Figure 2 for a sample of tantalum powder in graphite. Cluster ions, $Ta_xC_n^+$ up to x = 18 are observed and for TaC_n^+ with n = 14 have been observed. These types of cluster ions are not produced by SIMS and so are indicative of the extent of chemical reactions in the plasma.

The distribution of cluster ions that can be generated from a solid is dependent upon (1) the production method, due to differences in the magnitude and means of energy deposition, (2) the nature of the sample and the ion source conditions and (3) the time frame in which the cluster ions are formed and detected. Through studies employing several mass spectrometric techniques (FTMS, TOFMS, quadrupole and sector) with laser vaporization and particle bombardment, we have attempted to understand how the experimental conditions affect the size distribution, energies and types of cluster ions observed. Direct laser vaporization of carbon yields abundant and high-mass cluster ions, $[C_n]^+$, in contrast to sputtering, whereas both methods yield similar cluster ion species from some samples such as bismuth and antimony. Similarly, using ion/molecule reactions and MS/MS methods the structures and reactivities of mass-selected cluster ions can be probed. Cluster ions of the forms Bi_x^+, Sb_y^+ and $[Bi_xSb_y]^+$ were studied with low- and high-energy CID, with differences found that are dependent upon instrumental parameters. Our studies have focused on cluster ions of metals, semi-metals and mixed-metal systems.

HRGC/HRMS ANALYSIS OF BROMINATED/CHLORINATED ANALOGS OF TCDD AND TCDF IN MUNICIPAL INCINERATOR FLY ASH

H.Y. Tong and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588

The fly ash formed during the combustion process in municipal waste incinerators (MWI) is probably the major contributor of polychloro dibenzodioxins and dibenzofurans (PCDD/Fs) to the environment today. However, it is also of interest to analyze other halogenated analogs of PCDD/Fs in fly ash because 1) those planar analogs may have a potential hazardous impact on the environment, and 2) the information on those analogs in fly ash may be helpful for studying the mechanism by which PCDD/Fs are formed. In this presentation, some tetra congeners of brominated PCDD/Fs (BPCDD/Fs) are selected to demonstrate the feasibility and the difficulties in the analysis of fly ash for BPCDD/Fs by using HRGC/HRMS techniques.

The benzene extract of fly ash collected from the bottom of an electrostatic precipitator of a MWI was subjected to two different clean-up methods for comparison. They are the normal phase HPLC fractionation[1] and the multiple open column chromatography[2] which is commonly employed for PCDD/Fs analysis. Consequently, the sample fraction containing PCDD/Fs was analyzed for BPCDD/Fs on a Carlo-Erba GC (30 meter DB-5 column)/Kratos MS-50 MS (70 eV EI, 10,000 resolution). Three characteristic ions were selectively monitored for each BPCDD/Fs analyzed and their mass profiles with 300 ppm span were acquired for qualitative and quantitative analysis.

Our preliminary data from HRGC/HRMS analysis show that BPCDD/Fs elute into the same fraction along with PCDD/Fs in both clean-up procedures used because of the high similarities in structure and polarity between PCDD/Fs and BPCDD/Fs. This observation is consistent with the previous finding of polybromo dibenzodioxins and dibenzofurans present in the PCDD/F fraction obtained in a similar multiple open column chromatographic procedure[3]. Figure 1 shows some mass chromatogram data for several selected PCDD/Fs and BPCDD/Fs found in the extract of fly ash. Notice that 1) $BrCl_3$-DD elutes between TCDD and P_5CDD, and 2) it has the isomer distribution pattern similar to that of TCDD. These observations also apply to other monobromo PCDD/Fs found in the sample, and may provide some interesting information for study of the formation mechanism of PCDD/Fs in incineration process.

One of the primary difficulties in the analysis of trace amount of BPCDD/Fs in fly ash is the interferences caused by PCDD/Fs of high concentration as well as some polyhalogenated aromatic compounds having structures similar to PCDD/Fs. Those interfering compounds are difficult to be separated from BPCDD/Fs by the clean-up methods commonly used and also exhibit GC retention times close to that of BPCDD/Fs. As an example, Table 1 illustrates some potentially interfering compounds in the analysis of fly ash for $BrCl_3$-DF by GC/MS. Based on these MS data, accurate measurements of the masses and particularly, the isotope ratios of molecular ion clusters are essential for identifying BPCDD/Fs in fly ash because the GC retention time data for most of BPCDD/F standard compounds are not available yet. The mass profile data of some selected compounds found in the sample are shown in Figure 2, and indicate that the acquisition of mass profile data is highly recommended in such analyses.

The concentrations of $BrCl_3$-DD and -DF, on the basis of quantitative responses of P_5CDD and P_5CDF standards, were measured to be 18 and 6 ppb respectively, in comparison to 440 ppb of TCDD and 290 ppb of TCDF in the fly ash sample analyzed. Di- and higher bromo PCDD/Fs were not detected at a ppb level in this fly ash sample.

DEVELOPMENT AND APPLICATION OF A THREE-PHASE COUPLED CAPILLARY GC COLUMN FOR GC-MS ISOMER-SPECIFIC DETERMINATION OF BOTH 2,3,7,8-TCDD AND 2,3,7,8-TCDF IN ENVIRONMENTAL SAMPLES

L. A. Harden, T. O. Tiernan, J. H. Garrett, and J. G. Solch
Department of Chemistry and Toxic Contaminant Research Program
Wright State University, Dayton, Ohio 45435

Because of the relative toxicities of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) and 2,3,7,8-tetrachlorodibenzofuran (TCDF), there is intense interest in measuring these isomers specifically in environmental samples in the presence of other TCDD and TCDF isomers. Our laboratory recently described GC-MS procedures which utilize two separate gas chromatographic columns for this purpose. A DB-5 capillary column is used for detection and quantitation of 2,3,7,8-TCDD uniquely, while 2,3,7,8-TCDF is determined uniquely using a serially-connected DB-225/DB-5 capillary column, which we developed. The objective of the present study was to develop a single GC column which would resolve both 2,3,7,8-TCDD and 2,3,7,8-TCDF from all of their respective congeners, thereby permitting determination of both of these in a single GC-MS analysis.

Initially, the retention times of all 22 TCDD and 38 TCDF isomers on several different capillary GC columns (DB-5, SP-2250, DB-1701, DB-225, SP2401, and DB-WAX) were measured. These data were then used to predict what combinations of columns among those tested (coupled in series) would be effective in completely resolving both 2,3,7,8-TCDD and 2,3,7,8-TCDF. This was achieved by using a computer program, developed in our laboratory, for interpolating retention time data. This program assumes linear flow of each isomer through a given GC column, and the method is similar to that accomplished by graphical "window diagramming" procedures previously described in the literature(1). However, whereas the graphical method is limited to two-dimensional solutions, the computer model can yield multi-dimensional solutions.

The computer model described predicted that there were no possible combinations of pairs of coupled columns among those evaluated here (as listed above) which would uniquely resolve 2,3,7,8-TCDD and 2,3,7,8-TCDF. A three-column combination was therefore sought, and the computer model predicted that a combination DB-225/SP-2250/DB-WAX column would yield the desired resolution. Accordingly, sections of these three columns of appropriate length were coupled in series using butt connectors, and the resultant hybrid column was evaluated for retention or characteristics using all 22 TCDD and all 38 TCDF isomers. The retention data obtained on this initial column was then inserted into the computer program in order to predict optimum combinations of the component coupled column sections. The actual column was then adjusted (fine-tuned) to yield the optimum resolution in a series of successive approximations. This iterative calculation procedure ultimately yielded an experimental approach that compensates for variables in GC parameters, such as the flow gradient through the column.

The resolution of 2,3,7,8-TCDD and 2,3,7,8-TCDF from all of their respective TCDD and TCDF congeners on the finally constructed hybrid three-phase GC column is demonstrated by the mass chromatograms shown in Figures 1 and 2. Clearly, the column developed is quite effective.

INVESTIGATION OF ANOMALOUS DIOXIN SIGNALS IN DIOXIN ANALYSIS

D.R. Hilker, W.H. Ding, K.M. Aldous, S. Connor, and J. Jurusik
Wadsworth Center for Laboratories and Research
New York State Department of Health,
Albany, NY 12201

Gas Chromatography/mass spectrometry is widely utilized for quantitative analysis of pollutants in environmental samples. The isotopically labelled internal standard method of quantitation has been widely used for quantitation because of its inherent accuracy. This method relies upon a constant relationship between the amount of analyte and the ratio of the instrumental response of the analyte and internal standard. In this presentation we report the observation of the enhancement of the signal due to both 2,3,7,8-TCDD-$^{13}C^{12}$ and native TCDD in the restricted source of a high resolution mass spectrometer when a large amount of native 2,3,7,8-TCDD is present. Our data shows that this particular effect need not threaten the accuracy of quantitation of native TCDD in environmental samples. However, the accuracy of per cent recovery determinations could be significantly impaired as well as the accuracy of quantitation of other isomers. The literature contains references which cite signal enhancement caused by the presence of either known or unknown compounds in the source (1-4). Since this particular type of effect may depend upon source design, its presence or absence must be verified for each instrument. Our investigations to date of the effect and its implications for quantitation on two different mass spectrometers are given.

Five solutions were prepared each containing 1 ppm of 2,3,7,8-tetrachlorodibenzo-p-dioxin-$^{13}C_{12}$ ($^{13}C_{12}$-2,3,7,8-TCDD) and one of the following concentrations of native 2,3,7,8-tetrachlorodibenzo-p-dioxin (2,3,7,8-TCDD): 0.2 ppm (ng/µl), 1.0 ppm, 5.0 ppm, 25.0 ppm, and 45.5 ppm. These compounds had been shown by previous analysis to have a degree of purity commensurate with environmental standards.

Each of these solutions was analyzed with a Kratos MS-50 and a Hewlett-Packard MSD in GC/MS mode with electron impact ionization. The solutions were reanalyzed with the Kratos MS-50 in GC/MS mode with a "restricted" electron impact source. In this source all of the sample entrance ports to the ion chamber are either fitted with a sample introduction device or plugged. Experiments in the GC/MS mode on the MS-50 were done at high resolution (10,000 RP, 10% valley), with a lock mass and monitoring another PFK peak along with the two most intense molecular ions of $^{13}C_{12}$-2378-TCDD and native 2378-TCDD.

The areas of the gas chromatographic peaks in the m/e 334 ion chromatograms ($^{13}C_{12}$-2,3,7,8-TCDD) were obtained. Each of these areas, measured in ADC counts, were divided by the number of nanograms of $^{13}C_{12}$-2,3,7,8-TCDD in the injection to generate a $^{13}C_{12}$-2,3,7,8-TCDD sensitivity.

In another group of experiments a fixed amount of $^{13}C_{12}$-1,2,3,4-TCDD was added to each of the solutions mentioned above. After analysis on the Hewlett-Packard MSD the areas of the $^{13}C_{12}$-2,3,7,8-TCDD were determined and sensitivities were calculated as described above. A response ratio was calculated by dividing the $^{13}C_{12}$-2,3,7,8-TCDD sensitivities by the $^{13}C_{12}$-1,2,3,4-TCDD sensitivities. The response ratios are plotted versus the concentration of native 2,3,7,8-TCDD in the solutions (Figure 1).

Aliquots of the original five solutions were added to glass capillary sample containers. After solvent evaporation these capillaries were introduced into the combined EI/CI source of the MS-50 via the direct insertion probe. The areas of the peaks in the probe elution profiles were obtained and divided by the amount represented by the peaks in the elution profiles($^{13}C_{12}$-sensitivity). The sensitivities for the $^{13}C_{12}$-2,3,7,8-TCDD were divided by the native 2,3,7,8-TCDD to generate a response ratio. The $^{13}C_{12}$ sensitivity data and the response ratios were plotted versus the amount of native 2,3,7,8-TCDD added to the capillaries.

The response ratio data from the MSD versus native 2,3,7,8-TCDD concentration (Figure 1) appears to give a horizontal line despite some scatter. The relative standard deviation of all the response ratios in Figure 1 is less than 13%. The ^{13}C-sensitivity data from the MS-50 fitted with a normal electron impact source plotted versus native 2,3,7,8-TCDD concentration (Figure 2) appears to give a horizontal line despite some scatter. The plot of data taken from the MS-50 fitted with the restricted source does not appear to give a line with a slope of zero. The variance of these two data sets was analyzed using a one way, randomized block design and the hypothesis that the ^{13}C-sensitivity at each concentration is the equal. In the restricted source data set the hypothesis was rejected at the 99% confidence level suggesting that these ^{13}C-sensitivities are varying with native 2,3,7,8-TCDD concentration.

The variation in response ratio on the MSD is small and doesn't necessarily correlate with native 2,3,7,8-TCDD concentration. The coelution of large amounts of native 2,3,7,8-

TCDD into the MSD source has little effect on the response of $^{13}C_{12}$-2,3,7,8-TCDD and little effect on the accuracy of percent recovery calculations and quantitation. The variation in the $^{13}C_{12}$-2,3,7,8-TCDD sensitivity when determined with the MS-50 high resolution mass spectrometer fitted with a normal electron impact source does not appear to vary with native-TCDD concentration. Hence the response factor used in quantitation and percent recovery calculations will not change with the presence of large amounts of native 2,3,7,8-TCDD. Since other factors besides the amount of native 2,3,7,8-TCDD can effect the $^{13}C_{12}$-2,3,7,8-TCDD sensitivity further experiments with both MS-50 EI sources will utilize the $^{13}C_{12}$-1,2,3,4-TCDD containing solutions. The analysis of solutions by direct probe should differentiate "g.c." response enhancement (2) from enhancement effects that occur in the ion source (1). The combined EI/CI source appears to show an increase in response ratio with the amount of native 2,3,7,8-TCDD. The extent of the effect is not as large as reported in reference (1). The decrease in $^{13}C_{12}$-2,3,7,8-TCDD sensitivity with increasing native 2,3,7,8-TCDD may be due to operating without a lock mass at low resolution. In later experiments probe samples which contain $^{13}C_{12}$-2,3,7,8-TCDD and an internal standard will be analyzed at high resolution with a lock mass. A compound such as a higher chlorinated dibenzo-p-dioxin which evaporates from the probe capillary later than 2,3,7,8-TCDD could be used as an internal standard.

METABOLISM OF 2,3,7,8-TCDD J.H. McReynolds, J.R. Olson and S. Kumar; Toxicology Research Center, State Univ. of New York at Buffalo and Great Lakes Laboratory, State Univ. College at Buffalo; Buffalo NY 14214

Profound interspecies differences in the toxicity of 2,3,7,8-TCDD may be correlated with the ability of each species to metabolize or excrete the material. Less sensitive species such as the hamster (LD50=5000 ug/kg) show induction of metabolism by TCDD while more sensitive species such as the guinea pig (LD50 = 1ug/kg) lack this ability and rely on direct intestinal elimination for the excretion of TCDD. These differences limit the validity of extrapolations from other species to predict human toxicity of TCDD.

To aid in the identification of metabolites formed from in vivo experiments or from in vitro hepatocyte incubations, we have synthesized as number of potential TCDD metabolites that have been suggested or previously identified.(1,2) TCDD is expected to be metabolized by hydroxylation with and without chlorine elimination and/or migration. Synthetic metabolites were prepared by the condensation of 4,5 dichloro catechol with variously substituted ortho chloro nitro benzenes as reported by others.(3,4) Data are given for the predicted metabolites synthesized to date. Synthetic products were analyzed following diazomethane treatment on a 30m DB-1 column directly coupled to a KRATOS MS80RFA. EI spectra were generally useful for distinguishing the substitution patterns as shown in Fig. 1. Strong M-CH3 ions were produced by 2- or 3- methoxy substitution. Negative ion CI spectra were less useful for distinguishing substitution patterns. The NICI spectrum of metabolite 7 showed a base peak due to M-OCH3 and weak molecular anion in other runs (not shown but similar to that of 2 or 3) indicating that this species is particularly susceptible to oxygen contamination in the system. The dichloro dimethoxy species (10) did not give a useful NICI spectrum and the response of the trichloro mono methoxy product (9) was very weak.

Extracts from feces of rats treated with tritiated TCDD were analyzed by HPLC on a 25cm C-18 column eluted with 90% MeOH, 10% H2O and radioactive metabolite fractions collected and prepared for GC-MS analysis by diazomethane treatment. The fraction eluting at 20 min. corresponds to the HPLC retention time of 2-HO-1,3,7,8 TCDD with this identification confirmed by the GC-MS data shown in Fig. 2. The metabolite fraction collected at 15 min. is more heavily contaminated with endogenous fecal lipids in both the HPLC and GC separations but shows evidence of containing the 2-MeO TrCDD metabolite 9.

The utility of NICI in detecting metabolites of PCDDs is limited by the loss of response that is associated with chlorine loss and methoxy substitution. Identification of other metabolites will require further clean-up of the biological extracts. This effort will be aided by the availability of the synthetic metabolites. Cleaner samples will also alow the use of higer resolution GC conditions. Analysis of urinary extracts and hepatocyte incubations will be the focus of future experiments.

OPTIMIZATION OF MS/MS PARAMETERS FOR THE DETERMINATION OF CHLORINATED DIBENZO-p-DIOXINS AND DIBENZOFURANS IN ENVIRONMENTAL SAMPLES

D.H.SCHELLENBERG, B.A. BOBBIE, E.J. REINER AND V.Y.TAGUCHI
Ontario Ministry of the Environment,
Rexdale, Ontario, M9W 5L1, Canada

The determination of chlorinated dibenzo-p-dioxins (CDD) and dibenzofurans (CDF) by tandem mass spectrometry places rigorous demands on the instrumentation because of the sensitivity required to detect ultra-trace quantities and the selectivity needed to eliminate interferences typically encountered in environmental samples. Under these conditions optimization of instrumental parameters is critical.

Optimization of MS/MS instrument parameters is commonly performed using perfluorotributylamine (PFTBA) when analysing for general organic compounds. Unfortunately, the fragmentation of PFTBA under collision induced dissociation (CID) conditions does not parallel the behaviour of all analytes. According to the quasi equilibrium theory [1], the pattern and degree of fragmentation of the parent ion is dependent on its internal energy. Excitation by collision, electron impact, chemical ionization, FAB, etc., forms parent ions with a distribution of internal energies. Kenttamma and Cooks [2] have shown by using breakdown graphs (BG, a plot of the relative ion abundance vs internal energy) that parameters such as collision energy (CE) and collision gas pressure (CGP) have a significant effect on the internal energy of the parent ion and therefore its pattern of dissociation. Catlow et al [3] have shown that the optimum CE and CGP for one reaction will almost certainly not be the same for another reaction of that or any other parent ion. Therefore optimization of a particular fragmentation reaction using the analyte of interest is critical. The optimum values of the above parameters can be determined from the BGs.

Experiments were performed on a Finnigan MAT TSQ-70 triple quadrupole mass spectrometer equipped with a Varian 3400 GC and DEC 11/73 data system. Tuning was performed by introducing 1 ug of the analyte into the ion source using the direct insertion probe. The various tunable instrument parameters were then altered iteratively to maximize response.

BGs were obtained by scanning the instrument in the daughter ion mode and then plotting the % total ion current (%TIC) against CE or CGP. Sample data were collected by monitoring the loss of COCl from the two most abundant parent ions. Each run was split into five groups ranging from Cl_4DD and Cl_4DF in group one to Cl_8DD and Cl_8DF in group five. ^{13}C-CDD internal standards were also monitored.

Figure 1 shows CID-BG of PFTBA and four Cl_4DD isomers. The maximum relative abundance of the m/z 502 to m/z 219 reaction occurs at about 25 eV CE for PFTBA. This value is similar to the 25 eV obtained for 2378-Cl_4DD and values of approximately 21 eV obtained for the other Cl_4DD isomers for the COCl loss reaction. Figure 2 shows the CIDBG for PFTBA, 2378-Cl_4DD and 2378-Cl_4DF plotted vs CGP. The maximum relative (and absolute) abundance for the m/z 502 to m/z 219 reaction occurs at about 0.8mTorr for PFTBA while the maximum relative (and absolute) abundance for the loss of COCl from 2378-Cl_4DD and 2378-Cl_4DF occurs at about 3.3mTorr. A standard CGP setting was difficult to reproduce and a stablization period of a few minutes was required. Although the optimum CE are similar for PFTBA and the Cl_4DD isomers, the considerable difference in the optimum CGP setting and the size of the neutral lost (283 amu for PFTBA and 63 amu for CDD/F) indicates that for optimum instrument performance in multiple reaction monitoring (MRM), tuning on the analyte of interest is required. From the series of Cl_4DD/F to Cl_8DD/F that were determined, the M^+-COCl reaction optimized between 12 and 25 eV for a CGP of 3.3 mTorr. The CE was set for each congener type in each group because it can be set accurately through the keyboard and it does not require a stablization period.

Example 1 shows the mass chromatogram for a mixture of three Cl_4DD isomers (1234, 2378, 1278). Injections (A) and (B) were run at 27.5 eV and 22.5 eV CE respectively. As expected from the BGs, the 2378-Cl_4DD signal strength is enhanced in injection (A) and the 1234-Cl_4DD signal strength is enhanced in injection (B). Example 2 shows a series of Cl_4DD/F to Cl_8DD/F standards injected with a PFTBA tune (top) and a CDD/F tune (bottom). Note

the signal strengths in the CDD/F tune are considerably stronger than in the PFTBA tune. Example 3 shows the tetra region of a 10 g clam sample (top). The largest furan and dioxin peak were determined to be 150 ppt and 60 ppt respectively. The bottom mass chromatogram is of a fish (bass) sample. The largest furan peak is 20 ppt and the dioxin (2378) is 4 ppt. 2/10 ul of the extract were injected with a recovery of 95% for the internal standard giving a limit of detection of 0.2 - 0.5 ppt.

ACCURATE MASS DETERMINATIONS OF POLYCHLORINATED DIBENZOTHIOPHENES IN SOIL FROM A CAPACITOR PLANT'S INCINERATION SITE

Paul H. Peterman and Jon A. Lebo;
National Fisheries Contaminant Research Center; USDI,
Fish & Wildlife Service, Route 1, Columbia, MO 65201 and
Hilary J. Major
VG Analytical Ltd; Floats Rd; Wythenshawe, Manchester M23 9LE,UK

Chlorinated polycyclic aromatic compounds, e.g. polychlorinated dibenzofurans (PCDFs), dibenzo-p-dioxins (PCDDs) and biphenylenes (PCBPs) have been identified as pyrolysis products from the combustion of PCB-containing capacitors and transformers (1,2). Generally, these compounds are planar and very toxic. The relative compositions of the pyrolysis products vary considerably, depending upon the fire conditions.

From 1946-1964, capacitors containing PCBs, primarily Aroclors 1242 and 1254, were manufactured at a plant located in Crab Orchard National Wildlife Refuge, IL. Waste (defective) capacitors were routinely burned with automobile tires and diesel fuel in open bonfires. As expected, analyses of a soil core sample from the incineration site showed a high concentration of PCBs (3×10^6 ng/g or 0.3%) and lower concentrations of other chlorinated polycyclic aromatic compounds, e.g. PCDFs (570 ng/g), PCDDs (40 ng/g), PCBPs (9 ng/g) and polychlorinated naphthalenes (60 ng/g). Surprisingly, polychlorinated (Cl_2-Cl_7) dibenzothiophenes (PCDTs) and polychlorinated phenanthrene/anthracenes (PCPh/Ans) were both detected at 70 ng/g and were also tentatively identified by quadrupole full-scan GC/MS. Although the PCDTs have the same nominal molecular masses as the PCDDs, they elute 1-4 minutes later from a 30 m DB-5 capillary column. Since the PCDTs have chemical structures very similar to those of highly toxic PCDFs, and likely are also highly toxic and environmentally significant, we felt it necessary to confirm their identity. Unfortunately, no chemical standards of PCDTs exist. The Cl_3-Cl_7-PCDTs do not even have ACS CAS Registry Numbers. Therefore, we chose to obtain accurate mass measurements of the PCDTs.

Air-dried soil was Soxhlet-extracted, first with 60/40 benzene/methanol and then dichloromethane. The extract was processed through an extensive enrichment procedure (3) including a carbon-on-glass fibers separation technique. Initially, both selected ion monitoring and full-scan capillary GC/MS analyses were performed with a Finnigan 4023 GC/MS at 35 eV. Subsequently, capillary GC/high resolution (R.P. 10,000) MS analyses and complementary low resolution (R.P. 1,000) GC/MS analyses were performed with a VG 70-250S GC/MS at 70 eV using the same DB-5 GC column with 0.6 m retention gap. The oven program was 90 °C (1 min)-210 °C @ 15 °C/min, then 210 °C-300 °C @ 4 °C/min. Since the concentrations of PCDT isomers were low (0.05-10 ng/g), 1.3 g equiv. was injected for the high resolution, accurate mass measurements. PFK was constantly bled into the MS to ensure accurate calibration for each scan. To maximize sensitivity and accuracy, the MS was scanned at 360-250 d. @ 5 s/decade, with interscan reset 0.2 s for a total rate of 1 s/scan. The high resolution (R.P. 10,000) was chosen because a minimum of 9,200 would be required to distinguish the $(M+6)^{+\cdot}$ ion (m/z 319.9135) of co-eluting Cl_4-PCPh/Ans from the $M^{+\cdot}$ ion (m/z 319.8788) of Cl_4-PCDTs.

Definitive accurate mass measurements (AMMs) were obtained of those polychlorinated aromatics in the soil extract that exceeded about 1 ng injected. These included 19 peaks resulting from Cl_{2-5} PCDTs, i.e. a majority of the 34 peaks previously detected by quadrupole GC/MS. Several additional PCDT peaks were marginally detected (ion response S:N <4) below the level necessary for definitive AMMs. AMMs were obtained for at least two ions of each PCDT molecular ion cluster to compute its elemental composition. AMMs were typically from one scan, usually at the apex of a GC peak. For a few more highly concentrated PCDT peaks, AMMs were performed on two scans and each AMM was evaluated. All AMMs of PCDT $M^{+\cdot}$ ions and all but one AMM of $(M+2)^{+\cdot}$ ions were within 10 ppm of the exact masses of the PCDTs' elemental compositions. In some cases, the $(M+6)^{+\cdot}$ ion of Cl_4-PCPh/Ans could be detected and accurately distinguished from both the $M^{+\cdot}$ of Cl_4-PCDT and from PFK. Variance ranges are

given in the AMM summary report below:

ACCURATE MASS MEASUREMENTS SUMMARY REPORT

ISOMERS	#	Variance Range (mmu) (Theoretical-Observed) $M^{+\cdot}$	$(M+2)^{+\cdot}$	$(M+4)^{+\cdot}$	Elemental Composition Confirmed
Cl_2-PCDTs	1	-0.3/1.3	-4.0/1.7	ND	$C_{12}H_6Cl_2S$
Cl_3-PCDTs	7	-1.1/1.3	-0.7/0.8	-0.3/1.2 (3)	$C_{12}H_5Cl_3S$
(Interscan Data:		-0.6,0.5	0.8,0.4)	3.5/4.6 (2)	
				ND (2)	
Cl_4-PCDTs	8	-0.7/3.2	-3.0/1.5	0.2/1.9 (2)	$C_{12}H_4Cl_4S$
(Interscan Data:		-0.7,-0.2	1.5,0.1)	ND (6)	
		(-0.7,2.6)			
Cl_5-PCDTs	3	2.0/2.4	-1.7/0.3	2.2 (2)	$C_{12}H_3Cl_5S$
				ND (1)	
Cl_4-PCPh/Ans	6	-0.8/1.3 (5)	-0.4/3.4	-2.0/1.8 (5)	$C_{14}H_6Cl_4$
Cl_4-PCDDs (only 0.7 ng)	1	3.4	9.1	2.4	$C_{12}H_4Cl_4O_2$

Interscan Data denotes AMMs on two scans of an isomeric peak

Thus, the Cl_{2-5} PCDTs as well as some PCPh/Ans are now confidently identified from their elemental compositions. Although PCDT standards are not available, the GC retention times of the identified PCDTs are plausible relative to the retention times of PCDFs, PCDDs and PCPh/Ans.

Full-scan mass spectra of the PCDT and PCPh/Ans from the soil extract show very abundant molecular ion clusters and typical $(M-70)^+$ fragment ions. Quadrupole (at 35 eV) and low resolution magnetic sector (70 eV) mass spectra of peaks from Cl_4-PCDT compared quite closely. The $(M-CSCl)^+$ or $(M-79)^+$ fragment ions of PCDT were < 7% abundant in 35 eV spectra and not discernable in 70 eV spectra. In contrast, the $(M-COCl)^+$ is moderately abundant for both PCDDs and PCDFs. As expected, significant differences between 35 eV and 70 eV PCDT spectra were moderately abundant doubly-charged ions (m/z 160-3; m/z 142.5-144.5; and m/z 125-127) in the 70 eV mass spectra compared with very low abundant doubly-charged ions in the 35 eV mass spectra.

A NEGATIVE CHEMICAL IONIZATION GC/MS METHOD FOR THE DETERMINATION OF CHLORINATED PARAFFINS IN ENVIRONMENTAL SAMPLES

David H. Steele, Thomas M. Sack, and Leslie A. Moody
Midwest Research Institute, 425 Volker Blvd, Kansas City MO 64110

Chlorinated paraffins (CPs) are complex mixtures of chlorinated linear alkanes, (typically described by carbon chain length and percent chlorination). Common commercial formulations contain carbon chains in the range of 10 to 30, with percent chlorination ranging from 30 to 70% by weight. The major use for CPs in the United States has been as additives to cutting and machining oils, where they provide a self-sharpening mechanism by forming thin metal chloride films on cutting edges. CPs have been used extensively in Europe as plasticizing additives for polymers and paints, and as flame retardant additives for various materials (1); however, only minor usage for these purposes is noted in the United States.

While toxicological data on CPs is limited, chronic bioassay studies conducted by the National Toxicology Program (NTP) indicated carcinogenic activity for two formulations tested. Other studies have also demonstrated toxicological effects in various species. The available toxicity data and reported widespread aquatic CP contamination in Europe (2) have led to environmental concerns in the United States. Domestic usage patterns indicate that potentially significant CP releases into the aquatic environment will most likely occur from manufacturing operations; however, formulating and end use operations are also of concern.

In the past, such methods as thin-layer chromatography and dechlorohydrogenation followed by gas chromatography have been used for the quantification of CPs (2,3). Although these techniques are reasonably sensitive (ng levels), both suffer from a lack of specificity for the determination of individual CPs. The thin-layer chromatographic procedures use argentation to detect and quantify CPs and are therefore prone to interferences from any chlorinated species present. A lack of resolution between CP formulations has also been noted for the TLC procedure. The dechlorohydrogenation/GC technique quantifies CPs by replacing the chlorine atoms with hydrogen and measuring the alkane levels obtained. All alkanes native to the sample must be completely removed prior to GC analysis to avoid artificially high or false positive results. In addition, information concerning the degree of chlorination of the CP formulation is sacrificed.

Preliminary investigations into the use of negative chemical ionization (NCI) mass spectrometry for the detection of CPs has been performed (4,5). However, optimization of this technique and the demonstration of its effectiveness for use with environmental samples had not been demonstrated. This paper describes the single-laboratory evaluation of an analytical method for the determination of CPs in environmental samples at low to sub part-per-billion levels using GC/NCI-MS.

Based on available toxicity and production data, three CP formulations were chosen for investigation. These were Paroil 1160 (C10-C12, 50-60% Cl), Paroil 152 (C14-C17, 50-60% Cl), and Paroil 142 (C20-C30, 40-50% Cl). Samples of these materials for use as analytical reference standards were generously supplied by the Dover Chemical, Dover, Ohio. Environmental samples for method development and validation were collected from a stream which receives runoff from a CP production facility.

The analytical scheme is shown in Figure 1. Since it was known that CPs adsorb strongly to particulates, suspended solids were filtered from the water samples and analyzed separately. The CPs were removed from the water by liquid/liquid extraction with hexane. Particulate and sediment samples were Soxhlet extracted with hexane to remove the analytes. The extracts were cleaned up on acidic silica gel and activated alumina minicolumns, reduced to dryness and reconstituted in 25 to 50 L of isooctane for analysis. The extracts were chromatographed on a 30-m DB-5 fused silica capillary column, and the CPs were detected using NCI-MS on a Finnigan 4500 GC/MS system operating in a limited mass scan mode. Quantitation ions were chosen from the most abundant ion species for each formulation. Mass chromatograms from the analysis of a standard mixture are shown in Figure 2. Since CPs were determined to decompose in a heated GC inlet, sample extracts were introduced on-column at ambient temperature.

The method validation study was based on quantification results from analysis of a series of environmental samples. The experimental design (6) provided a statistical basis for the estimation of recovery and precision of the method when applied to the matrices. In

general, three replicate analyses at three spiking levels (1, 2.5, and 5 ppb for water; 200, 500, and 1000 ppb for sediments) were performed for each matrix. Four replicate analyses each of the unspiked matrices and the method blanks were also performed. For water, three distilled water spikes (controls) were also analyzed. Since no control sediment was available, four nonmatrix spikes were analyzed as a substitute. A complete discussion of the design, statistical treatment of the data, and the results of the method validation study is contained in the EPA final report (6).

Method recoveries for each CP formulation and matrix are depicted graphically in Figure 3. These recoveries were estimated as the slope (x100) of the calculated regression lines. Ninety-five percent (95%) confidence boundaries were computed based on the standard errors of the slope estimates and the sample sizes. For each matrix, the slope estimates of the three CP formulations were not found to be statistically different at the 95% confidence level; therefore, pooled recoveries were computed. The pooled recovery for water was found to be 106% with lower and upper 95% confidence limits of 92 and 120%, respectively. For sediment, the pooled recovery was 58% with a 95% confidence interval ranging from 52 to 64%. Method precision was estimated for each matrix as the coefficient of variation (100 x standard deviation/mean) of the replicate measured concentrations at each spiking level. Overall, method precision was better for sediments than for water. This is most likely due to the higher spiking levels used for this matrix (20-100 µg for sediments versus 1-5 µg for water). Precision also tended to improve with increasing spiking level. For both water and sediment, none of the background estimates were found to statistically differ from zero at the 95% confidence level.

The analytical method was found to be capable of quantifying CPs in water and sediment at the low to sub part-per-billion levels. While precision was found to be reasonable for this type of analysis, addition of appropriate surrogates and internal standards would be beneficial. This is especially true for the case of internal standards, since instability of the mass spectrometer source was noted throughout these analyses. Acceptable compounds for these purposes could not be identified during this work.

ANALYSIS OF NITRO-PAH METABOLITES AND THEIR DNA ADDUCTS BY NCI-GC-MS AND FAB-MS WITH B/E LINKED SCANNING

R.S. Annan, J. Bakthavachalam, R. Giese, P. Vouros
Northeastern University, Boston, Ma. 02115

Nitrated polycyclic aromatic hydrocarbons (PAHs) are a common source of environmental pollution. Two of these compounds, NO_2-Fluorene and NO_2-Pyrene account for 40-60% of the mutagenic activity found in automobile diesel exhausts. NO_2-PAHs are heavily metabolized, and a number of these metabolites are known to form covalent adducts with DNA.

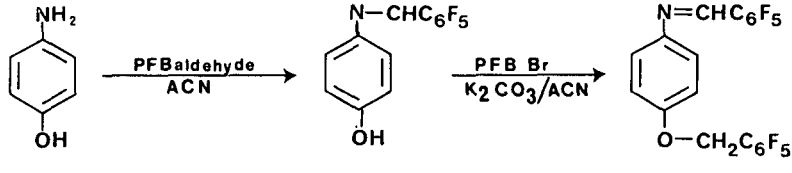
An electrophoric derivatization strategy is under development which will allow sensitive detection of the entire metabolic cascade of NO_2-PAHs by NCI-GC-MS. This type of screening is useful as an early warning indicator of exposure. The requirements for the derivatives are that they exhibit good electron capture properties, be formed in high yield and with a high degree of selectivity, form diagnostic ions under NCI conditions and that the EI spectra be structurally informative. Due to the multiplicity of functional groups present in NO_2-PAH metabolism, no simple derivatization reagent was found suitable for all compounds.

Using aminofluorene and aminopyrene as models the reactions of amino PAHs with a variety of elecrophoric reagents were studied. Pentafluorobenzylation (PFB) was found to be unsuitable because of low yields and multiple products. N-acyl derivatives were formed in high yields, but their NCI spectra showed multiple losses of HF, and in some cases high abundance ions resulting from retention of charge on the derivatization tag. Alkylation of the N-acyl compounds with either CH_3I or $F_5C_6CH_2$-Br resulted in simpler NCI in the latter case. There was not, however, a significant improvement in sensitivety under SIM conditions to warrant a two step derivatization.

The formation of a benzylidine derivative using PFB aldehyde occured in near quantitative yield, and resulted in the formation of a molecular anion under NCI. The reaction is specific for primary amines and leaves no reactive sites. The derivative of 2-NH_2-Fluorene is found to be 22 times more sensitive (300 fg S/N = 4) than the corresponding nitro compound.

The reaction of phenols with PFB-Br has been shown (1) to be the method of choice since it occurs in high yield, and results in selective formation of phenoxide ion.

Scheme I shows the strategy for the derivatization of all reported NO_2-PAH metabolites using *p*-aminophenol as a model.



Scheme I

Figure 1 shows an NCI-GC-MS chromatogram of a number of possible me tabolite models including positional isomers. All compounds are easily separated with the exception of *p*-nitrophenol and *o*-N-acetylaminophenol. However, because they have different NCI spectra (m/z 138 and m/z 150 respectively), they can be separated by mass chromatograpy.

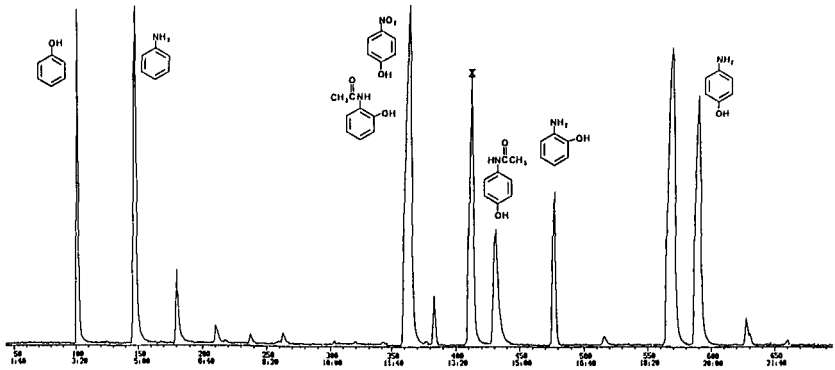


Figure 1. NCI-GC-MS: Separation of NO_2-PAH metabolite models as their electrophoric derivatives.

The analysis of NO_2 and other PAH metabolite-DNA adducts is difficult because of their high polarity, thermal instability, and small sample amounts. The normal FAB analysis of small amounts of these adducts, even after background subtraction, is hampered by the extensive matrix ion in terferences. Generally only M + H and M + alkali ions can be observed. We have found that the use of B/E linked scans for these compounds, even in the 200-500 nanogram range allows elucidation of certain structural features not visible in the normal FAB scan. Figures 2a and 2b show the FAB and B/E FAB scans for the benz(a)pyrene tetrol-deoxyguanine adduct. Ions present in the B/E scan are indicative of the parent (570), the aglycone (453), the PAH (303), and the deoxynucleoside (268). The lack of an M-NH_2 ion shows that the covalent bond is at the exocyclic amine. Figure 2c and 2d show a similar pair of analyses for the N-acetylaminofluorene-deoxyguanine adduct. The B/E scan of the aglycone (373) shows M-NH_2 (357), M-Ac (331), and the deoxynucleoside (267).

CHARACTERIZATION OF POLYCHLORINATED BIPHENYL PYROLYSIS MIXTURES

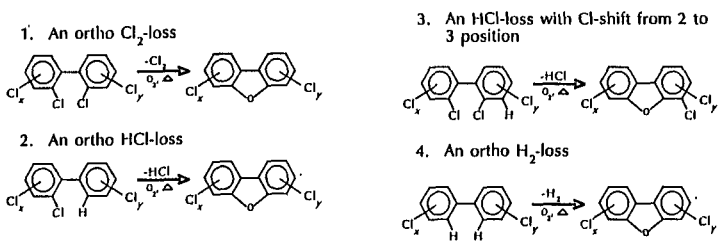
C.C. Alley, D.F. Groce, and D.G. Patterson, Jr.; Division of Environmental Health Laboratory Sciences, Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services, Atlanta, GA 30333

INTRODUCTION

Elevated polychlorodibenzofuran (PCDF) levels have been found in soot samples that were collected after transformer fires in Canada, the U.S.A., and Sweden (1). Buser and Rappe outlined four reaction routes (Figure 1) by which PCDFs are formed from pyrolysis of individual polychlorinated biphenyls (PCB) isomers (2). Mazer et al. synthesized all 38 tetrachlorodibenzofurans (TCDFs), using these reaction routes to predict which PCB isomer would yield the appropriate TCDFs. We have used these methods and synthesized the 38 TCDFs, the 28 pentachlorodibenzofurans (PnCDFs), and the 16 hexachlorodibenzofurans (HxCDFs).

FIGURE 1

PCB to PCDF Reaction Routes



EXPERIMENTAL

Weighed amounts of individual PCBs were pyrolyzed by the method of T. Mazer et al (3). Quantitative aliquots of each pyrolysis mixture were combined with a known amount of $^{13}D_{12}$-2378-TCDF as an internal standard. Each pyrolysis mixture was analyzed using a Finnigan MAT 4500 mass spectrometer operating in full-scan negative chemical ionization mode. The reagent gas was Methane. A 60 m DB-56, 0.25mm, 0.25mm fused silica capillary column was used and temperature programmed as follows: 100 C (2 min) to 260 C at 20 C/min, then to 300 C at 1 C/min and held at 300 C for 5 min. The ionizer temperature was 100 C, the injector temperature was 300 C, the electron energy was 70eV, and the filament was 0.25 mA.

This process allowed each class of congener (e.g., TCDF, PnCDF, HxCDF) to be identified. The principal ion of each individual PCDF was referenced to the m/z 318 ion from the internal standard so that we could quantitatively assess the relative importance of each reaction pathway and calculate the amount of each reaction mixture that should be combined to provide qualitative standards.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

RESULTS

In addition to the four previously determined reaction routes, two more PCB to PCDF routes have been identified: 1) the loss of H_2 with a 2,3-chlorine shift and 2) the loss of H_2 with a double 2,3-chlorine shift (Figure 2). Our method of analysis has allowed a quantitative assessment of the importance of each route for each PCB (Tables 1 and 2). Knowing the importance of each of these routes should allow a more quantitative method of predicting the PCDF levels and fingerprint from transformer accidents.

TABLE 1

ANALYSIS OF SELECTED HERBICIDES AND THEIR METABOLITES IN RIVER WATER SAMPLES BY CHEMICAL IONIZATION TANDEM MASS SPECTROMETRY

Colleen E. Rostad, Wilfred E. Pereira, and Thomas J. Leiker
U.S. Geological Survey
P.O. Box 25046, Denver Federal Center
Denver, Colorado 80225

Depth-integrated water samples collected during November and December 1987 from the Mississippi River and its major tributaries were extracted and analyzed initially by gas chomatography/ion trap mass spectrometry. Several commonly used herbicides and their degradation products were identified. In order to detect these compounds in a complex matrix with speed, specificity and sensitivity, a new method for analyzing these compounds was developed utilizing tandem mass spectrometry (MS/MS). The selected compounds included atrazine and its degradation products (deethylatrazine and deisopropylatrazine), simazine, metolachlor, alachlor and its degradation products (2-chloro-2',6'-diethylacetanilide, 2-hydroxy-2',6'-diethylacetanilide and 2,6-diethylaniline) and terbuthylazine (used as the internal standard).

Analytical standards for the selected compounds were analyzed by gas chromatography/positive ion chemical ionization mass spectrometry (GC/+CI/MS). The GC was equipped with a 30 m DB-5 fused silica capillary column. The commonly-used methane reagent gas was replaced with high purity isobutane which increased the ionization efficiency for these compounds 4 to 8 times over that produced by methane. The protonated molecules were then fragmented under collision activated decomposition using a variety of fragmentation conditions of collision energy and collision gas pressure. Argon was used as the collision gas. Collision energy was varied from -15 to -30 V, and collision gas pressure was varied from 1 to 2.5 torr. For each compound, fragmentation conditions were chosen to maximize the generation of one prevalent daughter ion. Because the collision gas pressure was not under data system control, it was set at an optimum value during the entire aquisition. The GC temperature program was set to the maximum rate possible, 20°/min, to minimize sample analysis time.

The scan range used to detect the resulting daughter ions was then limited to just one neutral loss from each protonated molecule. Sensitivity increased significantly. Coeluting or closely eluting compounds were analyzed by splitting the time between each compound. In one area of the chromatogram, four compounds elute very closely. The instrument spent 0.1 sec on the specified neutral loss of each compound sequentially, repeating the sequence throughout the entire elution time window. Sometimes common daughter ions were used simultaneously. It seemed possible that, daughter ions belonging to deisopropylatrazine (at mass 146) would interfere with daughter ions from deethylatrazine (at mass 146). Even at very high concentrations, daughter ion carryover between different compounds with identical daughter ions analyzed simultaneously did not occur.

The neutral loss, from the parent ion to the specified daughter ion, was then used for quantitative analysis. Standard mixtures of the compounds at 20 ng, 2 ng, 200 pg, 20 pg, and 2 pg per microliter were analyzed, with the internal standard, terbuthylazine, at 13 ng/ul. The detection limit (signal to noise, 3 to 1) for deisopropylatrazine and 2-hydroxy-2',6'-diethylacetanilide was 5ng and for diethylaniline and metolachlor it was 50 pg. The detection limit for the remaining compounds was 100 pg. The higher detection limit for deisopropylatrazine and 2-hydroxy-2',6'-diethylacetanilide was due partly to chromatographic and ionization limitations and partly to poor fragmentation in the MS/MS. As a result, sensitivity for these compounds was poor. The rest of the compounds fragmented into one prevalent daughter, which produced excellent sensitivity in the neutral loss mode. Instrument response for most of the compounds was linear over a 200 pg to 20 ng concentration range.

This methodology was then applied to the river water extracts. Reproducibility of the GC/+CI/MS/MS analysis on one of the river water extracts analyzed six times was excellent for some of the compounds. The percent relative standard deviation (%RSD) was less than 10% for diethylaniline, atrazine, and metolachlor. The %RSD was less than 25% for deethylatrazine, simazine, and alachlor, because they were present near detection limit concentrations. The other compounds, deisopropylatrazine, 2-chloro-2',6'-diethylacetanilide, and 2-hydroxy-2',6'-diethylacetanilide, were not found in the river water extract chosen for reproducibility studies.

The entire procedure, including injection, acquisition, and data manipulation, took only 20 min per sample. MS/MS was used to remove interferences, increase sensitivity, and decrease analysis time.

CONFIRMATION OF FENVALERATE IN ENVIRONMENTAL SAMPLES BY NEGATIVE ION CHEMICAL IONIZATION MS/MS

Charles J. Stafford and Douglas M. Swineford
U.S. Fish & Wildlife Service, Patuxent Wildlife Research Center,
Laurel, Maryland, 20708

A multi-year study was undertaken by the U.S. Fish & Wildlife Service to determine the environmental effects of several agricultural chemicals on the ecology of North Dakota's prairie pothole wetlands. As part of this study the synthetic pyrethroid insecticide fenvalerate was sprayed on agricultural crops adjacent to wetlands and residues of fenvalerate were measured in environmental matrices, including water, sediment, aquatic plants and aquatic invertebrates. Fenvalerate residues were determined in samples by extracting with organic solvents and analyzing the extracts by capillary column gas chromatography (GC) using an electron capture detector (ECD). Further sample cleanup was not necessary due to the separation power of capillary column GC and the specificity of the ECD allowing quantifiable limits on the order of 0.05 ng fenvalerate on column.

Confirmation of fenvalerate residues by electron impact (EI) GC/MS, which we normally employ (1), was difficult however, for two reasons: 1) extensive fragmentation by EI leads to low ion intensities (Fig. 1), and 2) matrix interference from co-extracted materials in environmental samples interferes with the GC/MS analysis. GC/MS analysis of a fenvalerate standard by EI using a Finnigan TSQ-70 required at least 1 ng for acceptable full-scan spectra (70 eV, source temp. 150°C, multiplier 1200 V). Interference from co-extracted materials present in the crude sample extracts made confirmation of fenvalerate at this level difficult. Analysis by methane negative ion chemical ionization (NCI, CH_4 @ 8 torr, 70 eV, source temp. 150°C) however, produced an single intense ion fragment m/z 211 $(C_{11}H_{12}O_2Cl)^-$ (Fig. 2) which allowed confirmation of 10 pg of fenvalerate standard, an approximate 100X increase in sensitivity over EI. Analysis of the same crude sample extracts by NCI produced very little interference.

Collision-induced dissociation of the parent m/z 211 ion by NCI MS/MS (Ar @ 1.4 mtorr, collision offset 4 eV, multiplier 1600 V) produced an intense daughter ion fragment m/z 167 $(m/z\ 211 - CO_2)^-$ (Fig. 3) providing further confirmation of the parent fenvalerate. Residues of fenvalerate in field samples of aquatic plants and snails were able to be confirmed by NCI and NCI MS/MS without cleanup. The selectivity of the negative ion formation processes greatly reduced matrix interference allowing confirmation of residues as low as 0.3 ppm.

USE OF MASS SPECTROMETRY IN ENVIRONMENTAL HEALTH EMERGENCIES: LABORATORY INVESTIGATION OF A POISONING EPIDEMIC IN SIERRA LEONE

R.H. Hill, Jr., C.A. Alley, D.L. Ashley, R.E. Cline, S.L. Head, L.L. Needham, and R.A. Etzel

Atlanta, Georgia 30333

In June 1986, an epidemic of poisoning occurred in Sierra Leone, West Africa, it involved 49 persons, 14 of whom died (1). These persons had sudden onset of weakness, dizziness, vomiting, and diarrhea that began within half an hour of eating. The most severely affected persons frothed at the mouth, were short of breath, had pulmonary edema, and lost consciousness. The cause of the illnesses was unknown, but it appeared to be a toxicant. We describe our laboratory's part in this investigation.

Experimental - Samples were extracted with ethyl ether. The ether extracts were concentrated and in some cases were subjected to cleanup by using silica gel chromatography. More than 120 samples were received and analyzed. Methane-positive chemical ionization mass spectrometry was performed by using a Finnigan 4500 GC/MS with a direct exposure probe. The mass range was scanned from 50 to 650 amu at 1 sec/scan. Proton nuclear magnetic resonance spectroscopy was carried out by using a Varian XL-300 NMR with a superconducting magnet. Quantitative analyses were performed with a Hewlett-Packard 5880 GC and a Melpar flame photometric detector in the phosphorous mode.

Discussion - Our approach in these types of environmental emergency investigations involves a) examining the available data for clues that suggest particular classes of toxicants; b) preparing samples and testing them for toxicity; and c) after a toxic sample has been identified, using analytical techniques to isolate, identify, and measure the toxicant (2). This poisoning epidemic seemed to be caused by a cholinesterase-inhibiting toxicant. The epidemiologic team showed a striking association with bread consumption 4 hours before the onset of illness (1). A bread sample discarded by villagers was then eaten by some ducks; within minutes these ducks died. Since a toxic sample was identified, we began our laboratory investigation with screening analyses of this sample. When we analyzed an extract of this bread using direct-exposure-probe positive chemical ionization mass spectrometry (see Figure 1.), we found a compound having a pseudo-molecular ion of 292. Among the compounds with molecular weight of 291 was the pesticide parathion (see Figure 2). Parathion is an extremely toxic pesticide with toxic properties that could easily account for the observed epidemic. A simultaneous examination of the bread extract by proton nuclear magnetic resonance confirmed that this pesticide was present. Parathion was also later confirmed by GC/MS. Analysis of various other items by using gas chromatography with flame photometric detection and GC/MS for confirmation supported the epidemiologic team's hypothesis that flour became contaminated during shipment by truck. Subsequent distribution of the contaminated flour to local bakeries in the towns of Kenema and Lalehun led to the sale of bread containing at least 400 ppm of parathion. Modern analytical instrumentation played a major role in this investigation, enabling us to identify an unknown toxicant within hours of receiving the initial bread sample.

Application of GC/MS/MS in the Analysis of Nitrosamines in Food and Food Related Products

Dorcas Weber, Nirisinha P.Sen and Benjamin P.-Y.Lau,
Food Research Division, Bureau of Chemical Safety, Food Directorate,
Health and Welfare Canada, Tunney's Pasture, Ottawa,
Ontario, Canada K1A OL2

A VG Analytical model 7070EQ, a hybrid MS/MS system of configuration EBQQ, was used to investigate the analysis of some commonly occuring volatile and non-volatile nitrosamines in food and related products. The instrument's first stage is a conventional EB configuration double focusing sector instrument with an off-axis detector for normal MS operation. For MS/MS operation, the ion beam is directed into a collision cell and another quadrupole mass analyser.

The EI+ spectra of the dialkyl-N-nitrosamines (dimethyl-, diethyl-, dipropyl- and dibutyl-) all show molecular ions with decreasing intensity as the length of the alkyl chain increases. The daughter ion spectra, using Argon as a collision gas, of most dialkyl-N-nitrosamines show a peak corresponding to the loss of 17 (OH) and, in the higher members of the homologous series, a loss of 42 corresponding to the loss of C_3H_6 from the alkyl chain. However, the dimethyl-N-nitrosamine only shows a peak corresponding to the loss of 30 (NO) from the parent molecular ion. The daughter ion spectra of the cyclic nitrosamine (N-nitrosopyrolidine, 1-nitrosopiperidine, and N-nitrosomorpholine) show a loss of 30 (NO) as one of the major ions.

Optimum CID operating conditions were established by two series of experiments. First the collision gas pressure was fixed at 1 x 10^{-6} mbar (total analyser pressure) and the collision energies were varied to obtain the optimum response. Then the collision energy was fixed at the optimum value and the collision gas pressure was varied. An example is shown in Fig. 1

Parent-daughter ion pairs were selected from the daughter ion spectra for multiple reaction monitoring operations (MRM). In most cases, two or more reactions were monitored for each component for confirmation .

Extracts of rubber nipples, rubber netting, smoked meat and apple wax were examined using this method. Typical chromatograms are shown in Fig 2. Most of the traces have little or no interference from different sample matrices indicating the high selectivity of the method. A comparison was also made using low (1K) and medium (5K) resolution for the same sample analysed by both the conventional SIM method and the MS/MS/MRM method. The result is shown in Fig. 3. The MS/MS traces show no interferences in the retention window monitored. As a result, the analysis can be carried out with a shorter GC column and shorter analysis time.

In certain samples, however, some interfering peaks were observed with the front end resolution at 1K. The selectivity can be improved by increasing the front end mass resolution. The result is illustrated in Fig 4 for a rubber nipple extract

In summary, GC/MS/MS has shown to be a sensitive and selective method for trace analyses of nitrosamines. The result is comparable to that obtained by medium (5 - 8 K) resolution using the conventional sector instrument. Selectivity can further be improved by increasing the front end resolution of the instrument.

DEVELOPMENT AND IMPLEMENTATION OF A GC-MS METHOD FOR SIMULTANEOUS DETERMINATION OF THIRTY-EIGHT BIOACCUMULATING COMPOUNDS IN FISH

J. G. Solch, J. H. Garrett, D. J. Wagel, L. A. Harden, M. S. Hanes, G. F. VanNess and T. O. Tiernan, Department of Chemistry and Toxic Contaminant Research Program, Wright State University, Dayton, OH 45435

In collaboration with U.S. EPA, we have recently worked to develop and evaluate a procedure for simultaneous measurement of some 38 organic compounds in fish tissue. This set of target analytes was selected by EPA on the basis of toxicity, bioavailability, metabolism and persistence of these chemicals in fish, as well as the quantities of such chemicals produced annually. The method developed was intended to utilize minimal sample preparation in order to reduce loss of target analytes. The sample extracts were to be amenable to full-scan capillary-column GC-MS analysis, and identification of analytes was to be based on GC retention time, responses at appropriate indicator masses, correct quantitation/confirmation ion intensity ratios, and library matching of mass spectra. The desired GC-MS calibration range was for 1-50 ng/µL of injected analyte.

The sample preparation ultimately developed entailed combining 20 g of ground fish tissue with 80 g of sodium sulfate, adding various surrogate and native standards, and Soxhlet extracting with hexane/methylene chloride. The extract was concentrated to a volume of 2 mL, and was then fractionated on a Biobeads SX-3 GPC column, using cyclopentane/dichloromethane as the mobile phase. The collected effluent fraction was concentrated and the GPC step was repeated. The internal standard was added to the final GPC fraction, after concentration. A set of samples prepared by these procedures for purposes of method validation are described in Table 1.

Initial studies indicated that the GC-MS response factors for the target analytes ranged from 0.011 to 1.200. This range, coupled with the need to analyze 1-50 ng/µL of injected sample, dictated a requirement for a 1:5000 linear instrument response range. To achieve this with the Kratos MS-25 Mass Spectrometer, a 100 volt amplifier was installed in lieu of the standard 10 volt amplifier. This resulted in an eight-fold increase of the usually attainable linear calibration range. A standard EPA software package was to be used for the data acquisition and processing, but this software utilizes a peak detection algorithm which fails when more than one MS peak is present in a given GC retention time window, as was frequently the case here, owing to the large number of compounds and matrix constituents in the fish extracts. This required development of a new algorithm which searches for and identifies the largest quantitation ion in a given window, which also satisfies other peak response and ratio requirements. This new routine correctly identified and measured intensities of analyte indicator ions even in the presence of other interfering peaks. The EPA software quantitation displays were also modified to show the appropriate number of significant figures and to display the measured quantitation/confirmation ion ratios.

Table 2 shows a summary of the data obtained using these methods in a validation study. These results indicate that the procedures described can successfully detect and quantitate 33 of the 38 target analytes in fish, with detection limits of 12.5 ng/g or lower. The calibration range was found to be linear for these analytes from 12.5 to 1250 ng/g. Pentachlorophenol, dicofol, dieldrin, chlorobenzilate and kepone were not reliably detected in fish by these methods.

THERMAL DECOMPOSITION OF A SERIES OF 2-CHLOROETHYL ALKYL AND ARYL SULFIDES

Dennis K. Rohrbaugh, Yu-Chu Yang and J. Richard Ward
U.S. Army Chemical RD&E Center, APG, MD 21010-5423

Compounds of the general class $RSCH_2CH_2Cl$ (2-chloroethyl sulfides) are commonly used in the synthesis of radioprotective materials and as simulants for mustard gas (bis[2-chloroethyl]sulfide). Our objective was to define the decomposition pathways of these compounds to determine what hazards are associated with the handling and storage of these compounds. Here we report the application of EI and methane CI GC/MS to characterize the thermal decomposition products of a series of 2-chloroethyl sulfides where R = methyl, ethyl, phenyl and benzyl and present a decomposition mechanism based on the formation of dimeric sulfonium salt intermediates to account for these products.

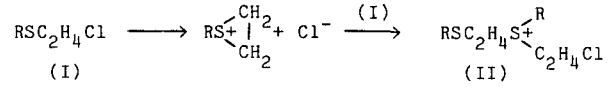
Samples were analyzed after two years of storage on a Finnigan model 5100 GC/MS using both EI and CI methods. The 15m SE-54 capillary column (split ratio 50:1) was programmed from 60°C to 160°C at 10°C per min. Injector temperature was 200°C and the interface temperature was 230°C. The CI reagent gas was methane (0.6 Torr).

Decomposition products observed are shown in the Table below.

Table. GC/MS Characterization of Aged $RSCH_2CH_2Cl$

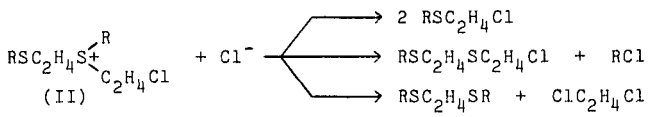
Component	Composition, Area %			
	$R=CH_3$ (CEMS)	$R=C_2H_5$ (CEES)	$R=C_6H_5$ (CEPS)	$R=C_6H_5CH_2$ (CEBS)
RCl	0.2	-	0.4	18.2
	-	-	-	trace
	0.4	1.7	-	2.3
$RSCH_2CH_2Cl$	93.0	94.4	95.4	44.8
RSR	-	0.2	0.1	13.5
RSSR	0.6	-	0.6	-
$S[CH_2CH_2Cl]_2$	0.6	0.06	-	5.6
$RSCH_2CH_2SR$	2.6	0.1	1.2	2.8
$RSCH_2CH_2SCH_2CH_2Cl$	1.1	0.1	-	7.9

The samples contained a number of degradation products derived from dimeric sulfonium ions which were absent in the freshly distilled products. These products, common to all four derivatives, can be rationalized by a decomposition mechanism which proceeds through the dimeric sulfonium salt II shown in Equation 1.

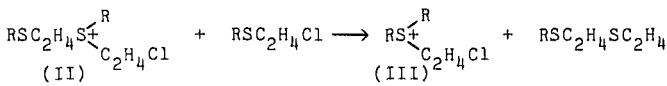


(1)

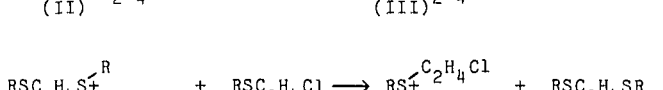
The products observed can be accounted for in terms of the decomposition of II via nucleophilic substitution. The three carbon atoms alpha to the charged sulfur in II are subject to nucleophilic attack. The two primary nucleophiles present in the neat solution are chloride ion and another molecule of $RSCH_2CH_2Cl$. Attack by chloride results in the three decomposition pathways shown in Equation 2 and attack by $RSCH_2CH_2Cl$ results in the formation of the secondary ions III and IV shown in Eqs. 3 and 4.



(2)



(3)



(4)

The sulfonium salt intermediate III can decompose directly to RSR, while IV can decompose directly to mustard and RCl. As shown in the Table, mustard, RSR, RCl and the products in Eqs. 2, 3 and 4 were all observed as products. Dithiane, which can be derived from II, was also detected. Oxidation and hydrolysis products were not observed. Because mustard is produced, safe handling and storage of these compounds is necessary.

The dithioethers produced in these studies are unusual in that more intense molecular ions were observed under EI conditions than under CI conditions. The reason for this is evident in the fragmentation chemistry. During chemical ionization, protonation of the sulfur enhances the leaving group ability and promotes formation of the thermodynamically stable ethylene sulfonium ion as shown below.

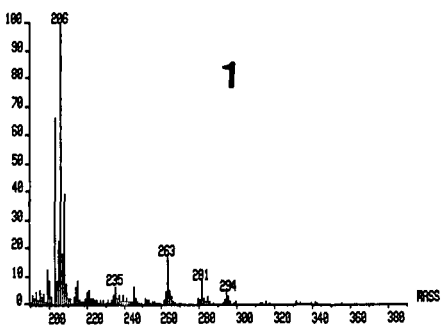
CHARACTERIZATION OF REACTION PRODUCTS OF CHLORINE DIOXIDE AND FATTY ACIDS OF WHEAT FLOUR USING MASS SPECTROMETRY.

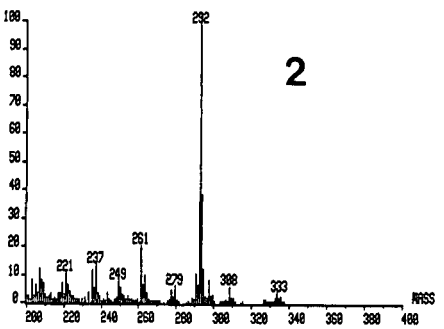
DAVID L. HEIKES, Total Diet Research Center, Food and Drug Administration, Kansas City, MO 64106

The Food and Drug Administration's Total Diet Program surveys table-ready foods for industrial chemicals and pesticides. During examination of several pastry items several unidentified gas chromatographic - microcoulometric and electrolytic conductivity responses were observed. Breads, cakemixes, muffins and soda crackers all contained these compounds at one time or another and at various levels. Since these foods have the common ingredient of flour, a survey of various types of flour was conducted. It was found that only bleached flour contained these unidentified chemicals.

Capillary column GC/MS indicated that these compounds which appeared as single peaks on packed column GC, were in reality comprised of two or more compounds which were nearly coeluting. This phenomenon suggested the presence of structural isomers. Further, most of these compounds showed a common similarity to the unsaturated mass spectral pattern exhibited by linoleic acid (i.e. m/z 41, 55, 67, etc.). Linoleic acid is the predominant fatty acid of wheat. No apparent molecular ions were observed.

Chlorine and chlorine dioxide are used to bleach wheat flour used in pastries and breads. It was therefore suggested, that the compounds observed in the pastries were reaction products of the indigenous linoleic acid and the bleaching agents. Electron impact spectra exhibited no apparent molecular ion and little or no evidence of chlorination (FIGURES 1 and 2). However, each spectra displayed a characteristic ion which could result from the loss of one or more molecules of HCl or cleavage of a former double bond which had received the addition of Cl and OH (1).





From this information and the proposed reaction products of chlorine and chlorine dioxide with unsaturated acids, a number of feasible compounds (FIGURE 5) were synthesized using classical procedures.

Several reagent gases were employed in the attempt to obtain molecular weight data through chemical ionization techniques. Ethylene oxide (2) proved the most useful (FIGURES 3 and 4).

ANALYSIS OF AMBIENT AIR SAMPLES UTILIZING AN AIR TOXICS INTERFACE SYSTEM BY MEGABORE CAPILLARY GC/MS/DS

R. L. Porch, J. T. Bursey, D. P. Dayton, R. A. McAllister,
J. Rice, D. E. Wagoner; Radian Corporation,
Research Triangle Park, North Carolina, 27709.

An interface system has been developed for the analysis of ambient air samples collected in 6-liter electropolished stainless steel canisters (see Figure 1). This system delivers a precisely measured volume of ambient air sample to any analytical device. The portable interface is being used with a GC/MS system and a VARIAN™ 3700 gas chromatograph, configured with a PID/FID and an ECD. The interface system can transfer an air sample stored in a canister under pressure, or under vacuum, and preconcentrate the organic content in a cryogenic trap packed with 60/80 mesh glass beads cooled by liquid argon (-189°C). Then the trap is heated to 204°C in 56 seconds and backflushed with helium to sweep the organic compounds directly on-column to a subambient (5°C) DB-624 0.53 mm x 30 m megabore capillary column. The column operates at a flow rate of 15 mL/min with a make-up flow of 15 mL/min into a glass jet separator. The interface system heated transfer line has a standard 2" 26 gauge syringe needle attached which is directed through the GC injection port cap and septum. A heated on-column injector liner allows the needle to fit inside the megabore capillary column.

Calibration canisters containing 90 uL of HPLC water (simulates the 70% humidity at 24°C during the collection of samples) were spiked at various ppbv levels of each target compound and allowed to equilibrate before analysis. The ppbv calibration concentrations vary depending upon whether full scan or MID analysis is required. The approximately 40 target compounds (primarily halocarbons and low boiling aromatic and olefinic compounds) typically have correlation coefficients of >0.99 in the full scan and MID mode. Samples from 34 different sites across the United States have been analyzed on a quadrupole GC/MS/DS and quantitated by linear regression using the Incos data system. GC/MD (multidetector) and GC/MS target compound identification comparisons are summarized in Table 1. Analysis of 15% of the site samples by both the GC/MD system and a GC/MS showed a compound identification confirmation rate of 95.4 percent. Currently the interface system is being modified to allow operation with internal standards.

Oak Ridge, Tennessee 37831

ABSTRACT

The compounds analyzed by EPA Method 625 are varied in their chemical and physical properties. These polar and nonpolar compounds range from volatiles to high-boiling compounds; some are thermally labile while others can undergo catalytic decomposition. The problem of nonlinear responses with respect to concentration by these chemical and physical properties is the subject of investigation.

The study was undertaken using a Kratos MS-50 and MS-25E GC/MS/DS system. Two experimental systems have been studied. The first system was composed of a Grob split-splitless injector, SPB-5 column connected to a 1-m deactivated column by a double-ferrule connector, and a stainless steel ionization chamber. The second system was composed of a cooled on-column injector with a 2-m precolumn, an SPB-5 column connected to the precolumn, a 1-m deactivated column by single ferrule connectors, and a gold-plated ionization chamber.

The linearity of the response factors for a range of concentrations for a Grob hot injector versus a cold-on-column injector is shown in Table 1. For the Grob injector (which was heated to 320°C and contained a deactivated glass liner), the difference between the response factor for the 100- and 10-ng/μL concentrations of the listed compounds was approximately two to three times, with no benzidine being detected at 10 ng/μL. However, with the cold-on-column injector with secondary cooling, the response factors showed essentially no change with concentration.

Even after the Grob injector was replaced, the GC peak representing benzidine showed problems with chemical absorption in the GC system. The benzidine peak eluted at 242°C, but still showed a detectable tail at 300°C. The problem was found to be caused by the double-ferrule connector used to connect the column to the precolumn and the interface column. After replacing the double-ferrule connector with a single-ferrule connector, the tailing factor at 25 ng/μL was reduced to 1.5.

The effects on the compounds by the source material were also large. Table 2 shows that in changing from a stainless steel ionization to one plated with gold, the area of the internal standards went up by a factor of 3. The area for phenol increased by a factor of 4, while the area for 4-chloro-3-methylphenol increased by a factor of 6. However, the areas for 2-nitrophenol, 2-methyl-4,6-dinitrophenol, and 2,4-dinitrophenol either stayed the same or dropped. The drop can be correlated with the pKa value. Because of this fact, it was determined that there must be active sites in the gold-plated source. After silylation of the gold source, a marked increase was noted in the areas of the nitro compounds. An overall increase in response factors was indicated by changing from a stainless steel to a gold plated source. This fact coupled with the large increase in absolute areas showed that the gold-silylation source was superior in its ability to produce a lower detection limit and a more linear response over a wider concentration range.

DETERMINATION OF ORGANIC COMPOUNDS IN DRINKING WATER USING LIQUID-SOLID EXTRACTION, CAPILLARY COLUMN GAS CHROMATOGRAPHY, AND HIGH SENSITIVITY FULL MASS RANGE MASS SPECTROMETRY

Thomas D. Behymer, James W. Eichelberger, and William L. Budde

U. S. Environmental Protection Agency, Office of Research and Development, 26 W. Martin Luther King Drive, Cincinnati, OH 45268.

A number of pesticides and industrial organic compounds are routinely determined in water using liquid-liquid-extraction, capillary column gas chromatography (GC), and full mass range mass spectrometry (MS). For many monitoring activities including industrial or municipal wastewater, landfill leachate, and groundwater near waste sites, conventional GC/MS methods with quantitation limits of about 10 ug/L (10 parts per billion, ppb) is adequate. But for the determination of organics in drinking water, quantitation limits in the range of 0.1-10 ug/L are needed, and it is highly desirable to retain the full mass range data acquisition of conventional GC/MS to ensure reliable identifications.

The objective of this work was to develop, for drinking water analyses, a general purpose analytical method with the following characteristics: (a) sensitivity for complete electron impact (EI) mass spectra with 0.1 ng injected (corresponding to 0.1 ug/L or 100 parts per trillion after extraction and concentration); (b) applicability to a minimum of 40 organic compounds of concern; (c) isolation of analytes with liquid-solid extraction (LSE) cartridges; (d) minimization of use and worker exposure to solvent (methylene chloride); (e) quantitative accuracy of 70% or better and precision of 30% RSD or better; and (f) strong quality control procedures incorporated into the method.

A group of about 40 compounds (Table 1) which have been found in drinking water supplies, and which are under study for potential adverse health effects, were added to water at 2 ug/L and 0.2 ug/L. These were extracted by passing one liter of water through commercially available LSE cartridges containing 0.9-1.g of reverse phase liquid chromatography packing materials. The compounds were eluted with 10 mL. of methylene chloride, and determined with capillary column high sensitivity full mass range GC/MS. The recoveries of most compounds were greater than 80% with detection limits in the target range. The results from one set of analyses at 2 ug/L (2 ppb) are shown in Table 1.

Table 1. Accuracy and precision data from seven determinations of the method analytes at 2 ug/L with liquid-solid extraction and the ion trap mass spectrometer.

ANALYSIS OF ORGANIC POLLUTANTS IN AIR AND WATER BY CAPILLARY COLUMN GC/MS

QIAO SHIJUN WU RENMING and GE NINGCHUN
Gansu provincial Institute of Environmental protection.CHINA

Methods for organic volatiles in air and water have been reported(1~5), However faster and simpler methods are needed both sampling and analysis of environmental organic pollutants.

In our experiment,the organic volaties in industrial air are adsorpt on a porous polymer(Tenax GC),the organic volatiles in drinking water are heated and carried out by nitrogen flow,which are adsorpt on Tenax GC.Both pollutants are transferred into a capillary column,and heat desorption onto a GC/MS system.These methods are simple,fast,convenient for analysis of trace organic pollutants in air and water.The methods have beed used for several years.

EXPERIMENTAL

Preparation of Tenax GC Tude.The sampling tude is 20 cm long stainless steel filled with 0.3 g of 60-80 mesh of Tenax GC.Initially,the column is precondtioned at 275°C in a nitroge flow for 24 hours.Befere sampling the tube is heated at 250°C in a flow of pure He for 30 minutes in oeder to eliminate any trace of organic compounds.

Sampling Procedure.For pollutants in industrial air,the Tenax GC tube is connected with a flow-meter and an oilfree air pump.The flow of air is controlled at 0.4 l/min for 30 minutes .The organic volatiles are adsorpt on Tenax GC.This is more simpler.

A schematic diagram of the simpling apparatus is shown in figure 1.The drinking water of 2 l is poured into the class tude,and a constnt temperature water of 50 °C is passed through the inlet of constant temperature water, in the meanwhile,a little flow of nitrogen is introduced into the water sample.Thus the organic volatiles are carried and adsorbed on Tenax GC.

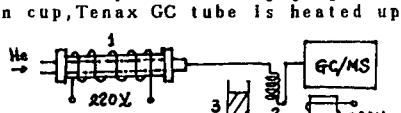
2. Tenax GC tube
3. nitrogen flow inlet
4. 5. inlet.outlet of constant temperature water of 50 °C
6. 7. inlet,outlet of cooled water

Fig.1 Simpling apparatus for water simple

Concentrating and Entering Sample Procedure. The Tenax GC tube is inserted into heat tube,with helium entering from one end for several minutes at a pressure of 0.4 kg/cm². then coil is placed into a lipuid oxygen cup,Tenax GC tube is heated up to 180°C for 15 minutes. So as to



1. heat tube
2. concentration tube
3. liqued oxygen cup
4. heat tube

Fig.2 The arrangement of simple concentration and entering

have the simple inside Tenax GC tube is desorbed and is cooled in the concentration tube.After concentration,the cup is removed and the concentration tube is rapidly inserted into the heat tube, having temperature suddenly rased up to 180 °C, the sample together with helium would enter the GC/MS system.

GC/MS system.The GC/MS system is a JGC-20KEP GC attached with a hydrogen flame detector and a programm temperature device, and a JMS-D100 Mass Sepectrometer with a JMA-0231 DATA processor.The capellary column is squalane column of stainless steel with inner diameter of 0.25 mm and a length of 45 m. An ionic soure of electron impact with ionization voltage of 3000 volts and electron multiplier voltage of 1900 volts is used. The resolution power is 1000.

Blank and Recovery Test. The whole sampling,concentrating and entering for drinking water and air sample are analyzed with blank tests and no foreign matters are found.The recovery test for water is made with chloroform,benzene and n-hepane, the recovery rates reached up to 88%, 91% and100%.While the absorbed method is tested with pentane,benzene,cyclohexane and the recovery rates are 94%,109% and 72%.

RESULT and DISCUSSION

Used these methods,the organic volatiles in Lanzhou drinking water are tested.Fig.3 is the total ionic chromatogram,from which 48 polutants are identified,there are 9 chlorides in drinking water. While 58 pollutants in industrial air are analyzed. These pollutants are ppb level.

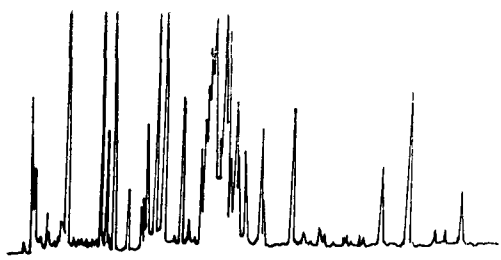


Fig.3 The total ionic chromatogram for drinking water

To analyse organic volatiles in water and air, the Tenax GC has been chose because it is hydrophobic,has a low adsorption strength allowing thermal elution of relatively high boiling compounds at about 250-275 °C,has a good thermal stability and does not react with most of the organic pollutants.

In our experiment,the samples are directly entered into the capillary column withour passing through avapourized chamber, in order to get higher sensidilites(6,7).

The invasion of water vapour or CO_2 in sample would do damage to the mass spectrum, the reason for this,we introduced a few minutes of helium into the Tenax GC tube before heat and concentoation causing the wate rvapour and CO_2 be brought out together helium.

ENVIRONMENTAL CHAMBER/MS TECHNIQUES FOR CONSUMER PRODUCT EMISSIONS

Charlene W. Bayer and Marilyn S. Black
Georgia Tech Research Institute
Atlanta, GA 30332

Volatile organic compounds (VOCs) are one of the major groups of contaminants found in the airborne indoor environment. Total VOC levels of greater than 1.0 mg/m3 indoors indicate inadequate indoor air quality and can result in acute and/or chronic health problems. VOCs are outgassed from a plethora of consumer products such as carpeting, wallpaper, adhesives, paints, fabrics, vinyl flooring, wood products, deodorants, cleaners, etc. (1). Determination of the etiology of VOC emissions is of prime importance for the improvement of indoor air quality.

A wide spectrum of VOCs are generally detected in the indoor environment, and usually the individual VOC detected is in the trace concentration of parts-per-billion volume or less. Often 50 to 100 compounds are observed at individual sampling sites (2). The complexity and trace quantities of the VOCs, as well as the variety of possible sources, creates a difficult sampling, analysis, and source determination problem. The general survey analysis approach can identify many of the airborne VOCs, but provides limited source data. Environmental chamber and mass spectral techniques are essential for the determination of VOC emission sources and for the construction of a data base of consumer product organic emission patterns. The use of an environmental chamber or headspace device eliminates unknown VOC sources, but does not eliminate the basic problems of sampling and analysis.

In this paper, various sampling and analysis techniques for consumer products emissions have been studied and compared. VOC emissions emanating from various consumer products were examined using two different collection techniques: 1) on-line, real-time GC/MS and 2) on-line solid sorbent collection followed by off-line analysis. Two types of direct analyses were investigated. The first consists of direct injection of emissions from a consumer product loaded into an environmental chamber which has been interfaced with a GC equipped with a mass selective detector (MSD) and/or flame ionization detector (FID). The second direct method scrutinized is direct injection of headspace collected emissions into a GC equipped with a MSD. Two types of on-line solid sorbent collection followed by off-line analysis techniques were studied. The first technique consists of loading consumer products into a controlled environmental chamber and collecting consumer product emissions on multi-sorbent tubes which are subsequently analyzed by thermal desorption (TD)/GC/MS. Loading of the consumer product into an ambient headspace chamber followed by collecting the VOC emissions on multi-sorbent tubes with subsequent TD/GC/MS analysis is the second method that was examined. Each of these four techniques were studied and compared to meet the following objectives: 1) optimization of VOCs detection sensitivity; 2) optimization of VOCs collection efficiency; 3) elimination of analyte reaction and decomposition; 4) optimization of individual VOC identification; 5) development of a consumer product emissions data base; 6) determination of VOC emission rates; and 7) correlation between laboratory and field results. Various consumer products emissions were studied to compare the four sampling and analysis techniques. The products studied were drapery material, drapery lining material, carpet, fiberglass insulation coated with a urea-formaldehyde resin, bathroom deodorants, and solid air fresheners.

In general, it was found that environmental chamber/multi-sorbent collection/TD/GC/MS was particularly useful for products outgassing trace

quantities of VOCs in the mid-boiling point range. This method easily detects VOCs in the low ppbv to high pptv range, because of preconcentration of the sample (1 - 25 L are commonly used) on the sorbent tube prior to analysis. The major disadvantages include unknown breakthrough volumes, particularly for the more volatile constituents; irreversible adsorption or inefficient desorption of some analytes; analyte losses and side reactions during sample storage prior to analysis; and thermal decomposition and reactions during desorption. The environmental chamber/GC/MSD is a useful technique for a broad range of analyte structures and volatilities. Lack of sensitivity is the primary disadvantage to this technique. Sample preconcentration is limited to the size of loop compatible with the system (usually 1 to 5 mL). Ambient headspace/multi-sorbent collection/TD/GC/MS is useful for small consumer product samples and for the detection of less volatile VOCs. Heated headspace analyzer/GC/MSD is useful for small consumer product samples and for detection of the less volatile and more reactive VOCs. Headspace techniques cannot be directly correlated to "real-life" conditions. The results are only qualitative. Heated headspace subjects the consumer product to harsher, unnatural conditions resulting in VOC emissions which would not be commonly found in an office or residential setting. The environmental chamber allows the simulation and control of conditions similar to those the sample would experience in actual field use. Tables 1 and 2 illustrate VOC detected in drapery material emission only using the environmental chamber or the ambient headspace. The second major

Dimethyldisulfide

advantage of the environmental chamber over the headspace units is that a larger sample size is analyzed. This allows for realistic results. Consumer products are not homogeneous throughout the entire product. The VOC emissions can vary depending on the portion of the sample that is used for the analysis. The larger the sample size used for the analysis, the more realistic the laboratory emission results will be to the field emission results.

COMPARATIVE DISTRIBUTION OF HYDROCARBONS IN AIRBORNE PARTICLES COLLECTED BY SIZE FRACTIONATION

***Rafael Infante**, Arnaldo Carrasquillo and Nidia Santiago*
Chemistry Department
Catholic University of Puerto Rico
Ponce, P.R. 00732

The aim of this study is to examine the type and the size distribution of organic compounds present in air particulate matter. Our special concern are the polycyclic aromatic hydrocarbons (PAH's) because of their potential adverse biological effects, including transformation of some of these substances to mutagens and carcinogens by mammalian microsomal enzyme system.

The airborne particulate samples were collected by an Andersen cascade impactor at five sampling sites in Ponce, PR in 1986. The cascade impactor separates particles into five size classifications from < 1.1 to 7.0 um. The cascade impactors were run for 72-hours periods in order to get enough sample for the analysis. A composite sample from four of the five sampling stations was analyzed following the analytical procedure outlined below.

An analytical procedure suitable for the analysis of organic components associated with each of the fraction was developed. It includes ultrasonic extraction with methylene chloride followed by concentration and analysis by high performance gas chromatography/mass spectrometry (HP 5995B GC/MS system). The major peaks in each of the fraction analyzed were identified by comparison of the mass spectra with an online library of over 20,000 spectra and by selective ion monitoring and retention time data. Quantitation was performed by integrating the ion current for the molecular ion for the PAH's and the m/z 85 ion for the normal alkanes. This procedure was tested by extracting a standard mixture of target compounds that included polycyclic aromatic hydrocarbons and normal alkanes and by extracting NBS Standard Reference Material 1649 (Urban Dust Organics). Extraction efficiencies at the 1 ng/ul level were obtained.

The general trends included the observation of low levels of the PAH's in the smallest size particles, < 1.1 uM. They where mostly observed in the west sampling site, which is close to a cement factory that burns coal for their energy demands. PAH's where also observed in the east site, these are probably generated by the agricultural burning activities of this area.

In contrast, aliphatic hydrocarbons both of anthropogenic and natural origin were observed. Their particle size distribution is shown in Figure 1. The distribution remained fairly constant in each of the four sampling stations. The concentration of several higher uneven aliphatic hydrocarbons was found to be higher than that of their even homologues due to contribution from natural sources.

APPLICATION OF MULTIFUNCTIONAL DERIVATIVE TO THE DETERMINATION OF NITRO-PAH's IN ENVIRONMENTAL SAMPLES BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

T. A. Dean and C. F. Poole; Wayne State University, Detroit, MI 48202;
J. Auld, The Detroit Edison Company, Engineering Research, Detroit, MI 48210

The N,N-dimethylamino derivative of nitro-PAH's, specifically nitro-pyrenes, provides a powerful analytical tool. Previously the amino derivative has been utilized to enhance the fluorescence of the nitro-PAH under investigation.[1,2] In the case of the amino derivative further sample handling after derivatization is limited by oxygen and light lability. The greater stability of the tertiary N,N-dimethylamine allows a more rigorous sample preparation/clean-up by way of a cartridge type cation exchange(SCX) procedure.[3] It is the SCX procedure that allows greater selectivity and a medium through which the analyte may be concentrated for greater sensitivity.[4]

Experimental

An aliquot of a particulate extract solution is placed in a 5mL vial equipped with a septum cap. If necessary a standard addition is added at this point. Approximately 5mg(½ match head) of Pt/Al_2O_3(5%Pt) catalyst and several drops of 37% formaldehyde solution are added to the reaction vial. After affixing the septum cap the vial is charged with 40psi of hydrogen and placed in a sonicator for 0.5 hour; at which time a fresh charge of catalyst, formaldehyde and hydrogen are added to the reaction vial. The recharge procedure is repeated three times for a total reaction time of 2 hours.

Strong cation exchange cartridges(Supelco SCX) are prepared by first removing the upper frit(it will become plugged by the catalyst fines) and replacing it with a tight plug of glass wool. The SCX surface is activated with 500uL of 0.5M phosphoric acid in 80/20 water/methanol and washed with 50/50 water/methanol. The reaction mixture is passed through the cartridge at a dropwise rate by a low vacuum. The cartridge + mixture is then washed with 500uL of 20/80 water/methanol. The N,N-dimethylamino derivative is eluted from the cartridge with 1.0M ammonia and collected in a 1mL volumetric flask. (See Figure 1)

If no SCX clean-up is to be used, then the derivative must be freed from the surface of the Al_2O_3 catalyst. This is accomplished by the addition of benzene to the reaction mixture, followed by centrifugation. An optimum response, independent of the amount of catalyst was found at a 2 fold dilution(1000uL of benzene added to 500uL of reaction mixture).

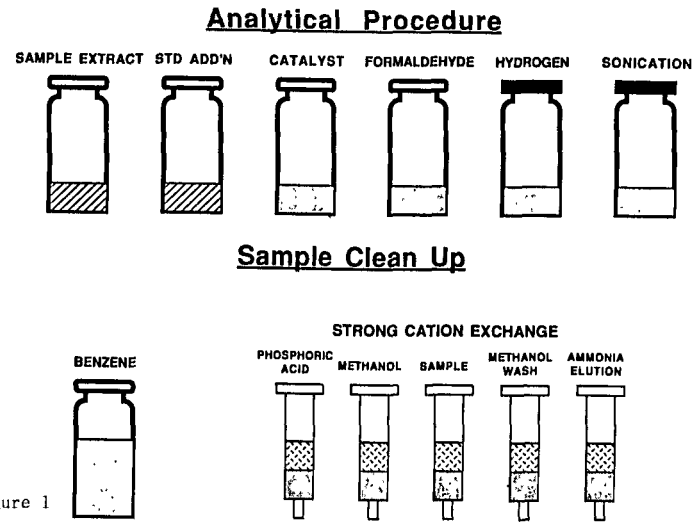

Figure 1

Results

Diesel exhaust, urban air, and coal flyash samples have been successfully analyzed by HPLC/fluorescence. In this particular study analyte concentrations of 50 to 200pg/uL of extract were prepared. Due to the very high fluorescence yield(240ex/370+em) and 10uL injections quantitative HPLC analysis was successful. Unfortunately, due to the limited sample capacity of capillary GC/MS quantitative analysis of these samples was not possible. However, selected ion recording MS analysis did qualitatively indicate the presence of the N,N-dimethylamino derivative at the 50 to 100pg level.

A COMPARISON OF GAS, LIQUID AND SUPERCRITICAL FLUID CHROMATOGRAPHIES IN COMBINATION WITH MASS SPECTROMETRY FOR DETERMINATION OF POLYCYCLIC AROMATIC COMPOUNDS IN ENVIRONMENTAL SAMPLES.#

W.D. Jamieson, R.K. Boyd, C.M. Elson*, M.A. Quilliam and P.G. Sim

Marine Analytical Chemistry Standards Program, Atlantic Research Laboratory, National Research Council of Canada, 1411 Oxford Street, Halifax, Nova Scotia, CANADA B3H 3Z1 (* on sabbatical leave from Saint Mary's University, Halifax, Nova Scotia, CANADA B3H 2C3).

Polycyclic aromatic compounds (PACs) are widespread pollutants of well established toxicity. Our interest in analysis for PACs in marine sediments, including development of reference materials, led to a critical evaluation of current protocols for quantitative analyses of 16 polycyclic aromatic hydrocarbons (PAH) designated as priority pollutants by the United States EPA. It was shown (1) that the standard methodology (reversed phase HPLC with single wavelength detection), when applied to real-world complex samples, yields results which combine high precision with high inaccuracy. The latter arises from incomplete chromatographic separations coupled with non-specific detection. We have pursued approaches to this problem which combine different separation selectivities of various chromatographic methods with sensitive and selective detection techniques, of which mass spectrometry (MS) is the most important. As discussed below, some shortcomings of mass spectrometry in this context can be alleviated by simultaneous recording of complete UV spectra using a diode array detector (DAD).

Several chromatographic techniques are available for separations of PACs: **(a)** gas chromatography (GC); **(b)** reversed phase liquid chromatography (RPLC); **(c)** normal phase liquid chromatography (NPLC); **(d)** supercritical fluid chromatography (SFC). Fused silica capillary columns are widely used in GC due to high resolving power and ease of coupling to a wide range of detectors, including MS. LC methods complement very well GC techniques (e.g. LC better for polar PACs, LC vs. GC differences in resolving isomers and interferences in complex mixtures). RPLC and NPLC offer medium resolving power, ability to analyze labile and high molecular weight compounds, excellent quantitative precision, and the possibility of interfacing to selective optical detectors as well as to MS. Though LC techniques are often better at PACs isomer separation than is GC, oxygenated PACs overlap with the PAHs and, given limited resolving power, this can lead to interference problems. Many of the advantages of GC and of LC are combined in SFC, which can be used with either capillary or packed columns (the latter with a wide variety of stationary phases). In our hands the efficiency of SFC is lower than that of the rival methods (almost certainly due to problems of interfacing to detectors); however the polar PACs elute much later than the PAHs, and the resolution within the polar group is also improved. These four separation methods provide complementary separation selectivities for PACs.

Simple ionization detectors, such as the flame ionization detector (FID) in common use with GC, are severely limited (1) in their usefulness in the present context. The photoionization detector (PID) is more selective for PACs; we have shown recently (2) that the PID is also compatible with SFC, and provides excellent sensitivity for PACs, under circumstances (e.g.. high CO_2 flow rates) where FID fails completely. However the PID is also a single parameter detector and is thus of limited

NRCC No. 29012

usefulness in the present context. In the same way, single-parameter detectors based on UV absorption (single wavelength) are reliable only if the chromatographic separation (HPLC or SFC) can guarantee complete separation of all analytes, a practical impossibility (1). Even UV-emission detectors (two parameters) are similarly limited in PACs analysis.

The availability of DADs, permitting complete UV-visible spectra to be acquired across all peaks in a HPLC or (with a high-pressure cell) SFC trace, represents an enormous advance in technology available for trace organic analysis of complex samples. However the information content of a UV-visible absorption spectrum is inherently low, and successful analyses of the present type (1) are not possible using a DAD alone.

The high sensitivity and universal applicability, coupled with high information content (implying high specificity) of MS, makes this technique essential for analyses of complex samples for PACs (1). Interfacing MS to GC and HPLC is now standard methodology; for PACs analyses by HPLC (both normal and reversed phase) we have found the moving belt interface to provide excellent results apart from low transfer efficiencies for the more volatile PACs, e.g. naphthalene (1). Increase in specificity at adequate sensitivity can be achieved by use of medium to high resolving power MS, or in some cases by monitoring the first ^{13}C isotope peak of the doubly-charged molecular ions ("half-massed" MS (3)(4)). The moving belt interface has also proved to be useful for packed column SFC/MS; excellent EI spectra can be thus obtained. Interfacing MS to SFC capillary columns is most easily accomplished by direct insertion of the column to the ion source via a suitable restrictor. We have had good success with this technique by operating the source under CI conditions using the CO_2 mobile phase as reagent gas. In positive ion mode, PACs give essentially only molecular ions with poor ionization efficiencies, presumably via charge exchange. However, in negative ion mode, a rich chemistry is revealed, with evidence for surprisingly effective isomer distinction (5).

Particularly powerful are combinations of several chromatographies plus several detection techniques. For example, a combination of RPLC with DAD plus MS (medium resolving power) in series was shown (6) to be capable of both resolving co-eluting compounds (via the MS reolving power) and also of identifying particular PACs isomers (via the UV spectra). We hope to extend this serial DAD/MS detection strategy to SFC in the near future. Cross-correlation of data from different chromatographies is also a powerful tool in the analysis of complex PACs mixtures (1).

In conclusion, it is emphasised that analysis of real-world samples such as marine sediments for PACs is an exacting task. To obtain reliable data the analyst must call upon all available techniques; simple strategies have been shown (1) to work for only the simplest mixtures.

ELECTRON IMPACT MASS SPECTRA OF POLYCYCLIC AROMATIC HYDROCARBONS: A REFERENCE COLLECTION.

Thomas R. Sharp*, Hongmee Lee+, Anna Ferguson#, Kenneth N. Marsh#, Ronald G. Harvey+.

* Center for Chemical Characterization and Analysis, Department of Chemistry, Texas A&M University, College Station, TX 77843.
# Thermodynamics Research Center, Texas Engineering Experiment Station, Texas A&M University, College Station, TX 77843.
+ Ben May Institute, University of Chicago, Chicago, IL 60637.

The polycyclic aromatic hydrocarbons (PAHs) have become an ubiquitous and significant environmental contaminant and, moreover, a major health risk. Although they have been known for many years, and the mass spectra of the basic parent polycyclic systems have been recorded, extensive systematic studies correlating molecular structure with mass spectral details have not been done. Sellier et al. [1] point this out in their recent report on such a study of anthracenes and related compounds.

As a continuation of the Thermodynamics Research Center Spectral Data Program - Mass Spectra (formerly the American Petroleum Institute Research Project 44 - Mass Spectral Data), we report the electron impact mass spectra of a collection of 209 polycyclic aromatic hydrocarbons. Samples which were impure have been purified or otherwise treated in order to include the highest quality data in this collection. The following points have been addressed and summarized as spectra have been collected and examined: the ability to identify compounds by library search procedures; abundance of doubly charged molecular ions; presence of rearrangement reactions; features useful in distinguishing isomeric structures. A significant percentage of these compounds have been found to be carcinogenic in animal tests. The composition of the compound collection is indicated by the class and numbers in Table I. Nomenclature of ring systems is consistent with that of Lee et al. [2].

Table I:

Composition of PAH Collection

# of rings	type	# of compounds
2	naphthalenes	7
2	1,1'-biphenyls	3
2	anthracenes	17
3	phenanthrenes	16
3	fluorenes	6
4	benzanthracenes	77
4	pyrenes	17
4	chrysenes	3
5	benzopyrenes	41
5	cyclopentapyrenes	7
5	dibenzanthracenes	6
	others	9

Our spectra have been searched against the National Bureau of Standards Library on our datasystem (VG 11-250J; 42000 spectra; purity fit search, fit factor 700 or greater). The results are given in Table II. We find that, for the 209 compounds examined, 56% could not be matched to any reference spectrum in the library, and 25% were "erroneously" matched to spectra of other compounds. This "erroneous match" group includes 10% of the compounds which were matched to related isomeric structures, and 15% which were matched to unrelated structures. These results suggest that the PAHs are underrepresented in the NBS library, and that the number of reference spectra in the library needs to be increased.

TABLE II:

NBS Library Search Results

Fits	38	18%
Near fits	21	10%
Wrong fits	32	15%
No fits	117	56%
Total	209	

Observation of doubly charged molecular ions is a nearly universal property in this collection. Jamieson and coworkers [3-5] have recently reported on the analytical utility of these doubly charge ions. 23 compounds exhibit M^{2+} intensities greater than 10% relative abundance. Many of the more highly functionalized compounds produce fragments for which there are observable intensities in the spectrum at 1/2 the mass of the fragment. Although the expectation that the larger PAH systems -- e.g. benzopyrenes -- would exhibit relatively high M^{2+} intensities, the phenanthrenes and fluorenes exhibit high M^{2+} intensities. One third of the phenanthrenes show 10% or higher M^{2+} intensities, and acenaphthylene ($C_{12}H_8$) shows 20% relative abundance of M^{2+}.

Several classes of rearrangements have been observed: neutral loss of CO from carbonyl-containing compounds; loss of H_2 from partially reduced ring systems; loss of HX from certain halogenated compounds: loss of the free acid moiety from esters in which the alcohol

is the PAH. Focusing on the loss of CO, there are 34 compounds in the collection having one or more carbonyl groups. (Esters and free acids are not included in this count.) Over 50% of the aromatic ketones (23 compounds) and aldehydes (7 compounds) exhibited very intense neutral losses of CO from $M^{+\cdot}$, and, for several diones, additional neutral loss of a second CO. Intensities of these $[M-28]^{+\cdot}$ and $[M-28-28]^{+\cdot}$ were typically 50% relative abundance or greater, base peak usually being $M^{+\cdot}$. For three compounds, $[M-28]^{+\cdot}$ is base peak. By contrast, four ketones in which the carbonyl group was located in an aliphatic sidechain exhibited no tendency to fragment by neutral loss of CO.

When possible, series of isomeric compounds have been compared to establish whether the electron impact mass spectrum alone can be used to differentiate between structural isomers or isomer classes. From the large number of benz[a]anthracenes, comparisons have been made of the mass spectra of the mono-, di-, and trimethylbenz[a]anthracenes, which will be described here. Four of the twelve methylbenz[a]anthracenes were recorded here. Eleven of the twelve are represented in the NBS library, and all are selected by library search, with purity fit factors greater than 90%, for each observed spectrum. Only slight differences in the intensities of the two main fragments - $[M-16]^+$, m/z 226 and $[M-27]^+$, m/z 215 - are observed. Differentiation based on mass spectra would not be possible. One would have to rely upon gas chromatography retention times or some other criterion for differentiation.

Spectra for ten of the possible 66 dimethylbenz[a]anthracenes were recorded. Only two isomers are represented in the NBS library - the 1,12- and 7,12- isomers. Ratios of the $[M-15]^+$ (m/z 241) and $[M-17]^+$ (m/z 239) ions change, as well as their relative abundances. Intensities of M^{2+} (m/z 128) and $[M-16]^{2+}$ (m/z 120) also change. Isomers containing a 7-methyl, and especially with a nearby second methyl, produce a large (>25%) $[M-15]^+$, with $[M-15]^+$ also being larger than $[M-17]^+$. These observations suggest that sufficient spectral differences exist to allow identification of these isomers at least into subgroups, if not into individual compounds.

Only eight of the possible 220 trimethylbenz[a]anthracene isomers were examined. Even so, relative abundance changes of $[M-15]^+$ (m/z 255) with respect to $M^{+\cdot}$ (the base peak), and with respect to $[M-31]^+$ (m/z 239) suggest a possible basis for isomer differentiation. The small data set examined, coupled with the fact that the prevalent substitution in the compounds observed is 12- and 7,12-substitution, do not permit our reaching any firm conclusions. However, the striking difference seen is the high $[M-15]^+$ in the one non-12-methylated compound in this data set.

All data were collected on a VG Analytical 70-S mass spectrometer and VG DS 11/250J datasystem. Nearly all of the compounds were crystalline solids, which were introduced into the mass spectrometer on the direct insertion probe. The probe was heated slowly in order to distill the compound being analyzed to evaluate sample purity and to avoid thermal degradation.

Full spectral data of all the compounds in this collection, as well as for a large number of other compounds and compound types, are available from the Thermodynamics Research Center.

Funds from National Science Foundation Grant CHE-8705697 permitted purchase of the mass spectrometer used in this study.

DETERMINATION OF TRANSIENT BIODEGRADATION INTERMEDIATES OF LINEAR ALKYLBENZENESULFONATES (LAS) BY NCI/GC/MS

Michael L. Trehy, William E. Gledhill, Robert G. Orth, Gerry Gasser, Carl B. Roper, B. Mason Hughes, and Victor W. Saeger
Monsanto Company; 800 N. Lindbergh; St. Louis, MO 63167

Hon-Nami and Hanya (1) developed a method to determine alkylbenzenesulfonates by GC/MS after conversion of the sulfonate group to the methyl sulfonate derivative. The derivatization procedure involved treatment with phosphorus pentachloride to form the acid chloride followed by treatment with methanol to convert the acid chloride to the methyl ester. In this paper we describe the advantages of using trifluoroethanol in place of methanol and have extended the derivatization procedure to include both linear alkylbenzenesulfonates (LAS) and the sulfophenylcarboxylates (SPC) which appear as transient intermediates during biodegradation of LAS. The formation and disappearance of the SPC can be followed both in laboratory microcosm experiments and by analysis of wastewater samples. No significant interferences were observed for the GC/MS method which permitted full scan spectra for samples spiked at 0.2 ppm.

The method offers significant improvements in sensitivity and selectivity over methods described in the literature. SPC can be determined by LC with UV detection (2) and by GC/MS after desulfonation (3). However both methods have significant drawbacks. The LC methods lacks sufficient selectivity and the ability to identify the SPC in environmental samples. The desulfonation technique is more complicated and can not differentiate sulfonates other than LAS and their corresponding carboxylic acids from LAS and its corresponding carboxylates. Although derivatization with diazomethane is possible (2) the reaction was difficult to reproduce and is hazardous. The trifluoroethyl ester derivatization procedure is relatively simple and selective for the sulfonates. The presence of the trifluoroethyl group greatly enhances sensitivity for NCI. A full scan mass spectrum is possible for 3 nanograms of sample. The sample derivatization procedure is described below. The derivatives are stable in hexane for at least a month. The method described below has a limit of detection of approximately 0.1 mg/L in full scan mode.

1. Evaporate a 4 ml sample in a Reacti-vial to dryness with a stream of nitrogen.
2. Add approximately 20 mg of phosphorus pentachloride, cap the vial and heat at 110 degrees centigrade for 3 minutes. Allow to cool.
3. Add 1 ml of hexane and extract for 1 minute on a Vortex Genie. Transfer the hexane to another Reacti-vial and evaporate to dryness with a stream of nitrogen.
4. Add approximately 0.3 ml of trifluoroethanol and heat at 70 degrees centigrade for 20 minutes. Allow to cool.
5. Add approximately 1 ml of hexane and 1 ml of deionized water and immediately extract for 1 minute on a Vortex Genie.
6. Transfer the hexane to another vial and concentrate to approximately 0.2 ml with a stream of nitrogen.

The LAS and SPC trifluoroethyl esters all have the m/z ion 163 as a characteristic MS fragment for $SO_3CH_2CF_3$ which can be used to selectively identify the sulfonates in complex environmental matrices. In addition, the mass

spectra for sulfonates also contain the parent ion and a fragment ion corresponding to the loss of trifluoroethanol in the case of SPC while LAS loses m/z 99 corresponding to the loss of the trifluoroethoxy group. In Figure 1 the parent ions corresponding to the SPC are plotted. The presence of the SPC can be detected. When the effluent of more efficient wastewater treatment processes, such as an activated sludge plant were analyzed the SPC were below the limit of detection of the present method. The relative absence of SPC isomers in the activated sludge wastewater treatment plant effluents indicates that all the isomers formed on biodegradation of LAS are further biodegraded. Biodegradation was not hindered by a recalcitrant isomer.

THE EFFECT OF SURFACE ACTIVITY ON QUANTITATION OF LINEAR ALKYLBENZENE SULFONATES [LAS] BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY.

J. D. Wernery, D. K. Brain, and D. A. Peake,

The Procter and Gamble Corporation, Cincinnati, OH 45217.

BACKGROUND. Quantitation of sodium linear alkylbenzene sulfonates (LAS) in detergents requires time consuming sample preparation and chromatography steps. Our first attempts to quantitate LAS by FAB MS using a single deuterated C_{12}LAS internal standard (1) resulted in errors of ca. 10-20% for alkyl chainlength distributions, compared to results obtained by desulfonation and GC analysis (DS/GC, 2) of the resulting alkylbenzenes.

Barber and co-workers (3) first recognized the role of surface activity in obtaining FAB mass spectra. Ligon and Dorn (4) used a homologous series of quaternary ammonium salts to demonstrate longer-chain surfactants dominate the glycerol surface, resulting in enhanced sensitivity relative to shorter-chain homologs.

SURFACE ACTIVITY vs CONCENTRATION. Because LAS homologs of different chainlengths have different surface activities and solubilities in the glycerol matrix, the distribution of sputtered LAS anions is skewed relative to the molar ratios of LAS homologs in solution. FAB(-) mass spectra were acquired from 10^{-2} to 10^{-4}M of C_{10}-, C_{12}- and C_{14}LAS in glycerol (Table 1). At lower [LAS], the abundance of C_{14}LAS is enhanced relative to the shorter-chain homologs. As [LAS] increases, the relative abundance of C_{10}LAS increases relative to C_{12}- and C_{14}LAS.

EFFECT OF ACQUISITION TIME. Changes in relative abundances for the equimolar mixture were also observed as a function of scan time. At the beginning of the run, and at lower [LAS], the more surface active species predominate. As the glycerol droplet evaporates, and at higher [LAS], the relative abundance of C_{10}LAS increases. Thus, the relative abundance of LAS homologs is highly dependent on [LAS] and signal averaging time.

QUANTITATION. To compensate for the surface activity differences between the LAS homologs, three deuterated internal standards [d_7-C_{10}, -C_{12}, and -C_{14}LAS] were chosen to bracket the LAS chainlength distribution. Calibration curves were obtained by monitering the d_0/d_7 abundance ratios vs ug LAS standard added. Negative ions monitored were:

C_{10}LAS	(d_0)	m/z 297	(d_7)	m/z 304
C_{11}LAS		m/z 311		
C_{12}LAS		m/z 325		m/z 332
C_{13}LAS		m/z 339		
C_{14}LAS		m/z 353		m/z 360

A series of pure 2-alkylbenzene sulfonate mixtures was analyzed to demonstrate the accuracy of the FAB MS method (Table 2). By using the internal standard approach, the homolog distribution and total amount of LAS determined are typically within ± 5% of the weighed amounts.

A commercial mixture of LAS was analyzed by FAB MS and the results compared with those obtained by DS/GC (Table 3). Without the use of internal standards, the FAB MS data is skewed relative to the DS/GC data. For example, the relative abundance of the C_{10}LAS homolog is 20% higher relative to the GC results. The homolog distribution obtained by FAB MS using the internal standard approach and by the DS/GC method are identical within the experimental error of the two techniques.

CONCLUSION. Bracketing with several isotopically labeled internal standards compensates for differences in surface activity of LAS homologs. FAB MS has major advantages over other methods in specificity, speed of analysis, and eliminates the need for sample cleanup.

ANALYSIS OF SULFONATED AZO DYES USING FAB AND CONTINUOUS FLOW FAB/MS

by

D.L. Miller and L.J. Peterson-Wright

Idaho National Engineering Laboratory, EG&G Idaho, Inc.
P.O. Box 1625, Idaho Falls, ID 83415

Increased interest in the ability to identify and quantitate environmental contaminants not amenable to conventional GC/MS analysis has been displayed by environmental scientists and regulatory agencies. This interest has resulted in the examination of a variety of compound classes not amenable to GC/MS and in the development and application of a variety of new analytical methodologies.

A compound class that has received considerable attention in the literature is that of the sulfonated azo dyes. Even though a great deal of work on azo dyes has been performed additional research is needed due to the large numbers of different dyes and their widely varying properties.

Thirteen sulfonated azo dyes (Aldrich Chemical) containing two, three, or four sodium sulfonate groups were examined as pure compounds and as aqueous solutions. The dyes were used as received from the supplier. All experiments were conducted on a Kratos MS890 equipped with an 8 kV MS50 type FAB source and an Ion Tech 11NF saddle field ion gun. Xenon was used in all experiments for the FAB gas. The thirteen azo dyes examined are given below.

Acid Black 24	Acid Violet 5
Acid Blue 80	Benzopurpurin 4B
Acid Blue 113	Brilliant Yellow
Acid Orange 63	Direct Orange 31
Acid Red 37	Direct Red 81
Acid Red 114	Direct Yellow 50
Acid Red 151	

All of the dyes were examined in both positive and negative ion modes of detection. The various dyes were examined using a variety of FAB matrices which included glycerol, thioglycerol, polyphosphoric acid, 3-nitrobenzyl alcohol, triethanolamine, PEG-600, and tetramethylene sulfone.

Peaks indicative of dyes were observed for nine of the thirteen dyes. For the remaining dyes peaks were observed which did not arise from the matrix but which could not be correlated with the know structure of the various dyes. It is believed that these unknown peaks are from other compounds present in the dye formulations which range from 40 to 100 percent dye. The most successful matrix was found to be thioglycerol which produced spectra for eight of the thirteen dyes, followed by 3-nitrobenzyl alcohol and glycerol which were useful for eight dyes and four dyes respectively. The remainder of the matrices examined were useful for no more than three of the thirteen dyes examined. In general, the best results were obtained using the negative ion detection mode. For the majority of the dyes examined the predominant spectral feature was the loss of a sodium from the intact dye molecule. In the case of the positive ion mode protonated molecular ions were observed as well as other ions indicative of fragmentation of the dyes. In many cases, using both positive and negative ion mode, peaks were observed which were believed to be due to other materials present in the dye formulations, which as was mentioned earlier were as low as forty percent dye. HPLC analysis was performed on a sample of the Acid Blue 80 used in

these experiments to determine the number of components present in the formulation. Acid Blue 80 was chosen due to the fact that this particular dye gave the most intense spectrum in both positive and negative ion mode and worked with five of the six matrices used. The results of the HPLC analysis indicated the presence of at least nine components three of which could be considered major components. Based on these results it was decided to investigate the use of continuous flow FAB/MS for applicability to analysis of azo dyes.

The continuous flow experiments were conducted using a commercially available system obtained from Kratos Analytical. An Isco uLC 500 pump was used to provide flow through the continuous flow probe at rates ranging from one to four microliters per minute. Acid Blue 80 solution (1 microliter) was injected into the flow stream of the probe using the HPLC injection valve supplied with the flow probe system. A variety of solvent systems were investigated but the majority of the work was performed using a 95:5 water/glycerol solution. Good results were obtained using the continuous flow system combined with both positive and negative ion detection modes. Spectra obtained using the flow probe system showed good agreement with those obtained using a conventional FAB probe. Experiments conducted in the positive ion mode were complicated by the fact that sodium dissociated from the dye appears to pass through the flow probe faster that the dye itself, resulting in a high degree of reaction with the glycerol present as the matrix. Repetitive injections of dye build up a large background of sodium/glycerol peaks which require a significant amount of time to purge out of the system (approximately one hour after four one microliter injections of 1 ppm dye solution). This behavior was not observed when negative ion mode was used although the overall sensitivity was lower in the negative ion mode. Based upon these results work is currently underway in which on-line HPLC separation and introduction via the continuous flow FAB system is being investigated. Of particular interest is the question whether dyes that did not yield spectra will do so once they are separated from the remainder of compounds present in the commercially available formulations.

Comparison of Dynamic and Equilibrium Head-Space Sampling of EPA Volatile Organic Compounds with Ion Trap Detection

Adam J. Patkin, Perkin-Elmer Corporation Norwalk, CT 06859-0090

The techniques of dynamic, or "purge and trap", and equilibrium head-space with ion trap detection are compared for the analysis of EPA regulated volatiles in water. Dynamic head-space is found to have lower detection limits, while equilibrium head-space is faster, easier, and eliminates carry-over.

INTRODUCTION

The U.S. Environmental Protection Agency (EPA) has promulgated the EPA series 500 and 600 methods for the GC/MS analysis of organic compounds is clean and waste water. Method 624 is for the analysis of waste water and Method 524.2 for clean, or drinking, water. Both methods specify the use of a dynamic head-space, or "purge and trap" sampler.

EXPERIMENTAL - Dynamic Head-space

EPA method 524.2 was used for the experimental conditions. Two modifications were made. First, the LSC-2 trap was desorbed and baked at 225 °C. This was found to improve the chromatographic resolution of early eluting gas peaks be more effective at removing residual water from the trap than the specified 180 °C. Second, the mass range was scanned from 50 to 300 μ instead of the 35 to 300 μ specified in the method. This removed interference caused by the methanol solvent of the standard with the co-eluting bromomethane. The 35 to 300 μ range could be used, but the results would then need to be displayed as a 50 to 300 μ mass chromatogram to show bromomethane at trace levels.

EXPERIMENTAL - Equilibrium Head-space

A 0.32-mm ID column with a 5μm methyl silicone phase was used, in contrast to the 0.53mm ID, 3μm VOCOL phase of Method 524.2. This thick film capillary column was found to give excellent retention of the purgable gases (chloromethane, vinyl chloride, and bromomethane) at 45 °C, eliminating the requirement of sub-ambient cooling found in the EPA 524.2 method. A faster temperature program halved the chromatogram length. The much shorter cycle time of equilibrium head-space makes up to four analyses per minute possible.

DISCUSSION

Table 1 shows the detection limits for dynamic head-space with the Ion Trap Detector, while Table 2 shows the detection limits for equilibrium head-space. Comparing Tables 1 and 2, the dynamic head-space approach is seen to be more sensitive than equilibrium approach. This is for two primary reasons. First, the dynamic method exhaustively purges the water sample, while the equilibrium method only samples a portion of the equilibrated head-space. Second, the dynamic method uses 25 ml of water, and the equilibrium method only 2 ml.

Equilibrium head-space, while not sufficiently sensitive for clean water analysis, has several significant advantages for waste water determinations.

Equilibrium head-space is faster than dynamic. After the sample is thermostatted, the injection cycle takes only 36 seconds. This compares to about one half hour with dynamic head-space. Several samples can be thermostatted at once, and automated analysis of up to 100 samples is possible. The oven cools to 45 °C, rather than 10 °C, eliminating the need for expensive and cumbersome sub-ambient cooling.

Equilibrium head-space is easier than dynamic. Sample preparation consists solely of hermetically sealing the sample in the vial. This can be performed at the analysis site, eliminating possible sample loss during laboratory transfers.

Equilibrium head-space is better suited for dirty or complex samples than dynamic. There are no frits or small diameter openings to become obstructed. Since the sampling vial is disposable, there is no cleaning required. The disposable sample vial eliminates any chance of sample cross-contamination.

CONCLUSIONS

Dynamic head-space with the Ion Trap Detector greatly exceeds the required EPA 524.2 method detection limits.

Equilibrium head-space with the Ion Trap Detector is less sensitive than dynamic, but still exceeds the required waste eater EPA 624 method limits with the Ion Trap Detector. It is also much more suitable than dynamic head-space for the analysis of dirty samples, such as sludges or soils.

ABSTRACT

A microbial treatment study was conducted with solid waste from polystyrene manufacturing. Contaminated soil containing polystyrene waste was subjected to microbial degradation using a batch reactor system. The overall experimental design and biological results of this study are not discussed in this summary. This presentation summarizes the capillary GC/MS analysis methods, results of these analyses, and major conclusions which can be drawn from these data. These results indicate that polystyrene wastes can be successfully degraded using this process. Various organic components of the waste were removed with degradation half-lives ranging from 24 to 72 hours.

INTRODUCTION

The primary factor that affects the cost of cleanup of a chemical waste site is the decontamination method used to remove the various contaminants from the site. To date, incineration has been the primary technique for the disposal of organic contaminants. In specific instances where wastes contain almost 100% organic components and have good BTU content, incineration can be both cost effective and environmentally sound. However, when the site consists primarily of soil which contains less than 10% organic components, microbial treatment costs can be lower than incineration costs, since neither incinerator fuel nor large incinerators are required. However, in order to use a potentially less expensive microbial treatment approach, it must be demonstrated that this alternative can actually reduce the amount of organic components below certain acceptable concentrations. The present paper summarizes results from a laboratory scale biological treatment study which was conducted using low-level polystyrene wastes.

SUMMARY

A laboratory batch biodegradation study, using an Aqueous/Soil Biotreatment Approach, was conducted in the spring of 1987. The purpose of this study was to evaluate the biodegradability of polystyrene waste, using indigenous microflora present in the soil. This presentation summarizes the analytical methods used, and important conclusions drawn from this study.

Seven biodegradation reactors (A - G) were analyzed in duplicate over a fourteen-day period. All reactors, except C and G, contained wastes. Reactors A and B were duplicate reactors to which mercuric chloride had been added. (Mercuric chloride was added as a bacteriacide.) Bioreactor D was a closed reactor and contained active microorganisms. Reactors E and F were duplicate reactors and contained active microorganisms. Reactors C and G, extraction glassware, and solvents were used for method blanks in this study. No quality control blanks contained any of the analytes of interest above the instrument level of detection, indicating that no false positives were reported. Anthracene-d_{10} was used as an internal standard and a system performance standard, a standard of crude oil, and a representative styrene waste were analyzed daily. These steps decreased the likelihood that false positives were measured.

Reaction vessels A, B, E, and F were sampled in duplicate on days 0, 1, 2, 3, 4, 5, 6, 7, 10, and 14 of the study. Reaction vessel D was sampled in duplicate on days 0, 7 and 14 Ten-mL sample aliquots were extracted with methylene chloride and the extracts were analyzed for extractable compounds. Instrumental analysis methods were developed so that concentration information for the major extractable chromatographable compounds in the waste could be obtained in each of the extracts. Figure 1 shows that over 95% of chromatographable components of the waste in the key reactors were reduced to non-detectable levels within 120 hours.

EXTRACTABLE ANALYTE IDENTIFICATION

Detailed compound identification can be best accomplished only after all possible isomers of identified compounds are obtained and retention times of authentic standards are compared to the retention times of the components in the waste. However, this detailed identification was not considered critical to the present study since degradation profiles of compounds and relative changes in concentration, were of primary concern. Therefore compounds which were not uniquely identified by standard library search algorithms were identified by molecular formula and/or molecular weight, when possible. No new chromatographable components were detected during the study, indicating that no new chromatographable degradation products were produced during biodegradation. Therefore, from a waste delisting standpoint, no priority pollutants or other chromatographable compounds should be present which could complicate proper disposal of these biodegradation wastes. Four representative degradation profiles are shown in Figure 2.

Figure 1. Total Concentrations of Waste Components in Vessels A, B, D, E, and F

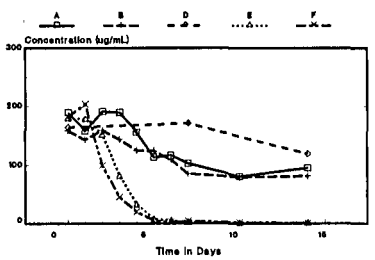

Figure 2. Biodegradation Profiles for Selected Analytes of Vessel E

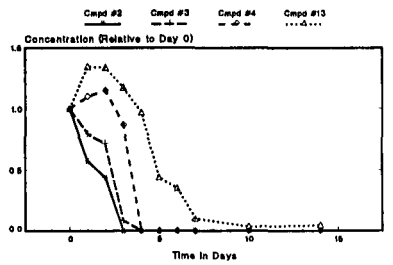

DATA ANALYSIS APPROACH

In order to study the degradation of a large number of compounds in a large number of samples, without sacrificing data quality, the present instrumental analysis approach was devised. Analysis difficulty was increased since many of the organic components were unknown and specific standard reference materials could not easily be obtained within the time constraints of the study. This analysis approach required that sixteen compounds, in seven biodegradation reactors, at ten different days, each be analyzed in duplicate. This resulted in the analysis of sixteen compounds in approximately 100 reactor samples. Approximately two-thirds of these samples contained the sixteen compounds of interest, with the remaining one-third being method blanks, reactor blanks, and QA/QC samples which did not contain the total array of analytes. However, the remaining 100 samples resulted in the generation of 3,200 concentration values and 4,800 additional values which required summing, averaging, and displaying in an efficient manner. Thus the GC/MS study was divided into data acquisition and data analysis phases which were designed to be interrelated and to produce high quality data in a cost effective manner.

Data Acquisition. An internal standard was used to estimate the absolute amounts of each analyte present in each extract. Analyte concentrations were calculated by using the total ion (or selected ion) areas of the analytes, the total ion (or selected ion) area of the internal standard, and the concentration of the internal standard to calculate the "Total Ion Concentrations" or "Selected Ion Concentrations". Figure 3 shows an example of output used to evaluate data quality and Figure 4 shows a portion of the capillary chromatogram and mass spectra of selected waste components.

Data Analysis. Capillary GC/MS analysis of each extract yielded: selected ion areas, total ion areas, retention times, and delta-retention times for all of the analytes in all samples analyzed. Figure 3 gives an example of the graphical data from which this information was obtained. The various digital data was stored in an ASCII file, corrected using EDIT/1000 when errors were observed, transferred to a personal computer, and imported into a LOTUS/1-2-3 template file for further data manipulation and display. Figures 1 and 2 are examples of portions of these reduced data displays. AdvanceLink on the HP-150 and Vectra ES/12 personal computers was used to transfer these ASCII files to the PCs, and 1-2-3 macros were used to assure that these files were placed in specific positions within the template file. Once imported to the template file, a format line was added to define what types of variables were present in the ASCII file and the ASCII data was then parsed into specific 1-2-3 cells. This data analysis approach assured that the primary mass spectrometric data was properly obtained, and that there was a minimum of transcription errors in the data transfer process.

U.S. EPA NATIONAL DIOXIN STUDY

RESULTS AND CONCLUSIONS FROM PHASE I, INTRODUCTION OF PHASE II

Douglas W. Kuehl, Brian C. Butterworth
U.S. Environmental Protection Agency
Environmental Research Laboratory-Duluth
6201 Congdon Boulevard
Duluth, Minnesota 55804

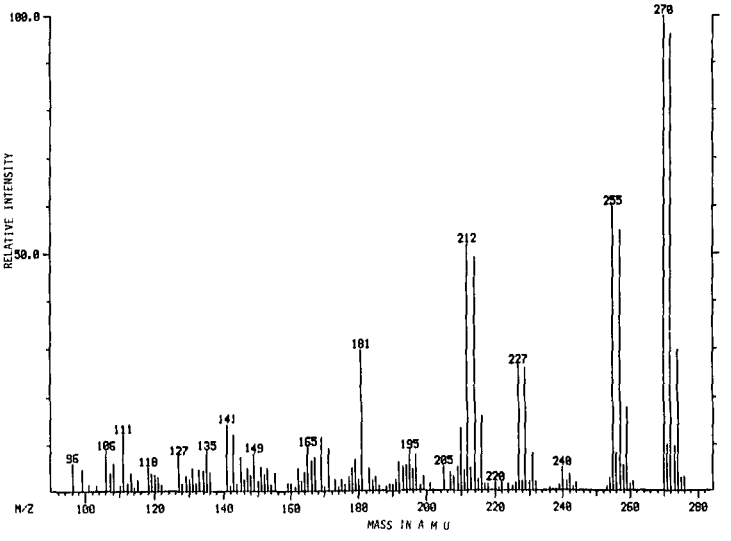
Donald Bahnick and Ray L. Hanson
CLSES, University of Wisconsin, Superior, WI 54880

In 1981 the Environmental Protection Agency initiated Phase I of the National Dioxin Study (NDS), a survey of sources, fate and distribution of 2,3,7,8-TCDD. The Environmental Research Laboratory at Duluth was responsible for the coordination of samples for Tier 7, an assessment of TCDD background levels, and for the analysis of fish. During the course of this study, we have made several progress reports at this conference[1,2]. that included assessment of QA/QC criteria for both low and high resolution mass spectrometry, and have offered unique ideas for the determination of a minimum level of quantification[3]. A report presenting the results of Phase I has been presented to Congress[4], and Phase II has been initiated. The objective of this presentation is to discuss results and conclusions of Phase I and to introduce Phase II.

Phase I: Samples were collected for analyses in three different categories, statistically selected sites, regionally selected sites, and sites in the Great Lakes. It was found that none of the fish from the statistically selected sites (N=90) were above the action level for human consumption, 25 pg/g, and that no detectable level (1 pg/g) of TCDD was found in 79% of the samples. These results contrast Great Lakes sites where 79% of the samples did contain TCDD (N=29), 8% of which were >25 pg/g. Thirty-one percent (31%) of the regionally selected sites (N=276) were positive with levels ranging to 85 pg/g. It was observed that fish collected near Kraft pulp and paper mills were more frequently positive and contained higher levels of TCDD than those of other watersheds[5].

Phase II: Phase II analytes include all biosignificant PCDDs and PCDFs, mercury, PCBs, and 50 industrial chemicals/pesticides. A primary objective of the PCDD/PCDF analyses is to further investigate the influence of pulp/paper mill discharge upon fish contamination. Over 400 bottom feeding fish are to be analyzed for Phase II. Preliminary results from the analyses of 171 fish showed that 66 samples had a total toxicity equivalent (TEF) value of 2.5 pg/g or greater. Of these samples, 33 of 33 samples collected below pulp and paper mills were positive for 2,3,7,8-TCDD, ranging in concentration from 1-118 pg/g with an average value of 17.4 pg/g. The other 33 positive samples, sites other than pulp/paper discharges, ranged in concentration from 1-34 pg/g, with an average value of 7.2 pg/g.

Analyses of these samples for PCBs and other industrial chemicals indicates that PCBs continue to be a major contaminate in fish. In addition, a mass spectral library of non-target analytes, including both identified and not identified entries, is being compiled. The library includes information on the frequency that a spectrum is observed and information on the types of industrial activities within the sampled watershed. Over 135 entries have been made into this library. An example of an unknown (Figure 1) frequently found in fish from watersheds receiving pulp/paper mill discharge is shown below.



Mass Spectrum of Unknown in Fish

ISOTOPE DILUTION MASS SPECTROMETRY IN THE ANALYSIS OF ENVIRONMENTAL SAMPLES. A COMPARISON OF EPA METHODS 1624/1625 AND 624/625.

M.C. Shepherd, P.J. Schrynemeeckers, D.A. Hayes, S.K. Mertens, F.L. Shore
Radian Corporation, P.O. Box 201088, Austin, TX 78720-1088

EPA Methods 624 and 625 are the usual required protocols for determining the organic "priority pollutants" in the water and wastewater matrices. Method 624 is the purge-and-trap GC/MS method for volatile organics using internal standard quantitation while Method 625 is the capillary GC/MS method for acid-base/neutral extractable organics. Both of these methods are subject to varying purging/extraction efficiencies of analytes versus internal standards or surrogate compounds from matrix to matrix.

To further improve the performance of GC/MS analyses for priority pollutants, Methods 1624 and 1625 were developed incorporating isotope dilution mass spectrometry for quantitation of target analytes. By spiking the sample with a known amount of a stable isotopically labeled compound for each analyte and quantitating against the labeled compound, the analyses would be automatically corrected for variances in purging or extraction efficiency. The addition of the labeled standards complicates the analysis by doubling the number of quantitation ions to be monitored. The increased number of ions being monitored increases the potential for the analysis to suffer interferences, especially from hydrocarbons. However, the option for internal standard quantitation is always available.

A comparison of the results from the isotope dilution methods versus the internal standard methods was performed for a set of nine wastewater samples. Some of the results of these comparisons are given in Table 1 and 2. Only those compounds that were detected in at least one of the nine samples are reported. The agreement is generally good (within factors of 2). While the target compound quantitation is comparable between the two methods, Methods 1624/1625 also require quantitation of labeled compound recoveries. In several of the samples analyzed in this study the internal standards suffered severe interferences from non-target hydrocarbons, thus making quantitation of labeled compound recoveries difficult if not impossible.

Associated with performing the isotope dilution methods are problems with labeled compound standards. Both expense and stability are critical factors. A complete set of standards which costs in excess of $3000 has a shelf life of approximately 30 days. Also, many of the compounds have limited stability. Acrolein-d_4 decomposes within days, while methyl ethyl ketone-d_3 is present as the d_8-substituted compound. The presence of the d_8-substituted methyl ethyl ketone is perhaps a result of deuterium exchange with the deuterated methanol solvent via tautomeric equilibrium.

A GC/MS/DS capable of automated processing of the data is essential in reducing the large volume of data these analyses produce. The Finnigan-MAT Incos® data system has a program within its AutoQuan® software to perform isotope dilution calculations. The Aquarius® software package used in conjunction with the Hewlett-Packard systems has similar programs. Both software packages were used in our laboratory in this comparison. Calibration curves were established at the beginning of the study and were successfully met over the two month duration of our study.

In conclusion, isotope dilution techniques can provide a more accurate measurement of analyte concentration especially if the analyte experiences losses in the analysis. However, the labeled standards required to perform these analyses are quite expensive and have limited stability. Additionally, the analysis is more susceptible to interferences.

The isotope dilution methods can be applied successfully if set up properly and the problems outlined above are compensated for.

GC/MS ANALYSIS OF BSTFA DERIVATIZED POLAR COMPONENTS OF DIESEL PARTICULATE MATTER (NBS SRM - 1650) EXTRACT

Bernd Wenclawiak, University of Toledo, Department of Chemistry, 2801 W. Bancroft St., Toledo, Ohio 43606; Trescott E. Jensen, and Joel F. O. Richert, Ford Motor Company, Analytical Sciences Department, Research Staff, Dearborn, Michigan 48121

Diesel particulate matter contains organic solvent extractable material that is mutagenic in the direct acting Ames assay. A polar HPLC fraction (Fraction 8) of diesel particulate matter (NBS SRM - 1650) dichloromethane extract contains about 11 % of the recovered mutagenicity in the extract (1). Additional separation of Fraction 8 was achieved with acid and base extraction partitioning(2). The GC/MS chromatograms for the polar fraction and the acid, base, and neutral subfractions were not very useful for identification of constituents as shown by the example in Figure 1(a). Benzo(c)cinnoline was the only component easily identified in the underivatized fraction.

N,O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) derivatization was found to be effective for several aromatic carboxylic acid and hydroxy standards selected as models of compounds expected to be in the polar fraction. The increase in molecular weight of the derivative was offset by the decrease in the polarity of the model compounds resulting in similar chromatographic retention times for the model compounds. Reaction of 10 uL of the BSTFA reagent (Pierce Chemical) with 10 uL each of the four samples at ambient temperature overnight was found to be adequate derivatization for the polar fraction as shown in Figure 1(b). Chromatographic definition of many derivatized components was sufficient for GC and GC/MS (EI and CI) analysis where hydroxy and carboxylic acid functional groups were observed. The components identified in this polar fraction of the extract include p-nitrophenol, benzoic acid, hydroxy benzoic acids, hydroxy benzaldehyde, hydroxyphthalimide, benzene dicarboxylic acids, naphthalene dicarboxylic acids, anthracene/phenanthrene dicarboxylic acids, and for some of these, the C_1 to C_3 alkyl homologs. Also, several methyl esters were observed. These include biphenyl dimethyl ester and benzene trimethyl ester.

Only one, two, and three ring aromatics were observed as trimethylsilane derivatives. The chromatogram in Figure 1(b) shows no peaks in the temperature range of 230 - 300 °C, where larger aromatics would be observed. If aromatics with polar functional groups and four or more rings were present in this polar fraction, they were not observed.

Derivatization of the acid, base, and neutral subfractions was only helpful for identification of components in the acid fraction. No derivatives were present or identifiable in the base or neutral subfraction. Some components observed as derivatives in the original fraction were not found in the acid, base or neutral fractions indicating chemical conversion is taking place during the extraction procedure. Derivatization did not facilitate identification of mutagens in the extract.

GC/MS ANALYSIS OF HYDROPHOBIC ORGANIC CONTAMINANTS IN CATFISH FROM THE MISSISSIPPI RIVER

Thomas J. Leiker, Wilfred E. Pereira, and Colleen E. Rostad
U.S. Geological Survey, Denver, CO, 80225

INTRODUCTION

The water quality of a given water system is often established by determining the concentrations of the organic contaminants that are contained within the water column. In many instances, this approach produces a false indication of acceptable water quality. Hydrophobic contaminants are often present at concentrations that are often below the detection limits of conventional analytical techniques. These types of compounds usually exhibit high octanol/water partiton coefficients and are selectively partitioned from the water column into the bed sediments and are selectively partitioned into the lipid tissue of stream biota.

The U.S. Geological Survey has been involved in a reconnaissance study to assess contaminant levels in the water column and stream biota from the Mississippi River and its tributaries. This covers a 1200 mile river reach from approximately Naples, Illinois to Belle Chasse, Louisiana. Preliminary data to date indicates that the water column contains relatively low concentrations (ng/L) of hydrophilic organic contaminants while the more hydrophobic contaminants are bioconcentrated in the lipid tissue, specifically catfish, of stream biota and are not detected within the water column.

EXPERIMENTAL

EXTRACTION and CLEANUP: 10 grams of homogenized tissue are mixed with 50 grams of granular anhydrous sodium sulfate, 1 ug D_{10}-Acenaphthene, 1ug Dibromooctafluoro biphenyl and extracted with 100 ml of 20 % (v/v) acetone/hexane using a Sonic Disruptor. After extraction the extract is dried through a column containing 15 grams sodium sulfate and concentrated by K-D. Prior to concentration 25 ml of ethyl acetate is added to the K-D to azetropically remove all hexane from the extract. The lipid material is removed form the extract by passing the extract through a gel permeation column containing 45 grams of Bio-Beads SX-3. The elution solvent is ethyl acetate at a flow-rate of 3.3 ml/min. The extract is further purified by passage through a column containing 20 grams of florisil. The final extract is adjusted to a volume of 10 ml. A 1.0 ml aliquot of the extract is screened by GC/ECD. The remainder of the extract is concentrated to a volume of 100 ul and analyzed by GC/MS.

GC/MS PARAMETERS: GC: HP-5840A, col. 30Mx0.2mm i.d. DB-5, initiial oven temperature; 50°C (hold for 3 min), program rate: 10°C/min., final temperture: 300°C (hold for 10 min.). MS: VG-7035H, resolution: 1000, mass range 150-500, scan-rate: 1 sec/dec, electron-energy: 70eV, emission current: 200 uA, accelerating voltage: 4Kv.

METHOD OF QUANTITATION: Standard Curves. Curves are generated from approximately 5 to 100 ppb using the ratio of diagnostic ions (TABLE I), generated for mass chromatograms, of the compound of interest with the internal standard, D_{10}-acenaphthene.

TABLE I
QUANTITATION ION

COMPOUND	m/z
D_{10}-Acenaphthene	162
Dibromooctafluoro biphenyl	454
Hexachlorobenzene	284
Lindane	217
Aldrin	263
DCPA (Dacthal)	301
tech-Chlordane	373 & 409
DDE	316
Dieldrin	263
Endrin	263
DDD	235
DDT	235
Trichlorobiphenyl	256
Tetrachlorobiphenyl	290
Pentachlorobiphenyl	324
Hexachlorobiphenyl	358
Heptachlorobiphenyl	392
Octachlorobiphenyl	426

Compounds are listed in order of elution from GC.

RESULTS

The Mississippi River and its tributaries exhibit widespread contaminantion with the following compounds: HCB, tech-chlordane, DDE, DDD, DDT, tetra-, penta-, hexa-, hepta-, and octachlorobiphenyl. Other compounds that have been detected include but are not limited too include di-, tri-, tetra-, pentachlorobenzene, pentachloroanisole, hexachorobutadiene, polynuclear aromatics, and chlorinated styrenes. Some areas such as the Missouri River at Hermann, Mo., Mississippi River at Chester,Ill., Helena, Ark., Arkansas City, Ark., and the Mississippi River at the confluence of the White River exhibit eleveted levels of hydrophobic contaminants.

CONCLUSIONS

The hydrophobic contaminants that are present in the water column at concentrations that cannot be detected at conventional detection limits are bioconcentrated to detectable limits within the lipid tissue of stream biota. As a result, stream biota are better indicators of true water quality.

HYDROCARBONS OF EVOLUTIONARY SIGNIFICANCE IN HOT SPRING MICROBIAL MATS

Jentaie Shiea and David M. Ward
Montana State University, Bozeman, MT, 59717

and Simon Brassell
Stanford University, Stanford, CA, 94305

Ancient microfossils have been interpreted as microorganisms which produced O_2 in photosynthesis (cyanobacteria), and thus might have oxygenated Earth's atmosphere. Alternatively they may have been microorganisms which did not produce O_2 (photosynthetic bacteria). We have studied hot spring microbial mats, built by modern microorganisms of either type, and considered analogs of the ancient communities in which microfossils are often found. By correlating hydrocarbon and microbial distributions in these mats, we hope to interpret whether hydrocarbons found in Precambrian sediments might be used to distinguish between these types of microbes.

METHODS

Cyanobacterial mats were collected from the Orakei Korako thermal area in New Zealand and from "Wiegert's Channel", Lower Geyser Basin, Yellowstone National Park. A mat formed by the green nonsulfur bacterium Chloroflexus sp. was collected from "New Pit" Spring, Mammoth Terraces, Yellowstone National Park. Chloroflexus aurantiacus strain Y400 was provided by Dr. M.T. Madigan (So. Ill. Univ.). Lyophilized samples were extracted with CH_2Cl_2. Hydrocarbons were eluted from alumina with hexane and analyzed by capillary gas chromatography--mass spectrometry (VG MM16 or VG70E-HF).

RESULTS AND DISCUSSION

C_{17} to C_{19} mid-chain branched monomethylalkanes were significant components in both cyanobacterial mats (Figures 1A and 2A). Mass fragmentography of key ions surrounding the site of methylation revealed suites of structural isomers with all possible branching positions (Figure 1B). Most modern cyanobacteria and mats they build contain some mid-chain branched monomethylalkanes (6), but this is the first report of whole suites of these hydrocarbons in cyanobacterial mats. The occurrence of these hydrocarbons as suites in Precambrian sediments and oils (up to 1.7 billion years old, see 3,5) was interpreted as a possible result of diagenetic reactions, but our results suggest that cyanobacteria may have directly contributed these compounds in Precambrian sediments.

Predominant hydrocarbons in the Orakei Korako cyanobacterial mat (Figure 2 A) were tentatively identified as dimethylalkanes. They were more volatile than the corresponding monomethylalkanes and their mass spectra indicated two pairs of fragments presumably generated from bond cleavage at each branch (e.g. m/e 85, 211 and 71, 225 for 4, 13-dimethylheptadecane, Figure 2B). Hydrocarbons tentatively assigned as dimethylalkanes were found in other cyanobacterial mats (4) and in Precambrian oils (3). The similar carbon number range and methylation compared to monomethylalkanes in this sample suggest that cyanobacteria may produce the dimethyalkanes.

The predominant hydrocarbons in Chloroflexus, and the "New Pit" Spring mat built by it, were C_{29} to C_{33} di- and triunsaturated alkenes (Figure 3A). Hydrogenation converted these to the corresponding n-alkanes (Figure 3B) ruling out cyclization. Accurate mass measurement eliminated the possible presence of heteroatoms. The most abundant hydrocarbon, hentriacontatriene ($C_{31:3}$), was also found in the two cyanobacterial mats as well as other hot spring mats containing Chloroflexus (2; unpublished data). Its presence in a lagoonal mat (1) may suggest a low-temperature Chloroflexus strain as an inhabitant. Long-chain alkenes are not known to occur in Precambrian sediments, but if diagenetic products of such distinctive compounds survive, they may be useful "chemical fossils" for the presence of this photosynthetic bacterium.

STRUCTURAL ANALYSIS OF PORPHYRINS: ANALYSIS OF IN VITRO PREPARED PORPHYRINOGENS USING AN ION TRAP MASS SPECTROMETER

G. J. Van Berkel, G. L. Glish, and S. A., McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121.

Porphyrins are a class of macrocyclic tetrapyrroles important in a number of fields. Detailed structural information on these compounds is often desired, but the structural information available from mass spectrometry is limited by the inability to fragment the extremely stable macrocycle. This problem can be circumvented by converting the porphyrin to the less stable porphyrinogen (hexahydroporphyrin) in vitro (Figure 1) since, using electron ionization (EI), porphyrinogens fragment to yield tri, di-, and monopyrrolic ions from which the pyrrole sequence of the macrocycle can be determined.[1,2] Little information on the structure of the individual pyrrolic units can be determined from these spectra, however, and secondary fragmentation of the substituent groups on the individual pyrrolic units can make spectral interpretation extremely difficult. We have found that analysis of porphyrinogens with the Ion Trap Mass Spectrometer (ITMS), using a variety of ionization techniques and multiple stages of mass analysis (i.e., MS^n, where $n \geq 2$) produces spectra that are less complex and contain more structural information than the EI mass spectra obtained using conventional instruments.

Porphyrinogen mass spectra were simplified through precise control of the ionization process and MS/MS analysis of the protonated porphyrinogen. The mechanism and energetics of the ionization process were controlled using selected reagent ion chemical ionization (SRICI) with both proton transfer reagents (e.g., CH_5^+ from methane) and charge exchange reagents (e.g., $N_2O^{+\cdot}$ from nitrous oxide). The degree of porphyrinogen fragmentation was found to correlate with the exothermicity of the ionization reaction which can be varied via the proton affinity or recombination energy of the selected reagent ion (Figure 2a and b). Using ammonia CI (select NH_4^+) the protonated porphyrinogen was produced without fragmentation. The MS/MS spectra of protonated porphyrinogens were found to contain the same structural information as the EI mass spectra, but in a more interpretable form (Figure 3).

The amount of structural information available from the porphyrinogen mass spectra was increased by using MS/MS and MS/MS/MS (MS^3) analysis. MS/MS analysis of the pyrrolic ions in the EI mass spectra provided information regarding the nature of the substituent groups on these pyrrolic units. The identity of the substituent groups present on the pyrroles can be determined in this manner and such spectra can be used to distinguish between structural isomers of the substituents. MS^3 analysis of the protonated porphyrinogen allows the nature of the individual pyrrolic units making up the tri- and dipyrroles to be determined (Figure 4).

Analysis of in vitro prepared porphyrinogens using the ITMS is a very powerful way to obtain structural information on porphyrins. Compared to conventional EI-MS analyses, analysis of porphyrinogens with the ITMS produces simple and easily interpreted spectra and the amount of structural information obtained is increased because of the ability to perform MS^n analyses.

MECHANISM OF PORPHYRIN HYDROGENATION AND DECOMPOSITION IN A CHEMICAL IONIZATION SOURCE

Gary J. Van Berkel, Gary L. Glish, and Scott A. McLuckey
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831

Several workers have reported evidence for the reduction of porphyrins and extensive fragmentation in the NH_3[1] and H_2[2] chemical ionization (CI) mass spectra, including fragmentation of the macrocycle. This observation is significant in that fragmentation in the electron ionization (EI) mass spectra of porphyrins is typically restricted to the side chains. Fragmentation of the macrocycle permits greater structural characterization of porphyrins via mass spectrometry. We have investigated the CI of selected model porphyrins and porphyrinogens both in a high pressure ion source and in an Ion Trap Mass Spectrometer (ITMS) in conjunction with MS/MS studies of the resulting ions in order to shed further light on the phenomena that underlie the observed reduction/fragmentation.

The MS/MS spectrum of the $(M + 7H)^+$ ion observed in the NH_3 CIMS of the porphyrins that we have investigated match those of the MH^+ ions derived from the corresponding porphyrinogen, the fully reduced form of the porphyrin. This confirms, as expected, that the porphyrin is reduced to the porphyrinogen in the ion source. Several mechanisms for the reduction can be envisioned. We have shown, however, that the reduction does not occur in the ITMS under any conditions normally used for CI. A major difference between CI in a high pressure ion source and the ion trap is the absence of a high concentration of electrons, radicals, and other reactive neutrals in the latter. Furthermore, ion source walls are much more likely to play a role in the chemistry that occurs in the high pressure ion source. We have found that the formation of reduced species in the high pressure source is inversely related to the source temperature (Figure 1). This behavior is consistent the higher volatility of the porphyrinogen relative to the porphyrin. The temperature needed to desorb etioporphyrinogen-III from the solids probe on the ITMS, for example, is 100 K less than that needed to desorb etioporphyrin-III. A plausible mechanism for the reduction of the porphyrin in the CI source is reduction by hydrogen radicals followed by protonation. Reduction of molecules containing the appropriate functional groups by hydrogen radicals under high pressure CI conditions has been shown to occur.[3] The evidence here suggests that the reduction occurs on the walls of the ion source from which the reduced species desorbs and is ionized by proton transfer (in the case of NH_3 CI) or electron transfer (in the case of H_2 CI).

It has been proposed that the fragment ions observed in the CI mass spectrum arise from fragmentation of the ionized porphyrinogen. We have noted, however, that most of the fragment ions observed in the mass spectrum differ by one to several mass units from those observed in the MS/MS spectrum of the $(M + 7H)^+$ ion (Figure 2). This indicates that the majority of the fragment ions in the mass spectrum do not arise from the unimolecular decomposition of the pseudomolecular ions. In light of the proposed mechanism for the reduction reaction, it seems likely that most of the fragment species arise from the thermal decomposition of the porphyrinogen and, to varying degrees, from the lesser reduced species followed by ionization in the CI plasma.

Characterization of Geoporphyrins from New Albany Bitumen and Kerogen by Tandem Mass Spectrometry

B.D. Beato and R.A. Yost, Univ. of Florida, Gainesville, FL 32611
J.M.E. Quirke and M.A. Concha, Florida International Univ., Miami, FL 33199
R.H. Filby and G.E. Mercer, Washington State Univ., Pullman, WA 99164-1300
G.J. Van Berkel, Oak Ridge National Laboratory, Oak Ridge, TN 37831

Geoporphyrins are biological marker compounds which provide information on fossil fuels, such as sample maturation and depositional environment of the sample. Tandem mass spectrometry (MS/MS) has been shown to be a valuable technique in fossil fuel research and exploration by facilitating structural analyses of complex mixtures of geoporphyrins. The Henryville bed of New Albany shale in Clark County, Indiana, is one of the richest sources of both nickel and vanadyl geoporphyrins known, containing about 9000 ppm of each. Shale consists of both bitumen, which is the organically extractable portion, and kerogen, which cannot be extracted with organic solvents by conventional laboratory methods. Very little is known about the composition of kerogen, but porphyrins can be extracted from it via pyrolysis. One primary goal of this research is to compare the porphyrins found in the bitumen with those from the kerogen. This should provide information on how porphyrins are bound to the kerogen matrix. A second goal is to compare nickel porphyrins with vanadyl porphyrins of the same carbon number to determine possible structural differences which are metal-dependant. The last phase of this work involves structure determination of single carbon number fractions of demetalated nickel porphyrins by determining the sequence of pyrroles around the macrocycle. The information obtained from these studies should be useful in oil exploration (porphyrin fingerprinting) and in maturation studies.

All experiments were performed on a Finnigan MAT TSQ45. Samples were introduced via a solids probe (1-2 μg solid sample, 90°C → 400°C @ 120 °C/min) and ionized by either EI (190°C, 70 eV) or hydrogen CI (150 °C, 0.95 torr H_2, 100 eV). Tandem mass spectrometry (MS/MS) was performed with a collision energy of 24 eV and collision gas pressures of 1.8 and 2.9 mTorr nitrogen for the vanadyl and nickel porphyrins, respectively.

Porphyrins from bitumen were separated by thin layer chromatography (TLC) into complex mixtures of nickel porphyrins with a carbon number range of C_{27} to C_{34} and complex mixtures of vanadyl porphyrins with a carbon number range of C_{28} to C_{33}. Similarly, kerogen yielded nickel porphyrins from C_{26} to C_{33} and vanadyl porphyrins from C_{28} to C_{32}. These fractions contained largely the two basic geoporphyrins: etio- and cycloalkano(CAP)-porphyrins. They are differentiated by the CAP porphyrins containing an isocyclic ring.

The EI/MS/MS daughter spectra of the $M^{+\cdot}$ ions of the porphyrins are characterized by β-cleavage of the various alkyl groups from the porphyrin macrocycle (Figure 1). The daughter spectra of the various porphyrins from the bitumen are very similar to those of corresponding porphyrins from the kerogen. This indicates that pyrolysis of the kerogen probably does not result in cleavage of carbon-carbon bonds, which implies that porphyrins are not bound though alkyl linkages to the kerogen.

The daughter spectra of corresponding nickel and vanadyl porphyrins are also very similar (Figure 2). This suggests that both types of metalloporphyrins reflect similar precursors.

Although the EI/MS/MS daughter spectra discussed provide information on the peripheral alkyl substituents on the central porphyrin ring, they do not indicate the relative sequence of the pyrroles in the central ring. Hydrogen CI was found to result in the decomposition of the porphyrins in the ion source to form ions indicative of mono- and dipyrrolic fragments. Single carbon number fractions for six different demetalated nickel porphyrins from both bitumen and kerogen were analyzed by H_2 CI/MS. The pattern of the dipyrrolic fragment ions in the H_2 CI mass spectrum (Figure 3, the labels correspond to the dipyrroles of Figure 4) of one of the fractions resembles that of a well-characterized C_{31} CAP from Serpiano shale (Structure I in Figure 4 from Ref. 1). In earlier H_2 CI/MS studies, dipyrrolic ions were shown to arise out of decomposition pathways which included cleavage of hydrogenated porphyrins. This can lead to a somewhat

complex spectrum further complicated by the fact that each dipyrrolic fragment can contain 0,1, or 2 meso-bridge carbons. The five other demetalated samples analyzed in this way also yielded specific dipyrrolic ion patterns which are useful in structure elucidation and help characterize the New Albany shale more completely.

Although the combination of EI/MS/MS and H_2 CI/MS analyses provides more structural information about geoporphyrins on a micro scale (less than 100 μg) than any other single technique, it does not allow unambigous structure determination except in very limited cases. The next phase of this research will involve the use of ^1H NMR of the demetalated geoporphyrins to further enhance structure elucidation.

A CALCULATING METHOD OF PETROPORPHYRIN STURCTURE ISOMERS COMPOSITION BY TANDEN MASS SPECTROMETRY

Xu Lina

Jianghan Petroleum Institute, Hubei, P.R.China

INTRODUCTION

Porphyrins and their congeners constitute near ubiquitious components of life forms at the cellular level and above.Therefore the study of structure of porphyrins has important scientific significance to inquire into the origin of life and petroleum.Petrophyrins is a complex mixture composed of a wide carbon number ranges of several alkyl-porphyrin series. The author analyses the composition of porphyrins in the source rock from Du-65 well of Liaohe Basin in China, for the purpose of clarify application of MS/MS technique in the field of organic geochemistry. Data were obtained on Finnigan MAT triple-stage quadrupole (TSQ-45 Model)GC/MS/MS/DS system.

RESULTS AND DISCUSSION

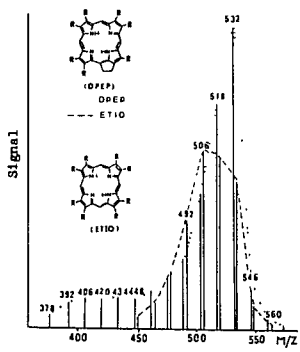

Fig.1 EIMS of the demetallized porphyrins.

EIMS (Fig.1) reveals that the demetallized porphyrins in source rock from Du-65 well include DPEP(58.8%) and ETIO(41.2%).
The EIMS has provided the informations on porphyrin skeletal types present and their canbon number ranges but little data on the structure of the individual components.To correlate the fragment ions with their molecular ions and gain more information about the structure and fragmentation of porphyrin pyrole-alkyl substituents, MS/MS can be employed.
MS/MS of Porphyrin Standards These daughter spectra of standards indicate:1.Porphyrins with extended alkyl substituents(>C_1)will produce MS/MS daughter spectra characterized by the intense daughter ions arising from ß-cleavage of those substituents. 2.Alkyl groups,approching in carbon number,have approximately equal probability of ß-cleaveges. Therefore MS/MS can be used to determine the relative number of n-alkyl substituents,differing in length,present in a compound.
MS/MS of C_{34}-C_{36} DPEP in Source Rock from Du-65 Well The daughter spectra of the C_{34}-C_{36} DPEP reveal the M^+ ions undergoes benzylic cleavage to produce $(M-CH_3)^+$, $(M-2CH_3)^+$ and $(M-CH_3,-C_2H_5)^+$ ions.In addition, C_{35} and C_{36} daughter spectra give $(M-3CH_3)^+$ ion and $(M-2CH_3,-C_2H_5)^+$ ion respectively.Loss of $\geqslant C_3$ groups was not observed.These daughter spectra reveal: 1.The C_{34}-C_{36} DPEP contain ethyl and propyl except for methyl. 2.The ratio of ethyl/propyl can estimate by the intensities of ions in the daughter spectra(see table 1 and Fig.2).
Since the MS/MS analysis of the standards demonstrated exclusive ß-cleavage, it can be assumed that the relative frequency with which a given alkyl group is lost from porphyrins of various carbon numbers does in fact correspond to the relative occurrence of these groups in those porphyrins.(It has one more carbon than the fragment that is lost).Therefore we can calculate the composition of petroporphyrin structure isomers.Calautation includes two steps. First,according to the carbon number of alkyl substituents,the number of substitute pieces and alkyl types, all kind of probable isomers were arranged. Second, the reasonable combination of isomers can be defined by all kinds of probable isomers. For example, out of C_{36} DPEP nucluse has fourteen

		D	0	3	4	1	0	3		4.6
3	M/Z 504 C_{34} n=12	A	5	0	2	5	25	0	32/4 =8.00	62.5
		B	3	1	3	2	6	2	estimate	25
		C	1	2	4	1	1	2	9.05 error 0.5‰	12.5

carbons (n=36-22=14), seven substitute places and three kinds of alkyl groups (methyl, ethyl and propyl) (cf. Fig.1). It has four kinds of probable isomers (A, B, C, D). When A:B:C:D=6:0:1:1 (molecular rate), the ratio of ethyl/propyl in isomers equal to 9.20 (see table 2). The relative error between this ratio (9.20) and estimating ratio (9.23) is 3‰. The result indicates that C DPEP contains seven ethylporphyrins (75%), triethyldimethyldipro-pylporphyrins (12.5%) and monoethyltrimethyltri-propylporphyrins (12.5%).

CONCLUSION

According to the structural information of por-phyrin pyrole-alkyl substituents provided EIMS/MS daughter spectra, the composition of indivi-dual porphyrin isomers can be calculated.

THE DETERMINATION OF FREE ALCOHOLS IN ZINC DIALKYL DITHIOPHOSPHATES BY MASS SPECTROMETRY/MASS SPECTROMETRY

V. P. NERO
Texaco Research Center
Beacon, NY 12508

INTRODUCTION

Zinc dialkyl dithiophosphates, ZDDPs, are used extensively as antiwear agents, corrosion inhibitors, and antioxidants in lubricants. ZDDPs are generally prepared from the reaction of various alcohols with phosphorous pentasulfide, followed by the addition of zinc oxide. The determination of unreacted alcohol in the ZDDP product is important in the optimization of the manufacturing conditions and for developing toxicological information. However, traditional analytical methods either failed to detect alcohols at the low percentage levels normally expected in ZDDPs or cause the product to release alcohols through decomposition.

A mass spectrometry/mass spectrometry method was developed which can detect and quantitate free alcohols in commercial ZDDPs at the subpercent level. The method is based upon a daughter ion analysis which detects possible alcohols along with deuterated surrogate alcohols. This procedure was then applied for the determination of free 2-ethylhexanol in commercial ZDDPs using 2-ethylhexanol (D17, 98%) as a calibration surrogate.

EXPERIMENTAL DEVELOPMENT OF PROCEDURE

The highest observed ion in the total ion mass spectrum for 2-ethylhexanol has a mass of 112.1 representing the loss of water. The highest observed ion for (D17) 2-ethylhexanol has a mass of 128.2 corresponding to the loss of HDO. Both molecules also have identical sensitivities, and corresponding mass spectra, when adjusted for the substitution of deuterium. Considering these findings, a daughter MS/MS method was developed based upon using 112.1 and 128.2 as parent ions. Since the daughter spectra were found to be highly dependent upon collision cell conditions, the collision offset energy in the second quadrupole was optimized to -4 eV and the argon collision gas pressure was optimized to 1.5 torr. These conditions resulted in very reproducible daughter spectra. The summation of fragmentation daughter ions C6H10, C6H11, and C6H12 or C6D10, C6D11, and C6D12 were selected for quantitation purposes. (The quantitation was based on the ratio of the summation of 82.1, 83.1, and 84.1 ion abundances to the summation of 92.2, 94.2 and 96.2 ion abundances.)

EXPERIMENTAL PROCEDURE

A 200 ug ZDDP sample, spiked at the 1.0% level by weight with (D17) ethylhexanol, was maintained at 20C to prevent possible thermal decomposition of the zinc dialkyl dithiophosphate ester at the 250C source temperature. The electron ionization current was maintained at 200 uA with 70 eV. The mass spectrometer, a Finnigan-MAT TSQ70, was operated in a daughter scan mode alternately scanning masses 112.1 and 128.2 as previously described. These alternate scans were reduced to an average scan from which the results were quantitated based upon the summation ratios of the 82 to the 92 series.

RESULTS

ZDDP samples, which were prepared from 2-ethylhexanol, and ZDDP samples, which were not prepared from 2-ethylhexanol, but were spiked with free 2-ethylhexanol at the zero to five percent level, were examined. Figure 1 shows a sample containing no free 2-ethylhexanol. Peaks 82, 83 and 84, representing free 2-ethylhexanol, were not detected. Peaks 92, 94 and 96, representing the deuterated alcohol, are readily observed. Figure 2 shows a sample containing free 2-ethylhexanol. The sample was determined to contain on the average 3.7% of the free alcohol with a 95% confidence interval ranging from 3.4 to 4.0%.

MASS SPECTROMETRIC ANALYSIS OF SEDIMENTS FROM AGED JET FUELS

Gene P. Sturm, Jr., Ronald D. Grigsby, John B. Green, and Dennis W. Brinkman

IIT Research Institute, NATIONAL INSTITUTE FOR PETROLEUM & ENERGY RESEARCH
P. O. Box 2128, Bartlesville, OK 74005

INTRODUCTION: The military is experiencing an increasing number of problems with JP-5 fuels provided under current specifications. These problems include formation of solids, increased corrosiveness, development of color, and increased viscosity upon storage of the fuels. With an ultimate objective of an increased understanding of mechanisms or pathways of degradation processes in jet fuels in order to correct those problems, gums and sediments formed during aging of the 350-550° F distillate cuts (JP-5 boiling range) from two West Coast hydrocracker streams were analyzed by GC/MS and low-voltage, high resolution mass spectrometry. For the latter technique, samples were introduced by probe microdistillation (PMD). Stability of hydrocarbon fuels, including aviation fuels, has been a concern for many years and the subject of several reviews[1]. Reactive hydrocarbons and heteroatomic compound types have been implicated in the degradation processes resulting in sediment and gum formation[2-7]. A free radical chain mechanism[8,9], electron transfer mechanism[10,11], condensation of oxidation products, and coupling of substrates by peroxides[6,7], have been proposed as mechanisms.

EXPERIMENTAL: A description of the fuel aging experiments is given in a separate paper[12]. Sediments from fuel A after 19 weeks at 80° C and 44 weeks at 60° C and from fuel B after 8 and 12 weeks at 80° C were analyzed by GC/MS (methylene chloride solution) and PMD/MS. PMD/MS data were acquired with a Kratos MS-50 mass spectrometer at a resolution (static) of 28,000 and an ionizing voltage of 12 eV. The probe temperature was controlled from -80° C to 350° C (sediment 80-95% volatilized). Data were processed by computer programs developed in-house (see paper MPB 50)[13] using a DEC Microvax II computer.

RESULTS/DISCUSSION: The fuel aging experiments at 60° C were characterized by a short induction period, followed by a period of rapid peroxide formation, and finally a period of decreasing peroxide content and increasing sediment formation. GC/MS and PMD/MS composite results for the four sediments are summarized in table 1. The GC/MS peak identifications were made by both retention time and mass spectral matching of authentic samples of the parent and, where available, alkyl-substituted homologs for the compound types shown unless otherwise noted in table 1. The compositions of the four sediment samples were very similar. Prominent compound types observed were alkyl-indenes, -1,2-dihydronaphthalenes, -naphthalenes, -1-tetralones, -indenols, and -1-naphthols. Lesser amounts of indanes, phenols, and indanols were detected. In addition, 2,3-benzofurans and o-phthalic anhydrides were identified by GC/MS. No sulfur or nitrogen compounds were detected in the sediment samples which is consistent with the low elemental S (<7 ppm) and N (<0.3 ppm) content of these fuels. The PMD/MS results indicated broader ranges of compound types and carbon numbers than the GC/MS results. Additional secondary-distributions of hydrocarbons, O-, O_2- and O_3-compounds observed by PMD/MS, were probably dimers of the prominent hydrocarbons and oxygen compounds determined both by GC/MS and PMD/MS. One trend observed was a shift from a prominence of hydrocarbons and O-compound types in the fuel B, 8 week, 80° C sample (consisting primarily of filterable sediment) to a prominence of O- and O_2-compound types in the other sediments (primarily adherent).

CONCLUSIONS: The composition of sediments from two hydrocracked fuels indicates that oxidation of alkyl-indans/tetralins, -indenes/dihydronaphthalenes, -naphthalenes, -benzenes, and their oxidation products results in formation of sediments or gums. The induction period and the inhibiting

effect of antioxidants[12] are consistent with a free radical chain mechanism. The presence of dimers is consistent with the condensation of oxidation products of alkylnaphthalenes and the coupling of substrates by peroxides[6,7].

ACKNOWLEDGMENTS: The authors give thanks to Bob Vrana, Shirley Yu, and Fred Tilley for aid in data acquisition. Financial support for the project provided by the U.S. Navy (Naval Air Propulsion Center) and the U.S. Department of Energy under Cooperative Agreement DE-FC22-83FE-60149 is gratefully acknowledged.

THE CHARACTERIZATION OF FUNCTIONAL FLUIDS BY HIGH TEMPERATURE CAPILLARY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

T. H. Wang

Technology Division

Pennzoil Products Company, The Woodlands, TX 77387

A new class of functional fluids, high molecular weight alkylated cyclopentanes were characterized by a novel high temperature capillary gas chromatography/mass spectrometric technique.

A wide-bore fused silica capillary column coated with the polar, thermostable stationary phase PZ-179 (a polyphenylether sulfone) was used for the initial GC separation. Typical programmed runs spanned a temperature range of 150-380°C illustrating the utility of this system in analyzing high boiling functional fluids. The chromatogram of two wax standards on a 60 meter 10% PZ-179 capillary column is shown in Figure 1. The base line was very stable up to C-54. The chromatogram of an alkylated cyclopentane is shown in Figure 2. The isomers of tridecyl-, tetradecyl- and pentadecyl cyclopentane were separated by this PZ-179 fused silica capillary column.

Following GC separation, the structures of alkylated cyclopentane functional fluids were confirmed by electron impact mass spectrometry. However, the parent peaks obtained by electron impact tended to be weak or absent, whereas normal phase liquid chromatography/thermospray mass spectrometry gave an intense $(M-1)^+$ peak and was consequently a better parent ion confirmation than traditional electron impact.

Other high boiling commercial functional fluids containing a large number of isomers were separated on this column and subsequently identified by mass spectrometry. Dibasic acid esters, pentapolyol alkanolates and polyalphaolefins are typical of the types of functional fluids analyzed by this method.

In summation, the combination of mass spectrometry and PZ-179 capillary column chromatography provides a powerful tool for qualitatively and quantitatively analyzing high boiling functional fluids.

A MOLECULAR BEAM MASS SPECTROMETRIC INVESTIGATION OF THE COMBUSTION OF SINGLE COAL PARTICLES*

Frank Green, J. Eugene O'Donnell, and David Robaugh

MIDWEST RESEARCH INSTITUTE
Kansas City, MO 64110

Alkali metal species have been identified as principal contributors to the corrosion of heat transfer surfaces and turbines in coal combustion and gasification systems. This corrosion often limits the life and operating temperature of these systems. To date, the information on the behavior of alkali species during coal combustion, particularly at the high pressures typical of pressurized fluidized bed combustors (PFBC) is very limited. This research was therefore undertaken to obtain data on the behavior of alkali species which would be suitable for testing combustion models.

The experimental approach chosen was that of following the reaction of single coal particles with various gas mixtures having temperatures, pressures, and flow rates which simulate PFBC conditions. The species leaving the particle surfaces were measured as a function of time by means of high resolution molecular beam mass spectrometry (MBMS). Particle temperatures were measured by optical pyrometry.

A combustor suitable for the performance of the single particle experiments has been designed and constructed. This combustor has been integrated with an existing MBMS system, which was modified to permit the optical pyrometric measurements and the rapid acquisition of the mass spectrometric data. Measurements have been made using three model coals of three different ranks: Sewickley bituminous coal; Decker subbituminous coal; and Beulah lignite. These measurements were made at temperatures of 1200 to 2000°F, pressures of 1 to 10 atm, and in various gas mixtures at a flow rate of 10 ft/sec. The major alkali species leaving the particle surface were found to be the gaseous metals, with only a small fraction of the total alkali metals present as the hydroxide. The known gaseous sodium oxides were below the limit of detection. Combustion times and combustion products and intermediates were also measured.

---

* This work was supported by the U.S. Department of Energy, Morgantown Energy Technology Center under Contract No. DE-AC-84MC21091.

Experiments were also performed to attempt to determine the behavior of gaseous sodium following its evolution from the coal particles. Measurements were carried out in which the concentration of gaseous Na was measured at different times/distances downstream from arrays containing 19 2-mm Beulah lignite particles. Combustion gases containing 5% and 19% O_2 were used. Although the resulting data showed considerable scatter, which was probably the result of variation in the compositions of the coal particles, good correlations were obtained from the least squares treatment of the data. The "phenomenological" rate law obtained based on these two series of experiments was:

$$-\frac{d\,(Na)}{dt} = 1.06 \times 10^{5}\ (Na)\ (O_2)^{\frac{1}{4}}\ \text{mole cm}^{-3}\ \text{sec}^{-1}$$

CHARACTERIZATION OF COKE MATERIALS FORMED ON ZEOLITE CATALYSTS: APPLICATIONS OF THERMAL CHROMATOGRAPHY-MASS SPECTROMETRY [1].

Benny R. Richardson, Thomas R. Sharp and James F. Haw
Department of Chemistry, Texas A&M University, College Station, Texas 77843, U.S.A.

Cracking catalysts, such as the Faujasite Y zeolite, are used widely in converting a broad range of various organic feedstocks to branched chain aliphatic and aromatic gasoline-range hydrocarbons. However, a carbonaceous material, called coke, forms in and around the zeolite crystallite, which clogs the passageways through the zeolite and covers its surface, isolating active sites from the hydrocarbon feedstock, and deactivating the catalyst. Application of new "thermal chromatography" [1] techniques to the characterization of these cokes simplifies the analytical task, and promises to provide information leading to a better understanding of the mechanisms involved in coke formation.

The Method: Thermal chromatography [1] is a method for desorbing organic compounds from a solid sample by heat rather than by classical solvent extraction. The technique (Fig 1) consists of placing a solid sample -- e.g., approximately 1 to 5 mg of coked zeolite -- directly into a chamber which is continuously flushed with a flow of helium carrier gas. While flushing is continued, the sample is heated at a predetermined rate from ambient temperature to as high as 600°C. The amount of volatile substances desorbing into the carrier gas is measured by passing it through a flame ionization detector (FID), and correlated with the temperature of the sample at which substances desorb. This experiment is referred to as a Level I thermal analysis, and is used for estimation of total amounts of adsorbed organics.

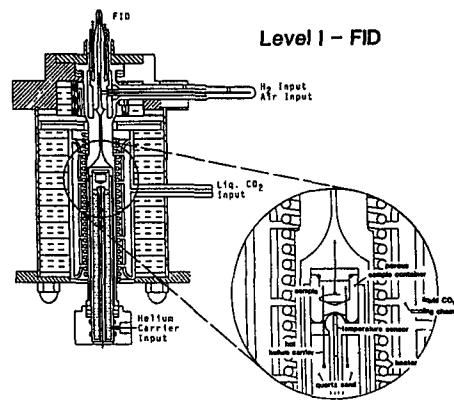

Figure 1: Level I thermal chromatography apparatus. Diagram courtesy of Ruska Laboratories [2].

Identification of specific compounds is achieved using thermal chromatography combined with gas chromatography-mass spectrometry (TC-MS, [1]), known as Level II analysis. A cold trap is placed in the flow path to collect and concentrate thermal fractions desorbing from the sample, e.g. below 200°C. The original solid sample is then cooled to retain any remaining adsorbed materials, while the cold-trapped thermal fraction is introduced onto a gas chromatographic column. Effluent from the column is introduced into an FID detector or, as in Fig 2, a mass spectrometer. After data collection on this first thermal fraction is completed, the original solid sample, having been held in the sample loader, can be reheated, e.g. to 450°C, to collect a second thermal fraction for analysis. This cycle can be repeated to completely characterize the materials adsorbed on the original solid sample.

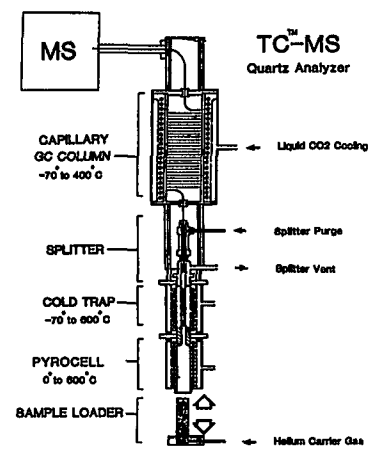

Figure 2: Level II thermal chromatography-mass spectrometry (TC-MS) [1] apparatus. Diagram courtesy of Ruska Laboratories [2].

Level I Characterization of Cokes: Six samples of Faujasite Y zeolite treated with a 1,3-butadiene feedstock were coked at different temperatures -- 150°C, 200°C, 300°C, 400°C, 500°C and 600°C. The results of Level I analyses of adsorbed organic matter on these samples are shown in Fig 3.

They indicate several "thermal classes" of compounds in the cokes, suggested by peaks in the desorption profiles. The amounts of desorbable organics per mg of zeolite are estimated by the areas under the curves, indicating a maximum amount of volatile material on the 200°-coked sample, with less on the samples coked at higher temperatures. These results are in contrast to percentage carbon determinations done on these same samples by an adaptation of standard organic elemental analysis procedures, which indicated a progressive increase in percentage (by weight) of carbon as the coking temperature was increased. The increase in the temperature at which the majority of material is desorbed also suggests that the organics on the samples coked at higher temperature are of progressively larger molecular weight.

Level II Identification of Components: Thermal fractions were collected and subjected to gas chromatography-mass spectrometric analysis. The lower temperature fractions consisted of low molecular weight unsaturated hydrocarbons, identified by mass spectral library matching, which could be logically related to the alkene feedstock used in the coking experiment. The higher temperature fraction contained series of substituted benzenes, naphthalenes, phenanthrenes, and higher polycyclic aromatic compounds, again readily identifiable by chromatographic retention times and mass spectral library matching.

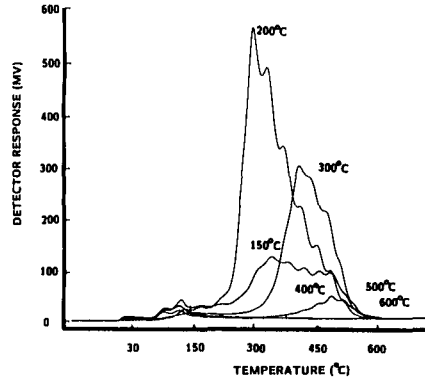

Figure 3: Comparison of amounts of desorbable organic materials on zeolites coked at different temperatures.

Experimental: Faujasite Y zeolite was obtained from Strem Chemical Co., and activated by two overnight exchanges with 1 M aqueous NH_4NO_3, followed by driving the ammonia off by a standard calcination procedure. The 1,3-butadiene feedstock (Matheson Gas Products, 99.0%) was adsorbed to the zeolite by mixing the diene into a stream of dry N_2 flowing over the activated zeolite, while the zeolite was maintained at one of the temperatures indicated above for one hour. Flows of both N_2 and butadiene were each 140 ml/min. The coked zeolite samples were then stored in a sealed inert atmosphere until analyses were performed.

Calibration of the Level I experiments for estimation of total desorbable organics on the zeolites was done using both pure n-C_{30} hydrocarbon and chrysene (Aldrich) as standards. Amounts of the standards were weighed into sample cups, run through Level I desorption, and the area under the FID response curve related to the amount of standard used. Standard curves showed excellent linearity, but different slopes for different standards, as expected.

GC separations of thermal slices during Level II analyses were conducted on non-polar bonded phase fused silica capillary columns (J&W Scientific, DB-1, 15m x 0.32 mm., 0.25 micron film). The mass spectrometer used was a Finnigan/MAT Ion Trap, controlled by an ITDS data system. Full scan spectra were recorded. Identification of components was aided by searching the NBS library version available on that datasystem.

Conclusions: This technique presents an ideal method for characterizing the organic compounds adsorbed on zeolite catalysts, or any solid or semisolid sample which has volatilizable materials adsorbed on its surfaces. It is an alternate, and in certain instances more desirable, technique to solvent extraction procedures in which the ability of the solvent to displace the desired substances from the surface becomes an important additional experimental variable.

DERIVATIZATION IN COMBINATION WITH LMS AND SIMS FOR ANALYSIS OF OXIDIZED COAL SURFACES.

*Jensen, N.J.; Sharkey, A.G.; Viswanadham, S.K.; Lineman, D.L.; Hercules, D.M. University of Pittsburgh, Pittsburgh, PA 15260

Ambient temperature surface oxidation of coal alters many of its physical and chemical properties important in direct utilization and conversion including heating value, agglomeration, coking quality, liquid yield and beneficiation. Characterization of this oxidation is challenging in that a surface phenomenon is involved. The purpose of this research was to develop methodology for characterization of specific compounds (i.e. functional groups) formed in the oxidation process using in situ derivatization reactions for specific functional groups in combination with the microprobe analytical methods of laser mass spectrometry (LMS) and secondary ion mass spectrometry (SIMS).

A number of potential derivatization reagents were identified for screening. However, to be suitable for coal analysis, these derivatization reactions must be applicable to a wide range of compounds with specific functionality and the reaction must occur at ambient temperature under relatively mild conditions. Mild conditions are essential to minimize extraneous reactions of the coal.

Derivatizations studied included: Girard's reagent, iminium perchlorates, pyridinium salts, -ylium dichloroiodates, bisulfites and 2,4-dinitrophenyl hydrazones for aldehydes and ketones; pentafluorobenzyl esters, carboxyl methylenium chlorides, tetra-ethylammonium salts, and t-butyl dimethylsilyl esters for carboxylic acids; and tri-ethylammonium-1-chloro-2-butene salts (TAB), 2-alkoxy phospholanes, boronates, sulfonate esters and di- and trimethylsilyl derivatives for alcohols and phenols. Many of these derivatives yield salts that are well suited to analysis by LMS and SIMS.

Sets of model compounds were derivatized with the reagents and products were analyzed by LMS and SIMS in both positive and negative ion modes. LMS spectra of the 2,4-dinitrophenylhydrazine derivative of benzaldehyde obtained on a zinc substrait are shown in figure 1. Those derivatives that yielded meaningful spectral data for a range of compounds analyzed on metal foil substraits were then studied on carbonaceous substraits. Both preformed derivatives and model compounds absorbed on charcoal and then derivatized were studied on charcoal to evaluate the effect of a carbon matrix. In general, the carbon matrix is not a problem as derivatization increases the mass of the ions of interest and clearly separates them from the low mass carbon clusters. The negative ion LMS spectrum of benzaldehyde derivatized in situ on charcoal with 2,4-dinitrophenylhydrazine is shown in figure 2.

The specific derivatizations for oxidized coal that were selected on the basis of data obtained for the model compounds included: Reaction with 2,4-dinitrophenylhydrazine followed by negative ion LMS analysis and reaction with Girard's reagent followed by SIMS for analysis of the carbonyl functionality; derivatization at pH > 11 with TAB for characterization of the OH functionality, particularly phenols; and derivatization at pH < 9 with TAB for identification of the acids. Negative ion LMS spectra for (a) nonderivatized, (b) 2,4-dinitrophenylhydrazine treated, and (c) TAB treated oxidized Illinois #6 coal are shown in figure 3.

Considering the list of reagents screened, the number that are applicable to coal analysis is very limited. The ability to form derivatives for a range of compounds under ambient conditions is a demanding requirement. The use of Girard's reagent, 2,4-dinitrophenylhydrazine, and TAB in combination with LMS and SIMS analysis have been shown to be suitable for extraction of specific chemical information from the complex oxidized coal matrix.

PROCESSING OF HIGH RESOLUTION MASS SPECTRAL DATA RECORDED FROM THE PROBE MICRODISTILLATION OF COMPLEX MIXTURES

by

Ronald D. Grigsby
IIT Research Institute
National Institute for Petroleum and Energy Research
P.O. Box 2128
Bartlesville, OK 74005

Processing and interpretation of the voluminous quantity of high resolution mass spectral data acquired in probe microdistillation experiments (PMD/MS) can be very labor-intensive without the aid of extensive computer software. Recently, modifications to and extensions of programs for processing and interpreting PMD/MS data have been completed. Use of the programs is illustrated with results obtained from the analysis of a jet-fuel sediment.

The sediment, a yellow-colored jelly, was recovered by filtration from a jet fuel aged at 80 deg C for eight weeks. It dissolved readily in carbon tetrachloride. The solution was loaded into a direct-introduction probe, and a stream of nitrogen gas was used to evaporate the solvent at room temperature. The probe and temperature programmer are described in the literature (1).

The sample was distilled into the ion source of a Kratos MS-50 high resolution mass spectrometer over a probe temperature range from -72 to +326 deg C at a programming rate of 10 deg C/min. The ion-source temperature was 250 deg C. Nominal 20eV electron bombardment was used for ionization and and 39 scans of the spectrum were recorded at 100 sec/decade and 25,000 resolving power.

Six FORTRAN programs, run sequentially, allow raw mass/intensity data from as many as 100 scans to be processed into qualitative and quantitative results. These programs are named "SPECTR", "READTAP", "PROB", "CHY", "INTCOR", and "ELMCRV". Another program, "XFER" (Data General software), is required to transfer the data to tape. All programs except "SPECTR" and "XFER" run on a Digital Equipment Corp. MicroVAX-II computer. "SPECTR" and "XFER" execute on a Data General NOVA/4 computer, which is a component part of the Kratos data acquisition system.

Programs "SPECTR" and "XFER" restructure the data into a tape format compatible with the input requirements of the MicroVAX-II. Transfer of data on tape to this computer is handled by program "READTAP". Program "PROB" accepts the data, consisting of 12C masses and intensities in order of decreasing mass, and converts the masses to the Kendrick scale, in which the mass of CH(2) is defined as exactly 14 amu (2). The data are processed to separate the reference peaks (originating from a calibration mixture run simultaneously with the sample) from the sample peaks.

Program "CHY" identifies ions belonging to specified homologous series, e.g., C(n)H(2n+z) or C(n)H(2n+z)O, where z represents the degree of unsaturation. A description of program "CHY" was presented at the 35th ASMS Conference in Denver, last year (3).

Program "INTCOR" uses the intensities of the reference peaks to correct intensities of the sample peaks for variations in ion-source extraction efficiency encountered during a probe microdistillation experiment. The corrections are based on the assumption that the intensities of the reference ions should remain constant during the run. This is an approximation when the reference mixture is introduced through an expansion-volume inlet (the usual procedure).

Program "ELMCRV" calculates elimination curves for the sample ions. By nonlinear regression, the time/intensity (or temperature/intensity) data for each ion are used to evaluate four parameters in a skewed Gaussian equation expressing the intensity of a sample peak as a function of time (or temperature). After they are evaluated, the parameters are used to calculate the maximum intensity of the curve, IMAX, the time (or temperature) at which the maximum occurs, T(IMAX), and the area under the curve, AREA. Ninety percent confidence intervals are included (1). Output from "ELMCRV" consists of line-printer plots of the curves and other results. If the regression analysis is successful, the goodness of fit, values of IMAX, T(IMAX), AREA, and the parameters with ninety percent confidence intervals are included. If a curve cannot be calculated because low intensities cause excessive data scatter, only the points are plotted. In this case, the time (or temperature) centroid and area obtained by adding the areas of trapezoids are calculated and given along with the maximum intensity and corresponding time (or temperature). Program "ELMCRV" also produces a table showing the T(IMAX), IMAX, AREA, and other information for each ion arranged in order of decreasing z number and increasing mass. Ninety percent confidence intervals are included with the statistical output. Table I shows partial results for molecular ions of elemental combination C(n)H(2n-10)O originating from the jet-fuel sediment. Comparison of the areas under the curves provides an estimate of the relative abundances of the components of the given elemental combination. Non-statistical results, i.e., temperature centroids, etc., are printed in a separate table at the end of the output.

Table I. Edited Output from Program "ELMCRV" Showing Statistical and Nonstatistical Results for C(n)H(2n-10)O Assignments in the High-Resolution Mass Spectra of a Jet-Fuel Sediment. Maximum ppm error = 10.

188.	40.89 +- 1.03	19.51 +- 1.19	471.69 +- 43.34
202.	39.57 +- 1.71	4.82 +- 0.43	127.11 +- 17.80

NON-STATISTICAL RESULTS ORDERED BY INCREASING MASS

M/Z	T(CENTR), MIN	T(IMAX), MIN	IMAX/10000	AREA/10000
104.	41.99	45.15	1.64	24.38
216.	46.28	38.83	1.51	30.80

The sediment from the jet fuel was found to consist predominantly of C(n)H(2n+z) and C(n)H(2n+z)O compound types with values of z ranging from -8 through -12. Other compound types with two and three oxygens were detected. Additional results are presented in paper No. MPB 45 by G. P. Sturm., Jr., R. D. Grigsby, J. B. Green, and D. W. Brinkman.

HYDROCARBON TYPE ANALYSIS BY NITRIC OXIDE CHEMICAL IONIZATION GC/MS

H. A. Petersen, I. Dzidic and H. V. Hart
Shell Development Company, P. O. Box 1380, Houston, Tx 77251

The conventional method of classifying hydrocarbons in mass spectrometry is by the number of hydrogen atoms relative to the number of carbon atoms as expressed by the letter z in the general empirical formula C_nH_{2n+z} (1). All members of a homologous series have the same z number. For paraffins, the most saturated hydrocarbon species, z= +2, for 1-ring naphthenes, z= 0, for 2-ring naphthenes, z= -2, etc.

In our laboratory we have developed a new approach for type analysis based on nitric oxide chemical ionization and GC/MS. The main advantage of this approach is that hydrocarbons of the same nominal molecular weight but different formula can be distinguished by their structurally characteristic ions formed under NO/CI and GC retention times. This method eliminates the need for high resolution mass spectrometry. In addition, hydrocarbons of the same molecular formula, such as acenaphthenes/biphenyls and acenaphthylenes/fluorenes can be distinguished since their GC retention times are different.

The quantification is based on an INCOS procedure which excludes the contribution of alkylbenzothiophenes to alkylbenzenes at z= -6 and the contribution of alkyldibenzothiophenes to alkylnaphthalenes at z= -12. Also z= -18 and z= -20 ion summing ranges are adjusted to include only those species eluting in the specific boiling ranges. The GC/MS is a Finnigan model 4535 equipped with a Townsend discharge mode of ionization. The GC uses a 2mm x 10 ft. glass column packed with 3% OV-101 on 80/100 Supelcoport.

Figure 1 shows that in a catalytically cracked light gas oil (CCLGO) feedstock, within the z= -12 series, the C_4-, C_5-, and C_6-alkylnaphthalenes can be distinguished from the C_0-, C_1-, and C_2-alkyldibenzothiophenes. The same was observed for benzenes and benzothiophenes within the z= -6 series.

Figure 2 shows that different aromatic structures with the same molecular formulas can be chromatographically separated and identified by selective detection of the M+ ions.

The quantitative results of the NO/CI GC/MS method presented by the block diagram are shown in Figure 3. Figure 3 represents the hydrocarbon composition of CCLGO "before" and "after" hydrotreating. Thus, the method reflects the changes in hydrocarbon composition brought about by hydrotreating.

The precision (the percent standard deviation) and the accuracy of the method are about 7-8% relative, for samples boiling in the range 300-900° F. The accuracy was estimated from spiking experiments with pure compounds. Since petroleum samples of accurately known compositions are not available, there is no satisfactory way of determining the accuracy of the method.

For comparison, the total aromatic content by NO/CI GC/MS was found to be higher by an average of 10% relative to the NMR and UV values. From the comparison it was not possible to establish the accuracy limits of the method since there is no satisfactory way of establishing the accuracies of NMR and UV determinations.

Solvent Extraction of An Indiana Shale and Characterization of the Oil Extract

K.V. Wood[1], Ramani Narayan[2], K.R. Stringham[1] and Shuyen L. Huang[2]
Campus-Wide Mass Spectrometry Center[1]
Chemistry Building
Laboratory of Renewable Resources Engineering[2]
A.A. Potter Engineering Center

Purdue University
West Lafayette, IN 47907

A novel perchloroethylene solvent extraction scheme has been investigated for obtaining oil from silicate-rich oil shales. While development of oil from oil shale has a lower priority than coal as an energy resource[1], a co-processing scheme using shale oil with coal would make the utilization of oil shale more viable. The proximity of oil shale and coal would enhance the economics of such a process. This combination can be found in both the Illinois and Appalachian basins of the Eastern United States where silicate-rich oil shales immediately overlie commercial coal fields[2]. Surface mining of this coal exposes huge tonnages of oil shale which effects more than 11,000 acres each year in Indiana and Illinois. The purpose of this study is to use mass spectrometry to characterize the specific organic makeup of the oil obtained from a perchloroethylene solvent extraction of a silicate-rich oil shale.

Experimental

The oil shale (Devonian member) was obtained from Daviess County, Indiana (C=5.17%, H=1.07%, N=0.44%). The shale oil was obtained by extraction with perchloroethylene (typically two grams of shale with 25 ml of perchloroethylene at room temperature). The mass spectrometric analyses included: Hydrocarbon type analysis - CEC 103; GC/MS - Finnigan 4000 (DB-1 capillary column); MS/MS - Finnigan TSQ (Collision energy 20 eV; Argon collision gas pressure 1.6 mtorr).

Results and Discussion

The GC/MS analysis shows a number of resolved peaks early in the chromatogram prior to a very intense unresolved envelope at increased column temperatures (Figure 1). The individual resolved peaks were confirmed to be the straight chain alkane series, C_{11} through at least C_{25} at which point the unresolved envelope obscured any remaining straight chain paraffins. The large unresolved envelope was analyzed using a variety of chromatographic conditions but none were found to effect anything resembling a clean separation. The bulk of the ions observed (80%) from an individual mass spectrum obtained from the region of the unresolved envelope, are low mass (i.e., m/z 41, 43, 55, 57) suggesting the presence of a predominance of saturated hydrocarbons. The hopane and sterane biomarkers could be identified on the trailing edge of the unresolved envelope.

Due to the very aliphatic nature of the extracted oil a hydrocarbon type analysis was obtained. The results (Table I) confirm the GC/MS and probe analysis that the predominant chemical constituents in the extracted oil are saturated hydrocarbons (over 40%). As can be seen from Table I the extracted oil also contains a significant amount of olefins/cyclo paraffins. In order to more completely characterize the compounds present in the extracted oil, tandem mass spectrometry was utilized. The parent spectrum of m/z 57 (Figure 2), an intense fragment ion characteristic of alkanes, gives an indication of the paraffin series present in the shale oil extract. Parent spectra of m/z 71 and 85 extend the paraffin carbon number range because the fragment ion used for the parent scan is a correspondingly higher alkyl fragment.

Since both the GC/MS and hydrocarbon-type analysis indicated the abundance of low mass fragmentations, the parent spectra of a number of representative ions (m/z 77, 79, 81, 83, 87, 89, 91) in addition to the previously mentioned paraffin series, were obtained as a preliminary screen in an attempt to determine the organic structure of other components in the unresolved hump. As would be expected from the hydrocarbon-type analysis, the parent spectra of m/z 81, z = -2, dicycloparaffins/cycloolefins, and m/z 83, z = 0, monocycloparaffins/olefins had the most intense series of ions (Figure 3).

The ion at m/z 81 is indicative of having the $C_6H_9^+$ structure. Therefore, the parent spectrum suggests the presence of a compound series having an alkyl chain extending through C_{22} which fragments to m/z 81. There are a number of possible precursor structures which fragment to m/z 81 but daughter spectra suggest a series of long chain alkyl cycloolefins comprise the significant component of the z = -2 series in the extracted oil.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

On the other hand, the ion at m/z 83 is indicative of having the $C_6H_{11}^+$ structure. This parent spectrum suggests the presence of a compound series having an alkyl chain extending through C_{25} which fragments to m/z 83. Daughter spectra suggest that olefins comprise the significant component of the z = 0 series in the extracted oil.

The combination of GC/MS, hydrocarbon-type analysis and MS/MS proved particularly valuable in providing complementary information for characterizing and identifying specific components in a shale oil derived from a perchloroethylene extraction scheme. This degree of characterization is necessary in order to assess the potential of an oil as a co-processing solvent with coal since certain types of hydrocarbons are known to be better proton sources than others.

Two recent advances are making GC/MS increasingly valuable for the detailed analysis of complex fossil fuels. Alternate ionization modes allow unequivocal identification of molecular ions; and the demonstrated equivalence of GC/MS data with conventional electron impact spectra, both at high and low voltages, allows accurate and reproducible quantification.

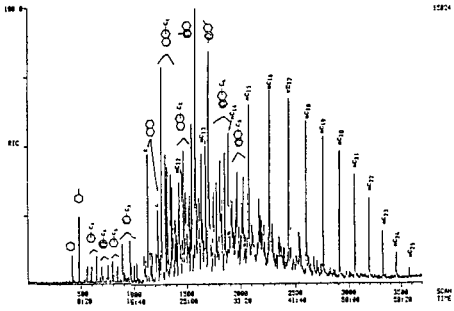
The use of isobutane chemical ionization for isoparaffins and naphthenes, and of low voltage ionization for aromatics and polar aromatics leads to unequivocal identification of molecular ions and improved deconvolution of unresolved GC/MS peaks.

These techniques are equally applicable to the total sample or to individual peaks. In the former case, the methodology allows one to closely relate composition to boiling range, as GC/MS retention times are easily related to boiling points.

Data obtained on various samples and blends also show extremely good agreement between GC/MS and conventional MS analyses using CEC mass spectrometers and ASTM published methods. We have reasons to believe that in fact the GC/MS analyses are slightly more accurate. These findings open a possibility for the of the use of GC/MS for enhanced hydrocarbon type analyses.

The increased scope of GC/MS for the analysis of complex hydrocarbon mixture are illustrated by several examples.

HIGH VOLTAGE EI GC/MS CHROMATOGRAM EXHIBITS OVERALL COMPOUND DISTRIBUTION STRUCTURE OF INDIVIDUAL COMPONENTS IN A COMPLEX MIXTURE CAN BE WELL-DEFINED FROM THEIR FRAGMENTATION PATTERNS.



IN LOW VOLTAGE EI, INTERFERING IONS FROM SATURATED COMPONENTS ARE ESSENTIALLY REMOVED AND EACH AROMATIC COMPOUND IS REPRESENTED BY ITS MOLECULAR ION. THESE FACILITATE THE CALCULATION OF AROMATIC COMPOUND DISTRIBUTION.

Petroleum Hydrocarbon Compound Type Analysis By Quadrupole Mass Spectrometer

T.R. Ashe, Imperial Oil Research
Research Division, P.O. Box 3022
Sarnia, Ontario, Canada N7T 7M1

For thirty-five years, quantitative mass spectral hydrocarbon compound type analysis of petrochemical streams has been performed using magentic single-focusing instruments. These instruments were predominantly CEC or DuPont 21-100 series mass spectrometers. In 1976, DuPont ceased manufacturing this type of instrument because of its limited market.

In 1985, EXXON mass spectrometrists formed a committee to identify suitable replacement instruments for both gas and liquids analysis. The major spectrometer vendors were contacted and requested to participate in the evaluation. Five vendors (Extranuclear, Finnigan MAT, Hewlett-Packard, KRATOS, and VG) agreed to analyze the liquid samples. Due to difficulties, only Finnigan MAT, Hewlett-Packard and KRATOS were able to finish the evaluation within the specified time.

Based on the results of the evaluation, a Hewlett-Packard 5970 quadrupole, Mass Selective Detector (MSD), with the large Brunfeldt Inlet system, was chosen to replace the DuPont 21-104 quantitative mass spectrometer at Esso Petroleum Canada, Sarnia, for liquids analysis. This choice also offered the advantage of low voltage ionization for aromatics compositional analysis which could not be performed by the DuPont 21-104.

The MSD has been used to analyze materials with boiling ranges from 50°F to 1050+°F. The first year of operation was spent in developing analysis software and comparisons between the MSD and the DuPont 21-104. The comparisons were excellent for lower boiling materials, naphthas, propylene tetramers and middle distillates. Due to its higher mass range and sensitivity, the replacement system is able to more accurately determine the higher molecular weight materials present in lube aromatic fractions. The aromatics data from the MSD is in excellent agreement with high resolution compound type analyses generated within the EXXON circuit.

Several errors and differences were identified in the saturates analysis software between the DuPont 21-104 and the MSD. Following a comprehensive study, several typographical errors were identified in the ASTM D-2786 published inverses. The method was also extended to higher carbon numbers.

Correlations have been developed between the results from the MSD and the DuPont 21-104 for lube aromatics (ASTM D-3239) and the Robinson Total Oil method.

The instrument has been in daily use with only a minimum of down time associated with mechanical or electrical faults. The long term repeatability of the MSD has surpassed that of the DuPont 21-104.

DEACTIVATION MONITORING OF CATALYST FROM WILSONVILLE PILOT PLANT BY LOW VOLTAGE PY-MS AND MULTIVARIATE ANALYSIS

Koli Taghizadeh, Rita H. Hardy and Burtron H. Davis
Kentucky Energy Cabinet Laboratory, Lexington, KY 40512

Henk L.C. Meuzelaar
Center for Micro Analysis and Reaction Chemistry, University of Utah
Salt Lake City, UT 84112

The objective of this study is to investigate the deactivation mechanisms of a NiMo catalyst used in the Wilsonville coal liquefaction pilot plant during run 249 (Wyodak coal) while operating in the RITSL (Reconfigured Integrated Two-Stage Liquefaction) mode.

Our approach is to compare and integrate Low Voltage (12 eV) Curie-point pyrolysis/desorption mass spectrometry data with conventional (e.g., elemental analysis and mineral matter) data by means of canonical correlation analysis methods. Both Py-MS and conventional data were obtained on 17 samples collected over a period of 110 days during run 249.

Py-MS conditions were as follows: sample size 100 ug, temperature rise time 5-6 s, equilibrium temperature 610°C, total heating time 10 s, inlet temperature approx. 210°C, electron energy 12 eV, mass range 20-290 amu, scanning rate 1000 amu/s.

In the beginning of the run the organic compounds build up rapidly on the surface of the catalyst. The mass spectrum of sample no. 3 (Figure 1), which was on stream for 12 days, shows the maximum accumulation of organic matter. This organic matter is composed mainly of heteroatomic hydrocarbons (quinolines, phenanthridines, and azapyrenes) which were identified by Py-GC/MS. Subsequently, the concentration of the organics detectable by mass spectrometry decreases gradually. During the later parts of run 249 (88 days and longer) the chemical composition of the remaining organic deposits reveals a shift from heteroatomic hydrocarbons to polynuclear aromatic hydrocarbons.

Canonical correlation analysis of Py-MS and conventional data sets reveals two canonical variates with canonical correlation coefficients of 0.99 and 0.95 respectively. The scores plot of Py-MS and conventional data in the canonical variates I and II subspace is shown in Figure 2 and reveals two trends; (1) a time trend ("catalyst aging") and (2) a nitrogen compound "desorption" trend.

The numerically extracted spectrum along the time axis reveals the accumulation of organic compounds in the early days and the desorption and/or coking of the organic materials in the later days (Figure 3). The spectrum along the nitrogen desorption trend reveals the shift from nitrogen-containing compounds (e.g., quinolines, azapyrenes) to aromatic hydrocarbons (naphthalenes, acenaphthenes and phenanthrenes) in the last few samples (Figure 4).

The loadings of conventional parameters in the canonical variates space (Figure 5) reveal high H, N, and C contents, as well as atomic H/C and N/C ratio's in the early process samples. The later samples, however, show the accumulation of inorganic components such as Na, V, Ni and Ca.

The wellknown rapid deactivation of catalyst during the early stages of the coal liquefaction process appears to be due to adsorption of basic nitrogen compounds on the acid sites of the catalyst. During the later stages of the run these basic nitrogen compounds are gradually replaced by metal cations which increasingly mask the active sites of the catalyst, thereby resulting in slow further deactivation.

The research reported here was supported in part by DOE contract DEFC22-85PC80009 as part of the Consortium for Fossil Fuel Liquefaction Science and by the Commonwealth of Kentucky, Kentucky Energy Cabinet.

STUDY OF NITROGEN CONTAINING COMPOUNDS IN FLUID CATALYTICALLY CRACKED OILS BY NH_3 CHEMICAL IONIZATION GC/MS AND MS/MS TECHNIQUES

D. V. DAVIS, D. B. CARDIN AND J. SCHERZER
Unocal Science and Technology Division, Brea, Ca., 92621

Nitrogen containing compounds play an important role in petroleum refining processes due to their potential as catalyst deactivators and pollutant precursors. In this study we have attempted to characterize the nitrogen containing species in a petroleum fraction (gas oil) both before and after processing thru a pilot plant Fluid Catalytic Cracking (FCC) unit. Preliminary to the study the samples were prepared by first separating both the product and feed into 3 cuts, material boiling below 450 F, material boiling between 450-670 F and material boiling at greater than 670 F. These cuts were further separated by Liquid Chromatography into fractions which were composed of mainly O and N containing species. These LC fractions were then analyzed by a combination of GC/MS and MS/MS techniques using NH_3 chemical ionization.

The Gasoline fraction provided the least amount of information of all fractions studied. The majority of the compounds in the feed were identified by library search as phenols and alkylated phenols. The presence of interfering fragment ions from these phenolic species prevented identification of nitrogen containing compounds in this sample. Many of these interfering ions were not present in the product however and some nitrogen containing compounds could be identified. These were benzamine (aniline) and alkylated benzamines.

The data for the 450-670F fraction and the >670F fraction were not obtained by GC/MS, but rather by MS/MS analysis of different homologous series of ions. The somewhat striking nature of the nitrogen types present before and after FCC processing is apparent in Figures 1A and 1B. These figures are composite NH_3 CI mass spectra of material thermally desorbed from the solid probe after introduction into the ion source. In 1A (feed) series are seen for alkylated indoles (m/z 118+14(n) n=1,2,3...), alkylated quinolines (m/z 130+14(n) n=1,2,3...), and alkylated carbazoles (m/z 168+14(n) n=1,2,3...). As well as an unidentified series (m/z 156+14(n) n=1,2,3...). Close examination of the MS/MS spectra for these series revealed that each single mass consisted of contributions from two isomeric components one of which was amine substituted. In 1B (product) many of the types are no longer present. Only the alkylated carbazoles and indoles are left. MS/MS data on this fraction showed the removal of the amine substituted isomers and that the alkyl substitutents had been altered to much shorter chains predominated by methyl groups.

The data for the >670F fraction is shown in Figures 2A and 2B. These figures are also composite NH_3 CI mass spectra of material thermally desorbed from the solid probe after introduction into the ion source. In 2A (feed) series are seen for alkylated carbazoles (m/z 168+14(n) n=1,2,3...), alkylated benzocarbazoles (m/z 218+14(n) n=1,2,3...), alkylated benzoquinolines (m/z 180+14(n) n=1,2,3...) and alkylated dibenzoquinolines (m/z 230+14(n) n=1,2,3...). Once again MS/MS data revealed the presence of isomeric amine substituted components at these masses. In 2B (product) only two types survive the alkylated carbazoles and benzocarbazoles. Again the alkyl groups are considerably shorter than in the feed usually just methyl groups.

APPLICATION OF GAS CHROMATOGRAPHY/MASS SPECTROMETRY TO THE STUDY OF BIOSOLUBILIZED COAL

J.A. Campbell, M. McCulloch, R.B. Lucke, R.M. Bean
Battelle, Pacific Northwest Laboratory
Richland, Washington 99352

INTRODUCTION

Biological conversion of low-rank coals by bacteria, fungi, or by enzymes they produce has been receiving considerable attention. These processes occur at ambient temperatures and pressures and may represent a potential cost savings for the processing of certain coals and lignites. In addition, microbial conversion of coal and coal-derived products is potentially an important technology for the production of clean fuels. Current technology for coal conversion requires both high temperatures and pressures which may result in the production of components that are more toxic than the original starting material.

Cohen and Gabriel (1) first reported that fungi could grow directly on, and metabolize leonardite, a naturally oxidized form of lignite coal. Wilson, et al. (2) have shown that the leonardite biodegraded product from C. versicolor was water soluble and contained no detectable polycyclic aromatic hydrocarbons (PAH) having three to six rings. In addition, the bioconverted material was inactive in the microbial histidine reversion assay for mutagenic activity. Campbell, et al., (3) have shown that the average molecular weight of the biodegraded product was 1800 daltons as determined by gel permeation chromatography.

In order to better understand the biosolubilization process, we have oxidized the starting leonardite and the biodegraded product with ruthenium tetroxide and sodium periodate to produce organic fragments that are lower in molecular weight which can then be analyzed. The resulting degradation products were derivatized and analyzed by gas chromatography/mass spectrometry (GC/MS). In addition, we have studied the reactions of model compounds having coal-related functionalities with the total organism, the cell-free filtrate, and the cell-free enzyme of C. versicolor. Many of the degradation products have been identified by GC/MS. Model compounds have the additional advantage of providing a much less complex matrix to examine as compared to the biodegraded product.

EXPERIMENTAL

Oxidation. The method utilized for the oxidation of leonardite coal and its biodegraded product was originally reported by Stock (4). The coal (0.3g) was added to a suspension of sodium periodate (34.2g) and ruthenium chloride trihydrate (30mg) in a mixture of carbon tetrachloride (20 ml), acetonitrile (20 ml), and water (30 ml) and the mixture was stirred vigorously for 12 hours. The aqueous layer was then extracted three times with equal volumes of ether, concentrated, derivatized with diazomethane, and analyzed with a HP 5988A GC/MS.

Model Compounds. The model compounds were prepared by dissolving approximately 10 mg of sample in 10 ml of methanol. Two hundred microliters of sample was added to the total organism, cell-free filtrate, or cell-free enzyme. After a specified incubation period, the solution was extracted with three equal volumes of chloroform, concentrated, and analyzed with a HP 5880 gas chromatograph with a flame ionization detector to determine the amount of degradation and a HP 5988A GC/MS to identify degradation products.

RESULTS AND DISCUSSION

A total ion chromatogram for the oxidized, biodegraded leonardite is shown in Figure 1. The dashed peaks indicate compounds that were tentatively identified. A comparison of the types of carboxylic acids identified for the starting coal and the biodegraded product is shown in Table 1.

No benzenedicarboxylic acids were produced from the oxidation of leonardite, but they were recovered from the biosolubilized product. On the other hand, leonardite produced a higher proportion of tetracarboxylic acids than the biosolubilized product. These results may reflect the action of the fungal enzymes on the leonardite coal to produce the biosolubilized product, or alternatively, the difference may be due to selective oxidation.

We have separated the cell-free filtrate into <10,000 MW and >10,000 MW fractions by ultrafiltration techniques. Gas chromatograms of (a) phenyl benzoate degraded by the <10,000 MW fraction and (b) phenyl benzoate degraded by the >10,000 MW fraction are shown in Figure 2. The peaks labelled (1), (2), and (3) have been identified by GC/MS. The model compound is completely degraded by the >10,000 MW fraction. It should also be noted that most of the coal biosolubilization occurs in the <10,000 MW fraction. These results seem to indicate that at least two mechanisms are responsible for the biosolubilization process, one of which may be hydrolysis.

APPLICATION OF CHROMATOGRAPHY/SECONDARY ION MASS SPECTROMETRY TO FUELS-RELATED MATERIALS: ANALYSIS OF POLYNUCLEAR AROMATIC HYDROCARBONS AND BIOMARKERS

L.K.L. Dean and K.L. Busch; Department of Chemistry, Indiana University, Bloomington, IN 47405 USA
G.J. van Berkel; Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831 USA.

The purification and identification of porphyrins from sediments, bitumens, and crude oils is an integral part in the use of porphyrins as biomarkers. This identification is often accomplished with the use of thin-layer-chromatography (TLC) due to the simplicity, speed, and low cost of this technique. Once these porphyrins are separated, they need to be detected and identified. Some common detection/identification methods include location of the spot under UV light, measurement of the R_f value, detection by fluorescence scanning, and extraction by any of a number of elution techniques. These techniques have the disadvantages that they require the use of standards of known responses, and that the spatial resolution of the separated spots is often compromised. The direct analysis of the chromatograms with a secondary ion mass spectrometer solves these problems.

Chromatography/secondary ion mass spectrometry (SIMS) not only provides identification based on the molecular weight of the sample, but also allows the spatial resolution of the sample to be retained so that selected ion monitoring can be used to obtain an image of the separated spots. In this technique, an extraction matrix is applied to the separated spots on the chromatogram and the chromatogram is introduced into the vacuum chamber. The chromatogram is then bombarded with 5-6 kev Cs^+ ions, and the secondary ions emitted from the intact chromatogram detected. A wide variety of compounds have been analyzed by this technique. The application of this technique to a number of porphyrins and polynuclear aromatic hydrocarbons will be discussed.

A variety of matrices have been used for the FAB analysis of porphyrins including: thioglycerol (1), m-nitrobenzylalcohol (2), and o-nitrophenyloctylether (o-NPOE) (3). Of these three possible matrices, o-NPOE was chosen due to its relatively lower vapor pressure and therefore longer lifetime under low pressure conditions. Free-base octaethylporphine (OEP), free-base deuteroporphyrin IX dimethylester (DME), and a number of metallo-OEP samples were analyzed by SIMS with the use of o-NPOE as the matrix. In each case, an abundant signal was observed for the molecular ion and a small degree of fragmentation was seen (see Figure 1). These results indicate that o-NPOE is a good matrix for the SIMS as well as the FAB analysis of these compounds.

To determine if the o-NPOE matrix was suitable for the extraction of porphyrin samples out of a TLC plate, a 50 µg sample of free-base DME was first spotted onto a silica gel plate and extracted from the face of the plate. The matrix was able to extract the sample; however, there was an apparent increase in background noise and an accompanying decrease in resolution. Samples of the porphyrins listed above were then spotted onto a silica gel TLC plate and developed by conventional methods. The developed spot was then saturated with o-NPOE and analyzed by SIMS. A 50 µg sample of each of the porphyrins produced an $M^{+\cdot}$ ion which could be detected but again there was an increase in background noise and fragmentation (see Figure 2). Even though the fragmentation increases, the molecular ion remains the most abundant peak in this region of the mass spectrum.

In 1984, two different matrices, antimony trichloride (4) and "a high boiling hydrocarbon fraction" (5) were introduced for the FAB analysis of polynuclear aromatic hydrocarbons (PAHs). In the present study of pyrene, benzo(a)pyrene, benzanthracene, coronene and 1,2,3,4-tetraphenylnaphthalene, both antimony trichloride and Santovac 5 (a diffusion pump oil) were tested as possible chromatography/SIMS matrices. The mass spectrum obtained from pyrene out of Santovac 5 contains the molecular ion. However, detection limits were in the high microgram range. The use of antimony trichloride as a matrix also produced abundant $M^{+\cdot}$ ions but the high vapor pressure of

this matrix precluded its extensive use. Due to the success of o-NPOE as a matrix for porphyrins, it was used here for the first time as a matrix for PAHs. A 50 µg sample of pyrene in o-NPOE was analyzed by SIMS and an abundant $M^{+\cdot}$ ion was observed as seen in Figure 3. A 50 µg sample of pyrene was then spotted onto a TLC plate and developed by conventional methods. The sample spot on the developed plate was saturated with o-NPOE and analyzed by chromatography/SIMS. The molecular ion for pyrene was observed with a slight loss in sensitivity (see Figure 4). O-NPOE was then tested as a matrix for the remaining PAHs listed above. All of these PAHs produced $M^{+\cdot}$ ions out of the o-NPOE matrix.

O-NPOE is a suitable matrix for the extraction of porphyrins and polynuclear aromatic hydrocarbons from silica gel TLC plates. Molecular ions ($M^{+\cdot}$) are obtained in each case with a large relative abundance. The adsorbed state of the sample on the TLC plate causes some additional noise and fragmentation in the mass spectra of these compounds; however, the molecular ion is easily distinguishable from the resulting fragments.

RADIAL VELOCITY DISTRIBUTIONS OF LARGE SECONDARY MOLECULAR IONS

W. Ens*, B. U. R. Sundqvist, P. Håkansson, A. Hedin and G. Jonsson
Div. of Ion Physics, Dept. of Radiation Sciences, Uppsala University
Box 535, S-751 21 Uppsala, Sweden
**Present address:* Physics Dept., University of Manitoba, Winnipeg, Canada R3T 2N2

For simple linear time-of-flight spectrometers it has usually been assumed that the acceptance of secondary ions desorbed from a solid surface is independent of mass [1]; in the absence of focusing elements, the acceptance is determined by the radial velocity of the secondary ions, the flight path and the size of the detector. In contrast to this picture, we report that the radial velocity distributions for large molecular ions desorbed by high energy (MeV/u) ion bombardment are considerably different from those of light ions and that they are correlated to the incident ion direction. The results have theoretical as well as practical implications.

Radial velocity distributions were measured for secondary ions from valine (117u), LH-RH (1183u), and bovine insulin (5733u). Secondary ions were produced by bombardment with ^{252}Cf fission fragments at normal incidence (on average) from behind the sample foil, with 72 MeV $^{127}I^{18+}$ ions (from the Uppsala EN-tandem accelerator) incident from the front at 45°, and with 18 keV Cs^+ ions incident from the front at 60°. The measurements were made using time-of-flight mass spectrometers equipped with deflection plates in the field-free region after the acceleration stage as illustrated in fig. 1.

Fig. 2 shows the measured intensity of the molecular ion of bovine insulin and a light fragment ion as a function of deflection voltage for fission fragments incident from behind the target foil. The intensity of *low mass* secondary ions shows a single-peaked symmetric distribution around a deflection voltage close to zero. This voltage corresponds

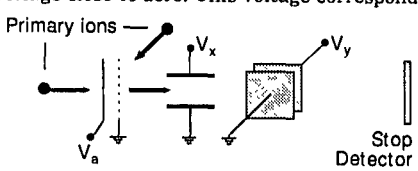

Figure 1 Schematic illustration of the experimental method. In a given experiment, primary ions (see text) were incident from the front *or* from behind.

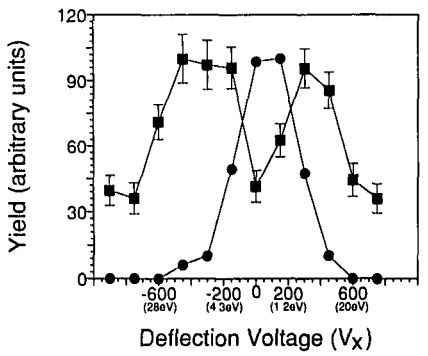

Figure 2 Yield of insulin molecular ions (■) and CH_3^+ ions (●) for fission fragments incident from behind.

to ions that are ejected perpendicular to the target; i.e. with zero radial velocity. However, for molecular ions of insulin, the distribution always shows a local minimum in the perpendicular direction.

Because of the proximity of the ^{252}Cf source to the target, the fission fragments have wide range of incident angles. A much better-defined angle of incidence is obtained from an accelerator beam. For a beam of 72 MeV $^{127}I^{18+}$ ions incident from the front at 45°, the intensity distributions as a function of deflection voltage are single-peaked for both light ions and insulin molecular ions. However, as shown in fig. 3, the distribution for insulin is shifted with respect to that for light ions when the deflection of the secondary ions is in the plane containing the incident beam direction (V_x).

The radial velocities of ions that strike the centre of the detector for the various deflection voltages were calculated assuming that zero radial velocity corresponds to the centroid of the distribution for light ions. The energy corresponding to the radial component of the velocity is indicated in parenthesis in figs. 2 and 3. The ejection angle was deduced from the radial velocity and previously measured axial velocities [2]. The data indicate that the average angle of emission for molecular ions of insulin is considerably

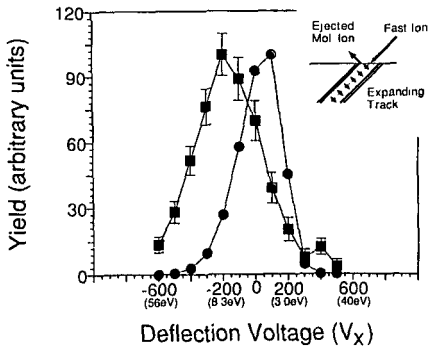

Figure 3 Yield of insulin molecular ions (■) and CH_3^+ ions (●) for $^{127}I^{18+}$ incident from the front at 45° to the normal.

different from that of light ions and that the direction is correlated to the direction of the incident primary ion. In figs. 2 & 3, the maxima of the distributions for insulin correspond to an angle of ejection of approximately 50° to the normal assuming, for the data of fig. 3, that the light ions are ejected perpendicular to the target. (There is some evidence suggesting that the ejection angle of the light ions is also shifted from the perpendicular but in the opposite sense to that of the molecular ions.) In the case of 45° incident ions, the secondary ions are directed away from the incident direction as illustrated in the inset in fig. 3. The same effect was observed to a lesser extent for molecular ions from LH-RH and for cluster ions of valine; the larger the cluster the more pronounced the effect.

It is difficult to reconcile these results with a thermal model of desorption in which the memory of the incident ion direction would be lost. Rather it appears that there is a collective motion of the lattice such as an expansion [3] or a shock wave [4] which transfers momentum outward from the track.

An important consequence of these results is that the required acceptance angle of the detector for large molecular ions desorbed by MeV ion bombardment is much larger than might be expected from measurements with low mass secondary ions. Time-of-flight mass spectra obtained with high energy bombardment have typically used very short flight tubes or an electrostatic particle guide [5] to maximize instrument acceptance. The effect of a simple einzel lens near the target is

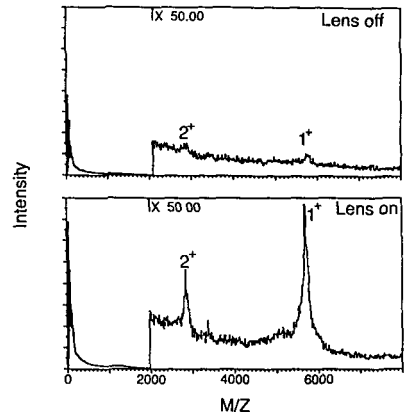

Figure 4 Positive time-of-flight mass spectrum of bovine ionsulin obtained with fission fragments incident from behind without secondary ion focusing (upper) and with focusing. The labels 1^+ and 2^+ correspond to singly and doubly charged molecular ions.

illustrated for a 75 cm flight path, 12 kV acceleration and a 2 cm diameter detector in fig.4. Without the lens, the molecular ions of insulin are barely observable above the background. The lens increases the overall count rate by about 40% but the molecular ion signal is enhanced much more dramatically.

In contrast to the results for MeV ion bombardment the yield of molecular ions of insulin ejected by 18 keV Cs^+ bombardment show the same dependence on deflection voltage as do the light ions. Therefore the effect described above, if present, is much smaller for keV ion bombardment.

SPUTTERING FROM THE GLASSY STATE AND PRESERVATION OF SPATIAL RESOLUTION IN CHROMATOGRAPHY/SIMS. S.J. Doherty and K.L. Busch; Department of Chemistry, Indiana University, Bloomington, IN 47405

In the direct mass spectrometric analysis of silica gel thin layer chromatography plates, the use of a "phase transition matrix" has been illustrated to increase both the absolute intensity and the duration of analyte signal, as compared to analysis without solvent or with liquid matrices, such as glycerol. These benefits can be obtained without compromising the inherent spatial resolution of the chromatographic separation. Developed TLC plates are overlayered with a low melting point glycerol analog, such as sorbitol (m.p. = 93°C). The TLC plate is heated until the matrix becomes tacky to the touch, and the plate is transferred to an aluminum platform inside the source of the chromatography/SIMS instrument. The temperature of the platform is raised to the appropriate level, using an external temperature controller, and positive or negative ion SIMS spectra can be obtained. Primary ion bombardment can be provided by either a low fluence cesium thermionic emitter, or by a highly focussable gallium liquid metal ion gun. Spatially-resolved extraction images can be generated by moving the xyz manipulator that houses the platform, while simultaneously performing selected ion monitoring experiments.

Figure 1 plots the signal intensity as a function of time for the intact cation of a precharged -onium salt extracted from silica gel TLC. The top plot was obtained using xylitol maintained at its melting point (95°) as the extraction matrix, while the lower plot was obtained with glycerol at room temperature. Xylitol can be seen to provide a much more stable secondary ion flux than glycerol. Though not shown here, the xylitol signal was monitored for over an hour, with no appreciable diminution of signal intensity. The pair of images at the top of Figure 2 illustrate that the phase-transition matrix can extract analyte from the support with limited diffusion in the x and y planes. The image on the left charts the spatial distribution of diphenylmethyl- (left peak) and diphenylethyl- (right peak) sulfonium bromides extracted from TLC with two discrete spots of extraction matrix. The matrix, sorbitol, was maintained just below its melting point. The image on the right was obtained after additional matrix was deposited in the space between spots. The original spatial orientations are maintained, and no analyte is observed to have diffused into the fresh matrix. The lower pair of images in Figure 2 illustrate the importance of rigorous temperature control. The image on the left was obtained from two discrete analyte spots, extracted by a common pool of sorbitol heated to just below its melting point. The analyte peaks are clearly distinguishable. The image on the right was collected from the same TLC plate, heated to just above the matrix melting point. The peaks have obviously diffused through the molten matrix, compromising the inherent spatial resolution of the separation.

The analytical utility of this technique is illustrated in Figure 3. The dipeptide glycylphenylalanine was extracted from a TLC plate with sorbitol maintained just below its melting point. The discrete mass spectrum is seen at the top of the figure. The peak at m/z 223 corresponds to the protonated molecule, while the ions at m/z 166 and 120 arise from the protonated and decarboxylated phenylalanine residue. The spatial distributions of each of these ions are provided below. This illustrates that spatial orientation can serve as an additional dimension of scientific information in the analysis of static forms of chromatography, analogous to the temporal profile typically associated with dynamic chromatographic separations.

The glassy state model is advanced to account for the observed behavior. In this model, thermal energy from the heated platform induces a semi-molten state in the phase-transition matrix. Viscosities, and by extension, diffusion coefficients, are approximately equal to those in the solid. Energy from the impact of energetic primary particles is sufficient to accomplish a localized phase-transition to the liquid state. Diffusional and energy dissipation processes in solution are greater than in the solid, leading to increased signal intensity and duration.

A CCD DETECTION SYSTEM FOR SIMS

Lisa K. Turner, David S. Mantus, Yong-Chien Ling, George H. Morrison;
Baker Laboratory of Chemistry, Cornell University, Ithaca, NY 14853

The ability of SIMS (secondary ion mass spectrometry) to provide images of the elemental composition of sample surfaces makes it a valuable technique for elemental localization in biological, metallurgical, and geological samples. The imaging capability, however, has been greatly underutilized, in part, due to the complexity of extracting quantitative information from an image. While the usual discriminations inherent in the production and transmission of secondary ions are present, imaging SIMS is also plagued by detector or detection system discriminations. The conversion of secondary ion intensities to digitized pixel intensities while retaining absolute geometric and densitometric fidelity is an important step towards achieving quantitative SIMS images.

At present, the CAMECA IMS-3f instrument used in our laboratory has a rather circuitous system of detection and digitization of secondary ion images. The ions strike a microchannel plate (MCP) to produce electrons that are accelerated towards a fluorescent screen (FS). The resulting photon image is recorded on 35-mm film or by video camera and subsequently digitized. This multi-stage approach to acquiring images can introduce non-linearity, degradation of spatial resolution, and signal losses at several points along the path (1). In addition, the responses of the the system's components change over time, and frequent calibration is necessary.

In an attempt to reduce the number of transductions, Odom, et.al.(2), replaced the fluorescent screen and subsequent recording media with a resistive anode encoder (RAE). This provides a more direct means of digitization but it is limited to signals no greater than 10^4 cts/sec.

In our approach, the entire conventional detection system, including the MCP, is replaced by a charge-coupled device (CCD). We use the CCD (Tektronix 512x512, backside-illuminated) to directly detect the ions. Because the CCD is used as an integrating detector, we have built a housing which also incorporates a conventional MCP/FS assembly for tuning and real time imaging (Fig 1). Both detectors are mounted along the same focal plane and can be moved in and out of the path of the beam.

The CCD is an array of MOS-like capacitors. When ions strike the device, electron-hole pairs are generated in the p-type Si, the number of which is proportional to the number of incoming ions. These electrons are swept into potential wells created in the n-type Si buried channel by appropriate voltages placed on the three gates which define each pixel. After the signal is integrated for a specified time, the accumulated charge is read from the chip by the process of charge-coupling.

After draining the signal from the CCD, it is digitized and stored temporarily in an image buffer in the controller unit (Fig. 2) Both the electronics and controller units were purchased (Photometrics, Ltd.) and provide all of the support circuitry for the CCD. These units are interfaced to a PDP 11/34 computer and TRAPIX image processor. The user can display an acquired digitized image within 10 seconds of detecting the ions with the CCD.

In preliminary experiments with this system, we have demonstrated that the CCD is sensitive to keV ions (Fig 3). Past applications of CCDs involved only photons, electrons, and MeV particles. The device has good linearity and very low noise when cooled -- only a few electrons per pixel per second -- and is excellent for long integrations. We are attempting to understand and predict the sensitivity of the CCD. This is dependent upon both the energy loss mechanism of the ions and the efficiency of the device to capture the electrons generated at different depths along the range of the ion. Figure 4 shows the results of calculations performed to model the performance of the CCD and relevant experimental data both as it exists currently (solid curve) and if the collection efficiency of generated electrons were made to be 100% (dotted curve) by a process known as QE-pinning (3).

Although determinative experiments are on-going, we have presented a system which provides spatially quantized secondary ion images directly, quickly, and easily. In addition, we have demonstrated for the first time the sensitivity of CCDs to keV ions.

MOLECULAR COMPOSITIONAL MAPPING BY SECONDARY ION MASS SPECTROMETRY

Greg Gillen and David S. Simons; Center for Analytical Chemistry
National Bureau of Standards, Gaithersburg, MD 20899

INTRODUCTION

A continuing goal of our research is the development of a molecular compositional mapping capability using Secondary Ion Mass Spectrometry. In this study, a Cameca IMS-3F equipped with a resistive anode encoder imaging system was used to acquire high lateral resolution molecular ion images of several organic compounds. Because severe degradation of the analyte molecular structure often occurs during ion bombardment, we have also studied some of the parameters which influence the degradation process.

EXPERIMENTAL

In the IMS-3F an Ar^+ primary ion beam strikes the sample which is maintained at 4.5 kV. The primary ion beam accelerating potential is adjustable, giving an ion impact energy which can be varied from ~2.5-13 keV. For imaging studies an impact energy of 8 keV was used. The beam was focussed to a spot and then rastered over an area of 500x500 µm. Typical current densities were 1-5 $\mu A/cm^2$. Digitized molecular ion images were initially stored on an IBM-AT computer. Subsequently, the image files were transferred to a VAX 11/780 computer for further processing. A DeAnza image processing system was used for display of the images in a thermal scale format.

MOLECULAR SECONDARY ION IMAGING

Molecular secondary ion images were obtained from model systems prepared by evaporating the compound of interest from saturated aqueous or ethanolic solution onto copper TEM grids. In all cases, the images were generated using the secondary ion signal of the intact parent molecular ion. Figure 1 shows a mass spectrum and molecular ion image of acetylcholine chloride generated using the parent molecular cation. Figure 2 shows a mass spectrum and molecular ion image of benzalkonium chloride, also generated using the parent cation. In both images, the spacing between adjacent grid bars is 25 µm. Molecular ion images have also been obtained from a number of other compounds including amino acids.

PRIMARY ION BEAM DAMAGE

The degradation of the parent molecular ion and structurally significant fragment ions can be a major impediment to the acquisition of a molecular ion image. To understand some of the parameters which influence the damage processes in bulk molecular solids, the decay of parent and fragment molecular ion signals were monitored as a function of primary ion dose. A typical decay curve for the parent cation of tetrabutyl ammonium bromide is shown in Figure 3. After an initial rapid decrease in molecular ion signal, the slope of the decay curve flattens (at doses of ~1-4x1014 ions/cm2) and very little decay is subsequently observed as the primary ion dose is increased. Parent molecular ion signals were observed for most compounds at primary doses of >1017 ions/cm^2. Similar behavior has been observed for all compounds studied including amino acids. Detection of significant molecular ion signals, after sputtering several tens of nanometers into the sample, suggests that it may be possible to conduct molecular (imaging) depth profiling experiments. From a practical standpoint, it would be desirable to increase the molecular ion signal in the high dose regime in order to increase the sensitivity of the analysis. One parameter which was found to affect the high dose molecular signal was the primary ion energy. As shown in Figure 4, for the parent molecular ion signal of methylene blue, an increase in the primary ion energy results in a decrease in the molecular ion signal. It might be expected that an increase in primary energy would increase the sputter yield and hence the detected molecular ion signal. By plotting the ratio of fragment ion/parent ion signals as a function of energy, it was found that the ratio increases in proportion to the increase in primary ion energy. Therefore, it appears that the2 decrease in molecular ion signal intensity may result from increased fragmentation of parent molecules by the more energetic primary beam. Studies are now in progress to determine what other parameters may influence the decay process.

CONCLUSION

We have demonstrated that it is possible to generate high lateral resolution molecular ion images from model systems using Secondary Ion Mass Spectrometry. Molecular ion signals were observed at high primary ion doses for all compounds studied. This may allow molecular depth profiling experiments. Studies of the effect of primary ion energy on the decay behavior of organic compounds indicated that a higher primary ion energy decreases the yield of intact molecules. This may result from increased fragmentation of the analyte molecule by the more energetic primary ion beam.

STATIC SIMS ANALYSIS OF NITROGEN CONTAINING HETEROCYCLIC AROMATIC COMPOUNDS

P.R. Mahaffy, D.N. Harpold and H.B. Niemann

Laboratory for Atmospheres, Goddard Space Flight Center, Greenbelt, Md. 20771

INTRODUCTION: A mass spectrometer is under development at NASA's Goddard Space Flight Center for use in the chemical analysis of the coma of a comet in a future rendezvous mission. In addition to two gas phase ion sources, and a positive and negative ion mode of operation, the instrument includes the capability to generate secondary ions from a cooled collector surface. The SIMS mode of operation is intended to facilitate the search for heavy, non-volatile organic molecules which may be present in the cometary coma. The instrument has been described previously.[1] Static SIMS laboratory studies are presently in progress in order to select optimal collector materials and operating conditions for candidate cometary molecules. The adsorption of three nitrogen containing heterocyclic aromatic compounds on silver and gold surfaces are described.

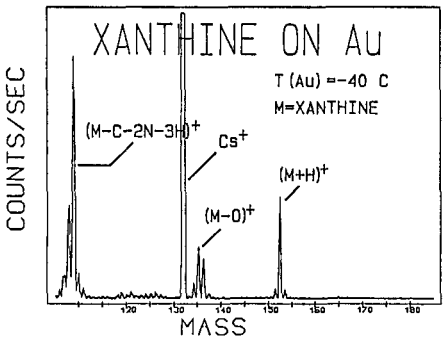
MASS SPECTROMETRIC ANALYSIS OF COMETARY MATERIAL: A number of missions to comet Halley were carried out in 1986[2]. Although the high flyby velocity of these spacecraft limited the quantitative mass spectrometer measurements to major coma species such as H_2O and CO, there were nevertheless strong indications that cometary organic chemistry is complex. For example, a plasma experiment detected ions of mass greater than 100 amu. The shape of this mass spectra, with peaks separated by alternating 14 and 16 amu has led to the suggestion[3] that polymerized formaldehyde (POM) is a possible cometary constituent. In another experiment[4], time-of-flight mass spectra were obtained of ions produced on dust impact at a surface. These spectra indicate that many cometary dust grains consist of molecules containing only carbon, hydrogen, oxygen, and nitrogen atoms (CHON particles). An extended list has been generated of possible molecules contained in CHON as suggested by the data from the dust impact experiment.[5] Several nitrogen containing heterocyclic aromatic compounds are included on this list.

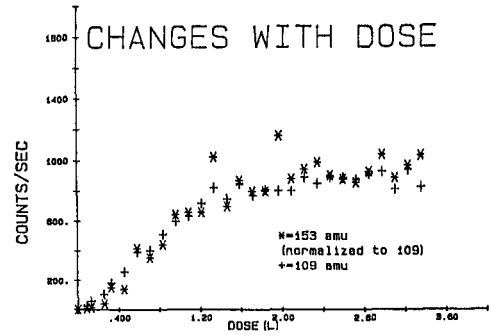
STATIC SIMS STUDIES: Adsorption of

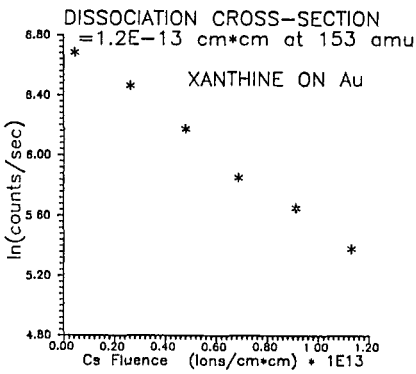
xanthine =  pyridine =  and adenine = 
was carried out on polycrystalline gold and silver foil surfaces. Surface cleaning was accomplished by cycles of Ar ion bombardment and 925 K annealing. UHV molecular beams of adenine and xanthine were generated by heating reservoirs of the molecular crystals. Feedback from a small Bayard Alpert gauge near the target and computer control of the reservoir heating power allowed precise dosing levels to be achieved. Pyridine was introduced through a leak valve. The cylindrical mirror energy filter allowed transmission of secondary ions in a band of approximately 16 eV (FWHM).

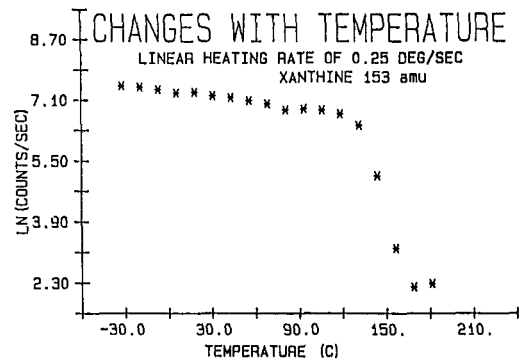
The xanthine/Au adsorption is characterized in some detail in the following 4 figures. The change with temperature of the parent xanthine peak was obtained with a linear temperature ramp of 0.25 deg/sec.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA









The energy of the cesium excitation ions was approximately 4000 eV in all cases. Adenine adsorbed on gold and pyridine on silver (not shown in the abstract) give strong molecular peaks at $(M+H)^+$ and M^+ respectively for surface temperatures of -40 and -60 C. The fragmentation pattern obtained for xanthine on silver was generally similar to that on gold, with differences in the relative strengths of the major fragment peaks. The strongest negative ion molecular peak for the three species was $(M-H)^-$ for xanthine on gold.

The SIMS mode of operation of the Neutral Gas and Ion Mass Spectrometer on the Comet Rendezvous Mission is expected to provide compositional information which is complementary to that from the gas phase ion sources. The nitrogen containing ring structures studied, to date, can be readily identified using the surface ionization technique. The extent to which detection efficiency is lost in the presence of other strongly adsorbing species needs further investigation.

APPLICATION OF A SIMS/TSQ SPECTROMETER FOR ORGANIC SURFACE ANALYSIS IN THE ELECTRONICS INDUSTRY

Bryan L. Bentz and P. Jane Gale

David Sarnoff Research Center
Princeton, New Jersey 08543-5300

A static SIMS instrument based on an extensively modified Finnigan MAT TSQ-15 triple stage quadrupole has been developed at the David Sarnoff Research Center for solid-state organic surface analysis. Surface compositional data for organic solids can be obtained in the positive and negative ion modes. Collisional dissociation of sputtered species is also available. The secondary ion optics for this instrument were designed using the electron optics program ELOP, written in-house. Drawn to scale in Fig. 1 is the geometric configuration of the electrodes. The potentials for the transport and collection of polyatomic ions sputtered from a large surface area by keV primary particles have been calculated. In practice we find that the actual electrode voltages that maximize the transmitted secondary ion signal agree generally to within 3-5% of the voltage values assigned in the computer modelling, except for the deceleration lens following the ESA, where a voltage on the final lens plates of -10V is typically used.

Surface analysis spectra are acquired under low-dose bombardment conditions using a 3 keV xenon neutral beam and an analog electron multiplier as detector. To verify that our many hardware modifications did not reduce the standard mass range of our TSQ instrument (1000 amu), we sputtered a solid CsCl pellet and acquired positive ion spectra of high mass clusters. Fig. 2 shows the mass resolution and peak shapes obtained for the cluster $Cs_5Cl_4^+$ [m/z 805] in the Q3 scan mode. Similarly we could establish that Q1 has the full 1000 amu mass range. Analytical samples are introduced to the homebuilt, 16-port SIMS vacuum chamber via a turbo-pumped load lock which has a base pressure of 2 x 10^{-8} torr.

With this novel SIMS instrumentation we have undertaken surface analytical studies of many insulating and conducting materials of interest in the electronics industry. The surfaces of spin-on glasses, CVD and plasma-deposited thin films, high temperature superconducting materials, conductive thermoplastics, and laminates have been successfully studied for compositional/structural identity or contaminant investigation. To demonstrate the capabilities of our SIMS/TSQ system in organic thin film research, we show in Figs. 3-5 the results of a study of two fluorocarbon-rich surfaces. Fig. 3 presents the positive ion SIMS spectrum of a thin disc of commercial Teflon. The spectrum of a 1000Å film of plasma-polymerized 1,3-perfluorodimethylcyclohexane and N_2 (Fig. 4) contains several peaks in the low mass region of the spectrum identical to those of Fig. 3, with the noted exception of an intense signal at m/z 114. To probe the identity of m/z 114 from this film, a collision-induced dissociation (CID) experiment was undertaken. Interpretation of the daughter ion spectrum of m/z 114 in Fig. 5 suggests that m/z 114 is a nitrogen-containing species and implies that nitrogen was incorporated in the polymer film during its growth in the plasma reactor. In Fig. 6 is shown the SIMS spectrum of the surface of a different type of polymer; poly(ethylene terephthalate) (Mylar). $(M \pm 1)^+$ of the repeating unit are detected in addition to structurally diagnostic fragment ions.

Characterization of Multilayer Thin Films by Laser-Induced Thermal Desorption Mass Spectrometry

Donald P. Land, Tsong-Lin Tai, John M. Linduist, John C. Hemminger, and Robert T. McIver, Jr. Department of Chemistry and Institute for Surface and Interface Science, University of California, Irvine, California 92717.

We report on the use of laser-induced thermal desorption (LITD) and post-ionization by an electron beam to characterize molecular species absorbed in and on the amorphous carbon layer which covers the surface of a computer magnetic hard disk platter. These hard disks are multilayer structures of which the magnetic layer is a mixed alloy of Co and Cr. A final layer of carbon is sputter deposited on top of the magnetic layer to act as a protective film and lubricant. Adsorption of molecular species in and on this carbon layer has been found to be of great importance to the performance characteristics of the magnetic disk. Identifying these species, however, presents a particularly difficult surface analysis problem since one is interested in detecting small quantities of carbon-containing molecules on an ill-defined carbon surface.

In our experiments, a 1 cm^2 piece of a hard disk is positioned in front of a hole in one of the electrodes of a 6 cm cubic FTMS analyzer cell. A focused laser beam (Lambda Physik model EMG 103 MSC excimer laser, wavelength 248 nm, pulse width 20 ns) enters the cell through a hole opposite the sample and strikes the sample at near normal incidence causing heating of a 0.2 mm^2 area. At low laser power, only neutral species are vaporized from the surface. Some of the neutrals desorbed from the sample pass through a pulsed 10 uA electron beam which traverses the center of the cell. Ions formed in the electron beam are trapped in the cell by the magnetic and electric fields, and are mass analyzed Fourier transform (FT) mass spectrometry.

Previous work in our laboratory has shown that this method can be used to identify a wide variety of organic molecules adsorbed on a single-crystal platinum substrate [1-3]. In most cases, the electron ionization fragmentation patterns were indicative of the original surface adsorbates.

Portions of a computer magnetic hard disk were introduced into a VG ESCALAB MK II for characterization using Auger electron spectroscopy (AES) and X-ray photoelectron spectroscopy (XPS). The data showed the presence of carbon, oxygen, and silicon along with other minor constituents. Also from these data we were able to ascertain that the silicon species was partially oxidized, and that some of the oxygen was similar to that found in graphite exposed to the air [4]. We then placed the samples in our LITD-FT mass spectrometer. Using low laser power densities (<1 MW/cm^2) only CO_2 and water desorb. The CO_2 desorption is consisitent with the XPS data which indicated the presence of oxidized graphite.

At slightly higher incident laser power densities (between 2 and 20 MW/cm^2), laser-induced thermal desorption produces a multitude of peaks up to 341 u, indicating that significantly large species desorb. Figure 1 is a typical mass spectrum that was taken at a power density of about 5 MW/cm^2. Peaks labeled by a star have been identified as poly(dimethylsiloxane) compounds, which are common to many silicon-based oils. At this power level, essentially the same pattern of peaks is observed after as many as 600 laser shots at the same spot on some samples. This indicates that the laser beam is not significantly decomposing these surface species and is not ablating the carbon film. Also, there is evidence that the clusters of peaks between 30 amu and 110 amu are the fragments of an aliphatic alcohol.

Depth profiling using argon ion sputtering with AES detection showed that all the silicon was removed after just one minute of sputtering (about 3 nm of C). The surface nature and amount of sample present indicate that the silicone oil was probably placed on the disk intentionally after manufacturing. Inadvertant contamination of the disk during or after manufacturing is unlikely since most pump oils are phenyl silicon oils which give very different mass spectra in our instrument. Samples of hard disks from different sources showed no evidence of silicon compounds under the same experimental conditions, but some did show evidence of hydrocarbons up to mass 417 u. These spectra obtained from disks manufactured differently show the utility of this technique to monitor

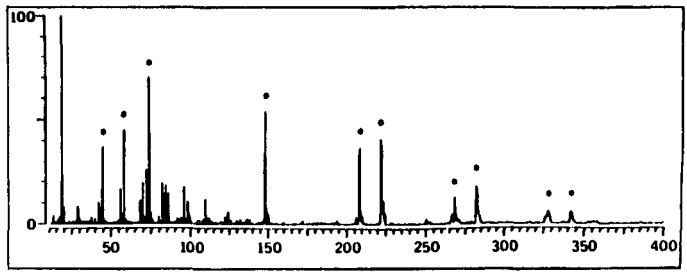

Figure 1: Laser-induced thermal desorption Fourier transform mass spectrum from the sputtered carbon surface of a computer magnetic hard disk.

surface composition on sputtered carbon films.

Since the surface temperature jump is proportional to the incident laser power density, one can use low power densities to desorb only weakly bound species and increase the power density to interrogate increasingly tightly bound compounds. Eventually one reaches power densities (>20 MW/cm^2) which cause ablation of the underlying metal substrates. Under these conditions ions are formed directly by the laser and molecular information about the surface species is lost, but a crude depth profile of the underlying layers can be accomplished. Laser ablation depth profiling is hampered, however, by the widely varying ablation threshholds for the different layers. The ablation threshholds for different materials appear to differ significantly and tend to be very sharp. We are finishing construction on an instrument which would use an ion beam to etch the surface followed by LITD at low power densities to detect the surface species and construct a depth profile.

Both the AES and XPS spectra showed evidence for Si, yet it is clear that the LITD results are far more useful for identifying the nature of the Si species. The ambiguity of vibrational spectroscopies from such surfaces is obvious, and the complications due to species originating from the substrate would hamper interpretation of secondary ion mass spectra or thermal desorp-tion spectra. Laser desorption, however is capable of desorbing large species without ablating the substrate and the FT mass spectrometer allows information to be obtained on a wide mass range for each laser pulse. The combination of these techniques is ideal for the molecular identification of unknown surface species.

SIMS MOLECULAR ION IMAGING OF ORGANIC MOLECULES ON SURFACES

Robert W. Odom
CHARLES EVANS & ASSOCIATES
301 Chesapeake Drive Redwood City, CA 94063

Secondary ion mass spectrometry (SIMS) is a sensitive method in the structural analysis of a wide range of organic species. The fast atom bombardment (FAB)[1] and liquid SIMS[2] techniques are often utilized as routine methods in the molecular weight and structural analysis of a number of complex organic and biomolecules dispersed in a glycerol matrix. The static or molecular SIMS technique has demonstrated monolayer detection sensitivities for a number of organic species adsorbed onto a variety of surfaces.[3] Several research groups have begun to employ static SIMS ion imaging techniques for molecular microanalysis.[4] If this SIMS molecular ion imaging technique can be developed to an analytically useful level, it could provide a method for localizing the distribution of molecular species at micrometer (μm) resolutions in such organic solids as polymers and biomaterials. This paper reports the results of SIMS ion imaging of several simple organic compounds dispersed onto Ag substrates. These compounds produce relatively intense, structurally significant secondary ion signals which can be localized at lateral resolutions on the order of a few micrometers.

Spatially dispersed organic layers were produced by an electrospray deposition[5] of dilute methanol/distilled water solutions of the compounds through a TEM finder grid onto the Ag substrate. Approximately 5 μL solutions of the various compounds having concentrations ranging from ~10^{-2} to 10^{-6} M were electrosprayed over a 3mm diameter area. The molecular areal density for the most concentrated solutions was on the order of 3 X 10^{17} molecules/cm^2. The SIMS analyses were performed on CAMECA IMS 3f and 4f instruments. Positive ion SIMS was performed using O_2^+, O^-, and Cs^+ primary ion bombardment and negative ion SIMS employed a Cs^+ primary beam. Secondary ion microscope images were acquired with the resistive anode encoder (RAE) detector which is a two-dimensional pulse counting detector having a spatial resolution on the order of 1 μm.[6] More intense secondary ion signals and better lateral resolutions for the molecular or pseudo-molecular ions were obtained using a microfocused Cs^+ beam on the IMS-4f and positive secondary ion spectroscopy. For these microbeam analyses, a 5 to 20 pA Cs^+ beam was focused to a ~1 μm spot diameter and was rastered over an area 200 μm X 200 μm. The secondary ion signals were detected on the electron multiplier in these analyses. Ion images were acquired using a specially designed primary beam raster circuit along with custom image acquisition hardware and software. The primary ion dose ranged between 8 X 10^{10} and 3 X 10^{11} ions/cm^2 at an impact energy of 5.5 keV.

A number of relatively simple molecules produced structurally significant positive secondary ion signals. These molecules included thymine, γ-aminobutyric acid (GABA), phenylalanine, dopamine hydrochloride, epinephrine, and acetylcholine chloride (ACh^+-Cl^-). Figure 1 illustrates an ion image of the m/z 137 species observed in the analysis of the residue of ~20 picomoles of dopamine HCl. This ion corresponds to the loss of the $NH_3^+ \cdot Cl^-$ from the molecule. This ion signal is not observed in the mass spectrum of a Ag substrate electrosprayed with a methanol/water blank solution. The pattern in this image is the masking produced by the finder grid. The grey scale to the right of the images shows the number of ion counts represented within each grey level. The useful ion yields (number of ions detected/picomoles of molecule deposited) for this ion was determined by performing a "depth profile" analysis of the sample until the signal disappears. The useful ion yield for the 137 ion obtained in this manner was ~1.6 X 10^5 ions/picomole of dopamine.

Figure 2 illustrates the variation in the useful yields for several ions produced from epinephrine as a function of the epinephrine loading on the Ag substrate. The decrease in the useful yield with increased loading suggests that Cs primary ion beam is damaging the sample at these higher loadings. All of these ions produced spatially resolved secondary ion images with lateral resolutions on the order of 2-3 μm.

These results suggest that molecular ions from sub-picomole quantities of these types of compounds can readily be detected in an imaging SIMS analysis. However, these samples are extremely simple compared to the complex chemical compositions of most biological materials. Attempts to

detect structurally significant ion signals of epinephrine, norepinephrine, dopamine and ACh in various regions of ~ 1 μm thick sections of rat brain tissues are underway. These samples are prepared by microtoming cross sections from frozen whole brain tissues and freeze drying these sections on a Si substrate. Sections have been prepared by Ms. Joan Hunter of the Pasarow Analytical Neurochemistry Facility at Stanford University Medical School (Stanford, CA) in collaboration with Dr. Kym F. Faull. Although it is possible to focus the Cs^+ microbeam onto various tissue regions, no structurally significant ions have yet been observed. The samples exhibit varying degrees of sample charging and analysis of these types of tissue sections using an electron flood gun is in progress.

TIME-OF-FLIGHT MASS SPECTROMETRY: A NEW INSTRUMENT FOR SURFACE CHEMICAL ANALYSIS WITH SUB-MICRON SPATIAL RESOLUTION:

A.R.Waugh, D.R.Kingham, C.H.Richardson and J.Wolstenholme, VG Ionex Ltd., Charles Avenue, Burgess Hill, West Sussex, RH15 9TQ, UK.

INTRODUCTION

When a surface layer is sputtered by a microfocussed ion beam a relatively small number of secondary ions are produced. In order to make the best possible use of the available signal it is necessary to employ a mass spectrometer with parallel detection of all masses, rather than a tuned spectrometer such as a quadrupole or magnetic sector system.

An energy-compensated time-of-flight mass spectrometer is well suited to this purpose. We have combined such a spectrometer with a microfocussed liquid-metal ion source which is able to give a pulsed beam of nanosecond duration. A high stability vacuum chamber and sample manipulator permit a resolution of better than 50nm when the gun is operated in the continuous mode for SEM or total ion imaging. Resolution of the order of 0.25μm can be obtained in mass-selected images in the pulsed mode of operation.

The instrument is also fitted with a Q-switched Nd:YAG laser. An harmonic generator produces second or fourth order radiation (531nm or 266nm) which can be focussed to provide a spot a few microns in diameter at the sample; this provides an alternative means of ionising sample materials.

With the instrument configured in this way the speed of Laser Microprobe analysis is complemented by the precision (extreme surface sensitivity and spacial resolution) of the time-of-flight SIMS (ToFSIMS) technique, so providing an important tool for surface chemical analysis.

PRIMARY SOURCES

The liquid-metal ion gun is currently fitted with a gallium liquid metal ion source operating at up to 30kV. The gun has condenser and focus asymmetric einzel lenses, a Wien mass filter with sufficient resolution to separate $^{69}Ga^+$ from $^{71}Ga^+$, octupole stigmators and scan rods. Auxiliary internal deflector plates can be used to chop the beam (5 to 50ns pulses can be selected by computer control) by scanning it across an aperture. A spatial resolution of <50nm has been achieved using a continuous beam and <0.25μm using a pulsed beam. The ion beam can be pulsed at up to 20kHz, the repetition rate being controlled by the computer.

In the Laser Microprobe mode of operation a "pilot" He:Ne laser is used to select the target area for the Nd:YAG ablating pulse. The laser beams are focussed using a mirror microscope objective which can also be used for viewing the sample via an eyepiece or a TV camera: this is connected to the digital framestore, allowing optical micrographs to be recorded on disk if required.

THE SPECTROMETER

In the time-of-flight mass spectrometer used in this work the secondary ions are accelerated by a high voltage applied between the sample and an extraction electrode. These secondary ions are extracted along the sample surface normal and enter the gridless, toroidal, energy-compensated analyser via a variable iris acceptance aperture. The accelerated ions pass around an energy-compensating electrostatic sector before impinging on a channel-plate detector. This electrostatic sector corrects for the initial kinetic energy spread of the sputtered secondary ions, thereby enabling good mass resolution to be achieved.

The spectrometer has a very high transmission and virtually all the ions leaving the surface may be focussed onto the detector. There is no inherent upper mass limit set by the spectrometer and SIMS spectra may be recorded with good sensitivity up to mass 8,000 and beyond. Post-acceleration may be applied to improve the registration of heavy ions by the channel-plate detector.

DATA COLLECTION

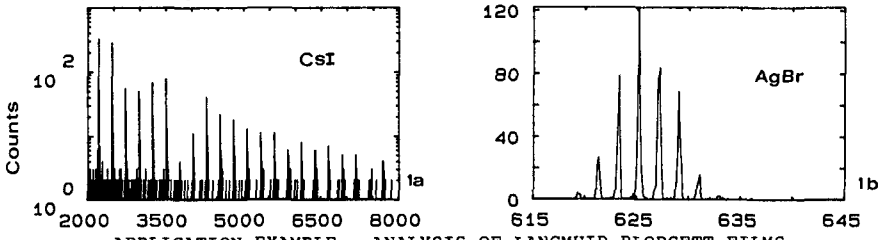
Time-of-Flight SIMS spectra are collected using a time-to-digital converter with 1ns resolution (LeCroy 4208). Digital delay generators can be used to veto signals from unwanted intense peaks (eg alkali metals) to avoid saturating the acquisition system. A fast CAMAC processor is used to sort the data and transfer it periodically to a PDP 11/73 with a digital frame-store. The datasystem can either acquire mass spectra with acquisition times of typically 10-100 seconds, or can simultaneously acquire both a mass spectrum and multiple mass-resolved secondary ion images of 64^2, 128^2 or 256^2 pixel resolution, with acquisition time typically around 120 seconds. Due to the parallel detection of the time-of-flight spectrometer, images can include ions at different masses (e.g. all the isotopes and all the cluster-ions containing a given element). Laser Microprobe data are generated using a single-shot laser pulse with analogue acquisition using a 200MHz, 8 bit 32,000 channel transient recorder.

INSTRUMENT PERFORMANCE

Examples of the spectral performance of the instrument are presented here:

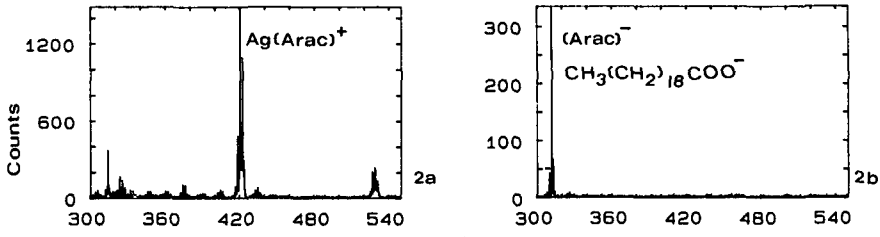
Fig.1 a) Spectrum from Caesium Iodide demonstrating the mass range of the ToFSIMS showing clusters up to 8000 amu.

Fig.1 b) Spectrum from Silver Bromide showing the isotope distribution of a cluster centred on mass 625. A mass resolution, M/Delta M, of 2500 FWHM at mass 625 has been achieved.



APPLICATION EXAMPLE: ANALYSIS OF LANGMUIR-BLODGETT FILMS

L-B films form as precise, uniform, layers of organic material on the surface of a suitable substrate. Data are presented from films of arachidic acid on silver. Fig.2a shows a positive ToF spectrum from a 3 monolayer film; the cluster ion silver arachidate is clearly seen. Complementary information (Fig.2b) is available from the negative spectrum in which the arachidate ion predominates because of its existing negative charge in the L-B film. (Courtesy of Dr. Joe Gardella, Chemistry Department and Surface Science Center, State University of New York at Buffalo, Buffalo, New York 14214).



CONCLUSION

A new time-of-flight mass spectrometry instrument has been built which is capable of:

i) surface molecular ion analysis up to at least 8000 mass units;

ii) surface molecular ion imaging with sub-micron spatial resolution under low damage STATIC SIMS conditions.

THE POSSIBLE RELATION OF STATIC SIMS ION YIELDS FROM Ni_3Mn TO SURFACE ORDERING

K.A. VINEBERG+ and P.H. DAWSON
NATIONAL RESEARCH COUNCIL, OTTAWA, and +McMaster University, Hamilton, Canada

INTRODUCTION

Yields of sputtered ions are known to be sensitive to surface chemistry. The relative yields of different species indirectly reflect the surface composition. Alloys which undergo order-disorder transitions as a function of temperature may provide interesting model systems for study. One limitation is a lack of knowledge of the relationship of the surface behaviour to that in the bulk. However, this in itself is a subject of considerable interest. A number of theoretical studies have been carried out previously (1) and some experimental observations have been made for Cu_3Au using LEED and ion scattering (2). No previous work has been reported on Ni_3Mn surfaces. Using 1 keV argon ion bombardment, "static" secondary ion yields were observed as a function of temperature from clean alloy surfaces. Surface composition and surface cleanliness were monitored using Auger electron spectroscopy. Significant yield decreases were observed above a certain critical temperature. Yields could be restored by annealing at a lower temperature. Different species had different quantitative behaviour. Auxiliary experiments in a sputtered neutral mass spectrometer indicated that the changes were largely in the ionised fraction rather than in the total sputtered yield.

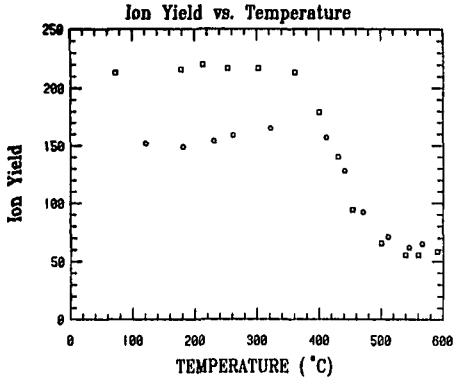
BULK PROPERTIES OF Ni_3Mn

For Ni_3Mn, the order/disorder temperature is at 510°C. There is also a magnetic transformation at a lower temperature (~ 465°C). The critical temperatures are highly dependent on the composition, decreasing with nickel enrichment.

EXPERIMENTAL RESULTS

SIMS YIELDS



Experiments were carried out on $Ni_3Mn(100)$ surfaces with sufficient time spent at each temperature to ensure thermal equilibration. The figure shows typical yield variations for Mn^+ and Ni^+. There is a significant yield decrease at a temperature near 400°C. The exact temperature was somewhat a function of past history of the surface (say ± 20°C). Similar changes were observed for $Ni_3Mn(111)$, for $Ni_{0.65}Mn_{0.35}$ (Polycrystalline) and for surfaces that had small quantities of the two most common contaminants - S and O. The yield of Mn^{2+} also decreased at the critical temperature but by a much smaller factor than that of Mn^+. Pure Nickel did not show any yield changes in this temperature range.

Similar decreases in yield could be brought about at lower temperatures by excessive ion bombardment.

Yields were restored by extensive annealing at lower temperatures.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

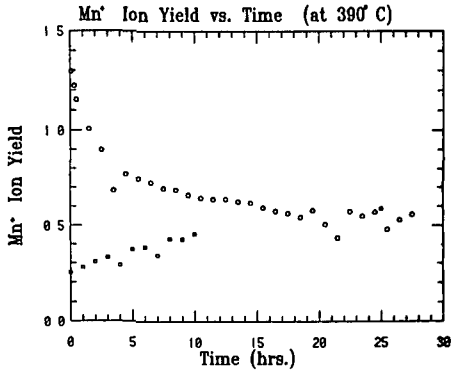
SNMS RESULTS

The yield of Ni atoms remained constant throughout the transition region.

AUGER RESULTS

In the transition region no appearance or disappearance of contaminants at the surface was observed (after the initial cleaning had been carried out). The Auger spectrum indicated no major changes in the Ni/Mn ratio in the surface layers during the transition. Repeated cycling (and the ion bombardment involved in the observations) slowly resulted in a depletion of Mn from the surface.

TEMPORAL BEHAVIOUR



The figure shows the approach to steady state at a temperature in the transition region when the temperature was suddenly increased from 350°C or suddenly decreased from 450°C.

The temporal data can be analysed in an attempt to extract time constants and *activation energies as shown in the two* following figures, one for the heating process and one typical of the cooling process. The data have a large scatter but are consistent with an activation energy of the order of 0.5 eV.

SURFACE PROPERTIES

The simplest situation would arise if the surface were a simple extension of the bulk. e.g. the $Ni_3Mn(100)$ surface would have an outer layer consisting of equal numbers of Ni and Mn atoms and a second layer consisting entirely of Ni atoms in the ordered state. The disordered state would be a completely random arrangement. However, various theoretical treatments suggest that the surface behaviour may differ from that of the bulk (2). For example, the calculations using a lattice gas model in the tetrahedron approximation show that the surface ordering/disordering temperature can differ from the bulk depending on the magnitude of the surface segregation energy to the pairwise interaction energies. Recent Monte Carlo simulations of the outermost eight atomic layers (Vurens et al) show that surfaces can order at very different temperatures from the bulk and that surface enrichment effects must be taken into acount.

DISCUSSION

Large changes in secondary ion yields were observed in a critical temperature range and these do not appear to be related to any changes in composition or impurity segregation that can be observed with the Auger analyser. The changes are predominantly in the yields of ions rather than the total sputtered yield, although the relative yields of different species undergo changes of different magnitudes. The changes have been observed with many different crystals of differing origins. SIMS yields may be sensitive to surface structural changes due to associated changes in electronic structure. Some such electronic changes have been reported in association with order/disorder phenomena (see photoemission results of Jordan and Sohal, J. Phys. C 15, L663 (1982)). The observations reported here occur well below the temperatures expected for the bulk order/disorder transition, but a surface transition is one possible explanation. Clearly a more detailed examination of the Ni_3Mn system would be required in order to demonstrate the validity of this hypothesis.

INDUSTRIAL APPLICATIONS OF FOURIER TRANSFORM MASS SPECTROMETRY (FTMS)

T G Blease, J H Scrivens, ICI PLC, Wilton Cleveland, UK, TS6 8JE
J J Monaghan, ICI PLC, Runcorn Cheshire, UK, WA7 4QD
D Weil, Nicolet, Madison, WI 5311, USA

The characterisation of polymer formulations which may include increasingly sophisticated additives forms an important part of the work of an industrial laboratory. Modern additives often show substantial increase in molecular weight with decreasing volatility over those used previously. Laser desorption mass spectrometry (LDMS) is a technique that offers considerable promise in the study of these materials.

Fourier transform mass spectrometry (FTMS) is well suited to coupling with pulsed laser desorption and a combination of the two techniques has been used to characterise additives and polymers of industrial interest. Another relevant ionisation technique for these materials is field desorption (FD) and a comparison of these two methods is made.

FTMS spectra were obtained with a Nicolet 2000 FT instrument using a Tachisto 215G pulsed CO_2 laser. FD spectra were obtained on a JEOL HX110 double focussing instrument of forward geometry. LD-FTMS spectra are characterised by abundant cation attachment ions and, to enchance this feature and reduce the ambiguity of the identity of the cation, all samples were doped with KBr.

Fig 1 shows the LD-FTMS spectrum of pentaerythritol tetrabehenate $C(CH_2OCOC_{21}H_{43})_4$ of mol wt 1424. The cation attachment ion at m/z 1464 is clearly seen together with abundant structural information. Demulsifiers are often formed by ethoxylating and/or propoxylating alkyl phenol formaldehyde resins. These materials are difficult to characterise but they do run well by LD-FTMS and an example is shown in Fig 2.

FIG 1

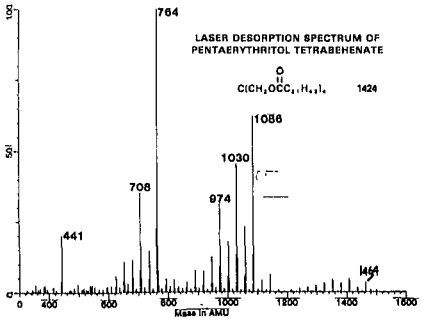

FIG 2

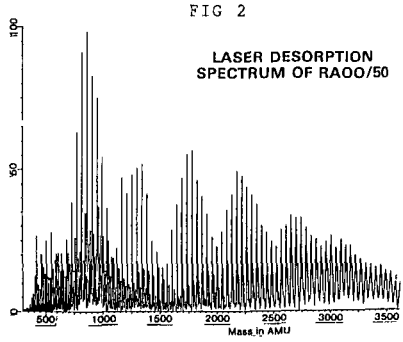

Thus LD-FTMS is a promising technique for the characterisation of polymers and polymer additives. A number of compound classes, of which the foregoing are some examples, have been successfully studied and the future of the approach looks bright.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10. 1988. San Francisco. CA

Although FTMS has been widely used, published collisionally activated dissociation (CAD) applications are rare. We have compared the results obtainable using a dual cell geometry FTMS instrument together with pulsed valve introduction of collision gas with those obtained previously on a BEQQ hybrid instrument. The problem chosen is the characterisation of the components of an epoxy resin extract. Our original hybrid MS-MS results on this were reported at the Denver ASMS meeting (1).

The collision gas introduction system in the dual cell FTMS instrument leads to the combination of high collision gas pressure with higher resolution conditions (low pressure) for ion detection. This reduces the problem of reaction of daughter ions with neutral molecules.

FIG 3

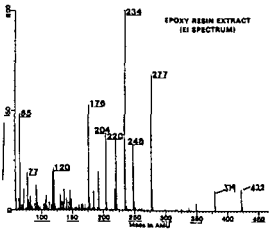

FIG 4

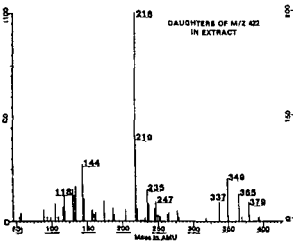

FIG 5

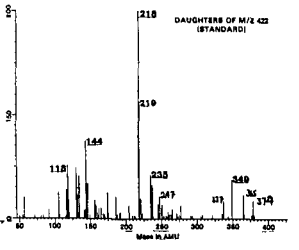

Fig 3 shows the EI spectrum of the extract. Figs 4 and 5 are the CAD daughter ion spectra of m/z 422 from the extract and a standard respectively. Good agreement between the two is obtained. Similar good agreement is found for the daughter ion spectra of m/z 277. For m/z 248, known to be a diaminodiphenylsulphone, the CAD spectra (Figs 6 and 7) confirm the 3,3' isomer to be present in the extract.

FIG 6

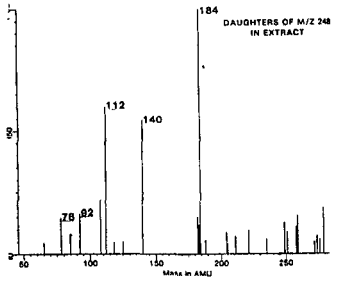

FIG 7

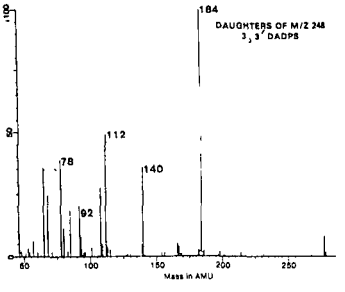

These results can be compared with the daughter ion spectra of m/z 422, 277 and 248 described previously (1) from a VG ZAB HSQ hybrid instrument with ImTorr of argon and 25 eV collison energy.

The CAD FTMS spectra clearly show that analytical problems can be solved by this technique. As currently operated, the energy transfer is greater than that commonly used in hybrid or triple quadrupole experiments. Initial results indicate that higher energy transfers may be possible with CAD FTMS than are possible in hybrid or triple quadrupole collision cells.

METHOD FOR AVOIDING INSTRUMENT RELATED ARTIFACTS IN TRIPLE QUADRUPOLE MASS SPECTRA - A STEP TOWARDS MS/MS CAD DATABASE

S. N. Ketkar and W. L. Fite
Extrel Corporation, Pittsburgh, PA 15238

With the widespread use of triple quadrupole mass spectrometers in analytical applications there is considerable interest in compiling a practical, standardized MS/MS CAD database. One of the key MS/MS parameters that can cause the relative intensities measured in different QQQ instruments for various progeny ions to differ significantly is the Mathieu parameter q_2 (RF voltage on Q2) and restrictive interquadrupole apertures, because of mass dependent focussing effects which determine how effectively parent/daughter ions can be contained within Q2 for emittance (transmission) into Q3.[1]

We report here the use of leaky dielectric endplates in a QQQ instrument as a way of removing the ambiguity associated with the choice of q_2 (RF voltage on Q2). The use of such endplates makes it possible to use all three quadrupoles in a QQQ instrument in a source limited mode.

Figure 1(a) shows the dependence of Q1MS intensity as a function of q_2 for a conventional triple quadrupole mass spectrometer with metallic endplates. Figure 1(b) shows the dependence of Q1MS intensity as a function of q_2 for a conventional triple quadrupole mass spectrometer with leaky dielectric endplates. As can be seen from Figure 1, the Q1MS intensity is independent of the choice of q_2.

We have also measured the cross section for the reaction $N_2^+ + SF_6 \rightarrow SF_5^+ + F + N_2$. Our results are summarized in Table 1. The results agree with the results of Martinez and Ganguli.[2]

Table 1

$$N_2^+ + SF_6 \rightarrow SF_6^{+*} + N_2$$
$$SF_6^{+*} \rightarrow SF_5^+ + F$$
$$E_{cm} = 5.3 \text{ eV}$$

Pulsed High Pressure Liquid Injection of Small Biologicals Into Time of Flight Mass Spectrometry

David M. Lubman and Ho Ming Pang
Department of Chemistry
University of Michigan
Ann Arbor, MI 48109-1055

The goal of this work is to develop a novel liquid injection method for introducing and ionizing small biological molecules in a time of flight mass spectrometer. This method involves using a high pressure pulsed liquid injection technique followed by resonance enhanced multiphoton ionization (REMPI). A unique feature of this method is that since REMPI depends upon the absorption of a resonant state, one can selectively ionize the analyte based upon the wavelength of the laser source while discriminating against the liquid solvent. Thus, one can achieve a separation of analyte and liquid carrier by the use of laser selectivity without the need for prior physical separation. In addition, REMPI can act as a versatile ionization source which can produce either soft ionization or extensive fragmentation by varying the laser input energy or wavelength. This contrasts to other liquid injection techniques where EI fragmentation methods often cannot be used because of the high pressure which results in the MS. Since the UV photons are transparent to the solvent, extensive fragmentation can be produced for structural studies.

The idea of using a pulsed high pressure liquid injection is particularly well suited for REMPI studies as compared to continuous injection techniques. Since a pulsed laser source is used to produce REMPI, it makes sense to use a pulsed injection source in order to optimize the amount of sample interrogated by the laser pulse and to reduce the duty cycle needed for pumping. Most significantly, though, the degree of solute-solvent cluster formation in this high pressure expansion can be controlled based upon the kinetics of the pulsed jet formation. It has been observed that if the pulsed laser source intersects the liquid jet at the front edge of the molecular beam pulse, then such clustering is minimized. If the delay is adjusted so that the laser probes further into the gas pulse, then extensive clustering is observed. Thus, in these experiments where typically 200 atm of CH_3OH at 70-80°C, or H_2O at 140°C or NH_3 at 130°C serves as the liquid injection carrier for the analyte through a 200 µm orifice into vacuum, there is minimal solute-solvent cluster formation observed. In continuous flow techniques, generally significantly higher temperatures are required in order to prevent clustering.

The experimental apparatus consists of a standard supersonic beam/TOF mass spectrometer device which has been described elsewhere (1). The key to this work is the development of a pulsed injection source for high pressure fluid injection. This valve can operate at up to 200 atm reservoir pressure at 180°C with a pulse width down to 100 µs. The valve is constructed so that it can be used with corrosive, polar fluids such as NH_3. Using this valve and liquid N_2 cryopumping the system can easily pump the injected liquid with an operating pressure of ~ 10^{-5} torr resulting. The laser ionization source is a frequency doubled Nd:YAG pumped dye laser operating at 280 or 320 nm.

In Table I are shown results of using pulsed liquid injection of methanol at 200 atm and 80°C of various catecholamine metabolites. The most salient feature of the tabulated results is that the molecular ion, $M^{+\cdot}$, results in every case at 280 or 320 nm, although often accompanied by several fragments of much lower abundance. There are no solute-solute clusters and minimal solute-solvent cluster ions detected where <2% of the total yield is due to such clusters. Also the mass spectra of Table I shows that at a given laser power the degree of fragmentation generally increases as the photon energy increases. In addition, extensive fragmentation can be induced for structural studies by either increasing the laser frequency or power as shown for tryptamine in figures 2a-c. The detection limit for this method has been

shown to be typically between 10-100 ng for the molecules in Table I and will vary according to the solubility of each compound in the solute and the laser ionization cross section.

TIME-OF-FLIGHT MASS SPECTROMETRY: MEETING CHROMATOGRAPHY'S CHALLENGE

Christie G. Enke, Department of Chemistry, Michigan State University
East Lansing, MI 48824-1322

As resolution and speed in chromatography have increased, the time available to acquire MS data on each eluting component has decreased. MS scan rates in excess of 10 scans per second are required to produce good peak profiles and non-skewed spectra for one-second wide chromatographic peaks. The technology in sector and quadrupole mass spectrometers are now very near their fundamental limits [1]. For a breakthrough in maximum data rate, non-scanning mass spectrometers such as the linear diode array detector coupled with a magnetic sector MS, fourier transform MS, and time-of-flight MS (TOF-MS) need to be considered. In the NIH/MSU Resource in Mass Spectrometry, we have chosen to explore TOF-MS as a possible answer to chromatography's challenge.*

In TOF-MS, a burst of ions leaving the source simultaneously can produce an ion abundance vs. arrival time (related to mass) signal in about 100 microseconds. Modern high-speed electronic devices, assembled by our group in the form of an integrating transient recorder (ITR), now make possible the digital acquisition of 10,000 TOF spectra per second. This greatly exceeds the data rate requirements of the fastest imaginable chromatography. To reduce storage requirements and improve the signal-to-noise ratio, 500 or more successive TOF transients are summed to provide effective scan rates of up to 20 scans per second [2]. The resulting spectra have no skew since each TOF transient is a true spectrum.

Mass resolution has long been a limiting factor for TOF-MS with gaseous samples. This is due to energy and spatial dispersion of the sample ions in the normal EI source. Current resolution-enhancement techniques are not adequate for chromatography/TOF-MS; time-lag focusing does not work over the entire mass range simultaneously and the reflectron cannot address the energy and spatial dispersion problems simultaneously. The need for an ion source energy and space dispersion compensation method which is mass independent has led us to explore the possibilities of dynamic mid-flight correction techniques. Four properties could be potentially adjusted to achieve simultaneous arrival for isomass ions: flight length, flight time, ion velocity, and ion acceleration These are illustrated in Figure 1. Concentrating on velocity correction first, we have modelled a mid-flight dynamic field system that promises to achieve a mass resolution of 2000 with a 500 K EI source having an ionization depth of 0.2 mm [3]. Our model differs from velocity compaction [4] in that the midpoint correction is designed to produce equal arrival times rather than equal velocities for isomass ions.

Another approach is to combine separate techniques to reduce the effects of energy and spatial dispersion. Pulsing the ion beam after a continuous current ionization source can reduce the spatial dispersion problem (and the reverse energy, or "turn-around" problem). We have used this technique in conjunction with an electric sector energy filter to achieve full range TOF mass spectra with good resolution [5]. A reflectron might have a sensitivity advantage over the electric sector in this application. The signal/noise ratio loss from beam pulsing is equal to the square root of the duty cycle. The number of mass channels simultaneously detected with TOF and ITR more than compensates for the fraction of the ion current not used. Detection limits approaching those of scanning instruments operated under single-ion monitoring mode could potentially be achieved if ions created over a larger fraction of the pulse repetition time could be simultaneously pulsed out of the source.

MS/MS also can benefit from "array-detection" mass spectrometry. The time required to collect the full MS/MS data (daughter spectra of all the parent ion masses) typically requires many minutes with current tandem mass filter instruments. Speeding up the data collection rate and making more efficient use of the sample could extend the benefits of MS/MS to a much broader range of samples. We have combined TOF/ITR with a magnetic sector mass spectrometer in a technique we call time-resolved ion-momentum MS (TRIMS) [6,7]. Each TOF transient provides the velocities of all the ions of a given momentum. Daughter ions have the velocity of their parents, but a lower momentum. Scanning the magnetic field strength once can provide the full set of MS/MS data collection over a one decade mass range in less than 20 seconds. Complete MS/MS data has been

obtained from sample compounds introduced by injection onto a packed column [8]. For still faster data acquisition, TOF could be used for both the selection and analysis stages of MS/MS. The feasibility of adapting a reflectron TOF MS/MS instrument for gaseous samples and high data rates is currently under study.

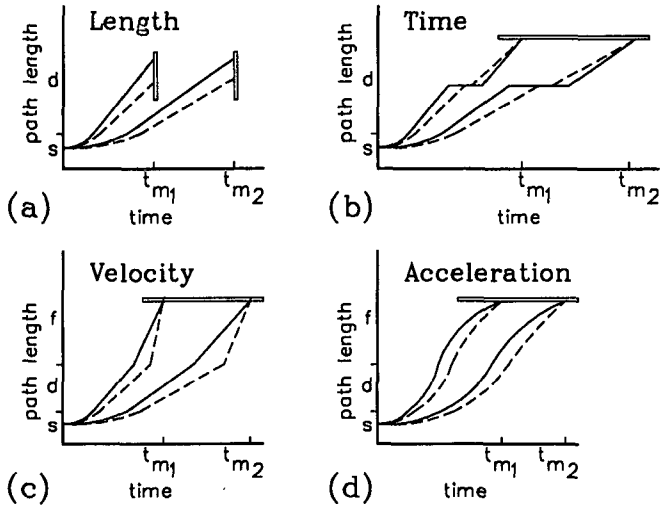

Figure 1. Four possible adjustment techniques to achieve equal arrival times for isomass ions pulsed from a gaseous sample source. The flight path (distance *vs.* time) is shown for ions of two mass values. For each mass, two different ion energies are shown. The source region and two field-free regions are labeled *s*, *d*, and *f*, respectively. In (**a**) the flight length is shorter for ions of lower velocity (some electric sector designs). In (**b**) faster ions are removed from the flight path for a longer time than slower ions (one way of viewing the function of the reflectron). In (**c**) a short dynamically changing acceleration field increases the velocity of slower ions more than that of faster ions. In (**d**) multiple dynamic field gradients adjust ion acceleration for equal arrival times.

MASS SPECTROMETRIC APPROACHES TO THE ANALYSIS OF BIOPOLYMERS

Charles N. McEwen

Central Research & Development Department
E. I. du Pont de Nemours & Co.
Wilmington, DE 19898

The subject of the 1987 Fall workshop held in Boston was "Mass Spectrometric Approaches to the Analysis of Biopolymers". The speakers for the workshop were John Shively of City of Hope, Klaus Biemann of MIT, Howard Morris of the Imperial College of London, Barbara Larsen of DuPont, Steve Carr of SmithKline & French, Vernon Reinhold of Harvard, and Don Hunt of the University of Virginia. In addition to the speakers, a poster session was held on the evening preceding the main session. The talks covered various aspects of protein and glycoconjugate analysis. Space constraints limit this discussion to methods of protein analysis.

Because proteins are a linear string of amino acids, the most common approach to sequencing is one in which the amino acids are clipped sequentially from the protein and analyzed using liquid chromatography techniques. Methods are available for clipping from either end of the protein, but for practical purposes sequencing is almost always done from the amino-terminus using Edman chemistry. Although the Edman chemistry usually proceeds in high yield, it is less than 100% efficient and some amino acids are not well behaved. As a result, the chemical background builds and after a number of cycles (normally 20 - 40) the results become ambiguous. For this reason, proteins are cleaved into peptide fragments that generally have fewer than 40 amino acid residues. The cleavage is effected by proteases such as trypsin which cleave after lysine and arginine except for lysine-proline combinations and usually arginine-proline combinations. Reverse phase HPLC is used to isolate the peptide fractions. Only about 20 pmole of a pure peptide is needed to sequence 20 - 40 residues. Usually 50 - 100 pmoles of each peptide fraction is submitted for amino acid analysis and 10 - 200 pmoles for molecular weight analysis by mass spectrometry. The sequence analysis, amino acid analysis, and mass spectral results should all agree. The major advantages of Edman gas phase sequencing are the sensitivity (ca. 20 pmoles to sequence 20 - 40 residues), and the reliability (<2% error rate). The Edman method fails if the amino terminus is blocked. Also, posttranslational modifications are frequently difficult to detect and identify using the Edman sequencing method.

Proteins structures can also be determined by sequencing and decoding the gene that codes for the protein of interest. Sequencing DNA is relatively fast and can now be done automatically. Identifying the cDNA that codes for the protein of interest is done by sequencing 5 or 6 amino acid residues from the protein and synthesizing radio labeled oligonucleotide probes that code for the sequence. Because there are 64 distinct codes and only 20 common amino acids, most amino acids have multiple codes. For this reason it is necessary to construct several

oligonucleotide probes, which when placed in the proper medium attach to the single stranded DNA that codes for the protein. Once the cDNA is fished from the matrix it can be sequenced and the code read. Recombinant technology can be used to produce large quantities of protein for further study. The oligonucleotide method is especially useful for large proteins and proteins isolated in small quantities (only about 10 pmoles are necessary to sequence a protein using this method). Drawbacks are occasional problems in obtaining a proper reading frame and frame shift errors. These problems are addressed by using any available mass spectral and sequence data. Posttranslational modifications are not coded for and thus not detected by this method.

Mass spectrometry provides information that is complimentary to the above methods, thus increasing the confidence in the sequencing results and reducing the time of analysis. Mass spectrometry also provides information not readily available from the conventional approaches. For example, identification of blocking groups and posttranslational modifications, sequencing of a blocked peptide, location of sulfur bridges, and sometimes even sequencing of the entire protein is often best accomplished using mass spectrometry. The mass spectrometric method is fast, but requires more material than either of the above methods for sequencing. Another drawback of mass spectrometry is the cost of the instrumentation. The cost is especially high for MS/MS instruments which are used in combination with CID to obtain sequence information.

Fast atom bombardment (FAB) is the ionization method of choice for peptide analysis. Molecular weight information can be obtained at the low picomole level with FAB. The method is fast but does not give sequence information on small amounts of peptide. When working with peptides for FAB analysis, polypropylene should be used for all transfer and storage and if possible the samples should not be allowed to dry or stand around for any substantial period before analysis. Acceptable solvents include acetic acid/water mixtures, methanol/water (0.1% TFA) mixtures, acetonitrile (0.1% TFA), TFA, and propanol. Common FAB matrices include m-nitrobenzyl alcohol (NBA), thioglycerol, thioglycerol/glycerol, magic bullet (dithiothreitol/dithioerythritol), and glycerol. Failures in FAB are often caused by too little sample, the sample sticking to walls, using the wrong matrix, too much salt (remove with SEP PAK), suppression of sample ion current by impurities, too high a mass for the scan range, or too low a mass (ions masked by matrix). The amount of sample needed for FAB analysis depends on the instrumentation available, the peptide, and information desired. Full scan MW information on substance P was obtained by Hunt, et. al. using a tandem QQ/FTMS instrument at the 0.1 pmole level, but some peptides are difficult even at the 100 pmole level. Sequence information requires from <100 pmoles (tandem QQ/FTMS) to several nmoles. Given sufficient sample and the proper conditions, almost all peptides will give MW information by FAB.

Secondary Mass Spectra from Impacts of Energetic Water Cluster Ions

R. J. Beuhler and L. Friedman
Chemistry Department, Brookhaven National Laboratory, Upton, NY 11973

Impacts of cluster ions containing from 25 to 150 water molecules and accelerated to total energies between 25 and 250 keV provide a means of studying "hot" collision spikes of varying size and depth. These collision zones in the target can be varied by choice of projectile to give spikes that contain thousands of atoms heated to 10's of volts and located close to the surface in dense atomic assemblies. Recently we measured sputtering yields from cluster impacts which were extremely large. Losses from the targets can be on the order of 10^5 to 10^6 atoms per impact which is "visible" by electron micrography (1). Sputtering yields from copper films evaporated on quartz crystal oscillators can be as high as 20,000 Cu atoms/cluster impact (2).

The purpose of the present work is to report preliminary measurements of secondary ions as a function of the size and energy of the impacting cluster. One series of measurements was made with a low resolution, high transmission, time of flight mass spectrometer utilizing the burst of secondary electrons from the projectile impact as the trigger signal. The secondary ions were detected in a modified Daly Detector operating at 20 keV, allowing more efficient detection of higher molecular weight fragments. Our initial results are quite different from other measurements of secondary ions from metallic and frozen gas targets, which usually yield atomic species as the most abundant secondary ions. In the present experiments, from a copper target, yields of copper clusters containing from several to 30 atoms were observed; the mass distribution of the secondary clusters was not sensitive to the projectile cluster size (from 50 to 150 water molecules) or to the cluster energy (from 50 to 250 kilovolts). Cesium Iodide coated carbon surfaces yielded at first a spectrum dominated by the Cs^+ and Cs_2I^+ peaks and including some hydrated species. As the CsI was depleted masses corresponding to carbon clusters containing up to 100 carbon atoms grew in. In general there was a correlation of the maximum cluster size and the heat of vaporization: targets with higher heats of vaporization yielded larger secondary clusters.

Considerations of the fact that an ion lifetime of at least 10^{-6} seconds is required for the detection of cluster ions in these T.O.F. experiments yielded an interesting conclusion on the amount of internal energy that a detectable secondary cluster can hold (2). The classical RRK rate equation can be recast in the form

$$k = \nu\left(1 - \frac{3\varepsilon}{n\rho}\right)^n$$

where ν is a frequency factor taken as approximately 10^{13} s^{-1}, ρ is the energy density in volts/atom, n is the number of internal degrees of freedom in the polyatomic fragment over which the excess energy is distributed, and ε is the threshold energy for decomposition, taken as the heat of vaporization. Rate coefficients on the order of 10^6 s^{-1} or smaller are necessary for the observation of the ion. For energy densities as small as twice threshold energies for decomposition, rate coefficients of 2×10^{12} s^{-1} are calculated for values of n between 12 and 10,000. The excess energy scales with the number of atoms in the polyatomic fragment. For clusters with 20 or more atoms it can be seen that energy densities must be reduced to values less than roughly 20% of threshold energies for decomposition to produce detectable fragments. Initial energy densities resulting from nuclear stopping of water-cluster oxygen atoms in most of the targets are approximately 50 volts/target atom, approximately an order of magnitude above most heats of vaporization. This would indicate that in the earliest stages of the sputtering process, atomic species must be the predominant detectable product.

Preliminary measurements of both the energy and mass of secondary ions are now being made with a quadrupole mass spectrometer. In general, atomic species from the target have higher kinetic energies than polyatomic ions. These observations are now being compared to a model of the hot spike where the atomic species come from the hot central core and the polyatomic species originate from the periphery of the hot spot where the energy density is less because of thermal conductivity away from the central core.

Unimolecular Fragmentation of Large Argon Ion Clusters.

P.G.Lethbridge and A.J.Stace, School of Molecular Sciences,
University of Sussex, Falmer, Brioghton BN1 9QJ, U. K.

A high resolution double focusing mass spectrometer in association with a pulsed supersonic nozzle has been used to study the unimolecular fragmentation of Ar_n^+ clusters for n in the range 30 - 200. All cluster ions within this range are observed to undergo the reaction;

$$Ar_n^+ \qquad Ar_{n-1}^+ + Ar$$

Some ions fragment with the loss of up to 4 argon atoms. A systematic study of the above reaction was achieved using both MIKES and linked scanning techniques, this revealed that the relative intensities of the fragment ions fluctuate considerably with n. Many of these fluctuations coincide with depleted or enhanced ion intensities present in the cluster ion normal mass spectrum.

A simple kinetic model based on unimolecular theory (RRKM) has been developed and can reproduce many of the features observed in both the fragmentation spectra and the normal mass spectrum. Of the two main variables involved in the model; reaction symmetry number and dissociation or binding energy, we have been able to show that only the binding energy is important in determining the fragmentation pattern. This was achieved by studying fragmentation patterns of certain mixed isotope cluster ions which have a reaction symmetry number of unity i.e: they have only one way in which they can loss a single argon atom. The range of binding energies used to reproduce the experimental trends indicate that, in large cluster ions, bonding is determined primarily by weak van der waals interactions.

Through the calculations, the experimental data are interpreted in terms of "stable" , "intermediate" and "unstable" cluster ions. Stable cluster ions have enhanced intensities in the normal mass spectrum, whereas unstable ions produce both depletions in the normal mass spectrum, and enhanced fragment ion intensities. The majority of ions can be represented by the intermediate case. The decomposition of these intermediate ions does not produce particularly intense fragment ions, and hence the normal mass spectrum is not significantly enhanced or depleted. The intermediate cluster ions are used as a reference point for the stable and unstable cases.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

it is proposed that unstable cluster ions consist of an atom weakly bound to an underlying stable cluster. A series of hard sphere stuctures are presented to account for some of the observed stable cluster ions. Each of these structures has evolved around a central Ar_2^+ ion, which is in turn contained within a linear trimer or tetramer. This offers the possibility for further charge delocalisation. It is concluded that, since the clusters are forced to accomodate the charge carrying unit, the positive charge appears to have a structural influence which extends well beyond the electrostatic limit. This is reflected in the fact that all of the structures have a waist region connected to two regular polyhedral end caps. These end caps consist of pentagonal and triangular faces which give the structures an overall icosahedral symmetry. An example is shown below.

CROSSED-BEAM STUDY OF THE COLLISION-INDUCED DISSOCIATION OF METHANE ION

S. Howard, K. Qian, J. Biggerstaff, A. Shukla, and J. Futrell
Department of Chemistry, University of Delaware, Newark, DE 19716.

In our continuing efforts to understand the dynamics of ionic dissociation processes activated by collisions with neutrals we have investigated the dissociation of CH_4^+ molecular ions to CH_3^+ and CH_2^+. New results for CH_2^+ obtained at 5.5 eV center-of-mass energy reveal some unique features which are presented here.

The crossed-beam instrument used in this work has been described in detail elsewhere [1] and only a few of its features are mentioned here. The high-pressure ion source customarily used in this apparatus was replaced by a low pressure source operated at 10^{-4}-10^{-3} Torr to generate a propulation of CH_4^+ ions typical of electron impact ion sources utilized in analytical mass spectrometry. The mass-selected ion beam is decelerated to its final collision energy by an apertureless exponential lens and crossed at 90° with a neutral beam of argon seeded with helium and expanded through three differentially-pumped vacuum chambers. Laboratory angular and energy distributions were taken at a series of angles from -3 to 50° for CH_2^+ ions.

Figure 1 shows the scattering contour diagram for the dissociation of CH_4^+ to CH_2^+ at a center-of-mass collision energy of 5.5 eV. There are three distinct maxima in the diagram which can be described as (1) superelastic forward scattering of CH_2^+ along the initial ion velocity vector, (2) strongly inelastic scattering intensity near the center-of-mass, and (3) CH_2^+ ions preferentially scattered at large angles.

Taking into account the sin θ factor by which differential scattering data are multiplied in the integration of Figure 1 to compute the total cross section, the principal mechanism is the feature at 45° (center-of-mass). This feature is predicted by an earlier study [2] of simple hydrocarbon ion dissociation which demonstrated that only a small amount of translational-to-internal energy conversion is required to initiate the lowest energy dissociation process at or near zero angle, but that large angle scattering accompanies the more endothermic CID channels. The linear correlation of energy deposition with scattering angle observed in that study [2] predicts that the highly endothermic (ΔH = 2.8 eV) dissociation process under present investigation would require smaller impact parameter collisions which sample the repulsive core of the potential hypersurface in order to deposit sufficient energy for the reaction to proceed. This results in large angle scattering and we infer the CH_2^+ intensity maximum at 45° results from the dissociation of CH_4^+ ions with modest internal energy proceeding via this impulsive mechanism.

Ions dissociating near zero scattering angle are promoted above the dissociation threshold by a grazing collision (large impact parameter). Such collisions promote a population of highly excited ions that require little or no translational-to-internal energy conversion to stimulate the dissociation process. Since the fragment ions found near the zero scattering angle in the contour diagram are near the circle locating the loci of velocity vectors corresponding to the energy which would be released if electronically excited CH_4^+ ions in the ^2E (D_{2d}) state generated ground state CH_2^+ and H_2, it is speculated that the precursor for these CH_2^+ ions may be CH_4^+ in this state. Since both CH_2^+ and H_2 may be formed with internal excitation, higher excited states could also be involved. The observation of superelastic scattering clearly identifies the precursor ion as from a population of CH_4^+ excited well above the dissociation limit for forming CH_3^+ (+H). These ions, initially formed in the ion source, have survived about 20 microseconds of flight time before

colliding with the neutral beam. Such long lived excited states of CH_4^+ have not previously been reported.

The remaining intensity in Figure 1 near the center-of-mass corresponds to CH_2^+ ions formed with nearly all of the collision energy transferred into internal energy of the fragmenting CH_4^+ ions with little kinetic energy release. This highly inelastic process is distorted by the transformation Jacobian used in constructing the contour diagram. This particular mechanism accounts for only a few percent of total intensity of CH_2^+.

SEQUENTIAL SOLVATION OF ATOMIC TRANSITION METAL IONS

Peter J. Marinelli and Robert R. Squires
Department of Chemistry, Purdue University, West Lafayette, IN 47907

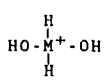
The structures, properties and reactivity of sequentially solvated transition metal ions have been investigated with use of a flowing - triple quadrupole instrument.[1] Transition metal cations are generated by electron ionization and Penning ionization of volatile metal carbonyl derivatives in the upstream source region of the helium flow reactor (P(He) = 0.3 - 0.5 torr). Solvated metal ions are formed by termolecular association reactions with added H_2O, NH_3 and various other neutral compounds. The following metal ion clusters have been produced:

$M^+(H_2O)_n$	$M^+ = V^+, Cr^+, Mn^+, Fe^+, Co^+, Ni^+$ $n = 1\text{-}3$
$M^+(NH_3)_n$	$M^+ = V^+, Cr^+, Mn^+, Fe^+, Co^+, Ni^+$ $n = 1\text{-}4$
$Cr^+(EtOH)_n$; $Cr^+(NCCH_3)_n$	$n = 1\text{-}6$
$Cr^+(C_2D_4)_n$; $Cr^+(THF)_n$	$n = 1\text{-}3$
	$Mn_2^+(D_2O)_{1,2}$

Unimolecular and bimolecular reactions of mass-selected cluster ions are carried out in the central quadrupole of the triple quadrupole analyzer where both pressure and kinetic energy effects may be characterized.

The thermochemistry for sequential solvation of the metal ions by H_2O and NH_3 has been estimated from the translational energy thresholds for desolvation induced by collision with argon target gas. A remarkable trend is found wherein for most every metal ion the second solvent-binding energy is significantly greater than the first, viz., $D[ML^+\text{-}L] > D[M^+\text{-}L]$ (Fig. 1). This is a striking departure from the normal decrease in successive solvent-binding energies of all other atomic ions for which data are available.[2] This is shown not to be an artifact of our appearance measurements by the reasonable agreement we can achieve in measuring H_2O and NH_3 solvation energies for Na^+, K^+ and other ions by this method.

The origins of the anomalous solvation energy ordering may be in the structures of the clusters and/or special electronic properties of the transition metal ions. We have carried out a variety of isotope labelling experiments aimed at detecting the presence of possible insertion structures. For example, consideration of the known M^+-H and M^+-OH bond energies[3] suggests that both $M^+(H_2O)$ or H-M^+-OH structures are feasible for the monohydrates. Both $M^+(D_2O)$ and $M^+(D_2O)_2$ ($M^+ = V^+, Cr^+, Fe^+, Ni^+$) fail to undergo H/D exchange in the presence of $CH_2{=}CH_2$ and $CH_2{=}CHCH_3$, and both types of ions react with H_2O by thermoneutral ligand exchange <u>without</u> H/D scrambling in the products. Furthermore, the 'mixed-isotope' cluster ions $M^+(H_2O)(D_2O)$ ($M^+ = V^+, Cr^+, Fe^+, Ni^+$) undergo CID by loss of either H_2O or D_2O; essentially no HOD-loss is observed. These experiments (among others) weigh heavily against the presence of structures of the type:



as the static forms for the dihydrates or as intermediates in the (non) exchange reactions. However, they do not rule out the possibility of mobile equilibria among isomeric structures:

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

$$M^+\text{-}OH_2 \rightleftharpoons \overset{H}{\overset{|}{M^+}}\text{-}OH; \quad H_2O\text{-}\overset{H}{\overset{|}{M^+}}\text{-}OH \rightleftharpoons H_2O\text{-}M^+\text{-}OH_2 \rightleftharpoons HO\text{-}\overset{H}{\overset{|}{M^+}}\text{-}OH_2$$

A structure for the dihydrate involving one inserted and one non-inserted H_2O ligand could account for the solvation energy orderings since it can be shown that H_2O binds more strongly to metal centers with higher formal oxidation states.

The rich reactivity of atomic metal ions with hydrocarbons and other organic compounds[4] is significantly diminished by partial solvation. Reactions of $M^+(H_2O)_n$ (n = 1-3) ions with various neutral substrates are described including alkanes, alkenes, alcohols and alkyl halides. Simple ligand substitution is evident in most cases, and oxidative insertion reactions by the metal appear to be impeded.

ISOMER CHARACTERIZATION VIA NEUTRALIZATION-REIONIZATION MASS SPECTROMETRY (NRMS)

C. Wesdemiotis, R. Feng, M. -Y. Zhang, M. Marchetti, and F. W. McLafferty

Chemistry Department, Cornell University, Ithaca, NY 14853-1301

Collisionally activated dissociation (CAD) has been used successfully in many cases for the characterization of ion structures in the gas phase. However, it may lead to indistinguishable CAD spectra for ionic isomers that can easily interconvert before dissociation because of low isomerization barriers compared to the respective dissociation thresholds. Such behavior is encountered with the 1- and 2-butene molecular cations and the isomeric $C_4H_4^{+\cdot}$ ions. In these cases, the fast equilibration between the ionic isomers, relative to the rate of dissociation, can be slowed down considerably by neutralization. Fragmentation of the neutrals produces structurally diagnostic fragments which can be detected with high sensitivity upon selective reionization to either positive or negative ions with the proper target. Thus, neutralization-reionization (NR) mass spectrometry combined with neutral dissociation provides the structural information that is missing in the CAD spectra.

Spontaneous dissociation of a neutral molecule can be effected upon neutralization with targets of low ionization energy (IE), e.g., Na (IE = 5.1 eV). Na neutralization of 1-butene cations produces 1-butene molecules with an average internal energy equal to the difference of the ionization energies of 1-butene (9.6 eV) and Na. This value lies above the fragmentation threshold of $CH_2{=}CH{-}CH_2{-}CH_3$ to $CH_2{=}CH{-}CH_2\cdot$ + $\cdot CH_3$ (3.2 eV), so that spontaneous dissociation takes place. Na anionization of the allyl radicals formed generates intense structurally characteristic allyl anions whose absolute abundance is 6 times larger than in the similarly obtained spectrum from 2-butene precursor ions.

Alternatively, neutral dissociation can be achieved by CAD of the intact neutral molecules resulting upon neutralization with, e.g., Hg or C_6H_6. Cyclobutadiene, methylenecyclopropene, butatriene, and vinylacetylene $C_4H_4^{+\cdot}$ cations, generated in the gas phase from appropriate precursors, can easily be distinguished on the basis of their neutralization-CAD-reionization spectra. Hg (or C_6H_6) neutralization gives the corresponding neutral molecules that dissociate differently upon CAD; the differences are best made visible by either reionization with He into positive (NR^+ spectra, Figure 1) or with C_6H_6 into negative ions (NR^- spectra, Figure 2). The fragmentation extent in the NR^+ spectra decreases in the order cyclobutadiene > methylenecyclopropene > 1,2,3-butatriene ≈ vinylacetylene, paralleling, thus, the calculated stabilities of these neutral molecules; as expected, cyclobutadiene and vinylacetylene give rise to the most intense $HC{\equiv}CH^{+\cdot}$ (m/z 26) and $H_2C{=}CH^+$ (m/z 27) peaks, respectively. The $C_4H_3\cdot$ radicals formed via $\cdot H$ loss from C_4H_4 are selectively detected upon anionization (Figure 2), and the $C_4H_3^-$ stabilities observed are consistent with the original C_4H_4 neutral structures. The spectra of Figures 1 and 2 are also useful for the characterization of C_4H_4 neutral molecules produced by ionic dissociation.

Additional structural information can be gained by mass-selecting individual ions in a NR spectrum, and subjecting them to CAD. For example, such MS/MS/MS experiments with the $CClH_3^{+\cdot}$ ions in the NR^+ spectra of $CH_3Cl^{+\cdot}$ and $CH_2ClH^{+\cdot}$ clearly show that methylenechloronium ylide, CH_2ClH, can survive intact for 10^{-6} s.

Neutralization of vinylalcohol cations followed by collisional activation of the neutral molecules and reionization to cations leads to recovered $C_2H_4O^{+\cdot}$ ions showing a CAD spectrum which is identical with that of the original vinylalcohol ions. This MS/MS/MS measurement proves that gaseous $CH_2{=}CH{-}OH$ does not tautomerize upon collisional activation to the more stable $CH_3{-}CH{=}O$ in the microsecond time-window.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

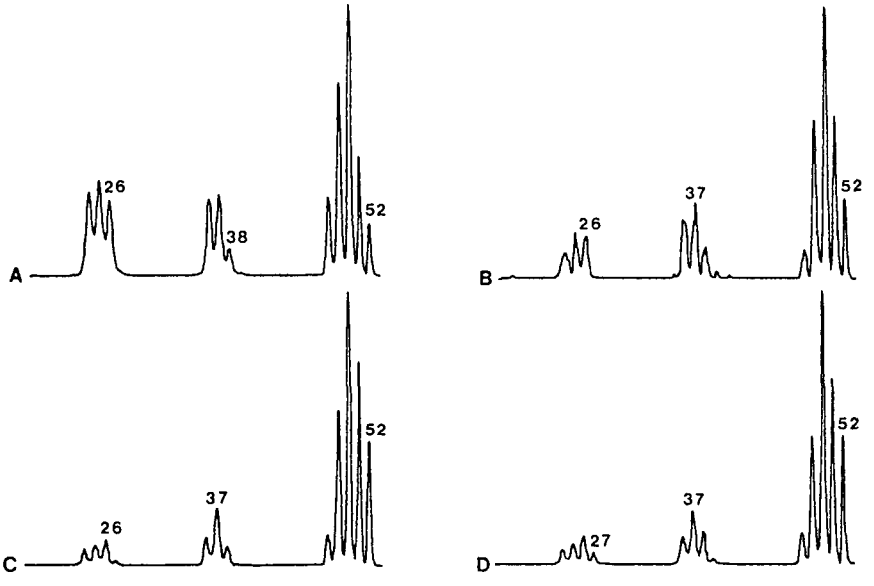

Figure 1. Hg/He NR^+ spectra of (A) cyclobutadiene, (B) methylene-cyclopropene, (C) 1,2,3-butatriene, and (D) vinylacetylene radical cations. The figures on top of the peaks represent m/z values. The transmittances used are 90% for Hg and 30% for He, corresponding to approximately 1 and 2 collisions per affected species, respectively. With He the neutrals can be dissociated in the first collision and the resulting mixture reionized in the second collision.

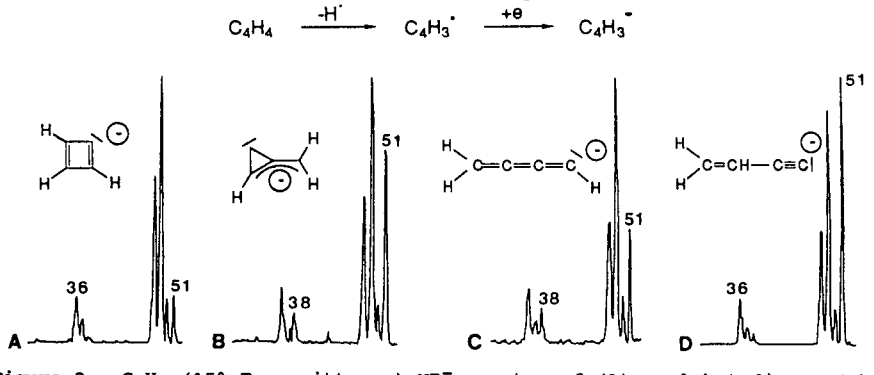

Figure 2. C_6H_6 (15% Transmittance) NR^- spectra of (A) cyclobutadiene, (B) methylenecyclopropene, (C) 1,2,3-butatriene, and (D) vinylacetylene radical cations. The $C_4H_3^-$ structures (m/z 51) are included in the spectra. 15% T corresponds to nearly 3 collisions per affected species, representing the neutralizing, dissociating, and anionizing collisions, respectively. The Hg (90% T)/C_6H_6 (30% T) NR^- spectra are very similar to these spectra.

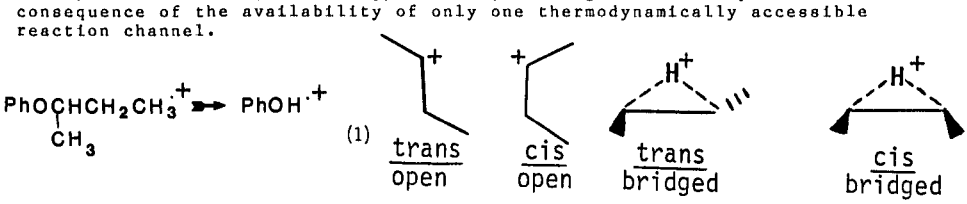
ON THE INTERMEDIACY OF ION-MOLECULE COMPLEXES IN UNIMOLECULAR DECOMPOSITIONS OF POSITIVE IONS

Richard W. Kondrat and Thomas Hellman Morton
Department of Chemistry
University of California
Riverside, CA 92521

Over the past decade we have described several ion-molecule complexes that are formed as intermediates in the unimolecular decomposition of alkyl aryl ethers. Two notable examples are [PhO· sec-$C_4H_9^+$] formed from the molecular ion of phenyl n-butyl ether and [PhO· tert-$C_5H_{11}^+$] formed from the molecular ion of phenyl neopentyl ether.[1] In 1987 Sozzi, Audier, Mourgues, and Millet reported MIKES experiments on phenyl sec-butyl ether and phenyl tert-amyl ether that exhibit regioselectivity in their decompositions to phenol molecular ion.[2] They interpret this regioselectivity as being incompatible with the intermediacy of the ion-molecule complexes above. Though it is entirely plausible that ion-molecule complexes may not intervene in these latter decompositions, regioselectivity cannot, by itself, be taken as conclusive evidence against ion-molecule complexes. Suppose that [PhO· tert-$C_5H_{11}^+$] is formed from phenyl tert-amyl ether. Unless it has enough internal energy, it will form only the thermodynamically most favorable products, $PhOH^{\cdot+}$ and $(CH_3)_2C{=}CHCH_3$ regiospecifically. In the case of phenyl neopentyl ether, the intermediate complex has enough energy to form $CH_2{=}C(CH_3)CH_2CH_3$, as well, and the two olefins are produced in the same proportions as in the biomolecular gas phase deprotonation of tert-amyl cation by simple ethers. But there is no necessity that phenyl tert-amyl ether form a complex with so high an energy content, and regioselectivity could be a consequence of the availability of only one thermodynamically accessible reaction channel.

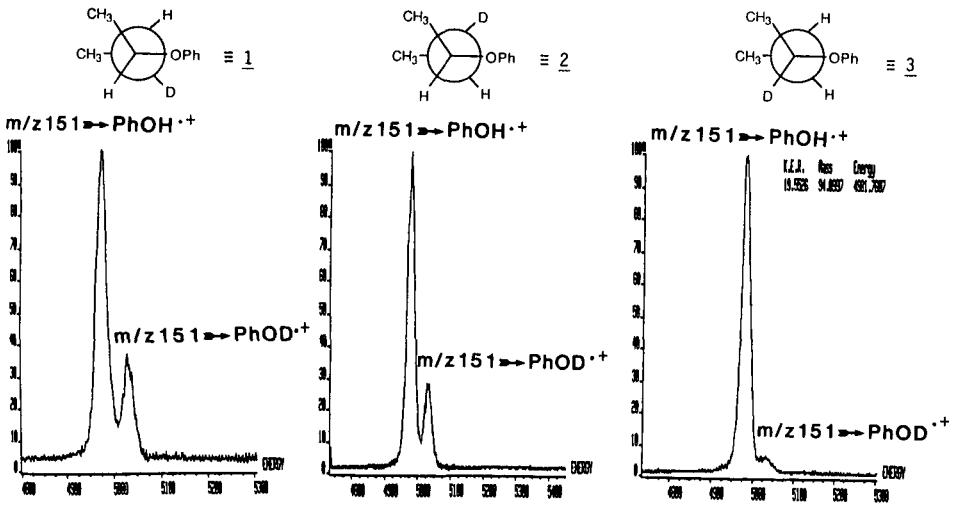


The same argument applies to the decomposition of phenyl sec-butyl ether, reaction 1, with an additional set of complications, for the structure of the sec-butyl cation is by no means certain. Solution phase studies admit of a variety of interpretations,[3] which can be summarized in terms of the four structures above: trans-open, cis-open, trans-bridged, and cis-bridged. The bridged structures might be frozen on the timescale of rigid molecular rotations (which is the lower bound for the lifetime of an ion-molecule complex). If the open structures do not possess enough internal energy to undergo hydride shifts or if the bridged structures should be frozen, then decomposition via [PhO· sec-$C_4H_9^+$] will yield 2-butenes via regioselective proton transfer.

Though the open structures can have chiral equilibrium geometries, it may be assumed that interconversion of enantiomorphic conformations is so rapid as to render them achiral, so that the methylene hydrogens will be enantiotopic. But the methylene hydrogens of sec-butyl ether become chemically nonequivalent (with one of them as the bridging atom) in a frozen, bridged structure. If we deuterate one of the three non-methyl positions in phenyl sec-butyl ether, there are several possible outcomes from an ion-molecule complex:

(i) Hydrogen scrambling that gives the same product distribution from all three d_1 isomers 1-3;

Collisionally Activated Decomposition spectra (8 kV) of molecular ions of racemic isomers of phenyl d_1-sec-butyl ether. Diastereomeric purities were 97% and 89%, respectively, for 1 and 2.



(ii) Open structures that do not scramble, leading to the same product distribution from the two diastereomers of $PhOCH(CH_3)CHDCH_3$, 1 and 2, and a different distribution from $PhOCD(CH_3)CH_2CH_3$, 3;

(iii) Frozen trans-bridged structures producing trans-2-butene as the only expelled neutral, resulting in exclusive D transfer from one $PhOCH(CH_3)CHDCH_3$ diastereomer and exclusive H transfer from the other.

(iv) Interconverting bridged structures, which will give the same outcome as (i).

The 70 eV mass spectra, MIKES, and CAD all give results that are not consistent with any of these outcomes. Each of the three isomers 1-3 gives a mixture of $PhOH^{\cdot+}$ and $PhOD^{\cdot+}$ daughter ions, but a different proportion in each case. The CAD, shown above, gives the result that is closest to ii, with proportions 76.5:23.5 for 1, 79:21 for 2, and 94:6 for 3. This can be interpreted in terms of the following alternatives. Either reaction 1 does not proceed exclusively via ion-molecule complexes, or else there must be a mixture of pathways, iii along with some other option (ii, for example, or frozen cis bridged ions whose proportion varies in response to an isotope effect that favors bridging hydrogen versus bridging deuterium). The first of these alternatives offers the more parsimonious explanation.

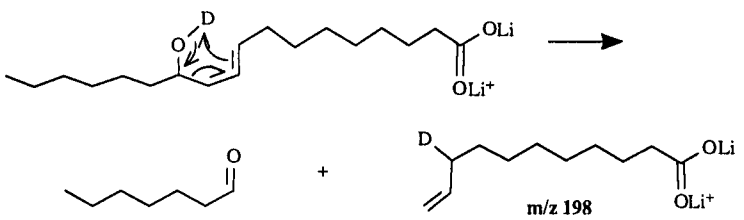
LOW-ENERGY DECOMPOSITIONS OF SOME CLOSED-SHELL IONS: NEW INSIGHTS ON CHARGE-REMOTE FRAGMENTATIONS

Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.
Michael L. Gross: Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0302.

High-energy collisional activation (CA) of closed-shell ions of long-chain fatty alcohols and acids induces decompositions that occur remote from the charge site.[1] One mechanism involves charge-remote 1,4-eliminations of H_2 to give alkenes and terminally unsaturated fatty alcohol and acid ions. The 1,4-eliminations of H_2 do not occur unimolecularly in the fast atom bombardment (FAB) ion source or as decompositions of metastable parent ions. The upper limit for the activation energy for the collision-induced 1,4-eliminations of H_2 was estimated to be 1.3-1.9 eV.[1a]

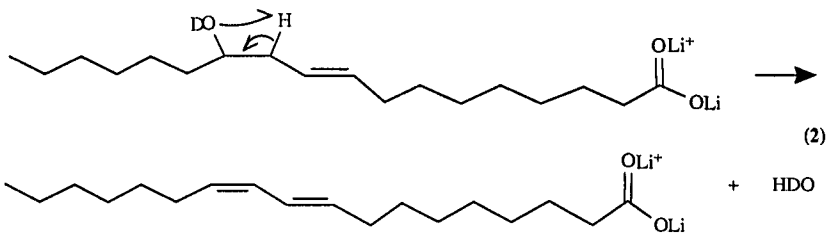
In contrast, $(M + 2Li - H)^+$, $(M + Li)^+$, and $(M - H)^-$ ions of ricinelaidic and ricinoleic (*trans*- and *cis*-12-hydroxy-9-octadecenoic, respectively) acids, and $(M + Li)^+$ ions of ricinoleyl alcohol and methyl ricinoleate, decompose by charge-remote fragmentations that arise unimolecularly both in the FAB ion source and from metastable ions. The unimolecular decompositions involve loss of H_2O and $C_7H_{14}O$: it is only upon CA that 1,4-eliminations of H_2 occur.

Linked-scanning, MS/CA-MS, and CA-MS/CA-MS, and deuterium labelling provide evidence that the mechanisms for the two unimolecular decompositions are analogous to the mechanisms of thermolytic decompositions of the neutral molecules.[2] The data indicate that the mechanism for the charge-remote loss of $C_7H_{14}O$ is an Ei *O*-hydro-*C*-allyl elimination (eq.1); the mechanism for the charge-remote loss of H_2O is a hydro-hydroxy



(1)

elimination (eq. 2).



(2)

The energetics of the two reactions can be evaluated from experimental data and from calculated enthalpies. Activation energies for the reverse reactions ($E^o_{rev(cal)}$)can be evaluated from experimentally determined kinetic energy released (KER) in the decompositions,[3] and ΔH_{rxn} can be calculated by using Benson's additivity rules.[4] By adding the $E^o_{rev(cal)}$ and ΔH_{rxn}, approximate activation energies (E^o_{for}) for the two

decompositions can be calculated. These calculated forward activation energies can be compared to experimentally approximated activation energies derived from the competitive loss of alkali cation from the $(M^+ Cat)^+$ ions of ricinoleyl alcohol ($Cat^+ = Li^+, Na^+, K^+, Rb^+$, or Cs^+). These results are shown in Table I.

Table I. Energetics of the unimolecular decompositions.

	$-H_2O$ (eV)	$-C_7H_{14}O$ (eV)
KER ($T_{0.5}$)[a]	0.07	0.06(CID) [e]
$E^o_{rev\ (calc)}$[b]	0 - 0.44	0 - 0.38
$\Delta H_{rxn\ (Benson's\ Rules)}$[d]	0.38	0.55
$E^o_{for} = E^o_{rev\ (calc)} + \Delta H_{rxn}$	0.82	0.93
$E^o_{for\ (Alc + Cat)^+}$[c]	<0.85	<<1.2

[a] KER measurements were made by using the MS-50 Triple Analyzer (Nebraska).
[b] Calculated by assuming either no reverse activation energy and no kinetic shift, or a KER of 0.16 - 1.0 times the reverse activation energy. See ref. 3.
[c] Determined by the competitive loss of alkali cation from $(M + Cat)^+$ ions of ricinoleyl alcohol.
[d] Calculated from tabulation in ref. 4.
[e] Part of the measured peak width is due to a small contribution from CID.

Assuming that the kinetic energy released in the decompositions is only 0.16 of E^o_{rev}, and there is no appreciable excess energy in the transition states, E^o_{for} calculated for the loss of H_2O by using the KER and ΔH_{rxn} (0.82 eV) closely approximates E^o_{for} determined experimentally (<0.85 eV). The calculated value for E^o_{for} for the loss of $C_7H_{14}O$ (0.93 eV) is not in as close an agreement with the experimentally determined E^o_{for} (<<1.2 eV), but there is evidence that this is a result of an experimental over-estimation of the forward activation energy: a competitive shift is probably reducing the detectability of this higher-energy decomposition pathway. The forward activation energy for the loss of $C_7H_{14}O$ is probably less than 1.0 eV.

These results show that charge-remote fragmentations are not limited to high-energy collisional activation because the decompositions can occur by different mechanisms and thus with different energy requirements. The collisionally-induced 1,4-eliminations of H_2 appear to have an activation energy in the range of 1.3-1.9 eV,[1a] whereas the unimolecular losses of H_2O and $C_7H_{14}O$ occur with activation energies less than 1.0 eV. The unimolecular decompositions occur both in the FAB ion source and as metastable ion decompositions. These results show conclusively that the charged site is not involved in the mechanisms of decomposition, and that charge-remote fragmentations are a class of mass spectrometric decompositions that are unequivocally analogous to thermolysis.

ENERGETICS OF REMOTE SITE FRAGMENTATION

V.H. Wysocki, M.M. Ross, R.G. Cooks*

Naval Research Laboratory, Washington, DC 20375
* Purdue University, West Lafayette, IN 47907

"Remote site" or "charge-remote" fragmentation is a type of ionic fragmentation for which bond cleavage is thought to be unaffected by the charge site.[1,2] The fragmentation occurs for a wide variety of compound classes and is analytically useful, e.g., for the determination of substituent positions and alkyl chain lengths in functionalized alkanes. Remote site fragmentation is proposed to occur by a 1,4 loss of H_2 and an alkene to produce a terminally unsaturated ion and has been studied extensively by high-energy collision-activated dissociation (CAD).[1] We report here results of our attempts to induce remote site fragmentation by (i) low-energy (0-200 eV) collisional activation with gaseous targets, (ii) surface-induced dissociation, SID (10-90 eV), and (iii) angle-resolved mass spectrometry (3 keV). Several compounds were utilized including $CH_3(CH_2)_{16}CH_2NH_3^+$, $CH_3(CH2)_7CH{=}CH(CH_2)_8NH_3^+$, $[CH_3(CH_2)_{16}CH_2]_2[CH_3]_2N^+$, $CH_3(CH2)_7CH{=}CH(CH_2)_8OHLi^+$, protonated 2- and 4-pentadecylpyridine, $CH_3(CH2)_{11}C_6H_4SO_3^-$, $CH_3(CH2)_{16}CH_2OSO_3^-$, and $CH_3(CH2)_{16}CO_2^-$. The goal of the research is further elucidation of the mechanism and energetics of the reaction. Areas of interest[3] include: (i) the amount of internal energy required to produce detectable remote site fragmentation, e.g. does the reaction have a low activation energy with no significant kinetic shift, a low activation energy and a large kinetic shift, or simply a high activation energy, (ii) the type of excitation required (e.g. electronic vs. vibrational), (iii) the time frame of the fragmentation, (iv) the sequence of bond breaking and bond formation steps which occur, (v) the relationship, if any, between the mechanisms of formation of product ions differing by only one mass unit, and (vi) the role of the charge site of the ion in the fragmentation, including the influence of competitive fragmentation pathways on the extent of remote site fragmentation.

The laboratory collision energy required to produce detectable remote site fragmentation varied from compound to compound in both low-energy CAD and SID experiments. In low energy CAD the fragmentation was observed for selected compounds at energies as low as 50 eV but increased in abundance with increasing collision energy over the laboratory energy range available (maximum 200 eV). In SID experiments, the fragmentation was observed at energies as low as 10 eV and increased or decreased in abundance with increasing laboratory energies depending on the compound. In the low-energy collisional activation experiments, the fragmentation was also found to be quite sensitive to target mass and collision pressure. For example, while abundant remote site fragments are produced upon low-energy collisions of pentadecylpyridine with Ar target, the other positive ions require collisions with the heavier target, Xe, in order to produce abundant remote site fragments (Figures 1 and 2). For all of the positive ions examined by low-energy CAD, single collision conditions appear to be preferable to multiple collision conditions, while for certain anions multiple collision conditions are preferable (competition between electron detachment and fragmentation may be a problem for some of the anions).

The low-energy CAD and SID spectra of lithiated oleyl alcohol were obtained for comparison with the high-energy CAD spectrum since the absence of Li^+ in the high-energy collisional activation spectrum has been interpreted[2] to indicate that the internal energy required to promote remote site fragmentation is lower than that required to form Li^+. The data show that Li^+ is the most abundant ion produced upon activation of lithiated oleyl alcohol at laboratory collision energies as low as 5 eV (CAD) or 10 eV (SID); remote site fragmentation may also be observed at selected collision energies. In contrast to the previously reported high-energy CAD spectrum of lithiated oleyl alcohol, our data (Figure 3) indicate that Li^+ is present following 8 keV collisions with He (it should be noted here that detection of the Li^+ was quite sensitive to the voltage applied to the conversion dynode since the kinetic energy of Li^+ fragment ion [(m/z 7 / m/z 275) x 8 keV] is low.

Angle-resolved mass spectra acquired at 3 keV for three different compounds indicate that the higher mass remote site fragments decrease in abundance as products are collected from progressively higher angles (Figure 4). In ARMS experiments, products detected from higher angles are generally believed to be associated with greater internal energy deposition. As has been observed in certain high-energy CAD experiments,[4] radical ions and even-electron ions are sometimes observed at adjacent masses in both the high- and low energy experiments (e.g. Figures 1 and 4) .

The examples discussed here indicate a complicated dependence of remote site fragmentation on internal energy deposition. Electronic excitation is probably not required since the fragmentation is observed at collision energies (< 100 eV) which correspond mainly to vibrational excitation. They also illustrate the complementary nature of low-energy and high-energy collisional activation data on remote site fragmentation. The results suggest that the energetics, and perhaps the mechanism, of the fragmentation may be more complex than previously suggested based on high-energy data alone. For example, some of the compounds examined might fragment via an ion/molecule complex following activation; this type of fragmentation would be directed by stabilization of the charge site of the molecule and could provide a connection between fragment ions separated by only one mass unit.

CHARACTERIZATION OF THE DISSOCIATION OF PROTONATED CYCLIC KETONES USING HIGH AND LOW ENERGY COLLISIONAL ACTIVATION: A PROTOTYPICAL HIGH ENERGY/HIGH ENTROPY DEMANDING REACTION: Jennifer S. Brodbelt-Lustig, R. Graham Cooks, Department of Chemistry, Purdue University, West Lafayette, Indiana 47907

Both enthalpic and entropic barriers are important factors in the dissociation channels of gas phase ions upon collisional activation. The accessible dissociation channels are dependent on the kinetic energy of the selected precursor ion, the nature of the target, the scattering angle through which products are collected, and the number of collisions that the precursor ion undergoes with the neutral target. Differences in product distributions resulting from CAD at keV energies and at eV energies have been accounted for in terms of the energy transfers involved. Larger collision energies promote reactions having higher activation energies since at least some of the precursor ions experience deposition of greater energies. The number of collisions a selected ion undergoes influences the time during which an ion may rearrange and also determines the number of steps of energy input.

A major fragmentation process of protonated 2,2,6-trimethylcyclohexanone after collisional activation under certain reaction conditions results in the protonated acetone ion. This is demonstrated using three methods: 1) deuterium labelling, 2) the sequential scanning capabilities of a hybrid mass spectrometer in which a comparison is made between the consecutive daughter spectrum for protonated 2,2,6-trimethylcyclohexanone and the daughter spectrum of protonated 2,2,6-trimethylcyclohexanone, and 3) by comparison of daughter spectra of m/z 59 ions generated from different precursors in an ion trap mass spectrometer. The reaction in which protonated acetone is formed involves two 1,2-methyl transfers and a ring contraction.

The fragment ion of particular interest in this study, m/z 59, is the most abundant daughter ion present in the daughter spectrum of protonated 2,2,6-trimethylcyclohexanone recorded at low collision energy in a triple quadrupole mass spectrometer, yet it is of low abundance in the high energy MIKES spectrum or in the ion trap spectrum (Figure 1). The striking contrast between the daughter spectra recorded in the different energy regimes can be attributed to the activation conditions used in each instrument. The triple quadrupole employs low energy, multiple collisions, while high energy, single collisions occur in the MIKES and very low energy, multiple collisions occur in the ion trap. When the collision gas pressure in the triple quadrupole instrument is reduced so that single collision conditions are attained, the resulting spectrum resembles the MIKES spectrum. This result implies that the internal energy distributions associated with eV and keV collisions are insufficiently different to cause large differences in product abundances.

It is apparent that the formation of m/z 59 is a high energy process which involves considerable bond reorganization. A process which has stringent enthalpic and entropic demands and involves multiple rearrangements of the cyclic ketone before fragmentation is that proposed by Wolfshutz and co-workers (1). In their report of methane chemical ionization of methylcyclohexanones, the authors proposed that the abundant m/z 59 ion represented a protonated acetone species formed by migration of two methyl groups to the carbonyl position (Figure 2). The decreasing abundance of the m/z 59 ion in the present study as the collision energy or pressure is reduced in the triple quadrupole experiments correlates with the formidable energy and entropic demands of the methyl shifts that occur during the dissociation of the protonated parent ion. In the MIKES instrument, formation of m/z 59 is not as readily accessible to the trimethylcyclohexanone ions because the parent ions experience just one collision before exiting the collision region. Since activation occurs in one step, extensive bond reorganization is not favored, and dehydration by simple cleavage is the preferred process. In the ion trap, the gentle collisions associated with helium as a target gas most likely prevent the parent ions from surmounting the high energy barrier for the dissociation of m/z 141 to m/z 59. In the limit of excitation by stepwise activation, only the <u>lowest</u> energy barrier is traversed as shown by multi-photon (IR) dissociation. Thus, access to m/z 59 requires several relatively energetic collisions to maximize both isomerization and barrier traversal.

Many ions of m/z 59 have been previously characterized and structures have been assigned to various ions formed from different precursors. The CAD behavior of the ion of m/z 59 produced by methane chemical ionization of trimethylcyclohexanone was studied as a function of activation voltage in an ion trap, and the results are compared to the CAD behavior of the m/z 59 ions produced by protonation of acetone, propionaldehyde, and allyl alcohol, and by electron ionization of diethyl ether and 3-methoxy-1-butanol (Figure 3). The plot for dissociation of m/z 59 from protonated trimethylcyclohexanone most closely resembles the plot for protonated acetone. The trends of ions of m/z 31, 41, and 59 follow parallel patterns; none of the plots for the other isomeric ions are remotely similar.

June 5-10, 1988, San Francisco, CA

A study of the complex rearrangement/fragmentation sequence (from which protonated acetone is formed) with respect to the effects of collision energy and number of collisions reveals that it is favored only at high energies and pressures. Large enthalpic and entropic barriers are indicated. High energy (keV) collisions that result in excitation of the parent ion do not favor this rearrangement, while the very low energy multiple collisions occurring in the ion trap are also inadequate for promotion of this dissociation pathway.

ANALYSIS OF CERAMIDE & GLYCOLIPID DERIVATIVES BY HIGH PERFORMANCE TANDEM MASS SPECTROMETRY

C. E. Costello, B. Domon[1] and J. E. Vath
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA
[1]Present address, CIBA-Geigy, Basel, Switzerland.

Ceramides, glycosphingolipids, gangliosides and other glycoconjugates play important roles in biological systems, functioning as components of membranes and cell walls, as intermediaries of cell-cell recognition, as agents in transport and as antigenic determinants, and others too many to enumerate. Delineation of the structural specificities that are required for the various activities is a formidable task. Heterogeneity of the components (N-acyl fatty acids, bases and carbohydrates) is often encountered and results in "average" rather than definitive determinations.

In our initial study (Domon and Costello, *Biochemistry*, 1988) we used high performance tandem mass spectrometry of the native compounds to address this complex problem and have shown that it is possible to assign structural details on the basis of product ions observed in the positive and negative ion FAB CID MS/MS spectra. Now we have extended this investigation to include derivatives, in order to improve sensitivity and to direct fragmentation along pathways that increase the information content of the spectra.

Peracetylated, permethylated (Fig. 1) and reduced derivatives have been prepared and analyzed. Deuterium labeled analogs have been used where necessary to remove ambiguity. Gas phase reagents and a microapparatus (Vath, Zollinger and Biemann, 1988) have been used for most reactions, to minimize sample loss. For ceramides and glycolipids that have only a few sugar residues, reduction alone enhances sensitivity significantly; high quality CID MS/MS spectra are obtained after the reduction of 25 ng (or less) of sample (Fig 2). Concomitant permethylation becomes more appropriate as the number of sugar residues increases, in order to control solubility in the matrix. The fragmentation patterns observed for the reduced and reduced/permethylated samples are consistent with those described for the underivatized samples, with some additions. The major fragments in the reduced compounds are designated U and V (Scheme 1). These occur adjacent to the charge localization site, at the amine. Because the procedure used for the reduction derivatizes olefinic bonds, the method also provides a means for their location. Peracetylated derivatives do not produce informative collision spectra, because ketene and acetic acid losses predominate.

Folate and Vitamin B_6 Bioavailability Studies with Human Subjects Using Stable Isotope Labelling and Electron Capture GCMS.

J.P. Toth, P.R. Trumbo and J.F. Gregory, Dept. of Food Science and Human Nutrition, University of Florida, Gainesville, FL.

Folate and Vitamin B_6 are water-soluble B-complex vitamins essential for nucleic acid synthesis, amino acid metabolism and lipid metabolism. The nutritional properties of these vitamins are complicated by the fact that most dietary forms must undergo metabolic conversion to bioactive forms. The proportion of a given dietary form that ultimately undergoes this activation is referred to as its bioavailability. Most of what is understood about this important nutritional parameter is based on animal experiments using radiolabelling. To extend such studies to human subjects we have developed methods based on deuterium labelling and GCMS monitoring of the labelled urinary metabolites.

The analytical procedure we have developed for folate bioavailability studies consists of:

1. Synthesis of d_2- and d_4- labelled folates;
2. Administration of labelled folates to volunteer subjects in amounts corresponding to normal dietary intake;
3. Collection of urine and isolation of folates by affinity chromatography using folate binding protein;
4. Chemical cleavage of all folates to a single analyte, para-aminobenzoyl glutamic acid (pABG), which retains all deuterium labels;
5. Isolation of pABG by reverse-phase HPLC. The isolated pABG is a mixture of labelled and unlabelled (do) forms;
6. Fluorimetric determination of total pABG;
7. Derivatization of pABG by reaction with 2:1 trifluoroacetic anhydride: trifluoroethanol at 90°C for one hour. The major product is a fluorinated lactam of MW 426 whose electron capture negative ion (ECNI) mass spectrum shows the molecular anion with very little fragmentation;
8. Detection of this derivative by ECNI mass spectrometry with selected ion monitoring at m/z 426, 428 and 430;
9. Calculation of the molar ratio of labelled-to-unlabelled derivative from the appropriate mass peak area ratios. For this calculation a calibration curve is prepared from standard mixtures of known isotopic composition. These curves are linear in the range of interest;
10. Calculation of absolute quantities of labelled forms from the results of (6) and (9).

A similar procedure was developed for vitamin B_6: d_2 and/or

d_5 vitamers are administered and urine collected; 4-pyridoxic acid, the major urinary metabolite of all B_6 compounds, is isolated as its lactone, 4-PAL; 4-PAL is acylated by co-injection with trifluoroacetic anhydride into a 250°C GC injection port; ECNI GCMS is performed with selected ion monitoring at m/z 164, 166 and 169, corresponding to $[M-CF_3CO]^-$ for the three isotopic species; isotopic species are quantitated as in the folate procedure.

Experiments thus far have shown that: a) normal dietary doses of labelled vitamers produce detectable and quantifiable signals from labelled urinary metabolites; b) label ratios in administered doses are preserved in urine extracts; c) utilization of pyridoxine-beta-glucoside, a conjugated dietary form of vitamin B_6, by human subjects is different from that observed in rats.

Negative Ion Fab Analysis of Fatty Acids in Insect Waxes: Cuticular Wax of the Honey Bee

Charles D. Warner, Dept. of Chemistry, Hastings College, Hastings, NE 68901

R. N. Hayes and M. L. Gross, Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588

The African honey bee was introduced into the domestic honey bee population of Brazil in 1956. The hybridization of the domestic honey bee with African honey bees is of potential economic impact because the hybridized bees are known to be less prolific producers of honey in comparison to domestic honey bees. Identificaton of subspecies of honey bees has been a difficult taxonomic problem. Traditional morphometric analyses involve time consuming measurement of body parts and statistical analysis. Chemotaxonomic methods are an attractive alternative since cuticular wax contains a variety of substances suitable for chemical analysis. The wax is composed mostly of hydrocarbons and waxes, but also contains fatty acids and more polar materials in lesser amounts[1]. Lavine and Carlson[2] used GC-MS and GC-FID analyses of cuticular hydrocarbons and pattern matching techniques to distinguish between subspecies of honey bees. Smith[3] analysed epoxide derivatives of the alkene fraction of the cuticular wax by GC-MS for this purpose. Chemotaxonomic analysis by mass spectrometry has been reported by Feneslau.[4] Previous work at MCMS[5] has shown the utility of negative ion FAB/MS for mixture analysis and structural identification of fatty acids.

Negative ion FAB analysis of cuticular wax and comb wax was investigated as a potential chemotaxonomic method. It is an attractive one since the analysis of the wax from one insect is very desirable, and the time from extraction of the wax to the analysis is short. Furthermore, the analysis does not require separation of the fatty acids from the wax before analysis. With triethanol amine as the FAB matrix, the fatty acid negative ions are selectively desorbed thus reducing chemical noise from other components of the wax. This is an important consideration, since the 10-25 mg of cuticular wax on each insect contains only about 10% free fatty acids.

The two most abundant fatty acid anions in the samples of cuticular wax analysed were C16:0 and C18:0 carboxylate ions (palmitate and stearate). Spectra reveal the presence of other negative ions at masses corresponding to saturated even numbered fatty acids from m/z 311 to 451 (C20:0 to C30:0). In addition to saturated fatty acids the spectra all show ions corresponding to unsaturated fatty acids. The most prominant ones are those with 16 and 18 carbons. Analysis of comb wax from African honey bees from French Guiana[6] again shows C16:0 and 18:0 fatty acids to be the most abundant fatty acids in the FAB spectrum.

Since the structure of the fatty acids in the wax might be a useful taxonomic marker, MS/MS analysis of some of the ions in the wax was undertaken. In particular, the m/z 367 ion in the cuticular wax of the wild bees was selected in the tandem mass specrometer and collisionally activated. The collisional activation spectrum showed remote-charge site fragmentation characteristic of the saturated fatty acid tetracosanoic acid, C24:0. Likewise, MS/MS analysis of the m/z 281 ion showed fragmentation characteristic of oleic acid. Other ions observed in the FAB spectrum of the wild bees were not subjected to MS/MS analysis because of sensitivity problems.

In all the FAB spectra, considerable background was observed even though the negative carboxylate ions were being desorbed from the triethanol amine matrix in preference to other substances present. As an alternative method for chemotaxonomic analysis the fatty acids in the cuticular wax or comb wax were derivatized as the pentafluorobenzyl (PFB) esters. The PFB esters of fatty acids have been used for analysis of fatty acids by electron capture GC.[7] When

the PFB esters are analysed by negative ion chemical ionization (NICI), loss of the pentafluoro benzyl radical produces fatty acid anions. Although the derivitization increases the analysis time from insect to spectrum, two advantages are obtained.[8] The sensitivity of the method is considerably better than FAB and matrix effects are greatly diminished. The sample of comb wax analysed by FAB which showed m/z 255 and 281 as the predominant anions now shows significantly less noise and the m/z 367 is the most abundant ion. Furthermore, the intensity of other ions at higher masses has dramatically increased. This may be due to surface effects in the FAB matrix. MS/MS analysis of the m/z 281 and 255 ions from this mixture of esters reveals that the acids are oleic and palmitic acids.

FAB, NICI and collisional activation will be useful tools for developing a chemotaxonomic method for fatty acids in insect waxes. FAB will be a fast method for screening wax for particular fatty acids. NICI of the PFB esters of fatty acids improves greatly on the sensitivity and appears to diminish the matrix effect observed with FAB.

IMAGING ANALYSIS OF BILE ACIDS USING CHROMATOGRAPHY/SIMS

Jocelyn C. Dunphy and Kenneth L. Busch
Department of Chemistry, Indiana University, Bloomington IN, 47405

The analysis of bile acids is often essential for understanding cholesterol metabolism and the role of steroids in biological systems, in addition to being an aid in diagnosing intestinal and liver disorders. Most methods for such analysis involve chromatographic separations followed by mass spectrometric detection. GC/MS following TMS derivatization[1], HPLC/FABMS[2], and radial compression HPLC followed by liquid secondary ion mass spectrometry (SIMS)[3] are a few examples. We have constructed a SIMS instrument for the direct analysis of thin layer chromatograms[4] and demonstrate here the potential of this instrument for direct, spatially resolved SIMS analysis of bile acids separated by silica thin layer chromatography (TLC). Since TLC is often used as a clean-up step prior to GC or LC separation, the direct SIMS analysis of the plate, which can provide qualitative and potentially quantitative information, dispenses with the need for the latter steps.

Positive and negative mass spectra of bile acids contained on thin layer chromatograms were acquired with modified ASYST software, using an average of 50 scans. Glycerol was used as the extraction matrix, and the area of the plate containing the acid of interest was affixed to the probe tip. The 3-dimensional images were obtained by inserting the entire TLC plate into the MS source and rastering the plate via an xy manipulator. A liquid metal gallium gun was used as the source of primary ions, and semi-molten sorbitol was used as the extraction matrix. Data were taken using ASYST software in the single ion monitoring mode, averaging 200 scans per point. Cholic acid, chenodeoxycholic acid and lithocholic acid were purchased from Aldrich Chemicals and used without further purification.

Positive ion spectra of these free bile acids do not show a strong $(M+H)^+$ ion but rather lose two or more molecules of water. Figure 1 shows the positive ion spectrum of cholic acid; m/z 373 is loss of 2 H_2O, and m/z 355 is loss of 3 H_2O. Negative ion SIMS mass spectra, however, give the $(M-H)^-$ ion as the base peak with no fragmentation. Figure 2 is the negative ion spectrum of cholic acid. Because negative ion analysis yields molecular weight information, it is the preferred mode for bile acids and salts. Further work has shown that the glycine and taurine conjugated bile acids give similar results. Figure 3 compares the images of a TLC plate spotted with cholic, chenodeoxycholic and lithocholic acids in the positive and negative ion modes. In the positive ion image, m/z 357 corresponds to loss of 2 H_2O from chenodeoxycholic acid, and m/z 355 comes from cholic acid as discussed above. Lithocholic acid does not show any major ion in the positive ion spectrum, and therefore no signal was obtained for this acid. Lithocholic acid does yield a large $(M-H)^-$ ion and this ion is monitored in the negative ion image. Cholic and chenodeoxycholic acid are imaged using their $(M-H)^-$ ions, 407 and 391, respectively. Comparison of spatial dimensions of the spots is adequate, but can be improved by careful control of the physical state of the sorbitol during analysis. Each spot corresponds to approximately 20 μg of acid; spatial resolution is 0.5 mm. The ability to correlate positive and negative ion analysis enhances selectivity and emphasizes an advantage inherent in TLC/SIMS, that of being able to repeat an analysis at a later time, since separation is accomplished in space rather than in time.

Ongoing work in TLC/SIMS of bile acids includes quantitation of the acids and salts using a deuterated internal standard, analysis of conjugated acids in dog bile, and 2-D HPTLC to resolve structural isomers of the dihydroxy bile acids.

NEGATIVE ION CHEMICAL IONIZATION-TANDEM MASS SPECTROMETRY OF FATTY ACIDS: IMPROVED SENSITIVITY AND STRUCTURAL INFORMATION

Roger N. Hayes, R.L. Cerny and M.L. Gross, Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE, 68588.

The technique of tandem mass spectrometry (MS/MS) has become a widely recognized tool for the rapid screening and analysis of mixtures.[1] Using this technique, a specific ion in a mixture can be mass selected and then collisionally activated (CA) to cause fragmentation of the selected ion. In this manner, the mass spectra of the individual components of a mixture can be determined.

Although FAB is an excellent technique which lends itself to the study of a wide range of compounds, the detection limits for this desorption ionization method are not high (ca. 10 ng for fatty acids). Furthermore, the properties of the matrix with regards to analyte suppression are recognized but not yet fully understood. For example, a 1:1:1 mixture of the fatty acids dodecanoic, 12-hydroxyhexadecanoic and octadecanoic are desorbed from triethanolamine matrix to give very different ion currents for each component of the mixture (Figure 1).

Negative ion chemical ionization (NICI) is known to provide exceptional sensitivity for compounds which contain electron capture groups. In NICI, ionization results from capture of a thermalized electron by an electrophoric analyte in a process known as resonance capture.[2] In this study we examined the utility of the pentafluorobenzyl (PFB) electrophore. PFB-esters of fatty acids were readily synthesized in high yields (> 95%) by using a slight excess of a 1:1 mixture of pentafluorobenzyl bromide and diisopropylamine in acetonitrile solvent. The reaction mixture was heated at 60°C for 1 hour. Excess reagents were evaporated under a stream of nitrogen, and the residue was dissolved in a minimum amount of acetonitrile. No further purification was performed, however, elution of the residue applied to a short silica column with dichloromethane solvent gave a product which was essentially pure as determined by GC/MS.

The PFB-derivatized fatty acids were introduced into the ion source of the mass spectrometer by using a direct insertion probe heated to 100°C. By using toluene as the reagent gas (0.1 Torr) to thermalize electrons, the PFB-ester derivatives yielded abundant $(M - PFB)^-$ anions. Because the energy of the reactive electrons were low, the amount of excess energy available to effect fragmentation was small. Thus, as is often the case for NICI, few structurally informative fragment ions were produced. However, the detection limits for the PFB-esters were very low; typically as little as 100 femtograms was required to observe a carboxylate anion in the mass spectrum.

Comparison of Fast Atom Bombardment and Negative Ion Chemical Ionization Tandem Mass Spectrometry for the Analysis of Fatty Acids.

Compound	Detection Limit FAB	Detection Limit NICI
Palmitic (C16:0)	25 ng	10 pg
Stearic (C18:0)	30 ng	10 pg
12-Hydroxy Stearic (12-OH C18:0)	45 ng	15 pg
Oleic (C18:1)	30 ng	10 pg

Fatty acid carboxylate anions, desorbed from a triethanolamine matrix by using FAB, decompose upon collisional activation (CA) to yield structurally informative charge-remote fragmentations.[3,4] Various functional groups along the alkyl chain including double bonds, branch points, and hydroxyl groups are readily located. Collisional activation of the fatty acid carboxylate anions produced from the PFB-ester by using NICI gave identical CA mass spectra (Figure 2). The CA mass spectra were, however, obtained with significantly smaller amounts of analyte; typically 10 picograms (Table 1). No suppression of individual analytes from an equimolar mixture was observed. Signal averaging was necessary for quantitative purposes because of slight differences in analyte volatility.

COMBINED LC-MS ANALYSIS OF NEUTRAL LIPIDS, GLYCOLIPIDS AND PHOSPHOLIPIDS IN TOTAL LIPID EXTRACTS

James E. Evans, Barbara A. Evans and Robert H. McCluer
Eunice Kennedy Shriver Center, Inc., 200 Trapelo Rd., Waltham, MA 02254

Lipids are major components of biological membranes that play important and dynamic roles in mediating the interactions of a cell with its environment. The need for convenient and informative methods for their analysis is apparent. This is a report of our attempts to develop an LC-MS procedure for the combined profiling of all the major components of the neutral lipid and polar lipid classes. This includes analysis of molecular species composition. This work extends the methods we have published (1,2) for LC-MS analysis of phospholipids and for neutral glycosphingolipids with recently developed LC-MS procedures for neutral lipids to provide the complete analysis of the major components of these fractions in a single analysis.

HPLC was performed using a 10cm x 4.6mm Brownlee cartridge column packed with 5um spherical silica. Normal phase chromatography was chosen to provide separation based on lipid polar characteristics rather than heterogeneity of the hydrocarbon chains. If solvents that produced a true solution of the polar sample components were used for injection, broad bands were obtained for the nonpolar components. So sample components were suspended by sonication in n-heptane for injection. Elution was by the gradient illustrated in Fig 1 with a flow rate of 1.0 ml/min. The LC-MS interface used was a Finnigan moving-belt type with an indicated vaporizer temperature of 310°C. Mass spectrometry was performed with a Finnigan 4500 in the positive ion, chemical ionization mode with ammonia as the reagent gas.

The HPLC system established provides separation of about 30 lipids in less than 25 min. The plots in Figs 2, 3 & 4 are plots that identify phospholipids, sphingolipids and neutral lipids present in the TIC shown in Fig 1. This data was obtained by injection of 200 ug of total Folch lower phase lipid (equivalent to 2 mg of fresh tissue) from adult rat brain. The separation of a standard mixture of nonpolar neutral lipids including hydrocarbons, sterol esters and fatty acid esters is shown in Fig 4. Several of these neutral lipids are not resolve well by our HPLC system, but can be analyzed by the use of characteristic ion plots. Molecular species and fatty acid composition data can be obtained for all lipids from their mass spectra.

This work was supported by NIH grant NS16447.

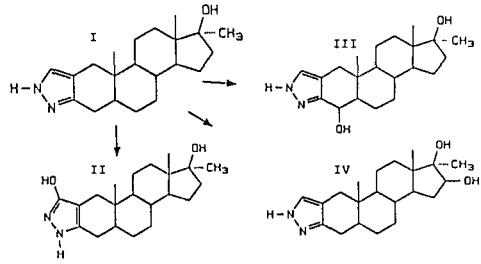
MASS SPECTROMETRICAL IDENTIFICATION OF TRIMETHYLSILYLATED AND N-METHYLATED STANOZOLOL AND ITS METABOLITES; Schänzer,W.,Opfermann,G. and Donike,M.; Deutsche Sporthochschule Köln, Carl-Diem-Weg 6, D-5000 Köln 41, F.R.G.

Stanozolol (Fig.1,I), an anabolic steroid with a condensed pyrazole ring, was first synthesized by Clinton et al. in 1959 (1). Besides its clinical use it is abused in sports to enhence performance. The use of anabolic steroids is banned by national and international sport federations. Therefore urine samples of athletes are controlled for the presence of stanozolol metabolites. The metabolites of I are isolated from urine (2), trimethylsilylated (TMS) and analyzed after gas-chromatographic separation by mass spectrometry (EI 70 eV). The metabolism of stanozolol was investigated and 10 urinary metabolites were identified. The main metabolites (Fig.1) 3'-hydroxy- (II), 4ß-hydroxy- (III) and 16ß-hydroxy-stanozolol (IV) were synthesized and studied by MS.

Fig.1 Metabolism of stabozolol



Methylation of I, III and IV with methyliodide in acetone/potassium carbonate (3) yields two N-methyl-isomers each in a ratio of approximately 1:1. The EI-spectrum of 1'-N-methyl-stanozolol is dominated by the ionic fragment m/z 108 which is an A-ring fragment (Fig.2) and can be explained by a retro diels-alder fragmentation. This retro diels-alder fragmentation pattern was reported for stanozolol itself by Budzikiewicz, Djerassi and Williams in 1964 (4). The scission of the A-ring between carbon 1 and 10 and carbon 4 and 5 was proved by deuteration of stanozolol in position 1,4 and 5. The 2'-N-methyl-stanozolol (Fig.3) shows a base peak m/z 110 which was confirmed as an A-ring-fragment with migration of two hydrogen atoms. The origin of this both hydrogen atoms is not quite clear. Deuteration of position 5 and 6 established that approximately 5% of the hydrogen transfer originates from position 5 and 15% from position 6. Deuteration of position 8, 9, 11 and 19 is under study.

Fig.2

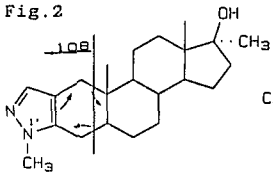


Fig.3

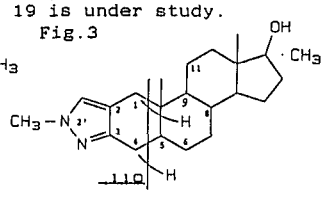

Fig.4

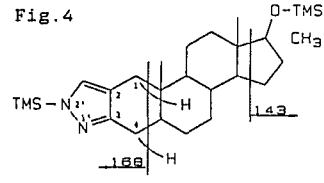

The trimethylsilylation of I, III and IV reacts to only one product each. The EI-spectrum of bis-TMS-stanozolol with a molecular ion m/z 472 shows an abundant D-ring fragment m/z 143 (Fig.4), and an A-ring fragment m/z 168 originating from scissions between carbon 1 and 10 and carbon 4 and 5 with migration of two hydrogen atoms. We assume that the TMS-group is at 2'-N because the location of the double bonds should favour this fragmentation.

Hydroxylation of stanozolol in position 3' yields a pyrazolone derivative which theoretically can exist in eight tautomeric forms, but only three isomers are observed after methylation. The 1',3'-N,O-bis-methyl-derivative (Fig.5) with a molecular ion m/z 372 shows a retro diels-alder fragmentation with an abundant ion m/z 138. The same fragmentation is observed for the 1',2'-N,N-bis-methyl-derivative. The 2',3'-N,O-bis-methyl-derivative shows a different fragmentation (Fig.6). Besides the ion m/z 138 the fragment m/z 140 with approximately the same intensity as m/z 138 is observed. This fragment m/z 140 can be explained with a fragmentation of the A-ring and migration of two hydrogen atoms.

To summarize, the fragmentations of the methyl-isomers of I and II demonstrate that a retro diels-alder fragmentation is preferred when a double bond is located between position 2 and 3 of the A-ring, otherwise an A-ring fragmentation with migration of two hydrogen atoms is apparent.

Fig. 5

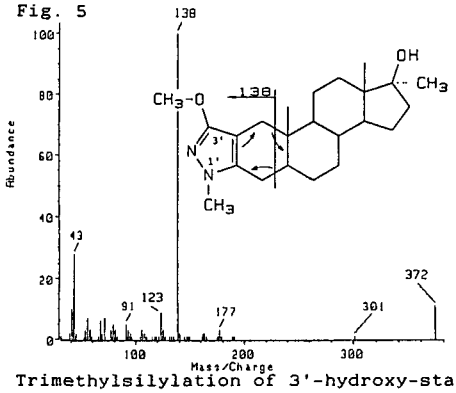

Fig.6

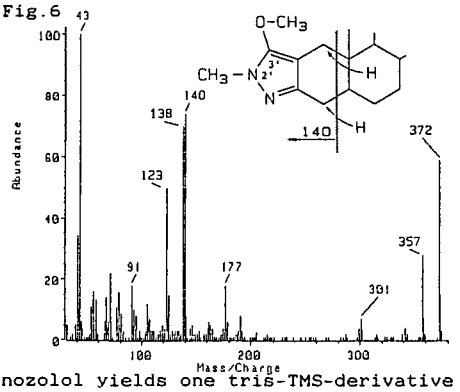

Trimethylsilylation of 3'-hydroxy-stanozolol yields one tris-TMS-derivative with a molecular ion m/z 560, a D-ring-fragment m/z 143 and an intense retro diels-alder fragment m/z 254 (Fig.7) of the A-ring.

Fig. 7

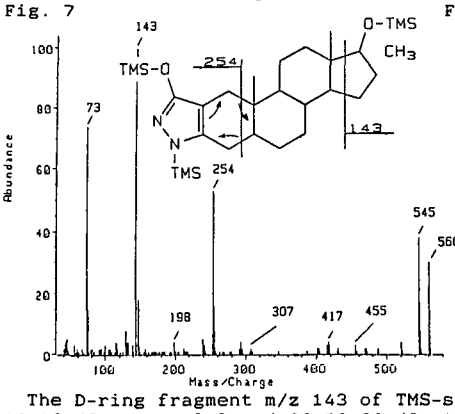

Fig.8

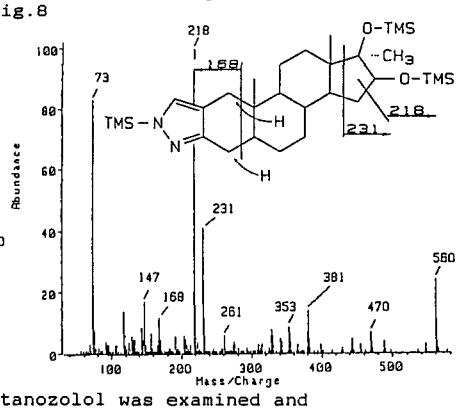

The D-ring fragment m/z 143 of TMS-stanozolol was examined and 16,16-d2-stanozolol and 20,20,20-d3-stanozolol were synthesized. The fragment m/z 143 can be explained with scissions between carbon 13 and 17 and carbon 14 and 15 and an elimination of one hydrogen from carbon 16, the same fragmentation as in tris-TMS-3'-hydroxy-stanozolol (Fig.7). Introduction of a trideuteromethylgroup in position 17 shifts the D-ring ion m/z 143 to m/z 146. Dideuteration in position 16 confirms that carbon 16 is part of the fragment. A base peak m/z 144 elucidates that one deuteium in position 16 is eliminated. But in addition to this ion m/z 144 the fragment m/z 143 is still present, with approximately 30% of the intensity of m/z 144. This ion can be explained by an exchange of the other deuterium atom in position 16 or an other fragmentation not involving carbon 16.

The D-ring fragmentation of 16ß-hydroxy-stanozolol shows the ions m/z 218 and 231 with high abundances (Fig.8). The fragment m/z 231 corresponds to m/z 143 in bis-TMS-stanozolol and originates from a scission between carbon 13 and 17 and between carbon 14 and 15, whereas the ion m/z 218 results from scissions between carbon 13 and 17 and carbon 15 and 16.

TANDEM MASS SPECTROMETRY, FAB AND EXPERT SYSTEM FOR THE ANALYSIS OF ACYLCARNITINES.

E de Hoffmann*, R. Libert** J. P. Draye** and F. Van Hoof**.

Depts of Chemistry* and Neuropediatry**, University of Louvain, Pl Pasteur 1, 1348 Louvain-la-Neuve, Belgium.

A method has been developed for the analysis of acylcarnitines in urine samples with a Finnigan TSQ70 triple quadrupole instrument. Sample preparation was done by ion exchange chromatography (1). For FAB, the matrix chosen is glycerol acidified with 0.1 M trifluoroacetic acid.

At a Xenon collision gas pressure of 0.08 Pascal and an offset voltage of -2 V, daughter spectra of carnitine conjugates molecular ions are very simple, as illustrated for octanoylcarnitine in Fig. 1. More fragments appear when heteroatoms are present in the conjugated acid chain. The main fragments observed result from neutral losses of either 59 or 161 u or appear at constant masses 85 and 144 u (Schemes 1 and 2). They are all candidates for selective detection of these compounds, but the neutral loss mass of 59 u and the constant ion at 85 u give better sensitivity. Fig. 2 displays the variation of the intensities of these ions with the collision offset voltage. Formation of the 85 u ion shows a broad maximum, and better sensitivity. Further experiments on samples from patients showed that parent scans of 85 u at -10 V collision offset voltage is indeed the best way to selectively detect carnitine conjugates.

An instrument control computer program automatically gets this parents of 85 u spectrum, selects the ten most intense even masses, and then acquires the daughter spectra of these ten ions. Averaging on four scans is performed. The whole acquisition time is about 2.5 minutes.

The left hand spectrum in Fig. 3 is part of the FAB spectrum of the carnitine conjugates extract from a patient with proven 3-hydroxy-3-methylglutaryl-CoA lyase deficiency. Matrix peaks are displayed on a black background. The right hand spectrum is the parent scan of mass 85. From the mass 162 (free carnitine), all the intense ions are carnitine conjugates, as was confirmed by their daughter ions spectra. In this parents scan of mass 85, the most intense peak from the matrix itself above 162 u is at 183 u, almost undetected in this sample. Acetylcarnitine appears at 204 u, and the following homologues at 218, 232 and 246 u. The 260 u peak (hexanoyl) is very weak, but a strong peak appears at 262 u. By comparison of GC/MS analysis of the fatty acids-TMS derivatives before and after hydrolysis of the conjugates, it appears that the only candidate for this mass is 3-OH-isovaleryl-carnitine.

The carnitine conjugates profile (parents of 85 u) from a patient with octanoyl-CoA dehydrogenase deficiency is displayed in Fig. 4. Short-chain fatty acids give only weak peaks. The first two intense ones have masses corresponding to octenoyl- (286 u) and octanoyl-carnitine (288 u). Higher masses can be interpreted either in terms of ω or β-oxydation products. For instance, 304 u can be either ω- or β-hydroxyoctanoylcarnitine, while 302 could correspond to β-ketooctanoyl-carnitine or to ω-hydroxyoctenoylcarnitine. Identification will need reference compounds.

GENERATION OF FATTY ACID METHYL ESTER PROFILES BY DIRECT CURIE-POINT PYROLYSIS GC/MS OF WHOLE CELL SAMPLES

Jacek Dworzanski* and Henk L.C. Meuzelaar
Center for Micro Analysis and Reaction Chemistry, University of Utah
Salt Lake City, Utah 84112

A novel, on-line pyrolytic derivatization technique has been developed which enables generation of fatty acid methylester (FAME) profiles from microorganisms as well as higher cells by GC/MS without the need for laborious and time-consuming sample preparation. Conventional GC-based methods for obtaining cellular FAME profiles generally require milligram amounts of sample and several hours of successive saponification, methylation and extraction steps [1].

The new pyrolytic technique shown in Figure 1 requires only microgram amounts of sample, thus enabling rapid profiling of a single bacterial colony. Moreover, samples are applied directly to the Curie-point pyrolysis filaments followed by the application of a single drop of derivatizing agent. Using short capillary columns (e.g., 3-5 m) in combination with a Finnigan MAT Ion Trap Detector, complete FAME profiles can be obtained in approximately 6 minutes.

Figure 2 shows a comparison of B. subtilis FAME profiles obtained by means of the conventional saponification, methylation and extraction (SME) method and the new on-line derivatization (OLD) technique, respectively. The two profiles are nearly identical in spite of the major differences in sample treatment. Apparently, under Curie-point pyrolysis conditions the OLD process goes to completion within a fraction of a second. The main origin of the FAME signals in bacterial preparations can be traced back to phospholipid cell wall constituents. As shown in Figure 3, a complex mixture of diglycerides and, to a lesser extent, monoglycerides and free fatty acids is obtained by direct pyrolysis of whole bacterial cells. Addition of the derivatizing agent effectively hydrolizes and methylates these lipid constituents, thereby resulting in the relatively simple FAME pattern.

Further advantages of the pyrolytic approach include high FAME yields from saponification-resistant lipids such as the highly characteristic mycolic acids of Mycobacterium species (see Figure 4). Especially the appearance of the characteristic C32 acid (mycocerosic acid) should be noted in Figure 4. Because mycocerosic acid is found only in mycobacteria a rapid and simple assay would be of great advantage in the diagnosis and treatment of chronic mycobacterial infections such as tuberculosis and lepra [2].

Disadvantages of the new OLD method are degradation of the more labile hydroxy-substituted fatty acids and a higher column background due to pyrolysis products from different cellular components. The latter disadvantage can largely be overcome utilizing the background subtraction capabilities of modern GC/MS software, as shown in Figure 4.

The research reported here was supported in part by DOD subcontract CG1728-88- 001 and by Institutional funds.

The development of a low-dead volume Curie-point pyrolysis GC/MS inlet which maximizes capillary chromatographic resolution by its narrow injection plug has been described [1]. Short column GC/MS has been studied [2,3] as a method which can greatly reduce analysis time while maintaining a useful level of resolution when the column is directly interfaced to the MS vacuum. This work, discusses the utility of this Curie-point pyrolysis inlet as an injection system for relatively large, polar and labile molecules with little or no pyrolysis in flash desorption. The simple injector operation and high linear velocity of a short column with a vacuum outlet permit rapid analyses which rival the ease of direct solids probe techniques with the strong advantage of significant chromatographic resolution. The low dead volume Curie-point pyrolysis inlet (Somatogenetics Instruments) was used with short columns (4m and 5m) directly interfaced to the vacuum of a Finnigan ITD and ITMS. For the analyses on the ITD a 4m x 0.25mm ID CP-Sil5 column (Chrompack) was used which had a linear velocity of 175cm/s and a volumetric flow of 4.0 ml/min (inlet 8 psig, column 60°C, transfer line 250°C). The conditions on the ITMS were a 5m x 0.32mm ID SE-30 column (J&W Scientific) with a linear velocity of 150cm/s and volumetic flow of 7.2ml/min (inlet pressure 3 psig, column 60°C, transfer line 250°C). To accomodate these high flows, the conductances out of the traps were increased by making several additional holes in the teflon spacers of the ITD and by removing the spacers entirely in the ITMS. Flash desorption was performed using 610°C Curie-point filaments with a temperature rise time of ca. 0.2s and 1s total heating time. The remaining analytical conditions (inlet T, GC program, etc) were varied according to sample being analyzed.

The chromatogram from a vulcanized rubber extract representing 5ug of the original solid is shown in Figure 1. Peaks from the antioxidant (di-t-octl-diphenylamine, mw = 339), an antiozonant (N, N-di-s-octyl-phenylene diamine, mw 332), and unreacted sulfur (S_8, mw 256) are indicated. The t-octyldi-phenylamine, which eluted at 4 min. 20s, was most likely an impurity in the antioxidant amounting to less than 2% of the di-octyl material. The molecular ions for these four compounds produced sharp symmetrical peaks with no tailing and clean baselines in their respective single ion chromatograms. The regular series of smaller peaks is due to n-alkanes from a paraffin wax antiozonant.

Figure 2 shows the reconstructed ion chromatogram for a mixture of 5 trichothecene toxins. The numbered peaks are 1:deoxynivalenol, 2:diacetoxy-scirpenol, 3:acetyldiacetoxyscirpenol, 4:J2-tetraol tetraacetate, and 5:T2-toxin. The EI spectra showed no molecular ions with loss of acetic acid to the highest mass ions for compounds 2, 3 and 4. The T-2 toxin lost pentanoic acid to give its highest mass peak at m/z 364 while the deoxynivalenol had a loss of 48 (eg. 18 and 30). H_2O chemical ionization (CI) produced good $(M + H)^+$ ions with extreme fragmentation for compounds 1-3, and isobutane CI still resulted in a loss of water from the T2 toxin with the ITD trap at 200°C.

The analysis of diglycerides is shown in Figure 3. The dipalmitin (mw 568) and distearin (mw 624) eluted while the column was isothermal (300°C). The three n-alkanes, C34, C36, and C44 are included for reference. The EI spectra of the diglycerides gave strong $(M-H_2O)^+$ peaks with abundant fragmentation. Unfortunately, with the traps at such high temperatures (ITMS at 160-180°C and ITD at 225°C), even isobutane CI did not prevent this loss of water in either short column or direct probe analysis. Only when the ion trap was overloaded (self CI occuring) did a small peak appear at m/z 513 for the dimyristin. Thus it remains uncertain whether the dehydration occurs merely in the ion trap or possibly in the inlet. Some pyrolysis of the diglycerides is evidenced by the presence of small free acid and monoglyceride peaks eluting in the first 3.5 min. of Figure 3.

In conclusion, Curie-point flash desorption is an effective injection technique for many moderately large, polar compounds with minimal degra-dation. The use of high linear velocity carrier gas in short capillary

columns with vacuum outlets allows rapid gas chromatography of these types of compounds without derivatization. Finally, the technique is applicable to inexpensive mass spectrometers such as the ITD with minor modification.

The authors acknowledge funding and samples for this work from B.F. Goodrich Company, and the Chemical Research, Development and Engineering Center, U.S. Army.

South San Francisco, CA 94080

Mass spectrometry has emerged as an essential tool in the protein sequencing laboratory. Mass measurements and sequence determinations by mass spectrometry very often are complementary to conventional amino acid analysis and microsequencing data. As a result, the efficiency and accuracy of microsequencing are improved when the peptide molecular weight is known. Sample amounts required for mass measurement and automated Edman degradation are comparable, on the order of 10-50pmole.

Typically peptides are generated by proteolytic digestion and separated by HPLC. Mass measurement for the collected fractions prior to sequencing identifies the number of peptides present (for coeluting peptides) and provides an estimate of the number of cycles of Edman degradation to program. Following sequencing, knowledge of the molecular weight shows whether the peptide was sequenced to the C-terminus, improves the confidence of residue assignments for low-level signals, and identifies the presence of post-translational modifications when they occur. Sequencing of peptide mixtures is aided when the molecular weight of each component is known; uncertainty of which residue corresponds to which sequence in a particular cycle is greatly reduced.

Confirmation of the sequence of synthetic peptides or peptides produced by recombinant DNA technology can be rapidly performed by mass measurement since the putative sequence is already known. Mass analysis is particularly useful for analyzing recombinant proteins, where the length of the gene product may be uncertain, protease or peptidase processing is likely, or post-translational modifications are possible.

Tandem mass spectrometry is used for sequencing in cases in which Edman degradation fails (e.g., blocked N-terminus) or post-translational modifications are present. Modified residues in synthetic peptides are also readily identified.

Confirmation of microsequencing results is illustrated in Figure 1. Shown are the sequence data and the molecular ion region of the spectrum of a CNBr peptide of bovine brain Protein Carboxyl Methyltransferase (PCMT), Mr~26,500. This enzyme catalyzes L-isoaspartyl/D-aspartyl methylation. The sequence data show diminishing levels near the C-terminus. The measured mass confirms that the sequence is correct and the C-terminus of the peptide was reached. The latter point is important since it shows that the C-terminus of the protein was identified because homoserine would otherwise be expected as the C-terminal residue of a CNBr fragment.

Mass spectrometry is an excellent technique for identifying post-translationally modified amino acids. Conventional microsequencing relies on retention time of the PTH-amino acids for identification, so modified residues are often unidentified or misidentified. Blocking groups at the N-terminus prevent sequencing althogether. Comparison of the peptide mass with the sequencing data usually flags any post-translational modifications. The identity of the modification can then be made by tandem mass spectrometry, amino acid analysis, and or other methods.

Figure 2 shows the sequence data and collision spectrum for a tryptic peptide from the large subunit of muskmelon Ribulose bisphosphate carboxylase/oxygenase (Rubisco), one of the enzymes involved in the dark reaction of photosynthesis. The cDNA sequence codes for ASVGFKAGVK. Initial inspection of the sequence data shows Phe in place of the first Lys. The mass spectrum shows MH^+=1005.7 which is 42u higher than expected from the cDNA sequence. Although acetylation of the Lys immediately comes to mind, thorough examination of the data show the modification to be trimethylation of the Lys. The collision spectrum of 1005.7 shows no significant peaks below m/z 599. The quaternary ammonium group on the Lys fixes the charge and directs the fragmentation as shown. Exact mass measurements as well as subsequent tests with a trimethyllysine standard on both the microsequencer and amino acid analyzer verified the identification.

STYRENE OXIDE ALKYLATION OF HUMAN SERUM ALBUMIN DETERMINED BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Richard B. van Breemen and Johnny Creech
Department of Chemistry, North Carolina State University,
Raleigh, North Carolina 27695-8204

Human serum albumin, which weighs 66,439 mass units according to the amino acid sequence determined by Edman degradation (1), is the most abundant protein in the blood plasma and functions as a carrier protein for many drugs, drug metabolites, and endogenous compounds. These properties help make albumin a frequent target molecule for alkylation by activated drug metabolites and other electrophilic compounds. Styrene oxide, an electrophilic epoxide, is the carcinogenic metabolite of styrene, and both are widely used in the manufacturing of plastics and a variety of other compounds (2). Mass spectrometry was used to identify the site(s) of covalent binding of styrene oxide to serum albumin.

[8-^{14}C]Styrene oxide was incubated with human serum albumin (molar ratio = 10:1) for 12 hours at pH 7.4 in 0.1 M phosphate buffer. Because of the high molecular weight of albumin, cleavage by cyanogen bromide followed by tryptic digestion was used to produce peptide fragments weighing less than approximately 5,000 mass units. This procedure enabled the mapping of peptides from albumin by mass spectrometry while preserving as much of the amino acid sequence as possible. This peptide map was compared to one developed for native albumin, which provided a convenient reference for the rapid identification of alkylated peptides. Reversed-phase HPLC was used to purify the seven cyanogen bromide peptide fragments and then the tryptic peptides as previously described (3). Scintillation counting of the HPLC column effluent was used to determine which peptides contained styrene oxide residues.

Positive ion fast atom bombardment (FAB) mass spectra were obtained using a JEOL HX110 double-focussing mass spectrometer equipped with a high field magnet and DA5000 data system. The resolution was 5,000, and the accelerating voltage was 10 KeV. Xenon gas at 3 KV was used for FAB, and the matrix consisted of thioglycerol with 3.5 ug nitrocellulose (4).

Peptide mapping of native human serum albumin by FAB mass spectrometry has confirmed the amino acid sequence of approximately 80% of the albumin molecule, which had been previously determined by Edman degradation. The molecular weights of the three smallest cyanogen bromide peptides (CNBr II, IV, and VII) were determined directly by FAB mass spectrometry and were 4353.50, 3353.65, and 4097.00 mass units compared to the theoretical values of 4352.99, 3353.63, and 4096.89 mass units respectively.

HPLC with scintillation counting indicated that primarily cyanogen bromide peptide IV (CNBr IV) had been alkylated by C14-labelled styrene oxide (Figure 1). CNBr IV of alkylated albumin was purified by HPLC and then analyzed by positive ion FAB mass spectrometry (Figure 2). Because the molecular weight of this peptide increased by 120 mass units compared to native albumin, CNBr IV of albumin had been selectively alkylated by only one styrene oxide molecule. Experiments are in progress to identify the alkylated amino acid(s) in CNBr IV.

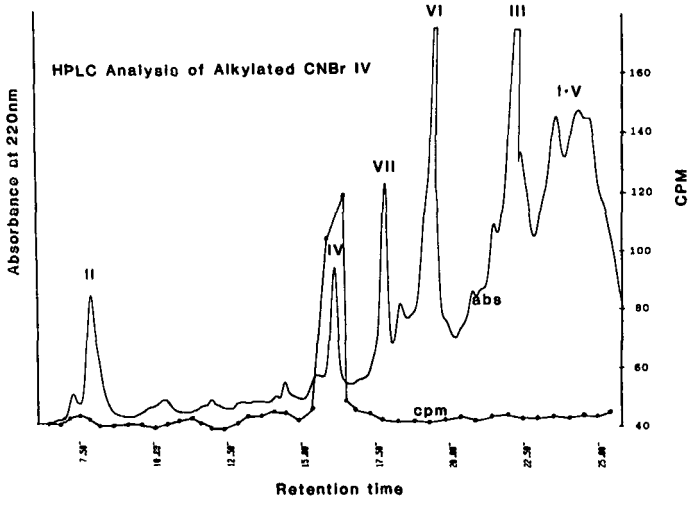

Figure 1. Reversed-phase HPLC purification of the cyanogen bromide peptide fragments of human serum albumin alkylated by [C14]-styrene oxide monitored by UV absorbance and scintillation counting.

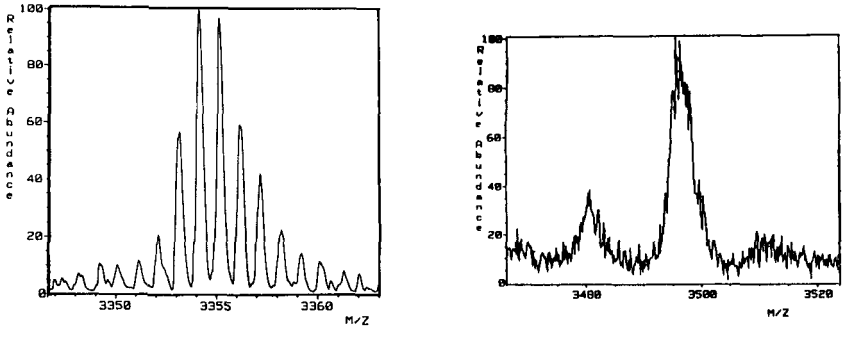

Figure 2. Positive ion FAB mass spectrum of A) native CNBr IV (Resolution = 1,000) and B) styrene oxide-alkylated CNBr IV (Resolution = 5,000) of human serum albumin.

FAST ATOM BOMBARDMENT MASS SPECTROMETRY STUDIES OF HUMAN RECOMBINANT GRANULOCYTE-MACROPHAGE COLONY STIMULATING FACTOR

B. N. Pramanik, T. L. Nagabhushan, J. E. Labdon, P. Reichert, Anthony Tsarbopoulos and P. P. Trotta. Schering-Plough Corp. Bloomfield, New Jersey 07003 USA

Human granulocyte-macrophage colony stimulating factor (GMCSF) is one of a family of hematopoietic factors which regulate the differentiation, activation and proliferation of multiple blood-cell types from progenitor stem cells (1). It has been cloned and expressed in various cell lines, including yeast, chinese hamster ovary and E. coli. The E. coli-derived GM-CSF used in this study contains 127 amino acids and has a molecular weight of c. a. 15 kDa.

FABMS mapping of GMCSF involved specific cleavage of GM-CSF with either trypsin or S. aureus V8 protease, followed by mass spectrometric determination of the molecular weights of the resulting mixture of peptides. The experimentally determined molecular weights of the peptide fragments were compared to those predicted from the cDNA-derived amino acid sequence.

The FAB mass spectrum of a tryptic digest of GM-CSF confirmed the presence of all predicted peptides with the exception of those containing cysteine (Table 1). Several incomplete cleavage products were also identified. Most of the predicted peptides from a V8 protease digest of GMCSF were also confirmed (Table 2) with the exception of V9 and V12, which form a high-mass disulfide linked peptide, and V1.

Disulfide bonded peptides were released after the crude tryptic digest was treated with DTT. The free sulfhydryl forms of T4, T10 and T12 were observed at m/z 3202, 2465 and 1950 respectively. This confirmed the presence of 2 disulfide bonds in GMCSF. Enhanced molecular ions were obtained for T4 and T12 after the digest was performed on GM-CSF which was S-alkylated with 4-vinylpyridine (PEC-GM-CSF). In the unreduced V-8 protease digest of GMCSF, an ion at m/z 2273 corresponding to the disulfide-bonded pair V8-S-S-V10 was observed (Table 2). DTT reduction of the digest caused this ion to disappear. These fragments contain half-cystines 54 and 93 respectively. The ion at m/z 3035 (V7-8-SS-V10) resulting from partial cleavage, also disappears after reduction and provides further evidence for this disulfide bond.

CNBr treatment (5 mg/mL in 88% HCOOH for 24 h) of a tryptic digest of PEC-GM-CSF confirmed the presence of two methionine residues in tryptic fragment T4. In a separate experiment, V8 protease peptide V3 was isolated by RP-HPLC and its sequence ions were determined by FABMS.

MAPPING OF COLICIN Ia BY HPLC AND MS/MS

A.M. Falick*, S. F. Mel,** R.M. Stroud,** G. Elliott*** and A.L.Burlingame*

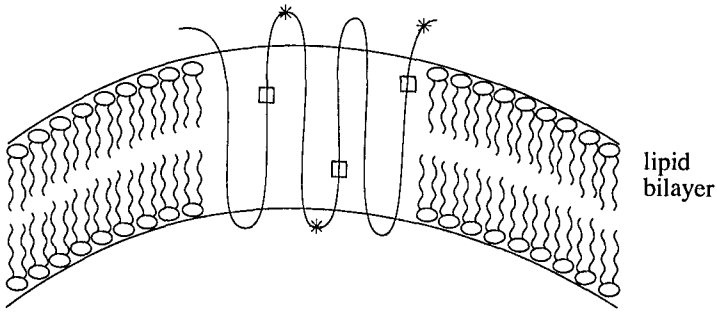
*Mass Spectrometry Facility, Dept. of Pharmaceutical Chemistry, **Department of Biochemistry and Biophysics, University of California, San Francisco, California 94143, and ***Kratos Analytical, Manchester, U.K.

Introduction

Integral membrane proteins are the most common transmitters of information between the extracellular and intracellular environments. Ion channels are found in numerous cell types, playing key roles in nervous system signalling, muscle contraction, and hormone release. Molecular level studies of ion channels have focused on molecules such as the acetylcholine receptor, a large (270kD), multi-subunit transmembrane glycoprotein. Colicin Ia is a smaller (67kD, 626 residues) monomeric bacterial ion channel, which is an excellent model for higher eukaryotic ion channel function.

Colicin Ia is made and released in a water soluble form during the SOS response in the colicin-producing strain of *E. coli*. It then binds to an iron receptor, the *cir* gene product, on the outer membrane of a sensitive (non-colicin-producing) bacterium. The protein subsequently inserts a channel forming region into the inner plasma membrane, thereby killing the cell.

The X-ray structure of the soluble form of colicin Ia is currently being solved in the Stroud laboratory. The structure of the soluble form of colicin Ia will certainly shed light on the membrane conformation of the molecule, but a topographical analysis of the latter form is critical to our understanding of the structure-function of this channel *in vivo*. We have therefore undertaken to map the membrane-bound form of colicin Ia, following which we will identify relevant features of the topography by means of specific labels (Fig. 1).



* extramembrane label □ intramembrane label

Fig. 1. Schematic of colicin in transmembrane form.

Experimental

Colicin Ia was purified from *E. coli* strain JK365, according to the method of Konisky, et al. (1970).

Proteolytic digestion was carried out with Endoproteinase Glu-C (*S. aureus* V8 protease) from Boehringer Mannheim. Digestions were done at 37°C for 1 hr in 0.05M phosphate buffer (pH 7.8) and 2.4M urea at an enzyme to substrate ratio of 1:5.

Mass spectrometry was done on a Kratos MS-50S, equipped with a high-field magnet, cesium liquid SIMS source (Falick, et al., 1986a), and cooled probe (Falick, et al., 1986b).

MS/MS experiments were carried out on a Kratos "Concept" 4-sector instrument equipped with a cesium liquid SIMS ion source and an electro-optical array detector (Elliott, et al., 1988).

Results and Conclusion

Proteolytic digestion of a 2 nmol sample of native colicin Ia was carried out with *S. aureus* V8 enzyme to cleave the molecule into a number of peptides. Following separation by HPLC, fractions were analyzed by liquid SIMS. Using this single enzyme, peptides representing 67% of the total 626 amino acid residues in colicin were identified.

Tandem mass spectrometry was carried out on several representative peptides, and the results confirm that the spectra contain sufficient information to allow the sequence of an unknown or modified peptide to be deduced. In addition to sequence information, MS/MS provides a means of distinguishing between different peptides whose masses are very similar or identical. Such pairs occur with moderate frequency in relatively small proteins such as colicin, and with much greater frequency with larger proteins. Some examples from colicin are shown in Table 1.

Sequence	Position	Mass (MH^+)

AGKRLSAAIAAREKDE	98/16	1685.9298

Table 1. Examples of Isobaric Peptides in *S. Aureus* V8 Digest of Colicin Ia

Colicin Ia is an example of a mid-size protein that can be successfully mapped using MS and MS/MS to identify the position of essentially every individual residue. Subsequent modifications for the purposes of determining topography or locating other covalent adducts are precisely locatable, provided that sufficient specificity can be achieved. The mapping and subsequent analysis of the modified form are possible on sub-nanomole quantities of protein, using the high-sensitivity MS techniques employed in this study.

Further work on colicin will first complete the map using other enzymes (endo Lys-C, endo Asp-N), then begin experiments with topographically-selective reagents.

ULTRA-HIGH SENSITIVITY MEASUREMENT OF PEPTIDES AND PROTEINS WITH keV AND MeV ION BOMBARDMENT

Viswanatham Katta, Louis I. Grace, Tanuja Chaudhary and Brian T. Chait
The Rockefeller University, New York, NY-10021.

We have recently made a detailed comparison of the spectra and the relative yields of a series of peptides desorbed from nitrocellulose (NC) surfaces by keV and by Cf-252 fission fragments. We showed that the use of NC significantly reduces the previously reported differences in the relative yield between the two bombardment techniques for electrosprayed samples [1]. In the present investigation we have extended this study to compare the effective sensitivities of the two bombardment techniques for a series of peptides (molecular weight range (1000-6000 u) desorbed from NC. The comparison was made using 30 keV indium ions in a pulsed ion bombardment time-of-flight (TOF) mass spectrometer (PIB-MS) and ca.100 MeV fission fragment TOF mass spectrometer (FF-MS). Both instruments were built at the Rockefeller University [2,3].

The PIB-MS was designed to achieve very high sensitivity by using a tightly focussed (to a diameter of 0.1 mm), high intensity primary ion beam to bombard the sample of interest, which can be concentrated onto a small area (0.3-3.0 mm^2).

The comparisons were made with peptide samples, which include arginine vasopressin (MW = 1083), a 32-residue synthetic peptide analogue of Calcitonin (MW = 3576) and bovine insulin (MW = 5733). The procedure involves deposition of about a micron thick layer of NC on sample insertion probes of PIB-MS (area 3 mm^2) and FF-MS (area 110 mm^2). A microliter of peptide solution (in 0.1% trifluoroacetic acid) was deposited on NC, left for 3 minutes to allow peptide sorption, and then the solvent was removed. Spectra were obtained with both instruments operating under similar conditions (accelerating potential = 2.75 kV and postacceleration potential = 7.5 kV).

As observed earlier [1], both instruments gave very similar spectra. As an example the PIB-MS and FF-MS spectra obtained from 2 picomoles of bovine insulin are compared in Figure 1.

We observed considerably higher effective sensitivity with our PIB-MS compared to our FF-MS. The yields of protonated arginine vasopressin with both instruments are compared in Figure 2 as a function of amount of sample deposited on the probes. It is seen that, of the two instruments the PIB-MS has higher sensitivity (about a factor of 40). This may simply be related to the fact that the same amount of sample is deposited in a 40 times smaller area on PIB-MS probe. Figure 3 shows the spectrum of arginine vasopressin obtained in a 30 minute run from a 20 femtomole sample.

With the PIB-MS, quasimolecular ion yields passed through a maximum when the deposited sample is in the range of 1-10 picomoles. Such a maximum lies in the range of 100-1000 picomoles for FF-MS. This results in considerably shorter run times required with PIB-MS, as is evident from Figure 1.

We observed that with both instruments the relative yield of intact multiply protonated peptide ions increased significantly as the amount of sample deposited decreased. Thus for example, the intensity ratio of $(M+2H)^{2+}$ to $(M+H)^{+}$ observed in the PIB-MS spectrum of bovine insulin increased by an order of magnitude when the deposited sample size decreased from 200 picomoles to 20 picomoles (see Figure 4). We are presently investigating this phenomenon.

In an effort to elucidate the structures of important biomolecules, we have conducted investigations of covalent bond compounds and extended the study to include non-covalent bond species. Non-covalent linked metal-peptide complexes have been investigated by plasma desorption mass spectrometry while covalent bond heme derivatives have been investigated by FAB.

I. Metal-Linked Dimer of the Cysteine-Rich Region of TAT III Protein from HIV

An 18-amino acid peptide (tat_{21-38}) that contains the cysteine-rich region of the TAT-III protein from HIV has been synthesized [1]. These cysteines serve as metal ligands in the intact protein, causing TAT-III to form metal-linked dimers in vitro. As proposed in Figure 1, four metal ions (M) coordinate in tetrahedral geometries with 14 cysteine thiolate ligands (s) of tat_{21-38} region. This cysteine-rich peptide can also inhibit dimerization of intact Tat-III by forming metal-linked heterodimers. If these heterodimers are unable to transactivate viral transcription, the synthetic peptide could be a lead compound for drugs to treat AIDS.[2]

As shown in Figure 2, plasma desorption spectra permitted direct observation of the metal-linked dimer. The "dimer" peak is less well resolved than the monomer peak but the major species are tat dimers with four bound Cd^{2+} ions adjusted by the addition of Cl^- anions, or subtraction of protons, to achieve a single charge. The "codesorption" of Cl^- is reasonable since $CdCl_2$ was present in these samples. Molecular ions of Zn^{2+}-linked dimer were also observed, however with reduced intensity (not shown). This may indicate a weaker linkage of Zn^{2+}-complexes than Cd^{2+}-complexes.

II. Intermediates Involved in Covalently Bound Heme-Protein Adducts in the Course of Suicide Inactivation of Heme Proteins

During the metabolism of CCl_4 and various other xenobiotics by P-450 cytochromes, these cytochromes become inactivated and produce abnormal hemederived products covalently bound to the protein. Although the molecular mechanism of this process has yet to be elucidated, it appears that in each case a radical intermediate is involved. For example, CCl_4 is reduced by a ferrous P-450 to the trichloromethyl radical. In this study a model system of this reaction, consisting of photoreduced myoglobin and $BrCCl_3$, has been developed to help elucidate the mechanism of the P-450 inactivation.

Myoglobin was reduced under anaerobic conditions by dithionite or by photoreducing system containing EDTA and flavin. The ferrous form was treated with $BrCCl_3$ and a rapid loss of the absorbance due to the ferrous form was observed. The reaction mixture was separated by C_4-reverse phase column into four major soluble components (non-protein associated modified heme) and the protein-heme complexes. The non-protein associated adducts were identified by FAB mass spectrometry (see Fig. 3) as CO_2H, CCl_3OH, and $2(CCL_3)$ adducts of the prosthetic heme (Fig. 4). These products all result from the attack of the trichloromethyl radical on the I-vinyl.

Further study of the protein associated modified heme products will be carried out via PD and FAB mass spectrometry. Information on the covalently bound heme-protein adducts is an important step in understanding the protein inactivation mechanism.

SYNTHESIS OF A DEUTERATED ANALOG OF LEU-ENKEPHALIN FOR FAB QUANTITATIVE ANALYSIS.

Benfenati E., Chen S., Fanelli R., Icardi G. Istituto Mario Negri, 24100 Bergamo and 20157 Milano, Italy.

INTRODUCTION

FAB has become a valuable technique for studying peptides. The FAB mass spectra of many peptides have been interpreted and this technique is useful to elucidate the chemical structure of unknown peptides Only a few quantitative studies have appeared using the FAB technique.
One of the advantages of MS quantitative analysis is that a stable isotope labelled analog of the compound can be used as internal standard. We describe the fast and easy synthesis of a deuterated analog of Leu-enkephalin (LE) by proton exchange of this peptide with CF_3COOD and its use as internal standard.

EXPERIMENTAL

Preparation of internal standard: LE (1 mg) dissolved in CF_3COOD (50 µl) was heated at 70°C for 2 hours, then the acid was evaporated under a stream of nitrogen. This process was repeated four times. The obtained deuterated LE was treated with 25% NH_4OH at room temperature to hydrolize the acetilated peptide formed as contaminant during the reaction.
FAB mass spectrometry: all analysis were done on a VG 70-250 mass spectrometer with standard FAB source and target. Xenon was used as bombarding gas and accelerated at 8 kV. Quantitative measurements were carried out acquiring spectra from m/z 450 to m/z 600, at a scan time of 4 sec/decade
Quantification: a constant amount of internal standard dissolved in H_2O / glycerol (2:1) was added to varying amounts of LE. 2 µl of the solutions, containing 10 ng of internal standard and 10-40 ng of LE, were transferred to the surface of the FAB probe. The water was removed in the vacuum block of mass spectrometer before the introduction of the FAB probe into the ion source. Glycerol remained on the probe as matrix. Scans (15-20) were acquired, and average values of absolute peak intensity were used to make the calibration curve. This procedure was repeated with solutions containing 40 ng/µl of internal standard and 25-250 ng/µl of LE.

RESULTS

The deuterated LE negative FAB spectrum is shown in Fig.1. The main molecular ion contained two deuteria (m/z 556). Is possible to observe the absence of undeuterated specie (m/z 554). We have also treated the deuterated LE with a solution 0.1N HCl because the extractive procedure from biological tissues involve a similar conditions treatment. We didn't observe a proton-deuterium exchange after the acid treatment, therefore the synthetized deuterated LE seems to be an appropriate internal standard for biological samples analysis.
The procedure we described for deuterated LE synthesis introduced a third deuterium, in a rather mobile position, that was eliminated by the treatment with NH_4OH.
We observed two advantages in using negative mode instead of positive mode: the current of LE molecular ion was more stable and the liquid matrix caused a lower noise.

To compare the efficiency as internal standard of deuterated LE with that of a LE analog, we tried to use as internal standard Tyr-DAla-Gly-Phe-DLeu (DADLE). It was no possible to obtain a standard curve due to the different behaviour of the two peptides DADLE is desorbed before LE, and this leads to an unstable ratio of the peak intensity between internal standard and LE.
With the deuterated LE as internal standard this problem doesn't exist. We could obtain two different standard curves. The first one was made using 10 ng/µl of deuterated LE as internal standard and 5-20 ng/µl of LE (Fig 2), the second one with 40 ng/µl internal standard and 25-250 ng/µl LE (Fig 3) In both cases the correlation coefficient is over 0.99.

CONCLUSIONS

In the quantification of LE by FAB, two kinds of internal standard, a chemical analog or a stable isotope labelled LE, may be used. Although the analog is easy to obtain from commercial source, its chemical behaviour, in extraction, purification and instrumental analysis, can be different from the compound of interest.
The use of the stable isotope labelled LE we synthetized as internal standard overcome the problems above. Furthermore, its synthesis is fast, easy and cheap.

CHARACTERIZATION OF BIOTECHNOLOGY PRODUCTS AMINO ACID ANALYSIS OF PEPTIDES BY LC/MS

Teng-Man Chen and John Coutant
Merrell Dow Research Institute, Cincinnati,OH 45215

In recent years the use of high performance liquid chromatography (HPLC) for the analysis of derivatized amino acids has become the method of choice over classical techniques, especially in the analysis of protein/peptide hydrolyzates. Several chemistries for derivatization of the amino acids exist but one of the more popular ones has been the use of phenylisothiocyanate (PITC) to form the phenylthiocarbamyl (PTC-) amino acids. The identification of these derivatized amino acids has been based on retention time comparision with standards. This can cause problems for complex mixtures or unique amino acids as the chromophore for UV detection is due to the derivative and differences in UV spectra are minimual. The use of a small dedicated thermospray LC/MS as a routine detector for amino acid analysis can provide qualitative as well as quantitative data.

Acid hydrolysates were derivatized with phenyisothiocyanate (PITC) using the procedures described by Bidlingmeyer et al [1]. The chromatography was performed on a Nova Pak C-18 column using a gradient system of acetonitrile and 0.05 M ammonium acetate. The chromatography was done on a Waters 600-MS system designed for LC/MS and in-line UV detection was acquired with a Waters 490-MS detector. The LC/MS system was a Vestec 101/ Hewlett Packard MSD low cost, dedicated system.

The thermospray (TSP) mass spectra of all the PTC-amino acids are characterized by weak protonated molecular ions, $[M+H]^+$, and intense ions due to the loss of water, $[M+H-H_2O]^+$. A typical mass spectrum is shown in Figure 1A for the PITC derative of isoleucine. It was observed that N-methyl amino acids react to produce the phenylthiohydantion (PTH-) amino acids instead of the PTC-amino acids. The mass spectra of this derivatives are characterized by intense protonated molecular ions as shown in Figure 1B for the PTH-N(methyl)-isoleucine derivative.

The advantages of such a system are in its ability to uniquely identify each amino acid. In cases where peptides contain unique or modified amino acids, the use of LC/MS allows identification of the amino acid or in certain cases, the dipeptide produced by hydrolysates.

FAB Mass Spectrometric Investigation of *in vitro* Metabolism Within the Disulfide-Linked Core of Atrial Natriuretic Factor

B.L. Ackermann, T-M Chen, J.E. Coutant, and J.M. Berman
Merrell Dow Research Institute, Cincinnati, OH 45215

Atrial Natriuretic Factor (ANF), a cyclic peptide hormone, is currently under investigation for its potent diuretic and vasorelaxant properties (Fig.1). While several synthetic ANF analogs have shown pharmacological activity, their therapeutic usefulness is limited by rapid metabolism in the kidney (1,2). The current approach to analog design has, therefore, focused on structures less susceptible to protease attack. The results presented here represent an investigation of *in vitro* metabolism within the disulfide-linked core of ANF, with particular attention given to the highly susceptible Cys^7-Phe^8 bond (3,4). For this purpose, two truncated analogs of ANF were digested by the bacterial endopeptidase thermolysin, known to have a specificity similar to the kidney-isolated enzyme EC 3.4.24.11 (5). The resultant degradation products were analyzed using HPLC and FAB-MS.

The structures of the analogs studied are shown in Figure 2 where the arrows indicate the sites of hydrolysis observed under thermolysin digestion. A total of 9 products were identified for $rANF_{5-23}$-NH_2 and 8 for $rANF_{7-23}$-NH_2. However, the difference in stability between the two analogs was rather dramatic as evident from their respective half-lives (Fig.2). This result can be directly related to the relative stability of the Cys^7-Phe^8 bond; this was the site of primary hydrolysis for $rANF_{5-23}$-NH_2 yet remained intact in all products identified for $rANF_{7-23}$-NH_2 (6). These data suggest that the Cys^7-Phe^8 bond may be stabilized towards endopeptidase attack by removing the N-terminal side chain from ANF.

Several methods have been used to identify products from proteolysis of ANF including amino acid analysis (2,3,4), protein sequencing (3,4,7), and RIA (7). FAB-MS offers a convenient alternative to these more time-intensive methods. In the case of ANF, where only a limited number of products are possible, direct identification can be made from the observed MW. An exception occurs, however, for products formed from initial hydrolysis within the disulfide-linked core of ANF as all products have a MW 18u above that for the intact substrate. Fortunately, this problem is easily rectified by reducing the disulfide bond to yield two smaller peptides whose MWs uniquely specify the position of initial hydrolysis. This process is illustrated in Figure 3 for one of three primary hydrolysis products of $rANF_{7-23}$-NH_2. In this case, reduction occured in the thioglycerol matrix during FAB and enabled both the intact substrate (m/z 1724) and the reduced products (m/z 291, 1436) to be observed. The position of hydrolysis specified by the data was Gly^{20}-Leu^{21}.

CHARACTERIZATION OF GUINEA PIG PANCREATIC HORMONES BY MASS SPECTROMETRY

M. Alai and R.J. Cotter, Johns Hopkins University, Baltimore, MD 21205
P C Andrews, Purdue University, Lafayette, IN 47907
D F. Steiner, Howard Hughes Medical Institute, University of Chicago, Chicago, IL 60637

The guinea pig (GP) has several biochemical pecularities in comparison with other mamals. In particular, studies have revealed interesting divergences in the pancreatic hormones of guinea pig; e.g. the sequence of guinea pig insulin has changes in 17 out of 51 residues compared with porcine insulin. Also, guinea pig seems to be the only mamal in which the structure of glucagon is not fully conserved, with 5 of the 9 carboxy terminus amino acids being different. There is also a major difference in the concentrations of pancreatic peptide hormones of GP and other mamals. In addition, guinea pig may exhibit new modes of processing pro-hormones, as in the case of pancreatic polypeptide. The guinea pig pro-pancreatic polypeptide (pro-PP) is predicted to be 126 amino acids (aa), including a 26 residue signal peptide which is followed by the 36 aa PP sequence and a 64 aa C-terminal extension. There is 89% identity between the aa sequence of GP and human PP. In GP pro-PP, however, a Ser for Arg substitution occurs in the processing site at the carboxyl terminal of the PP domain. This substitution converts the dibasic processing site (Lys-Arg) to Lys-Ser. Although, such substitution would seem to inhibit the proteolytic clevage, the amino acid sequence data and radioimmunoassay suggest that efficient proteolytic clevage takes place at the Lys-Ser site and the mature PP is released. Our objective was to verify such abnormal processing by measuring the molecular weight of PP, and also verify the masses of highly substituted peptide hormones of guinea pig pancreas.

By plasma desorption we have verified the molecular weights of GP insulin and glucagon. The measured masses were different by ±1 amu from the expected numbers. We have also isolated and analyzed other GP pancreatic peptides; the assignment of the structures to the ions was made possible by sequencing the amino terminal of unknown fractions, since the full amino acid sequence of many of the peptides analyzed is not known. Guinea pig prosomatostatin (MH^+ 7066) was found to be identical to rat pro-SS in the first 39 amino acids, except for residue 19. The molecular ion of oxyntomodulin suggests presence of an Arg instead of the c-DNA predicted Asn-35. Amino acid sequence analysis also favors presence of an Arg at that site. The amount of oxyntomodulin was found to be higher in guinea pig pancreas than other mamals. The yield of this peptide was approximately equivalent to glucagon.

PDMS analysis of GP-PP confirmed that pro-PP despite a substitution in its processing site, is released as a mature 36 aa peptide. In addition, we have demonstrated that the C-terminal glycine is removed enzymatically to yield a carboxyamidated PP.

STRUCTURAL FINGERPRINTING OF ASN-LINKED CARBOHYDRATES AT SPECIFIC ATTACHMENT SITES IN GLYCOPROTEINS BY MASS SPECTROMETRY, S.A. Carr, G D Roberts, A. Jurewicz, B. Frederick and M. Vettese, Smith Kline and French Laboratories, King of Prussia, PA 19406

Recently we developed a mass spectrometry-based strategy (referred to as carbohydrate mapping) for simultaneously defining the sites of attachment of Asn-linked oligosaccharides in glycoproteins and determining the extent of glycosylation at each site (1). We have now extended this strategy to provide composition (in terms of hexose, deoxyhexose, N-acetylhexosamine and sialic acid) and molecular heterogeneity for oligosaccharide chains from specific attachment sites in glycoproteins (2,3). As in the the carbohydrate mapping strategy, the reduced and alkylated glycoprotein is first cleaved with proteases of known specificity such as trypsin. Approximately 10-20% of this protein digest is then treated with PNGase F to release all Asn-linked oligosaccharides. Potential glycopeptides are identified by comparing the RP-HPLC profiles of the digests obtained prior to and after digestion with the glycosidase. Peaks which disappear or are greatly attenuated in the chromatogram of the sample after digestion with the glycosidase are likely to be glycopeptides with carbohydrate linked to Asn Fractions containing these specific peaks are preparatively isolated from the tryptic digest and analyzed by FABMS to determine the molecular weights of peptides that have been co-purified with the glycopeptides. In favorable cases signals for the glycopeptides may be observed. Subsequently, the fractions are digested with PNGase F and re-analyzed by FABMS to identify the glycosylation-site peptide and its sequence location.

The HPLC-derived fractions consisting of mixtures of peptide and carbohydrate are subsequently peracetylated with acetic anhydride ($^1H_6$ or $^2H_6$) and pyridine, 1:1 (v/v) overnight. Aliquots of the peracetates are examined by FABMS Subsequently, the acetylated extracts are directly permethylated using potassium *tert*-butoxide in dimethyl sulfoxide and analyzed by FABMS. The resulting FAB mass spectra are dominated by $(M+H)^+$ and $(M+H\text{-}MeOH)^+$ peaks for each of the parent oligosaccharides present in the fraction which provide composition in terms of hexose, deoxyhexose, N-acetylhexosamine, and sialic acid. In addition, the relative ratios of these peaks indicate the relative abundances of the various carbohydrate homologs present in the mixture Following analysis by FABMS the permethylated carbohydrate fractions are converted to the partially methylated alditol acetates and analyzed by GC and GCMS for determination of linkage. Carbohydrate structural classes for oligosaccharides at specific attachment sites in the glycoprotein can then be proposed by combining the FABMS and methylation analysis data.

We have applied this strategy in our structural studies of the carbohydrate chains of recombinant tissue plasminogen activator glycoprotein expressed in a variety of mammalian and insect expression systems (3). For example, several potential glycopeptide-containing fractions were obtained from a tryptic digest of ca 10 nanomoles of reduced and carboxymethylated protein (expressed in Chinese hamster ovary cells) by comparative HPLC mapping as described above. Aliquots of each fraction were analyzed by FABMS, but signals readily assignable as glycopeptides were not observed for reasons previously discussed. The remainder of each of these fractions was then digested with PNGase F and analyzed by FABMS For example, Figure 1 compares the FAB mass spectra of fraction 35 from this digest prior to and after digestion with the glycosidase Two new $(M+H)^+_{ave}$ signals were observed in this fraction at m/z 3020 and 2459 that were not present in the FAB mass spectrum of this fraction prior to digestion with glycosidase (Fig. 1, bottom). These masses correspond uniquely to the predicted $(M+H)^+$ for the tryptic peptides Gly_{102}-Arg_{129} and Gly_{102}-Lys_{124} in which Asn_{117} (in the consensus sequence) has been converted to Asp following release of carbohydrate (1-3).

The released carbohydrates in these fractions were detected following peracetylation, extraction and permethylation. The FAB mass spectrum of the derivatized carbohydrate from Asn_{117} (located in HPLC fraction 35, see above) exhibits four clusters of peaks at m/z 1525, 1730, 1934 and 2138 that correspond to $(M+H\text{-}MeOH)^+$ for $(Hex)_n(HexNAc)_2$, where n = 5, 6, 7 and 8, respectively. Methylation analysis of this fraction indicated the presence of 1→2, 1→3, 1→6 and 1→4 linked mannose, but no galactose. These data indicate that the carbohydrate at Asn_{117} in tPA has a high mannose structure The relative ratios of the $(M+H\text{-}MeOH)^+$ peaks in the FABMS data indicate that approximately 45% is Man_5, 40% Man_6, 10% Man_7 and less than 5% Man_8

The carbohydrates attached to Asn_{448} were characterized in a similar manner. FABMS of the peracetylated and permethylated HPLC-fraction shown to contain the glycosylated Asn_{448} site (Fig. 2) yielded five major clusters of peaks at m/z 2584.7, 2947.1, 3396.2, 3757.9 and 4207.5 corresponding to the $(M+H)^+$ for $NANA_m(HexHexNAc)_nHex_3HexNAc_2DeoxyHex$, where m = 1-3, n = 2-4 and NANA represents N-acetylneuraminic acid (Fig. 3). A very weak peak is also observed at m/z 4568.9 which corresponds to m = 4, n=4. The gaps of 449.5 and 361.4 Da between the clusters correspond to the incremental masses for a permethylated lactosamine unit and permethylated N-acetylneuraminic acid, respectively. These data reveal that Asn_{448} has a complex sugar attached that is monofucosylated and has from 1 to 4 NANA units. The relationship of the number of NANA units to HexHexNac units strongly suggests that the carbohydrate attached to Asn_{448} in tPA is is a mixture of bi-, tri- and tetraantennary chains Although the patterns and molecular weights obtained by FAB do not enable one to unambiguously make this distinction, methylation analysis studies of this fraction supports the presence of bi-, tri- and tetraantennary chains, with triantennary dominating

STRUCTURAL ANALYSIS OF INTERLEUKIN-1α AND INTERLEUKIN-1β BY MASS SPECTROMETRY

G. D. Roberts, S. A. Carr, C. A. Meyers, K. O. Johanson, L. M. Miles
Smith Kline and French Laboratories, King of Prussia, PA 19406
and B. N. Green, VG Analytical, Ltd., Manchester, UK

The interleukin-1 (IL-1) family of proteins plays a crucial role in the pathogenesis of many human diseases, functioning as a key mediator in the response of the host to various infectious, inflammatory, and immunologic challenges. This array of activities resides in two distantly related proteins, IL-1β and IL-1α with molecular masses of 17 to 18 kDa. The recent availability of large amounts of recombinant protein will permit extensive structural studies to be undertaken and help to clarify the diverse functions of IL-1 proteins. Fast and reliable analytical procedures are needed to verify structures that have been determined by sequencing of the gene and to identify posttranslational modifications that may be present. FABMS and tandem MS can fill this niche and are especially useful in the structural studies of rationally mutated forms of proteins. We have characterized the primary structures of recombinant IL-1α and IL-1β produced by recombinant methods by direct molecular mass measurements on the intact proteins by FABMS and by FABMS peptide mapping.

Direct mass measurements were performed at VG Analytical, Ltd. using a high voltage (35 kV) CsI FAB gun (B. N. Green, 1987). For IL-1β the mean of five measurements was 17,365.7 +/- 15 Da (expected MH^+_{ave} is 17377.0). The error is -11.3 Da, or 0.06% of expected. For IL-1α the mean of five measurements was 18,026.0 +/- 39.2 Da (expected MH^+_{ave} is 18,048.6). The error is -22.4 Da or about 0.1% of expected. Unfortunately direct MW determination of proteins by MS often lacks sufficient sensitivity and mass measurement accuracy to detect structural variants that may be present at low, but significant levels.

To circumvent these problems limited cleavage strategies employing Asp-N and CNBr were used to obtain large proteolytic fragments (MW ≤ 10,000) that could be detected and mass measured with greater sensitivity and accuracy. Using this approach we obtained 100% sequence coverage of IL-1α with CNBr (Fig.1). Analyses employing CNBr and Asp-N gave less overall coverage of the protein, but provided valuable information on the COOH-terminus and on the site of deamidation (see below). A complementary set of fragments was also obtained by trypsin digestion of CNBr cleaved IL-1α. Complete coverage of the carboxyl-terminus of the protein was not achieved until the protein was reduced and alkylated (see below) The combined FAB mass spectral data from the trypsin and Asp-N digests of carboxamidomethylated and CNBr treated IL-1α cover 97% of the molecule (Fig.1).

The carboxyl-terminal sequence of IL-1α could not be confirmed by conventional approaches because it was completely resistant to digestion with carboxypeptidases. Consequently, digests using other proteolytic enzymes were considered and performed. For example residues 151-159 were shown to be present by the signals at m/z 1077.7 in the FAB mass spectrum of a CNBr/Asp-N digest, while residues 153-159 were confirmed by a strong signal at m/z 815.3 in the FAB mass spectrum of a CNBr/trypsin/chymotrypsin digest. Interestingly, the FAB mass spectra of a CNBr/trypsin digest failed to show the expected tryptic peptide consisting of residues 136-159; similarly, residues 137-150 were not detected in the CNBr/Asp-N digest. However, the expected signals were detected in proteolytic digests of carboxamidomethylated IL-1α (for example, see m/z 2723.5, residues 136-159 in Fig. 1). These observations suggest that the presence of free sulfhydryl groups in a protein that is subjected to CNBr treatment or proteolysis may produce erroneous results and, therefore, when working with cysteine containing compounds, reduction (if necessary) and alkylation is desirable.

An isoform of IL-1α, present at 3% of the level of the expected protein, was isolated by isoelectric focusing and subsequently analyzed by FABMS. The FAB mass spectra of IL-1α and IL-1α isoform were compared. In the spectrum of IL-1α residues 35-53 were indicated by a peak at m/z 2057.7, while this peak in the spectrum of IL-1α isoform was shifted upward one mass unit to m/z 2058.6, suggesting that an amide had been converted to the corresponding acid in this part of the protein. Similarly, the MH^+ peak, m/z 1445.2, for residues 36-48 was found to be shifted upward in mass by one mass unit in the FAB mass spectrum of a CNBr/Asp-N digest of the isoform compared to that of the native material (Fig. 1). Cleavage between residues Ala_{35} and Asn_{36} by the enzyme Asp-N strongly suggests that Asn_{36} has been converted to Asp_{36} in the isoform, which is also consistent with the observed mass shifts To unambiguously establish that Asn_{36} (versus Gln_{38} or Asn_{47}) had deamidated, the peptide of MH^+ 2058.6 from the CNBr/trypsin digest of the isoform was mass selected from the complex mixture (without chromatographic isolation or purification) and analyzed by tandem MS on a VG ZAB SE-4F. A series of amino-terminal B fragments (....NH-CHR_n-CO^+, n = residue number) were obtained that, beginning at the B ion corresponding to cleavage after residue three in this peptide, were shifted upward in mass by one mass unit, establishing that residue 36 is an Asp rather than an Asn, and that residues 38 and 47 have the in-chain masses for Gln and Asn, respectively.

IL-1β was studied less extensively than IL-1α. Signals observed in the FAB mass spectrum of a tryptic digest of reduced and carboxymethylated IL-1β account for 150 of the 153 residues in the protein (98% coverage).

In conclusion, we have shown that FABMS and tandem MS when used together are fast and reliable analytical procedures for verifying the entire amino acid sequences of small proteins and establishing the presence and nature of blocking groups and other posttranslational modifications that may be present.

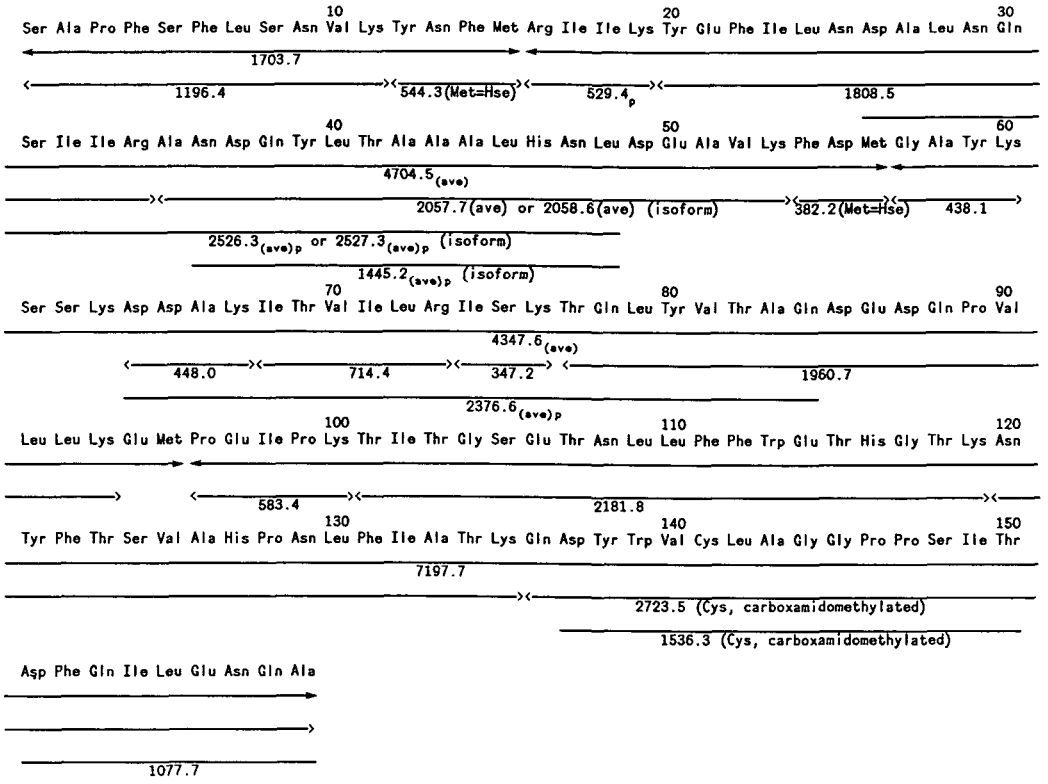

Figure 1. Amino acid sequence of IL-1α and IL-1α isoform indicating the peptides identified by FABMS of a CNBr digest (◄——►), a CNBr/trypsin digest (<——>) and a CNBr/Asp-N digest (——) of the two proteins. Peptides arising by incomplete cleavages are denoted with the subscript p. In cases where overlapping or redundant peptides were observed from the same or from different digests of the proteins, only the largest peptide signals are shown for clarity.

The elucidation of the primary structure of polypeptides from their FAB mass spectra is a challenging task which would be rather tedious without using computer-assisted strategies. Numerous approaches (1-5) were developed to rationalize the information content of these complex spectra and to reconstruct the peptide molecular structure from it. Unambigious deduction of the amino acid sequence from a FAB spectrum has nonetheless proved to be difficult even for peptides of moderate size (M<2000 Da). Although the information relating to the primary peptide structure can be extracted from the conventional mass spectrum, tandem mass spectrometry (MS/MS) offers considerable advantages when the analyte signal is likely to be suppressed by either matrix ions, salt adducts or impurities. The present work investigates the utility of using MS/MS (Tandem hybrid, BEqQ configuration) in conjunction with two different strategies to characterize the amino acid sequence of small peptides.

The first strategy ("brute force" approach) is an improved version of the program developed by Hamm et al. (2) which generates all possible sequences from a given composition using an efficient recursive procedure. All possible sequences are then compared in turn with the experimentally observed spectrum, using only the number of matches of fragment masses as a selection criteria.

The other strategy ("sequential" approach) generates first the potential peptide composition from the mass measurement, relative isotopic cluster peak intensities and diagnostic ions for the amino acid content (the composition found in this step can be submitted to sequence analysis via the first strategy). From each composition, sequences are generated by subtracting repetitively the masses of five fragments that correspond to 5 fragmentation schemes known for peptides (B,Y",Z",C" A(7)). Whenever a match is found, the intensity of the ion is used as a subscore. During the generation of sequences the averaged intensity for all fragment ions found is calculated, then multiplied by a weighting factor accounting for the number of consecutive sequence ions for a given scheme. Finally sequences with the ten highest scores are retained.

For polypeptides of M<800 Da, the degeneracy of peptidic empirical formulae will be small with respect to the given input provided that some amino acids can be identified to restrict the number of solutions. In fact one can use some approximation on the mass of the compound instead of measuring the exact mass and isotopic abundances in order to generate a list of peptidic empirical formulae. This approximation is possible since any peptide mass will lie between two extremes described by polyleucine and polycysteine, which represent respectively the highest and lowest mass sufficiency for a given nominal mass. Application of this approach for 6 small linear peptides ranging from 555 to 740 Da is shown in Table 1. Only a limited number of peptide empirical formulae and compositions can be generated under these boundaries. However, as the mass of the peptide increases it is crucial to identify as many amino acids as possible since the degeneracy of empirical formulae becomes important. The two most probable peptide

NRCC No. 29080

sequences generated using the two approaches described earlier are reported in Table 2. As can be seen from these results, both approaches were fairly successful in assigning the true sequence. The high number of matches and scores obtained from these potential sequences reflects the validity of the predicted fragmentation schemes and the wealth of information obtainable from the daughter ion spectrum. Similar analyses were conducted on peptides of higher mass. A mass tolerance of 15 p.p.m. from the exact mass was used in the "sequential" approach, whereas the exact amino acid composition was given in the "brute force" approach. The results obtained are presented in Table 3. These results show that for each peptide either the correct or a closely related sequence was generated in both approaches. In this case the number of mismatches is not related to limitations in the computer algorithms but is a direct reflection of the quality of the MS/MS data.

The main limitations are: [1] Degeneracy of sequences containing lysine (K) or glutamine (N), [2] In cases where many compositions are possible matching of only the masses might not provide enough discrimination among possible solutions, [3] The difficulty of experimentally fragmenting higher mass peptides M>800 Da by low collision energy CID processes is reflected by the low number of matches and scores.

DIGIT PRINTING OF PROTEIN VARIANTS

Hayashi,A.[*1], Wada,Y.[*1], Matsuo,T.[*2], Katakuse,I.[*3], Matsuda,H.[*2]
*1, Osaka Medical Center & Research Institute for Maternal & Child Health
*2, Institute of Physics, College of General Education, Osaka University
*3, Department of Physics, Faculty of Science, Osaka University (JAPAN)

An ultramicro method using secondary ion (SI) mass spectrometry was developed for the structural analysis of protein variants. This method is based on the mass spectrometric detection of the change in molecular weight which is accompanied by amino acid substitution of protein variants, and provides digitalized data on peptide analysis. Since the feature of this method may be comparable with the conventional "Finger Printing", we called it "Digit Printing".

Procedure: Purified and S-aminoethylated proteins were digested with trypsin, directly or after cleavage with cyanogen bromide, and a peptide mixture was examined with mass spectrometer without further purification. In addition to trypsin digestion, lysine endopeptidase, staphylococcal V8 protease, glycinamidation or Edman degradation were used for the modification of proteins. Mass spectra were obtained with a Matsuda-type mass spectrometer with SI mass spectrometric ion source and the data were analized with JMA-2,000 data analysis system on line.

Preliminary Experiment: A study, performed on 4 kinds of normal globin chains (α, β, γ and δ) and several hemoglobin variants whose structural abnormality was already known, proved the accuracy, reliability and reproducibility of this method.

Application to Hemoglobin Variants: As an example, the result on Hb A_2 Honai was shown in this figure. Compared with mass spectra from normal δ(a) and abnormal δ(b), the peak T10 at m/z 1,507 was missing and a new peak at m/z 1,477 appeared in b, showing a shift of 30 mass unit. From this result and the electrophoretic properties of this variant, it was concluded that glycine residue at 69th position was replaced by arginine in the abnormal δ chain of Hb A_2 Honai. The results of structural analyses were summarized in the table.

	83	90	95
δT10 (m/z1507)	Gly-Thr- -	- -Ser-Glu-Leu-His-Cys-Asp-Lys	
(m/z1477)	Gly-Thr- -	- -Ser-Val-Leu-His-Cys-Asp-Lys

Hb F Yamaguchi*	$^{A}\gamma^{T}$ 80 Asp → Asn	40	reported
Hb A_2 Indonesia	δ 69 Gly → Arg	1	reported
Synthetic Variant	α 42 Tyr → Phe	1	
Synthetic Variant	α 42 Tyr → His	1	

* These variants were detected by neonatal mass screening in Osaka Prefecture, Japan.

The structure of 13 natural and 2 synthetic hemoglobin variants were determined or confirmed with this method. Among them, 5 new variants included. All γ chain variants were detected by neonatal mass screening and their structural analysis was performed using dried blood on filter paper.

Application to Other Protein Variants: The method was used for the structural analysis of a prealbumin variant extracted from the plasma of a patient with familial amyloidotic polyneuropathy. The result was identical with the one obtained by the conventional method with valine replaced by methionine residue at 30th position. Further, it was successfully applied to the accurate assignment of amide residues in mammalian calmodulin molecule.

Conclusion

(1) The reliability of Digit Printing was confirmed on various kinds of human hemoglobin variants with known structural abnormality which included electrophoretically and chromatographically silent mutations.

(2) This technique was successfully applied to the structural analysis of human hemoglobin and other protein variants, including several new variants.

(3) In spite of its limit in detecting leucine ≠ isoleucine substitution, this technique showed several advantages over conventional method: very high sensitivity, easy and speedy operation, and accurate detection of abnormal peptide.

ANALYSIS OF PHENYLALANINE LIBERATED UPON HYDROLYSIS OF THERAPEUTIC PEPTIDES USING CAPILLARY COLUMN GC/NCIMS. D.J. Liberato, E.P. Heimer E.K. Fukuda, M. Ahmad and W.A. Garland, Departments of Drug Metabolism and Peptide Research, Hoffmann-La Roche Inc., Nutley, New Jersey 07110

The requirement for sensitive and selective bioanalytical methods has increased in proportion to the desire for a better understanding of biological processes at the molecular level. In particular, the continued growth in the use of peptides and proteins in biomedical and clinical research has generated an increased need to develop alternative techniques for the quantification of peptides and proteins at low concentrations. Great progress has been made in the sensitive determination of peptides and proteins in biological samples utilizing both immunoassay and bioassay techniques. However, it is recognized that these techniques are not always precise (no reference standard) or specific. The studies detailed here are an exploration of the utility of quantifying Growth Hormone Releasing Factor by GC/NCIMS analysis of phenylalanine (Phe) liberated after hydrolysis of GRF samples that contain stable isotope labelled ($^{13}C_6$-Phe^6)-GRF as the reference.

The most sensitive analytical techniques for the analysis of phenylalanine (Phe) all involve the derivatization of the amine to form an amide, followed by further derivatization of the carboxylic acid to form an electronegative ester. In the studies reported here, the carboxyl group was converted to a pentafluorobenzyl (PFB) derivative and the amine group was acetylated. Table I summarizes results from experiments undertaken to optimize the GC/NCIMS sensitivity of PFB-Phe by comparing the following N-acyl derivatives: acetyl, trifluoroacetyl, pentafluoropropionyl and heptafluorobutyryl (HFB). All derivatives gave spectra characterized by $[M-PFB]^-$ ions. The derivative that gave the greatest ionization efficiency was PFB-HFB-Phe; its NCI mass spectrum is shown in Figure 1.

Figure 2 illustrates using [Ring U-$^{13}C_6$] - Phenylalanine that the GC/NCIMS technique is very sensitive. However, although 1 pg of this stable isotope labelled material injected on column yields a good signal at m/z 366, the data illustrated in Figure 3 demonstrate that there is significant background contamination. The chromatogram in Figure 3 was obtained from an experiment in which 1 ng of $^{13}C_6$-Phe was added per tube prior to derivatization, as the reference standard. In experiments over 4 weeks (N=18 tubes) the mean contamination was found to be 0.8 ng/tube (CV=89%). Experiments to determine if the source of this background contamination was from the solvents or reagents involved separately lyophilizing 10 times the amount used in our procedure into tubes that also contained 1 ng of $^{13}C_6$-Phe as reference. These studies undertaken in duplicate found no increased background.

To determine the feasibility of the quantitative analysis of GRF (1-44)-NH_2, mixtures of GRF and ($^{13}C_6$-Phe^6)-GRF were hydrolyzed, derivatized and subjected to GC/NCIMS. Injections of duplicate samples were made on the GC/MS system and quantitative analysis was carried out by isotope dilution and selected ion monitoring, using the ratio of $[M-PFB]^-$ ions from PFB-HFB-Phe(m/z 360) and PFB-HFB-$^{13}C_6$-Phe(m/z 366). A typical calibration curve for GRF, generated using a stable isotope labelled reference standard, is shown in Figure 4. It is linear over the range 240ng-8µg. Background contamination prevented analysis below approximately 100 ng.

The detection limit for derivatized $^{13}C_6$-Phe was on the order of 100fg-1pg, indicating that the quantification for a peptide of molecular weight 5,000 containing one phenylalanine should be in the range of 10-100pg. However, because of background amino acid contamination of unknown origin, quanatification at these levels is not practical, We are currently attempting to improve the technique for the 1 ng range. In addition, we are also in the process of applying the technique utilizing a peptide that contains a non-naturally occurring amino acid that should not suffer from background interference.

Morphinans in Mammals

K.F.Faull, G.J.Feistner and C.J.Weitz, Departments of Psychiatry and Pharmacology, Stanford University School of Medicine, Stanford, Ca 94305.

The work of Davis and Walsh and others around 1970, which suggested the possibility of morphine biosynthesis in mammals, spawned an investigation for naturally occurring morphine in extracts of mammalian tissues and led to the detection by several groups of substances recognised by antisera raised against morphine. Dr. Avram Goldstein and colleagues at Stanford developed a sequential blank procedure to help in the identification of these compounds in tissue extracts. In the sequential-blank proceedure glassware, reagents and columns were sequestered exclusively for extractions. A tissue-less extraction was always performed with an appropriate volume of extraction solvent. This blank sample was carried through all steps of the purification. Each tissue extraction followed behind its own sequential blank in the same glassware and columns. Using this approach three peaks of immunoreactivity were repeatedly observed when extracts of brain and adrenal were chromatographed on reverse phase HPLC (Figure 1) in the absence of immunoreactivity in the corresponding sequential-blank extracts.

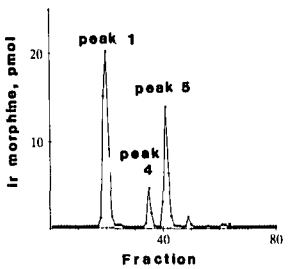

Figure 1. Typical HPLC profile of ir morphinans extracted from Bovine hypothalamus.

Sufficient quantities of these peaks were isolated for unequivocal structural identification by GC/MS. As a further precaution against false positive results, GC/MS experiments were conducted with GC columns naive to the morphinan(s) in question, and retention times and mass spectra of authentic compounds were obtained only after the biological sample had been analysed.

Using this approach two of the immunoreactive peaks in bovine brain were identified as the trifluoroacetyl (TFA) derivatives by GC/MS as morphine (peak 1) and codeine (peak 4) purified from ca. 1200 bovine hypothalami (wet wt. ca 20kg) [Weitz et al., PNAS 83; 9784-9788 (1986), and reported at the 35th ASMS meeting in 1987]. The identity of the third peak of immunoreactivity (peak 5) has recently been established as 6-acetylmorphine by GC/MS and GC/high resolution MS of the TFA derivative from material isolated from ca. 1750 bovine hypothalami (wet wt. ca 28kg) [Weitz et al., PNAS in press]. 6-Acetylmorphine has not been previously described as a natural product in plants or animals. It has long been known as the metabolite in part responsible for the biological properties of heroin (3,6-diacetylmorphine). However, we have excluded slaughterhouse or laboratory contamination by any morphinan as well as derivation from the morphine in tissues during our procedures. 6-Acetylmorphine is more potent than morphine in vivo chiefly by virtue of its greater penetration into the central nervous system, and we conclude that it is a normal constituent of mammalian brain.

In the opium poppy the pathway of morphine biosynthesis (Figure 2) has been elucidated by the incorportion of labelled precursors. Intramolecular coupling of reticuline to form salutaridine is the critical step that generates the morphinan skeleton and defines the stereochemistry of the series. The possibility of morphinan biosynthesis in mammals has been raised by our recent demonstration of the conversion in vivo and in vitro of reticuline to salutaridine by rat liver [Weitz et al., Nature 330:674-677(1987)]. In this work we identified the product synthesised from reticuline by tissues using GC/MS. This necessitated the development of a procedure for the analysis of salutaridine in quantities down to a few picomol.

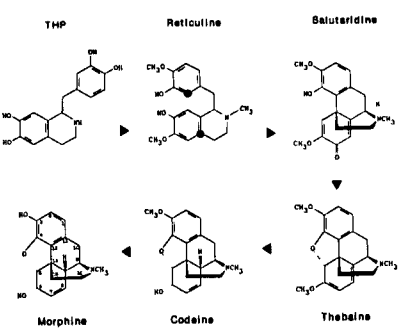

Figure 2. Biosynthetic pathway for morphine in the opium poppy, P. somniferum. THP (tetrahydropapaveroline) is derived from tyrosine and dopamine. The carbons marked by dots in reticuline participate in oxidative coupling to generate salutaridine.

Attempts to chromatograph underivatised salutaridine (free base) were unsuccessful, presumably because it decomposed during passage through the bonded-phase medium-polarity fused-silica capillary column. This result was obtained in spite of the fact that underivatised morphine and codeine (free bases) eluted with reasonable retention times and good peak shapes from the same column. Attempts to derivatise salutaridine on the hydroxyl function by treatment with silylating reagents and perfluoro-acid anhydrides were unsuccessful, presumably because of steric restrictions. However, salutaridine was successfully derivatised by treatment with O-[pentafluorobenzyl]hydroxylamine HCl in pyridine (75°C, 1 hr.). The resulting oxime derivative gave the expected EI mass spectrum, and under electron capture conditions had abundent high mass ions suitable for SIM (Figure 3).

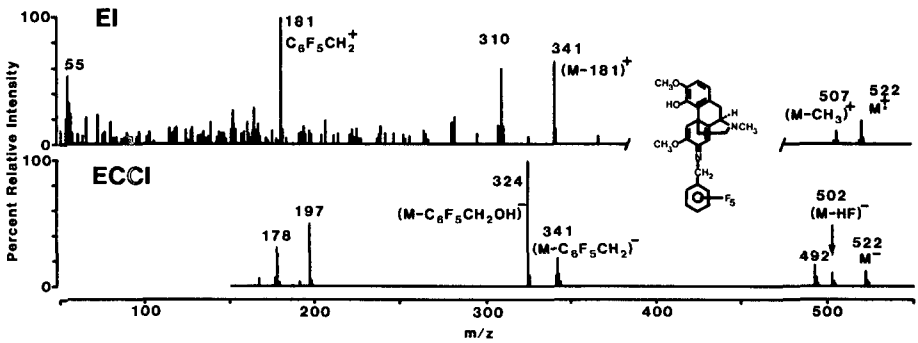

Figure 3. EI and electron capture negative ion mass spectra of the O-[pentafluorobenzyl]-hydroxylamine derivative of salutaridine. Presumed structures of some of the ions are indicated.

The sensitivity obtained for the molecular ion with this derivative under electron capture conditions exceeded that obtained under EI conditions by ca. 200-fold. At the 30 picomol level, under electron capture-SIM conditions, the 4 predominant ions (m/z 522,492,341,324) yielded intense peaks with signal/noise ratios between 23/1 and 33/1.

Analysis of the biosynthetic product obtained from in vitro incubations of reticuline with rat liver homogenate produced the results shown in Figure 4. The biosynthetic product and salutaridine standard produced specific ion currents with retention times and relative peak areas that were identical within experimental error. A pre-boiled control homogenate did not generate selected ion currents with the retention time of interest. The unusual features of the intra-molecular coupling necessary for the conversion of reticuline to salutaridine suggest that it is likely to be catalysed by a specific enzyme.

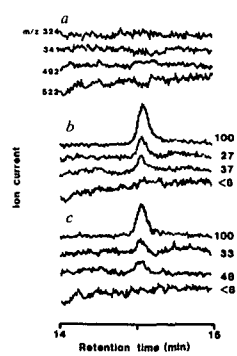

Figure 4. SIM chromatograms obtained under electron capture negative CI conditions for: a)pre-boiled control; b)putative salutaridine biosynthesis product; c)salutaridine standard.

The physiological significance of the naturally occuring morphinans found in mammalian brain is unclear: an essential element necessary for the demonstration of physiological significance would be evidence of control of tissue concentrations or turnover of morphine following experimental manipulation. Furthermore, a complete biosynthetic pathway for morphine in mammals has yet to be demonstrated: essential components of such a demonstration would be: 1)evidence of biosynthesis from putative precursors; 2)evidence for the presence of these biosynthetic precursors as normal constituents of mammalian tissues. Our future work in this area will be directed towards addressing the issue of the natural occurrence in mammals of the morphine biosynthetic precursors.

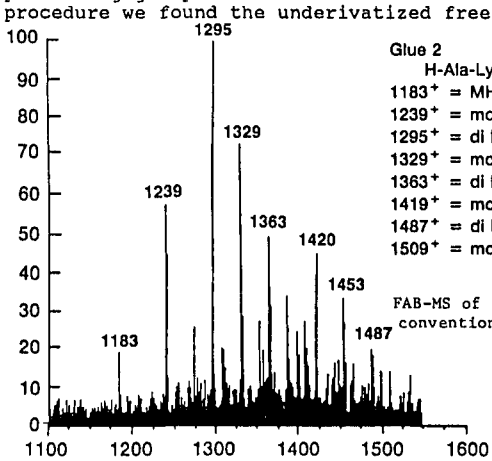
CHARACTERIZATION OF SYNTHETIC ADHESIVE DECAPEPTIDES BY FAB-MS AND HPLC-MS;

M.K.Gabriel, D.M.Hindenlang, R.D.Sedgwick, M.D.Swerdloff, and J.I.Williams
Corporate Technology Allied-Signal, Morristown, NJ 07960

Introduction. Natural protein glues are an important aspect of adhesion technology and the proteins responsible for the attachment of marine organisms to surfaces in the presence of water are especially interesting. Recent literature on polyhydroxy and phenolic proteins from intertidal mussels has focused attention of specific repeating decapeptide sequences. In order to further investigate structure activity relationships of these repeat units, a series of related decapeptide glues have been made by soild-phase synthetic techniques. The synthetic decapeptide products have been analyzed by Fast Atom Bombardment-MS and Thermospray HPLC-MS.

Experimental. Protected glue peptides were synthesized on PAM resin using modified Merrifield SPPS chemistries. All terminal amino groups were protected with t-butyloxycarbonyl with side chain amino groups in Lys protected with 2-chlorobenzyloxycarbonyl or triflyoroacetyl. Phenolic groups (Tyr) were protected with 2-bromobenzyloxycarbonyl while aliphatic alcohols in Ser, Thr and Hyp were protected with benzyl groups. The conventional cleavage and deprotectron step was modified to eliminate use of HF. We started with a detailed analysis of the complex reaction products from the modified cleavage/deprotection reactions. This was achieved by combinations of the following techniques. (1) Analytical scale HPLC with diode-array detection (HP 1090) followed by FAB-MS on the crude products using a VG Analytical ZAB-HF mass spectrometer; (2) Preparative scale HPLC (Spectra Physics 8100) followed by HPLC-MS (Varian 5020) using Thermospray ionization on a VG Mass Lab 30-250T Triple Quadrupole mass spectrometer. These techniques were used appropriately in a feedback loop to guide the development of more successful cleavage and deprotection steps.

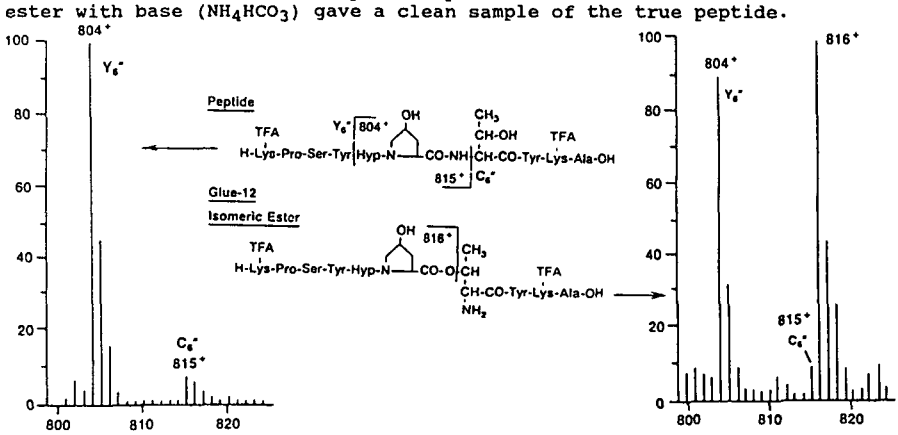
Modified Cleavage and Deprotection. Initially the method of Yajima et al.* using trifluoromethane sulfonic acid (TFMSA) with trifluoroacetic acid (TFA) was tried. This led to very complex reaction mixtures which HPLC showed to contain as many as 20 components. FAB-MS showed that these components were in fact derivatives of the targeted glue decapeptide sequence. The components were butoxy, benzyloxy, chlorophenoxy and bromophenoxy derivatives of the peptide with combinations of up to any four of these radicals adding to the decapeptide at its phenolic and hydroxlyic amino acids. We conclude that the solid-state synthesis was efficient and that deprotection and cleavage from the resin was complete but that deprotection was followed by complex attack on the peptide by protecting-group radicals to form the observed derivatives. By this procedure we found the underivatized free peptide to be a minor product.



Glue 2
H-Ala-Lys-Pro-Ser-Tyr-Hyp-Hyp-Thr-Tyr-Lys-OH
1183^+ = MH^+
1239^+ = mono butyoxy Glue-2
1295^+ = di butoxy Glue-2
1329^+ = mono butoxy mono benzyloxy Glue-2
1363^+ = di benzyloxy Glue-2
1419^+ = mono butoxy di benzyloxy Glue-2
1487^+ = di benzyloxy mono clorobenzyl oxy Glue-2
1509^+ = mono butoxy tri benzyloxy Glue-2

FAB-MS of complex mixture from conventional synthesis of Glue-2

The one-step TFMSA/TFA cleavage and deprotection was abandoned in favor of a two-step deprotection and cleavage strategy. Both steps were monitored by HPLC and FAB-MS and the following procedures were shown to be effective. (a) Deprotection of the peptide on the PAM resin requires controlled addition of TFMSA to the resin in a m cresol:DMS:TFA mixture at 0°C. (b) Cleavage of the peptide from the resin requires reaction in a thioanisole: 1,2-ethanedithio:TFA mixture with controlled addition of TFA:TFMSA at 0°C. These procedures indicated the complete elumination of all derivatized peptide products. However, cleavage from the resin in acid solution always gave an HPLC trace showing two components. FAB-MS of this mixture showed a single molecular weight at the correct value for the targeted peptide. This was confirmed by on-line HPLC-Thermospray-MS which indicated that the two components were isomers. Preparative HPLC followed by FAB-MS showed the later eluting component to be the true peptide while the earlier eluting isomer was formed by replacement of a backbone peptide linkage by an ester involving the secondary alcohol in threonine. Thus for Glue-12 the true peptide shows an intense 804^+ due to Y_6'' and a weak 815^+ due to C_6''. The isomeric ester also shows 804^+ (Y_6'') but an intense 816^+ in which an amide has been replaced by an ester. Treatment of the isomeric ester with base (NH_4HCO_3) gave a clean sample of the true peptide.



Using these methods we have synthesized a series of decapeptides and some larger analogues and confirmed their sequences by FAB-MS. In general the most intense fragments involve cleavages adjacent to Hyp or Pro giving ions of the type Y_n''. Fragments retaining the N terminus are less intense but frequently gave more complete sequence information. The series A_n was frequently complete for the decapeptides with abundant confirmatory evidence of the sequence coming from partial B_n and C_n'' series.

STRUCTURAL CHARACTERIZATION OF TWO FORMS OF CELLULAR RETINOL BINDING PROTEIN, TYPE II USING A COMBINATION OF FAB AND EI MASS SPECTROMETRY AND EDMAN CHEMISTRY:

W.H. Schaefer*, D.E. Ong, B. Kakkad, and I.A. Blair,
Departments of Biochemistry and Pharmacology, Vanderbilt University, Nashville, TN 37232. and *present address: Department of Drug Metabolism, SmithKline and French Laboratories, King of Prussia, PA 19406.

Vitamin A is essential for the regulation of growth and differentiation of epithelial tissues, as well as for vision . Several forms of vitamin A, including retinol, retinal, retinoic acid, and fatty acid esters of retinol, are involved in its function, transport, and storage. Each of these forms is essentially water-insoluble and the utilization of retinoids appears to require specific carrier or binding-proteins to overcome this hydrophobicity. Cellular retinol-binding protein type II (CRBP II) is the most recently described intracellular retinol-binding protein (Ong, D.E. (1984) J. Biol. Chem. 259, 1476-1582). In adult rats the highest levels of CRBP II are found in the small intestine. It accounts for more than 1% of the soluble protein recovered from the jejunal mucosa, suggesting a role for CRBP II in the absorption of retinol in the small intestine.

CRBP II can be completely resolved into two forms (CRBP IIA and CRBP IIB) that appear to be almost identical. Both forms are present in the same tissues and are present in whole rat pups and rat small intestine in equimolar quantities. CRBP IIA and IIB are very similar in molecular weight and both bind retinal as well as retinol. One observed difference between the two forms was the amount of endogenous retinol recovered bound to the proteins after purification. CRBP IIA was isolated with ten-fold more endogenous retinol bound than CRBP IIB; however, their binding constants and absorption spectra in vitro are indistinguishable.

The gene coding for CRBP II has been isolated from a rat small intestine cDNA library using oligonucleotide probes based on the amino acid sequence of the amino terminus of CRBP IIA (Li, *et al.* (1986) Proc. Natl. Acad. Sci. USA 83, 5770-5783). The nucleotide sequence of the gene was determined and the amino acid sequence deduced for CRBP IIA was identical to the sequence of the amino terminus of the protein established by Edman sequencing. CRBP IIB was found to be resistant to Edman degradation impeding structural characterization. Thus, it was not known whether CRBP IIB was structurally similar, but not identical to CRBP IIA, or whether the two proteins were actually products of the same gene, but had undergone post-translational modification. We have compared the structures of CRBP IIB and CRBP IIA using a combination of techniques including amino acid composition and sequence analyses, and FAB and GC/EI-mass spectrometry to determine the structural features that may be responsible for the differences observed between these two forms of CRBP II. Reduced, carboxymethylated forms of CRBP IIA and CRBP IIB were cleaved with trypsin, and underivatized forms of both proteins were cleaved with cyanogen bromide. . The peptides produced were separated by HPLC prior to structural characterization. Purified tryptic peptides that were too large for FAB mass spectral analyses were digested further with S. aureus V8 protease. Peptides spanning the entire length of both protiens were recovered from the trypsin digests. The sequence of the blocked amino terminal peptide from CRBP IIB was determined by GC/EI-MS following derivatization of the pepitde with BSTFA. Furthermore, these studies provide confirmation for the derived amino acid sequence of CRBP IIA.

Conclusions

1. A combination of methodologies including FAB and GC/EI-mass spectrometry, as well as amino acid composition and sequence analyses was useful for comparing the structures of CRBP IIA and CRBP IIB.
2. GC/EI-mass spectrometry was important for determining the sequence of the blocked amino terminus of CRBP IIB.
3. These structural analyses show that the amino terminus of CRBP IIB is acetylated, but that of CRBP IIA is unmodified. (For example, FAB mass spectra of amino terminal peptides from both proteins are shown in Figure 1.)
4. No differences in the primary structures of the amino terminal regions of either protein were detected that could have directed the acetylation of CRBP IIB, or the deacetylation CRBP IIA. The initiator methionine is absent from both CRBP IIA and CRBP IIB.
5. The amino acid sequences of both proteins are identical and confirm the structure deduced from the sequence of the cDNA for CRBP IIA.

QUANTITATION OF HIGH MOLECULAR WEIGHT NEUROPEPTIDES BY THERMOSPRAY HPLC/MS.

R. D. Voyksner, T. Pack, and F. Williams, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709.

Neuropeptides have been found in many regions of the human body. They are in greatest abundance in tissues and fluids of the central nervous system. The fact that these peptides are active in the picomolar range, coupled with the existence of many different individual peptides, places an enormous burden on analytical methodology for their detection.

Thermospray HPLC/MS was successfully applied to a class of neuropeptides called endorphins. The thermospray spectra acquired for α-, β-, and γ-endorphin were simple, showing $[M+H]^+$, $[M+Na]^+$, $[M+2Na-H]^+$ ions and double and triple charged ions ($[M+2H]^{+2}$, $[M+3H]^{+3}$). In negative ion detection $[M-H]^-$, $[M-2H]^{-2}$ and $[M-3H]^{-3}$ were observed. Thermospray spectra exhibited no fragment ions indicative of the amino acid sequence. The presence of multi-charged ions permitted detection of peptides (β-endorphin) which have molecular weights beyond the mass range of the instrument. The thermospray spectra also exhibited a low noise background compared to the FAB/MS spectra for the same compounds.

Thermospray HPLC/MS ion currents for the endorphins were very dependent on the thermospray vaporizor temperature, tip condition, and repeller voltage. For the analysis of the endorphins, the vaporizor was operated at 90-94°C, a 5-10°C lower temperature than conventional thermospray HPLC/MS. The lower temperature results in only 75-85% solvent evaporation. The source temperature was raised to 270°C, about 20-50°C above normal, to provide heat to insure evaporation and prevent freezing from the adiabatic expansion of solvent in the source. The vaporizor tip also plays a critical role in the acquisition of acceptable thermospray spectra. The tip was cut to insure a straight and long stream (10-15 cm) of water at 1 mL/min (at ambient temperature and pressure). These conditions, coupled with the lower vaporizor temperature, appear to enhance the ion evaporation process necessary for the ionization of peptides.

The repeller in the thermospray source plays an important role in the high mass sensitivity and relative intensity of multi-charged ions to single-charged ions in thermospray. Usually a repeller voltage of 100-150V was optimal for the $[M+H]^+$ ion current for α-endorphin (mw 1745). However, these high voltages resulted in reduced ion currents for the double charged ions of β- and γ-endorphin. Ion currents for the multi-charged ions were optimized at lower voltages, usually in the 40-70V range. Due to the variety of peptide molecular weights encountered, the repeller was operated in the 60-80V range to give the best compromise in sensitivities for the single and multi-charged ions.

The development of suitable quantitative methods by thermospray HPLC/MS required the use of internal standards. The internal standards evaluated for the determination of β-endorphin include leu^5-β-endorphin, N-acetyl-β-endorphin, β-endorphin fragment 1-27, β-endorphin (camel), and γ-endorphin. The internal standards α-endorphin, des-try-γ-endorphin and dynorphin-β were evaluated for the quantitation of γ-endorphin. The use of these internal standards improved the injection to injection reproducibility in the HPLC/MS analysis. Usually the relative standard deviation for replicate injections was 5-6%. N-Acetyl-β-endorphin appeared to be the best choice for an internal standard for the determination of β-endorphin. The low relative standard deviation of N-acetyl-β-endorphin (2%) and its co-elution with β-endorphin compensated in part for slight instrumental changes during the analysis. However, most of the test compounds evaluated (except γ-endorphin) were suitable as internal standards for β-endorphin. The three internal standards evaluated for γ-endorphin all proved suitable.

Calibration curve generation and quantitation of plasma extracts and cerebral spinal fluid (CSF) extracts for β- and γ-endorphin was successful by HPLC/MS. Calibrations were generated using multiple ion detection, monitoring the $[M+H]^+$ or $[M+2H]^{+2}$ ions for the internal standard and target endorphin. The calibration for β-endorphin, using N-acetyl-β-endorphin or β-endorphin fragment 1-27 as an internal standard, was linear (correlation coefficient 0.998) over a range of 30 pM to 300 pM. The γ-endorphin calibration, using α-endorphin as an internal standard, was linear from 10 pM to 300 pM (correlation coefficient 0.994). The HPLC/MS chromatogram for the analysis of β-endorphin and γ-endorphin in plasma or CSF exhibited few matrix interferences at the retention time for these endorphins or internal standards. The ratio of the peak areas for the internal standard to the target peptide was used to determine the amount of endorphin from the calibration curve. The measured values (Table I) were usually within 10-20% of the amount spiked.

June 5-10, 1988, San Francisco, CA

The coupling of an immobilized enzyme column (trypsin) after the HPLC improved the specificity and sensitivity for the MS detection of the endorphins. Trypsin hydrolyzes the lysine and arginine amino acid bonds, resulting in several fragment peptides. For example, the hydrolysis of ß-endorphin results in the five tryptic fragment peptides (T_1-T_5) shown below:

YGGFMTSEK	SQTPLVTLFK	NAIIK	NAYK	KGE
T_1	T_2	T_3	T_4	T_5
MW1018	MW1132	MW557	MW493	MW442

The hydrolysis of the peptide has two advantages. First, identification of the peptide such as ß-endorphin does not need to be based on one ion, such as the $[M+2H]^{+2}$, but can be based upon the detection of the tryptic fragments ion. Second, detection of the fragment peptides can result in 10-30 times better sensitivity than the detection of the unhydrolyzed peptide. It appears that the lower molecular weight fragment peptides are more efficiently ionized, transmitted, and detected than the unhydrolyzed peptide.

The HPLC-trypsin hydrolysis-MS methods were used to generate a calibration curve for ß-endorphin. The calibration was based upon tryptic fragment T_1 for ß-endorphin (mw 1018) and fragment T_1 for the internal standard leu^5-ß-endorphin (mw 1000). The calibration was linear (0.97) over the concentrate range of 5-380 pM of ß-endorphin.

Formulated polypropylene, like most commercial polymers, is a complex substance. Typically it will contain residual oligomers, various additives and catalyst residues in addition to the polymer itself. Characterisation of commercial polymers can yield useful structural information together with some knowledge regarding the processing history of the polymer. Also, characterisation of the additives present in a compounded polymer can help establish its formulation specification.

Nine polypropylene samples originating from different sources were investigated using two methods; direct pyrolysis-mass spectrometry (Py-MS) and thermal desorption -gas chromatography/mass spectrometry (TD-GC/MS). Computerised pattern recognition methods were used to help interpret the results from both methods. The TD-GC/MS system used consisted of an Envirochem Unacon 810A thermal desorber unit and high temperature furnace interfaced to a VG7070 GC/MS with Finnigan Super Incos data system. The sample loaded into a quartz tube was continuously purged with helium and heated using the programmable furnace (temperature profile RT-150°C @24°C/min, final temperature held for 10 mins). The volatiles released during heating were concentrated by consecutively collecting and desorbing them in two selectively adsorbent trapping devices connected in series before being transferred in the form of a narrow band plug of sample to the capillary column of the GC for analysis. Composite mass spectra were calculated by summing the spectra contained in a chromatogram and correcting for background. This procedure was carried out for each analysis.

The Py-MS system used consisted of a Pye Unicam Curie-point pyrolyser interfaced to a Balzers QMG511 quadrupole mass spectrometer controlled by a Digital PDP 11/23 computer, which was also used for data storage and some pre-processing. Preheating of the pyrolyser (180°C) was required to prevent condensation of the pyrolysis decomposition products, the pyrolysate, consequently the volatiles studied in the thermal desorption experiments were not studied in these analyses. Pyrolysis (770°C for 15s) was carried out under vacuum. 20 scans were performed per analysis and an average mass spectrum was calculated in each case.

Principal component analysis[1] (PCA), a pattern recognition method from the Einsight package (Infometrix Inc.), was used to help interpret and compare the mass spectral results. PCA enables a two-dimensional overview of any relationships that may exist between samples (and/or variables) to be achieved. The principal component plots obtained using the TD-GC/MS mass spectral data, which was normalised with respect to total ion intensity, are presented in figures 1 and 2. Good intra-sample reproducibility is indicated by the clustering of the triplicate analyses for each sample in both plots. In Fig 1. samples B and E are well separated from the others, this was found to be due to an antioxidant, (2,6,di t-butyl 4 methyl phenol), that was only present in these samples. By removing samples B and E and performing a further PCA the relationships between the rest of the samples was explored in more detail, this plot for the reduced set of polypropylene samples is shown in fig 2. The composite mass spectra of several of these samples were indistinguishable to the human eye, but were differentiated with some confidence using PCA. Good inter-sample differentiation is shown for all the samples analysed. PCA carried out using the Py-MS data, however, showed no significant differentiation between the samples.

Conclusions

TD-GC/MS/pattern recognition has been shown to be a successful method for the differentiation of commercial polypropylene samples. These results illustrate the potential of this technique for studying other polymer systems. Direct Py-MS was unable to differentiate these samples due the absence of residual volatiles and the domination of the spectra by relatively uninformative polymer peaks.

PD-MS AND FAB-MS IN THE SEARCH FOR NEUROPEPTIDES

G.J. Feistner[1], P. Roepstorff[2], P. Højrup[2],
K.F. Faull[1], C.J. Evans[1], and D.F. Barofsky[3]
[1]Department of Psychiatry, Stanford Medical Center, Stanford, CA 94305

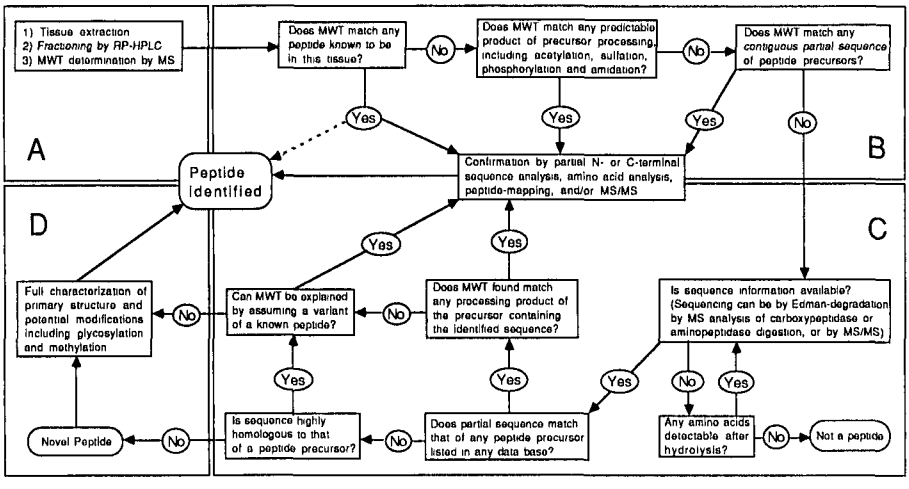
[3]Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331

The molecular weights (MWTs) of peptides can conveniently and rapidly be determined by mass spectrometry, even when the sample consists of a mixture of peptides. In the search for novel neuropeptides, MWT information is very powerful in that it allows to quickly identify known peptides and to concentrate efforts on potentially new ones. The benefit obviously will be greatest when the MWTs are known early in the investigation. Fortunately, it appears that only a single reversed-phase HPLC step is needed to obtain the peptides of an acidic tissue extract in a form suitable for either FAB-BE-MS or PD-TOF-MS (Scheme 1, section A). The tissue extract chosen for investigation was bovine posterior/intermediate pituitary. It provided a number of known peptides, which were useful for the evaluation of our methodology, as well as the potential of finding new peptides, especially those which could be predicted to derive from known precursor molecules.



Scheme 1 Algorithm used for the identification of peptides.

The mere knowledge of the MWTs can suggest a known peptide, a peptide arising via a known *processing pattern of a precursor*, or a *peptide arising from a precursor by a yet unidentified* processing pattern (Scheme 1, section B). We screen for the latter possibility by looking for a match of a measured MWT with that of any peptide corresponding to a contigous partial sequence of a precursor peptide using a computer program developed for this purpose. This has, in particular, made the identification of POMC(83-103) (MWT 2081; see Fig. 1) straightforward. Only after all the above options have been exploited without success, do we try to obtain sequence information, screen (if necessary) protein data bases for sequence homology, and try to predict the peptide under consideration from the combined knowledge of partial sequence and MWT (Scheme 1, section C). Always trying to predict a possible candidate helps us to select a suitable confirmative experiment and to

avoid failures such as the attempt to sequence an acetylated peptide. Purification to homology and full characterization of primary structure and possible modifications (Scheme 1, section D) are reserved for those cases where we encounter a novel peptide or modifications such as glycosylation, which prevents prediction of the MWT, or as methylation, where a consensus sequence leading to such a modification is not known.

We found processing products derived from the genes of vasopressin- and oxytocin-neurophysin as well as proopiomelanocortin. In summary, the identified peptides (Fig. 1) account for the entire lengths of the precursor molecules, suggesting that we may indeed detect the majority of the peptides present. Those processing products which, to our knowledge, have been isolated and characterized for the first time from bovine tissue, are highlighted with a dot matrix. It is worthwhile to point out that we could observe peptides regardless of originating precursor and posttranslational modifications. Mass spectrometry therefore provides a unique combination of specificity and broad applicability not offered by any other methodology.

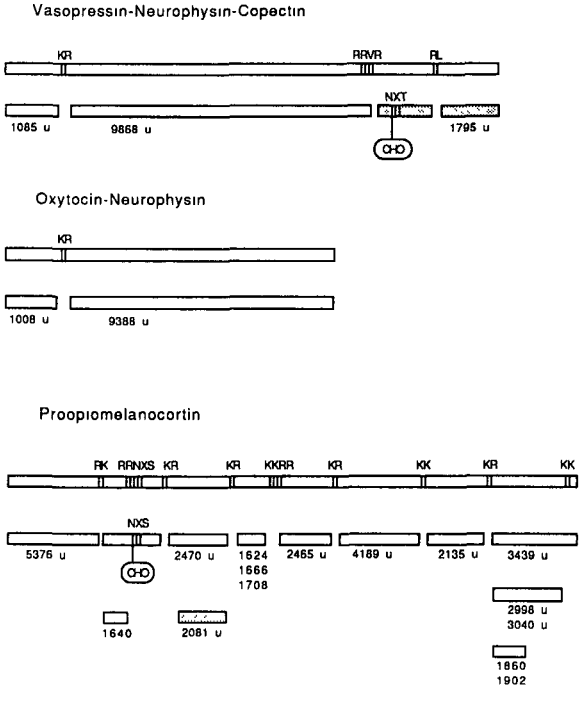


Fig. 1

Processing products from three precursor molecules that were identified following the algorithm outlined in Scheme 1. Multiple mass numbers correspond to acetylated and non-acetylated products.

When comparing PD-TOF-MS versus FAB-BE-MS (R=500) for their usefulness in the routine screening for neuropeptides, using a mass range of 0-22,000 in PD-TOF-MS and of 11,000-1,000 in FAB-BE-MS, we found that due to its integral nature the PD-TOF-MS measurement achieves about an order ofmagnitude greater sensitivity. On the other hand, PD-TOF-MS was somewhat less accurate (± 3 u up to MWT 5,000) than FAB-BE-MS (± 1 u). The accuracy of the measurement for the larger neurophysins (MWT 9,000-10,000) and the N-fragment of POMC (MWT approx. 5400) is not yet known, because they seem to comprise of several closely related compounds, which are still under investigation. An accuracy of ± 3 u is good enough for predicting many peptides, but fails to distinguish between amidated peptides and their corresponding free acids. Also, searching for possible matches of an experimental MWT with a contiguous partial sequence of a precursor will give too many unnecessary suggestions if a window of ± 3 u is allowed. For these types of problems we routinely employ FAB-BE-MS with unit resolution over a mass range of 3,600-600 u, whereupon we achieve an accuracy of better than ± 0.2 u.

THERMOSPRAY MASS SPECTROMETRY OF METHIONINE ENKEPHALIN

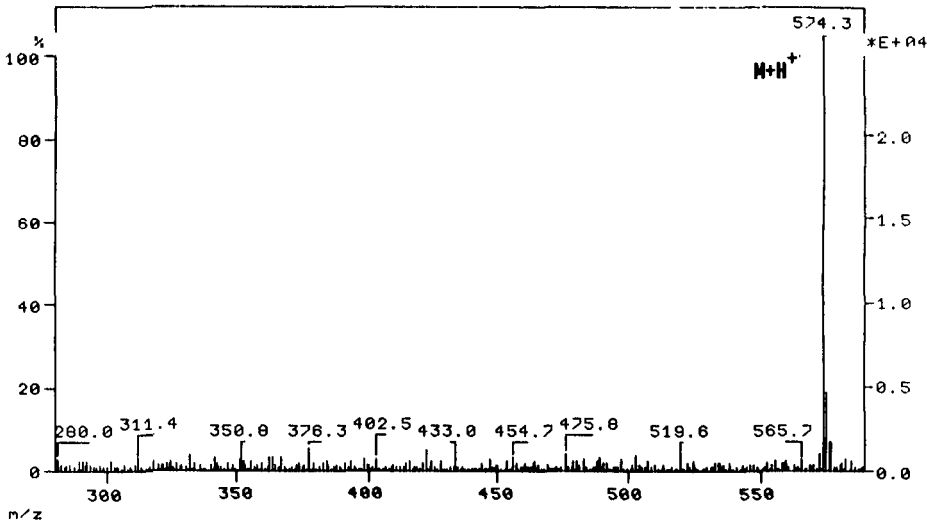
Louis L. Martin and Joseph F. Greer
Drug Discovery Department, Pharmaceuticals Division
CIBA-GEIGY Corporation, 556 Morris Avenue, Summit, New Jersey, 07901

Detection sensitivity limits for the peptide methionine enkephalin (TYR-GLY-GLY-PHE-MET) have been reported to be as low as 250 pg using fast atom bombardment mass spectrometry (Tolun et al., 1987). In this paper, assay conditions and sensitivity levels for the detection of methionine enkephalin by thermospray mass spectrometry are described.

Samples were analyzed on a Finnigan MAT TSQ-70 triple quadrupole mass spectrometer equipped with a Finnigan MAT Thermospray Interface. A Waters model 510 pump was used in combination with a Scientific Systems model LP-21 pulse dampener. Direct liquid injections (10 ul) were made using a Rheodyne model 7125 syringe loading sample injector. A mobile phase consisting of 60% acetonitrile in water was used. Since methionine enkephalin is ionized at neutral pH, it was not necessary to include a buffer in the mobile phase. In fact, sensitivity was lower with a mobile phase consisting of 0.05 M ammonium acetate in 30% methanol. Likewise, the use of either filament or discharge ionization was found to reduce sensitivity.

Maximum sensitivity was obtained in the negative ionization mode under the following conditions: vaporizer temperature, 125°C; repeller, -62.5 V and flow rate, 1.1 ml/min. Manipulation of any one of these parameters dramatically altered sensitivity for methionine enkephalin. On the other hand, varying the aerosol temperature between 170 and 270°C had little effect on sensitivity. Thus, an aerosol temperature of 190°C was selected for routine analyses. Under these conditions, 1.0 ng injections of methionine enkephalin produced peaks which were approximately three times the mean noise level.

Figure 1. Positive thermospray mass spectrum of methionine enkephalin at a vaporizer temperature of 90°C.



In the positive ion mode, manipulation of the the vaporizer temperature was found to affect not only sensitivity for the molecular ion for methionine enkephalin, but also the degree of fragmentation of the compound. Thus, at a vaporizer temperature of 90°C, only the molecular ion ($M+H^+$) for methionine enkephalin could be seen (Figure 1). On the other hand, at a vaporizer temperature of 120°C, ions corresponding to the peptide fragments, PHE-MET and GLY-PHE-MET, were also prominent in spectra of methionine enkephalin (Figure 2). Varying the vaporizer temperature was found to affect the fragmentation of leucine enkephalin in a similar manner. In the negative ionization mode, the molecular ions $(M-H)^-$ for methionine and leucine enkephalin were found to be much more stable and little or no fragmentation of these compounds was observed even at a vaporizer temperature of 120°C.

These results demonstrate that detection limits for methionine enkephalin by thermospray mass spectrometry are comparable to those obtainable by fast atom bombardment. Sensitivity may be further improved by altering the percentage of acetonitrile in the mobile phase, by the addition of a buffer (other than ammonium acetate), or by substitution of methanol for acetonitrile. Thus, thermospray may prove to be a very useful technique for the analysis of enkephalins and related peptides.

IMPORTANT FACTORS IN THE FAB/MS ANALYSIS OF LARGER PEPTIDES; G. S. Peterson, J. Elliott, W. J. Roberts, K. Williams, W. J. McMurray; Yale School of Medicine, New Haven, Ct. 06510.

Peptide analysis by mass spectrometry has become a rapidly growing field. Increasing attention has been given to the fast atom bombardment (FAB) technique for this class of biochemicals due to its ease of use and good sensitivity. Despite the facility of this technique, it becomes increasingly important to select the best conditions for the analysis as the molecular weight of the peptide increases and/or sample size decreases.

A large number of peptides with molecular weights above 1800 daltons were analyzed by FAB on a VG ZAB-SE mass spectrometer, and an attempt was made to correlate the following factors with molecular ion abundance: 1) matrix selection, 2) N-terminal acetylation and C-terminal amidation, 3) calculated hydrophobicity index (H.I.)[1], and 4) calculated[2] and measured HPLC retention on a reverse phase C-18 column (RPC).

Matrix selection was found not to be critical, although below 2500 daltons magic bullet (DTT : DTE, 4 : 1) gave better data with hydrophobic peptides. For hydrophilic peptides, and all peptides larger than 2500 daltons, thioglycerol was the matrix of choice. When magic bullet was used with hydrophilic peptides, more intense salt adducts (M+K) were observed. Acetylation and amidation increased the molecular ion abundance in every case, presumably by rendering the peptide less hydrophilic.

The best overall indicator of FAB behavior was the HPLC retention measured by RPC. In general, peptides with longer retention times gave more intense MH+ ions, and in many cases this correlated with a less positive H.I. value for those peptides. Peptides with a large positive H.I. value, in most cases, gave poor FAB sensitivity. Additionally, it was found that a concentration of basic amino acids (LYS, ARG) near the C-terminus enhanced FAB sensitivity compared to the expected values based on HPLC retention, while concentration of the same residues near the N-terminus had the opposite effect. Above 3000 daltons, all indicators failed to predict FAB sensitivity, and it is believed that the ability to desorb the molecule is the overriding concern for these large peptides.[3]

This presentation surveys some of our initial applications of plasma desorption (PD) mass spectrometry. Obviously, the technique is well-suited for determining the molecular weights of biomacromolecules. Molecular weights determined in this fashion can be used to verify and correct DNA sequences (1,2), to confirm reaction products (3), to provide mass balance as a guide during protein modification (4) and to count and locate disulfide bonds in proteins (5). As an example, the PD mass spectrum of a heat-stable serine protease, secreted from Thermomonospora YX, is given in figure 1. We were interested in this material because its reported molecular weight is $\leq$14,500 u (6), determined by HPLC retention behavior and SDS/polyacrylamide-gel electrophoresis, which is much lower than those of other heat-stable proteases ($\geq$20,000 u). PD mass spectrometry established that the correct molecular weight is 19,063 $\pm$ 10 u. Figure 2 contains the PD mass spectrum obtained from 10 nmole of proteinase K, an alkaline protease derived from a fungus, tritirachium album limber. This is the highest molecular weight species that we have successfully analyzed to date. The analysis required ~12 hr integration time and the measured molecular weight was within 1.3% of that calculated based on the known primary structure.

PD mass spectrometry can also be used to complement standard biochemical tools such as amino acid analysis and Edman degradation. Figure 3 contains a PD spectrum of a polypeptide fragment isolated from a proteolytic enzyme of known primary structure. Less than 400 pmoles of the fragment, thought to be an autolysis product, were available for analyses. Ten cycles of automated Edman degradation established the N-terminus of the molecule. PDMS provided the molecular weight. By combining results from both experiments, the identity of the fragment was readily established. Incidentally, this fragment could not have been identified in a single Edman degradation analysis because of it's size (it contains over 100 amino acids).

We have used PD mass spectrometry to verify the structure and assess microhomogeneity of various enzyme inhibitors. These quality control studies were undertaken prior to forming enzyme-inhibitor complexes which often produce single crystals suitable for subsequent x-ray diffraction studies.

We have evaluated the peptide "mapping" capability of PDMS and have compared results with those obtained by static FABMS (7). These experiments are similar to those previously reported by Jardine and coworkers (8). In our studies, several peptide mixtures were prepared by the limited proteolysis of glucagon using the enzymes trypsin, chymotrypsin and pepsin. The mixtures were separated using reverse phase HPLC and each peak was collected, lyophilized and identified using FAB, PD and Edman sequencing (where needed). After the compositions of the mixtures had been established, the unseparated mixtures were analyzed by static-FAB and PDMS. A typical set of results is shown in figure 4. This mixture, produced by the pepsin digestion of glucagon (enzyme/substrate = 3.8×10^{-5} mole/mole, ambient temperature, T=2 hr), contains six major products accounting for more than 80% of the chromatographic area. Of these, only two are hydrophobic (9). Not surprisingly, these are the only two components detected with static-FABMS. Fully two-thirds of the mixture is not detected. The PD mass spectrum, on the other hand, clearly reveals signals for all of the components in the mixture including the intact parent which accounts for less than 1% of the total chromatographic area. A comparison of the peptide "mapping" capabilities of PDMS and continuous-flow FAB (10) is currently in progress in our laboratory.

To date, we've found PDMS to be a very useful complement to static-FABMS. It extends our accessible mass range at least up to 30,000 u. Furthermore, sensitivity is excellent. As little as 1 pmole of material is required in favorable cases. Another major advantage is that the technique does not require the use of a viscous liquid matrix as in static-FAB. Therefore, it is applicable to materials that fail by FAB due to solubility problems.

Furthermore, elimination of the liquid matrix, i.e., requirement of surface activity, minimizes problems associated with the selective detection of components in mixtures. Finally, PDMS is amenable to a high degree of automation and can be efficiently operated unattended.

THE STUDY OF ACETAMINOPHEN CONJUGATE FORMATION BY OXIDATIVE ELECTROCHEMISTRY AND THERMOSPRAY MASS SPECTROMETRY

T.A. Getek and W.A. Korfmacher
National Center for Toxicological Research
Jefferson, AR 72079

ABSTRACT: Since its initial development, thermospray mass spectrometry (TSMS) has proven to be an exceptional interface for liquid chromatography-mass spectrometry (LC-MS) and an unique ionization mode for nonvolatile compounds. Because TSMS utilizes a continuous flow of liquid into the thermospray (TS) source, it may be used as a flow injection analysis (FIA) device for monitoring chemical reactions in solution. In this study, the reaction of acetaminophen (APAP) after electrochemical oxidation with glutathione (GSH) was monitored and evaluated by TSMS at varying pH and mole ratios of GSH:APAP; behavior at varying electrochemical potential was also examined. The mixing of GSH with the electrolyzed APAP, that is, N-acetyl-*p*-benzoquinoneimine (NAPQI), formed on-line the acetaminophen glutathione conjugate (APAP-SG) on the time scale of one second.

EXPERIMENTAL: The configuration of the pumping system is shown in Fig. 1. The syringe pump contained a 3.3 x 10^{-5} M APAP solution in 90/10 H_2O/CH_3OH at 0.1 M ammonium acetate which was pumped through the electrochemical (EC) cell at 0.7 mL/min by the syringe pump. The reciprocal pump carried the same solution but without the APAP at a flow of 0.7 mL/min. GSH was injected and mixed with the APAP after the APAP had been oxidized to NAPQI. The comparison of the expected and observed charge generated by the electrolysis confirmed a two-electron oxidation.

RESULTS AND DISCUSSION: The TS mass spectra of the before and after oxidation of APAP and reaction with GSH are shown in Fig. 2. The peaks at m/z at 457 and 184 (Fig. 2B) are indicative of APAP-SG and APAP-SH, respectively, as reported earlier [1]. The selective ion monitoring (SIM) of the reactants and products is shown in Fig. 3. Note the large dips and valleys in the SIM of m/z 150 and 108 indicating the chemical reaction of NAPQI with GSH. Extensive APAP-SG conjugation began at +0.15V as clearly shown by the appearance of m/z 457 and 184.

Experiments were undertaken to evaluate the effect of varying GSH:APAP mole ratios on the formation of APAP-SG. At mole ratios of 0.2:1 and 1:1 GSH:APAP, m/z 184 is detected but not m/z 457. A minimum of 2:1 mole ratio was necessary to observe $[APAP\text{-}SG+H]^+$ at m/z 457. Observance of m/z 184 prior to detection of m/z 457 suggested that the APAP-SG was formed but due to the lack of intensity of the m/z 457 ion and instability of the APAP-SG conjugate to the TS process, only the fragment for APAP-SH was observed.

Lowering the pH of the ammonium acetate liquid carrier affected the formation of APAP-SG by delaying and inhibiting the reaction. At lower pH, the oxidation of APAP is more difficult, thus a more positive potential for the EC cell is needed before the APAP-SG ion is detected by TSMS.

In summary, the information obtained from this study and similar studies can lead to a better understanding of plausible *in vivo* processes, assist in optimizing the chemical synthesis of conjugates for further experiments, and is a rapid means (ca. 1 sec) to produce on-line thermally labile compounds, such as APAP conjugates, so that thermospray conditions may be adjusted in order to observe maximum intensity for $[M+H]^+$ or a specific fragment. These results are an extension of the utility of solution electrochemistry mass spectrometry (SECYMS) for evaluating redox events by TSMS [2].

RECOGNITION AND CHARACTERIZATION OF GLUTATHIONE CONJUGATES USING TRIPLE QUADRUPOLE MASS SPECTROMETRY

Conjugation with glutathione represents an important route for the detoxification and subsequent excretion of xenobiotics or their metabolites. Structural analysis of these conjugates therefore represents an important approach to the characterization of reactive metabolites and the elucidation of toxic mechanisms of xenobiotics. We have recently described[1] analyses of glutathione conjugates using fast atom bombardment and hybrid tandem mass spectrometry in which characteristically collisionally activated decompositions were observed.

However, the nature of the conjugated moiety has a significant effect on the observed fragmentations, suggesting that recognition of the presence of glutathione conjugates in biological extracts is best achieved by tandem MS using several scan modes. Thus, for example, scanning parents of m/z 130 (derived from the gamma-glutamyl moiety) together with neutral loss (232 u, 129 u) scans indicates the presence of glutathione conjugates of compounds of varying structure.

Here we report the application of triple quadrupole mass spectrometry with mixed mode scanning to the recognition and characterization of glutathione conjugates in biological extracts. The analytical strategy involves: 1) continuous flow FAB/tandem MS analyses with rapid switching between the recording of conventional mass spectra and both parent ion and neutral loss scans characteristic of glutathione conjugates; 2) a second analysis in which daughter ion scans are recorded for relevant parents identified in stage 1.

THERMOSPRAY LC/MS DETECTION OF GLUTATHIONE- AND GLUTATHIONE-DERIVED CONJUGATES IN BILE AND URINE OF MICE TREATED WITH 3-HYDROXYACETANILIDE, A NONHEPATOTOXIC REGIOISOMER OF ACETAMINOPHEN:

Mohamed S. Rashed, Timothy G. Myers, Sidney D. Nelson; Department of Medicinal Chemistry, Univ. of Washington, Seattle, WA 98195.

Introduction

3-Hydroxyacetanilide (AMAP) is a nonhepatotoxic regioisomer of acetaminophen(APAP). Despite lack of toxicity, AMAP produces nearly as much *in vivo* covalent binding to liver proteins as acetaminophen.[1] *In vitro* covalent binding from AMAP occurs four times faster than from APAP.[2] AMAP is metabolized *in vitro* to two diphenolic compounds, 2-acetamidohydroquinone and 3-hydroxyacetaminophen. Further oxidation to quinones was suggested to result in the observed covalent binding. Incubations of AMAP in presence of glutathione (GSH) abolished covalent binding and resulted in the formation of two isomeric *mono*-GSH conjugates of 4-acetamido-*o*-benzoquinone (AOBQ) and 2-acetamido-*p*-benzoquinone (APBQ) and a *bis*-GSH conjugate of the latter. The identity of these conjugates was determined by co-chromatography with synthetic standards.

The objective of the work presented here was to determine if these conjugates or their metabolic breakdown products were biliary or urinary metabolites of AMAP in mice.

Experimental

Synthesis:

N-acetyl-3-methoxy-*p*-benzoquinone imine (MAPQI) was prepared by silver oxide oxidation of 3-methoxyacetaminophen as previously reported for the synthesis of NAPQI.[3]

The synthetic thioether conjugates were prepared by adding the quinone (0.1 mmol) in acetonitrile to the appropiate thiol in phosphate buffer pH 7.4. The mixtures were acidified after 30 min and the conjugates were purified by HPLC. The purified adducts were characterized by 300 MHz ^1H NMR in D_2O. Molecular weight information of some of the conjugates was obtained by LSIMS analysis.

Animal Treatments:

Phenobarbital pretreated male Swiss-Webster mice (16-25g) were fasted for 12 hrs then administered [ring-UL-^{14}C]AMAP (600 mg/kg) ip. The gall bladders were excised 3-4 hrs after injection and the bile collected was acidified to pH 2.0 with formic acid and filtered through a Nylon-66 filter. Urine was collected for 24 hrs in cups containing 15 mg ascorbic acid and immersed in dry ice/acetone. The urine was filtered first through cotton wool then through a Nylon-66 filter.

Analytical:

HPLC was performed with an LKB 2152-2SD dual-pump instrument equipped with an LKB 2152 variable wavelength UV detector set at 254 or 280 nm (LKB, Bromma, Sweden). Analyses and purification were carried out on a 5-u Ultrasphere C_{18} column (10 mm X 25 cm) protected with a 5-u Ultrasphere precolumn. Mobile phase consisted of solvent A: water/acetonitrile/glacial acetic acid (96:2:2 by volume); solvent B: acetonitrile. A linear gradient was employed from 0% B to 20% B in 40 min with a flow rate of 2.0 ml/min.

LC/MS analysis was carried out with an LKB 2150 pump and LKB 2152 controller HPLC sytem interfaced to a Vestec Thermospray LC-MS Model 201 dedicated LC/MS system (Vestec Corp., Houston, TX). The column used was a 5-u Ultrasphere C_{18} (4.6 mm X 15 cm) protected with a 5-u Ultrasphere precolumn. The mobile phase consisted of 90% 0.1 M ammonium acetate and 10% acetonitrile isocratically pumped at a flow rate of 1.0 ml/min. Operating temperatures for the thermospray interface were T_1 (vaporizer) = 140°C; T_2 (tip) = 270°C; source block = 350°C ; jet (vapor) = 320°C. The system was operated in the positive ion mode with the filament off.

Results and Discussion

TSP-LC/MS analysis of the acidified bile samples provided direct evidence for the presence of the GSH conjugates of AOBQ and APBQ. In addition LC/MS provided evidence for the presence of two isomeric GSH conjugates of a novel quinone imine, N-acetyl-3-methoxy-p-benzoquinone imine (MAPQI). The spectra obtained for these compounds showed protonated molecular ions and characteristic fragmentation due to neutral loss of the glutamate moiety. The base peak ions corresponded to cleavage of the thioether bond on the cysteine side of the molecule to yield protonated aryl thiols (fig. 1).

MAPQI was synthesized and found to react with GSH to give one major GSH conjugate which was determined by ^{1}H NMR to be 3-(glutathion-S-yl)-5-methoxy-acetaminophen.

TSP-LC/MS was used for characterisation of products of reactions of the quinones with cysteine or N-acetylcysteine.
The spectra obtained showed protonated molecular ions and other characteristic fragments corresponding to the protonated aryl thiol and the protonated diphenolic moieties (fig. 2).

LC/MS of urine from mice treated with AMAP allowed detection of mercapturates of AOBQ and MAPQI. In addition, glucuronic acid conjugates of the parent compound AMAP and of its diphenolic metabolites were detected in urine by LC/MS.

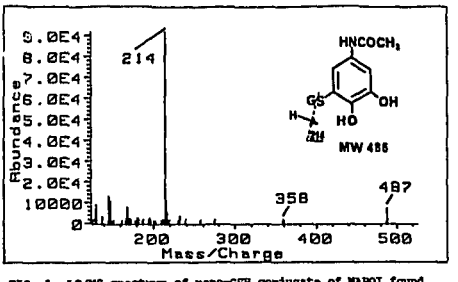

FIG. 1 LC/MS spectrum of mono-GSH conjugate of MAPQI found in bile of mice treated with AMAP.

APPLICATIONS OF TANDEM MASS SPECTROMETRY TO THE CHARACTERIZATION OF DERIVATIZED GLUTATHIONE CONJUGATES

Paul G. Pearson, William N. Howald, * Michael D. Threadgill and Thomas A. Baillie.

Department of Medicinal Chemistry, School of Pharmacy, University of Washington, Seattle WA 98195, and * Medical Research Council Radiobiology Unit, Didcot, Oxfordshire OX11 ORD, U.K.

Conjugates of the endogenous tripeptide glutathione (γ-glutamyl-cysteinyl-glycine; GSH) represent an important class of metabolite as they may arise from from the interaction of GSH with reactive electrophilic species, which are generated metabolically from drugs or other xenobiotics. Typically these reactive species, which have been implicated in various xenobiotic-induced toxicities, are short-lived and pose complex analytical problems. Consequently, analytical methods to identify GSH conjugates in biological matrices are valuable as the structural information derived provides a unique insight into the chemical nature of the reactive species.

The objectives of the present investigation were two-fold. Firstly, to employ an aqueous phase derivatization procedure to convert glutathione conjugates to either their alkyloxycarbonyl or benzyloxycarbonyl derivatives to permit convenient isolation from a biological matrix. Secondly, to examine the behaviour of the functionalized GSH conjugates by collisionally-activated dissociation (CAD) methods in conjunction with fast atom bombardment (FAB) and tandem mass spectrometry, in order to obtain detailed structural information by examination of their daughter ion spectra. As a model compound for this investigation we chose S-(N-methylcarbamoyl)glutathione (SMG; 1), a metabolite of the anti-neoplastic agent N-methylformamide (NMF ; Threadgill *et al.*, 1987).

Experimental: SMG (1), generated in incubations of rat hepatocytes with either NMF or $^{13}C_2$,^{15}N-NMF (5mM) , was converted to its N-benzyloxycarbonyl dimethylester derivative (3) and purified by HPLC as described previously (Pearson *et al.*, 1988) . Daughter ion spectra of the MH^+ ions from (3), an authentic sample of (1) an N-ethoxycarbonyl dimethylester (2) and a *t* -butyloxycarbonyl dimethylester analog (4), were recorded on a VG 70 SEQ hybrid tandem instrument of EBQQ geometry, equipped with an Ion Tech fast atom gun, and a VG11/250 data system. Samples (5-10μg) were dissolved in methanol (3μl), and added to a glycerol matrix (3μl) containing 0.1N HCl (1μl). Ionization was achieved following bombardment with xenon (6keV) as the primary beam, and conventional FAB spectra were recorded at an accelerating voltage of 8 kV. CAD was performed in the first (rf-only) quadrupole, employing helium as a collision gas (1 x 10^{-6} Torr) with collision energies of 38-40 eV. Daughter ion spectra were recorded, either *via* the data system in the multi-channel-analysis mode and subsequently mass-measured, or by means of an oscillographic recorder.

Results and Discussion: Conventional FAB analysis of(1)-(4) afforded spectra with prominent MH^+ ions. Under CAD conditions structurally-informative fragment ions were observed for (1)-(3), the origins of which are depicted in Figure 1 (adapted from nomenclature proposed by Gaskell. S.J. ; personal communication).(1) underwent loss of the γ-glutamyl moiety (129u) as the major route of fragmentation to yield ion ***e*** ; expulsion of the elements of methylisocyanate (CH_3NCO) from the MH^+ (to yield ion ***i***), or from the ***e*** fragment were also prominent cleavages. Thus, daughter ions indicative of both xenobiotic and tripeptide elements of SMG were clearly observed. Conversion of (1) to (2) or (3) induced a profound change in the relative abundances of ions ***a-k*** , most notably in the intensity of fragment ***a*** (elimination of glycine methyl ester ; see Figure 1), which

dominated the spectrum of (2) and (3; figure1). Ion *e* remained an important mode of fragmentation, as did the expulsion of methylisocyanate (57u) from the respective MH^+ ions. Shifts in m/z values in the spectra of (2) and (3), and isotopic labelling, confirmed these assignments. Therefore, the CAD spectra of (2) and (3), in common with (1), are characterized by ions diagnostic for the drug residue and GSH moiety. In addition, (2) and (3) displayed neutral losses indicative of the functionalized amino and carboxyl groups. In contrast, the CAD spectrum of (4) was dominated by two ions resulting from fragmentation of the *t* -BOC group itself, *viz* m/z 437 $(MH\text{-}C_4H_8)^+$ and m/z 393 $(MH\text{-}CO_2C_4H_8)^+$,and thus conveyed little structural information.

The results of this study demonstrate the value of an aqueous phase derivatization technique. The enhanced HPLC properties, increased lipophilicity, and the introduction of a UV chromophore in (3), served to expediate the isolation and analysis of GSH conjugates. The derivatized GSH conjugates of NMF, when examined under CAD conditions, have mass spectral features similar to underivatized S-aryl and S-alkyl GSH conjugates. One notable exception involved a prominent neutral loss of alkylisocyanate, which appears to be unique to metabolites of the structure "H-Y-CO-SG "(where "Y "is a heteroatom). The prominence of ions *a* and *e* in the CAD spectra of (2) and (3) facilitates neutral loss scans for the elimination of both the derivatized glycine and γ-glutamyl residues, and in principle provides a greater degree of specificity for the detection of GSH conjugates of unknown structure, when compared with a corresponding underivatized conjugate. This approach illustrates the utility of aqueous phase derivatization techniques, accompanied by FAB/MS/MS methodology, in the rapid isolation and characterization of glutathione conjugates from a complex biological matrix.

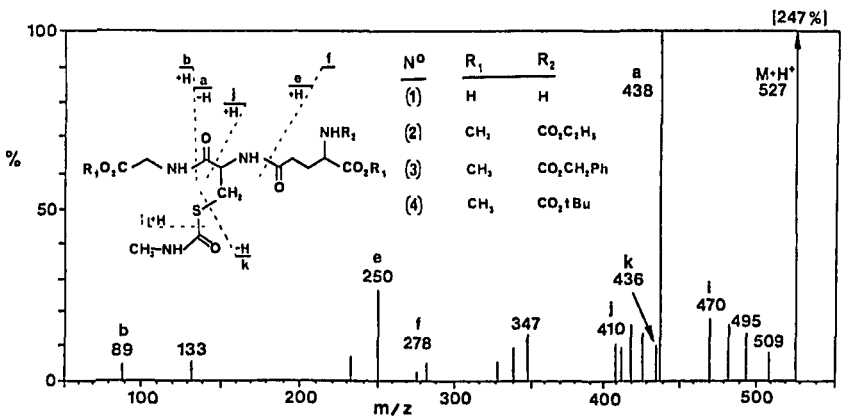

Figure 1. CAD daughter ion spectra of the MH^+ ion of (3); the scheme details the origin of the daughter ions and structures of (1)-(4).

Screening for Mercapturate Conjugates of Xenobiotic Substances in Urine using Negative Ionization and Neutral Loss Scanning

A. Daniel Jones[(1)], Carl K. Winter[(2)], H. J. Segall[(2)], and Michael H. Buonarati[(2)]

(1) Facility for Advanced Instrumentation

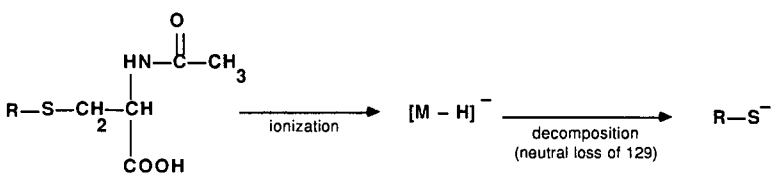
University of California, Davis, CA 95616

Mercapturic acids (*N*-acetyl-L-cysteine conjugates) of toxic substances are important end products of detoxification via glutathione conjugation. The appearance of mercapturates of xenobiotic chemicals in urine indicates metabolic conjugation of electrophiles to glutathione *in vivo*. Stereoselectivity in the processes leading to glutathione conjugation can be determined by measuring the amounts of diastereomeric mercapturates excreted in urine[1]. It has also been proposed that the levels of mercapturates in urine can be used as chemical markers of toxic exposure[2].

In the course of an earlier investigation[3], negative FAB ionization was used in conjunction with MIKE spectra for the direct and specific detection of the mercapturic acid conjugate of *trans*-4-hydroxy-2-hexenal (t-4HH) in the urine of rats which had been dosed with t-4HH. The daughter ion spectrum obtained using negative ionization was remarkably simple, characterized by abundant ions which arose from cleavage of the C—S bonds. A significant neutral loss of 129 D appeared to offer the prospect of group-specific detection of mercapturic acids similar to methods developed by Straub and coworkers for other polar conjugates[4].



To determine whether this neutral loss scan was applicable to a wide range of mercapturates, full scan and daughter spectra were generated for synthetic mercapturate conjugates of alkyl halides (*cis*-1,3-dichloropropene and benzyl chloride), hydroxyalkenal products of lipid peroxidation (*trans*-4-hydroxy-2-hexenal and *trans*-4-hydroxy-2-nonenal), styrene oxide, and 1,2-naphthalene oxide.

Ionization of Mercapturic Acids

Negative ionization methods (FAB, hydroxide CI, and chloride CI) yielded intense $[M-H]^-$ ions for all of the synthetic conjugates. Greater amounts of fragmentation were observed using hydroxide CI relative to the other two ionization methods, and this is attributed to the relatively high proton affinity of OH^-. Small amounts of adduct ions (e.g. $[M+Cl]^-$) were also observed using CI, but alkali metal cation attachment was minimal using FAB even in the presence of 0.1 M NaI in the matrix (dithiothreitol:dithioerythritol). Positive ionization gave intense $[M+H]^+$ except for the hydroxyalkenal and naphthalene oxide conjugates, which gave strong $[M+H-H_2O]^+$ ions. Alkali metal cationization was significant upon addition of NaI to the matrix.

Ion Fragmentation

For all of the mercapturate conjugates studied, decomposition of $[M-H]^-$ resulted in simple daughter spectra characterized by three or fewer principal daughter ions. An abundant daughter corresponding to a neutral loss of 129 D was observed for each mercapturate, and was usually the most abundant daughter ion.

Few generalizations can be drawn regarding decomposition of $[M+H]^+$ ions. Daughter spectra were more complex than observed for negative ionization, and yielded far more structural information. Daughter spectra of $[M+Na]^+$ were even more complex than the daughters of $[M+H]^+$.

Detection of Mercapturates in Urine Extracts

Samples of rat urine were collected and known amounts of authentic mercapturate standards were added. Acidic fractions of ethyl acetate extracts of the urine were analyzed by using chloride desorption chemical ionization, using linked metastable neutral loss scanning (neutral loss of 129) on a VG ZAB-HS-2F mass spectrometer. Sufficient decomposition occurred without addition of collision gas to the first field region to permit detection of all of the added mercapturates at 10 ng/mL levels in the urine.

Current efforts are directed at optimizing sample clean-up procedures and preparing pentafluorobenzyl ester derivatives of the mercapturates, which will be analyzed using electron capture ionization and GC/MS.

FD and MS/MS studies of high mass polymers,

Moore, C and Barton, E.C
Kratos Analytical, Barton Dock Road, Urmston, Manchester M31 2LD, UK

Fast Atom Bombardment ionization is often used in the analysis of high molecular weight compounds (<1000 mass units). The structure of the pseudo molecular ions generated by this technique may be probed using MS/MS. During the recent analysis of some silicone oils the aforementioned techniques were found to be of little value. However, field desorption ionization and combined with high resolution accurate mass measurements did allow us to partially determine the structure of the oil.

In Figure 1 is a FAB mass spectrum of neat silicone oil of molecular weight 800 mass units. The oil might be expected to have the following general formula;

$$R- \begin{array}{c} CH_3 \\ SiO- \\ CH_3 \end{array}_{n} -R_1$$

As n increases the mass of the ion will increase by 24 mass units e.g. m/z 221, 295, 369 etc. If molecules having different R groups are present then series of ions separated by a common mass difference will be observed eg 207 221, 281 295, 355 369, etc.

In Figure 2 is the field desorption mass spectrum of the same oil sample. Data were obtained by scanning from mass 4000 at 30 sec decade^{-1} at a resolution of 3000. In contrast to the data in Figure 1, no significant ions were observed below mass 739. Once again 2 series of ions differing in mass by 14 mass units were observed and the expanded spectrum in Figure 3 shows that the higher mass series is the most intense above 1700 mass units.

The individual molecular ions do not dissociate unimolecularily or after collisional activation and therefore no MS/MS data have been obtained on them.

By computer assisted peak matching of the m/z 813 ion against a porphyrin reference of mass 770.3526, the accurate mass of this ion was found to be 813.2653 mass units. The most probable elemental composition is therefore,

$(SiOme_2)_9\ C_6H_{13}NO_3$ (m/z = 813.2587)

Other accurate mass measurements confirmed that the nominal mass difference of 74 mass units was due to $(SiOMe_2)$.

Field desorption is obviously a good method for ionizing silicone oils, since very clean spectra are obtained. Data are currently being obtained on higher molecular weight oil samples and these are producing ions around 8000 mass units.

Electron Impact Ionization Mass Spectra of Polystyrene Oligomers by ThermaBeam LC/MS

G.G. Jones, *R.W. McCoy and R.E. Pauls, Amoco Corporation Naperville, Il 60566; R.C. Willoughby, EXTREL Corporation, Pittsburgh, PA 15238.*

The analysis of polystyrene oligomers by mass spectrometry is made difficult because of their low volatility and ease of thermal degradation. The thermal depolymerization of bulk polystyrene begins at less than 300°C, considerably below the estimated boiling point of MW 2000 polystyrene (1). As a result, the highest reported oligomer detected under electron impact ionization conditions with solids probe introduction is the n = 11 oligomer, mass 1202, in a sample with an oligomer distribution out to at least n = 27 (2). Successful approaches to volatilization-ionization include field desorption, TOF-SIMS, laser microprobe, and chemical ionization. These techniques, applied either directly or with prior LC separation, provide molecular weight information out to beyond 5000 amu, but little or no additional structural information.

Particle beam LC/MS interfaces, in common with moving belt interfaces, remove enough solvent to allow generation of electron impact ionization mass spectra. In the ThermaBeam interface, particles from an aerosol produced by a thermal nebulizer pass through a two-stage jet separator and impact the wall of the ion source, where vaporization occurs. The results of this study, which demonstrate the detection of polystyrene molecular ions out to mass 1930, n = 18, suggest that the vaporization of sub-micron sized particles from a hot source wall is different from and certainly more effective than, bulk vaporization from a heated surface.

Experimental. Polystyrene GPC standard (Mw = 1250), Polymer Laboratories, LTD.) was chromatographed on a 2mm i.d. by 25 cm long Ultrasphere ODS 5 µm column (Beckman Instruments) with the following gradient: 100% methanol to 50%/50% methanol/THF in 40 min.; flow rate 0.4 ml/min. Injection size was typically 50 to 100 µl of a 3.4 mg/ml solution of polystyrene in 80/20 methanol/THF. The LC/MS interface was an EXTREL ThermaBeam (TM) particle beam interface consisting of a thermal nebulizer, expansion region and two-stage jet separator. An EXTREL ELQ-400-2, 2000 amu mass range quadrupole mass spectrometer was used in the EI mode with 70 eV ionization energy. For the maximum molecular weight detection experiment, the mass resolution was adjusted for 2-3 amu wide peaks between 1000 and 2000 amu with a scan range of 80-2000 amu.

Results. Butyl capped polystyrene oligomers were detected out to beyond n = 18, m.w. 1930, by LC/MS with ThermaBeam (TM) particle beam interface and electron impact ionization conditions. As shown in Figure 1, molecular ions were observed up to mass 1930 under very low resolution (2-3 amu wide peaks), high sensitivity conditions. The mass spectrum of the 13-mer, Figure 2, was taken under unit mass resolution conditions. The molecular ion of the 13-mer, mass 1410, is only 0.1% of the mass 91 peak at a source temperature of 250°C.

Source temperature plays an important role in the vaporization of the oligomer particles. At 200°C source wall temperature, only oligomers out to about n = 10 were effectively vaporized, a finding in remarkable agreement with Udseth's determination of 205°C as the evaporization temperature of the decamer from a rapidly heated (1000°C/sec) rhenium filament (2). at a source temperature of 315°C, peaks out to n = 20 were observed in the total ion chromatogram.

ASSESSMENT OF RESIDUAL VOLATILES IN PHENOLIC NOZZLE COMPOSITES OF THE SPACE SHUTTLE SOLID ROCKET BOOSTER

J.G. Moncur, P.C. Pinoli, W.P. Holst III, T.L. Ely
Lockheed Missiles and Space Co., Palo Alto, CA 94304

Residual volatiles in ablative tape wrapped carbon and glass phenolic nozzle composites of the Space Shuttle solid rocket booster have been studied. Assessment by helium atmosphere temperature programmed mass spectrometry (Ref. 1) at 25C to 950C, and dynamic headspace gas chromatography mass spectrometry (Ref. 2) at 260C for 15 minutes identified water as the most abundant volatile component present. Carbon dioxide, other entrained atmospheric gases such as nitrogen, and isopropyl alcohol were minor components present.

Quantitative assessment of residual water content and total volatile weight loss were achieved by an automated Karl Fischer proceedure in 260C, two hour inert gas desorptions. Hundreds of test panels, demonstration fired samples, uncured prepreg systems, and witness samples were tested over a one year term. Water was shown to be the major outgassing volatile at 260C, typically 70-90% of the total volatile weight loss. Typical carbon phenolics had moisture contents from 2.5-5.5 wt.%, while glass phenolics had lower moisture and total volatile contents.

The effect of residual water on nozzle components was assessed by thermomechanical analysis. Dynamic crossply expansion curves were shown to clearly exhibit independent response to pore pressure from residual volatiles inititally, and pyrolysis gases secondarily. Pyrolysis gas chromatography mass spectrometry identified phenol, cresols, and dimethyl phenols as the principal pyrolysis gases above 300C. Water induced pore pressure in ablative phenolic composites is beleived to induce "pocket erosion" when ply anlges approach 90° to the gas flow and "ply lift" when the wrap angle approaches the gas flow direction.

MONITORING POLYESTER POLYMERIZATIONS BY K^+IDS WITH MASS SPECTROMETRIC DETECTION:

William J. Simonsick, Jr., M. C. Grady
E. I. duPont de Nemours & Co., Ltd.
Philadelphia, PA 19146

Polyesters are the reaction products of polyfunctional acids and alcohols. Many of today's commercial polyester resins are prepared from mixtures of diacids and diols. This mixture of ingredients imparts a desirable balance of physical properties to the finished polyester resin. For example, dipropylene glycol imparts flexibility and toughness to a resin whereas neopentyl glycol provides corrosion resistance. The molecular weights of these starting materials are different. Therefore, a mass spectrometric technique which furnishes molecular weight information would be an excellent tool for sequencing oligomer chains and monitoring the progression of the early stages of a polyester polymerization. Under our operating conditions the recently developed K^+IDS technique affords only molecular weight data of oligomers.

The K^+IDS technique is easy to implement, and requires only a mass spectrometer equipped with a rapid heating probe (>100°C/sec) for sample introduction. Rapid heating makes it possible to desorb intact oligomers. Under our operating conditions, K^+IDS furnishes only molecular weight information in the form of $[M+K]^+$. The simplicity of the spectra, affording only molecular weight information, is sufficient to assign molecular formula to the ions seen in the K^+IDS mass spectra of polyester syntheses. For example, Figure 1 shows a portion of the K^+IDS mass spectrum taken of a polyester synthesis. The hydroxyl terminated trimers with the proposed structures are displayed.

All K^+IDS experiments were performed on a Finnigan 4615B quadrupole GC/MS. The mass spectrometer was tuned using Tris-(perfluoroheptyl)-S-triazine. The mass spectrometer was scanned at 1000 Daltons (Da)/sec. The desorption process of polyesters and the reproducibility of K^+IDS were evaluated using selected ion monitoring.

We used preparative gel permeation chromatography to enrich the high molecular weight fraction of the polyesters followed by K^+IDS analysis. Ions corresponding to eleven units (m/z > 1400 Da) were detected. The raw materials loading was checked using K^+IDS. We monitored the progression of neopentyl glycol, hexanediol, azelaic acid, isophthalic acid polymerization. K^+IDS is well suited for the analysis of low molecular weight polyesters.

OLIGOMER ANALYSIS BY POTASSIUM IONIZATION OF DESORBED SPECIES WITH MASS SPECTROMETRIC DETECTION

William J. Simonsick, Jr., Thomas P. Volpe
E. I. duPont de Nemours & Co., Ltd.
Philadelphia, PA 19146

Mass spectrometry has not enjoyed widespread use for polymer analysis. This can be attributed to the low volatility of polymers. There are a variety of methods which have recently become available for the desorption and subsequent ionization of nonvolatile or thermally labile compounds. Unfortunately, many of these techniques are not available with our current mass filtering system, a quadrupole, or they require a substantial capital investment. We modified a direct exposure technique which we have at our disposal to accommodate the analysis of nonvolatile/thermally labile substances. The technique utilizes rapid heating (>100°C/sec) to desorb intact molecules with minimal thermal decomposition.

Once in the gas phase, the analyte must be ionized. Several techniques are available to accomplish this task. Initially we used electron impact MS (EIMS) to study a 90:10 methylmethacrylate (MMA) butylacrylate (BA) low molecular weight macromonomer. The EIMS was rich in fragment ions, however, very little structural information could be gathered because of the extensive fragmentation. Chemical ionization MS using isobutane as the reagent gas imparts less energy to the molecular ion thereby reducing fragmentation. Unfortunately, only monomeric protonated MMA (m/z = 101 Daltons (Da)) and BA (m/z = 129 Da), MMA dimer (m/z = 201 Da), and adduction ions were observed.

To further reduce the observed fragmentation we selected an ionization technique based upon the thermionic emission of potassium from an alumino-silicate matrix. This ionization technique referred to as K^+IDS (K^+ ionization of desorbed species) affords a "pseudomolecular ion" in the form of $[M+K]^+$ hence molecular weight information is easily obtained (1). Little energy is imparted to the molecular ion. Therefore, no significant fragmentation is observed. When directly analyzing oligomeric mixtures, data interpretation is facilitated by a simplified MS. Figure 1 shows the K^+IDS spectrum of the 90:10 MMA/BA macromonomer discussed above. Notice the cationized chains $[M+K]^+$ with no observable fragmentation. Each ion can easily be assigned a molecular composition with a knowledge of the starting monomers. For example, the ion seen at 339 Da corresponds to the potassium cationized MMA trimer terminating in a double bond. Each additional MMA adds 100 Da thereby giving rise to the envelope whose formula can be written 39 + 100n where n is the number of MMA units. If a BA (molecular weight = 128 Da) is substituted for an MMA in the trimer chain a net gain of 28 Da will be observed in the K^+IDS MS (128 Da - 100 Da = 28 Da). Hence, the ion seen at 367 Da corresponds to the potassium cationized chain which contains two MMA units and one BA [(200 Da) + (128 Da)] + K^+ = 367 Da. K^+IDS provides the analyst with an absolute molecular weight distribution, differentiates copolymers from polymer blends, and furnishes data concerning the specific chemical composition and the relative abundance of each oligomeric chain.

June 5-10, 1988, San Francisco, CA

All experiments were performed on Finnigan 4615B quadrupole GC/MS system. An EI source configuration was used in all K^+IDS experiments. The ion source pressure (ion gauge) was $<10^{-6}$ Torr with a source temperature of 200°C. The mass spectrometer was tuned with Tris-(perfluoroheptyl)-S-triazine.

We investigated and optimized the operating parameters involved in the K^+IDS technique and applied the method to the study of oligomeric additives, methylmelamines, low molecular weight epoxy resins, and several synthetic mixtures. Using K^+IDS we have assisted polymer chemists toward the synthesis of targeted materials. The molecular weight snapshot provided by K^+IDS allows one to characterize oligomers by both molecular weight and chemical composition. This is useful data to the polymer chemist and K^+IDS furnishes this information in a five minute experiment.

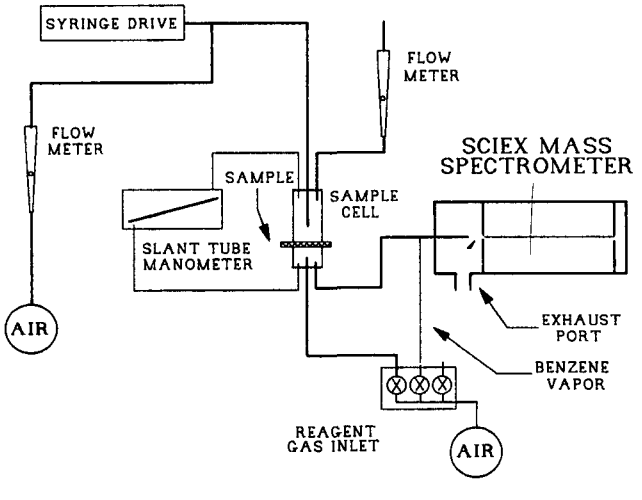
APPLICATION OF APCI MASS SPECTROMETRIC DETECTION TO PROBLEMS IN MASS TRANSFER

John W. Halliday
U.S. Army Natick R,D&E Center
Natick, Massachusetts 01760

Atmospheric pressure chemical ionization (APCI) mass spectrometry has proven a versatile and valuable detection system in studying the transport of various chemical entities through an assortment of barrier materials. These barriers range from packaging materials designed to protect the soldier's food to materials used in protecting the soldier from the effects of exposure to hazardous chemicals. Packaging barriers such as used in the Meal, Ready to Eat (MRE) are designed to keep food degrading agents (oxygen, moisture, and bacteria, for example) out and quality enhancing factors in. Barriers to permeation or penetration by toxic chemicals are used in the fabrication of garments, shelters, and other structures designed to protect the soldier.

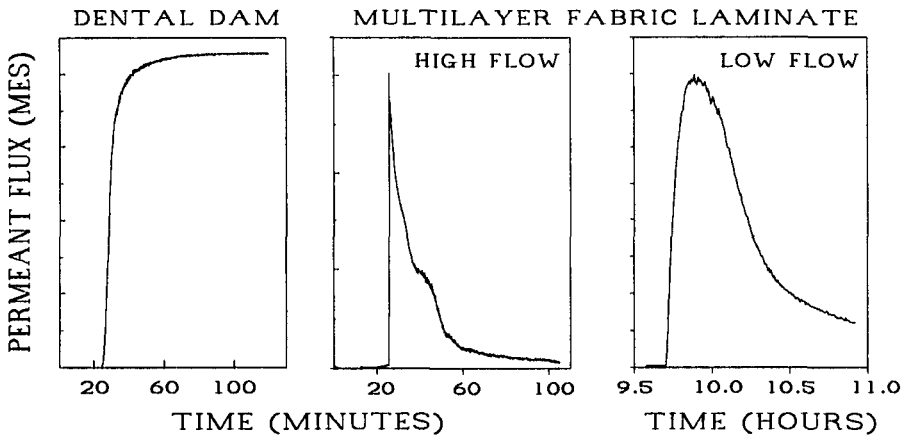
Mechanisms for transport of the undesirable agent through the material encompass both diffusion/permeation and infiltration/penetration. Minute cracks and holes in the barrier material may permit the encroachment of the undesirable agent by physical infiltration, subject to some driving force such as a pressure gradient. In other cases transport is by permeation which, in some cases, approaches ideal Fickian diffusion.

Three areas of application are presented here: detection of packaging defects in MRE pouches, testing of chemical protective fabrics, and development of methodology for evaluating defects in shelter materials. The latter two applications make use of a permeation type experiment. The general features of the apparatus used in such studies is shown below.



An important feature of the apparatus is the ability to establish a pressure differential across the sample by balancing the exhaust pumping from the Sciex APCI front end with the other gas flows involved. This pressure differential is a driving force for infiltration through discrete fissures and for transport of vapors through air permeable materials containing a sorptive layer.

Transport characteristics for liquid droplet challenge of two materials representing an elastomeric and an air permeable, multilayered fabric are illustrated in the following figure. The permeant used was



methyl salicylate (MES). Benzene vapor served as the source of $C_6H_6^+$ reagent ions used to form the MES positive ion. Detailed and highly time-resolved transport profiles that are obtained using inocuous, but relevant, compounds supplement the sparser data obtained from testing with the actual toxic compound.

The protective capacity of new, lightweight shelter and tentage materials against these same hazardous compounds would be compromised by the minute defects (cracks, fissures, worn spots) that might be induced by storage, handling, and environmental abuse factors. Using an approach similar to that just described, the pressure dependence of the transport behavior is used to determine components of infiltration and permeation type behavior. This information is used to evaluate impact on the protective capacity.

Incursive defects in packaging materials are evidenced by detection of component(s) of the contained food on the outside of the package. Several sampling approaches were evaluated in a general feasability study. Tomato sauce was used as the food component; the negative ion of acetic acid was monitored. The most effective method involved scanning the pouch surface with a thin "sniffing" tube attached to the Sciex's APCI front end. A small funnel shaped device attached to the probe increased sensitivity significantly. This approach also provides important spatial information.

APCI detection provides, then, the sensitivity, versatility, and time resolution essential to the types of studies outlined here. It can be physically interfaced with a wide variety of apparatuses designed to measure, in real time, the concentration of a host of permeating species of widely differing compositions.

QUANTITATIVE ANALYSIS OF REACTIVE DECOMPOSITION PRODUCTS USING THERMALLY LABILE SALTS*

John J. Morelli, Michael A. Grayson, Clarence J. Wolf,
McDonnell Douglas Research Laboratories, St. Louis, MO, 63166

Periodic evaluations of raw materials are necessary to detect fluctuations in chemical or physical composition and thus to prevent the manufacturing of substandard goods. Quantitative methods must be developed which address each raw material component. Quantification of reactive decomposition products is often integral to complete understanding of existing interactions among individual components in polymer-based materials. Evolved gas analysis mass spectrometry (EGAMS) can supply qualitative information about polymeric additives and the effects of these additives on thermal decomposition; however, quantitative information is difficult to extract. An EGAMS analysis makes use of a solids probe to heat the sample of interest in the ion source of the mass spectrometer. A linear heating rate is employed. Volatile compounds evolved from the sample during the heating cycle are immediately ionized. The experiments described here covered a temperature range from 40°C to 333°C.

Recently, our attention focused on quantitative analyses of ammonia and hydrogen fluoride (HF) gaseous pyrolysis products from formulated polymer based wire insulations and harness jackets. Ammonia (NH_3) is a pyrolysis product of flame retardants containing ammonium salts and hydrogen fluoride (HF) results from thermal degradation of poly (tetrafluoroethylene ethylene) copolymer-based wire insulations. Both NH_3 and HF are reactive gases with deleterious effects. To quantify these materials, the thermal instability of labile salts was useful. Ammonium bromide (NH_4Br) was used as a reference material for ammonia quantification, whereas, sodium bifluoride ($NaHF_2$) is used to quantify HF evolution. The pertinent thermal degradation reactions are:

1) $NaHF_{2\,(s)} \rightarrow NaF_{(s)} + HF_{(g)}$

2) $NH_4Br_{(s)} \rightarrow NH_{3\,(g)} + HBr_{(g)}$

The reactive nature of NH_3 and HF requires that reference salts and analytes be subjected to nearly identical environments. That is, use of the solids probe is preferred both for the references and samples. A solid diluent must be chosen and a method of homogenizing the analyte within the diluent devised. The diluent material for NH_4Br was 120/140 mesh glass beads and had a thermal window between 150 and 500°C. Alternatively, sodium fluoride (NaF) was chosen as a diluent for $NaHF_2$. TGA analysis indicates NaF is also stable over the temperature range of interest. The diluent is homogenized with the calibrant by gently grinding the mixture with a mortar and pestle.

An important assumption is that variations in ion envelope profiles as a function of temperature will not adversely affect the accuracy of our method. A sample of ammonium sulfamate $NH_4NH_2SO_3$ and NH_4Br were submitted for analysis without the concentrations being communicated to the analyst. The standards used were varying concentrations of homogenized NH_4Br with glass beads.

Figure 1 illustrates that NH_4Br and $NH_3NH_2SO_3$ have very different m/z 17.0265 ion profiles; however, the accuracy of the method is comparable for both the NH_4Br and $NH_4NH_2SO_3$ unknowns.

*This research was conducted under the McDonnell Douglas Independent Research and Development program.

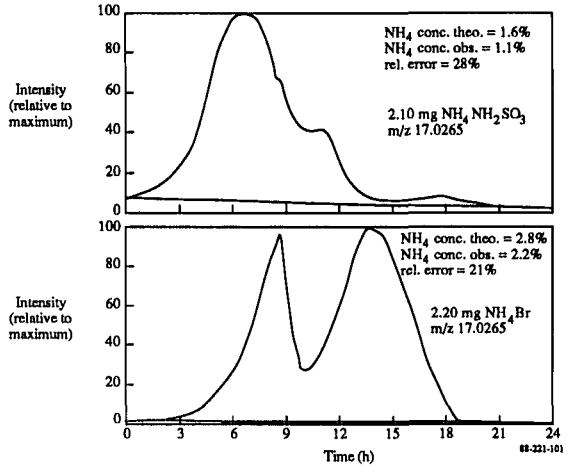

Figure 1.

We have utilized the methodology described to quantify the evolution of HF during thermal degradation of irradiated Tefzel wire insulations manufactured by a variety of suppliers. Of primary concern is the HF evolution between ambient and 200°C, and the variation of this quantity among various suppliers. Wire constructions were obtained from the suppliers of interest in the form intended for use in manufacturing. These constructions were sampled by cutting approximately 2 mm of the wires. The cuttings weighed approximately 1 to 3 mg and had approximately 500 μg of insulation associated with them. Some samples were studied with the conductor absent.

Table I indicates the amount of HF observed among several wire insulations. The yield of HF from the "D" constructions is much lower than that of the other constructions studied. Within the precision of our analysis, we do not see any certain effect on HF evolution by the conductor.

LOW-TEMPERATURE THERMAL AGING OF POLY(PHENYLENE SULFIDE) [PPS]*

Michael A. Grayson and Emilie G. Smith
McDonnell Douglas Research Laboratories
St Louis, MO 63166
and
Michael J. Robinson
McDonnell Douglas Astronautics Company
Huntington Beach, CA 92647

Poly(phenylene sulfide) is an important thermoplastic system for the fabrication of parts for many aerospace applications. It has low water uptake and good strength-to-weight ratio characteristics. However, because it is a high-molecular-weight, fully reacted polymer chain, processing temperatures in excess of the melt temperature are used to achieve the low viscosities necessary for void-free composite fabrication. In some cases, the temperature of processing is sufficiently high that thermal decomposition of the resin may occur. This possibility is of greater concern in some processing techniques, such as hot-gas filament winding, than in others, such as compression molding.

In this study, we wished to determine the thermal degradation processes which occur at the lowest temperatures in order to determine the extent of thermal degradation during hot-gas filament winding. Toward this aim, we exposed samples to controlled thermal environments and subsequently performed evolved gas analysis mass spectrometry (EGAMS). The data from these experiments were compared to determine changes in the compounds evolved and selected ions were used to obtain tandem mass spectra for further elucidation of the degradation process.

Samples of Ryton Type 'A' poly(phenylene sulfide) coated on AS4 Carbon fibers were obtained from Phillips Petroleum Co., Chemicals and Catalysts Division, Bartlesville, OK. The PPS/Carbon fiber pre-preg (PPS/C) was dried to constant weight and stored in a dessicating environment until sample treatment or analyses. According to thermogravimetric analysis (TGA) and evolved gas analysis mass spectrometry (EGAMS), approximately 1% of the sample weight was lost by the evolution of trapped indigenous compounds. Consequently, all samples were treated at 387°C for one hour in a dry nitrogen environment to drive off indigenous compounds prior to further studies.

Samples of PPS/C were aged for four hours in dry nitrogen at five different temperatures in the range of 327 to 447°C. Subsequently, EGAMS measurements to 430°C were performed to determine changes in the compounds evolved as a result of the short-term thermal aging. The primary compounds observed from pyrolysis of the as-received sample were hydrogen-deficient oligomers with four to seven repeat units and molecular weights of n*(108). Montaudo et al. (Ref. 1) have observed similar compounds in their studies and determined that the hydrogen deficiency is the result of macrocyclic ring formation. In our experiments with thermally aged PPS/C samples, we observe in addition to the n*(108) series several more series with greater hydrogen deficiency given by the general rules n*(108)-2 and n*(108)-4 (see Figure 1). The abundance of these latter series increases relative to the n*(108) series with increasing thermal aging temperature.

To elucidate the structure, tandem MS experiments were performed on selected ions from the thermal degradation of the aged PPS/C samples. In particular, the MS/MS spectra of the 430 and 432 ions representative of the two series n*(108)-2 and n*(108) for n=4 were studied in detail. Noting the facile loss of a sulfur and the loss of 183, a dibenzothiophene fragment, from the 430 ion, we postulate this compound to have a structure containing two dibenzo-

*This work was performed under the McDonnell Douglas Independent Research and Development program.

thiophene moieties linked by a sulfur atom. Thus, the 430 ion provides evidence for intrachain cyclization in PPS/C samples subjected to thermal aging. When the MS/MS spectrum of the 432 ion is compared with that of the 430, the same losses are observed with nearly the same relative intensities. This result suggests that some portion of the n*(108) series of compounds produced may be due to intrachain cyclization rather than macrocyclic ring formation. Tandem MS spectra of other pairs of products at n=5 (538 and 540 daltons) and n=6 (646 and 648 daltons) have similar fragmentation patterns, suggesting that the formation of the benzothiophene moiety via intrachain cyclization occurs in the higher oligomers as well.

The formation of increasingly hydrogen-deficient oligomeric series as aging temperature is increased clearly indicates the presence of one or more dibenzothiophene moieties in the thermally aged PPS macromolecule. Thus intrachain reactions are important in the low-temperature thermal degradation processes of PPS. Such reactions may actually explain changes in mechanical properties attributed to interchain crosslinking reactions postulated earlier by Brady (Ref. 2).

FRAGMENTATION OF POLYSILOXANES UNDER ELECTRON IMPACT: DIFFERENCES FOR OLIGOMERIC SERIES

P. Jane Gale and Bryan L. Bentz
David Sarnoff Research Center
Princeton, New Jersey 08543-5300

In spite of their broad use--or perhaps because of it--not a great deal of analytical information on polymeric organosilicon materials has been published. In particular, very few mass spectra are included in the commonly available libraries. Since we frequently find ourselves identifying such materials, either because we are interested in them for themselves or because they appear as contaminants in systems we are studying, we have begun to collect the spectra to form our own library. In so doing, we have found evidence for some interesting chemistry in the spectra which we highlight here. The compounds of interest have one of two general structures: linear molecules of the type $R_3SiO[Si(R_2)O]_nSiR_3$ and cyclic species, $[R_2SiO]_n$.

Silicones are easily ionized by electron impact (EI). Fragmentation is often extensive, but it usually follows predictable rules. Thus, the large number of fragment ions actually facilitates identification by aiding in structure elucidation. The compounds are less easily ionized by methane chemical ionization (CI), and, in general, we have not found CI a particularly useful technique for their analysis. Silicones are easily sputtered, however, and secondary ion mass spectrometry (SIMS) has proved an excellent means for determining their presence, either as coatings or as contaminants, on surfaces. The EI spectra presented here were obtained with an HP 5985B GC/MS. The SIMS spectra were obtained with a Finnigan MAT TSQ-15 modified in our laboratory for surface analysis.

On the following page the spectra of four molecules typical of those we encounter are shown. The structures attributed to fragment ions are merely suggested structures. In general, structural assignments for the fragment ions of smaller molecules are fairly certain, since most losses are unique and rearrangements are obvious. Assignment of structures to the fragment ions of larger molecules, particularly those from oligomeric species, is more speculative. In these molecules, several more or less equivalent sites of ionization exist and associated with each of these are a number of fragmentation pathways. In addition, several quite plausible fragment ion structures may have the same nominal mass. In determining empirical formulae for the fragment ions, we are guided by the relative intensities of the silicon isotope peaks. We also check proposed mechanisms for consistency within an oligomeric series. Finally, we compare fragment ion structures for series having different alkyl substitutents, since similar patterns are expected.

Comparison of the spectrum of the ethoxy oligomer with that of the decyl methyl oligomer shows that in general the ethoxy siloxane fragments less under electron impact than does the decyl methyl siloxane. Similar results were found when spectra for each of the n=1,5 oligomers from each series were compared, implying that the ethoxy substitution somehow stabilizes longer Si-O-Si chains. The added stability appears comparable to that imparted by cyclization. We suggest that this increased stability is due to the formation of secondary Si-O-Si bridges within the fragment ion structure when $C_2H_5OC_2H_5$ is split out. Fragmentation to an even number of silicon atoms is favored. This is not surprising, since, with an even number of silicons, each skeletal Si-O-Si triad can be stabilized. All alkoxy siloxanes might be expected to behave in this fashion, since in principle all can eliminate dialkyl ether and form secondary intramolecular oxygen bridges. We did not, however, observe bridged ions in the spectra of methoxy siloxanes; hence, operation of the bridging mechanism in the fragmentation of electron-impact-ionized alkoxy siloxanes must depend in part on the ease with which dialkyl ether can be eliminated. Some measure of the extent to which ether formation is favored can be gained by comparing heats of formation of the potential ethers. For the two ethers discussed here, ΔH_f for $C_2H_5OC_2H_5$ is some 20 kilocalories greater than ΔH_f of CH_3OCH_3.

[1]Charles Evans & Associates, Redwood City, CA

[2]Departments of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO.

Laser ionization mass spectrometry (LIMS) is a microanalytical materials analysis technique which has been extensively applied to elemental characterization of materials and has more recently found application in the analysis of organic species.[1] Organic characterization of polymeric materials employed in various industrial applications (e.g. semiconductor and optical fiber materials processing and aerospace applications) are particularly interesting since the performance criteria of many devices are ultimately dependant on the materials' micro-composition. We have recently initiated a LIMS characterization of various organic polymers in order to determine the ability of the laser microprobe technique in distinguishing different compositions. This characterization entails acquiring positive and negative ion mass spectra at three different laser irradiances, qualitatively evaluating the spectra for structurally significant or unique peaks and applying principal component analysis (PCA)/discriminant analysis to the data set in order to determine whether the spectra separate into distinctive classes. The laser irradiances employed are designated as low, intermediate, and high corresponding to ion intensities near threshold, ~10X and ~100X above threshold, respectively. These analyses were performed on the model LIMA 2A laser microprobe mass spectrometer manufactured by Cambridge Mass Spectrometry, Ltd (Cambridge, England) which has been described previously.[2] A representative positive ion mass spectrum produced from a thin section (~2 µm thick) of poly(1,4 butylene terephthalate) is illustrated in Figure 1. Two kinds of signals are generally recognized in the mass spectra: C_xH_y cluster ions arising from rearrangement of the molecular structure and structurally significant molecular fragments, such as the aromatic ions C_6H_5, $C_6H_5CH_2$, C_6H_5O, or C_6H_5CO. A weak signal for this latter ion is observed in Fig. 1. Although these molecular fragment ions do provide valuable structural information, the low intensity of these structural ions rarely provide unambiguous identification of the polymer structure.

A principal component analysis (PCA) technique[3] employing canonical variate or discriminant analysis[4] was applied to a limited mass spectral data set produced from seven different polymers in order to determine whether PCA could provide distinctive classification of the spectra. Figure 2 illustrates the canonical variate scores for the first two components produced in a PCA analysis of the high irradiance positive ion data for these polymers. The identification of the various samples in this plot are the following: (1)-Nylon 6, (2)-Nylon 12, (3)-Poly(1,4 Butylene Terephthalate), (4)-Polycarbonate, (5)-Polystyrene, (6)-Spurr's Epoxy Resin, and (7)-Mylar D500 [Poly(Ethylene Terephthalate)]. The data reduced to 12 principal components which described over 80% of the variance while the canonical variate analysis yielded four components which accurately classified over 65% of the spectra. The canonical variate scores for the two components displayed in Fig.2 form distinct clusters which indicates that the canonical variates for the various polymers are reasonably distinct. Each number in the plot represents

the scores for a single mass spectrum in the data file and the spectra from several polymers overlap (i.e. there are less than seven numbers for each polymer type), suggesting that the laser microprobe data are highly reproducible. More accurate classification could result from utilizing a larger data base. A similar analysis of the high irradiance negative ion data yields two canonical variates which accurately classified 55% of the spectra. Thus, the positive ion data seems to provide a more unique pattern of spectral peaks. This type of classification is continuing for other polymer formulations and analysis conditions and ultimately we hope to develop a reference library for laser microprobe polymer analyses.

NEGATIVE ION FAB MASS SPECTROMETRY OF PROCYANIDIN OLIGOMERS

J.J. Karchesy and L.Y. Foo, Department of Forest Products; E. Barofsky
B. Arbogast, and D.F. Barofsky, Department of Agricultural Chemistry
Oregon State University, Corvallis, Oregon 97331

We have previously reported on positive ion FAB mass spectrometry, utilizing linked scanning, of procyanidin oligomers [1]. In the present work we report on a complimentary study of negative ion FAB mass spectrometry of this same group of compounds; as with our positive ion FAB analyses, we have made extensive use of linked scanning to obtain structural information. In recent independent studies, negative ion FAB has been employed to assist in both the structural elucidation and analysis of mixtures of procyanidin oligomers, glucosylated flavanoid oligomers, and derivatives [2-5].

Mass spectra of the dimeric procyanidins B-1, epicatechin(4β→8)catechin (I); B-7, epicatechin(4β→6)catechin (II); epicatechin(4β→2)phloroglucinol (III); A-1, epicatechin(4β→8; 2β→O→7)catechin (IV); and trimeric procyanidins epicatechin(4β→8)epicatechin(4β→8)epicatechin (V); epicatechin(4β→8) catechin(6→4β)epicatechin (VI) were obtained off both a VG 7070E-HF mass spectrometer and a KRATOS MS-50 TC mass spectrometer. Both instruments have standard FAB sources that use Ion Tech saddlefield atom guns. A 5:1 mixture of dithiothreitol and dithioerythritol (commonly referred to as magic bullet) was used as the FAB matrix liquid. Approximately 10 μg of sample compound was dissolved in about 1 μl of magic bullet for analysis; the samples were bombarded with 8 keV xenon atoms. Metastable decomposition pathways were established by B/E linked scanning without collisional activation.

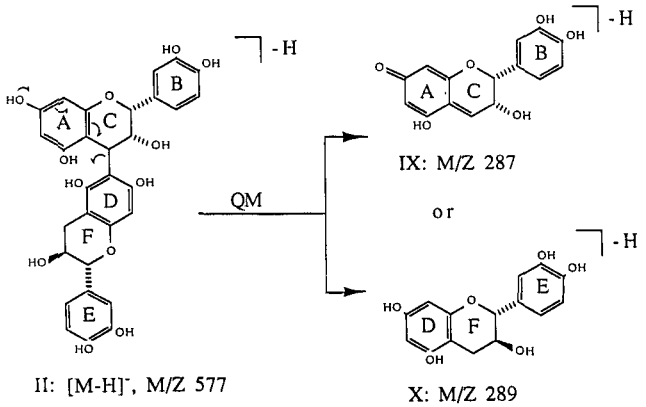
Table 1.

Compound	Ions Observed					
	$(M-H)^-$	RDA	RDA-H_2O	Monomer	Dimer	Other
I.	577(100)	425(25)	407(11)	287(12),289(18)	--	273(-)
II.	577(100)	425(29)	407(8)	287(8),289(24)	--	273(-)
III.	413(100)	261(14)	--	287(7),125(14)	--	--
IV.	575(100)	423(25)	--	285(19),289(10)	--	--
V.	865(100)	713(14) 425(10) 423(7)	695(4) 407(10) 405(4)	287(17),289(20)	575(9),577(10)	--
VI.	865(60)	713(13) 425(29)	695(6) 407(19)	287(20),289(15)	577(100)	--

Retro-Diels Alder (RDA) fission results in characteristic $(M-H-152)^-$ ions for each of the compounds studied (Table 1). In two instances, compounds I and II, a mass peak at m/z 273 (seen only in the B/E spectrum due to a coincident matrix peak) can be rationalized on the basis of a second, consecutive RDA fission from the original RDA fragment ion m/z 425.

A quinone methide (QM) mechanism of interflavanoid bond cleavage is proposed to account for the two different sequence ions that are produced from the $(M-H)^-$ ion of B-1 and B-7 (Scheme 1). The proposed formation of quinone methide from procyanidins under FAB conditions is supported by numerous examples in which gas phase decompositions under mass spectrometric conditions can be accounted for by mechanisms invoked to explain reactions in solution chemistry [6-10]. This mechanism is consistent with the sequence

ions produced by cleavage of B-type interflavanoid linkages in the trimers as well. Most importantly, this mechanism demonstrates that the upper and lower isomeric flavan units can be distinguished after cleavage of the bond between them. This has positive implications for future research on analytical methods that might identify the points of attachment for other groups, such as glycosides, DNA adducts, etc., on a procyanidin oligomer.



Scheme 1.

Because the QM mechanism results in unsymmetric cleavage about the interflavanoid bond, a linear (V) and a branched trimer (VI) can be distinguished by the dimer ions they produce. With V, cleavage of the upper interflavanoid bond gives a dimer at m/z 577 while cleavage of the lower interflavanoid bond gives a dimer at m/z 575; subsequent RDA fissions of each of these give ions at m/z 425 and m/z 423 respectively. By contrast, VI gives a dimer at m/z 577 (II) upon cleavage of the upper bond and a dimer at m/z 577 (I) on cleavage of the lower bond. Subsequent RDA fissions of I and II give indistinguishable ions at m/z 425.

CHARACTERIZATION OF EPOXY DERIVED OLIGOMERS BY FAST ATOM BOMBARDMENT MASS SPECTROMETRY.

The recent general applicability of fast atom bombardment mass spectrometry (FAB/MS) to biopolymer systems has sparked considerable interest in the use of this technique to characterize synthetic polymers. Our laboratory, as well as several others, has begun to examine the fragmentation patterns of oligomers in order to identify and/or confirm the type of structures formed during a particular curing process.

Specifically, we have studied the curing products of methoxyglycidyl ether of Bisphenol A (MGEBA) with 4-aminodiphenyl sulfone (ADS) and 4,4'-diaminodiphenyl sulfone (DDS). The major products of the first reaction mixture (MGEBA/ADS) were first separated by preparative liquid chromatography and enough material collected in order to perform more conventional structural identification techniques (i.e. NMR and IR). Once the structure of each product was established by these techniques, the FAB/MS studies served the dual purpose of confirming the identity of the products and of establishing a data base regarding the relationship between mass spectral patterns and molecular structure. In every case the major fragmentations were directed by the common MGEBA portion(s).

In addition to providing molecular weight information, which confirms the identity of the oligomers, the fragmentation patterns of the mass spectra can also be used to distinguish between different isomeric linkages of the same oligomer. As an example to illustrate this point, the spectra of the two 2:1 (MGEBA:ADS) isomeric products are shown in Figures 1 and 2. Although the molecular weight as well as many of the fragments are common to both isomers, there are two features which distinguishes between the two. The first, and most prominent, is the relative intensity of the peak at m/z 544 compared to the molecular ion. The formation of this ion is favored for the first isomer because the ion is a quaternary amine which is formed by cleavage beta to the nitrogen from either MGEBA moiety and resonance stabilized by the adjacent aromatic electron density. On the other hand, in order for the second isomer to form the ion at m/z 544, cleavage must take place between the methylene and methine carbons adjacent to the ether oxygen resulting with an ion which has a positive charge on the methylene and little adjacent electron density to stablize that charge. The second difference is the peak at m/z 260 for the first isomer (Figure 1) which can only be formed by a tertiary amine and the corresponding ion at m/z 246 for the second isomer (Figure 2) which is indicative of a secondary amine.

By identifying the types of fragmentations which occur in these products, we established a data base which relates fragmentation patterns to molecular structure. We then used this information to characterize the products of the related MGEBA/DDS system using only FAB/MS and the material collected from one HPLC run.

Having the ability to identify reaction products from a chromatographic run, we may envision on-line HPLC-FAB/MS using the moving belt interface in order to identify the minor and trace components of these and other reaction mixtures, as well as the intermediates which are highly reactive or unstable for long periods of time.

Methylation Studies of Protein and Nucleic Acids

W.G. Stillwell, Liang-Shang Gan, John S. Wishnok, Hou-Xiao Xu, and Steven R. Tannenbaum. Department of Applied Biological Sciences, Massachusetts Institute of Technology, Cambridge, MA 02139.

We have begun an investigation of the use of methylated nucleic acids and methylated proteins as indicators of prior exposure to methylating agents in laboratory animals and humans. We chose the carcinogen N-nitrosodimethylamine (NDMA) as the methylating agent for study. NDMA is metabolized in animals to a reactive species capable of methylating nucleic acids and protein. The major DNA adduct formed in vivo and in vitro is 7-methylguanine, however, 3-methyladenine, O^6-methylguanine, as well as methyl phosphotriesters, are found in minor amounts. Methylation is also a naturally occurring process and background levels of methylated nucleic acids and proteins arising from biological sources are observed.

In this work we studied the urinary excretion of 3-methyladenine and 7-methylguanine, as well as methyl esterified amino acids in hemoglobin, as indicators of exposure to methylating agents. The ferret was used in these studies because this species is (1) a better model than the rat for the human stomach and (2) is larger than the rat thus simplifying surgical procedures.

We have also studied the urinary excretion of 3-methyladenine and 7-methylguanine, as well as nitrosoproline and nitrate, in a human population characterized by an increased incidence of gastritis accompanied with elevated levels of urinary nitrate.

METHODS. Male ferrets (600-875 gm) were administered 0.5, 2.0, and 5.0 mg/kg N-nitrosodimethyl-d_6-amine. Urine samples from baseline, 0-24, 24-48 hr post-dosing periods were collected. One ml blood samples were also collected at selected intervals. Isolation and analysis of 3-methyl-d_3-adenine, as well as other purines in urine, were carried out by a modification of a published procedure (1) using 3-ethyladenine as the internal standard. Quantification of 3-methyladenine and 3-methyl-d_3-adenine in extracts of urine was accomplished by GC/MS analysis of the t-butyldimethylsilyl derivatives using selected-ion-monitoring (SIM) at m/z 206 (M-57) for 3-methyladenine, m/z 209 for the d3-analog, and m/z 220 for 3-ethyladenine. Analysis of adducted hemoglobin was conducted after basic hydrolysis of the isolated globin fraction followed by ultrafiltration, extraction, and derivatization of the labeled (d_3) methanol with pentafluorobenzoyl chloride. Negative-ion-chemical-ionization GC/MS was used to quantify the amount of labeled methanol formed from d_6-NDMA.

RESULTS AND DISCUSSION. Analysis of hemoglobin in the ferret showed that methyl ester formation accounted for 25-30% of total hemoglobin modification (approx. 0.6% of the total dose) in the early 24-hr samples. The sensitivity of the GC/MS analysis was such that levels as low as 10 ng of methyl-d_3-ester per gm of hemoglobin could be detected.

Excretion of 3-methyl-d_3-adenine in urine showed a linear dose-response relationship in the range studied and accounted for approx. 0.06% of the total dose administered. Figure 1 shows the SIM traces of the urine extract obtained from the ferret administered 5.0 mg/kg d_6-NDMA; the amount of 3-methyl-d_3-adenine excreted was 1.8 ug. The baseline value of 3-methyladenine excretion was 476 ng/24 hr (the SIM traces for this analysis are shown in figure 1). Ferrets typically excrete 300 to 600 ng of 3-methyladenine per day.

Other purine bases including adenine, guanine, 1-methyladenine, 7-methylguanine, N^2-methylguanine, N^2-dimethylguanine, 8-hydroxyadenine, and 8-hydroxyguanine were also detected in both ferret and rat urine. SIM traces for the analysis of adenine, 7-methylguanine, 8-hydroxyadenine, and N^2-dimethylguanine in control ferret urine are shown in Figure 2.

In the human studies, 3-methyladenine was assayed as described above at m/z 206 and m/z 209 (for the d_3-analog used as internal standard); the corresponding ions at m/z 336 and 339 were used for 7-methylguanine. In a low nitrate group (N=23) a median value of 5.3 ug/24 hr for 3-methyladenine excretion was obtained. In a high nitrate group a wide variation of excretion was noted (range 2.4 to 123.8 ug/24 hr); median values of 8.9 to 9.1 ug/24 hr were observed in this group (N=20). In the highest nitrate

subset, the range of excretion was identical to the range of combined high-nitrate group, but the median value for the excretion of 3-methyladenine was somewhat lower (5.8 ug/24 hr). Excretion of 7-methylguanine for the high nitrate group appeared to be slightly higher than that for the low nitrate group. There was slight correlation between excretion of N-nitrosoproline and 3-methyladenine in these subjects.

INTRODUCTION

Particle-assisted desorption ionization techniques have been used sucessfully in mass spectrometry for studies of non-volatile and thermally sensitive biomolecules. In particular, solid SIMS incorporating a time-of-flight (TOF) mass analyzer combines high sensitivity with a very high mass range, and the mass spectra are relatively free from the significant chemical noise that is usually associated with the matrix employed in liquid SIMS, i.e. fast atom bombardment.

We have investigated the use of TOF-SIMS as an analytical tool to characterize and differentiate protected isomeric di and trinucleotides, as shown in Table 1 . These compounds, synthesized at McGill (1), include three pairs of positional isomers of an unusual kind: they contain either 3'-5' or 2'-5' phosphodiester linkages. Also included in these studies is one pair of diastereomeric branching trinucleotides, involved in the maturation process of messenger RNA.

Mass spectrometry was performed on the Manitoba TOF II instrument, which incorporates an ion mirror (2). We will demonstrate how the use of this technique can reveal striking differences between these very closely related biomolecules.

EXPERIMENTAL

1. Sample preparation:

All oligonucleotides were dissolved in methanol at a concentration of ca 1 mg/ml. A few μL of each solution were then deposited on aluminum foil treated to give a boehmite, AlO(OH) , surface (3).

2. Mass spectrometry:

Sample targets were bombarded by a pulsed beam of 23 keV Cs^+ primary ions. The secondary negative ions produced were accelerated to -5 keV, allowed to drift along the field-free region of the flight tube, then detected by microchannel plates. No electric field was applied on the ion mirror in the current study; therefore, only "direct"mass spectra were obtained. An accompanying paper (4) describes how this instrument can also be used as a "tandem-like" mass spectrometer.

RESULTS AND DISCUSSION

Detection of quasimolecular ions and sequence information have been obtained for each oligonucleotide. Contrary to what was observed with unprotected, normal 3'-5' oligonucleotides (5), 5'-phosphate sequence ions (X^- ions(6), see figure 1) are not always more abundant than the corresponding 3'-phosphate sequence ions (Y^- ions). This can be explained in part by the presence of bulky silyl protecting groups in all the compounds studied. On the other hand, indicators of isomeric form have been found in every instance. For example, the ratio of X^- ions/Y^- ions (with or without protecting groups) becomes smaller for positional isomers containing a 2'-5' phosphodiester linkage. In the case of dinucleotides, an increase in the yield of A^{Bz}- is also noted. These observations

may be related, as depicted in scheme 1. In 2'-5' isomers, anchimeric assistance can be provided by neighboring 2'phosphate oxygens, facilitating the loss of the base moiety, therefore competing with X^- ion formation pathways. A similar rationale has been used to explain differences between diastereomeric $A^{U}U$ and arabino-$A^{U}U$, the latter showing both a reduced A^{Bz}- ion yield and an increase in the production of X^- ions (7).

In addition to providing quasimolecular ion detection, base sequence information and protecting group nature and location, many unequivocal indicators of isomeric form were found for each pair of oligonucleotides studied. Time-of-flight SIMS hence constitutes a powerful tool in mass spectrometric investigations of subtly different biomolecules such as these.

MASS SPECTROMETRIC AND CHROMATOGRAPHIC PROPERTIES OF RING-PENTA FLUOROBENZYLATED NUCLEOBASES USED IN THE TRACE DETECTION OF ALKYL DNA ADDUCTS

Gerhard M. Kresbach, R.S. Annan, M.G. Saha, R.W. Giese, and Paul Vouros
Barnett Institute, Dept. of Chemistry, and Dept. of Medicinal Chemistry,
Northeastern University, Boston, Massachusetts 02115

Exposure of humans to chemicals as well as radiation raises the risks of carcinogenesis and mutagenesis due to the formation of adducts in DNA. A specific type of damage is the introduction of small alkyl and hydroxyalkyl groups in nucleobases, e.g. the O^2-methylation of cytosine and the conversion of thymine to 5-hydroxymethyluracil (HMU).

Our laboratory has been interested in the development of chemical derivatization techniques for the trace level detection of modified DNA bases using electrophoric groups and negative chemical ionization mass spectrometry (NCI-MS). The selection of derivatives is based on several requirements, including a) the formation of analyte specific ions under NCI-MS, b) the capability to yield structurally diagnostic ions by EI and/or PCI, c) high yield and adequate chemical stability, and d) good chromatographic performance for GC-MS and LC-MS at trace levels.

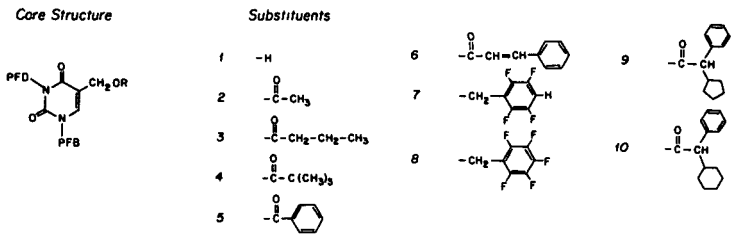

Figure 1: Electrophoric 5-hydroxymethyluracil derivatives

Derivatization with the pentafluorobenzyl (PFB) group as an electrophore was found to comply with most of these demands. N_1,N_3-bis-PFB-HMU with either a free hydroxyl group in position 5 or there further derivatized (Fig. 1) was used as a model compound for hydroxylated nucleobases and demonstrated the impact of PFB in the NCI mode on the main fragmentation pattern and the strong influence of the side chain on the relative ion intensity (Fig. 2). Generally the fragment $[M\text{-}PFB]^-$ was observed as the base peak, serving as diagnostic ion. Fig. 3 shows the separation of 40 fmol each of several of these derivatives by LC-MS using a moving belt interface and selected ion recording of the $[M\text{-}PFB]^-$ -ions. Separation of the same compounds at a 10 fmol level by GC- MS resulted in a comparable signal/noise ratio and demonstrated again the applicability of the transport type interface in trace analysis.

The validity of these results was confirmed in a study of a wide variety of modified bases. $[M\text{-}PFB]^-$ as base peak in NCI is a common feature in all ring-pentafluorobenzylated nucleobases. Well defined protonated molecular ions can be obtained in the PCI mode. Under EI conditions, information about the core struc ture of the base as well as about exocyclic substitution can be obtained, thus facilitating the identification of unknown adducts. Differentiation of positional isomers is possible in some cases.

In summary, pentafluorobenzylation can be used successfully for the detection of alkyl DNA bases at low picogram levels by GC-MS and LC-MS using a moving belt interface.

In continuation of our studies on urinary nucleosides, we wish to report the isolation and characterization of two new nucleosides, 5-carbamoylmethyluridine I and 5-carbamoylmethyl-2-thiouridine II (Fig. I) from normal human urine. A 24 hour urine (1500 ml) was processed according to the previously described procedure (1). The two unknown nucleosides I and II were purified by HPLC and were obtained in 240 ug and 25 ug respectively. The uv spectra of nucleoside I were similar to those of the 5-substituted uridines [λ_{max} (nm) 266 (pH 1 and 6.0) and 265 (pH 11.0)]. The nmr spectrum in D_2O exhibited resonance at 5.96 ppm for the anomeric proton and at 7.8 ppm for C_6H of uridine. The upfield resonance at 3.35 ppm could be assigned to the methylene protons of the 5-substituent. A trimethylsilyl derivative of I gave a highest mass ion at m/z 646 (Fig. 2) which could be assigned to $M^{+\cdot}-CH_3$ ion of penta TMS derivative (mol. wt. 661) of the nucleoside I. The fragment ion at m/z 546 (M-115) represents the loss of CON-TMS from the side chain while the fragment ion at m/z 386 arises from the silylated base after the cleavage of the glycosidic bond. The ions at m/z 349, 259, 243, 217 and 169 confirm the presence of an unmodified ribose sugar in the molecule. The mass spectra of the penta TMS derivative of authentic I were similar to those of the TMS derivative of unknown urinary nucleoside I, thus supporting 5-carbamoylmethyluridine as the structure of the nucleoside I.

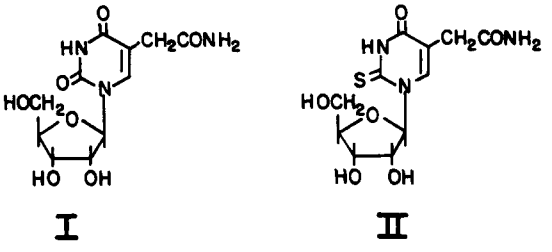

Fig. I

The uv spectra of the nucleoside II exhibited maxima at 275 nm at pH 1 and 7, and at pH 11 maxima shifted to 242 nm with a prominent shoulder at 271 nm. These uv spectra were similar to those of the 5-alkyl-2-thiouridine. A TMS derivative of nucleoside II (Fig. 3) exhibited the highest mass ion at m/z 572. This was assigned to the $M^{+\cdot}-CH_3$ ion of the TMS derivative of dehydration product of II. Authentic 5-carbamoylmethyl-2-thiouridine silylated under identical conditions also exhibited a highest mass ion at m/z 572 assigned to the $M^{+\cdot}-CH_3$ ion of the tetra TMS derivative of the dehydration product. A dehydration product ion ($M-H_2O$) was observed also in the mass spectra of the $(TMS)_5$ derivatives of I. The mass ions m/z 348, 259, 245 and 217 indicate an unmodified ribose sugar. The EI GC/MS spectra for silylated urinary nucleoside II and silylated authentic II are identical, thus supporting the structure II for this urinary nucleoside.

The nucleoside (I) was first isolated from the alkaline hydrolysate of tRNA from Bakers yeast and wheat embryo[2]. More recently, it has been shown to be present in the first position (Wobble) of the anticodons of $tRNA^{Pro}$ and $tRNA^{Val3}$. The isolation of nucleoside II from other biological sources such as tRNA has not been reported. The uridine derivative 5-methoxycarbonylmethyl-2-thiouridine, however, has been isolated from yeast tRNA hydrolysates and has been shown to be present in the Wobble position of the anticodons for $tRNA^{Lys}$ and $tRNA^{Glu}$ from Bakers yeast. Control experiments indicate that the urinary material could originate from

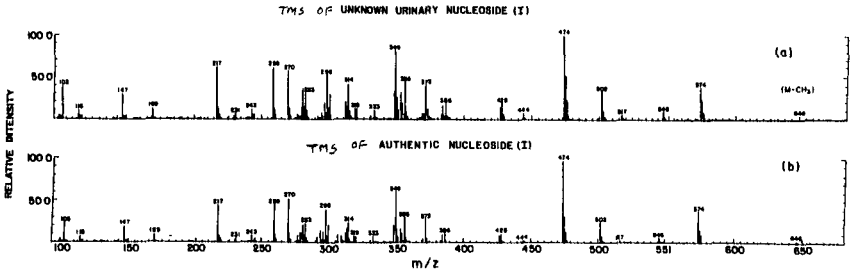

Fig. 2

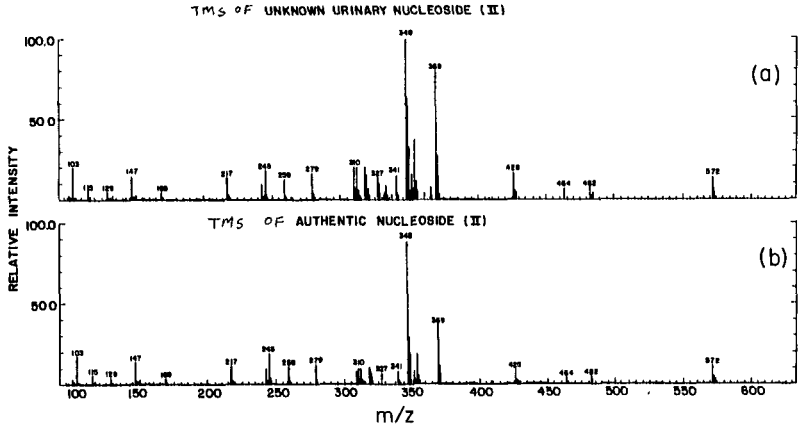

Fig. 3

the 5-methoxycarbonylmethyl-2-thiouridine under the isolation procedure. Nucleoside I, excreted in the urine, is most probably derived from the tRNA turnover. With few exceptions, uridine in the first (Wobble) position of the anticodon in tRNA is replaced by hypermodified uridines or thiouridines substituted at the 5-carbon. It has been demonstrated that some of the hypermodified uridines amplify the Wobble recognition while others such as 2-thio derivatives restrict the recognition. These nucleosides thus, appear to play some role in codon-anticodon interactions. The enzymatic controlled modification mechanism of nucleosides has been shown to be a sensitive indicator for monitoring normal cellular events. Study of the excretion levels of these two modified nucleosides may prove useful in the investigation of the modification phenomena and its role in nucleic acid functions, cell differentiation and turnover rates.

Roswell Park Memorial Institute, Buffalo, New York 14263

Of more than 65 modified nucleosides known to be present in mammalian tRNA, 21 have, so far, been detected in human urine[1]. Anticodon adjacent modified nucleosides of tRNA, such as N-[(N-9-β-D-ribofuranosyl-purin-6-yl-carbamoyl)-L-threonine (t6A), 1-methylinosine, N2-dimethylguanosine, .. are included in this group. Some of these compounds are known to be present in higher levels in the urines of cancer patients as compared to normal human urine[1]. Ribose modified nucleosides such as the 2'-O-methyl-nucleosides are pesent in mammalian tRNA, mRNA, rRNA and HnRNA. We have been interested in developing suitable clean-up and GC-MS assay procedures for the detection and quantitation of these modified nucleosides in human urine. This report describes a capillary GC-MS procedure for the detection and identification of four 2'-O-methylnucleosides, 2'-O-methyladenosine, 2'-O-methyluridine, 2'-O-methylguanosine and 2'-O-methylinosine in human urine.

A 50 ml sample of urine was fractionated as previously described[2]. The non-cis-diol fraction (0.14 M boric acid eluate) from the DEAE borate column was further fractionated by reverse phase HPLC (ODS C-18 column eluted with 0 → 50% MeOH in water in one hour). An aliquot of each of the collected fraction were lyophilized, dried over P_2O_5 under vacuum at 100° for 2 hours, and then derivatized by heating with 2.5 µl of BSTFA (with 1% TMCS) and 2.5 µl of anhydrous pyridine at 100° for 1.5 hours.

GC-MS analyses were carried out on a Finnigan 4500 GC-MS system using a DB-1 (bonded phase) capillary column (30 M long, film thickness 0.25µ). A splitless injection was made using a Grob injector (temp. 280°) and the column oven was programmed from 80° (2 min hold) to 200° (20°/min) and then to 280° (5°/min; 5 min hold). The mass spectrometer was operated at an ionization voltage of 70 eV and a dynode voltage of -3.0 kV.

Comparison of GC retention times and full mass spectra with those of the authentic standards (Table I) led to the unequivocal identification of the 2'-O-methyladenosine (M^+ m/z 497), 2'-O-methyluridine (M^+ m/z 474), 2'-O-methylguanosine (M^+ m/z 585) and 2'-O-methylinosine (M^+ m/z 498) in one normal human urine and from the urine of a patient with chronic myelogenous leukemia. The identity was further confirmed by spiking the urine samples with appropriate authentic standards.

Table I

GC Retention Times (Minutes) of Silylated 2'-O-Methyladenosine, 2'-O-Methyluridine, 2'-O-Methylguanosine and 2'-O-Methylinosine Isolated from Human Urine and Authentic Standards

	Normal Urine	Leukemic Urine	Normal* Urine	Authentic Standard
1. 2'-O-Methyladenosine $(TMS)_3$	18.02	18.01	18.00	18.07
2. 2'-O-Methyluridine $(TMS)_3$	15.25	15.20	15.28	15.20
3. 2'-O-Methylguanosine $(TMS)_4$	20.35	20.15	20.30	20.20
4. 2'-O-Methylinosine $(TMS)_3$	16.92	16.98	17.05	16.92

*Sample of urine fraction was spiked with approx. 25 ng of appropriate authentic standard before derivatization.

This paper constitutes the first report on the presence of 2'-O-methylinosine (Fig. 1) in human urine; 2'-O-methyladenosine has earlier been isolated from the urines of immunodeficient children[3] and the presence of 2'-O-methylguanosine (Fig. 2) has been inferred from radioimmunoassay[4].

Structural Studies of DNA Covalent Adducts of a Styrene Metabolite by ^{32}P Post-labeling and Liquid Secondary Ion Mass Spectrometry (LSIMS).

S. Kaur, K. Pongracz, W. Bodell and A.L. Burlingame, University of California, San Francisco, CA.

Introduction Epidemiological evidence suggests that many industrial chemicals are carcinogenic. Activation of the parent compound *in vivo* may produce electrophilic intermediates capable of attacking nucleophilic sites in DNA. Structural assignment of covalently modified nucleotides are hence important in elucidating the mechanisms involved in the early stages of chemical carcinogenesis. The presence of DNA-styrene oxide covalent adducts detected by ^{32}P post-labeling[1] has been recently reported in humans occupationally exposed to styrene[2]. This paper reports structural studies of *in vitro* DNA and deoxyguanosine (dGMP) adducts of the metabolite styrene oxide (S.O.) using a combination of ^{32}P post-labeling, chemical synthesis and mass spectrometry.

Results and Discussion DNA (calf thymus, 0.5mg) or 3'-dGMP (0.5mg) in 1ml of 30mM Tris-HCl (pH 7.5) were reacted with 5µl of S.O. (24h, 37°C). Unreacted S.O. was extracted with diethyl ether. The DNA was enzymatically digested using micrococcal nuclease and spleen phosphodiesterase (to yield 3'-dNMPs) and ^{32}P post-labeled (converted to 3'5'-dNDPs at pH 9 by incubation with ^{32}P-ATP, and T_4 kinase, 30 min.; followed by apyrase, 30 min.) The S.O. adducts were separated from the non-modified nucleotides by reversed phase TLC (0.4M ammonium formate, pH 6). After transfer to a PEI cellulose plate, the adducts were resolved by 2-dimensional chromatography (1: 1.8M lithium formate, 4.25M urea, pH 3.5; 2: 0.36M LiCl, 0.22M Tris-HCl, 3.8M urea, pH 8; 3: 1.7M Na_2HPO_4, pH 6; eluting the latter two in the same direction). Autoradiography indicated at least 5 adducts in each case; adducts 1 and 2 accounting for *ca.* 90% of the total radioactivity. Adducts 1 and 2 isolated from the dGMP reaction co-chromatographed with 1 and 2 from the DNA reaction. Reaction products for other mononucleotides were minor and did not elute in this region of the chromatogram.

To identify the major post-labeled adducts 1 and 2 the reaction products from a larger-scale dGMP reaction were fractionated by HPLC and aliquots of each fraction were post-labeled and submitted to LSIMS. Thus, 3'-dGMP (10 mg, 1ml Tris-HCl) was reacted with 100µl S.O. (24h, 37°C). The adducts were isolated by HPLC (10µm, 250x10mm i.d.; solvent A=10 mM NH_4OAc, B=MeOH; t=0 min., A=100, B=0; t=60 min., A=30, B=70; t=70 min. A=0, B=100) and aliquots were ^{32}P post-labeled to locate the fractions containing 1 and 2. 1 (t_R 55-60 min.) and 2 (t_R 50-55 min.) had identical LSIMS mass spectra (mol. ion m/z 586; negative ion mode) indicating structural isomers (Fig.1a). The high resolution spectra showed the elemental compositions $C_{26}H_{30}N_5O_9P$ (∂ 3-5ppm) indicating the presence of 2 S.O. molecules per adduct in each case. Adducts 1 and 2 PEI co-chromatographed with 1 and 2 isolated from the DNA reaction.

One of the minor adducts was identified by PEI co-chromatography with a synthetic standard 6-O-(2-hydroxy-2-phenyl)-2'-deoxyguanosine-3'-monophosphate[3]. The synthetic standard was characterized by high resolution EIMS (as the trimethylsilyl derivative), and UV and ^1H NMR (500 mHz) spectroscopy. One possibility for the major adduct corresponding to alkylation at two sites in the dGMP would be alkylation at the O-6 and N-2 positions. (Alkylation involving the N-7 substituent results in cleavage of the glycosidic bond and the resulting adduct would not be detected by the post-labeling procedure). Thus, in order to obtain an O-6, N-2 diadduct, 6-O-(2-hydroxy-2-phenyl)-2'-deoxyguanosine-3'-monophosphate was reacted with 10 µl S.O. (24h, 37°C). The adducts (t_R 50-55 and 55-60 min.) were isolated by HPLC (as above). ^{32}P post-labeling also showed the same retention behavior as 2 and 1 , respectively, from the DNA and dGMP reactions. The LSIMS spectra (mol. ion m/z 586, negative ion mode) were consistent with the presence of two S.O. moieties (Fig. 1b).

The DNA alkylation reaction was repeated on a larger scale in order to isolate adducts for structural studies. DNA (calf thymus, 100mg; 30mM Tris-HCl, pH 7.5, 100ml) was reacted with 300 µl S.O.(24h, 37°C). In addition, 4x0.5mg (1ml Tris-HCl each) were reacted with ^{14}C-8 S.O.(25 µCi) and 5 µl unlabeled S.O. Unreacted S.O. was extracted with EtOAc and the DNA was further purified by repeated precipitation (5X). After digestion (micrococcal nuclease, spleen phosphodiesterase) the 3'-dNMP adducts were isolated by reversed phase HPLC (as above, Fig. 2). Retention times of the adducts were determined by comparison with those of the labeled ^{14}C adducts. Co-chromatography of 7-(2-hydroxy-2-phenylethyl)guanine identified the major adduct (not detected by post-labeling). ^{32}P post-labeling of aliquots of the HPLC fractions showed 1 and 2 to elute at t_R 50-60 min. 1 and 2 co-chromatographed (PEI) with 1 and 2 isolated from the dGMP reaction (i.e. diadducts, see above). The fractions from the DNA reaction containing 1 and 2 were further purified (reversed phase HPLC, microbore). LSIMS spectra could not be obtained for these fractions, presumably due to the presence of salt impurities still remaining. However, the fact that the major adducts detected by post-labeling from the DNA reaction have identical HPLC retention and PEI co-chromatograph with diadducts 1 and 2 from the dGMP reaction indicates that the structures are similar.

Conclusion (i) *In vitro* DNA-Styrene oxide adducts can be detected by the ^{32}P post-labeling procedure at modification levels of 1 in 10^4 nucleotides (*in vivo* levels of 1 in 10^8 have been reported1), (ii) *In vitro* DNA reactions with styrene oxide result in alkylation mainly at the dG residue, (iii) The major site of alkylation on the dG residue is at the N-7 position. These adducts readily depurinate and are not detected by the ^{32}P post-labeling procedure, (iv) The adducts detected by the ^{32}P post-labeling procedure represent a minor fraction (*ca.* 5%) of the total adducts. Alkylation in the major post-labeled adducts appears to be at both the O-6 and N-2 positions (hydrogen bonding sites in the Watson Crick model) resulting in the formation of diadducts, (v) A minor adduct co-chromatographs with 6-O-(2-hydroxy-2-phenylethyl)-2'-deoxyguanosine-3'-monophosphate[3], (vi) The low level of adduct formation (1 in 10^4 nucleotides) makes it difficult to rationalise the presence of adducts representing alkylation at two sites in a single residue, (vii) While the ^{32}P post-labeling procedure is a highly sensitive method of DNA-adduct detection, no structural information is revealed. The combination of ^{32}P post-labeling and mass spectrometry provides a powerful tool for both the detection and characterization of DNA alkylation products.

LOW NANOGRAM DETECTION OF NUCLEOTIDES USING FAB-MS

Q.M. Weng, W.M. Hammargren and K.H. Schram, Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.
C. Borysko, L. Wotring and L.B. Townsend, College of Pharmacy, University of Michigan Ann Arbor, MI 48109

Despite the success of FAB-MS for analyzing non-volatile compounds, such as nucleotides, lack of sensitivity has been a severe restriction. Reports describing the FAB-MS analysis of nucleotides as the free compounds required sample levels in the ug/ul range[1,2]. The goal of this work was to examine the effect on detection limits in FAB-MS by analysis of the trimethylsilyl derivatives of selected mononucleotides[3].

In order to optimize sensitivity, experimental conditions were determined using adenosine 5'-monophosphate (AMP;**1**) as a model compound. AMP was chosen because it has been studied extensively, both as the free compound and as its TMS derivative. Also, it is amenable to analysis by EI, CI, and FAB-MS[3] and is readily available. After methods were optimized for AMP, reference standards of two clinically important nucleotides were analyzed: tricyclic nucleoside 5'-monophosphate (TCN-MP;**2**)[4], a potential anticancer agent undergoing clinical trials[5] and 5-fluoro-2'-deoxyuridine-5'-monophosphate (FdUMP;**3**), the active metabolite of the widely used anticancer drug, 5-fluorouracil[6].

Table 1 shows the results of the sensitivity studies for the selected mononucleotides analyzed by FAB-MS as both the free compound and TMS derivative. Low detection limits for $AMP(TMS)_3$ (10 ng), $TCNMP(TMS)_3$ (5 ng), and $FdUMP(TMS)_2$ (5 ng) were achieved by FAB-MS. The results were obtained by analysis of the TMS derivatives with m-nitrobenzyl alcohol (NBA) as the matrix and scan averaging in the negative ion detection mode. Figure 1 shows the negative ion FAB-MS spectrum of 5 ng FdUMP as its TMS_2 derivative. Hydrolysis of one or more of the labile TMS groups occurs, with the extent of hydrolysis greatest when glycerol is used as the matrix. Using NBA as the matrix, loss of two TMS groups was observed, while the non-protic tetraglyme matrix usually displayed loss of one TMS group as the most intense peak with the molecular ion of the fully derivatized compound as a minor peak. Complete incorporation of TMS groups for AMP (five), TCNMP (five) and FdUMP (four) was confirmed using EI and CI.

This FAB-MS procedure has been applied to the analysis of TCNMP samples isolated from L1210 cell cultures and purified by HPLC. Samples with quantities (ug levels) of TCNMP estimated at several times the detection limit showed no sample-related peaks, possibly due to the presence of buffers or other artifacts which interfere with derivatization.

Additional sensitivity may possibly be obtained with other derivatizing reagents or by the use of aprotic matrices using a heatable/coolable FAB probe.

This work was supported by NIH grant CA42309.

Investigation of the Fragmentation Patterns of the TMS Derivatives of 2', 3' and 5'-Deoxynucleosides

M.L.J. Reimer, T.D. McClure and K.H. Schram
Department of Pharmaceutical Sciences
College of Pharmacy, University of Arizona
Tucson, Arizona 85721

The recent discovery of two novel 5'-deoxynucleosides[1,2] in human urine has generated interest in the mass spectrometry of isomeric deoxynucleosides and their derivatives from the standpoint of both analytical detectability and structural characterization. In an effort to establish the fragmentation pathways of the 5'-deoxynucleosides, a comparative examination of the 2', 3' and 5' isomers of four deoxypurine nucleoside series has been undertaken. The specific compounds under investigation include 2'-, 3'- and 5'-deoxyadenosine (dAdo), deoxyguanosine (dGuo), deoxyxanthosine (dXao) and 2'- and 5'-deoxy-2-fluoroadenosine (d2FAdo), all of which were studied in both free and trimethylsilyl (TMS) derivatized forms. Although the formation and assignment of the ions of TMS derivatized nucleosides has been discussed[3,4], little has been reported concerning the differences in the spectra of the three deoxyisomers, particularly concerning the ions characteristic of each of the compounds. Using the deoxyadenosines as models, low resolution-electron ionization (EI) mass spectra and chemical ionization-collisional activation (CI-CA) daughter ion spectra are reported.

Samples were obtained either commercially (dAdo, 3'-dAdo, 5'-dAdo, dGuo: Sigma Chemical Co.; 3'-dGuo: Yamasa Shoya Co., Tokyo) or synthetically (dXao: deamination of dGuo) or were donated (5'-dGuo, 3'-dXao, 5'-dXao: Dr. K. Nakano, PL Comprehensive Research Institute, Osaka, Japan; d2FAdo, 5'-d2FAdo: Dr. J. A. Secrist, Southern Research Inst., Birmingham, Ala.). TMS derivatives were prepared by standard procedures[3]. All spectra were acquired on a Finnigan MAT 90 mass spectrometer using standard EI (70eV) and CI (NH_3) modes of ionization. Linked scans of daughter ion spectra were obtained using a B^2/E scan law (V constant) with CA (air) in the first FFR of the BE instrument.

Several distinguishing features can be found in comparing the EI mass spectra of the 2', 3', 5' series. The 2'-deoxypurine nucleosides are characterized by a $[M]^{+\cdot}/[M-15]^+$ ratio > 1 (except deoxyguanosines), a base peak at $[B+1]^{+\cdot}$ (except d2FAdo) and an intense peak at m/z 103. The 3'-isomers can be differentiated from the 2'-analogs by a $[B+30]^+$ base peak, a strong $[B+116]^+$ signal and a weakly-abundant ion at m/z 103. The 5'-isomers are easily distinguished from the 2'- by a $[B+30]^+$ base peak (except 5'-dGuo and 5'-d2FAdo) and abundant ions corresponding to $[B+116]^+$, $[S-H]^{+\cdot}$ and $[B+128]^+$. Features of the 5'-spectra that are not present in the 3'-compounds include the ions $[B+128]^+$, $[S-CH_2O]^+$ and $[C_3H_3O_2\ (TMS)_2]^+$.

The CI-CA linked scan spectra of 2', 3' and 5'-dAdo (daughters of $[MH]^+$) also provide a means for differentiating between deoxynucleoside isomers. Intense metastable transitions corresponding to the formation of $[M-90]^{+\cdot}$ and $[C_3H_3O_2(TMS)_2]^+$ distinguishes the 3'-deoxyisomer from its 2'- and 5'-analogs. A unique aspect of the 2'-dAdo spectrum is the absense of $[B+131]^+$ and $[B+116]^+$ daughters, both of which are evident in the spectra of the 3'- and 5'-deoxynucleosides.

In conclusion, significant differences in fragmentation are observed between structural isomers of 2', 3' and 5'-deoxypurine nucleosides. CI linked scanning (with collisional activation) affords complementary structural information when used in conjunction with "normal" EI spectral acquisition.

ANALYSIS OF PRODUCTS FROM THE REACTION OF THE TRIETHYL LEAD KATION WITH A HEXANUCLEOTIDE

E.-M.Rustler and M.Linscheid

Institut für Spektrochemie,
Bunsen-Kirchhoff-Str.11
D-4600 Dortmund 1, POB 101352,
West Germany

INTRODUCTION:

Lead tetraalkylates, used as additives to gasolines and still widespread in the environment, are metabolized in the liver to yield cationic species. The toxic potential of such cations in man has been reported[1].
In addition, it has been shown that mitosis is influenced at lower concentrations, whereas cleavage of chromosomes occurs at higher dose levels of alkylates[2].
For a detailed study of the reaction of lead alkylates on a molecular level, we have synthesized as model target the selfcomplemental hexanucleotide CGATCG in sufficient amounts to allow the necessary biophysical studies.

SYNTHESIS OF THE HEXANUCLEOTIDE:

The systhesis was performed according to a modified phosphotriester method in liquid phase[3] by block condensation (2 + 2) and (4 + 2); purification by RP-HPLC, PRP1-column; the structure confirmation was done by 400 MHz NMR including two dimensional studies, by negative ion FAB mass spectrometry and by UV spectroscopy. The melting point was determined also, to make shure that the reaction at room temperature takes place with the double stranded form rather than the single standed oligonucleotide.

THE REACTION

A twentyfold excess of triethyl lead chloride was allowed to stand with the hexanucleotide for 10 days in a buffer solution at pH 7; a longer reaction time did not change the pattern. The reaction mixture was separated by ion exchange chromatography into fractions, which were directly analyzed by FAB MS; a subsequent separation by HPLC was done only at an analytical scale to correlate the MS results with the chromatography (fig.1). From the fragmentation pattern one can deduce the structures of the smaller oligonucleotides produced in the course of the reaction.

CONCLUSION:

The lead trialkylate cation as the most toxic metabolite of the tetra-alkyl-lead compounds induces cleavage of the DNA stand, apparently predominately between G and A; a sequence priority (GC) may be discussed rather than single strand preference, since in that case the smaller oligonucleotides should occur in larger amounts.. The cleavage of chromosomes by heavy metal species could be caused by the same mechanism.

In general, a well defined model system like the one shown here can serve to study the toxic reactions of xenobiotics as well as the interaction of drugs with DNA (studies are in progress); the results of such reaction models can be used as guides in the course of in vivo studies or in drug design.

INTRODUCTION

The methylation of nucleosides in DNA is regarded as an important factor in the regulation of genes in higher organisms[1]. The most frequent modification occurs in adenosine and cytidine (here at the 5-position of the base) and the significance is still subject to investigations. In addition to regulation the activity of endonucleases may be influenced by the degree of methylation. To establish the role of 5-methyl-deoxycytidine (5mdC), sensitive and precise determinations of the base composition of DNA's are necessary and some procedures have been developed, which are usually based on the analysis of the hydrolysis to nucleobases; namely HPLC[2], radioactive labelling, immunoassay, GC-MS[3] and complete sequencing have been used. The problem is that the published procedures are either insensitive, difficult to calibrate or amenable to cross contamination by RNA impurities.
Our method for the quantitative analysis of 5mdC in DNA is based on GC-MS (using electron impact) and multiple / single ion recording. Since we use the trifluoroacetylated derivatives of nucleosides rather than of nucleobases, contamination from RNA-components, which may contain methylated bases, have been excluded. For clean up a sequence of steps for removal of proteins and RNA impurities was developed.
For the MS analysis, a Siemens Sichromat 3 gaschromatograph was directly coupled to a VG 7070E mass spectrometer, run at a resolution of 1000.

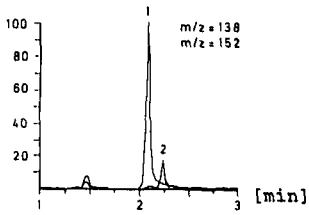
THE METHOD

We have chosen the trifluoroacetylation rather than the silylation, since the products were easily purified from excess reagent and stable enough; in addition some intense ions could be used for the single ion recording experiments. As can be seen from the chromatograms, only the pyrimidines are derivatized completely.
In the first step, the chromatographic conditions have been developed using mixtures of deoxynucleosides and were transferred to the separation of hydrolysates (fig.1). Aza-deoxycytidine was chosen as an internal standard, because its chromatographic properties and its mass spectrum are similar enough to 5mdC; to enhance the sensitivity even further, only m/z 152 was detected in single ion mode, which is a minor signal in the mass spectrum of deoxycytidine itself and therfore, it could serve as the final internal standard (fig.2).
We constructed the analysis function (fig.3) using standard addition and the hydrolysate of the DNA from drosophila melanogaster as matrix.
The DNA of the phage ΦX174 was selected[3] to verify the results, because its DNA is fully sequenced and contains 1 5mdC in 5386 nucleotides.

CONCLUSION

We have shown that 5mdC in DNA can be analyzed with very high sensitivity and accuracy.
The full clean up procedure needs c. 5 µg of DNA.
The sensitivity is 13 fmol of the base in a matrix of hydrolyzed DNA.
The accuracy has been established by analysis of the DNA of phage ΦX174.

For drosophila melanogaster the amount is below the detection limit; since the sample is 0.15 µg (=441 pmol), the content is less than 0.3 µmol/mol or less than 1 modified base per 330,000 unmethylated nucleobases. The genom of drosophila contains therefore at maximum 240 5mdC's overall, which renders 5mdC as a factor for the regulation of genes in the DNA of drosophila melanogaster very unlikely.



1 = deoxycytidine (m/z 138)
2 = 5mdC (m/z 152)

Fig.1 Pyrimidine - nucleosides from calf thymus DNA ; selected ion recording of m/z 138 and m/z 152 for detection of cytidine and 5mdC

MAGNESIUM METABOLISM IN HUMANS: QUANTITATION OF STABLE ISOTOPES BY FABMS

Ya-mei Liu[a], David L. Smith[a],
Patricia Neal[b], and James Lemons[b]

Despite the physiological importance of magnesium, the dynamics of magnesium metabolism have not been investigated. This is primarily because the half-life of the longest lived radioisotope of magnesium is only 21.8 hours. Hence, studies extentding over periods of several days, and preferably several months, have not been possible. Although stable isotopes of magnesium are available highly enriched, they have rarely been used as tracers because analytical methods for their quantification in biological materials have not been readily available. We report here on a method for the accurate quantification of stable isotopes of magnesium, which is based on fast atom bombardment mass spectrometry.

These analyses were performed on a Kratos MS-50 high resolution mass spectrometer equipped with a FAB ion source. Magnesium ions are desorbed from the surface of the sample, which is dried on stainless steel probe tips in the prevacuum stage of a standard solids probe introduction inlet. A mass resolution of 3500 was used to prevent the recording of isobaric ions derived from other elements that might be present in the sample. Beams of the isotopes of interest are sequentially focused on the collector by changing the ion accelerating and electric sector voltages. These signals are recorded and manipulated with a data acquisition system, which was developed especially for this purpose.

Urine samples (usually 2 ml) were prepared for isotopic analysis by adding an equal volume of saturated NaOH solution, followed by brief centrifugation 12 hrs later. The $Mg(OH)_2$ precipitate was dissolved in 30 μL of 6 N HCl. Approximately 1 μL of the solution was applied to the probe tip. Plasma samples (600 μL) were freeze-dried, and ashed at 600 ° to remove organic substances. Inorganic residues remaining after ashing were dissolved in 6 N HCl and analyzed as described above.

The precision with which ion abundances can be determined was investigated by measuring the $^{24}Mg/^{25}Mg$ and $^{24}Mg/^{26}Mg$ ratios for a urine sample ten times. The CVs for these replicate measurements were 0.10 % and 0.09%, respectively. The accurate quantification of isotopic tracers of magnesium in urine is demonstrated by results given in Figure 1, which is a plot of the determined enrichment vs the calculated enrichment of ^{25}Mg and ^{26}Mg in four spiked urine samples. The slopes of the lines are 1.01 and 0.99, respectively. The potential applicability of this

method for investigating the dynamics of magnesium metabolism *in vivo* is illustrated in Figure 2, which gives the ^{25}Mg enrichment in the urine of a lactating woman for 125 days after tracer administration.

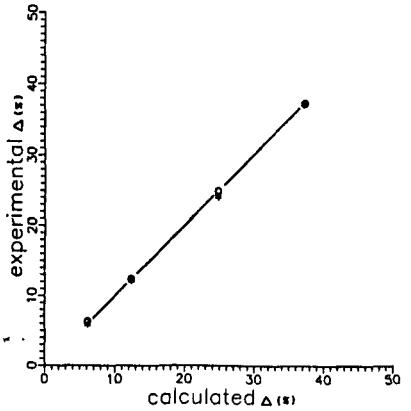

Figure 1 Plot of determined vs calculated enrichments of ^{25}Mg and ^{26}Mg in urine spiked with tracer isotopes.

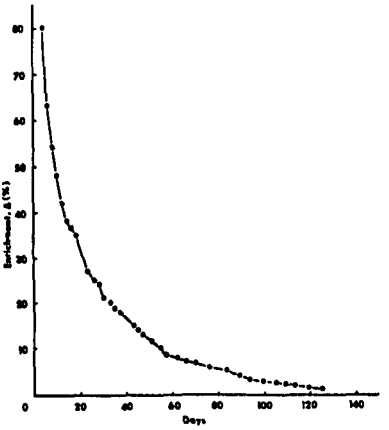

Figure 2 Tracer enrichment in the urine of a lactating woman who received 570 mg of ^{25}Mg intravenously.

EQUILIBRATION OF CALCIUM ISOTOPIC TRACER IN INFANT FORMULA

Nancy E. Vieira and Alfred L. Yergey
National Institute of Child Health and Human Development, NIH, Bethesda, MD, 20892.

Clinical research using stable isotopic tracers assumes that the tracer is rapidly equilibrated with the naturally occurring material in the system to which the tracer is administered. In our clinical protocols, an oral tracer is administered via food such as milk or infant formula. This tracer is added to the food and allowed to "equilibrate" overnight. While incomplete equilibration in food is not an important issue in studies of children and adults, due to the low stomach pH of 2 (1), it possibly becomes important in studies of premature infants where gastric pH is 3-5. Under such conditions it may be possible that preferential absorption of the tracer could occur due to incomplete equilibration of the tracer and natural calcium. Since the *calculation of fractional absorption assumes all calcium will have the same* bioavailability, preferential absorption of some portion of the calcium in the premature infant's intestine would falsely bias the fractional absorption.

Infant formula, Enfamil with Iron (Meade-Johnson, Evansville, IN.), was used for these experiments. ^{42}Ca (93.77% enriched, Oak Ridge National Resaerch Laboratory, Oak Ridge, TN) was added to 5 ml of formula in amounts expected to a yield standard curve ranging from 0-300Δ% excess based on the total amount of calcium found in the aliquot by standard flame atomic absorption spectrophotometric measurement procedure (Perkin-Elmer Model 5000, Perkin-Elmer Corp., Norwalk, CN)). All ratios were measured relative to ^{48}Ca using a Finnigan MAT THQ thermal ionization quadrupole mass spectrometer (Bremen, FRG). Fractionation correction was made using 43/48 as the normalizing ratio. Precision of the measurements for the 42/48 ratio was 0.8%, and the accuracy of the natural abundance ratio compared to the NBS ratio of 3.519 was -1.5%.

A variety of conditions for equilibration including variation in time, temperature and pH were tested: 1) room temperature at overnight, 1 day, 2 days, and 6 days; 2) refrigerated (4°C) at 1 day, 2 days, and 6 days; 3) pH 3 at room temperature for 1 day; 4) 47°C for 20 minutes

Table I shows the linear regression lines of the various treatment conditions. The expected Δ% excess was calculated based on the total calcium per ml in the formula (Meade-Johnson reported 0.466 mg/ml; our laboratory analysis measured 0.452 mg/ml). The slopes of all the lines suggest either of 2 explanations: a) that the added tracer was preferentially not precipitated, a result opposite to previous observations (2), or b) that the total calcium in the formula was greater than reported and determined.

Following a nitric acid, microwave digestion of the formula using a CEM Microwave Digestion System, Model MDS-81D (CEM Corp.,Indian Trail, N.C.) the total calcium was redetermined by flame atomic absorption spectrophotometry. Duplicate digests yielded total calcium concentrations of 0.566 and 0.554 mg/ml. Recalculation of the expected Δ% excess with the mean of the duplicates (0.560 mg/ml) resulted in the linear regression lines with their respective standard error of the mean ($S_{y.x}$) shown in Table II. As seen, these data suggest that: 1) the added tracer equilibrates with the naturally occurring calcum in the Enfamil, and 2) standard flame atomic absorption spectrophotometry analysis of dilute, undigested formula, directly aspirated into the flame yields a falsely low total calcium concentration.

TRACE-METALS ANALYSIS BY GAS CHROMATOGRAPHY-MASS SPECTROMETRY EMPLOYING VOLATILE CHELATES

S.K.Aggarwal, M.Kinter, M.R.Wills, J.Savory and D.A.Herold
Department of Pathology, University of Virginia Medical Center,
Charlottesville, VA 22908, U.S.A

Introduction

The determination of trace metals in biological specimens is important in view of their clinical, nutritional and toxicological effects. There has been increasing concern in recent years about the accuracy of the published values for the concentrations of trace elements in human body fluids. Since isotope dilution mass spectrometry has the potential of being incorporated into a definitive analytical technique, we have developed a method for measuring the isotope ratios of metals using capillary column gas chromatography - mass spectrometry (GC/MS) employing a general purpose organic mass spectrometer which is more commonly available to various laboratories. Conditions were optimised for the quantitative preparation of metal chelates and for the mass spectrometric analysis by GC/MS. Precision and accuracy was evaluated for isotope ratio measurements of Cr, Ni, Cu and Zn using thermally stable, volatile chelates containing about 10 ng of the metal.

Experimental

Reagents: Chromium acetylacetonate and trifluoroacetylacetone (TFA) were obtained from Alfa Products. Sodium diethyldithiocarbamate (Na(DEDTC)) was obtained from Aldrich Chemical Company. Lithium bis(trifluoroethyl)dithiocarbamate (Li(FDEDTC)) was synthesised using bis(trifluoroethyl)amine, n-butyllithium and carbon disulphide. Aliquots from standard solutions of Cr, Ni, Cu and Zn were diluted with distilled and deionised water (DDW). The solvents n-hexane and methylene chloride were of HPLC grade.

Preparation of metal chelates: A stock solution of $Cr(AA)_3$ in CCl_4 was prepared to give a final concentration of about 10 ng Cr/µL. For the preparation of $Cr(TFA)_3$, Cr(VI) was reduced to Cr(III) using a freshly prepared solution of 0.1 mol/L sodium sulphite. The pH of the solution was maintained at 5.0 using acetic acid - sodium acetate buffer. A 0.1 mol/L solution of TFA in n-hexane was used and the reaction was performed at 60° C for about 2 hours in a water bath. Diethyldithiocarbamates of Cr, Ni, Cu and Zn were prepared by using a 0.1 mol/L solution of Na(DEDTC) in DDW. The reaction conditions consisted of addition of about 1 mL of pH 4 acetate buffer solution to about 100 uL of the metal salt solution (containing about 10 µg of the metal) followed by addition of about 300 µL of 0.1 mol/L solution of Na(DEDTC). The solution was shaken on a vortex shaker for about 2 minutes and the chelate was extracted into methylene chloride. Fluorinated diethyldithiocarbamates were prepared under the conditions similar to those of unfluorinated compounds except for the use of a pH 3.0 acetate buffer solution.

Gas Chromatography/Mass Spectrometry: The mass spectrometer used was a double focusing, reverse geometry instrument (Model 8230, Finnigan MAT) with a SpectroSystem 300 data system. Fragmentation patterns were obtained using exponential scanning mode (1 sec/decade). Data for the isotope ratio measurements were acquired in the selected ion monitoring (SIM) experiment, monitoring m/z corresponding to the various isotopes in the molecular/fragment ion. A resolution of about 1000 was used in either of the two modes. For the SIM experiment, the source and the collector slit widths were optimised to achieve flat peak tops. A DB-1 bonded phase fused silica capillary column was used. One µL of the sample containing about 10 ng of the metal was injected on column at a temperature of 100°C followed by a 25° or 15°C/min ramp to 300°C.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Results and Discussion

The 70 eV EI mass spectra of various unfluorinated diethyldithiocarbamates and fluorinated diethyldithiocarbamates showed the molecular ions $(M)^{+\bullet}$ for all the chelates studied in this work. The high intensity peaks (molecular ion $M^{+\bullet}$ for Ni, Cu and Zn chelates and fragment ion $(M-L)^{+}$ for Cr chelates) containing the cluster of metal isotopes were used for isotope ratio measurements. For $Cr(DEDTC)_3$ and $Cr(FDEDTC)_3$, measurements were also performed using the molecular ion. The results obtained on isotope ratios measurements are given in the Tables 1 and 2. It can be seen that different isotope ratios can be obtained with a precision of 1-3% (at 95% confidence limits) and there is good agreement between the theoretically expected isotope ratios (calculated using the reported natural abundances of the metals and the contributions of various isotopes of C, N, O and S) and the experimentally measured isotope ratios.

Conclusion

A GC/MS method employing a commonly available organic mass spectrometer and using thermally stable and volatile metal chelates has been developed for the precise and accurate isotope ratios measurements of Cr, Ni, Cu and Zn. The method offers high sensitivity (down to parts-per-billion level) and is promising for the determination of trace metals using isotope dilution technique. The Na(DEDTC) and Li(FDEDTC) chelating agents are attractive compared to the acetylacetonates due to ease of preparation of chelates and the possibilty of multi-element analysis.

COPPER ISOTOPE RATIO MEASUREMENT BY LOW TEMPERATURE THERMO-IONIZATION

Y. Fujii, M. Hosoe*, M. Nomura and M. Okamoto
Research Laboratory for Nuclear Reactors
Tokyo Institute of Technology, O'okayama, Meguroku, Tokyo 152 Japan
* The National Defense Academy, Hashirimizu, Yokosuka 239 Japan

There has been a relatively large uncertainty in the value of the atomic weight of copper arising from the difficulty in the measurement of the copper isotope abundance ratio. This tendency appears also in other middle-heavy elements. Usually thermo-ionization is applicable for the precise measurements of isotope ratios, specifically, for metal elements. Thermo-ionization efficiency usually depends on the chemical forms of the samples of the concerned elements. The sample chemical form, therefore, should be closely examined for the thermo-ionization mass spectrometry measurements.

In the previous paper we have found that copper is ionized at low temperatures compared with the ordinary multi filaments method[1]. In the present work more detailed considerations have been directed to the relation between temperature (ionizing filament currents) and the intensity of the created ion beam.

Experimental: Mass spectrometric study on copper isotope analysis was made by using a mass spectrometer Finnigan-MAT 261 equipped with a thermo-ionization ion source incorporated with double filament ionizing units. Copper samples examined were a NBS copper standard sample and a commercially available $Cu(NO_3)_2$ reagent. Three chemically different forms, i.e. electroplated metal, $Cu(NO_3)_2$ and CuI, were examined. The electroplated sample was prepared on an evaporating filament by applying direct current between the filament and an anode inserted in a $Cu(NO_3)_2$ solution. The CuI was prepared also by adding HI to a $Cu(NO_3)_2$ solution on an evaporating filament where Cu(II) was reduced to Cu(I). The amount of each sample

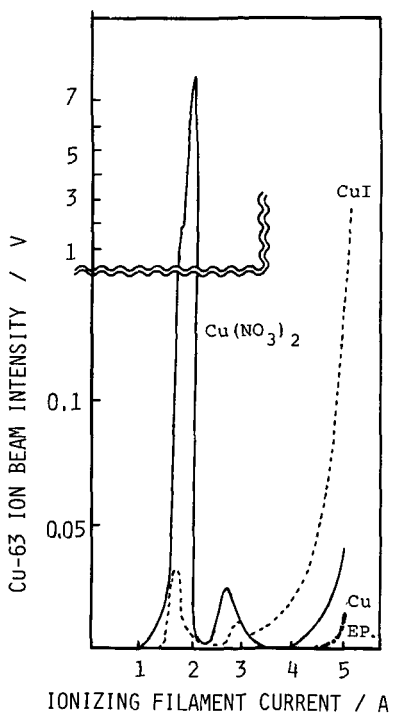

Fig. 1. Cu ion beam vs. filament current (1 V = 10 pA)

was, approximately, in the range of 20 - 100 μg.

Results and Discussion: Fig. 1 shows the relation between the intensities of Cu-63 ion beam and the ionizing filament current. Copper (electroplated) is seen in Fig. 1 to be ionized only at very high temperatures, while CuI is ionized mainly in the high temperature region and produces a week ion beam at around 1.8 A. The ion beam of $Cu(NO_3)_2$ shows a drastic dependency on the temperature of the ionizing filament: the beam intensity significantly increases at the temperature below 1000 °C (ca. 1.5 A). This condition was applied to determine the isotopic abundance ratio of commercially supplied $Cu(NO_3)_2$ reagent(see Fig. 2). The low temperature ionization is not only convenient but also realizes a very small time variation of the measuring data. Thus, the small error range of the copper isotopic ratio is obtained. The determined isotopic ratio ($^{63}Cu/^{65}Cu$) of the commercial reagent is presented in Fig. 2. The directly observed value has shown to well coincide with the value of NBS standard certified as 2.2440 ±0.0021.[2] A detailed isotope measurement study on the NBS standard sample will be given elsewhere[3]. It is another advantage of the present technique that copper nitrate in an aqueous solution can be used as a sample without special pretreatments.

MEASUREMENTS OF BORON ISOTOPES BY NEGATIVE ION THERMAL IONISATION MASS SPECTROMETRY

P.J. Turner, J.E. Cantle, P. Barrett, Z. Palacz
VG Isotopes Ltd., Winsford, Cheshire, CW7 3BX, U.K.

The magnetic sector VG 336 has been used to measure the isotopic composition of 1 ug of Boron with a precision of better than 0.1% at the 95% confidence limit, using negative ions. These results are superior to those previously published using a quadrupole analyser and comparable to data obtained on large radius magnetic instruments.

Introduction

The VG 336 can mass analyse both negative and positive ions. The accelerating voltage is easily reversible using the M806 focus unit controlled by the versatile SECTOR software. Boron can be measured either as a positive ion $(Na_2\ BO_2)^+$, $(Cs_2\ BO_2)^+$ or as a negative ion $(BO_2)^-$. The positive ion method can give precise isotope measurements if the mass fractionation can be well constrained. In addition, the positive ion beam is greatly inhibited by the presence of impurities. For example, $Na_2BO_2^+$ is isobaric with ^{88}Sr. Consequently sample processing must produce a highly pure separate - which may not be easy and may introduce blank problems.

With negative ions, there is essentially no interference in the mass range of interest. Several workers have shown that the BO_2 ion beam is greatly improved by 2-3 orders of magnitude by the addition of a weak $Me^2(NO_3)_3$ solution, where Me = Ca,La,Na. Furthermore, the BO_2 signal produced is stable over several hours. Therefore, we have undertaken several experiments to test the effect of various loading procedures on the size of the ion beam and assess the performance of the VG 336 in negative ion mode.

Mass Spectrometry.

The VG 336 thermal ionisation mass spectrometer is equipped with an MS 806 focus control unit, which can reverse the polarity of the 4kV accelerating voltage. The VG 336 has a 36 cm effective radius, and has fixed axial and adjustable off axis Faraday collectors. The collector slit of the axial collector is 0.6mm in width, the off-axis 1mm. (0.6mm is required to obtain resolution of U in positive ion mode). HT reversal does not affect the magnet calibration. Figure 1 shows the excellent peak flat obtained on the off axis collector.

Method & Results

B was run on single Re filaments, with 1 ug B (NBS 951) loaded with lul 100 ng $M(NO_3)_3$ where M = Ca or La. Initial work used La $(NO_3)_3$ as an aid to BO_2 production. However, beam sizes were disappointing. Samples were loaded at filament currents of 0.5A, 0.8A and 1A, and it became noticeable that samples loaded at lowest currents had the highest beam size (8.10^{-13}A). NBS 951 measurements on 6 samples loaded at 0.5A gave a mean of 0.246135, SD 0.22%. The ion beam did not last for very long (20 minutes).

We therefore decided to try Ca $(NO_3)_3$. Samples were loaded at room temperature on outgassed beads. The results were excellent. BO_2 consistently appeared at 1.85-1.9A filament current and a stable beam occured at 2.3A which could last for several hours. A mean of 5 measurements gave 0.24708, SD 0.166%. This was substantially less fractionated than with La, though this may be due to the lack of filament current in the Ca experiment. Furthermore, the ion beam was stable enabling over 100 ratios to be collected. The internal precision over 100 ratios was 0.009% in the best case indicating negligible mass fractionation effects. A subsequent batch of 5 beads using the same loading technique, but using unoutgassed Re gave an external mean of 0.247851, SD 0.28%. The ratio is higher, but within error; however the unoutgassed beads did not give reproducible ionisation characteristics. This may in part be due to the different surface characteristics of an unoutgassed filament relative to an outgassed one. Stable ion beams did not occur until 2.4-2.5A, and some of the runs lasted only 30 ratios. Nevertheless, the internal precision was generally 0.1%, even over 30 ratios.

A further turret of outgassed Re with 1 ul of lug B + 1 ul 100 ng $Ca(NO_3)_2$ loaded at room temperature, gave the following results:- Ion beams were generally 1.10^{-12}A and stable over 1-2 hrs. Mass fractionation was negligible. BO_2 appeared at 1.9A and was stable at = 2.3A. Total warm-up time was 45 mins. The results are presented in Table 1. The mean of 6 beads was 0.24777 with a standard deviation of 0.074%. This is substantially better than previously obtained and indicates that a slow warm-up time and outgassed beads give the best results.

The precision of these data is significantly better than published results taken on a quadrupole analyser, and is comparable with results obtained by positive ion techniques on larger instruments (See references). This method will therefore give excellent results provided filament preparation is well constrained.

QUANTITATIVE GAS ANALYSIS BY MASS SPECTROMETRY AT THE PART-PER-TRILLION LEVEL: THE HELIUM-3 CONTENT OF ATMOSPHERIC AIR

T. A. Davidson and D. E. Emerson

U.S. Bureau of Mines, Helium Field Operations
Amarillo, Texas 79101

OBJECTIVE

Helium is found in the atmosphere, ground water, ocean water, soil, rock, and natural gas. Because the processes that are known to form the helium isotopes are very different, the relative abundances of helium-3 and helium-4 provide geochemical data that is necessary to the identification of the sources of the helium found in these media.

Quantitative analysis of helium-3 in gases at the part-per-trillion level is required for the determiniation of the helium-3 content of natural gas. Air provides a convenient model system for this analysis. The purpose of this Bureau of Mines study is to establish a direct quantitative determination of helium-3 in near-surface air at the parts-per-trillion level.

EQUIPMENT

Samples were collected in 1-liter stainless steel sample cylinders equipped with stainless steel regulating valves using a portable, non-lubricated air compressor.

Samples were handled with a specially designed stainless steel inlet system with welded connections, metal gasketed fittings, and indium seals. A 180-degree, single focusing mass spectrometer, modified with highly stable electronics and interfaced to a Teknivent 1050 Data System and an IBM XT-286 Personal Computer, was used to analyze the samples.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

METHOD

Aliquots of air were prepared by passing air from the sample container through a drying tube into the inlet system. The dried air was then reduced to 25.00 torr (approximately 4.66 millimoles) with the vacuum pumps to provide the aliquot. The aliquot was then allowed to contact a charcoal trap at -197 °C and then a trap filled with titanium wire at 25 °C. While these traps were removing all gases except helium and neon from the aliquot, the background current readings were made for 3 minutes with the mass spectrometer tuned to the helium-3 peak. After a precise time lapse, the aliquot was admitted to the analyzer. The data collected consisted of two successive 3-minute averages of the electrometer output voltage. The data were corrected for the background and then summed to provide a measure of the helium-3 detected. Each such measurement was compared with identically made measurements using gravimetrically prepared standard mixtures of similar, but precisely known, composition to establish a value for the helium-3 content of the sample.

RESULTS

One hundred measurements were made on seven samples of air collected under various atmospheric conditions at Amarillo, Texas. No variations between samples were detected in helium-3 content. The helium-3 content of atmospheric air is determined to be 7.27 ± 0.20 parts in 10^{12} (parts per trillion).

CORRECTION OF INTERFERENCES IN THE DETERMINATION OF OXYGEN-18 CONTENT IN ORGANIC MATERIALS

Mourad Aissa, Northrop Services, Inc., Research Triangle Park, NC 27709
and
Gary E. Hatch, US Environmental Protection Agency, Research Triangle Park, NC 27709.

The determination of oxygen-18 content in organic materials requires conversion of the sample oxygen to a suitable compound such as CO_2 for isotope ratio mass spectrometry. Figure 1 shows a schematic diagram of the experimental procedure which is based on the combination of the Unterzaucher method for oxygen determination (1) and isotope ratio mass spectrometry.

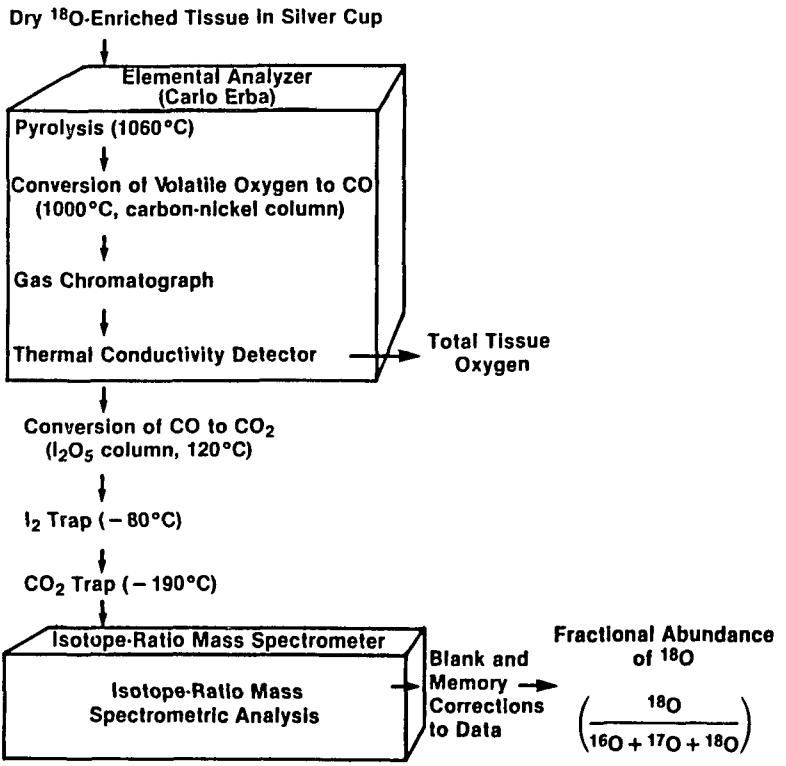

Figure 1. Schematic diagram of the method for determination of oxygen-18 in organic sampler.

Isotopic and mass interferences occur during the CO_2 conversion process where the sample oxygen is first converted to CO by pyrolysis at 1052°C and passage through a specially packed carbon column, and then oxidized to CO_2 in a column of I_2O_5 at 120°C. The main interferences are the blank effects that arise from an oxygen pool unrelated to the sample being analyzed, the CO oxidation, and the memory effect. A published mathematical treatment of this problem that uses mass and isotopic balance equations to derive a model for the correction of the mass spectrometry measurements (2) was modified to include all processes involved. The resulting general model expresses the i-th sample oxygen-18 actual fractional abundance, $F_{s,i}$, as a function of the measured fractional abundance, $F_{c,i}$, and the sample size (in oxygen atoms), $N_{s,i}$:

$$F_{s,i}=\left(2F_{c,i}-F_I\right)+\frac{N_B\left(2F_{c,i}-F_I-F_B\right)+\sum_{j=1}^{i-1}N_{s,i-j}\,ae^{-jb}\left(2F_{c,i}-F_I-F_{s,i-j}\right)}{N_{s,i}\left(1-\sum_{l=1}^{p-i}ae^{-lb}\right)} \qquad i=1,p$$

F_B, F_I are the oxygen-18 fractional abundances of the blank and the I_2O_5 respectively; N_B is the number of oxygen atoms from the blank; a and b are the memory clearance parameters, and p is the number of samples in a batch. Determination of the correction parameters (F_I, F_B, N_B, a and b) is crucial to the accuracy of the method. N_B and F_B are the parameters most likely to fluctuate from batch to batch and most susceptible to vary with such factors as pyrolysis column age and sample composition. For this reason an empty sample container was included in each sample batch and blank related parameters were directly determined. The remaining correction parameters were determined using Santrock's approach (2). Verification of the method was conducted using Benzoic acid isotopic standards which were prepared by exchange with enriched water (3). Results shown in Table 1 indicate close agreement between samples analyzed by pyrolytic decarboxylation and those treated through the analysis system. As expected, the deviation between the two groups increased with sample enrichment. The results confirm the validity of the interference correction procedure, especially for natural abundance samples. Further work is needed to study the effect of impurities and to improve results from highly enriched samples.

Isotopic Standard	n	Pyrolytic Decarboxyl. $^{18}F \times 10^3$	Unterzaucher Procedure $^{18}F \times 10^3$	Δ (percent)
BA-1	10	2.0262 ± 0.0017	2.0227 ± 0.0054	− 0.17
BA-2	10	2.1034 ± 0.0052	2.1114 ± 0.0079	+ 0.37
BA-3	5	2.4716 ± 0.0089	2.5032 ± 0.0188	+ 1.26
BA-4	5	2.9818 ± 0.0121	2.9480 ± 0.0207	− 1.58

Simultaneous Detection of Multiple Isotopes by Gated Pulse Counting in Resonance Ionization Time-of-Flight Mass Spectrometry

L.W. Green and F.C. Sopchyshyn
Chalk River Nuclear Laboratories, Chalk River, Ont., Canada, K0J 1J0

Resonance ionization mass spectrometry with pulsed tunable dye lasers has attracted much interest from the isotope ratio community in recent years, because of its inherent high selectivity and sensitivity. However, it has a number of features that impede precise quantification of isotope ratios: fluctuating laser beam intensity, isotopic selectivity, duty cycle loss, and fast pulse signal characteristics. In this paper we describe a time-of-flight based mass spectrometry system that overcomes many of these impediments, and isotope ratio results are presented for uranium and barium; the uranium samples were from the NBS uranium isotopic standard series.

The time-of-flight mass spectrometer featured a 1-meter drift tube, a two stage acceleration region with static electrode voltages, and a micro-channel plate detector. A tunable dye laser charged with Rhodamine 590 dye was operated at a repetition rate of 100 Hz and focussed in the source region just above the sample filament. A gated pulse counter was used for signal quantification and it featured 300 MHz bandwidth components for accurate processing of the fast pulse signals. These signals were processed such that each isotope of interest was counted in a separated channel of a counter, and such that all isotopes of interest were processed in each laser pulse. The minimum pulse pair resolution was 4 ns. The detection system did not impose a limit on the pulse repetition rate, and rates as high as 20 kHz could have been used if a copper vapour pump laser had been available.

The resolution and signal-to-noise qualities of the instrument are illustrated by the spectrum of U500 in Figure 1. Background count rates were as low as 0.0001 ions per pulse. Results for replicate measurements of isotopes of approximately equal abundance showed precisions of 0.3% and 0.4% relative standard deviation for Ba and U, respectively. Results for a wide range of uranium ratios are shown in Table 1 and show excellent agreement with certified values in all cases. Precisions for the more extreme ratios were poorer because of the relatively small number of counts obtained for the minor isotope in each case.

For these uranium results the dioxide ion was used as the analyte ion, to avoid large wavelength dependent biases observed for the metal ion. The errors were likely associated with isotope shifts and hyperfine splittings, and are a topic of current study. No such biases were observed for uranium oxides or barium.

MODIFICATION OF JMS D-300 TO THE MASS SPECTROMETER FOR PRECISE ISOTOPIC ANALYSIS:

N. Torigoye*, H. Nishimura** and M. Shima***; *Geophys. Inst., Tokyo University, Tokyo 113, **Dept. of Geosci., Naruto University of Education, Tokushima 772, ***National science Museum, Tokyo 110, Japan

The purpose of this work is to analyse precise isotopic ratios by a compact virtual image double focussing mass spectrometer with surface ionization source. New magnetic controll- and data acquisition system was introduced.

Details of the original equipment of JMS D-300 are as follows; 1. It had the virtual image double focussing geometry, which ensured the high mass resolution relative to its small mass analyser, e.g. 15cm radius 60° magnetic field and 120° electrostatic field. 2. For the mass analyser system, the hall probe and the magnetic field stabilizing circuit were contained. 3. The magnetic field scan was available by setting the switches on the front panel, which was made up of one direction and constant speed. It was not suit for precise analyses beacuse a lot of time was spent for background measurement. 4. The ion current is collected by faraday cup or the 16-stage secondary electron multiplier for lower intensity. These currents are converted to voltage by the vibrating reed electrometer, and recorded by the chart recorder.

Modifications in the present work were divided into two parts.

Automatic Magnetic Field Controll: The interface boad with 16 bit-DA converter, shown in Fig.1, was set into 16-bit computer(NEC PC9801). The digital data with 16 bit (0 to 2^{16}) calculated by computer program represented magnetic field intensity. They are sent to DA converter and transfered to voltage which is used as reference value on setting the magnetic field by the stabilizing circuit described above. This new system enabled peak hopping method in which discrete digital data were commanded to the DA converter for changing magnetic field stepwisely.

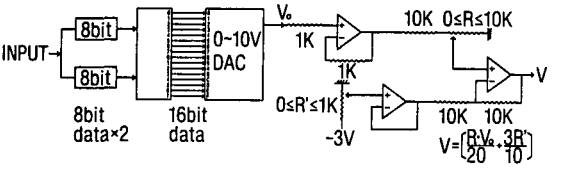

Fig. 1 The magnetic field controll Interface circuit

Data Digitizing: Two separated electrometr, Keithley Model 642 with MOS FET Op-Amp and Takeda Riken TR8401 vibrating reed electrometer, were connected to faraday cup and multiplier respectively, while originally one vibrating reed electrometer controlled both. The out put voltage of these electrometers were measured by digital multimeter with 6 1/2 figuars (Takeda Riken TR6878). The data were collected into computer through GP-IB interface for processing successively. This system excluded any expected error occurred by manual operation.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Performance of the plan is found to be satisfactory as shown in Table 1., in comparison with the ideal condition for precise isotopic analyses (10^{-4}).

Table 1.
CONDITIONS FOR ANALYSES OF PRECISE ISOTOPIC RATIOS

CONDITIONS	IDEAL	JMS-D300 MODIFIED
High mass resolution	M/ΔM; 400-600	> 350
Width of peak top	$\frac{W(\text{peak top})}{W(1/2\text{hight})} \rightarrow 1$	0.75
Flatness of peak top	< 0.1 %	< 0.5 %
Instant responce of magnetic field	< 1 sec	< 1 sec
Instant responce of detecter	< 1 sec	< 2 sec
Low noise level	$< 10^{-16}$Amp	$< 10^{-15}$Amp
Data processing	digital & analog	digital & analog
scanning of magnet	peak hopping	peak hopping
Stability of magnet	stay on peak top	< 10 % of peak top

Measurement scheme were programmed by computer with following points; 1. The magnetic field scan was made stepwisely for each peak center one after another, which were preset before the each run. 2. To reduce errors of isotopic ratio due to instability of ion current, each peak was measured between reference isotope. 3. In the normal scan, periods of measurement and waiting time of each step were 3 to 5 sec. and 2 to 3 sec., respectively.

To test the performance on precision of analyses, reagents of some elements were measured. As an example, measured data for Sr reagents are shown in Fig. 3. These results shows; 1. The accuracy of analysis was found to be better than 0.01% when the isotope ratio was in the order of unity. 2. For less abundant isotopes, as low as 10^{-4} like ^{40}K, precision and reproducibility of the analyses were within 1%. We conclude that introduction of automatic magnetic controll and on-line data processing system was succesfull in high precise isotopic analyses by the compact virtual image double focussing mass spectrometer.

SIMULTANEOUS DETERMINATION OF TRACE LEVELS OF GROUP IIIA AND VA HYDRIDES IN SILANE BY SIM GC/MS

Jeffrey M. McGuire
Hercules Incorporated
Research Center
Wilmington, DE 19894

The need for ultrapure raw materials in the semiconductor industry is essential. In particular, high purity silane is critical for silicon device fabrication processes. The purity of this gas must be monitored wherever slight variations in reagent quality can impact process yields dramatically. Group IIIA and VA hydrides, such as diborane, phosphine, and arsine represent particularly undesirable impurities because they can be incorporated as dopants in silicon. This work describes a capillary GC/MS method of analysis for trace levels of diborane, phosphine, and arsine in silane/helium mixtures using the technique of selected ion monitoring (SIM).

An initial literature survey indicated that GC with a photoionization detector (PID) would be highly suitable for detection of phosphine and arsine at ppb levels (1). However, this system would not be applicable to the analysis of diborane or silane, due to the high ionization potential of these inorganic hydrides, and the current limit of UV lamp energies available for the PID. SIM mass spectrometry was chosen as the GC detector, due to the universality of MS and the sensitivity achievable by single ion monitoring.

The analyses were performed on a Hewlett-Packard MSD using a direct interface. Gas samples were introduced using a stainless steel gas sampling valve (2 cc loop at 350 mm Hg) connected in-line with the carrier gas and capillary inlet of the HP Model 5890 GC. Chromatographic separation was accomplished on a fused-silica capillary column (bonded methyl 5% phenyl silicone stationary phase), 50 m long, with an inner diameter of 0.32 mm, and a film thickness of 5.0 µm. A splitless injection mode was used. The column oven was held at -30°C for 5 minutes, and then programmed from -30°C to 100°C at 15°C/min.

For the SIM experiments, the following ions were monitored with a dwell time of 25 milliseconds each: 77.90, 75.80, 34.00, 33.00, 30.90, 29.90, 27.00, and 26.00. These ions were chosen from additional SIM experiments in which areas for a group of five ions at $\pm$ 0.1m/z intervals from the nominal mass were recorded. The m/z value showing the largest background subtracted area was monitored during the SIM quantitation experiment.

Figure 1 shows the combined single ion current chromatograms obtained from the GC/MS analysis of individual standards (~200ppm each in helium) of silane, diborane, phosphine, and arsine.

Calibration curves were constructed from these individual standards and two reference standard mixtures which contained 100ppm (Mole percent) each of silane, phosphine, and arsine in helium and 5ppm each of these hydrides in helium. Due to the reactivity of diborane, this hydride was not included in the reference standard mixtures, and further experiments were suspended. Figure 2 shows the calibration curves for the Group VA hydrides in the presence of silane. As the curves indicate, good linearity was obtained in the 1-200ppm concentration range.

Table I lists the limits of detection, where a concentration was adopted that gave peaks on the SIM trace which exceeded the noise level by a factor of two.

This method has been employed in the analysis of dopants in silane mixtures. Table II shows the results of such an analysis, where a silane mixture containing 5-6ppm of arsine and phosphine dopants was analyzed before and after exposure to a Nanochem^R resin purification system. The Nanochem^R resin consists of reactive organometallic species functionalized on a high surface area support designed to scavenge impurities. As indicated, the analysis clearly demonstrates the ability of this technique to monitor trace levels of the hydride impurities.

A rapid capillary GC/MS method has been developed for the separation of B_2H_6, and quantitation of trace levels of PH_3 and AsH_3 in silane mixtures by the external standard method. SIM mass spectrometry is used for detection. The method shows good linearity and precision between 1ppm and 200ppm, with detection limits of <0.1ppm by volume.

Characterization of nickel complexes by fast atom bombardment mass spectrometry:

Roczko, A.; Viswanadham, S. K.*;, Snarkey, A. G., Hercules, D. M., Department of Chemistry, University of Pittsburgh, Pittsburgh , PA 15260

Mass spectral analysis of metal complexes that are ionic, non-volatile and thermally labile has always been a problem by conventional electron-impact methods. The advent of 'soft ionization ' methods that include secondary ion mass spectrometry, plasma desorption, laser desorption, field desorption and fast atom bombardment (FAB) techniques have allowed a wide range of ionic and non-volatile materials to be analysed by mass spectrometry. The present study is aimed at characterizing nickel complexes of triphenylphosphine (tpp) and related ligands by fast atom bombardment mass spectrometry.

The metal complexes studied are given in table 1 along with their molecular weight. In order to identify a useful matrix for the FAB analysis, FAB spectra of compounds 1,5,6,8 and 10 were investigated using glycerol, thioglycerol, triethanolamine ,tetraglyme and m-nitrobenzylalcohol matrices. Spectra obtained by glycerol and thioglycerol showed peaks due to ligands and adduct ions of the ligands with matrix compounds and matrix generated fragments. Triethanolamine, as a matrix completely suppressed the desorption of the metal complexes. Spectra obtained using tetraglyme and m-nitrobenzyl alcohol as matrix showed ions that are structurally significant and characteristic of the complex compounds. All the spectra reported in this study were obtained using either tetarglyme or m-nitrobenzyl alcohol as a matrix. Fab spectra of compounds 3 and 11 are shown in figs. 1 and 2 respectively as typical examples.

Nickel complexes having NiL_nX_2 type structure (1-9) where L=mono or bidentate .igand and X=Cl,I,Br or CO commonly showed the loss of X when X is chlorine , while loss of HX was observed in the case of compounds having X= I or Br. This $(M-H)^+$ or $(M-HX)^+$ ions subsequently lost another X moiety leading to $(M-2X)^+$ or $(M-HX-X)^+$ ions in their mass spectra. When X=CO , the highest mass peak observed corresponds to $(M-2CO)^+$ ion. Only compounds 8 and 9 showed the formation of ions $(M+H)^+$ and $M^{+\cdot}$ ions respectively. Formation of intact ligand ions is seen in the case of compounds 1 and 3 only.

Fragmentation in these complexes was favored to occur at Ni-ligand bond; ions due to fragmentation within the ligand is not commonly seen. Bis(tpp)nickel dicarbonyl loses a phenyl group from $(M-2CO)^+$ ion leading to an ion at m/z 505. Ion formation due to recombination of some of the structural moieties of the complex were also observed. Bis(tpp)nickel(II) chloride, for example show ions due to $(2tpp-H)^+$ at m/z 523, and $(tpp+Cl)^+$ at m/z 297.

Compounds having a bidentate ligand (5, 6 & 7) showed an interesting ion corresponding to the loss of methylene moieties that are bridging the two phosphorus atoms complexed to the nickel atom, from their $(M-2X)^+$ ion where X=Cl or CO. This ion corresponds to m/z 428 in the case of compound 6. This common fragemnt will aid in gaining insight into the ligand in these complexes.

Complexes having the same four ligands connected to the nickel atom commonly showed ions due to loss of one and two ligands from the molecule. Only tetrakis(triethylphosphite)nickel showed the presence of molecular ion. FAB spectrum of this compound is also an exception in that extensive fragmentation corresponding to the losses of species within the ligand are seen.

FAB spectra of nickel complexes of triphenyl phosphine and related ligands thus show structurally significant and characteristic ions for their characterization. Fragmentation commonly occurs at metal-ligand bond and fragmentation due to bond breakage within the ligands was not common.

Acknowledgement: The authors thank Dr. J. M. Miller and Dr. K.Balasanmugam for providing fab spectra of some of the complexes.

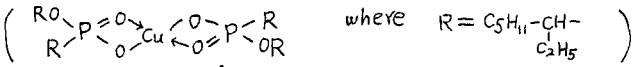
A STUDY OF FABMS OF 2-ETHYLHEXYL PHOSPHONIC ACID MONO-2-ETHYLHEXYL ESTER AND ITS COPPER SALT

M.Yuan, S.Liu*, Y.Zhu and X.Li
(Changchun Institute of Applied Chemistry, Sitalin Str. #109, Changchun, Jilin 130022, China)

Acidic phosphorus compounds are a type of extractants with a good extractability for lanthanide, in which alkyl phosphonic acid monoalkyl esters possess the most excellent separation behaviour. However the application of EIMS to analyze the extractants and extractives has been severely limited. The limitation has arisen due to unsufficient ions in gas phase, thermal decomposition of samples in preference to volatilization. For example, copper salt of 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester



starts to decompose at 190°C under 1 atm. FAB technique is one of the so-called soft ionization methods, which is powerful for the mass spectrometric analysis of low volatility and thermolabile products. However little is known of the FAB ionization mechanism. FAB is an attractive because quasi-molecular ions can be found besides fragment ions.

According to the previously proposed models for FAB ionization,[1] molecules M are ionized by protonation or proton abstraction. This mechanism can be used to explain the formation of $(M+H)^+$ in most FAB cases, but not to the formation of M^+ and $(M+2H)^+$ ions.

All measurements were performed on VG 7070E mass spectrometer. A VG Commercial FAB source was employed. FAB gas was Ar with kinetic energy 8keV. The Ar^+ ion beam current was about 1 m Amp. Glycerol(G), triethanolamine (TEA) and 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (HL) were used as matrices. The preparation of CuL_2 was made using the methods described in literature (2).

The positive and negative FABMS of HL (without glycerol) are shown in Figure 1a and 1b respectively. The major ions observed in the spectra are $[(HL)_2+H]^+$ at m/z 613, HLH^+ at m/z 307 and fragment ion $(HLH-C_8H_{16})^+$ at m/z 195 in the positive FABMS of HL as well as $[(HL)_2-H]^-$ at m/z 611, L^- at m/z 305 and fragment ion $(L-C_8H_{16})^-$ at m/z 193.

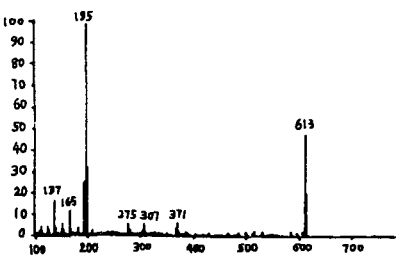


Fig.1a positive FABMS of HL

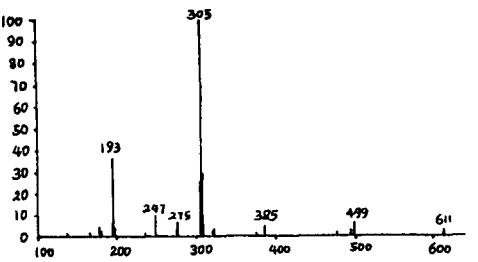

Fig.1b negative FABMS of HL

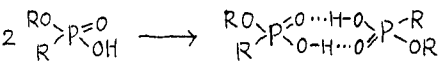
Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

The most striking feature of Figure 1a is the intensity of protonated dimer $[(HL)_2+H]^+$ much stronger than HLH^+, which is different from the usual FAB spectra like glycerol. This feature reflects the state of HL in the liquid. Ma and coworkers[2] reported that most of HL molecules in the liquid are dimerized through intermolecular H-bonds i.e.



Under fast atom bombardment a proton is captured or abstracted from surrounding molecules to form $[(HL)_2+H]^+$, HL_2^-, HLH^+, L^- ions. The other channel to form HLH^+ is unimolecular decomposition of $[(HL)_2+H]^+$ in gas phase, and HLH^+ further decomposes into $(HLH-C_8H_{16})^+$, which were verified by B/E linked scan technique. In the negative FABMS of HL, intensity of HL_2^- ion are weeker than L^-, which may arise from geometry and H-bond reasons. Therefore FABMS provides the information of liquid phase reactions to a certain extent.

Table I and II list the positive and negative FABMS of CuL_2 respectively. Unusual ion M^+ and $(M+2H)^+$ as well as M^-, $(M-H)^-$ and $(M+H)^-$ were observed. A new FAB ionization mechanism should be proposed, which may contain electron capture, hydrogen radical abstraction and capture processes as follows:

$$CuL_2 \longrightarrow CuL_2^{\ddagger}+e$$
$$CuL_2 \longrightarrow (CuL_2-H)^{\cdot}+H^{\cdot}$$
$$CuL_2+e \longrightarrow (CuL_2)^-$$
$$(CuL_2-H)^{\cdot}+e \longrightarrow (CuL_2-H)^-$$
$$CuL_2^{\ddagger}+2H^{\cdot} \longrightarrow (CuL_2+2H)^+ \quad \text{or} \quad Cu(HL)_2^+$$
$$CuL_2^{\ddagger}+H^{\cdot} \longrightarrow (CuL_2+H)^-$$

From oxidation-reduction point of view, positive FABMS of CuL_2 shows a lack of ions containing Cu(II). The containing copper species observed in the spectra are either Cu(I) or Cu(III), latter is quite rare in solution. Pelzer and coworkers[4] reported that oxidation-reduction processes do occur as a result of the FAB process also.

MATRIX EFFECTS IN IR-LASER DESORPTION OF NEUTRAL MOLECULES.

R.C. Beavis, J. Lindner, J. Grotemeyer, E.W. Schlag

Institut für Physikalische und Theoretische Chemie, TU München
Lichtenbergstr. 4, D-8046 Garching, Germany.

In the analysis of dipeptides using Infra-Red (IR) laser desorption of neutral molecules followed by resonantly enhanced multiphoton ionization (MUPI), several interesting ionic species were observed:

1) M-18 u : The intensity of this species was dependant on sample preparation, desorption conditions and the peptide sidechains involved.

2) M-16 & M-17 u : These species were only present when the N-terminal residue contained an aromatic group.

The work presented here was an attempt to understand the mechanism of production of these three ion and to see whether the fragmentation of the parent molecule was caused by the desorbing (IR) or the ionizing (UV) laser.

The mass spectrometer used is a BRUKER TOF 1 and has been described elsewhere [1]. For this study, it is important to understand that the desorption and ionization are completely separated in both time and space, with ionization occuring approximately 160 μsec after and 80 mm away from the site of desorption. This separation allows the study of the desorption without intererence from ionization.

A method for affecting the desorption process in a simple way is to change the chemical environment of the sample molecules. In IR desorption of neutral molecules, the threshold for the detectable emmision of molecules is typically 10^4 W/cm^2. Such low photon fluxes do not produce multiphoton effects in a solid and only serve to heat the sample. Therefore, one reaction that may occur is pyrolysis of a peptide at the surface. By changing the chemical enviroment of the molecule during desorption, it should be possible to affect the intensity of species occuring because of a pyrolytic reaction.

The mechanism resulting in $(M-18)^+$ was found to be a pyrolytic dehydration, probably the formation of a C-terminal ketene. Derivatization studies indicated that the C-terminal hydroxyl group participated in the reaction, but the N-terminal amino group did not. Figure 1 demonstrates that the addition of a simple sugar (glucose) can suppress the formation of the $(M-18)^+$ species. The intensity of the $(M-18)^+$ species could not be recovered by changes in the MUPI conditions (i.e. by changes in the UV laser wavelength or power density).

The two additional species, $(M-16)^+$ and $(M-17)^+$, were also studied by this method. Figure 2 shows the effect of adding a sugar to a peptide with an N-terminal aromatic group. The changes in peak intensities can be explained by the suppression of the $(M-18)^+$ species and its C^{13} satellite. The intensities of these species can be altered by changing the ionization condition. Therefore, these two species are true fragment ions, produced by absorption of further UV photons after ionization. The peaks shapes shown in Figure 2 also indicate that the $(M-17)^{+\cdot}$ species has a larger metastable contribution, while the $(M-16)^+$ species has a smaller metastable amount and is relatively stable. A possible reason for this difference is that $(M-16)^+$ was produced by the loss of an $NH_2\cdot$ radical, leaving an even electron ion, while $(M-17)^{+\cdot}$ was formed by the loss of NH_3, leaving a less stable odd electron ion. The necessity of having an N-terminal aromatic species to form these ions also suggests that there may be some resonance stabilization involved in the formation pathway.

These results demonstrate that:

1) Modification of the chemical environment of the sample by the use of a matrix is a useful method of distinguishing between desorption or MUPI induced fragmentations;

2) Sugar matrices eliminate the $(M-18)^+$ species from the mass spectrum by suppression of the formation of an $(M-H_2O)$ neutral species; and

3) The $(M-16)^+$ and $(M-17)^+$ ions are formed from the molecular ion of the peptide after the multiphoton ionization.

Uranium Concentration in Fossils

Jun OKANO and Chiaki Uyeda

College of General Education, Osaka Univ., Toyonaka, Osaka, 560 JAPAN

Recently it is known that fossil bones tend to accumulate uranium. The uranium concentrarion, C_u in fossils has been measured so far by γ ray spectroscopy or by fission track method. We applied secondary ion mass spectrometry, SIMS, to detect the uranium in fossil samples. The purpose of this work is firstly to investigate the possibility of semi-quantitative analyses of uranium in fossils, and secondly to study the correlation between C_u and the age of fossil bones. The further purpose of this work is to apply SIMS to measure the distribution of C_u in fossil teeth.

A modified Hitachi IMA 2A ion microprobe was used in this work. The primary ions were 10.5keV $O_2^+(O^+)$ and the probe diameter was 80-300μm. A piece of fossil sample was polished by emery paper to make the analyzing surface flat and the sample was mounted in a stainless steel crucible with pure indium. The sample and the crucible was dried in an oven at 100 °C for 24hrs and then attached to the sample holder of the ion microprobe. Electron spray was applied to compensate the charge on the sample surface induced by the primary ion bombardment.

SIMS mass spectra of uranium in U-glasses and fossil samples have three main peaks of U^+, UO^+ and UO_2^+. Among those, UO^+ is usually most intense although the relative intensities vary to some extent by the change of setting of the energy window. In this work, the energy window was set at the maximum trasmission of UO^+, and the sum of the intensities of U^+, UO^+ and UO_2^+ was taken as the intensity of uranium.

Figure 1 shows the relation between C_u and the SIMS intensity of uranium. The SIMS intensity is normalized to Ca^+ intensity and furthermore corrected for the stoichiometry. G611, G613 and G615 are the standard glasses of National Bureau of Standards. These glasses consist mostly of SiO_2, Na_2O, CaO and Al_2O_3 whose proportions are the same for the three glasses. The C_us are 461.5ppm for 611, 37.38ppm for 613 and 0.823ppm for 615. 120b is the phosphate rock standard of NBS which holds uranium of 128.4ppm. C_us of Dali bone, Arago bone and Barbados coral were determined by γ-ray spectroscopy. It was found that the plots of the standard glasses were well on a straight line as shown in the figure. Althought the plots of the fossil samples and the phosphate rock are scattered to some extent, we adopted the

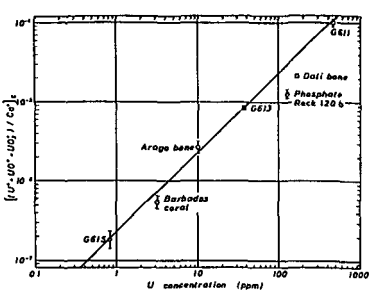

Fig.1 Calibration line for the estimation of C_u

straight line for the glasses as the tentative calibration line to carry out semi-quantitative analyses of uranium in fossil samples. This will be valid with an allowance of a half order of magnitute.

The list of the fossil bone samples and the results are shown in Table I and Fig.2. It is clear that there is a general tendency of increasing C_u with the age of the fossil samples. With a few exception, most data are plotted between the line A, $C_u=1\times10^{-4}t$, and the line B, $C_u=1\times10^{-2}/\sqrt{t}$ as shown in Fig.2.

Figure 3 shows the variation of C_u in the fossil teeth. It has been known that C_u in dentin part of fossil teeth is high and that in enamel part is low. The distribution of C_u from the border of dentine-enamel to the inner part of enamel was measured for three fossil teeth samples. This results seem to show that the diffusion of uranium from dentin to enamel has progressed throuout the fossil age.

Evaluation of Fast Atom Bombardment Mass Spectrometry for the Study of Cementitious Stabilized Wastes

J. V. Headley, P. W. Brooks* and P. Hannak

Alberta Environmental Centre, P.O. Bag 4000, Vegreville, Alberta TOB 4LO, Canada
*Geological Survey of Canada, 3303 - 33 St., NW, Calgary, Alberta, Canada

Solidification and stabilization processes(S/S) are of importance for the treatment and disposal of hazardous industrial wastes containing heavy metals, organometallics and polymeric contaminants . Little is known about the mechanism of containment, the nature of contaminant-matrix interactions and the partitioning of the waste in cementitious materials.

Release mechanisms have been investigated using elemental analyses of treated wastes and chemical analyses of leachates. Direct study however, addressing the chemical nature of metal containment in cementitious materials has received little attention.

In this paper, results are reported and evaluated for fast atom bombardment mass spectrometry (FAB/MS) studies of (a) Portland cement standard reference materials and (b) Portland cement standards containing heavy metal contaminated wastes. The wastes contained at least one of four heavy metals (Cd, Cr, Pb, V) covering a range of molar concentrations (0.01 M - 0.4 M), with known moisture content (27-32%). Binder systems studies included normal Portland cement type II and cement kiln dust with sodium silicate additives. The latter were selected to promote heavy metal-silicate interactions.

The studies were conducted on a hybrid VG 70S mass spectrometer with EBQQ geometry, using methanolic suspensions of the cementitious materials deposited on the FAB target. Negative ions and positive ions were collected using continuous mode detection.

The major components of the Portland cement standards yielded abundant positive ions; the corresponding negative ions were poorly observed. For example, standard reference material containing CaO, (64.5% by weight), yielded abundant ions for the series Ca^+, CaO^+, $CaCaOCaO^+$. Likewise for cementitious material containing lead contaminated waste, Pb^+, $PbOH^+$, $PbCaO^+$, $PbSiO^+$, $PbOHCaO^+$, and $PbOSiO^+$ are the major ions observed. Similar species were observed for waste containing Cd, Cr, and V.

Conditions were attained in which matrix species are tagged by ion-molecule reactions occurring in the FAB ion source. The reproducibility of the FAB mass spectral data (Table 1) is thus dependent on (a) the homogeneity of the subsamples and (b) the stability and duration of the ion beam. As shown in Table 1, the reproducibility of the technique is satisfactory.

The results indicate that FAB/MS is a viable technique for the study of cementitious stabilized wastes. For example the FAB mass spectra contained a preponderance of metal ions associated with SiO groups, for binders with sodium silicate additives. Likewise the abundance of the metal hydroxide ions were observed to be dependent on the S/S process. Future work is warranted to correlate the abundance and distribution of the metal-ligand species with containment mechanisms for S/S processes.

Table 1 Reproducibility data for FAB/MS of cementitious stabilized waste contaminated with lead

Ion	Relative Abundance	%RSD	Range	No. of Determinations

ANALYSIS OF AIR AND MOISTURE SENSITIVE ORGANOMETALLIC COMPOUNDS USING AN ARGON STREAMING INTRODUCTION SYSTEM

L. M. Mallis

High Resolution Mass Spectrometry Facility
The University of Iowa
Iowa City, Iowa 52242

C. Ting, M. S. Hammer and L. Messerle

Department of Chemistry
The University of Iowa
Iowa City, Iowa 52242

The reaction chemistry of a new class of metal-metal doubly-bonded species $(Cp^*MX_2)_2$ [M = Ta; X = Cl, Br, BH_3; Cp^* = η-$C_5(CH_3)_5$] has been under development. These species, which are prepared by reductive dimerization of high-valent mononuclear precursors, are highly air and moisture sensitive. The emphasis on reactivity studies with small molecules (e.g., H_2, C_2H_4) have resulted in a need for routine mass spectrometry of these highly sensitive, high mass organodimetallics The principal impediment to these studies is routine sample introduction under conditions which preserve the integrity of the sample.

The development of dinuclear early transition metal organometallic chemistry, particularly of species with metal-metal bonds, has been slowed by a reliance on relatively slow X-ray diffraction methods in characterization of the dinuclear unit. In addition, the use of X-ray diffraction also suffers from potentially severe sampling errors. Mass spectrometric methods would be of tremendous value in determining the nominal mass, nuclearity of reaction products (through isotope patterns) and fragmentation patterns of organodimetallics. The extreme air and moisture sensitivity of early transition metal organodimetallics has limited the routine application of mass spectrometric methods in compound characterization.

In this paper, a technique for introduction of such air and moisture sensitive compounds is presented. This technique uses argon to purge the sample introduction environment. In general, the compounds mentioned above show a significant increase in molecular ion formation when this argon streaming sample introduction technique is used. In addition, for some of the dimetallic compounds sample introduction with argon provides the opportunity to observe the intact molecular ion. In all cases, the spectra were obtained using a VG ZAB-HF mass spectrometer in the electron-impact ionization mode.

Three different organo-dimetallic species were analyzed. In general, the structure of these compounds is thought to contain a metal-metal double bond The X-ray structure of $(Cp^*TaBr_2)_2$ is shown in Figure 1. A 4.05 fold increase in sensitivity is observed for the selected molecular ion (m/z 952) of this compound (see Table 1). For the BH_3 adduct of this compound, a 3.27 fold increase in sensitivity was observed (m/z 688, see Table 2). The Cl adduct of this series produced a 15.3 fold increase in sensitivity for the selected molecular ion (m/z 774; see Table 3).

The technique of argon streaming increases the chance of observing the molecular ion cluster for such compounds. Further modifications on the method of sample preparation and introduction are currently underway. In addition, a method for sample introduction during a fast atom bombardment experiment is currently under development.

CHARACTERIZATION OF AIR-SENSITIVE METALLOPORPHYRINS BY FABMS

Emirgul Tolun and Julie A.Leary

Chemistry Dept. University of California, Berkeley, CA 94720

There is significant interest in metalloporphyrins for both biological and industrial reasons.The difficulty in obtaining large X-ray quality single crystals of these compounds, particularly the metal-metal multiply bonded metalloporphyrin dimers have necessitated the use of mass spectrometry to establish their dinuclearity. The octaethyl porphyrin (OEP) and meso-tetratolyl porphyrin (TTP) dianionic complexes containing tungsten and rhenium are extremely oxygen sensitive and begin to decompose in the presence of small levels of oxygen in solution.

In this presentation we report the development of specific handling procedures for FABMS of oxygen and water sensitive organometallic compounds and its application to the analysis of tungsten and rhenium porphyrins.

All samples run on a Kratos MS-50 double focussing mass spectrometer equipped with a DS-55 data system. Vacuum distilled tetramethylene sulfone (sulfolane) was used as a matrix.Sample preparation and loading were done under nitrogen or argon in a Vacuum Atmospheres HE 43-2 dry-box.

Table 1 is a summary of the results obtained for the positive ion FABMS of W and Re metalloporphyrins. In general, molecular ion was present in each spectrum.

All spectra also exhibited some oxygenated form of the metalloporphyrin. At this point it has not yet been determined whether the oxygenated products were produced in the mass spectrometer, during sample preparation and mounting or whether these by-products were already present in the original samples.

The major ions observed for the dinuclear complexes $[Re(OEP)]_2$ and $[W(OEP)]_2$ include the molecular ion, the Metal(OEP) ion and the ions corresponding to M+14, M-14 and M-28 (Figure 1).M-14 and M-28 type ions probably arise from the loss of CH_3 and C_2H_5 respectively, with the transfer of hydrogens to the macrocycle. Ions corresponding 14 mass unit additions either to the molecular ion or fragment ions, may be metal carbenes forming as a result of methyl losses from one molecule and attachment of the metal of another molecule in the gas phase.

Computer simulated isotope patterns were in excellent agreement with molecular, oxygenated and fragment ions.

DESIGN AND CHARACTERIZATION OF A RADIO FREQUENCY (RF) POWERED GLOW DISCHARGE SOURCE FOR SOLIDS MASS SPECTROMETRY

R. Kenneth Marcus, D. Duckworth, and W. Kolar
Department of Chemistry, Clemson University
Clemson, SC 29634

Glow discharge mass spectrometry has evolved into one of the most powerful of methods for performing direct solids elemental analysis. While the technique is applicable to a wide range of alloy and semiconductor systems, one limiting factor is the inability to analyze insulating (non-conducting) materials without some form of matrix modification. The approach typically taken for such analyses, is to mix the sample specimen (in powder form) with a metal powder such as Cu, Ta, or graphite. In doing so, the sample becomes diluted and the ability to obtain depth-resolved analyses is lost.

In this laboratory we have designed and constructed a radio frequency powered glow discharge source to perform direct solids elemental analysis of metals and insulators. By applying a radio frequency (13.56 MHz in this case) potential to an insulating surface, the rate of the capacitor-like decay response to a voltage pulse is overcome, resulting in a psuedo-continuous plasma. By choosing the appropriate electrode geometry, a d.c. bias potential develops on the cathode (sample) resulting in its bombardment by positively charged argon discharge gas ions. In addition to the advantage of being able to sputter insulating materials directly, it is expected that the lower operating pressures of the rf glow discharge (mtorr vs. torr for the d.c. case) will provide enhanced depth profiling capabilities.

EXPERIMENTAL

Figure 1 is a diagrammatic representation of the instrumentation employed in the rf glow discharge system. The rf glow discharge is powered by a 1 kW generator (Model RF-10, RF Plasma Products) which is coupled via an automatic LC matching network (Model AM-10) for efficient power transfer. The operating power of the plasma is continuously variable over the 5-50 watt operating range employed here. Analytical samples are in the form of 0.5" diameter, 0.4" thick, disks which are mounted on a water cooled stainless steel holder. The holder is encapsulated in a Macor sleeve with a steel shutter employed to restrict the sputtering to the sample surface. The sample holder is flange mounted to a stainless steel six-way cross which forms the source region.

A quadrupole-based glow discharge mass spectrometer system designed and assembled in this laboratory is employed to sample the rf plasma ions. The system consists of Extrel C-50/400 components housed in a vacuum chamber which is differentially pumped by a pair of Leybold Hereaus RPK series cryopumps. Ions exiting the source region pass through the first pumping stage into the analyzer region where they are focussed by a two-element lens into a Bessel Box energy analyzer. The Bessel Box is employed both as a means of normalizing ion energies and of determining relative kinetic energies of the various plasma species. Ions are detected by a conversion dynode-channeltron pair in both analog and ion counting modes. Output from the electrometer is fed to an X-Y plotter to record spectral scans. Relative ion intensity measurements are performed through a Hewlett Packard 9835A computer with Extrel peak-hopping measurement routines.

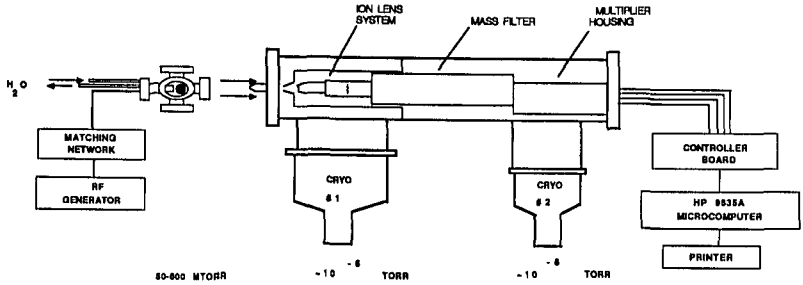

Figure 1. RF powered glow discharge mass spectrometer system.

RESULTS AND DISCUSSION

Figure 2 is an rf glow discharge mass spectrum of NBS C1122 copper-beryllium alloy. The mass spectra produced by the rf glow discharge source are quite similar to those of the d.c. glow discharges with ion currents on the same order of magnitude (3X10-11 amps for $^{63}Cu^{+}$ here). Certified minor components of this alloy are shown in expansions of the spectrum with their respective elemental concentrations. The plasma source operates stably with a variation of the ^{54}Fe ion signal of ~3% over a 40-minute time period. Detection limits are difficult to assign, at this point, due to non-ideal rf grounding (noise) and an inability to optimize the sample-to-skimmer cone distance.

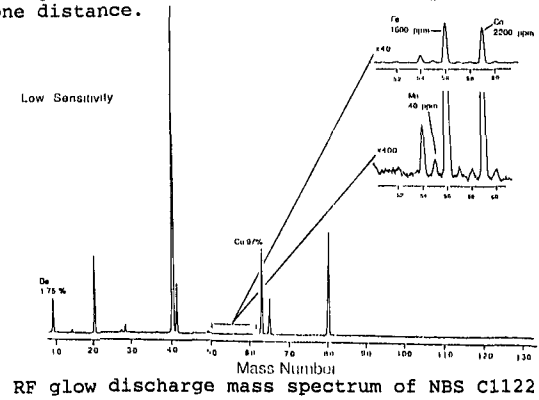

Figure 2. RF glow discharge mass spectrum of NBS C1122.

As was expected, the operating regime of the rf glow discharge ion source is much different from its d.c. counter part. Also different from the normal d.c. source is the relatively limited range of operating parameters (0.1-0.4 torr, 5-50 watts) over which high ion populations are extracted. It should be noted that the plasma operates stably at higher powers at each pressure and in fact the conditions of higher pressure and powers would seem to be those employed for atomic emission spectroscopy. We believe that these pressure-power relationships indicate a shift in the optimal sampling position in the plasma negative glow.

Future studies of the rf glow discharge source will focus on its application to the analysis of insulating materials and in reducing electronic noise pick-up from the plasma generator. Given the magnitude of the matrix ion current and the source stability (after only weeks of investigation), it is believed that the rf glow discharge operating as an atomization/ionization source may be a viable method for direct solids elemental analysis of both conducting and insulating sample matrices.

ATMOSPHERIC PRESSURE PLASMA MASS SPECTROMETRY - CONSIDER THE SOURCE

R.D. Satzger

U.S. Food and Drug Administration
Cincinnati, Ohio 45202

Atmospheric pressure plasma mass spectrometry is a multi-element technique with excellent detection limits and the capability to provide isotope ratio information enabling isotope dilution. The commercially availabe Ar ICP ion source principally generates singly charged monatomic species. Its high gas temperatures facilitate liquid sample introduction with few ionization suppression problems which cannot be handled through dilution due to the excellent sensitivity of the technique.

However, argon containing molecular background ions can interfere in the determination of the principle isotopes of K, Ca, V, Cr, Mn, Fe, Ni, Co, Ge, As and Se. Also, the Ar plasma does not generate substantial quantities of Br^+, Cl^+, and F^+ which are only partially ionized. Therefore, in an attempt to reduce the argon containing molecular background and provide the capability to determine the halogens as positive ions, the He microwave induced plasma (MIP) source is being investigated in this laboratory using a laboratory built atmospheric pressure plasma sampling mass spectrometer.

In this work an electrothermal vaporizer (ETV) is investigated as a means of sample introduction to the He-MIP. Use of ETV in conjunction with a He plasma provide several advantages. Background peaks in the mass spectrum due to the presence of water when using aqueous solution nebulization as a means of sample introduction are reduced. Major background ions present in a 350W He-MIP are dependent on sampling position. $^4He_2^+$ is the principal ion in the backgound spectrum when sampling the plasma on center at a distance of a few millimeters. A second advantage of the ETV/He-MIP is the ability to reduce the matrix effects observed during solution nebulization into the He plasma, through selective volatilzation of interferents. In many cases the volatility of major matrix species differs from that of the analyte enabling a separation before introduction to the plasma source. A third advantage is the ability to analyze samples which present great difficulties to solution nebulization techniques. Volume limited samples, viscous samples and solid samples may be introduced to the plasma using electrothermal vaporization.

The electrothermal vaporizer assembly is a modified HGS-500 graphite furnace which was formerly used for atomic absorption analyses. The distance between the center of the graphite tube vaporizer and the plasma is approximately 13 cm. The MIP torch assembly requires two He gas flow. A tangential He flow rate of 8.5 L min^{-1} sustains a 350W plasma during all phases of sample introduction (sample loading, drying, ashing, vaporization). The sample aerosol carrier gas flow rate is 1.5 L min. The plasma is sustained in a 1 cm deep TM^{010} resonant cavity at a frequency of 2455 MHZ. All data acquisition was in the analog mode. Optimum sampling position, gas flows, ion lens potentials and mass filter tuning were accomplished during continuous introduction of methyl chloride, methyl bromide, methyl iodide or Hg vapor, depending on the mass of interest.

Initial experiments have demonstrated that the optimum sampling position at 350W is approximately 2 mm above the center of the plasma with a microwave cavity/sampler separation of 4 mm. At this position, NO^+ and O^+ are the principal ions in the mass spectrum. An estimated detection limit for all elements investigated (Se, Cd, Sn, Au, Pb) based on the response for a 5 ng injection is below 50 pg. Relative standard deviation of successive manual injections of Pb was 14%. Peak widths for Pb and Au were approximately 8 sec when using a 5 second ramp to 2000°c. Separation of matrix interferences and isoboric overlaps using the ETV will be discussed.

76 Carbon And Oxygen Stable Isotope Geochemistry Of Ammonia Beccaril In China Seas And Its Geological Implicatons. He Zhe, Wang Xung And Kau Ya Ping, P. O. Box 18, Qingdao, China.

Ammonia Beccaril Samples from the China Seas and Huanghe River Delta have been determined in carbon and oxygen stable isotopes. Results are so obvious to indicate that the carbon and oxygen stable isotopes are implication of sedimentary environments, so that they are useful tools for facies analysis of carbonate deposits.

The oxygen stable isotopic of foraminifera is related to temperature and salinity of sea water. Foraminifera will deplete oxygen-18 with increasing temperature and decreasing salinity. Therefore, the foraminifera in transitional environments will show lighter values both in carbon and oxygen stable isotopic composition. For example, the oxygen-18 of Ammonia is the lightest in Ginyin Island to the south China Sea, and at the mouth of Changjian River, $\delta^{13}C$ and $\delta^{18}O$ are lightened owing to the flux of fresh water. Samples from Gingdao No.1 Bathing Beach and Leichou Bay show values at level in $\delta^{13}C$ and $\delta^{18}O$ indicating same boundary conditions occurred in the two bays. Results reconfirm the conclusion that the carbon-13 values are closely related to photosynthesis.

The results from the Huanghe River Delta demonstrate that the ammonia beccaril lived in a transitional environment, very typical isotopic values were observed. In a plot of carbon-13 vs. oxygen-18, it was noted that all of the results were concentrated in small area. This is typical for foraminifera from transitional enviroments. Samples plotting far from this area may result from diagnesis of fresh water.

MASS SPECTROMETRIC STUDIES OF AIR/MOISTURE SENSITIVE COMPOUNDS BY CF-FAB

M.Barber, D.J.Bell, M.Morris, L.W.Toller, M.Woods, G.A.Gott, P.P.MacRory, C.A.McAuliffe, UMIST, Sackville St., Manchester, UK.

INTRODUCTION

In standard probe FAB analysis, a liquid matrix is used to dissolve the sample under investigation. This has given rise to problems in some cases where interaction between sample and matrix occurs [1]. Sample introduction via a continuous flow FAB is an alternative approach where the amount of matrix present may be reduced or eliminated [2,3].

The study of manganese/phosphine compounds is of particular interest because of their ability to bind small molecules, e.g. they reversibly bind dioxygen in a manner that closely resembles the properties of both haemoglobin and myoglobin. Gas separations are also possible using these complexes [4]. Previous attempts at FAB mass spectrometric analysis of analogous phosphine oxide complexes proved unsuccessful, with suspected sample disproportionation in the matrix.

EXPERIMENTAL

A commercially available (Kratos Analytical) continuous flow FAB probe [5] was used in conjunction with a Kratos MS50RF-TC. The spectrometer was operated at 6kV, and scanned at 3 $s.dec^{-1}$ under data system (DS90) control. The instrument was equipped with an Ion Tech FAB gun operated at 8kV with Xenon gas.

Samples were introduced to the probe tip by passing the capillary through a septum into the sample system under investigation. The pressure was stabilised by heating the source block accordingly, thus preventing sample freezing and capillary choking. Between sample introductions, the capillary was flushed with dry toluene for five minutes, so eliminating any memory effects.

The normal FAB sample preparations were carried out in a fume cupboard by syringing sample from the sealed system and applying to the probe tip. The introduction and acquisition was done as quickly as possible to reduce the air exposure time. The source heating was turned off.

RESULTS AND DISCUSSION

a) Tertiary Phosphines

The mass spectra of two tertiary phosphines (Fig. 1), both air sensitive, show intense ions relating to the $M^{\cdot +}$ entity, with little or no oxidation evident when using continuous flow FAB. Structural confirmation of the phosphines may be derived from the fragmentation patterns, and no clusters or adducts of the phosphines are manifest.
In contrast, on normal FAB analysis with limited exposure to air, the ion pertaining to the protonated phosphine oxide species predominates.

b) Manganese Halide / Phosphine Complexes

The mass spectra of the manganese halide/phosphine mixtures (Fig. 2) show ions suggesting that the phosphine(L) contains a minute

amount of phosphine oxide(OL). Copper (from the probe tip) is found to complex as Cu(I) with L, and the Mn(II) reacts with OL in preference to L. Both $Mn(OL)X_2$ and $Mn(OL)_2X_2$ have been isolated. The unexpected result is the appearance of an ion sixteen daltons higher than the $(Mn(OL)_2X)_+$ entity that suggests the presence of either $Mn(OL)(L)(O_2)X_2$, or the less likely $Mn(OL)_2X_2O$.

CONCLUSION

Continuous flow FAB mass spectra of a number of air/moisture sensitive compounds were attained with relative ease. This method permitted facile analysis of some sensitive and extremely odorous compounds with contamination of neither the sample nor the laboratory. A species was observed that suggested the possible binding of molecular oxygen to a manganese phosphine/phosphine oxide complex.

ANALYSIS OF SYNTHETIC AND NATURAL POLYMERS USING PYROLYSIS SHORT COLUMN GC/MS

J.M. Richards, Somatogenetics Instruments Inc., Broomfield, CO 80020; W.H. McClennen, J.A. Bunger, and H.L.C. Meuzelaar, Center for Micro-Analysis and Reaction Chemistry, University of Utah, S.L.C. UT 84112.

Pyrolysis-gas chromatography-mass spectrometry (Py-GC-MS) has long been used in the analysis of synthetic and natural polymers for quality control, material characterization and in the study of degradation and biomass conversion. However; Py-GC-MS has the disadvantage of often very long analysis times (>100min), and the loss of highly polar and high MW pyrolysis products on the column. Decreasing the analysis time, and increasing the throughput of polar and high MW compounds would greatly enhance this technique for the analysis of polymers and biopolymers.

Short column-gas chromatography mass spectrometry (SC/GC-MS) has been studied and demonstrated [1,2] as a method which can greatly reduce the time required for analysis while maintaining a useful level of resolution. Further increases in analysis speed can be achieved by interfacing the column directly with the vacuum of a mass spectrometer since the optimum carrier gas velocity for a column with a vacuum outlet is higher than for a column with an atmospheric outlet (ca. 2 times higher for 2.5m x 0.25mmID column [2]). Thus, a short column which is interfaced directly with the vacuum of the mass spectrometer allows increased analysis speed by virtue of the reduced column length and the increased carrier gas velocity. A short column GC-MS system with a vacuum column outlet and a pyrolysis inlet should be capable of rapid analyses of polymers and biopolymers.

A low dead volume Curie-point pyrolysis inlet (Somatogenetics Instruments) was used with short columns (4m and 5m) directly interfaced to the vacuum of a Finnigan ITD and ITMS. For the analyses on the ITD a 4m x 0.25mm ID CP-Sil5 column (Chrompack) was used which had a linear velocity of 175cm/s and a volumetric flow of 4.0ml/min (inlet 8psig, column 60°C, transfer line 250°C). The conditions on the ITMS were a 5m x 0.32mmID SE-30 column (J&W Scientific) with a linear velocity of 150cm/s and volumetric flow of 7.2ml/min (inlet pressure 3psig, column 60°C, transfer line 250°C). Pyrolysis was performed using 610°C Curie-point filaments with a temperature rise time of ca. 0.2s, and 1s total heating time. The remaining analytical conditions (inlet T, GC program, etc) were varied according to sample being analyzed.

Analysis of synthetic polymers shows the ability to rapidly characterize these samples and detect relatively high MW compounds without derivatization. The analysis of Biomer rapidly identified the diisocyanate, polyol and chain extender components used in the synthesis of Biomer (4,4'-methylene-bis-(phenyl isocyanate), poly(tetramethylene oxide) and ethylene diamine respectively). Also a hindered amine light stabilizer, an antioxidant (poly(2,2'-diisopropylamino ethylmethacrylate) and 4,4'-butylidene-bis-(6-*t*-butyl-*m*-cresol) respectively) and phthalate additives or contaminants were detected in under 10 minutes. Large polyol oligomers up to n=7 (MW=522) are detected in this analysis.

The analysis of Silastic yields a series of polymer fragments which includes high MW fragments (figure 1). This series of fragments begins with the tetramer fragment which elutes in ca. 20s and concludes with the dodecamer (n=20) at 7min 40s. This dodecamer fragment (MW~1480) is one of the highest molecular weight compounds which has been detected by gas chromatography methods without derivatization.

The speed with which underivatized polar compounds can be analyzed is demonstrated by the analysis of cellulose (figure 2). Both the polar monomer (levoglucosan m/z163) and isomers of the dehydrated monomer (levoglucosenone, m/z145) are detected in under one minute. The separation of isomers of levoglucosenone and the small amount of tailing of the levoglucosan peak show that resolution and chromatographic quality are not sacrificed for the sake of rapid analyses.

Diketopiperazines characteristic of amino acid pairs are detected in the analysis of oligopeptides. Diketopiperazines characteristic of Gly-Pro, Phe-Pro, and Tyr-Pro are detected in the analysis of β-Casomorphin acetate. In principle these compounds can be used in the sequencing of proteins.

The analysis of Walnut wood produced a complex chromatogram which contains peaks characteristic of the saccharide (xylose, hexose and cellulose) and lignin portions of the wood. Compounds characteristic of the syringol and guaiacol units are the dominant lignin fragments. Also, a naphthol wood preservative is detected (figure 3).

The analysis of a dichloromethane extract from a styrene/butadiene rubber compound shows the ability to rapidly detect additives present in the rubber compound. Relatively polar and high MW compounds, such as antioxidants (di-*t*-octyldiphenylamine mw=332 and poly(2,2,4-trimethyl-1,2-dihydroquinoline) dimer detected

at mw=376), antiozonant (N-(1,3-dimethylbutyl)-N'-phenyl-*p*-phenylenediamine mw=268), sulfur (S_8 mw=256) and fatty acids (myristic acid mw=228, palmitic acid mw=256, and stearic acid mw=284), are eluted in under 10 minutes.

The results of this study show the capability of Py-SC/GC-MS to rapidly analyze complex polymeric materials. The combination of pyrolysis and SC/GC-MS (with a vacuum GC outlet) enables rapid detection of relatively high MW and polar compounds which are difficult or impossible to detect using longer columns with an atmospheric pressure outlet. There is relatively little loss of resolution due to the shorter column, while ample information can be collected for the characterization of complex materials.

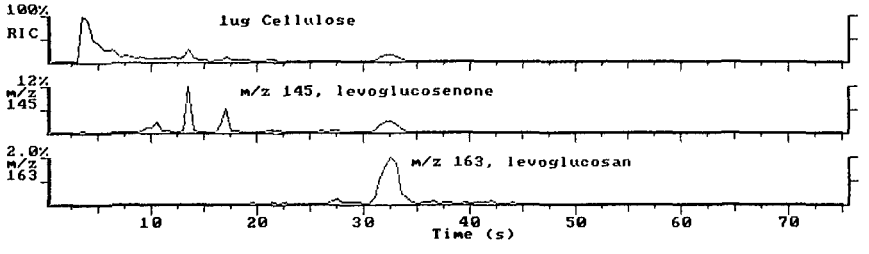

Figure 1. Reconstructed ion current and selected ion chromatograms from the analysis of cellulose. The polar monomer compound, Levoglucosan (*m/z* 163) and the dehydration product of the monomer, levoglucosenone (*m/z* 145), are detected in under 1 minute. Note that isomers of levoglucosenone are resolved. Isobutane chemical ionization.

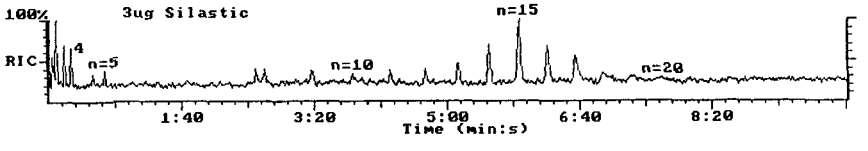

Figure 2. Reconstructed ion current from the Py-SC/GC-MS analysis of Silastic. Fragments of the polymer up to 20 repeat units in length are detected. The n=20 fragment (MW~1480) is one of the highest MW compounds detected via GC *without* derivatization.

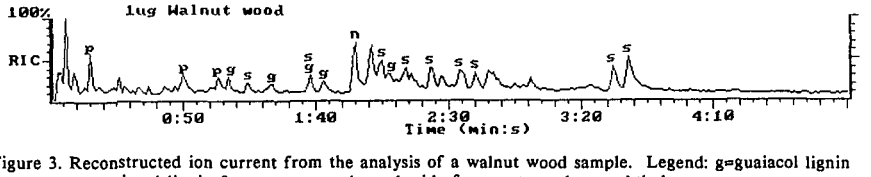

Figure 3. Reconstructed ion current from the analysis of a walnut wood sample. Legend: g=guaiacol lignin fragments, s=syringol lignin fragments, p=polysaccharide fragments, and n=naphthol.

PEPTIDE ANALYSES USING CONTINUOUS-FLOW FABMS

Richard M. Caprioli
The University of Texas Medical School
Houston, TX 77030

Continuous flow (CF) FABMS (1) has been used for the analysis of peptide mixtures which were obtained from enzymic digests of proteins as well as those that have been synthetically prepared. Typically, CF-FAB will involve injection of aqueous samples into a carrier-flow solution containing 95% water, 5% glycerol, and 0.1% TFA. In comparison, standard FAB involves dissolving a small amount of aqueous or solid sample in 80-90% glycerol containing TFA or oxalic acid. The CF-FAB technique has several advantages over the standard FAB technique for peptide analyses. These include higher sensitivity and lower limit of detection because of reduced background chemical noise, reduced ion suppression effects, compatibility with aqueous samples, and capability as an on-line interface for gradient microbore LC/MS applications. The major disadvantages are the initial time required to set up the pump and flow solvent and stabilization of the probe in the source, typically about 15 min. Also, because microcapillary methods are being used, solutions should be filtered to remove solid particles and microbore capillary plumbing carefully done to avoid connections with large dead-volumes.

Depending on the nature of the information sought, the analyses of peptide mixtures using the CF-FAB technique can be accomplished in a number of different modes of operation. In the case where there are a great number of samples to be analyzed, direct injection via a microinjection valve provides a fast and facile method for the introduction of a sample every 2-3 min without cross-contamination. Individual samples may also be analyzed in this way to take advantage of the higher sensitivity of the technique. Reaction mixtures such as those produced from proteolytic digests can be analyzed by direct injection, a one-step elution from a C-8 column or other support medium to which it has been absorbed, or by gradient elution HPLC methods. Again, each method has particular advantages and drawbacks relative to the others. Briefly, direct injection is simple and fast, and since it does not require binding to any media, has the least potential for loss of samples through irreversible adsorption. However, ion suppression effects are maximized since all the peptides are present at the same time and peptides having the same mass cannot be distinguished. Single-step elution of a peptide sample previously adsorbed to a solid phase with a high percentage of organic solvent allows pre-purification and concentration of the sample. One obtains a gross fractionation of the sample so that all the peptides are not present at the same time, although it may still be difficult to distinguish peptides of the same nominal mass. Microbore gradient LC/MS techniques provides better separation of individual components of a mixture over time, minimizing ion suppression effects and providing maximum resolution of individual peptides. However, such an analysis is more time-consuming, ranging from 20-40 min or more for a typical gradient separation.

These points are illustrated for the analysis of the tryptic digest of human apolipoprotein A-I (apo A-I). In a 20 min LC/MS analysis, 25 tryptic fragments were identified in the mass range m/z 2000 - 400. The overall response and sensitivity for this mass range was determined by analyzing the digest at different dilutions, allowing 240, 24 and 2.4 pmol to flow into the MS source. Most of the peptides were readily identified at good signal-to-noise levels even at the lower concentration. Figure 1 shows the CF-FAB mass spectrum of one of these tryptic fragments.

Minimization of ion suppression effects using CF-FAB is illustrated for the analysis of a mixture of seven heptapeptides that have been synthetically prepared. The sequences are similar; the N-termini are Ala-Phe-, the C-termini are -Asn-Gly, and the middle three residues varied from hydrophobic to hydrophilic residues. Figure 2 shows the CF-FAB and standard FAB analyses of this mixture. It is seen that major ion

suppression effects are operating in the case of standard FAB for peptides I, III, and V. This is greatly reduced in the analyses utilizing CF-FAB. The results are also interesting because the peptides suppressed the greatest are the more hydrophobic of the group, although all the peptides have hydrophilic indices. This suggests that for these types of peptides, other factors such as peptide-peptide interactions and secondary structure may also play a major role in the production of ions from the liquid sample. This is discussed in more detail elsewhere (2).

We have shown that CF-FAB can be used effectively for the analysis of mixtures of peptides and has several advantages over standard FAB techniques. When used as an LC/MS interface, complex mixtures can be analyzed at the 1-5 pmol level using wide mass range scans. We believe that this technique provides a most effective means for analyzing protease digests and other peptide mixtures.

OPIOID PEPTIDE MEASUREMENTS WITH FAB-MS

Dominic M. Desiderio
Departments of Neurology and Biochemistry,
University of Tennessee, Memphis,
800 Madison Avenue, Memphis, Tennessee 38163

State-of-the-art mass spectrometric (MS) methods are used effectively to identify and to quantify neuropeptides in biological CSF, plasma, and tissue extracts with excellent sensitivity and specificity. RP-HPLC gradient elution (1-3) is performed on a Sep-Pak treated peptide-rich fraction from a biologic extract, and the eluent is monitored by a variety of post-HPLC detectors to maximize amino acid sequence information: UV (200 nm) provides the analog absorption trace; receptorassay analysis (RRA) of 90 one-minute fractions provides the metabolic profile of opioid receptoractive peptides (4); radioimmunoassay (RIA) of selected fractions provides immunoreactivity information; and two modes of fast atom bombardment mass spectrometry (FAB-MS) provide additional structure information: corroboration of the (M+H)+ of the expected peptide (5), or MS/MS in the selected ion monitoring (SIM) mode to monitor an amino acid sequence-determining fragment ion unique to that peptide, for quantification with maximum specificity. FAB-MS-MS-SIM of solutions of synthetic leucine enkephalin is sensitive to the 70 femtomole (6) and attomole level (7).

The objective of this research program is to identify and measure endogenous opioid peptides that are extracted from biologic tissues and fluids at the maximum level of molecular specificity and detection sensitivity. At present, the greatest need in neurochemistry is not necessarily detection sensitivity but rather the more crucial parameter, molecular specificity, which is an experimental parameter that can be provided only by amino acid sequence information derived from gas-phase, wet-chemical, or MS/MS sequencing methods. It is our opinion that MS methods maximize molecular specificity and attain a detection sensitivity that rivals that of immunoassay (6,7).

METHODS

Tissue preparation. After acquisition, post-mortem human pituitaries, pituitary tumors, placental tissues, and human teeth are frozen rapidly in liquid nitrogen, and stored at -70° C. Tissue is homogenized in acetic acid. Acidified acetone further precipitates proteins. The peptide-rich fraction is eluted from a Sep-Pak with 50% acetonitrile in TFA, and lyophilized.

Radioreceptor assay (RRA). A radioreceptor assay is used to measure opioid receptoractivity, which is contained in the HPLC fractions (4), to obtain a metabolic profile. Tritiated etorphine is a broad-based ligand that competes with a wide range of opioid peptides for binding to opioid receptors in a canine limbic system P2 preparation.

Radioimmunoassay (RIA). Commercial RIA kits are used to measure immunoreactivity (ir-) eluting from the gradient HPLC.

Mass spectrometry. FAB-MS produces a (M+H)+ ion of peptides in those HPLC fractions demonstrating immuno- and receptoractivity. VG 7070E-H and Finnigan MAT 731 instruments are used.

Mass spectrometry/mass spectrometry (MS/MS). MS/MS selects a unique amino acid sequence-determining fragment ion arising from a peptide, defines more accurately the amino acid sequence of the peptide to be measured in the biological extract, and extends the information beyond only the nominal mass of the peptide (2). In principle, a first MS produces the (M+H)+ ion, and a second MS produces the mass spectrum of that selected ion. In a two-sector MS instrument, equivalent data are obtained with a B/E linked-field scan, which collects product ions

arising from a precursor ion. A known amount of stable isotope -incorporated peptide internal standard, which posses identical HPLC and MS properties with the endogenous peptides, is added to quantify the endogenous peptide.

RESULTS AND DISCUSSION

Opioid receptoractivity in a human chromophobe adenoma obtained from pituitary neurosurgery was profiled (1). All HPLC fractions were also assayed for ir-ME content using a commerical RIA kit. The fractions near the HPLC retention time of synthetic ME showed immuno- and opioid receptoractivities. An additional unidentified ME-like immunoreactive peak, which also demonstrates receptoractivity, was found in a more hydrophobic (later-eluting) area of the gradient elution. Those data demonstrate the limited structure information and molecular specificity that can be provided by RIA (2). Furthermore, the two HPLC areas are still not proven to contain only one compound.

In other studies, FAB-MS/MS confirmed the presence of ME in the appropriate fractions from an HPLC-gradient from the calcified portion of human teeth (3), and demonstrated that ten times more ME-receptoractivity occurs in the calcified portion versus the soft pulp tissue of human teeth. FAB-MS demonstrated an (M+H)+ corresponding to dynorphin 1-8 extracted from human placenta (5).

HPLC, RIA, RRA, and the MS-determined molecular weight of a peptide - when those analytical methods are used either individually or in combination - provide insufficient information concerning the structure of a peptide; only amino acid sequence-determining information provides structure certainty. MS/MS provides the highest level of molecular specificity to ensure identification of peptides in biological tissues (2,3), and recent FAB-MS/MS results indicate femtomole (5) to attomole sensitivity (6). We are extending these studies to the analysis of beta-endorphin by the use of a trypsin-generated peptide fragment NAIIK (7), peptides in cornea tissue (8), and tuftsin in human plasma (9).

OLIGOPEPTIDE ANALYSIS BY FT-MS

Jeffrey Shabanowitz, Patrick R. Griffin, Nian Zhou Zhu,
John R Yates, III, and Donald F. Hunt
Department of Chemistry, University of Virginia,
Charlottesville, Virginia 22901

Molecular weight analysis of oligopeptides and small proteins in the mass range, 1-13 kDa, by liquid secondary ion mass spectrometry on a tandem quadrupole Fourier transform mass spectrometer (QFTMS) has been described in an earlier publication from this laboratory (1). Use of laser photodissociation on the above instrument to obtain the complete sequence of amino acids in small oligopeptides of unknown structure has also been reported (2,3). To obtain data of this type, peptide (10-50 pmol) in 0.5 ul of 5% acetic acid and 0.5 ul of 3:1 thioglycerol/glycerol is bombarded with 10 keV Cs^+ for 2-4 msec resulting in the peptide being sputtered into the gas phase as $(M+H)^+$ ions. These ions are then transferred through the fringing fields of a 7-T superconducting magnet via rf-only quadrupole rods, trapped in an elongated ion cyclotron resonance cell, and photodissociated with a 10 nsec pulse from an ArF excimer laser. The resulting trapped ions are excited by a rf pulse containing a range of frequencies that causes the ions to move coherently in orbits at cyclotron frequencies characteristic of their individual masses. Image currents produced by this motion are amplified, digitized, and Fourier transformed to generate a mass spectrum. Data from 50-200 such experiments on the same 10-50 pmol sample are acquired and summed in seconds to produce the desired mass spectrum. The total experiment time to produce the required data is seconds, and the total sample consumption time is less than a second. Examples of the kind of sensitivity and sequencing information obtainable by this technique are described below.

Molecular weight determination requires only 2-10 pmol of peptide for routine analysis up to 6000 amu as illustrated by the low resolution mass spectrum from 10 pmol of porcine insulin in Fig. 1. A detection limit of high femtomoles (loaded on the probe) is possible for most peptides below 2000 molecular weight as shown by the mass spectrum obtained on 100 fmol of substance P in Fig. 2.

Although use of laser photodissociation with the quadrupole Fourier transform mass spectrometer to obtain oligopeptide sequence information is successful, only 30% of the peptides give complete sequence analysis. However, some sequence information is always discernable and only 10-50 pmol of peptide is necessary. As illustrated in Fig. 3 and Fig. 4 the majority of the sequence can be read directly from the spectrum, which only takes seconds to acquire. The oligopeptide shown in Fig 3. resulted from an acid hydrolysis reaction on a larger fragment generated by an endopeptidase Glu-C digest of the major isoform of a small calcium binding protein. The majority of Y-type ions can be read directly from the spectrum obtained on 50 pmol of sample derived from a 200 pmol endopeptidase Asp-N digest of rabbit sex steroid binding protein that is being sequenced in our laboratory.

The final example, shown in Fig. 5, is the nearly complete sequence obtained from the methyl ester of 10 pmol of a tryptic fragment derived from a total of just 40 pmol of apolipoprotein A-1. The protein was isolated using 2D-gel electrophoresis from cerebral spinal fluid, which contains thousands of proteins at the 0.02-10 pmol level. After separation the apolipoprotein A-1 spot from several gels were electroblotted onto nitrocellulose, eluted, digested with trypsin, HPLC'd, and screened using the QFTMS. The sequence of apolipoprotein A-1 is already known but was chosen to check feasibility of the methodolgy. An aliquot of the digest was used to screen for molecular weight of the predicted tryptic fragments. 12 out of 37 residues were readily identifiable, accounting for over 50% of the molecular weight of the protein. The sequence derived from the oligopeptide fragment shown in Fig. 5 yielded a series of amino acids which would be excellent candidates for manufacturing a probe for DNA cloning experiments.

Even though the complete unambiguous sequence is not always attainable, a wealth of sequence information is always obtained using the QFTMS.

Progress in the Mass Spectrometric Analysis of Peptides and Proteins at the Picomole Level

Bradford W. Gibson, Zhonghua Yu, A.L. Burlingame and William Aberth

Department of Pharmaceutical Chemistry, University of California, San Francisco, CA., 94143

The analysis of peptides and proteins by mass spectrometry has undergone major improvements since the introduction of liquid secondary ion mass spectrometry (LSIMS). The application of LSIMS (or FABMS) to the structure determination of proteins has been used to sequence proteins directly and to verify the correctness of DNA-deduced protein sequences [1]. The success of these efforts were largely dependent on the ability to determine the molecular weights of peptides in complex mixtures; a procedure often referred to as 'peptide-mapping'. Recently, we have attempted to improve upon the sensitivity of mass spectrometric 'peptide-mapping' for the analysis of proteins and bio-active peptides. Several areas in the current protocols for peptide analysis has been investigated with emphasis on improving sample preparation, ionization efficiency and ion detection systems. In these studies, considerable use has been made of a prototype Wien mass spectrometer with a channel electron multiplier array (CEMA) [2].

One of the major advantages of the Wien instrument is its ability to expand (zoom-out) and contract (zoom-in) the observed mass range. The mass range that is focused on the detector is dependent on the E and B fields. At maximum B, the E field determines the masses that will pass through and strike the detector, giving the smallest mass range at the highest resolution possible. In this mode, several high mass peptides and small proteins were analyzed at the sub-nanomole level, including EGF [3], tryptic peptides isolated from FABP [4] and a rat trypsinogen mutant [5]. However, by lowering the magnetic field, a larger mass range can be simultaneously focused on the detector. This allows one to first zoom-out for simultaneous detection over a very large mass range (e.g. m/z 500-3,000) and then zoom-in on a smaller mass range of particular interest

In order to apply the 'zoom-in/zoom-out' approach, we digested 100 pmoles of rat heart FABP with trypsin and isolated 16 fractions by microbore HPLC. Under these conditions, each peptide fraction had a elution volume of approx. 50 µL. In the first experiment, a 2 pmole equivalent (1µL) was directly analyzed over a mass range of m/z 650-1,700 (Fig. 1). For these experiments, the primary Cs^+ current was reduced 100 fold (10^{-9}A) such that the CEMA detector would not be overloaded by a excessive count rate. However, even with this small Cs^+ flux, a spectrum was obtained which contained a significant ion cluster centered at m/z ≈1030. Now, by adjusting B to its maximum and selecting a value for E to pass this ion cluster through, a zoom-in scan can now be obtained showing a resolved, more abundant molecular ion (Fig. 2). Thus, in screening a series of peptides of unknown mass, a 'zoom-out/zoom-in' strategy is an extremely effective approach. As previously stated, the zoom-out scans often required that the Cs^+ beam be operated at a very small flux. While this had the effect of reducing the overall sensitivity, it had the advantage of conserving sample since little sample is consumed under these conditions. Thus, by using an initial large mass range accumulation to detect the presence of peptide ions with a weak Cs^+ beam, the remaining sample still on the probe tip can be used more efficiently in the zoom-in scan.

The sensitivity of combined microbore-HPLC and Wien MS 'zoom-in' analysis was evaluated by analyzing a several 100 pmole peptide fractions. Small aliquots (10%, 1% and 0.1%) were directly analyzed on the Wien MS and MH^+ ions were clearly defined at the 1 and 10 pmole levels, but were generally weak in the 0.1 pmole spectra. A comparison was also made between directly applying a 1 pmole aliquot to the probe and loading a 1 pmole aliquot of a peptide sample tube that was first dried and then re-dissolved. This drying procedure reduced the MH^+ abundances between 3-10 fold for most peptides. Clearly, it is essential that the smallest possible volume be obtained in the last chromatographic step so drying and concentrating steps can be avoided.

Recently, a 1 inch diode array detector with superior resolution and counting efficiency to the CEMA has been constructed and equipped on a double focusing Kratos MS 50 RF mass spectrometer. In this configuration, it has been shown to increase ion detection efficiency by at least a factor 50 or more [6]. Our own experience using this instrument has allowed us to successfully analyze a series of high mass protein fragments from cytochrome b_5 (m/z 10,000) using 100-300 pmoles of sample. To fully take advantage of this ion detection system, a tandem four sector mass spectrometer has been constructed which has this diode array detection system for MS-II. In order to accumulate an entire daughter ion scan, the mass range is covered in sequential steps of 4% of the mass range under computer control. In this configuration, we have obtained mass spectra of peptides in the 10-100 pmole range with excellent signal to noise characteristics.

THE McLAFFERTY REARRANGEMENT IN THE UNIMOLECULAR DISSOCIATION OF FORMATE ESTERS

Qingmei Zha, R. N. Hayes, M. L. Gross and G. G. Meisels
Department of Chemistry University of Nebraska-Lincoln Lincoln NE 68588
T. Nishimura
Control Spectroscopy Development The Upjohn Co. Kalamazoo MI 49001

The unimolecular dissociation of propyl formate ion was studied using both photoelectron photoion coincidence (TPEPICO) and tandem (MS/MS) mass spectrometry. The major fragment ions observed in the breakdown graph (Fig. 1) are $C_3H_7OH^+$ (m/z 60), $HC(OH)_2^+$ (m/z 47), $C_3H_6^{+\cdot}$ (m/z 42), $C_3H_5^+$ (m/z 41) and CH_2OH^+ (m/z 31). The main feature of the dissociation of propyl formate that differs from the dissociation of methyl formate[1] and ethyl formate[2] is that the appearance potentials of the three fragment ions of m/z 60, m/z 47 and m/z 42 are identical to the ionization energy of the propyl formate molecule. This means that the dissociation of the propyl formate ion occurs nearly simultaneously with ionization, and that the molecular ion dissociates without the need to acquire significant internal energy.

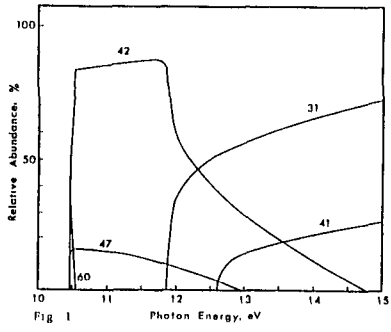

Fig 1

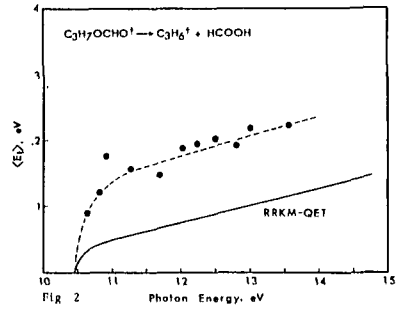

Fig 2

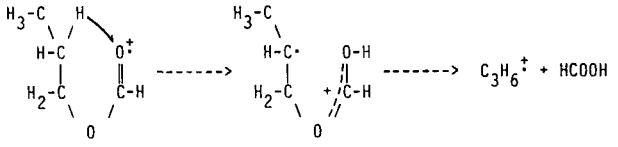
The average kinetic energy release (KER) for the formation of $C_3H_6^{+\cdot}$ derived from the TPEPICO experiment is compared with the calculated value based on statistical theory (Fig. 2). RRKM-QET predicts that about 4 % of the available excess internal energy should be converted to translational energy. The experimental data indicate a conversion that is approximately 0.1 eV higher than that predicted by the RRKM-QET calculation, in reasonable agreement with statistical theory.

$C_3H_6^{+\cdot}$ (m/z 42) has the highest relative abundance in the breakdown graph. A plausible mechanism for the formation of $C_3H_6^{+\cdot}$ is the McLafferty rearrangement.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA



The observed kinetic energy release for the formation of $C_3H_6^{+\cdot}$ suggests a reverse activation energy of about 0.1 eV. The concurrent formations of parent ion and $C_3H_6^{+\cdot}$ at threshold suggest that the molecular ion rearranges to an intermediate isomeric structure prior to decomposition. Moreover, this would allow for the existence of a potential energy barrier between the molecular ion and fragment ion. The formation of this intermediate isomer, the distonic radical cation formed by a gamma-hydrogen transfer, is the first step of the stepwise McLafferty rearrangement.

This reaction mechanism is also observed for the formation of $C_2H_4^{+\cdot}$ (m/z 28) from ethyl formate ion[2]. The only fragment ion observed in the MIKE spectrum of butyl formate (Fig. 3) is $C_4H_8^{+\cdot}$ (m/z 56). These fragment ions correspond to $[R-H]^{+\cdot}$ (for HCOOR, where R is alkyl).

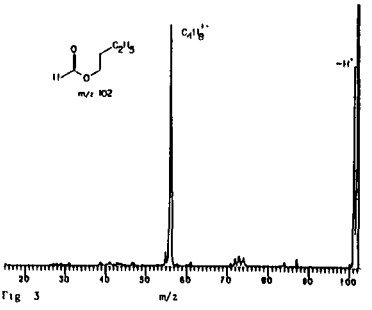


Fig 3

This dissociation behavior, which appears to be the predominant mode of formate ester decomposition at low internal energies differs from a model proposed previously[3]. The first band in the He I photoelectron spectra of formate esters corresponds to the excitation of the nonbonding electron from carbonyl oxygen, which favors the gamma-hydrogen transfer to carbonyl oxygen required by the McLafferty rearrangement. The $[R-H]^{+\cdot}$ ion is thus readily formed at low internal energies.

THE INVOLVEMENT OF RING HYDROGENS IN THE REACTION $C_6H_5NH_2^{+\cdot} \longrightarrow C_6H_5^{+\cdot} + HNC$

Jeffrey A. Zimmerman and Rebecca M. O'Malley
University of South Florida, Tampa, Florida 33620.

The metastable decomposition reaction of the aniline radical cation $C_6H_5NH_2^{+\cdot} \longrightarrow C_6H_5^{+\cdot} + HNC$ has been well studied by single and multiphoton ionization (MPI) and also by electron impact. Burgers et al. have confimed experimentally that the identity of the neutral produced in the reaction is HNC and not HCN (1). More recently the cyclopentadienyl structure of the ionic product has also been confirmed (2). In this paper we present electron impact and 266 nm MPI data obtained using an aniline/aniline 2,3,4,5,6-d_6 mixture which indicate clearly that the reaction has two components. The major component involves the loss of a hydrogen atom originally attached to the nitrogen atom in the aniline molecule, whereas the minor component involves the loss of a hydrogen atom originally attached to the ring.

The data shown here were obtained using a laser/time-of-flight mass spectrometer. Ion acceleration is achieved with a system of three grids. The first of these, the ion draw-out grid, initiates ion acceleration and is pulsed to a voltage of -200 V at a known and variable time after the laser light crosses the source. This delay time (time-lag) can be set at 0.1 μs intervals in the range 0-5.0 μs and can be varied in order to vary the allowed reaction time. All data shown were obtained using an approximately 1:1 aniline/aniline 2,3,4,5,6-d_6 mixture.

Electron Impact 70 eV and 20 eV electron impact spectra are shown for comparison purposes. The 20 eV spectrum shows clearly that in the aniline-d_5 system two reactions are occurring

$$C_6D_5NH_2^{+\cdot}\ (m/z = 98) \longrightarrow C_5D_5H^{+\cdot}\ (m/z = 71) + HNC$$

$$C_6D_5NH_2^{+\cdot}\ (m/z = 98) \longrightarrow C_5D_4H_2^{+\cdot}\ (m/z = 70) + DNC$$

Metastable $C_5(H,D)_6^{+\cdot}$ Formation: MPI at 266 nm. It is known from our previous studies that using a low intensity 266 nm laser beam it is possible to excite a large fraction of the neutral molecules with three photons such that the molecular ion is in the energy range for metastable decomposition to occur. The 266 nm unfocussed spectrum shown indicates that the two reactions identified under electron impact were again observed.

Measurement of Relative Rate Constants for the Two Aniline-d_5 Reactions. MPI spectra of the same aniline/aniline-d_5 mixture were recorded as a function of reaction time using an unfocussed, low intensity (0.25 mJ) 266 nm laser beam. Peak heights for m/z = 66 from aniline and m/z = 70 and 71 are plotted versus time-lag. Assuming that ion loss effects are negligible and that ion focussing effects are similar for these similar mass ions relative rate constants for the reactions were obtained from a first order plot of $-\ln(1-B/B_\infty)$ versus time. (B is the product ion intensity). The rate constant for the production of $C_5H_6^{+\cdot}$ (from $C_6H_5NH_2^{+\cdot}$) is approximately equal to that for the production of $C_5D_5H^{+\cdot}$ (from $C_6D_5NH_2^{+\cdot}$). However the rate constant for the production of $C_5D_4H_2^{+\cdot}$ (from $C_6D_5NH_2^{+\cdot}$) is approximately 0.75 times that for the production of $C_6D_5H^{+\cdot}$ (from $C_6D_5NH_2^{+\cdot}$). It appears that in the deuterated aniline two different reactions are occurring, one of which involves the breaking of a carbon-deuterium bond.

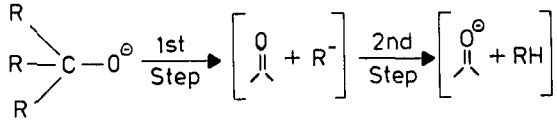
The application of butyl nitrite CI and linked scans to study the deprotonation of alcohols.

Ibrahim, S, Wilson, J.M. and Moore, C.
Kratos Analytical, Barton Dock Road, Urmston, Manchester M31 2LD, UK.

This study looked at the fragmentation of alkoxide anions eg



In particular, at the relative energetics of the two steps of the process. Data are available in the literature for the tert-Butoxide Anion[1].

The alkoxide anion was prepared by hydrogen abstraction from tertiary alcohols using butyl nitrite as the reagent gas in the chemical ionization source of a mass spectrometer.

i.e.

$$BuONO + e^- \quad BuO^- + NO \qquad (1)$$

$$BuO \quad + R_3COH \quad R_3CO \quad + BuOH \qquad (2)$$

The butyl nitrite was introduced into the CONCEPT IS mass spectrometer via a length of silica tubing which sampled the vapour in a vial half filled with liquid butyl nitrite[2]

First consider fragmentation of 1,3 dideuteroalkoxide (Scheme 1), assuming that the first step is reversible, cleavage of the bonds α to the oxygen gives 2 identical products. These two ion-dipole complexes lead to one of two products. The ratio of the two product ion abundances are a direct measure of the primary kinetic isotope effect.

i.e.
$$\frac{I_{196}}{I_{195}} = \frac{k_H}{k_D} = \underline{2{\cdot}4}$$

The ratio was obtained by a B/E linked scan from the $(M-1)^-$ ion (Figure 1). Looking now at the 1,1 dideuteroalkoxide (Scheme 2), α-cleavage gives two different ion-dipole complexes. The relative rates of decomposition of these two complexes is / which was determined in the previous experiment.

For the 1,1 dideuteroalkoxide therefore,

$$\frac{I_{196}}{I_{195}} = \frac{k_H}{k_D} \cdot \frac{K_{\alpha D_2}}{K_{\alpha H_2}} = 0{\cdot}7$$

From which the magnitude of the secondary isotope effect is,

$$\frac{K_{\alpha H_2}}{K_{\alpha D_2}} = \underline{1{\cdot}7}$$

These data show that,

(1) Butyl nitrite CI is a good method for obtaining alkoxide ions in good yield.

(2) Using linked scans ion labelled materials to selectively follow the decomposition of the alkoxide ions we have obtained,

(a) A direct measurement of a primary kinetic isotope effect of 2.4.

(b) An indirect measurement of a secondary isotope effect of 1.7.

(3) It follows from (a) and (b) that our assumption of reversibility in the 1st step is valid and that the 2nd step is rate determining.

The effect of strong anharmonic potential on unimolecular dissociation dynamics: The energy selected n-butanol and i-butanol ions

Jian-dong Shao, Tomas Baer, and David K. Lewis
Chemistry Department, University of North Carolina, Chapel Hill, NC 27514

Photoionization and threshold photoelectron photoion coincidence (TPEPICO) methods[1] were used in this study.

The PIE spectra show that the only dissociation channel of the n-butanol ion below 11.2 eV is the loss of H_2O. The activation energy for the H_2O loss channel is 0.19 eV. According to statistical theory fast dissociation rates would be expected. However, in Fig.1 a number of fragment ion time of flight (TOF) distributions near the dissociation limit show slow dissociation feature. Furthermore, the asymmetric TOF distributions cannot be fitted with a single exponential decay. A two component decay, $P(t) = \exp(-k_+t) + \exp(-k_-t)$ (1), was used in the data analysis and results are listed in Table I.

Four major fragmentation paths can be seen from the PIE spectra of i-butanol. The corresponding reactions are, in order of increasing threshold energy:

$$(CH_3)_2CHCH_2OH^+ \rightarrow \begin{cases} C_4H_8^+ + H_2O \\ CH_3OH_2^+ + C_3H_5 \\ C_3H_6^+ + H_3COH \\ C_3H_7^+ + H_2COH \end{cases}$$

The first two reaction channels involve slow dissociations even though the activation energies are only 0.31 and 0.41 eV respectively. Several of their TOF distributions are shown in Fig.2. The H_2O loss channel can be well represented by a single exponential decay. On the other hand, the loss of C_3H_5 proceeds via a non-exponential decay. Also, the data were fitted with Eq.(1). The results are listed in Table II.

The loss of H_2O in both n-butanol and i-butanol ions suggests the formation of $C_4H_8^+\cdots OH_2$ complex before the dissociation. According to the thermochemical data and the observation of slow dissociation rates, the product ion most likely has the structure of methylcyclopropane. The ground state of a similar ion-dipole complex, $c\text{-}C_3H_6^+\cdots OH_2$, was found[2] to be between 0.4 and 0.6 eV more stable than the dissociation products. With these assumptions, the potential energy surfaces can be constructed as shown in Fig.3 and 4. The dissociation limit 2-butene ion-water complex is much lower than the activation energy barrier of n-butanol ion. Therefore, statistically, the k_4 is fast and shown as the fast component in the TOF spectra. The both ions dissociate through the methylcyclopropane ion-water complex on much like potential energy surfaces. According to the TOF spectra of i-butanol ion, the methylcyclopropane ion-water complex can be counted for the slow component shown as the peak tails. The slow component for the C_3H_5 loss in the i-butanol ion dissociation can be understood with the double well model[3].

Nevertheless, the conventional RRKM calculation predicts much faster dissociation rates for the methylcyclopropane ion-water complex. The minimum calculated rate is 10^8 sec^{-1} for a very tight activated complex and 10^9 sec^{-1} for a more reasonably loose complex. These rates are two to three orders of magnitude greater than is experimentally observed. The discrepancy may be caused by the assumption of harmonic oscillators in calculating densities of states. However, simple first order corrections to the harmonic potential, such as the van der Waals potential, are not sufficient to resolve this problem because the ion-dipole potential is far more anharmonic than a van der Waals potential. Further theoretical work is required to understand this problem more completely.

Stereochemical Control of CID Reactions of Peracetylated Hexoses and Amino-Hexoses.

J.L.C.Wright and R.Guevremont,
National Research Council of Canada, 1411 Oxford St., Halifax,
Nova Scotia, Canada B3H 3Z1.

Sequential mass spectrometry (MS/MS and MS/MS/MS) has been shown to be useful for the identification of hexose and amino-hexose stereoisomers (1,2) in glycoconjugates. The fast atom bombardment (FAB) spectrum of a simple conjugate includes an abundant, even-electron ion (m/z 331 for hexoses and 330 for amino-hexoses) formed by the loss of the aglycone from the anomeric position (C-1) of the terminal sugar group. The relative abundances of fragment ions formed in collision induced dissociation (CID) reactions of these ions appears to be a function of the stereochemistry of the ion. The mechanism of the CID reaction and the reason for this stereochemical specificity have been studied using sequential mass spectrometry and isotope labelling experiments on a hybrid mass spectrometer (VG Analytical ZAB-EQ, BEqQ geometry). Modifications of this system to permit unlinked E-Q scans have been described (3).

The daughter spectra of m/z 331 of the hexoses are deceptively simple. This spectrum contains abundant fragments at m/z 271, 211, 169 and 109, which would suggest a mechanism of sequential losses of two acetic acid molecules, a ketene (CH_2CO), and a final acetic acid moiety. Anomalies in this pattern have been noted (4,5) and mechanisms proposed to account for a single, concerted loss of acetic acid and ketene (without a long-lived intermediate ion).

MS/MS/MS experiments have shown that the CID reaction of acetylated hexoses is characterized by two major competing parallel pathways. The grand-daughters of m/z 271 (m/z 331 to m/z 271 to grand-daughters) include ions with m/z 211, 169, and 109, whereas the grand-daughters of m/z 211 include m/z 169 and 127 but with low abundance of m/z 109. This indicates that separate pathways lead from the parent m/z 331 to each of m/z 271 and m/z 211. If these ions were part of a single, common sequential mechanism, the grand-daughters of m/z 211 would necessarily include all those of m/z 271, including abundant m/z 109.

MS/MS and MS/MS/MS experiments with per($^2H_3$)acetylated hexoses further supported the observation of two parallel CID reaction pathways. The CID daughter ion spectrum of these compounds included a pair of ions at m/z 172 and m/z 173, shown in Fig.1. The grand-daughter spectrum of m/z 280 (d_9 of m/z 271) yielded only the fragment of m/z 172 and the grand-daughter spectrum of m/z 217 (d_6 of m/z 211) yielded only m/z 173. Possible reactions(4,5) are shown in Fig.2. Since the grand-daughters of m/z 280 (d_9) included low abundance of m/z 173, the ion m/z 280 (d_9) cannot be a precursor of m/z 217 (d_6). The fragments m/z 280 (d_9) and 217 (d_6) are therefore formed independently from the parent ion. This pathway is illustrated in Fig.3.

Isotope label experiments with ($^2H_3$)acetates at C-4, at C-6, and at both C-4 and C-6 simultaneously have suggested further complexity of the CID reaction process. Fig.4 illustrates unimolecular decomposition of m/z 337 (d_6) in the 2nd field free region of a BEqQ geometry instrument, and the quadrupole resolved version of the same spectrum near m/z 169. The low-energy quadrupole spectrum (below 10eV collision energy) is the same as shown in Fig.4. There are no less than 4 different species which would have a m/z ratio of 169 (without deuterium labels). Similarly (not shown) m/z 211 appears as 3 distinct species.

The abundances of ions in the daughter spectra of m/z 331 of the hexoses will be a combined result of the relative importance of the two CID reaction pathways, and the stability and lifetimes of the various ions in each pathway. These parameters appear to vary for each stereoisomer, and are possibly controlled by the tertiary structures of the ions. For example, the single-step concerted reaction leading from m/z 271 to 169 (Fig.2,3) involves interaction between acetates at C-2 and C-4 of the hexoses. Molecular models show that, for the most favourable conformation

NRCC No 29011

of the hexose ring, these acetates are considerably closer together in galactose than glucose. The proximity of these acetates may facilitate the decomposition reaction, and explain the low yield of m/z 271 from galactose.

The above explanation fails for allose (which differs from glucose only at C-3). The lower abundance of m/z 172 shown in Fig.2 suggests decreased importance of the 331 to 271 to 169 to 109 pathway in the case of allose. The elimination of acetic acid from the allose C-3 position (m/z 331) may be restricted because the hydrogens at C-2 and C-4 are both trans relative to the acetate at C-3.

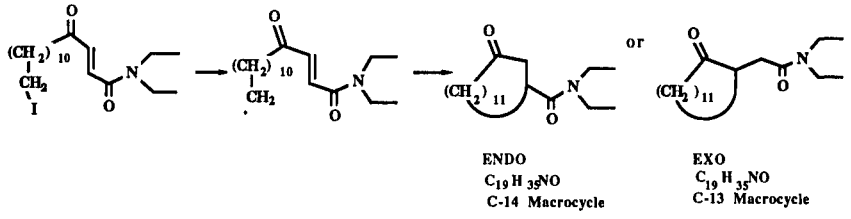
GC/MS Identification of Macrocycles;

George R. Dubay, Vincent Chang, Ned A. Porter; Dept. of Chemistry, Duke University, Durham, NC 27706; 919-684-3549

INTRODUCTION:

Macrocyclic rings are found in many natural products including muscone. A general synthetic approach was developed by Porter and co-workers using an intramolecular radical cyclization to form the macrocyclic ring (Figure 1). This scheme affords efficient preparation of the desired products. The reaction does give a mixture containing several cyclic and acyclic products. Characterization of this mixture frequently required HPLC separation followed by NMR analysis. In general, this is slow and time consuming. NMR analysis is complex for muscone and analogous macrocycles because they are such simple compounds. At times the methylene portion of the NMR at high resolution is quite complicated and unambiguous structure assignment is not possible.

Figure 1. Formation of Macrocyclic Rings



In these radical cyclizations macrocycles of two different sizes are formed (Figure 1). They are referred to as endo, all methylenes inside the macrocycle, and exo, one methylene between the ring and the amide carbonyl. In both cases, a methylene is adjacent to a carbonyl and the carbon bearing the amide side chain. Thus, the methylenes are observed at similar positions in the NMR. Indeed, for some products NMR is not able to be used for an unambiguous structure assignment. As a result, some other technique was required for structure assignment.

In this paper we report that capillary GC/MS using EI and PCI is capable of distinguishing the products formed during reaction. Separation and quantitation of the major products was achieved using the capillary GC. Mass spectrometry was then used to identify the macrocyclic and acyclic compounds formed. This provided a very rapid and specific method of analysis to test the efficiency of the cyclization reaction.

RESULTS AND DISCUSSION:

The mass spectra of the endo and exo cyclization products showed characteristic fragment ions in the EI which allow us to differentiate between the two ring sizes formed. In Figure 1 it can be seen that the endo product has no methylene adjacent to the ring on the amide side chain. The exo product has a methylene between the amide and the macrocyclic ketone. Most of the spectra for these two compounds are very similar as expected. Yet, a distinctive difference is found in the relative abundance of two ions. The exo compound fragments with a McLafferty type rearrangement giving an abundant ion at m/z = 115. An ion was present in the spectra of the endo product at m/z = 115, but the abundance of this ion was 8 times smaller. By contrast, the endo product has its base peak at m/z = 128; this ion is explained by a similar McLafferty type rearrangement and cleavage of two C-C bonds to give an even electron ion as shown (Figure 2). This reaction is relatively rapid due to the stability of the products formed. In contrast, the fragment ion at m/z = 128 for the exo product is 5 times less abundant. This is consistent with the fact that formation of this ion requires more complex fragmentation chemistry for the exo structure.

The PCI-MS spectra confirm these observations. Protonation of the amide to give the MH^+ ion is the dominate reaction for both in PCI and few fragment ions are present. In the spectra of the exo product an ion is observed at m/z = 116. This is a simple cleavage which follows the same hydrogen migration pathway observed in the EI-MS. In the PCI-MS spectra of the endo compound this ion is not observed. There is not enough energy available to produce the complex fragmentation required to form this ion in the latter case. This strongly supports the assignment made from the EI spectra. Thus, the use of routine EI- and PCI-MS spectra allows identification of the products of reaction.

Capillary GC was shown to provide separation and quantitation of the reaction mixture. This is extremely useful because it eliminated the time consuming use of HPLC and NMR. In addition, NMR failed to characterize the amides studied here. So, GC/MS analysis is the method of choice.

This work was extended to another case in which a chiral amide was used to control the stereochemistry of the products. Two chiral centers were present near the reactive site. The endo and exo products in this case are mixtures of diastereomers. Capillary GC was able to separate the four diasteromers with baseline separation. The EI-MS spectra were able to distinguish the endo and exo conformers formed and show that a cyclization was stereoselective for the endo products. Here too, NMR was unable to differentiate the products and mass spectrometry was the method of choice.

In conclusion, we have shown the power of capillary GC/MS to solve problems that were not solved by NMR and HPLC. It is our goal to understand the fragmentation of synthetic products to determine where mass spectrometry can be employed to aid in the solution of structural problems.

ELECTRON IONIZATION-INDUCED FRAGMENTATION OF α,β-UNSATURATED ESTERS: A STUDY ON THE *META* AND *PARA* DERIVATIVES OF ETHYL α-FLUOROCINNAMATE*

C. Dass[1], C. N. Robinson[2], J. L. Pflug[3], and D. M. Desiderio[1,4]

Departments of Neurology[1] and Biochemistry[4], University of Tennessee, Memphis, TN 38163; Department of Chemistry[2], Memphis State University, Memphis, TN 38152; Frank J. Seiler Research Laboratory[3], United States Air Force Academy, Colorado Springs, CO 80840.

The present study was undertaken to understand mass spectral fragmentation pathways of the gas-phase ions generated by electron ionization (EI) of 21 *meta* and *para* benzene ring substituted ethyl α-fluorocinnamates of the general formula RC_6H_4-CH=CF-$COOC_2H_5$, where R=H, m- and p-CH_3, p-NMe_2, m- and p-OCH_3, p-C_6H_5, m- and p-OC_6H_5, m- and p-CN, m- and p-NO_2, m- and p-CF_3, m- and p-F, m- and p-Cl, and m- and p-Br. The specific goal was to understand the influence on fragmentation of the fluorine atom attached to the α-carbon atom and of the various aromatic ring substituents.

The research was accomplished by acquiring 70 eV low-resolution EI mass spectra (on HP 5985 GC/MS). The elemental compositions of the fragment ions were confirmed by the accurate mass data. The B/E linked-field scan coupled with CAD was used to corroborate the assigned fragmentation pathways. The genesis of the fragment ions was also confirmed by acquiring the B/E and B^2/E linked-field scans (Table 1) of a few selected fragment ions formed from p-methyl derivative. The accurate mass and linked-field scans data were obtained on VG 70E-HF.

All the compounds yielded $M^{+\cdot}$ as the base peak except the p-NMe_2 and m-CF_3 derivatives and followed a common fragmentation pattern. Direct cleavage of the bonds *a*, *b*, and *c* resulted in the elimination of $\cdot OC_2H_5$, $\cdot COOC_2H_5$, and $\cdot C_2H_5$ radicals, respectively (Scheme 1) to yield ions **a**, **b** and **c**. The cleavage of bonds *a* and *c* also generated ions of m/z 45 and 29, respectively. Alternative routes leading to ion **b** were the losses of CO and COOH from ions **a** (Scheme 1) and **d** (Scheme 2), respectively. Ion **a** also fragmented to **a'** by HF loss. Direct expulsion of HF from the $M^{+\cdot}$ of these esters was energetically unfavorable, but occurred frequently from the product ions that were formed in the primary fragmentation steps of the $M^{+\cdot}$. For example, ion **b'** was formed from the styryl ion (**b**) by the loss of a molecule of HF.

These compounds also participated in a variety of structural rearrangements. For example, the McLafferty rearrangement (Scheme 2) yielded ion **d**, which decomposed further to structure **d'** by expulsion of HF. Another interesting H rearrangement involved the ethyl group and the C=C of the fluoroacrylate side chain. A concomitant loss of the $COOCH_2CH_2$ moiety, or equivalently the simultaneous expulsion of CO_2 and ethylene from the resulting intermediate structure **e** yielded ion **e'**. The driving force for this reaction was the resulting stable styrene ion (**e'**). Subsequent elimination of H_2 or HF from **e'** resulted in the generation of phenylacetylene ions $\mathbf{e'_1}$ or $\mathbf{e'_2}$, respectively. Intramolecular acylation of the aromatic ring (Scheme 3) in the acylium ion **a** and concomitant loss of the *ortho* ·H radical was also observed to yield an ion **f**. Alternatively, a similar cyclization may also occur in **d** with the concomitant loss of H_2O.

The rearrangement involving bond formation between the fluoroacrylate side chain and the R group with subsequent elimination of benzyne yielded ion **g** of general formula R-CH=CF-$CO_2C_2H_5$. Migration of F atom was also observed in the $M^{+\cdot}$ (1,2-F shift with the subsequent loss of $C_4H_5O_2$ moiety) and in **b**, although these reactions were not very prominent.

In conclusion, (a) EI of the α-fluoro cinnamates leads to extensive fragmentation, (b) the substtution of α-fluorine atom stabilizes the cinnamates (c) an electron-donating group stabilizes the $M^{+\cdot}$ of the fluoroesters compared to the electron-withdrawing groups; the effect was more pronounced in the *meta* isomers.

* The research will appear in *Org. Mass Spectrom.* **23**, (1988)- in press.

MECHANISM OF FRAGMENTATION OF DIQUATERNARY AMMONIUM SALTS BY FAST ATOM BOMBARDMENT;

M. T. Cheng; ICI Americas Inc., Richmond, CA

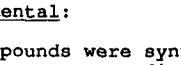
Multiple charged ions are often observed in mass spectra obtained with desorption ionization methods. By observing doubly charged ions one essentially doubles the mass range of a sector type mass spectrometer. Cooks in 1980 (1) reported the study of diquaternary ammonium salts by secondary ion mass spectrometry, and reported three major processes: dication emission, electron capture, and charge separation. This report investigates the requirements for dication emission, and the mechanism of charge separation in saturated systems by FAB mass spectrometry.

Experimental:

All compounds were synthesized by alkyliodide alkylation in acetonitrile; the structures were confirmed by NMR and mass spectrometry. FAB mass spectra were obtained on a VG7070E-HF mass spectrometer with an Ion Tech gun, and the samples were dissolved in glycerol.

Results and Discussion:

The FAB mass spectra of compounds I, II, and III show the expected loss of methyl as the highest mass peak due to charge



$Me_3\overset{+}{N}(CH_2)_n\overset{+}{N}Me_3$

I n = 2

II n = 6

III n = 12

separation mechanism. No singly charged molecular cation is observed because electron capture cross section is virtually zero for these saturated compounds. For compound III where the charge sites are separated by 15.9A a doubly charged molecular ion is observed. This is confirmed by the observation of the ^{13}C isotope peak one-half mass unit above the dication peak at m/z 143.5. In order to observe dication emission, the two cationic sites must Be separated by at least 9.5A, therefore for compound II where the charge sites are separated by 8.7A, no dication is observed. Unfortunately I presently do not have data for compounds where n = 7, 8, 9, 10, or 11 to confirm the 9.5A separation requirement. Nevertheless, one should begin to observe doubly charged ions at n = 8, where the charge separation is approximately 10A.

To investigate the charge separation mechanism, compounds IV, V, VI were synthesized.

$Me_2\overset{+}{R}N(CH_2)_6\overset{+}{N}RMe_2$

IV R = ethyl

V R = *n*-propyl

VI R = *i*-propyl

The FAB mass spectra for these compounds show the loss of methyl cation due to charge separation as the highest mass peak. For Compound IV, the peak at m/z 215 is due to the loss of methyl cation, and the m/z 201 peak is due to the loss of ethyl cation (Figure 1). The ratio of the loss of ethyl to the loss of methyl is approximately 0.8, if the processes are completely random, the ratio is 0.5, therefore, there is a definite preference towards the loss of ethyl cation. For compound V, the ratio of the loss of *n*-propyl to the loss of methyl is approximately 0.8 (Figure 2), similar to compound IV, and for statistical losses, the ratio is 0.5. These results are not unexpected, both ethyl and *n*-propyl cations are primary cations with approximately the same stability (2) and are more stable than methyl cation. Therefore, the loss of ethyl and *n*-propyl are favored over the loss of methyl cation. This result is

confirmed by the mass spectrum of compound VI (Figure 3), where a secondary alkyl (*i*-propyl) replaces the primary alkyl group. The ratio of the loss of *i*-propyl cation to the loss of methyl cation is approximately 1.2, where as for a random process the ratio is 0.5. This is so because the secondary *i*-propyl cation is much more stable then the primary *n*-propyl cation (Table 1).

BORATE IONS IN THE GAS PHASE. FAST-ATOM BOMBARDMENT OF CONDENSED-PHASE BORATES

Robert J. Doyle, Jr.
Chemistry Division
Naval Research Laboratory
Washington, DC 20375-5000

The intractable properties of crystalline and vitreous, condensed-phase, boron-oxygen compounds have always hindered the generation and analysis of gas-phase, boron-oxygen species. Recently, structures of gas-phase boron oxide cations, generated by fast-atom bombardment (FAB) of boron trioxide (B_2O_3), were proposed on the basis of collision-induced dissociation (CID).[1] The experiments employed a high-temperature FAB sample holder which eliminated problems with hygroscopicity and provided a molten sample for fast-atom bombardment by xenon atoms.[2] It was concluded that boron oxide cations typically contain integral BO_3 triangles and terminal -B=O units, in which case boron is exclusively 3- or 2- coordinated with oxygen.

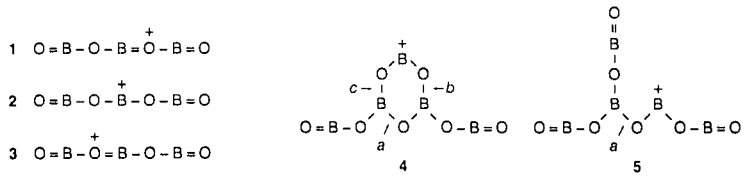

Figure 1. Proposed structures for $B_3O_4^+$ and $B_5O_7^+$.

Figure 1 shows proposed structures for $B_3O_4^+$ and $B_5O_7^+$. Structures 1-3 represent the three equivalent forms of $B_3O_4^+$ in which electron sharing and resonance serve to enhance the stability of this species. Structures 4 and 5 show the possible cyclic and acyclic isomeric forms of $B_5O_7^+$. Both proposed structures are reasonable in light of the collisional-activation spectrum of $B_5O_7^+$. Structures 4 and 5 illustrate a significant problem with the CID of boron oxides; it cannot be determined by CID techniques whether or not the boron oxide ions generated by FAB of B_2O_3 contain the partially aromatic boroxol ring that is found in condensed-phase B_2O_3.

The present study involves the determination of the structures of boron-oxygen anions (borates). Borates generated by the fast-atom bombardment of vitreous boron trioxide are found to contain integral BO_3 triangles and terminal -B=O units, in common with boron oxide ions. The most abundant species observed were BO^-, BO_2^-, $B_2O_4^{-\cdot}$, $B_3O_5^-$, and $B_5O_8^-$. The fast-atom bombardment of crystalline samples of $Li_2B_4O_7$,

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

$Na_2B_4O_7$, $Zn_3B_4O_9$, $Zn_2B_6O_{11}$, and $K_2B_{10}O_{16}$ also yielded BO^-, BO_2^-, and $B_3O_5^-$. Collision-induced dissociation and collision-induced charge inversion were used to examine $B_3O_5^-$ and $B_5O_8^-$ generated from all of the above mentioned samples. Two diagnostic charge-inversion reactions are:

$$(1)\quad B_3O_5^- \text{ ----> } B_2O_2^{+\cdot} + {}^{\cdot}BO_3 + 2e^-$$
$$(2)\quad B_5O_8^- \text{ ----> } B_3O_4^+ + B_2O_4 + 2e^-.$$

The significance of these reactions lies in the structures of the neutral products. The proposed structures of the ${}^{\cdot}BO_3$ molecule (stabilized by six equivalent forms) and the B_2O_4 molecule (stabilized by two equivalent forms) are shown in Figure 2. The direct loss of ${}^{\cdot}BO_3$ must occur from an acyclic parent anion containing a terminal BO_3 unit or a cyclic parent anion (Figure 2).

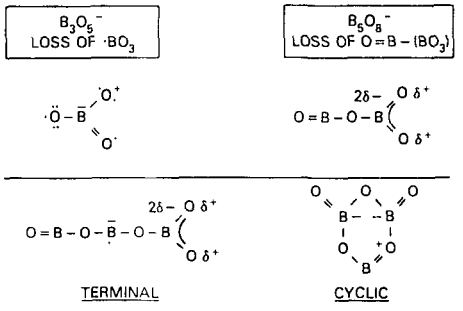

Figure 2. Proposed structures of ${}^{\cdot}BO_3$, B_2O_4 and $B_3O_5^-$.

The acyclic $B_3O_5^-$ anion, with a terminal BO_3 unit, does not exhibit canonical structures that allow for delocalization (and hence stabilization) of the negative charge. The cyclic $B_3O_5^-$ anion, however, exhibits several resonance forms that would provide delocalization (similar to that found in boroxol rings) and it is therefore suggested that the parent anion is cyclic. Similar arguments may be made for the $B_5O_8^-$ ion based upon the neutral loss of B_2O_4.

CHLOROFLUOROCARBONS IN THE ENVIRONMENT:

A REVIEW

Mario J. Molina
Jet Propulsion Laboratory
Pasadena, California 91109

It has been 14 years since the publication of the first paper on depletion of stratospheric ozone due to the release of chlorofluorocarbons (CFC's) to the atmosphere (1). Because of their unusual stability and low toxicity, CFC's were regarded as ideal industrial chemicals and are widely used in refrigeration, as solvents for cleaning electronic boards, for foam insulation, etc. Ironically, it is this chemical inertness that allow the CFC's to survive for long periods of time in the environment and to eventually diffuse above the ozone layer where they are broken apart by solar UV radiation. The decomposition products include chlorine atoms, which speed up the destruction of ozone through a catalytic cycle: each chlorine atom may destroy tens of thousands of ozone molecules before leaving the stratosphere, mostly in the form of hydrogen chloride, which is efficiently scavenged by rain.

Numerous laboratory studies, field measurements and computer modeling calculations have essentially confirmed the validity of the CFC's - ozone depletion theory. Both atomic chlorine and chlorine monoxide have been detected in the stratophere, demonstrating that the postulated catalytic chain reactions are actually occurring. Many other species have also been measured, e.g., hydrogen chloride (HCl), chlorine nitrate ($ClONO_2$), hydrogen fluoride (HF), hydroxyl radicals (OH), etc. Stratospheric ozone levels are predicted to decrease by several percent towards the end of the century, assuming that the emission of CFC's continues at current rates. This depletion is predicted to occur mostly in the upper stratosphere, where ozone is being produced in largest quantities. In the lower stratosphere, ozone in predicted to increase somewhat, partially compensating the losses higher up. Even if the total amount of ozone were to remain the same, a substantial redistribution could have a serious impact on the climate by changing the temperature profile of the atmosphere. One of the worrisome aspects of this CFC theory is the long time scale involved: the effect of a release of CFC's at any given time is only felt about a decade later, and it persists for a period of over a century. Levels of chlorine in the stratosphere are expected to continue increasing for many decades even if production and release of CFC's were to level off.

In response to public concern over the effects of CFC's on stratospheric ozone, the United States banned the use of CFC's as propellants in aerosol sprays in 1978; Canada, Sweden, Denmark and Norway subsequently imposed similar regulations. In September 1987, 24 nations - including the United States and nearly all the major industrial countries - signed an agreement to freeze the consumption of CFC's at 1986 levels and to halve the usage by 1999. This historic agreement, known as the "Montreal Protocol", must be ratified

by at least eleven countries before it becomes official in 1989.

It has been established that a statistically significant drop in ozone levels has already occurred, particularly in the winter months at high latitudes. Also, ozone depletion has already been detected in the upper stratosphere. Furthermore, the ozone levels over Antaractica dropped last October to the lowest ever observed anywhere in the atmosphere -- more than 50% total column ozone depletion, with more than 95% disappearing around 18 km altitude. The discovery of this mysterious "hole" was unexpected. A change in ozone concentration of this magnitude was not anticipated by atmospheric scientists, suggesting that the ozone layer is influenced by processes not previously recognized. Two sets of theories were competing to explain this phenomenon. The dynamical or meteorological theories consider the hole to be the result of ozone redistribution in the atmosphere. In contrast, proponents of a chemical origin assume man-made pollutants as the cause and they believe that ozone is actually being destroyed through some unusual chemical processes. Recent findings have shown conclusively that this "ozone hole" is due to the release of man-made CFC's. Laboratory measurements demonstrated how catalytically active chlorine can be released in the presence of ice particles, which exist over Antarctica as "polar stratospheric clouds". Ground-based and aircraft measurements have yielded large amounts of information supporting the chlorine-ozone destruction mechanism.

ATMOSPHERIC TRANSPORT OF PESTICIDES BY FOG

Majewski, M.S.[1], Glotfelty, D.W.[2] and Seiber, J.N.[1]

[1]Department of Environmental Toxicology, University of California, Davis, CA 95616

[2]Soil Nitrogen and Environmental Chemistry Laboratory, Agricultural Environmental Quality Institute, U.S. Department of Agriculture, Beltsville, MD 20705

We are examining the vapor-moisture-particulate distribution of atmospheric organic compounds in fog in several rural locations in California, and in residential districts in Maryland. Fog water was collected using a rotating screen type sampler, while the interstitial gases, aerosols and particulates were collected using a dichotomous impactor. Each fog water sample was filtered through a glass fiber (GF) filter before being extracted using a multi-residue extraction procedure. The extracts were fractionated into chemical classes of increasing polarity using HPLC techniques. Each sample was analyzed by GC using various element selective detectors.

The MD fogs had a greater particulate load than did the CA fogs which is most likely due to the manner in which the homes are heated (oil, coal and wood). All of the fog samples foamed when shook indicating the presence of surface-active materials contained in the fog droplets. The filtered samples were also pale yellow in color with a major portion of this color being removed in the dichloromethane extraction.

The pH of the MD fog ranged from 2.5 - 4.5 with the major ionic species being SO_4^{2-}. The pH of the CA fog ranged from 5-7 with the acidity being reported to be controlled by a balance between sources of SO_4^{2-} and NO_3^-, and agricultural sources of NH_3.

Various types of organic compounds were found including plasticizers, flame retardants, PAH's, and pesticides. The CA fog yielded a greater variety and higher concentrations of pesticides than did the MD fog. The organophosphorus (OP) pesticides including parathion, diazinon, chlorpyrifos, and methidathion, were found in the greatest abundance in CA which may be attributed to their use as dormant sprays during the winter months. The OP pesticide concentrations frequently exceeded 10 ppb in the fog which is 2-3 orders of magnitude greater than commonly reported for pesticides and other neutral organics in rain from other locations.

The measured pesticide distribution between fog water and the interstitial air strongly favored the water phase resulting in large aqueous phase enrichments (EF) (Table 1). Table 1 represents averaged values of samples taken at three CA locations. EF is defined as the ratio of the pesticide concentration in fog water to that in air, divided by the Henry's law coefficient (H) of the pure compound. The enrichment in the fog droplets for those pesticides that are more volatile and/or less water soluble (DEF and pendimethalin) seem to be more pronounced.

The reason for this enrichment is unknown at this time. Temperature effects and sampling artifacts have been ruled out because of the similar EF values for each pesticide at the various CA sampling locations. One explanation may be the presence of surface active materials which would enhance the uptake of the pesticides into the droplets. The

acidity of the fog may also enhance the uptake of certain N-containing and even neutral compounds by altering the character of the surface active materials. These enrichment factor results imply that H is not a good quantitative estimate of the distribution of pesticides between fog droplets and the interstitial air.

The toxic oxygen analogs (OA) of a number of the OP's were also found in the fog water. Their source is uncertain. It is known that these OAs form in gas phase reactions between the parent compound and ozone. The OA's also occur in high concentrations in dry surface dust which, subsequently, may act as condensation nuclei for the fog droplets. Also, high oxidant levels are possible within the fog droplets, indicating that *in situ* conversion of the parent compound may occur. We found that high OA levels occur during clear, sunny days with lower levels during the following night time fog. These data suggest that the oxons are formed primarily during the day and are taken up into the fog after it forms. The lower OA concentrations under foggy conditions may result from slower formation at night, or from preferential scavenging of the oxons by fog and transport to the surface early during the fog event.

The dichotomous sampler filtered the interstitial fog air and trapped the suspended particulate matter. These particulates were also analyzed for their pesticide concentration, however, it is not clear whether these results accurately reflect the fraction of pesticide present on the dry, unactivated aerosol particles in the foggy air. It is possible that some adsorption from the vapor onto the trapped particulates, or conversely, desorption from the trapped particulates to the vapor may have occurred.

The concentration on the particulates ranged from 4-40% of the total pesticide distribution between the fog water, vapor, and particulates, depending on the compound and fog event. Conversely, only traces of pesticides were found on the particulates filtered out of the collected fog water. This implies that if the pesticides were originally present on the particulates, then almost complete desorption to the solution occurred by the time the samples were extracted. The extractions were done usually within 2-3 hours from the time of collection.

TABLE 1. Distribution and EF for selected pesticides in CA fog.

Pesticide	Concentration Fog water ($\mu g\ L^{-1}$)	Concentration Air ($\mu g\ L^{-1}$)	Air-to-Water Distribution ($ng\ m^{-3}$)	Enrichment Factor (EF) ($x10^{-6}$)
Parathion	23.2	4.0	0.24	310
Chlorpyrifos	2.6	6.2	2.5	190
Diazinon	16.8	3.9	0.24	310
DEF	0.52	0.08	0.15	2200

BACKGROUND ENVIRONMENTAL CONCENTRATIONS OF DIOXINS AND FURANS

Brian Eitzer and Ronald A. Hites, School of Public and Environmental Affairs and Department of Chemistry, Indiana University, Bloomington, Indiana 47405

Abstract. A method of analyzing ambient air for dioxins and furans in the femtogram per cubic meter range has been developed. The method is used to compare dioxin and furan concentrations in air collected at three locations with the concentrations found in rain and sediment. These comparisons suggest that atmospheric transport followed by particle deposition is a primary method of dispersing these compounds throughout the environment.

Introduction. The incineration of municipal waste leads to the production and emission to the atmosphere of polychlorinated dibenzo-p-dioxins (PCDD) and dibenzofurans (PCDF) (*1-10*). Once in the atmosphere, these compounds can travel long distances before being deposited into the environment; this is demonstrated by their presence in the sediment of a remote lake whose only input of these compounds could be from atmospheric sources (*11*). To understand these transport and depositional processes, it is necessary to examine these compounds in each of the various compartments so transformations which occur between the sources and sinks can be studied. Previous work has focused on either combustion sources (*1-10*) or sinks such as sediment (*11-13*), leaving the transport medium, the atmosphere, to be studied.

We have undertaken a study aimed at determining the concentration of these compounds in the ambient air of Bloomington, Indiana. Bloomington was chosen because it is the proposed location for an incinerator designed to burn a mixture of municipal waste and polychlorinated biphenyl (PCB) contaminated materials. Thus, this study will provide baseline atmospheric concentrations of these compounds which can be used later to evaluate the performance of the incinerator. In addition, we will be able to improve our understanding of the atmospheric transport and depositional processes.

Experimental. Air has been sampled at three sites in Bloomington. These sites include two sites which had the highest predicted particulate concentrations from the incinerator proposer's computer model and one site in the downtown area about which the local population is centered. All sampling sites are located on roofs of buildings which are 2-4 stories tall. Sets of samples have also been taken at two comparison locations. These are a much more rural site, Trout Lake, WI, and a more urban site, indianapolis, IN.

Air has been sample with a modified high-volume air sampler. Air is drawn through a glass fiber filter and then a polyurethane foam (PUF) plug. These materials are analyzed separately giving a determination of particulate bound (on the filter) and vapor phase (in the PUF plug) compounds. It is important to note that vapor phase compounds could absorb to the filter or particulate bound compounds can be "blown-off" the particulate matter or pass through on very small particles; thus, the two phases are operationally defined.

Rain is sampled with a one square meter wet only collector. The sampler is designed so that as rainwater is collected it is pumped through a glass fiber filter to create operationally defined particulate bound and dissolved phases.

The sample clean-up procedure is described more completely elsewhere (*14*) and consists of Soxhlet extraction followed by column chromatography. Prior to extraction, samples are spiked with two carbon-13 labeled isotopic compounds (OCDD and 1,2,3,7,8 PCDF) which are used as internal standards. A series of external standards are used to measure response factors for each level of chlorination as compared to the internal standard. These external standards are also used in conjunction with published retention indices for PCDD (*15*) and PCDF (*16*) to get isomer specific information for some of the congeners. Only congeners containing four or more chlorines are examined. After clean-up, the samples are analyzed by high resolution gas chromatographic low resolution mass spectrometry; the mass spectrometer is operated in the electron capture, negative ion mode with selective ion monitoring (SIM). It is important to note that this ionization mode gives a poor response for 2,3,7,8-TCDD.

Results. Previous work has shown that the chloro-homologue profile of dioxins and furans changes as one progresses from source to sink (*12-13*). The profile changes from one in which no chloro-homologue dominates to one in which OCDD is predominate. if it is assumed that the quantity of combustion sources at a close proximity are greatest for a large city (Indianapolis), second for a smaller city (Bloomington), and smallest for a rural community (Trout Lake), then a hypothetical transect of chloro-homologue profiles with distance from source can be created by examining the chloro-

significant portion of the atmospheric burden. Third, as the air is "transported" from the "source" region, it undergoes a transformation to a profile dominated by the OCDD. Fourth, as the air is "transported," the concentrations decrease by either degradational or dilution processes. It should be noted that the Indianapolis and Trout Lake concentrations are sets of samples taken over a two week average vs. the long term average for Bloomington.

Figure 2 compares the chloro-homologue profile in the Bloomington average air with Bloomington rain and average Great Lakes sediment. The fact that the chloro-homologue profile in the sediment closely resembles that for the particular bound material suggests that particle deposition (wet or dry) is the primary depositional mode of these compounds from the atmosphere.

To further examine depositional processes the flux to the sediment measured previously (*12*) is compared to the flux implied by the measured air concentrations. The implied flux is determined by multiplying the air concentration by the depositional velocity and proper conversion factors. Other work has given an estimated depositional velocity of 1 cm/sec for organic compounds (*17*). This data comparison is given in Table I for fluxes implied by either the total or particulate bound only concentration. If the two rural sites are compared, it is seen that the Trout Lake flux is less than Siskiwit Lake but it should be noted that Thunder Bay, Ontario (a city of 100,000) is approximately 40 miles Northwest of Siskiwit Lake. The average Great Lakes flux lies somewhere between Indianapolis and Bloomington which seems correct as there are both urban and rural areas in the Great lakes area.

Table I. Comparison of measured and implied fluxes.

	PCDD & PCDF CONCENTRATION		IMPLIED FLUX	
	TOTAL	PART. ONLY	TOTAL	PART. ONLY
	pg/m^3	pg/m^3	pg/cm^2yr	pg/cm^2yr
TROUT LAKE	0.53	0.28	17	9.0
BLOOMINGTON	2.2	1.6	70	51
INDIANAPOLIS	5.2	4.1	165	130

MEASURED AVERAGE GREAT LAKES SEDIMENT FLUX = 120 pg/cm^2yr

MEASURED SISKIWIT LAKE FLUX = 20 pg/cm^2yr

The data shown suggest the following scenario. Combustion produces a large variety of chloro-homologues. As these compounds are transported through the atmosphere, a degradation process occurs on the vapor phase. This process reduces the total air concentration, but significant amounts remain in the vapor phase due to equilibrium with particulate bound material. This equilibrium favors the particulate bound material for the higher chlorinated homologues, and thus they undergo less degradation. Eventually. the particulate matter deposits from the atmosphere and enters the biosphere where it can be deposited in sediment or on plant matter which can be taken up through the food chain.

Acknowledgments. We thank the Westinghouse Electric Corporation and the U.S. Environmental Protection Agency for support.

Determination of the Photoinduced Loss Rate of Low Vapor Pressure Molecules by Mass Spectrometry.

Robert Orth

Environmental Sciences Center, Monsanto Company, 800 N. Lindbergh Blvd., St. Louis, Missouri 63167.

The fate of compounds such as chlorinated organic compounds in the environment depend on their rates of biodegradation and chemical degradation. This paper discusses the photodegradation of polychlorinated dibenzo-p-dioxin(PCDDs) and dibenzofurans (PCDFs). The PCDDs and PCDFs have vapor pressures which are lower than 10^{-4} torr which limits the experimental method for determining the photoloss in the vapor phase. An apparatus which minimizes the problems associated with studying low vapor pressure photoinduced loss was constructed. The apparatus and the associated dynamics has been described previously(1,2) in which a mass spectrometer is directly coupled to a quartz gas cell. PCDDs and PCDFs are passed through the cell which may or may not be irradiated with various wavelengths of light The mass spectrometer monitors the gas phase concentration of the analytes allowing the kinetic studies to be conducted.

The objectives of the study are; to determine the photoinduced quantum yield for 2,3,7,8 tetrachlorodibenzo-p-dioxin, 2,3,7,8-TCDD, over the region of the light spectrum from 200 nm to 300 nm; to examine the variation between various PCDDS isomers with respect to 2,3,7,8-TCDD; and to finally determine the relative rate difference between tetrachlorodibenzofuran, TCDF, and 2,3,7,8-TCDD. The variability among TCDD isomers was examined by varying the number of Cl on each benzene ring i.e. all the chlorines on the first ring (1,2,3,4-TCDD), 3 on first ring and 1 on the second ring (2,3,4,8-TCDD), and the symmetric 2 by 2 (2,3,7,8-TCDD). The variation between congeners involve the determination of the photoinduced loss rate 1,2,3,4,7 pentachlorodibenzo-p-dioxin with the TCDDs. The relative rate between TCDF and TCDD was examined using 2,3,6,8-TCDF vs 2,3,7,8-TCDD.

As can be seen in Figure 1 the light on curve using the 325 broad band filter does induce a loss for TCDD as compared to the no light loss curve. The two loss curves are for 2,3,7,8 and 2,3,4,8-TCDD. The 2,3,7,8-TCDD is lost at a faster rate than the 2,3,4,8-TCDD The photon flux was measured using acetone as a reference. Therefore the quantum yield for 2,3,7,8-TCDD was calculated to be 0.03 ±70%. The major uncertainty in the quantum yield arises from difficulty in measuring the photon flux. The relative rate constants have a better precision of ±15%.

Figure 2 shows the relative half life obtained from the rate constants for loss with respect to 2,3,7,8-TCDD for each of the PCDDs and PCDFs examined. The results shows that for this group the 2,3,7,8-TCDD has the shortest half life of the group while the pentaCDD is 2.3 times longer then the 2,3,7,8-TCDD. Thus as the chlorination increases the half life increases. The other isomers have a longer half life than 2,3,7,8-TCDD but are comparable between themselves.

Figure 3 shows the results obtained for the photoloss of 2,3,7,8-TCDD and 2,3,6,8-TCDF as a function of wavelength. 2,3,6,8-TCDF has two apparent maxima at 300 nm and 260nm. The 2,3,7,8-TCDD shows a maximum photoloss at 300nm. The maximum for 2,3,7,8-TCDD corresponds with the maximum observed for the absorption of light in a hexane solution. Considering the observed wavelength dependence for photoinduced loss for TCDF and TCDD and the sunlight flux in this region of the light spectrum, the life time of these molecules in the vapor phase with sunlight present is going to be finite.

With the low vapor pressures experienced with these compounds the amount of sample on the surface of the photolysis cell can be larger than that in the gas phase. The loss due to light could therefore be arising from the molecules on the surface photodegrading, not the vapor phase molecules. A second surface photodegradation could also arise from a molecule which is photo-excited in the gas phase but requiring a surface interaction for degradation to occur. To determine if the surface is a major contributor to the above photoloss determinations the surface area of the photocell was decreased by a factor of two. By keeping the photon flux the same as in the larger cell an observed change in the rate constant of 0.5 times should be observed if the above mechanisms are the major contributor The rate constant did not change within experimental error. Thus this surface process is not a major contributor to the observed loss.

In conclusion the TCDD and pentaCDDs were found to photodegrade in the UV region with a maximum for photoloss occurring at 300nm for the TCDDS and TCDFs. The quantum yield for 2,3,7,8-TCDD was 0.03±0.02. 2,3,7,8-TCDD was found to have the shortest relative life time compared to the other PCDDs. Also as the number of chlorines increase from 4 to 5 the relative half life compared to 2,3,7,8-TCDD increases by a factor of 2.3.

PEAK EXPOSURE AND DISSIPATION RATE MEASUREMENTS OF HALOGENATED VOLATILE ORGANIC COMPOUNDS IN INDOOR AIR

Joachim D. Pleil,* William A. McClenny
Environmental Monitoring Systems Laboratory
U S. Environmental Protection Agency
Research Triangle Park, NC 27711

Karen D. Oliver
Northrop Services, Inc. – Environmental Sciences
Research Triangle Park, NC 27709

The indoor breathing space is often subjected to various volatile organic compounds (VOCs) from human activity, which can greatly impact the quality of the air. Because the indoor environment is restricted in volume and the exchange rate between indoor air and outdoor air is generally low, even seemingly small emissions (high-level and short-term or low-level and long-term) can cause human exposures of concern. The ambient (outdoor) air can also be similarly affected when local point sources emit large volumes of VOCs into the considerably larger local air volume.

Measurement of VOCs is generally performed with time-integrated sampling and subsequent detailed analysis. The two predominant sampling methods are solid absorbent sampling with Tenax-gas chromatography (GC) and whole-air sampling with SUMMA® polished canisters or Tedlar® bags. Typical sampling periods are 12 and 24 h.

The currently used methodology for VOC determination does not address the time-dependent nature of such emissions, with the exception of screening devices such as real-time systems that include photoionization detectors (PIDs) or portable GCs. Though such instruments can yield some time-resolved data, the "total response" nature of the former and the low-quality resolution of the latter method tend to result in ambiguous VOC data.

Our laboratory has developed three related high-resolution GC methods to address the need for time-resolved measurement of VOCs. These are

1. automated, repetitive sampling and analysis performed on-site;
2. multiple, sequential grab sampling with subsequent laboratory analysis; and
3. automated sequential syringe sampling (SSS) with subsequent automated multiple analyses in the laboratory

These methods have been used in a variety of situations to demonstrate their utility and to document the variations in concentration of halogenated VOCs.

For the first method, the analytical instrumentation must be in place at the sampling site and is thus of limited utility for other than developmental work. An automated repetitive analytical cycle was used to measure hourly concentrations of VOCs in our laboratory building; some representative data for tetrachloroethene are given in Figure 1. This system, employing high-resolution GC with parallel flame ionization and electron capture detectors, was then installed in a mobile laboratory for use in ambient (outdoor) sampling. Also, the mobile laboratory can be parked next to a building and with appropriate sample delivery can be used for indoor air VOC determination.

The second method, sequential canister sampling and analysis, removes the necessity for on-site analytical equipment; however, the method requires a great deal of operator intervention. Here, a number of evacuated SUMMA® polished sampling containers are manually opened at certain intervals to collect whole-air grab samples for subsequent detailed GC/MS laboratory analysis. This method was applied to an indoor situation involving the use of a "hot tub" spa wherein bromine pool chemicals are used as an algicide. Representative data are presented in Figure 2.

Finally, the third method was developed to streamline and fully automate both the sampling and analytical phases of time dependent VOC determination. By using a modified, commercially available SSS system, 12 consecutive 150-cm^3 whole-air samples could be collected and then transported to the laboratory for fully automated GC/MS analysis. The SSS system is pre-programmable in the laboratory to collect samples on a variety of time scales ranging from 2 to 90 min/sample The only work required from the field operator is sampler transportation and placement at the site of interest Upon return to the laboratory, the SSS is connected to a manifold, and the analytical system automatically performs analyses of all 12 collected samples and prints

calibrated reports for 40 compounds of interest. Because the analytical phase requires no ongoing operator intervention, it is generally performed overnight to free the instrumentation for other workday analyses. Representative data from two tests, bathroom air during shower activity and residential air during use of household spray products, are given in Figures 3 and 4. Figure 3 shows the temporal variability of chloroform correlated to water use and shows para-dichlorobenzene (presumably from an air freshener) as unaffected. The household product test showed many use-correlated variations; dichloromethane and methyl chloroform had maximum levels exceeding 300 ppbv and 200 ppbv, respectively. Other correlated variations for carbon tetrachloride, methyl chloride, and trichloroethylene are presented in Figure 4.

The results from this variety of experiments demonstrated that (1) halogenated VOCs often exhibit order of magnitude changes in concentration, (2) time scales of changes vary and depend upon the compound, (3) absolute magnitudes of concentrations and dissipation rates can vary widely for different compounds in the same test, and (4) unexpected compounds (such as carbon tetrachloride) can occur. All three methods described here were capable of producing high-quality peak exposure and dissipation rate measurements for halogenated VOCs despite the variabilities inherent in indoor air situations.

EXACT MASS ERRORS IN FOURIER TRANSFORM MASS SPECTROMETRY: EXPERIMENTAL EVIDENCE FOR INDIRECT COULOMBIC MECHANISMS

S. S. Yang, D. L. Rempel and M. L. Gross
Midwest Center for Mass Spectrometry,
Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304

New calibration procedures based on accurate ion dynamic models are a means to reduce systematic mass measurement errors in Fourier transform mass spectrometry. Systematic errors have been shown to increase with ion number.[1,2]

The fact that errors increase with ion number might be attributable to coulombic interaction amongst the ions. There are two developments upon which models of coulombic interaction might be based: one makes use of uniform ellipsoidal ion clouds[3] and the other exploits averaging[4].

To the extent that the errors can be explained or removed by applying these developments to the ion motion during the detection time, the errors will be said to be due to "direct" mechanisms. Otherwise, the errors will be said to be due to "indirect" mechanisms.

Experimental evidence is given for two mechanisms which are thought to be indirect. The first appears as a correlation between ionization period processes and changes in the dependence of error on ion number. The second appears as a correlation between trap field shape and dependence of error on ion number. The experimental evidence of these mechanisms is most visible in experiments designed to test the veracity of models based on the developments.

General parameters were: magnetic field = 1.2 T; trap disk = 1.007 V, outer segment = 1.705 V; filament bias = -70 V. Trap was a .0254 m cubic trap which was compensated by segmenting the trap plates into two parts.[7] The material was 304SS. Excitation was three sequential rf bursts, .345 V b-p for 700 us applied at the calibrant ion frequencies corresponding to m/z = 77 and m/z = 120 of acetophenone and at the test ion frequency corresponding to m/z = 105, except the test ion was excited for 650, 700, or 750 us.

Exact mass measurement errors were obtained by first fitting the equation $m = (a/f) + (b/f^2)$ to the known masses and measured frequencies of the two calibrant ions. Then the measured frequency of the test ion was used in the fitted equation to calculate the calibrated mass. The difference between the calibrated mass and the true mass is the mass measurement error.

In fig. 1, the error as a function of the electron beam time-current product varied with changes in beam time when the test and calibrant ion orbit sizes were different. This observation would suggest that a factor other than ion number was also influencing the errors as the ion number is varied. This effect confounds efforts to test ion-ion coupling models in circumstances involving different orbits.

As a parameter in this factor, time does not play a significant role. Extending the beam time from 3 ms to 18 ms had little effect. This would suggest that electron-ion collisions or ion-ion collisions during the ionization period were not responsible for the effect. Time delay between the ionization and excitation periods produced only small changes in the high orbit error behavior. This would suggest that evolutionary processes after the ionization period were not responsible as well. One possible mechanism is the modification of the ion cloud state by the electric field of an electron beam that is not perfectly coaxial with the trap electric field center. Magnetron motion did affect the error dependence in the case where the trap electric field center was shifted by using bias on the transmitter plates, and in the case where overt magnetron excitation was applied. Electron beam trapping of ions[6] at 500 nA is suggested appearance of asymmetry with respect to magnetron excitation. As a check, asymmetry was observed when the trap field center was moved by using transmitter plate bias.

The shape of the trap electric field affects the dependence of error on ion number. The error dependence for the compensated trap conforms more closely to an affine function. This observation supports the notion that the errors recorded here are electric in origin.

A tentative explanation for the difference between compensated and uncompensated trap performance can be found in the notion that only a fraction of the ion population is detected. The detected fraction is determined by the shape of the electric fields.[7] As the electric fields are modified by increasing ion number, the detected portion of the ion population can change. As the relationship of the detected portion to the whole cloud changes, the effect of ion-ion coupling changes, and a different frequency shift per ion number is produced.

For the uncompensated trap, it is known that the detected fraction for low ion number is a subpopulation with moderately high z-mode amplitudes. For high ion number, the uncompensated trap behaves like a compensated trap, in which the detected ion fraction is a subpopulation with moderately low z-mode amplitudes for all ion number.[7] In fig. 2, the frequency slope changes only for the uncompensated trap as expected.

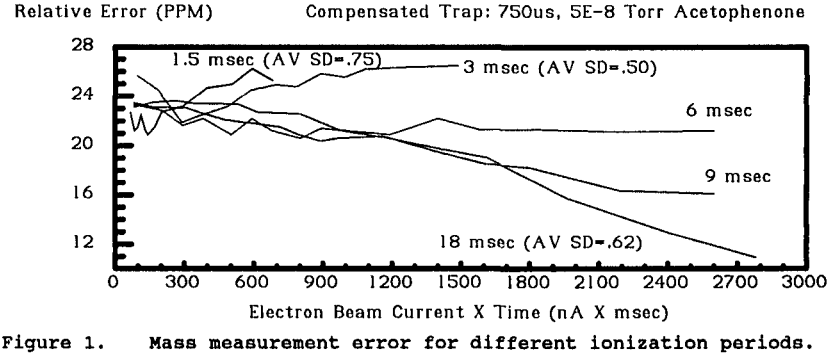

Figure 1. Mass measurement error for different ionization periods.

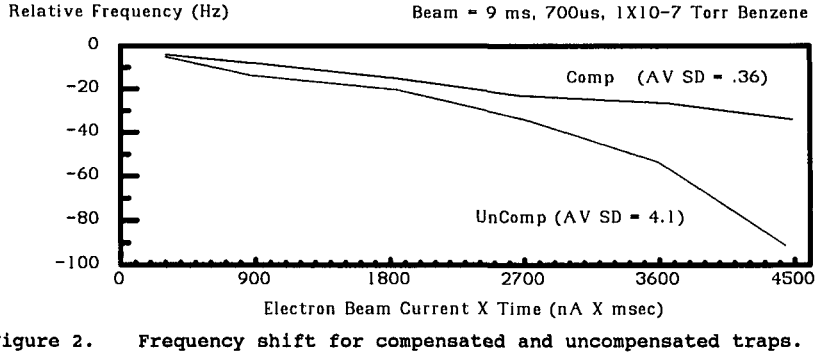

Figure 2. Frequency shift for compensated and uncompensated traps.

NEW AND IMPROVED MASS CALIBRATION LAW FOR FT/ICR MASS SPECTROMETRY

Mingda Wang and Alan G. Marshall

Deartment of Chemistry (and Dept. of Biochemistry)
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

For a trapped-ion cell with quadrupolar potentials, Ledford et al. were able to relate ICR frequency (ν) to ionic mass (m) in the absence of ion-molecule collisions according to:[1]

$$m = A/\nu + B/\nu^2 \qquad [1]$$

It has proved remarkably successful for wide-range mass calibration, presumably because: (a) most FT/ICR ion traps closely approximate the quadrupolar potential, and (b) the additional ion-ion Coulomb "space-charge" potential in actual experiments is evidently approximately quadrupolar.[2]

Nevertheless, collisions can shift an FT/ICR spectral peak, as shown in Figure 1. The Fourier transform of a causal, linearly-polarized (i.e., mathematically real) exponentially-damped sinusoidal signal yields the usual spectral peak at positive frequency, but also a mirror-image peak at negative frequency. Ordinarily, we ignore the negative-frequency peak, because it has no direct physical significance. However, as the collision rate increases (so that the frequency-domain peak(s) broaden), the "tail" of the negative-frequency peak shifts the positive-frequency spectral peak maximum slightly to lower frequency.

For a magnitude-mode Lorentzian spectral peak, the frequency shift, $\Delta\omega = 2\pi\Delta\nu$, resulting from ion-molecule collisions can be shown to be

$$\Delta\omega \approx -1/(2\omega_0\tau^2) \approx -\xi^2/(2\omega_0) \qquad [2]$$

in which $\tau = 1/\xi$ is the time-domain exponential damping constant, and ν_0 is the observed ICR frequency in the absence of ion-molecule collisions.

The remarkable result of this treatment is that the usual approximations lead to a four-term mass calibration (Eq. 3).

$$m = A/\nu + B/\nu^2 + C/\nu^3 + (BC)/(A\nu^4) \qquad [3]$$

Although there are two new terms, there is only one new parameter, C, which can be obtained from the FT/ICR magnitude-mode peak width in the high-pressure limit.[3] Several interesting conclusions follow from Figure 1. First, most of the frequency shift arises from overlap of the dispersion components of the magnitude-mode spectrum. Thus, phasing of the spectrum to give absorption-mode display reduces collision-induced frequency shifts to a negligible level. Second, the negative-frequency peak is a direct consequence of linearly-polarized detection. Thus, quadrature detection also eliminates collision-induced shifts, by detecting a circularly-polarized signal with no negative-frequency component.

We have compared iterative best-fits (with various weight factors) of actual ICR mass/frequency data to Eqs. 1 and 3. The new 4-term mass calibration law typically improves mass calibration accuracy by a factor of ~2 over the 2-term law. Moreover, the 4-term fit gives random errors throughout the mass range, whereas the 2-term equation typically gives systematic mass errors (e.g., positive at the high end of the calibrated mass range).

The authors thank W. J. van der Hart for helpful discussions. [This work was supported by grants (to A.G.M.) from N.S.F. CHE-8721498 and The Ohio State University.]

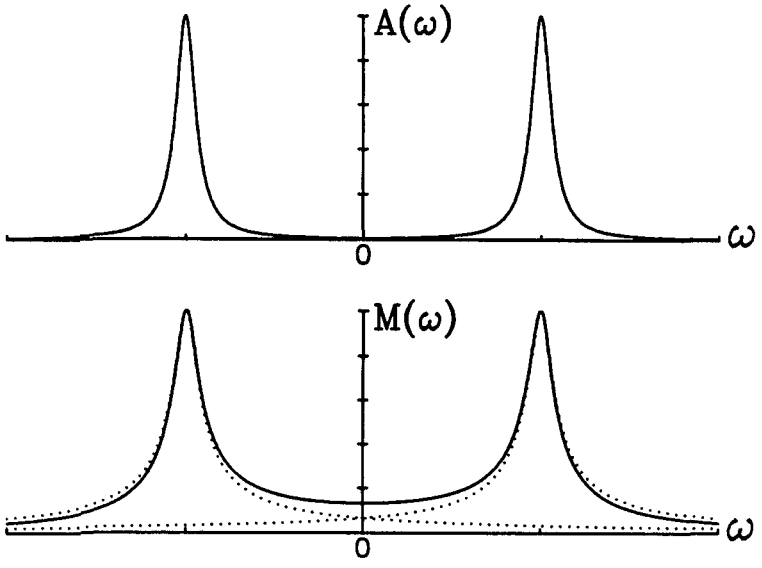

Figure 1. Absorption-mode (top) and magnitude-mode (bottom) spectra obtained by Fourier transformation of a linearly-polarized exponentially damped sinusoidal time-domain signal. Although the negative-frequency peak has no direct significance, its spillover into the positive-frequency spectrum can shift (to lower frequency) the maximum of the positive-frequency peak. In each spectrum the dotted curves represent the right- and left-circularly polarized components, and the solid curves represent the linearly polarized spectrum. Practically speaking, the shift is negligible in absorption-mode, but can reach several ppm in magnitude-mode.

EXTENSION OF LOWER MASS LIMIT IN DIRECT-MODE FT/ICR MASS SPECTROMETRY BY MEANS OF ALTERNATE DELAY SAMPLING

Francis R. Verdun, Tom L. Ricca, and Alan G. Marshall

Department of Chemistry (and Dept. of Biochemistry)
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

According to the Nyquist theorem, the highest signal frequency which can be represented without foldover (aliasing), in a Fourier transform frequency-domain discrete spectrum is one half of the time-domain sampling frequency. For example, since ion cyclotron resonance (ICR) frequency is inversely related to ionic mass-to-charge ratio m/z, the highest ICR frequency (corresponding to the lowest correctly represented m/z) in direct-mode FT/ICR mass spectrometry is restricted to one-half of the maximum sampling frequency, or m/z ~18 at ~3.058 T, for a maximum sampling frequency of about 5.2 MHz. We now show that interleaved addition of two digitized time-domain transient signals, one of which is delayed by one-half of one sampling period with respect to the other, generates a time-domain discrete waveform which is indistinguishable from a single waveform produced by sampling at twice the original sampling rate. Thus, provided that the two time-domain transients have (or have been normalized to) the same magnitude, one can double the Nyquist-limited frequency range by means of interleaved sampling.. If the sampling period is divided into three or more equal parts, with interleaved addition of three or more correspondingly delayed transients, the same method can further increase the upper frequency limit. With respect to signal-to-noise ratio, the interleaving method is equivalent to two-fold oversampling of the time-domain signal.

Experimental

FT/ICR spectra were acquired with a Nicolet FTMS-1000, operating at 3.058T [1]. Ions were produced by electron impact in a standard FT/ICR event sequence. Methane and perfluoro-tri-n-butylamine were introduced at partial pressures of 10^{-9} torr.[2] Software-programmed delays proved suitable for testing the method at relatively low sampling rates (<500 kHz), but were not applicable at high sampling rate. The maximum speed of our Nicolet analog-to-digital converter (ADC) is 1/3 of 16 MHz, or 5.33×10^6 samples per second. Thus, extension of the Nyquist limit by means of interleaved sampling requires a delay increment of ~100ns. Unfortunately, the smallest programmable delay increment for the Nicolet 1280 hardware is 8 cycles of an 8 MHz clock, or 1 ms. Therefore, the receiver amplifier output was routed to an external module, through which the signal was either passed without further delay, or manually switched through a series of linked gates of appropriate duration. The different time-domain digitized transients were stored in memory and interleaved afterwards by a simple Fortran routine. No noticeable artifacts were detected during our experiments. Simulations showed that differences of less than 5% (in delay time or magnitude) between the two time-domain data sets are not critical.[2]

Results

In FT/ICR spectrum A, singly-charged ions from 11.73 to 3000 μ were coherently excited and their composite time-domain signal was sampled directly at 4 MHz (to give a Nyquist low-mass limit of 23.47 μ). The ICR signals arising from ions with m/z values below that limit appear folded-over into the displayed mass range.

Spectrum B was produced by FFT of a data set formed by interleaving the time-domain data of the previous Figure with a second time-domain data set acquired with an additional delay of 125 ns between the excitation and reception events. ICR spectral peaks which were folded-over in spectrum A are now displayed at their correct frequencies (and m/z-values). The expanded scale inset reveals the expected CH_2^+ at m/z = 14.015 μ and a small artifact peak due to imaging of CF_3^+ at an apparent m/z = 14.145.

Conclusion

For a given maximum ADC rate, the FT/ICR lower mass limit varies directly with magnetic field strength. For example, at 7.0 T, our maximum ADC rate of 5.33 MHz would limit the lowest observable (without foldover) m/z to ~43 μ. For that same ADC maximum rate, interleaved acquisition can reduce the lower mass limit by a factor of 2 (or 4 or more). Thus, the present method offers a useful alternative to quadrature detection (see paper # ROC 1115).

In Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometry, ions are conventionally detected in a single-section ion trap typically consisting of two end cap electrodes and four side plate electrodes. Up to now, it has generally been assumed that the optimal electric field profile in an FT/ICR ion trap is the quadrupolar potential provided by hyperbolically curved side and end plates.[1] We have shown that such a design does in fact reduce the variation of ICR frequency with ion cyclotron orbital radius.

However, the same end-cap d.c. voltage that traps the ions from escaping along the magnetic field direction also forces ions radially outward, thereby setting an absolute limit to the highest m/z value observable by FT/ICR. The ultimate upper mass limit is the m/z value at which a stable orbit no longer exists (i.e., the quadrupolar electric outward radial force is larger than the Lorentz inward radial force, independent of initial ion velocity).[1] That upper mass limit is shown as the 100%-ejection curves in Figure 1, for three representative magnetic field strengths. However, in this work, we note that a more severe constraint is that the ICR orbital radius of a thermal ion of sufficiently high mass may exceed the transverse radius of the ion trap (~2-5 cm). Since thermal ions have a Boltzmann distribution in speeds, a calculable fraction of ions of a given m/z will be ejected at any given trapping potential and magnetic field strength. As a practical guide, Figure 1 also shows the effective upper mass limit for which 99% of the (room temperature) thermal ions of that m/z will have ICR orbital radii less than the transverse dimension of the trap. The new upper mass limit should be a better practical estimate, since a trapped ion must be further excited by ~1 cm in radius in order to be detected. The present results go far toward explaining why FT/ICR sensitivity and mass resolution for ions of high m/z fall well below the values extrapolated from those observed for ions of low m/z.

We are therefore led to consider non-quadrupolar electric potentials for FT/ICR ion traps. Figure 2 shows one of our recent designs, consisting of an elongated (6:1 aspect ratio) three-section cell, compared to a more conventional cubic cell. A plot of electric potential along the z-axis shows that the electric potential drops to less than 10 μV in the center of such a cell, when 1 V is applied to the two end plate electrodes! We have experimentally confirmed that electric field-induced ICR frequency shifts are significantly reduced when ICR detection is limited to the central field-free region of the three-section cell. These and other new ion trap designs will be discussed in an upcoming publication.

HARTLEY TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

Christopher P. Williams and Alan G. Marshall

Dept. of Biochemistry (and Dept. of Chemistry)
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

In FT/ICR mass spectrometry, a linearly-polarized (i.e., mathematically "real") time-domain signal, f(t), is converted to its corresponding frequency-domain spectrum, F(v) (which is re-scaled to give a mass spectrum), by use of a complex Fourier transform.[1] The complex FT and its inverse differ by a sign in the exponent:

$$F(v) = \int_{-\infty}^{+\infty} f(t)\, e^{-2\pi i v t}\, dt = \int_{-\infty}^{+\infty} f(t)\, [\cos(2\pi v t) - i \sin(2\pi v t)]\, dt$$

$$f(t) = \int_{-\infty}^{+\infty} F(v)\, e^{2\pi i v t}\, dv = \int_{-\infty}^{+\infty} F(v)\, [\cos(2\pi v t) + i \sin(2\pi v t)]\, dv$$

The same spectrum can be obtained without resorting to mathematically complex notation, by use of the "Hartley" transform, to give the Hartley spectrum, H(v):

$$H(v) = \int_{-\infty}^{+\infty} f(t)\, [\cos(2\pi v t) + \sin(2\pi v t)]\, dt = \int_{-\infty}^{+\infty} f(t)\, \mathrm{cas}(2\pi v t)\, dt$$

The Hartley spectrum (see Figure) can thus be thought of as the sum of the usual absorption and dispersion spectra, and contains the same information as the conventional complex FT spectrum. For example, the real and (negative of the) imaginary components of the FT spectrum may readily be recovered from the even and odd components, E(v) and O(v), of the Hartley spectrum:

$$E(v) = \frac{H(v) + H(-v)}{2} = \int_{-\infty}^{+\infty} f(t) \cos(2\pi v t)\, dt$$

$$O(v) = \frac{H(v) - H(-v)}{2} = \int_{-\infty}^{+\infty} f(t) \sin(2\pi v t)\, dt$$

Similarly, the magnitude and phase spectra, M(v) and $\phi(v)$, may be computed as easily from the HT spectrum as from the FT spectrum:

$$M(v) = \sqrt{\frac{H(v)^2 + H(-v)^2}{2}} \quad ; \quad \phi(v) = \arctan\left[\frac{-O(v)}{E(v)}\right] = \arctan\left[\frac{H(-v) - H(v)}{H(v) + H(-v)}\right]$$

The Hartley transform is interesting for both conceptual and computational reasons. The fundamental principle is that cosine and sine are already orthogonal functions; therefore, there is no need to separate them as the real and imaginary parts of a complex number. Stated another way, if the Fourier transform gives the projection of a frequency-domain vector (length = magnitude and angle = phase) onto two orthogonal (cosine and sine) axes, then the Hartley transform is the projection of that same vector onto a single axis bisecting the sine and cosine axes:

$$\mathrm{cas}(\theta) = \cos(\theta) + \sin(\theta) = \sqrt{2} \cos[\theta - (\pi/4)] = \sqrt{2} \sin[\theta + (\theta/4)]$$

It is also interesting to note that, unlike the Fourier transform, the Hartley transform and its inverse are identical in form:

$$f(t) = \int_{-\infty}^{+\infty} H(\nu)\, \mathrm{cas}(2\pi\nu t)\, d\nu$$

For real data, a complex FFT takes twice as long as a (real) FHT, when both are similarly optimized (e.g., precalculation of trigonometric identities). However, one should be aware that it is possible to construct an FFT algorithm for real data, in which the original N time-domain (real) data points are first separated ("shuffled") into two halves consisting of the odd-numbered and even-numbered data points. The two time-domain data halves are then treated as real and imaginary parts of a complex data set, transformed by the conventional complex FFT, and the final frequency-domain spectrum recovered from the result. For a real data set, such a "real FFT" algorithm also runs twice as fast as a complex FFT. We have confirmed (on an Atari 1040 ST computer, 8 MHz, 1 megabyte RAM, 68000 processor) that the Bracewell radix-2 FHT[2] is essentially the same in computational speed to a similarly optimized radix-2 FFT, for real data sets from 1K to 8K in size. We have also implemented the FHT on our Nicolet 1280 computer and applied it to experimental time-domain ICR transients to obtain *magnitude-mode spectra identical to those obtained by FFT.*

HIGH-RESOLUTION MULTIPLE ION SIMULTANEOUS MONITORING BY MEANS OF MULTIPLE FOLDOVER FT/ICR MASS SPECTROMETRY

Mingda Wang and Alan G. Marshall

Dept. of Chemistry (and Dept. of Biochemistry)
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

In any form of Fourier transform spectrometry, the Nyquist criterion requires that a sinusoidal signal be sampled at least twice per cycle in order that its apparent frequency (after discrete FT) represent its true frequency. If the sampling frequency, $\nu_{sampling}$, is less than the true signal frequency, then the apparent peak frequency in the FT spectrum will be "folded over" into the displayed frequency range from $\nu = 0$ to $\nu_{sampling}$

In particular, for FT/ICR mass spectrometry[1], ultrahigh mass resolution requires a long time-domain data acquisition period, whereas coverage of a wide mass range requires a rapid time-domain sampling rate, if foldover is to be avoided. For typical FT/ICR data sets (e.g., 16K-256K time-domain data points), one is usually forced to choose between wide mass range (at relatively low resolution because of the limited number of data points per peak) and high mass resolution (over relatively narrow mass range, in order to define each peak position more precisely).

In general, high-resolution FT/ICR mass spectra are acquired in heterodyne mode over a narrow mass range, as shown in Figure 1 (middle). However, when the true ionic **mass-to-charge (m/z) values** (and thus the ICR frequencies) are known but the relative **abundances** of ions of different m/z are not (as in multiple-ion monitoring), then time-domain sampling at a frequency well below the Nyquist limit can "fold over" the ICR signals from ions of widely separated m/z-values into a single narrow band (and thus high-resolution) spectrum. Applications for intentional undersampling to induce foldover include:

(a) **Increased mass calibration precision**, by folding over low-mass calibrant peaks into a narrower mass range (with higher digital resolution).[2]

(b) **Extension of FT/ICR low-mass limit**. For example, Cody et al.[3] employed a single foldover to detect and identify ions whose m/z-values were too low (and whose ICR frequencies are therefore too high) to satisfy the Nyquist limit. Such procedures should be especially useful at higher magnetic field strength (e.g., 7 tesla).

(c) **High-resolution multiple-ion monitoring of ions of widely different m/z.**[4] For example (see Figure 2), we have produced a single direct-mode (i.e., no heterodyning) mass spectrum of an electron-ionized mixture of respiratory gases (H_2O, N_2, O_2, CO_2, N_2O) at a resolution sufficient to resolve CO from N_2 and CO_2 from N_2O. The number of foldovers (up to >1000) differs for different ions.

(d) **Isotopic resolution for ions of widely different m/z.** In gas-phase ion-molecule reaction kinetics and equilibria measurements, it is desirable to be able to resolve $(M+H)^+$ from the M^+ ions which contain one carbon-13, particularly when (as for unknown and reference bases of widely different basicity) the two ions are of comparable abundance.

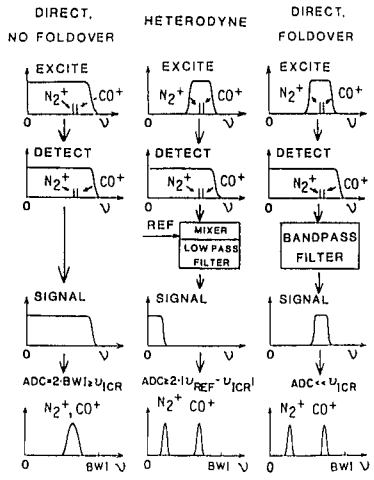

Figure 1. Three FT/ICR detection modes. In each case, the time-domain signal is sampled at a frequency of 2.BWI.

Left: Direct mode without foldover.

Middle: Heterodyne mode. The amplified ICR signal is mixed (i.e., effectively multiplied by) a reference sinusoid of nearly the same frequency. The mixer output, consisting of signals at the sum and difference of the ICR and reference frequencies sum and difference frequencies of the ICR and reference signals, is then passed through a low-pass filter to eliminate the higher (summed) frequency component. The desired (initially high-frequency) ICR signal is thereby converted to a relatively low frequency signal which can thus be sampled a low digitizing rate for a long time, to produce a narrow-range mass spectrum with high analog and digital resolution.

Right: Direct mode with foldover.

RESOLUTION IMPROVEMENT IN FTMS BY HARMONIC DETECTION

Y. Pan, D.P. Ridge, Alan L. Rockwood

Department of Chemistry, Univ. of Delaware, Newark, DE 19716

Recently we have developed a technique for obtaining higher resolution in an ion cyclotron resonance (ICR) mass spectrometry by observing harmonic signals. The experiment has been done both in the continuous wave (CW) mass spectrometer and Fourier Transform mass spectrometer. In the CW experiment the second harmonic signal was detected and the resolution was shown to be two times better than the fundamental one[1]. On a Nicolet FTMS-2000 spectrometer the third harmonic signal was clearly observed and the resolution was three times better than the fundamental one. The harmonic signal is especially useful in resolving high mass peaks because it does not require increasing the magnetic field or acquisition time.

Harmonics originate in the fact that the field of the orbiting ions sensed by a finite electrode varies nonlinearly with distance. The signal detected is therefore not a pure sinusoidal wave and contains higher harmonics.

Figure 1 shows the fundamental, the third harmonic, the fifth harmonic and the seventh harmonic of the m/z 128 signal in naphthalene. In these spectra the linewidth is determined by the observation time. For each harmonic the width of the x axis is one amu. The improvement in resolution with harmonic order is evident. The enhanced resolution also comes at the cost of signal to noise ratio.

If the linewidth is determined by observation time or by collision frequency or other homogeneous mechanism, then the widths (δf) of all the harmonics are the same as that of the fundamental. Since the frequency (nf) of the nth harmonic is higher than that of the fundamental (f), the resolution will be correspondingly higher ($nf/\delta f$). The resolution increases in proportion with harmonic order. This is evident in Fig. 1.

A cell may be designed to optimize a particular harmonic[2]. An array of M receiving electrodes arranged to have D_{mh} symmetry can be used to detect certain harmonics selectively. The sum of the signals from all the electrodes will contain harmonics of order M, 2M, 3M, etc. If the sum of signals from alternating pairs of electrodes are subtracted from the sum of signals from the remaining electrodes, harmonics of order M/2, 3M/2, 5M/2, etc.(M must be even in this case). The two arrangements are indicated schematically in Fig 2.

This work presents a new method of data processing for Fourier transform ion cyclotron resonance (FTICR) mass spectrometry that results in improved mass resolution for a time-domain data set of given size. The time-domain signal x(t) arises from the superposition of n periodic signals, one for each ionic species present, all having a characteristic period (frequency). A single period of the resulting time-domain waveform x(t) of length (t_2 - t_1) not only represents the signal over the interval t_1 to t_2, but it also represents x(t) for all values of t. One such period contains all the information necessary to obtain the desired frequency-domain spectrum. In order to obtain improved resolution, a single period can be used as a basis to reconstruct or extend the time-domain signal x(t) to any desired length yielding much improved frequency resolution. This technique of signal extension will be referred to as data-filling.

The main benefit of the technique is to extend the length of transient signals that otherwise would decay rapidly with time or in cases where the total acquisition time is limited. High resolution is normally obtained by operating the FTICR mass spectrometer in the heterodyne mode, allowing transient image current signals to be digitized for extended lengths of time. Unfortunately, during long acquisition times ion/neutral collisions dephase the ion's motion resulting in a loss of signal and ultimately limiting the resolution. In some cases the signal decay is not significant over the acquisition time, but the resolution is limited by the finite amount of fast digitizer memory available. Especially when working at lower magnetic fields much longer data acquisition times are desired to compensate for the lower magnetic field values.

Once the time-domain spectrum has been recorded the length of one period must be determined. Initial results were obtained by manual inspection of the time domain spectrum. This approach is not practical for rapid analysis or for when the signal decays rapidly and exhibits a generally noisy appearance. If the periods of the individual signals are known in advance, then the period of the resulting waveform is given by the lowest common multiple of periods. However, when a number of components comprise the time domain waveform calculation of the lowest common multiple for the n periods can be time-consuming. Pattern recognition techniques are currently used to determine the overall periodicity.

The periodicity is determined by the computer using a simple search routine. A pattern vector is obtained by assigning each time domain point a value of one or zero depending on the sign of each point. This reduces the problems associated with slowly decaying transient signals. Feature extraction is accomplished by assigning a portion of the pattern vector as a search interval and searching the rest of the pattern vector for repeating units. Care must be taken when selecting the search interval in order to avoid aliasing. The search interval is typically chosen as a fraction (1/10 to 1/20) of the total number of points.

After the period has been determined a reconstruction of the time domain waveform x(t) is possible. The heterodyne time-domain spectrum of CO and N_2 is shown in Figure 1. A portion of the original data one period in length is extracted as shown in Figure 1C. These data are duplicated and added together (see figures 1D and 1E) phase consistently. This process is repeated and the reconstructed data set doubles in size with each step. The size of the reconstructed data set is limited only by the amount of computer memory available. The FWHM resolution for CO has been increased from 78000 for the original data to 8,200,000 for the data-filled spectrum.

Problems arise when the period does not fall on a integer multiple of the digitizer time step. This can cause a phase discontinuity resulting in distorted peak shapes after Fourier transformation or in "ringing", the presence of additional low amplitude frequency components through the frequency spectrum. The effects of such a discontinuity can be lessened by digitizing at a higher rate. Figure 2 shows a data-filled mass spectrum for carbon monoxide and nitrogen identical to that shown in Figure 1 except that the transient signal was sampled at twice the digitization rate. Note in Figure 2 the "ringing" observed in Figure 1 is absent. Further increases in resolution are possible by further data-filling to larger-sized data sets.

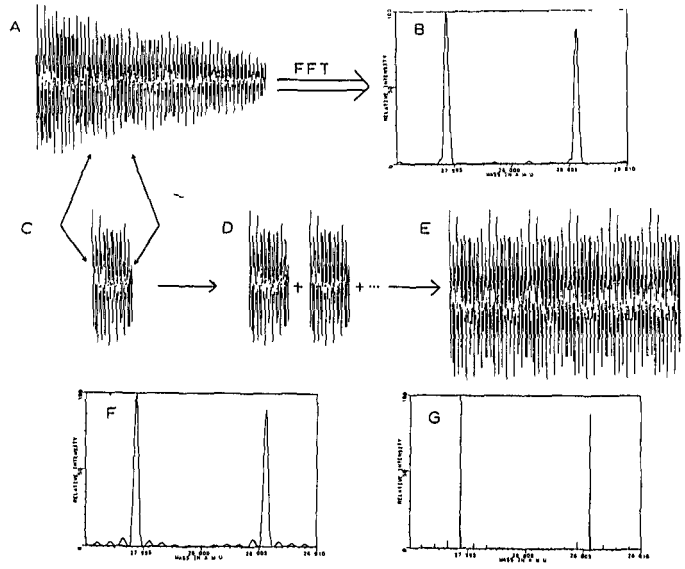

Figure 1.
A) A 512 point heterodyne time-domain spectrum of CO and N_2.
B) Mass spectrum of CO and N_2 obtained by Fourier transformation.
C) A representative portion of the data is extracted to serve as a basis for data-filling.
D) Data-filling of the time-domain waveform is accomplished by duplicating the basis with phase continuous addition of the data.
E) A 512 point time-domain waveform obtained by data-filling.
F) Mass spectrum of CO and N_2 obtained from a 512 point data-filled time-domain spectrum.
G) Mass spectrum of CO and N_2 obtained from a 65536 point data-filled time-domain waveform.

Figure 2.
Mass spectrum of CO and N_2 obtained by data-filling the time-domain spectrum to 65536 points prior to Fourier transformation. The FWHM resolution for the Co and N2 peaks is 8 X 10^6.

TWO DIMENSIONAL FTMS

M. Bensimon, T. Gäumann, J. Rapin and G. Zhao
Department of physical chemistry
Federal School of Technology
CH-1015 Lausanne, Switzerland

In Fourier Transform Mass Spectrometry (FTMS), the movement of the ions can be treated in an analogous manner to the spin precession in the "NOESY" 2D-NMR technique. The possibility of easily changing the pulse sequence on a standard instrument with software modifications only, allows the established NMR techniques to be carried over to the field of mass spectrometry. The two dimensional Fourier transform mass spectrometer [2D-FTMS] permits one to measure in one experiment all the ion-molecule reactions and fragmentations that take place in a mass spectrometer cell during a reaction period varying between one ms and several seconds. The ion movement is shown in Fig. 1 where a and c are the two exciting pulses, separated by the variable time t_1, (b). d corresponds to the resulting ion amplitude. During this time the ions may react, photofragment, etc. The modulation of the ion amplitude is shown in Fig. 2 for the reaction of CH_4^+ with CH_4 : the resulting CH_5^+ carries the same modulation frequency as CH_4^+, contrary to CH_3^+. Heterodyne (high resolution) [1] and broadband [2] mode are possible in both dimensions as far as the capacity of the memory will allow. Ion-molecule reactions in mixtures of differently labelled toluenes show one application of the method. In a relatively short time a good overview of the different type of reactions can be obtained. Irradiation with a CO_2-laser (10 μm) allows to simulate metastatable decays in an ICR spectrometer. For the moment, the main difficulties are the incompatibility of the MS-software with 2D, the conditions for an optimum signal-to-noise ratio without excessive harmonics and the choice ot the most useful presentation of the results.

AN ION TRAJECTORY MODEL FOR FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY.

B.A. Hearn, C.H. Watson, G. Baykut, and J.R. Eyler
Department of Chemistry, University of Florida
Gainesville, Florida 32611.

An ion trajectory model was developed from an analytical solution of the equations of motion for Fourier transform ion cyclotron resonance mass spectrometry in two dimensions for an ion subjected to a swept-frequency excitation. The motion of ions as a function of time was calculated using various excitation waveforms, which provided the final coherent radius of an ensemble of ions, the center of motion of the ensemble of ions, and the number of ions that exceeded the cell boundaries. The model allowed the randomization of the phase of the initial thermal velocity of each ion with respect to the excitation waveform. The magnetic field, the number of ions for each ensemble, the mass of the ions, and various ion excitation parameters could be varied.

As an example of the utility of the model, the x-y motion for m/z 100 using a chirp of 12.5 volts from 0 to 944128 Hz consisting of 4096 steps over a time period of 0.5 ms is shown in figure 1. Initially, the ion has a small radius from its thermal velocity. Due to the changing frequency, each step is not broadcast for an entire period. Early in the chirp excitation, as the low frequency voltages are output, the average potential the ion experiences is not zero, so the ion drifts in the y direction due to the forces from crossed electric and magnetic fields. This drift is not desirable because it limits the maximum radius that the ion can be excited to without being ejected. The radius should be as large as possible because in FT ICR mass spectrometry, the signal is proportional to the radius of the ion[1]

$$v = kNq^2rB / m$$

where v is the instantaneous ICR voltage signal, k is a constant, N is the number of excited ions, q is the charge of the ion, r is the radius of the ensemble of ions, B is the magnetic field, and m is the ion's mass. Changing the chirp's lowest frequency to 47972 Hz enabled an 18 volt excitation waveform to be broadcast without ejecting the ions. The result was a larger radius, thus a larger signal.

A comparison of chirp excitation with SWIFT[2] excitation was performed, with an excitation window chosen for a range of m/z 100 to 500 for the two techniques. The mass cutoff for the two techniques, shown in figure 2, indicates that SWIFT gives much more selective excitation. The model was also used to give an upper limit for the excitation voltage for a pulsed excitation, which was approximately 20% higher than that determined experimentally.

STUDIES OF ION MOTION IN AN ICR CELL BY DUAL CELL FTMS

J.P. Honovich and S.P. Markey
National Institute of Mental Health, Bethesda, Maryland 20892

The Nicolet FTMS-2000 contains two nearly identical cubic (1 7/8") ICR cells separated by a common trap plate (conductance limit). A 2 mm hole allows ion transfer between the differentially pumped cells. The trapping oscillation (Z axis motion) is studied by creating ions by electron impact ionization in the high pressure source cell followed by pulsing the common trap plate to ground potential. Ions are then free to move on a new potential surface over both cells. After the variable transfer period the ion population in either the source or analyzer cell is sampled.

Figure 1 shows the experimental results for the detection of m/z 128 (naphthalene) in the analyzer cell as a function of grounding time on the conductance limit. We have worked on modeling three features of these curves: 1) peak locations (transfer time), 2) shape of peaks, and 3) approach to a 50% randomization.

A numerical integration model (4th order Runge-Kutta) allows ions to be formed in a quadrupolar source cell followed by a transfer period where ions are allowed to oscillate on a specified potential surface over both cells. The potential V(z) is represented by the form $V = K_1Z^2 + K_2Z^4$ where the higher order term is required due to the nonharmonic nature of the dual cell when the conductance limit is grounded. Ions are created in the source cell with a position and velocity distribution using the aid of random number generator. Theoretical transfer curves use up to 800 initial ions and their z axis position is calculated as a function of transfer time.

The potential along the centerline z axis in a cubic six-sided box with one non-zero face voltage (V_t) can be calculated as below.

$$V(z) = \sum_{n=1,3,\ldots}^{\infty} \sum_{m=1,3,\ldots}^{\infty} \frac{16V_t \operatorname{Sinh}(\gamma z)}{mn \operatorname{Sinh}(\gamma c)} \operatorname{Sin}(n\pi/2) \operatorname{Sin}(m\pi/2)$$

$$\text{where} \quad \gamma = \sqrt{n^2 + m^2}$$

The cell potential was calculated at 5% intervals along the cell axis and a simplex curve fitting routine gave the following best fit (K_1 = .55, K_2 = .45). Using this potential in the numerical model yielded the transfer curve shown in Figure 2. This model gives good results for the transfer time but is apparently "too anharmonic" by comparison with the experimental results shown in Figure 1, in terms of early randomization between cells.

Figure 3 shows the calculated effect of increasing the anharmonic z^4 term. By inspection, the experimental results shown in Figure 4 for m/z 78 from benzene are most consistent with calculated results using K_1 = .75, K_2 = .25 as in Figure 5. This agreement between the calculated and observed results allows the use of K_1 = .75, K_2 = .25 to define the effective cell potential experienced by the ions.

CONCLUSIONS OF MODEL

1) The ability to randomize ions made in the source cell is highly dependent on the anharmonicity, and hence, on the geometric dimensions of the ICR cell. 2) If rapid randomization is desired, as in the case of high losses through the conductance limit, one should lengthen (or narrow) the ICR cell. 3) If it is desired to keep the ion packet together the cell should be slightly shortened (or broadened). 4) This model gives a sensitive measure of the "effective" cell potential within the dual cell ICR.

IMPROVEMENT OF THE ELECTRIC FIELD IN FT-ICR TRAPPED ION CELL.

Y. Naito and M. Inoue,
Department of Applied Physics and Chemistry, The University of Electro-Communications, Chofu-shi, Tokyo, 182 Japan.

In FT-ICR trapped ion cell ions are confined by a magnetic field and an electrostatic field. The conventional FT-ICR cell has a cubic or a cylindrical geometry and consists of six electrodes. The pattern of the electrostatic potential surfaces formed in the cell is quite complex and results in a complicated motion of ions. It is characterized by three periodic motions; cyclotron, magnetron and oscillation in the direction parallel to the magnetic field. The magnetron motion is the precession of the center of the cyclotron trajectories about the cell axis and produces undesirable effects such as shift in the cyclotron resonance frequency and appearence of sidebands in the frequency domain spectrum. The motion results from the forces exerted on ions by the magnetic field and electric field component perpendicular to the magnetic field.

We have found that the electric field in the cylindrical cell can be improved by dividing the conventional trapping electrodes in a concentric manner and by applying appropriate potentials to the divided electrodes. Using the cylindrical coordinates the radial (Er) and the axial electric field component (Ez) are given by

$$E_r = \sum_{\ell=1}^{\infty} \frac{2V_t J_1(k_\ell r)\cosh(k_\ell z)}{A J_1(k_\ell A)\cosh\{k_\ell (L/2)\}}, \quad E_z = -\sum_{\ell=1}^{\infty} \frac{2V_t J_0(k_\ell r)\sinh(k_\ell z)}{A J_1(k_\ell A)\cosh\{k_\ell (L/2)\}}$$

where A is the inner radius of the cell, Vt is the trapping potential, J_0 and J_1 are Bessel functions and $J_0(k_\ell A)=0$

Note that Er/Ez ratio deponds on r and z, but is independent of Vt. In case of the improved cell, Er and Ez are given by

$$E_z = -\sum_{\ell=1}^{\infty} \frac{2k_\ell J_0(k_\ell r)\sinh(k_\ell z)}{A^2\{J_1(k_\ell A)\}^2\cosh\{k_\ell (L/2)\}} (C_{1\ell} V_{t1} + C_{2\ell} V_{t2} + \cdots)$$

$$E_r = \sum_{\ell=1}^{\infty} \frac{2k_\ell J_1(k_\ell r)\cosh(k_\ell z)}{A^2\{J_1(k_\ell A)\}^2\cosh\{k_\ell (L/2)\}} (C_{1\ell} V_{t1} + C_{2\ell} V_{t2} + \cdots)$$

where Vt1, Vt2, ... are trapping potentials applied to each divided trapping electrodes. It has shown that the electric field in the improved cell is expressed by a linear combination of the applied potentials and Er/Ez ratio is variable. Therefore the radial electric field component Er can be reduced without decreasing the trapping efficiency.

We have constructed a cylindrical cell which has three pairs of trapping electrodes with different apertures arranged on both sides of the cell.[1] Measurements of magnetron frequencies were made with various combinations of the trapping potentials using an FT-ICR spectrometer built in this laboratory.[2]

We have confirmed that the magnetron frequency is greatly decreased and can be controlled by a linear combination of the trapping potentials. The

results suggests that homogeneity of the electric field is significantly improved.

HIGH PRESSURE ION SOURCE FOURIER TRANSFORM ION CYCLOTRON RESONANCE SPECTROMETRY

P. Kofel and T.B. McMahon
Department of Chemistry, University of Waterloo, Waterloo, Ont., Canada, N2L 3G1.

The technique of high pressure ionization combined with a magnetic sector mass analyzer has provided an abundance of thermochemical data on gaseous ions and molecules during the past two decades [1,2]. However, the analysis of the ions leaving the high pressure sources was limited to nominal mass analysis and relatively low masses.

High mass capability, high mass resolution, the possibility of structural characterization by dissociation experiments and of extended ion molecule reactions makes the FT-ICR technique [3] a superior tool to study ions. But only with the development of the external ion source [4,5] the FT-ICR instruments became attractive for ionization techniques with high gas loads, such as high pressure ionization

A high pressure ion source and ion transfer system was built and coupled (Fig 1) to a CMS 47 FT-ICR spectrometer equipped with a 4.7 T superconducting magnet [6]. The pressure differential between the ion source at 5 mbar and the ICR cell at $5x10^{-9}$ mbar is achieved by four pumping stages, including three turbomolecular pumps

The design of the high pressure ion source is similar to those described in the literature [1] Ions are produced by impact with electrons from a magnetically shielded, pulsed 2 keV electron gun The primary ions diffuse through the field free ionization chamber, thereby undergoing subsequent reactions in hundreds of ion molecule collisions. Thermal equilibrium conditions for these ion molecule reactions can be established between room temperature and 300° C . Ions reaching the exit aperture of the source are accelerated and transferred through gas flow restrictions and the fringing fields of the magnet to the ICR cell and trapped therein. Once trapped in the ICR cell, the ions can either be observed directly with high resolution, be structurally characterized by collision induced dissociation or react with species introduced only into the ICR cell region.

A novel injection lens / decelerator assembly was designed. It consists of an einzel lens followed by a cylindrical decelerator with 20 mm radius and 100 mm long, 0.55 m from the ICR cell at a field strength of 0.10 T . In our ion optics calculations this combination showed excellent qualities in decelerating and injecting the ions through the fringing fields of the superconducting magnet. The amount of energy, which is transferred from the axial to the radial velocity components of the ions by the magnetic mirror effect, can be kept below 1 eV with such a combination, increasing the number of ions that are trapped in the ICR cell [7].

An overview spectrum of air with traces of water is displayed in Fig 2. Due to the high pressure and long residence time in the ion source, most of the O_2^+ typically present in CI spectra has reacted with the water trace molecules and formed water cluster ions $H_3O^+(H_2O)_n$ at m/z=37, 55, 73, 91 and 109, corresponding to n=1,2,3,4 and 5, resp.

Reaction of the water cluster ions of air (Fig. 2) with acetone molecules at $2x10^{-7}$ mbar for 0 25 s in the ICR cell resulted in the spectrum of Fig 3. The complex reaction sequences involved are subject of our continuing experiments.

A negative ion high resolution spectrum of m/z=71 from traces of carbon tetrachloride and water in air (Fig 4) resolved the two peaks $ClHCl^-$ and $Cl^-(H_2O)_2$, as was confirmed by both accurate mass measurements and high resolution isotope peak analysis.

These preliminary experiments show the wide range of applications of the instrument to exact mass measurements, structural characterization and reaction mechanisms of ions from a high pressure ion source

THE IMPLICATIONS OF ION INJECTION FROM AN EXTERNAL ION SOURCE ON THE DYNAMICS OF TRAPPING AND DETECTION IN FT-ICR

C.D. Hanson, E.L. Kerley, M.E. Castro, and D.H. Russell
Department of Chemistry, Texas A & M University
College Station, Texas 77843.

Although the high resolution and high sensitivity of FT-ICR for the analysis of biomolecules was recognised early, the theoretical potential of the technique has not yet been realized. Ionization methods incompatible with the high vacuum requirements for detection by FT-ICR methods, have led to the development of differentially pumped external ion sources. Ions produced in an external source must be injected into the ICR cell by electrostatic methods. To accomplish injection, the ions are given appreciable translational energies. The effect of the kinetic energy on ion trapping and detection is difficult to study in simple cubic ICR cells. The complicated issue of ion motion and ion kinetic energy can be modeled in a two-section cell. By giving ions translational energy prior to the partitioning event, the effect of moving ions from an external source to ICR cell can be systematically studied. The impact of kinetic energy on partitioning efficiency and ion detection can be related to ion transfer from an external source.

The effect of radial translational energy imparted to the ions during the injection from an external ion source can be modeled in a two-section cell. By utilizing the conductance limit orifice as an ion skimmer, it is possible to differentiate between ions of different radii upon partitioning[1]. During the partitioning event, ions having cyclotron radii smaller than the orifice of the conductance limit will be transferred efficiently from the source to analyzer region. If an ion is accelerated into a larger cyclotron radius prior to partitioning, when the ensemble of ions are partitioned through the orifice, the ion of larger radius will be selectively discriminated against. The use of this selective ion partitioning has been studied both theoretically and experimentally. By using this technique, it is possible to profile an ions radius (i.e., translational energy) by monitoring its partitioning efficiency.

It has been demonstrated that an ion which is translationally excited to a larger cyclotron radius by a resonant oscillating electric field can be de-excited (*i.e.*, lose translational energy in the X-Y plane) by inverting the phase of the applied rf field with respect to the phase of the cyclotron orbit.[2,3] In this manner the translational energy of selected ions can be systematically regulated by an excitation/de-excitation technique.[4] Ions which are originally excited to radii which exceed the dimensions of the conductance limit orifice can be de-excited to radii acceptable for partitioning. Contained in figure 1 is a schematic of the procedure for investigating the effect of translational energy and relative phase angle in a two-section cell. Following ion production in the source region (A), all ions are excited to larger cyclotron radii by an rf excitation sweep (B) Selected ions are de-excited to the original radii by applying a second rf sweep which is 180° out of phase with respect to the cyclotron motion of the selected ions (C). The phase of the second pulse is selected by a variable delay between the first and second excite pulses. If the delay between the pulses corresponds to an odd integral of $n\tau/2$ (where τ is the period of the cyclotron orbit) the second excite pulse will be phase inverted. The radius of the de-excited ion can be analyzed by utilizing the orifice of the conductance limit. Only ions de-excited to energies corresponding to the dimensions of the orifice of the conductance limit will be partitioned into the analyzer region of the two-section cell (D).

The effects of excess translational energy have also been modeled theoretically. Contained in figure 2 is a computer simulation of a ensemble of ions of a specific m/z being excited by resonant excitation in a 3 T magnetic field. The ions were given thermal energies (*i.e.*, translational energy corresponding to electron impact ionization) and random phases with respect to the phase of the rf excitation. The resulting packet of ions (A) have a small radial and phase distribution cycloiding about a well defined center of rotation (B). Ions which are initially given

significant translational energies *prior to excitation* (*i.e., energies* corresponding to injected ions of *ca.* 3 eV) produce a poorly defined ion packet (figure 3). Owing to the extreme significance of the definition of the ion packet on ion detection, initial translational energy of ions trapped in an ICR cell is of profound importance.

Before FT-ICR analysis of high mass biomolecules can be considered as routine, *information as to the nature of trapping*, detection, and quantification of the technique must be understood. Preliminary *results from studies* performed on a system equipped with a two-section cell indicates that quenching of excess kinetic energy is important before a stable detection orbit can be achieved.

FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY OF METAL IONS GENERATED BY LASER DESORPTION IN AN EXTERNAL SOURCE

Robert R. Weller[a], Sahba Ghaderi[b], Othmar Vorburger[c] and Ben S. Freiser[a]

[a]Department of Chemistry, Purdue University, West Lafayette, IN 47907
[b]IBM General Products Division, San Jose, CA 95193
[c]Nicolet Instrument Corp., P.O. Box 4508, Madison, WI 53711

Fourier transform ion cyclotron resonance mass spectra have been obtained for metal ions generated by laser desorption in a source external to the ICR analyzer cell and high magnetic field. Prior work (1-4) has demonstrated the potential advantages of external ion generation and has thus far utilized SIMS, FAB, EI, and MPI sources. In contrast to these methods, LD generated ions required no acceleration or special ion optics to produce an ion signal comparable to that obtained using the conventional configuration where the ions are desorbed from a target inside or immediately adjacent to the analyzer cell. Metals that have been generated in the external source include Fe, Cr, Co, Cu, Pd, Rh, Pt, Au, La, and Al.

The experimental arrangement consists of an extension to the analyzer flange of a Nicolet FTMS-2000 dual cell FT-ICR to which a four way cross was connected. Metal samples were either mounted permanently on a screen in the external source or were mounted on the 45° beveled end of a solids probe (Figure 1). LD was accomplished using the focussed fundamental beam from a Nd:YAG laser.

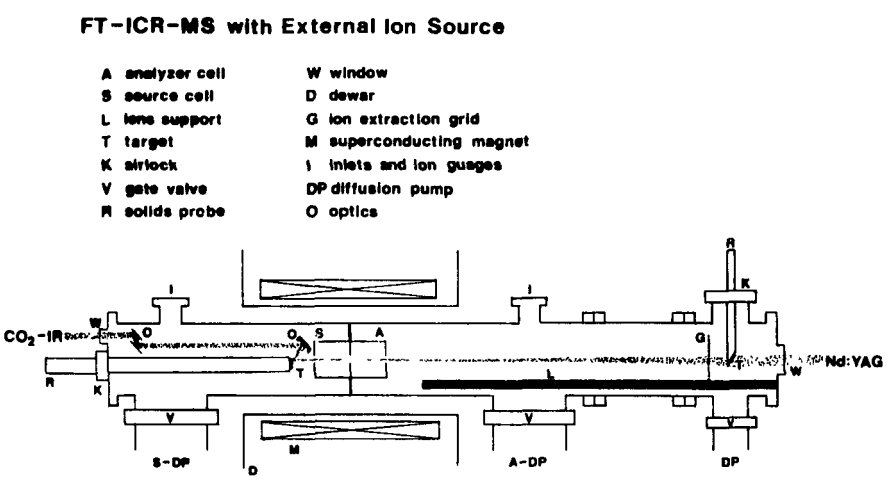

Figure 1.

The positive ions produced could be blocked from entering the analyzer cell with the application of a +35 V potential on a grid located just inward of the target. No signal was observed at the cell unless at least a 2.5 to 3 ms delay was placed between the laser pulse and the detect sequence, suggesting that the ions which have the proper energy spread to be trapped in the ICR cell are travelling a long (spiral?) slow path. Studies with a movable aperture show that the ions are focussed as expected by the magnetic field, but come from a broad source. For example, in contrast to the unrestricted 10 cm bore of the vacuum system, only 75% of the ions pass through a 5 cm diameter aperture located 10 cm from the target.

There are several advantages with being able to produce LD ions in an external source. First, the optics are very simple due to the short beam path once inside the vacuum chamber. Second, many studies of metal ion chemistry have had interferences due to background oxygen. Permanently mounted samples in the external source allow the system to be operated at base pressures (10^{-9}torr) since a solids probe does not have to be used. Third, the presence of two low pressure analyzer cells allows for more complex reaction schemes to be studied, e.g. LD metal ions are trapped and reacted in the source cell, product isolated and transferred back to the analyzer cell where further reactivity or photochemical studies can be undertaken.

Future work involves modifying the experimental arrangement so the laser plume is towards the analyzer cell. Also being developed is a Cs^+ source for SIMS studies. Further down the line the system will be greatly expanded with a cluster source patterned after that in ref. 3. All of these techniques combined with the advantages of FT-ICR-MS will greatly enhance the studies of the chemistry of metal ions.

FAST ATOM BOMBARDMENT COMBINED WITH FOURIER TRANSFORM MASS SPECTROMETRY

P. Grossmann, P. Caravatti, M. Allemann, H.P. Kellerhals
Spectrospin AG, Industriestrasse 26, 8117 Fällanden, Switzerland

Fast atom bomardment (FAB) uses a beam of high energy atoms (kilovolts energy), to desorb the sample from a liquid matrix. Typically glycerol or some other suitable liquid is used as a matrix, argon or xenon is used as fast atoms. FAB turned out to be very successful for many compounds which are intractable by the commonly used ionization modes electron impact (EI) and chemical ionization (CI). FAB produces quasi-molecular ions and significant fragment ions of many thermally labile and/or polar compounds. FAB-MS was therefore readily accepted and is nowadays routinely used in analytical mass spectrometry.

Fourier transform mass spectrometry (FTMS) has seen rapid developments during the last five years (1-3). Traditionally used and appreciated as one of the best methods for studying ion-molecule reactions, FTMS is nowadays more and more used as a reliable analytical method for structural elucidations. This is due to the well proven capability of FTMS for high resolution, exact mass determination and MS/MS-experiments.

The combination of FAB with FTMS provides therefore some attractive features for structural analysis. However, FTMS requires ultra high vacuum for high resolution (better than 10^{-8} mbar) and FAB is dependant on a large concentration of glycerol or a similar liquid resulting in a vapor pressure higher than 10^{-5} mbar. A direct coupling of FAB with FTMS is therefore not feasible.

One possibility of solving this pressure associated problem is to separate the ion generation and ion detection in space. We developed a differentially pumped, external ion source used for GC-FTMS (3) and presented in Figure 1. Ions are extracted from the ion source and transferred into the ICR-cell with 3 keV. The ions are decelerated shortly before entering the detection cell, are trapped within the cell and subsequently measured. In this work we removed the GC and mounted the FAB gun on the ion source. 7 keV argon atoms were used to produce the FAB-FTMS spectra. The pressure in the ion source was typically $2 \cdot 10^{-4}$ mbar, in the ICR cell about $5 \cdot 10^{-9}$ mbar. High resolution spectra of glycerol will be presented to demonstrate the resolving power of this FAB-FTMS-configuration. Resolutions of over 400'000 (for m/z 93) and 100'000 (for m/z 277) could be achieved. The FAB-FTMS spectrum of Leu-enkephalin is shown in Fig. 2. The protonated molecular ion (m/z 556) and sequence fragments like in classical FAB-MS are observed. Broad band and high resolution FAB-FTMS spectra of Tetra-Alanine will be presented to show the advantage of high resolution and the similarities with the classical FAB-mass spectrum.

High Precision Multipurpose Solid Sample Probe for Field Desorption Ion Cyclotron Resoonance Spectrometry

I. Pezsa, H. Knoll and K. P. Wanczek,
Inorganic Chemistry, NW 2, University of Bremen, D-28 Bremen 33,
and H. B. Linden,
Linden-ChroMasSpec, D-28 Bremen 61, West Germany

For the use with ultra high vacuum ion cyclotron resonance spectrometry a high precision multipurpose solid sample probe has been developed. The probe is suited for the use with high magnetic field ICR. The probe is introduced in the ultra high vacuum system with the aid of a differentially pumped vacuum lock, such that the probe tip is located directly in front of the ICR cell in the region of highest magnetic field. The probe has an exchangeable tip, where different kinds of targets, a sample evaporator, or a field desorption emitter can be fixed.

The Fourier transform ICR spectrometer utilized in the study is based on the Spectrospin CMS 47. It is equipped with a 7 Tesla magnet with 89 mm room temperature bore and a cylindrical ICR cell. The instrument is controlled by an Aspect 3 000 minicomputer. The ICR ultra high vacuum system is pumped by a 600 l/s diffusion pump, equipped with a liquid nitrogen baffle. The base pressure is below 10^{-9} mbar.

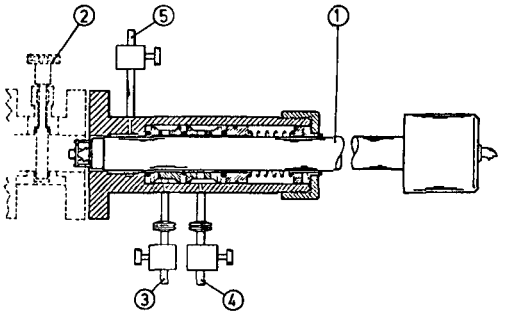

Fig. 1. Vacuum and pushrod arrangement.

In Fig.1 the vacuum and pushrod arrangement are shown. The pushrod (1) is prepared for the FD operational mode and shown in the withdrawn position with the gate valve (2) closed. The length of the pushrod is 1,000 mm, its diameter is 20 mm. It is manufactured from nonmagnetic stainless steel tube. The vacuum lock is differentially pumped. Vacuum lines (3) and (4) are connected with one two stage rotary pump, vacuum

line (5) with another. The down pumping time after introducing the pushrod in the vacuum lock is only a few seconds. Similarily, after opening the gate valve (2), a base pressure below 10^{-9} mbar necessary for ultra high resolution is reached in a few seconds. This is, in addition to the high pumping speed, mainly due to the elaborate arrangement of the sealing elements and the differential pumping system, and to the ultrahigh precision manufacturing of the pushrod surface. The dead volume of the vacum lock is very small. Surface roundness and unevenness are much better than 1 µm.
Vacuum lock and pushrod are developed in cooperation with and manufactured by Hanseatische Präzisions- und Orbit-Technik, Bremen, West Germany.
The probe has a relatively large diameter. This is of great advantage and does not cause any problem if utilized with an ICR spectrometer. The mechanical stability is great. The probe can be located reproducibly in front of the ICR cell with a deviation of less than 0.5 mm, only guided by the vacuum lock. The diameter of the tip is also larger than usual. Therefore four standard high voltage vacuum feedthroughs can be used. Potential differences of more than 12 kV can be generated between the feedthroughs and to ground. The probe tip is designed to fit various types of sample carriers, probe targets, and ionization systems. In the Fig. 2 the setup for field desorption is shown. The emitter (1) is held by two demountable supporting rods (2); (3) is the counter electrode, (4) is a shielding electrode.
Emitter and FD electronics are manufactured by Linden-ChroMasSpec, Bremen, West Germany.

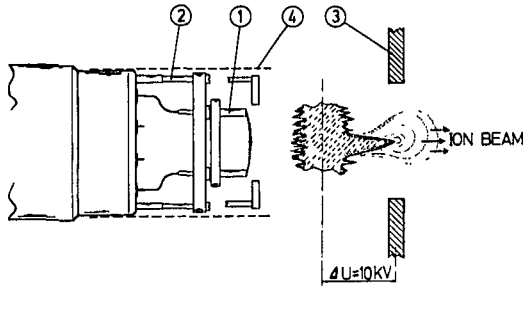

Fig. 2. Interchangeable probe tip with FD emitter.

The FD mode of operation is tested with several organic compounds and with cesium iodide.

DIRECT DETERMINATION OF SURFACTANTS ON TEXTILES BY LASER DESORPTION FOURIER TRANSFORM MASS SPECTROMETRY. M.P. Chiarelli[1], D.A. Peake[2], and M.L. Gross[1] [1]. Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588. [2]. Procter and Gamble Corporation, Cincinnati, Ohio 45217.

The purpose of these investigations is to determine if laser desorption can be applied to the analysis of surfactants on textiles. Laser desorption of mono- and dipeptides was shown to proceed independently of the sample support at sufficiently high laser power densities (1). Thus LD/FTMS should be well-suited for the direct analysis of surfactants on textiles.

All experiments were executed on a home-built FTMS interfaced to a Nicolet 1000 data system (2). The cloth to be analyzed was about 0.5 cm square and was stretched over a copper support with a teflon sleeve. Solutions were allowed to saturate the cotton cloth before analysis. The laser power densities employed throughout this study were in the range of 3-6 x 10^8 W/cm^2 at a wavelength of 266 nm, 1-3 x 10^9 W/cm^2 at 532 nm, and 5-10 x 10^9 W/cm^2 at 1064 nm.

Dimethyl-distearyl ammonium chloride was chosen for an initial demonstration because it is a surfactant normally found in detergents. Desorption was executed from a copper substrate and cloth to compare the working power density ranges over which spectra could be acquired for the two supports. The working range of the copper was larger than that of the cloth due to a larger sample thickness on the copper resulting from a smaller surface area. Spectra obtained from both supports were the same, showing ions resulting from methyl and stearyl losses in addition to a molecular ion. Detection limits were ca. 125 μg/gram cloth.

Homolog Mixture Determination: Next we wanted to determine if relative quantities of surfactants could be analyzed by LD/FTMS. A five component mixture of C_{10}-C_{14} sodium alkyl benzene sulfonates was utilized. The percent relative abundances of the $(M - Na)^-$ ions were assessed at 3 different wavelengths and energies from both cloth (Table I) and copper (Table II) supports. The LD ion distributions are compared to homolog distributions determined by GC/FID to judge accuracy. Laser desorption from the copper showed better sensitivity than LD from the cloth where no C_{14} homolog was observed in most determination. This is due to the difference in surface areas between the two supports as discussed above. Ion distributions from the cloth are more accurate than those obtained from the copper at 1064 nm. Sample depositions on the cloth is not preceeded by solvent evaporation as is the case for copper, where slight differences in solubility may cause discrimination in sample precipitation. Resonant desorption compared to LD at 1064 nm. This may be caused by slight differences in the homologs absorbtivities or the relative energies of the homologs' S_1 states.

Quantification Range Determination: Next we wanted to ascertain the range over which an analyte may be quanitated. Solutions of $C_{12}H_{25}SO_4Na$ and $C_{12}D_{25}SO_4Na$ were deposited on the cloth in different ratios and laser desorbed at a wavelength of 1064 nm. The ions observed were of the $(M - Na)^-$ and $(2M - Na)^-$ type, one of the latter being a mixed dimer. The theoretical, monomer, and total ion abundance ratios from LD are plotted against the ratio of the compounds on the cloth. The monomer ratio (m/z 290 and m/z 265) best approximates the theoretical one. The data indicates that the analyte may be detected in the mixed dimer, m/z 578, when present as low as 1:40 to the deuterated standard.

Strategy for Sequencing Oligopeptides Using Laser Desorption Fourier Transform Mass Spectrometry

Liub-Chii Yang and Charles L. Wilkins*
Department of Chemistry, University of California, Riverside, CA 92521

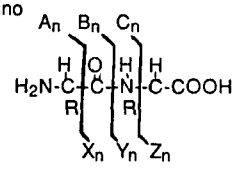
Introduction

Gramicidin D has been studied by Cody[1] and coworkers as well as Drochon[2]. Cody and coworkers[1] identified 12 of the 15 amino acids in Gramicidin D using laser desorption Fourier transform mass spectrometry (LD/FTMS) with Collision-Activated Dissociation (CAD). Drochon[2] identified all of the 15 amino acid residues in gramicidin D by using direct chemical ionization triple quadrupole mass spectrometry with CAD. Although Cody used only positive ion LD/FT mass spectra, several papers[4-7] suggest that complementary information can be obtained by concurrent consideration of negative ion spectra. That premise is explored in the research reported here, which investigates use of the complementary information derived from positive and negative ion LD/FT mass spectra and CAD as an oligopeptide sequence tool.

Results and Discussion

Strategy for Sequencing Linear Oligopeptides. Nomenclature used here is that proposed by Roepstorff[8]. Detailed procedures for sequencing oligopeptides by using both positive and negative ion LD/FT mass spectra obtained with CAD are as follows:

1. the molecular mass is determined by locating $[M+H]^+$, $[M-H]^-$, $[M+K]^+$, and $[M+Na]^+$ ions.
2. characteristic fragmentation patterns are used to identify particular amino acid residues. For example, if ions $[M+H-17]^+$, $[M+H-42]^+$, and $[M+H-60]^+$ are present, then the oligopeptide contains at least one arginine at the carboxylic acid terminus.
3. sequencing is begun by identifying corresponding series of ions in the positive and negative ion spectra. One series, $[Y_n+2H]^+$ and $[Y_n]^-$ ions, can be distinguished because the positive ions are 2 dalton higher than the corresponding negative ions.
4. the $[B_n]^+$ and $[B_n]^-$ series of ions are assigned. These ions have the same masses in both positive and negative ion spectra.



Because Y series ions indicate the oligopeptide sequence starting from the carboxyl terminus and the B series the sequence beginning with the N-terminus, the two will overlap. Thus, in most cases a complete sequence can be derived, even though neither series is necessarily complete.

Examples. Figures 1 (a) and (b) show the molecular mass region of the LD/FT mass spectra for gramicidin D. From the Y series of ions in the negative and positive ion spectra, the sequence can be read as 29-Val-Gly-Ala-Leu-Ala-Val-Val-Val-Trp-Leu-Trp----. The mass difference between the B_{max} ion and the molecular ion is 60 daltons. From the B series, the sequence can be read as 60-Trp-Leu-Trp-Leu-Trp-leu-Trp-Val-Val-Val-Ala-Leu----. Because a portion of the sequence in the Y series overlaps a portion of the B series sequence, the complete sequence can be read as 29-Val-Gly-Ala-Leu-Ala-Val-Val-Val-Trp-Leu-Trp-Leu-Trp-Leu-Trp-60. Mass spectra of cyclic oligopeptides do not display the same relationship between positive and negative ion spectra as linear oligopeptides. For example, the negative ion spectrum of gramicidin S reveals one partial sequence, 130-Leu-Orn-Val-Pro-Phe-Leu----. The positive ion spectrum displays another partial sequence Leu-Phe-Pro-Val-Orn-Leu-Phe----. Based upon the two sequences derived from the positive and negative ion spectra, a complete sequence, cyclo(Leu-Orn-Val-Pro-Phe-Leu-Orn-Val-Pro-Phe) can be proposed.

"Unknown"s. 18 "unknown" oligopeptides, selected and purchased by a third party and supplied to us as "blind" samples were examined to test the method. Correct structures were deduced for 14 of these. Using "unknown" A as an example, it is possible to distinguish lysine from glutamine by analyzing the negative ion spectrum. Glutamine loses 18 and 74 dalton fragments from

the deprotonated molecular ion, whereas lysine does not show such a fragmentation pattern. The triplet fragmentation pattern consisting of consecutive loss of two 18 dalton fragments from the Y series of ions is observed throughout the negative ion spectrum. After the loss of the first glutamine, only one peak corresponding to the loss of 18 daltons from the Y series of ions is observed. After the loss of the second glutamine, no peak corresponding to the loss of an 18 dalton fragment appears.

Conclusion

Use of both positive and negative ion laser desorption Fourier transform mass spectra for the analysis of oligopeptides has been demonstrated. For gramicidin D, all 15 amino acid residues were identified and the correct sequence deduced. By examining the relationships between the positive and negative ion spectra, it is possible to distinguish linear oligoeptides from cyclic oligoepeptides. Finally, complete structures of 14 of the 18 "unknown" oligopeptides were sucessfully determined using this method.

STORED WAVEFORM INVERSE FOURIER TRANSFORM EXCITATION: ANALYTICAL APPLICATIONS FOR FOURIER TRANSFORM MASS SPECTROMETRY

R. B. Cody*, S. D. Goodman, R. E. Hein, D. A. Weil
Nicolet Analytical Instruments
5225 Verona Rd., Madison, WI 53711

Stored waveform inverse Fourier transform (SWIFT) excitation [1-4] is a powerful method for controlling excitation, acceleration, and excitation of ions infrequency-based mass spectrometric techniques such as Fourier transform mass spectrometry (FTMS). In the SWIFT method, the operator defines the requested excitation spectrum in terms of desired resolutions, masses, and energies. Inverse Fourier transform methods are used to automatically design the time domain excitation waveform which will produce the desired effect.

SWIFT provides a number of benefits including simplified operation and increased control for all FTMS experiments, increased selectivity for excitation, improved selectivity for single- or multiple-ion-monitoring, and capabilities for performing very complex experiments such as Hadamard transform MS/MS [8].

One application of SWIFT involves increased parent ion selectivity in MS-MS experiments [4]. The resolution for excitation depends on the same factors as resolution for detection: increasing the excitation time increases the selectivity of ion excitation in the same way that increasing the observation time increases the resolution for ion detection. We have used a prototype SWIFT apparatus to separate the carbon 13 isotope from acridine from the molecular ion of 9-methylfluorene in an MS/MS experiment. For this example, a resolution of 10,000 is required to separate the parent ions. Much higher resolution is expected once heterodyne capabilities are implemented.

Isolation of trace components in complex mixtures is possible by using SWIFT even in the presence of interferences at the same nominal mass. A an example, we have isolated benzothiophene from butylbenzene in a petroleum fraction with added perfluorotributylamine (internal calibrant). Prior to ejection, the abundance of benzothiophene was only 0.2% (relative to the base peak at 69 u). SWIFT has also been used to obtain MS/MS and MS/MS/MS spectra for several major and minor components in an asphaltene sample.

By removing many of the variables associated with swept frequency excitation, ultrahigh resolution measurements over a narrow mass range are facilitated by using SWIFT. As an example, we collected ultrahigh resolution spectra for a complex petroleum distillate. Spectra were obtained at >100,000 resolution over a 3 u mass range about m/z 190 and a 10 u mass range about m/z 300 in the mixture.

Multiple ion monitoring provides increased selectivity by only exciting ions of interest. In addition, increased sensitivity is possible because ions can be excited to a higher orbit by using SWIFT than by using broadband chirp excitation [7]. As an example, high resolution multiple ion monitoring was used to detect characteristic ions from methyl stearate in the presence of background interferences.

LASER MICOPROBE FOURIER TRANSFORM MASS SPECTROMETRY: INSTRUMENTATION AND APPLICATIONS:

M. Pelletier, G. Krier, F. Tollitte, J. F. Muller; Laboratoire de Spectrometrie de Masse de Chimie Laser, Universite de Metz, Metz, Cedex, 01 France
D. Weil and M. Johnston, Nicolet Instrument Corporation, Madison, WI 53711 U. S. A.

Laser desorption/ionization was the first soft ionization method coupled to a Fourier transform mass spectrometer for the introduction of nonvolatile thermally labile compounds. Laser desorption/FTMS (LD/FTMS) was initially used to generate metal ions for metal ion chemistry studies, later as an alternative to FAB, and recently for surface analysis. Herein, we report preliminary data obtained on a modified Nicolet FTMS-2000. Three-dimensional sample manipulation, small laser spot size and viewing optics (Figure 1) have been added to the instrument.[1]

To reproducibly and precisely position a sample, an x, y, z sample-stage manipulator was constructed, using bimetallic materials which are unaffected by strong magnetic fields of 3.0 Tesla. The prototype manipulator has a maximum translational displacement of 5 mm and minimum x, y translational displacement of 6 microns. Z-axis manipulation allows maintenance of laser focus with variations in surface topography.

Laser desorption/ionization is performed using an excimer laser charged with KrF, (λ = 249 nm) with a pulse energy of 3.5 mJ delivered in 20 ns. The laser energy is controlled by an iris attenuator and measured with a photoelectric detector (Joulemeter) positioned after the iris. Energy at the sample surface is approximately 70 mJ with a power density of 2×10^9 W/cm^2. A 10.6 cm focal length quartz lens focuses the laser beam through the conductance limit, to a minimum 6 micron spot size diameter. The sample stage is illuminated by light transmitted by using a flexible polymer lightpipe. A magnified (20X) image of the sample stage is viewable through an endoscope.

The performance of the laser microprobe/FTMS was compared with results obtained using a laser microprobe Time-Of-Flight mass spectrometer.

A glass sample was analyzed in order to separate metal (rare earth) ions from metal oxide ions. The glass sample was prepared from mainly SiO_2 and PbO with 10% impurities: 2% chromium, 2% cobalt, 2% tin, 1% neodymium, 1% samarium, 1% europium and 1% gadolinium. To separate $^{142}NdO^+$ ions from $^{158}Gd^+$ ions, a resolution of 7,250 is required. Figure 2a shows the positive ion mass spectrum of the glass sample obtained by the TOF instrument. All of the rare earth impurities metal ions were observed, but poor mass resolution makes the separation of metal oxide ions from metal ions difficult. For comparison, Figure 2b was obtained with the FTMS at medium resolution. Partial ejection of Pb^+ enhances the detection of the rare earth ions. Figure 2c was obtained at high resolution >26,000 (FWHH) over a 35 Daltons mass range and the doublets at mass 158 and 160 can be identified as NdO^+ and Gd^+ (Figure 2d). Accurate mass measurements and an elemental composition program permitted the assignment of most peaks in the 142 - 176 Dalton mass range to a unique molecular species. For the remaining peaks, theoretical isotope abundances were used to eliminate one of the peaks. For example, at nominal mass 144: $^{144}Sm^+$ and $^{144}Nd^+$ are possible. From the theoretical isotope abundaces (11% and 88%), one can eliminate the $^{144}Sm^+$ ion.

As an additional test of the mass resolution for the microprobe FTMS, a nickel-chromium alloy with 2% of titanium was examined. With chromium and titanium in the same sample, a doublet consisting of $^{50}Cr^+$ and $^{50}Ti^+$ is present, requiring ~40,000 resolution for separation. This doublet was separated by the high resolving power of the FTMS instrument (Figure 3) with a measured resolution (FWHH) of > 100,000.

Surface profile analysis of integrated circuit chips requires high spatial resolution, small laser spot diameters and accurate sample positioning. To demonstrate the usefulness of the laser microprobe FTMS for such applications, positive and negative ion mass spectra were obtained from four separate components of a circuit chip. On the metallic part, doubly-charged tin was separable from singly-charged cobalt and nickel metal ions.

Conclusion:

The high mass resolution and mass accuracy of FTMS coupled with a prototype laser microprobe interface and sample introduction method demonstrate the usefulness of FTMS for surface characterization and the ability to eliminate mass spectral interferences.

THE APPLICATION OF NOVEL ION TRAP SCAN MODES FOR HIGH SENSITIVITY GC/MS

D.B. Tucker, C.H. Hameister, S.C. Bradshaw, D.J. Hoekman, and M. Weber-Grabau
Finnigan MAT, San Jose, California 95134

The quadrupole ion trap mass spectrometer has the capability to simultaneously store ions over a wide range of m/z values prior to analysis. A practical limitation exists, however, in the number of ions that can be mass analyzed with unit resolution. Excess ions create space charging within the trap volume, shielding some ions from the RF level that would normally expel them and thus degrading resolution (Figs. 1a-b). The application of two different scan modes, axial modulation and Selective Mass Storage, overcome this limitation.

The physical description and explanation of axial modulation is described elsewhere (1). Briefly, the technique involves the application of an AC voltage signal to the endcap electrodes of the ion trap analyzer assembly during the data acquisition phase of the scan function. Resolution is improved dramatically, allowing the use of much longer ionization times to improve sensitivity (Fig. 1c). A series of analyses of Peregrine falcon egg extract demonstrates the detection of pesticides and polychlorinated biphenyls (Figs. 2a-b). The amounts injected were quantitated with external standards to be 8.5 ng p,p'-DDE (43 ppm/dry sample), 35 pg trans-nonachlor (175 ppb), and 29 pg nonachlorobiphenyl (145 ppb). Background substracted spectra of these compounds are correctly identified in a search of the NBS library (Figs. 3a-b).

There are several significant advantages of axial modulation as applied to ion trap mass spectrometry. The most important, of course, is the order of magnitude improvement in sensitivity achieved while maintaining unit mass resolution. But further, as a result of improved ion statistics, quantitation at low levels is more accurate. Linear quantitation curves can be obtained down to the picogram level (Fig. 4a-b). Isotope ratio patterns are readily discernible against background noise, improving the comparison with the NBS library.

Normal full scan function of the ion trap utilizes only RF voltages to isolate and analyze ions. Selective Mass Storage involves the application of a DC pulse, momentarily operating the trap near the apex of the stability diagram (q=0.78 and a=0.15). As a result, only ions of a single m/z value remain stored in the trap to be mass analyzed in RF-only mode. The expulsion of the majority of ions prior to mass analysis greatly reduces space charging effects. In selective ion monitoring mode, this reduction allows the use of very long ionization times to accumulate ions of the desired mass to charge ratio. An example of this effect is seen in the chromatogram of 1 pg of hexachlorobenzene (Fig. 5). With SMS of the molecular ion (m/z=284), a signal-to-noise ratio of 50:1 is achieved.

Selective Mass Storage can also be used in chemical ionization experiments to isolate a particular reagent ion and expel any EI fragments prior to mass analysis. In this case, the DC pulse is applied after the ionization pulse but prior to the reaction period. The ions that are then mass analyzed are generated solely by reagent ion/analyte reactions.

Characterization of Tandem Mass Spectrometry in the Quadrupole Ion Trap

Jodie V. Johnson and Richard A. Yost
Chemistry Department, University of Florida
Gainesville, FL 32611

Tandem Mass Spectrometry (MS/MS) consists of five processes: (1) ionization of the sample, (2) mass selection of an ion characteristic of the analyte, (3) collisional activated dissociation (CAD) of this parent ion with neutral gas molecules or surfaces to produce daughter ions followed by (4) mass analysis and (5) detection of these daughter ions. Most of the applications of MS/MS to the determination of trace analytes have been performed with Tandem-in-Space instruments (e.g. triple quadrupoles) where the MS/MS processes occur in separate, distinct regions of the instrument. The ion trap mass spectrometer (ITMS) represents a new approach to instrumentation for MS/MS. With the ITMS, the MS/MS processes all occur sequentially in the same physical space, and thus, MS/MS is Tandem-in-Time. Here we report the results of the characterization of the different ITMS parameters which affect MS/MS, as well as evaluations of the MS/MS efficiencies and sensitivity.

Operation of the ITMS. The Finnigan MAT Ion Trap Mass Spectrometer is a quadrupole ion trap consisting of a ring electrode and two electrically connected end-cap electrodes. Application of a radio frequency (RF) voltage to the ring electrode of the quadrupole ion trap relative to the end caps creates a symmetrical three-dimensional quadrupole electric field within the electrode surfaces. When ions are created within this quadrupole field, they are either trapped or ejected depending upon the specific mass-to-charge ratio (m/z) of the ion and the applied field parameters (the magnitude and frequency of the RF voltage). Those ions which are trapped will obtain an oscillatory motion with a unique secular frequency which is again dependent upon an ion'z m/z and the applied field parameters. In order to perform MS/MS of a particular ion, all ions below the parent ion of interest are ejected from the ion trap. This parent ion is "tickled" by applying an auxillary AC (tickle) voltage to the end caps. When the frequency of the tickle voltage has the same frequency as the secular frequency of the parent ion of interest, that ion begins to resonate, increasing its kinetic energy and orbit and undergoing collision with the helium buffer gas present in the ion trap. Provided the magnitude of the tickle voltage is sufficient, the ion will undergo CAD to produce daughter ions.

Experimental. All experiments were performed on a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) operated at 100 °C with approximately 1 mtorr helium buffer gas under methane positive chemical ionization (PCI) conditions with approximately 2-3 X 10^{-5} torr methane. For studies on the effect of CAD parameters, diethylethylphosphonate (DEEP) was introduced via a Granville-Phillips fine metering valve to give a constant indicated pressure of approximately 0.1 X 10^{-5} torr. For the evaluation of MS/MS sensitivity, GC/methane PCI-MS/MS analyses were performed on a series of diisopropylmethylphosphonate (DIMP) in methanol standards of varying concentrations.

Results and Discussions. The methane PCI-CAD daughter spectrum of the $(M+H)^+$ ion of DEEP is characterized by daughter ions at m/z 65, 93, 111, and 139 (Figure 1). It was found that the efficiency of CAD is very dependent upon the frequency and magnitude of the tickle voltage and the time (CAD reaction time) for which it is applied. Variation of the tickle frequency demonstrated that the efficiency of CAD varied rapidly over a narrow range of frequencies with the maximum CAD occurring at the secular

frequency of the parent ion (Figure 2). Although the width of the tickle frequency band increased with increasing tickle voltage, it was possible to "tickle" the parent ion with unit mass resolution. It was also found that the length of the CAD reaction time and the magnitude of the tickle voltage required for the onset of CAD are inversely related. Following the onset of CAD, the amount of CAD increased with increasing tickle voltage and CAD reaction time (Figures 3 and 4). However, a maximum level of CAD was reached which was dependent upon the applied CAD parameters. With optimized CAD parameters, greater than 80% overall CAD efficiency could be obtained. The sensitivity of the ITMS was evaluated by the GC/PCI-MS/MS analyses of standard solutions of diisopropylmethylphosphonate (DIMP). A limit of detection of approximately 7 pg injected was obtained with a linear dynamic range of 3 orders of magnitude. It was possible to obtain full mass range daughter mass spectra of the $(M+H)^+$ ion on only 15 pg injected (Figure 5). The linear dynamic range was limited in the upper range by space charging. Space charging resulted in broadening of the ion profile and reduced CAD efficiencies due to a shift in the secular frequency of the parent ion to lower frequencies; thus, effectively reducing the coupling of the tickle voltage into resonating the parent ion.

COMPUTER SIMULATION OF ION TRAJECTORIES IN A QUADRUPOLE ION TRAP MASS SPECTROMETER

Randall E. Pedder and Richard A. Yost
Department of Chemistry, University of Florida
Gainesville, Florida 32611

Introduction. Ion motion in a quadrupole ion trap mass spectrometer (ITMS) is described by the Mathieu equation. BASIC computer programs were created which calculate the trajectory of an ion in an ion trap by solving a modified form of this equation using a Fourth order Runge-Kutta algorithm. These programs were compiled using Borland's Turbo BASIC on an IBM PC compatible

Theory. A modified form of the Mathieu equation is used to calculate the motion of an ion in the 'z' direction of an ITMS:

$$\frac{d^2z}{d\xi^2} + (a_z - 2\, q_z \cos 2\xi)z = (\, b_z \cos \alpha\, \xi\,)z$$

with 'a', 'q', 'b', and 'α' defined as follows:

$$a_z = \frac{-\,4eU}{mz_0^2\omega^2} \qquad q_z = \frac{-\,2eV}{mz_0^2\omega^2}$$

$$b_z = \frac{-\,4eV_t}{mz_0^2\omega^2} \qquad \alpha = 2\,\omega_t/\omega$$

where ξ is the phase of RF voltage, e is the charge on an electron, U is the applied DC voltage, V is the zero to peak RF voltage, m is the mass-to-charge-ratio of a given ion, ω is the angular frequency of the field applied to the ring electrode, z_0 is the trap radius in the z direction, V_t is the zero to peak tickle voltage, and ω_t is the tickle frequency.

This equation assumes the superposition of two hyperbolic fields: the field caused by the RF voltage applied to the ring electrode, and the field caused by the application of a tickle voltage to the endcap electrode. The right hand side of this perturbed Mathieu equation contains the term for tickle voltage; if no tickle voltage is applied, this equation reduces to the more traditional unperturbed Mathieu equation. The computer programs which use this equation assume that the tickle voltages applied to the two endcap electrodes are 180° out of phase.

Motion in the 'x' and 'y' directions are described by the traditional unperturbed Mathieu equation.

Resonant Excitation. When a tickle voltage is applied across the endcaps of an ITMS any ions whose secular frequency corresponds with the tickle frequency will resonate, increasing the magnitude of their excursions in the 'z' direction with a corresponding increase in acceleration and kinetic energy. Collisions of these energized ions result in Collisionally Activated Dissociation (CAD). The application of a tickle voltage is modeled by solving the perturbed Mathieu equation. While maximum kinetic energy (most energetic daughter spectra) is obtained while exciting an ion at its secular frequency, excitation at frequencies near this secular frequency also result in excitation. Figure 1 shows the resolution of resonant excitation from a daughter experiment performed on the molecular ion of n-butylbenzene (m/z 134) in a Finnigan MAT ITMS. Figure 2 shows the simulated final kinetic energy of an ion based on the same experimental conditions, resulting in similar peak shape and bandwidth when compared with the experimental data. Note that typical ITMS MS/MS experiments employ much lower voltages and longer tickle times, resulting in narrower bandwidths (higher resolution) than shown in this example.

Electron Energy. The trajectory of a 12.5 eV electron injected through an endcap into an ion trap mass spectrometer was modeled by solving the Mathieu equation of motion for this very light "ion". The electron trajectory is unstable (electrons are too light to be stored in an ITMS) but the electron has a brief but finite residence time in the ion trap (low nanosecond range). Only electrons injected when the ring RF voltage is positive

result in ionization (see Figure 3); during negative RF phases, the electron is repelled back toward the endcap electrode resulting in a very short residence time and low electron energy (less than 6eV). In Figure 4 it can be seen that electron energy in an ITMS is dependent upon the ionization RF voltage. When the Automatic Gain Control (AGC) software of the Finnigan MAT Ion Trap Data System is used, the average electron energy is about 54 eV. EI mass spectra obtained with this electron energy should be extremely similar to standard 70 eV EI mass spectra.

QUANTITATIVE EVALUATION OF ION INJECTION INTO A QUADRUPOLE ION TRAP

J.C. Schwartz and R.G. Cooks
Chemistry Department, Purdue University, W. Lafayette, IN 47907

M. Weber-Grabau and P.E. Kelley
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

The ion trap operated in the mass selective instability mode has proved to be a relatively simple, yet versatile instrument for mass spectrometric studies. Ionization traditionally takes place inside the trap by injecting ionizing electrons, and thus excludes the use of methods not compatible with internal ionization such as FAB, glow discharge, etc. Successful trapping of externally generated ions which are then injected into the ion trap allows many different ionization methods to be coupled with the quadrupole ion trap.

To study in detail the operating parameters and characteristics of the process of ion injection into an ion trap, a simple apparatus consisting of an external EI source, ion injection lens assembly, and a quadrupole ion trap was constructed (Figure 1)[1].

The SIMION program was used to investigate the ion optics of the entire system including the source, injection lens system, and trap end-cap electrode. The results confirmed that the injection lenses can indeed focus the ion beam into the trap as designed and that the middle injection lens can be used to gate the ions into the trap at the appropriate time (Figure 2). Ion currents were measured at various points in the system in order to determine transmission and trapping efficiencies. The transmission of the injection lens system was 9%. Overall intensity of spectra obtained by injection vs. ionization <u>in situ</u> was 4 %. Therefore an efficiency of trapping injected vs. internally formed ions of 44% is implied, with the transmission characteristics of the injection system limiting the sensitivity.

Mass spectra for both positive and negative ions after injection were recorded over a range of ion energies from 10 to 60 eV. Spectra for FC-43 and 1,1,2,-trichloroethane are shown in Figure 3. Background ion intensity observed in earlier experiments was eliminated and ion intensity improved by including a source magnet. Due to the high ion energies and high pressures, CID accompanies ion injection as evidenced by the low abundance of the m/z 219 fragment and the large m/z 131 ion abundance in the positive FC-43 spectra, and the large m/z 169 ion abundance in the negative ion spectrum of FC-43, determined to be a daughter of m/z 452 ion.

Several parameters were found to have dramatic effects on the trapping of injected ions. Argon ions were used to investigate these parameters. The gate lens potential behaves as the ion optics predicts for focussing different energy ions into the trap (Figure 4.). A damping gas (He) is <u>essential</u> for successful trapping of injected ions, while it only <u>improves</u> performance of the trap for ions formed within it (Figure 5).

The Rf level during injection is a very important parameter. If an ion oscillates at a subharmonic of the Rf frequency, it can gain energy from the Rf and be ejected from the trap causing a local minimum in the intensity vs. q curve. For example at a **q** of .635, the ion oscillates at exactly 1/4 the Rf frequency and therefore a drop in intensity is observed (Figure 6). In comparing these curves for different ion energies, one notices that the onset of successful trapping occurs at higher Rf values for higher ion energies (Figure 7). This is to be expected as the Rf amplitude determines the depth of the potential well formed inside the trap.

Preliminary computer modelling studies show successful trapping occurs only during a narrow range of phases of the Rf around the downward zero crossing of the Rf amplitude and that approximately 5 or more stabilizing collisions are required.

This work demonstrates that ion injection is a viable method of coupling an external ion source with the ion trap. It should be possible to use any type of ion source. Ample sensitivity is observed in ion injection spectra and the data is of comparable quality to normal ion trap spectra. Under the conditions used, CID occurs as a result of the injection process. Several parameters have profound effects on the injection spectra and must be optimized when performing ion injection.

COUPLING OF AN ATMOSPHERIC SAMPLING ION SOURCE WITH AN ION TRAP MASS SPECTROMETER

Keiji G. Asano, Gary L. Glish, and Scott A. McLuckey
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN

The Ion Trap Mass Spectrometer (ITMS) is characterized by a number of features that make it potentially useful as the MS/MS instrument in a device that analyzes for trace organics in air. Among these features are its high MS/MS efficiencies, relatively small size, ruggedness, capability for mass-selective storage, and flexibility in scan modes. The present approach to ionization in the ITMS, viz. formation of ions within the ion trap, is not, however, optimal for the direct sampling of ambient air. We have developed an atmospheric sampling glow discharge ionization (ASGDI) source that has proved to be very useful for real-time trace analysis of organics in air when coupled with a beam-type MS/MS instrument. We have therefore interfaced this ASGDI source with an ITMS. The success of this combination hinges on how well ions that issue from the ion source can be injected and trapped in the ITMS.

Figure 1 shows a schematic of the ASGDI source/ITMS combination. A three elememt lens situated between the ion source and the ion entrance end cap of the ITMS serves the dual role of facilitating the transport of ions to the ion trap and pulsing the ion beam. Two half-plates constitute the center element of the lens. When both half-plates are held at the same potential either positive or negative particles are injected into the ion trap. Charged particles are deflected from entering the ion trap by changing the voltage of one of the half-plates. An off-axis conversion dynode electron multiplier is used to detect the ions and to avoid background noise arising from photons that issue from the glow discharge.

Both positive and negative ions have been successfully injected from the ASGDI source and trapped in the ITMS. We have found that the efficiency with which positive ions are trapped increases rapidly with He background pressure as indicated in Figure 2. Total positive ion signal increases by a factor of 40 over the pressure range indicated. We have noted several ways in which positive ions can be observed in these studies. These include: electron ionization in the trap, positive ion injection, and charge transfer within the ion trap from injected ions to ambient neutrals. Products from electron ionization are observed at low background pressures where injected ions are not efficiently trapped. At higher pressures, the mass spectrum is dominated by injected ions. Charge transfer to organic neutrals in the ion trap is observed when large concentrations of reagent ions formed in the ion source are allowed to accumulate. Organic ions formed in the ion source unaugmented by ions from charge transfer in the ion trap can be observed by operating the ion trap so that reagent ions are not trapped.

Electrons are injected under the same conditions for negative ion injection resulting in electron ionization within the trap. The positive ions formed in the trap can rapidly neutralize injected anions if they are allowed to accumulate. This situation can be avoided either by operating

the trap so that ions of m/z<34 are not stored or by applying a DC voltage to the ring to reject positive ions. The total negative ion signal observed, like the positive ion signal, also increases with He background pressure but tends to level off at about 10 mtorr. In these preliminary studies we have been able to obtain mass spectra and MS/MS spectra from anions formed from low levels (ppb and less) of nitro compounds in periods of 1 s and less.

These studies indicate that positive and negative ions can be injected from a high pressure ion source and trapped in the ITMS with sufficient efficiency to be analytically useful. These preliminary results indicate that the ASGDI source/ITMS will be a powerful combination for determination of trace organics in air. It seems likely that optimization of the injection experiment and measures to better accommodate the high background pressures required for trapping will improve the performance of this combination.

NON-CHROMATOGRAPHIC APPLICATIONS OF ION TRAP MASS SPECTROMETRY

P. H. Hemberger, W. D. Spall, C. P. Leibman, and T. M. Cannon
Los Alamos National Laboratory
Los Alamos, NM 87545

Instrumentation based on the Finnigan Ion Trap Detector is being developed at Los Alamos National Laboratory for real-time, in situ point monitoring of (1) combustion products and (2) vapor phase sub-surface transport of volatile organics at chemical waste areas. The sensitivity of the ion trap detector was determined for a variety of compounds to assess its suitability for these applications. An exponential dilution method was used to determine the detection limits for trace organic vapors in air. This is a dynamic calibration where a known concentration of organic vapor in a calibrated volume is continuously diluted by a constant flow of air to the vessel. The concentration of organic vapor (C) at any time is $C=C_0 \exp[-(Ft/V)]$, where C_0 is the initial concentration, F is the flow rate of the diluent gas, t is the elapsed time of dilution, and V is the flask volume.

Two gas-sampling systems for the ion trap detector have been evaluated. The first is the direct sampling of gases at atmospheric pressure through a leak valve. The limits of detection for organic compounds using this method approach 1 part per million. For environmental monitoring, lower detection limits can be achieved by replacing the leak valve with a silicon membrane. This provides an enrichment of the organic vapors over permanent atmospheric gases with a concomitant lowering in detection limits. Detection limits with membrane sampling were typically in the low part-per-billion range. Operation of the membrane at elevated temperatures did not improve the overall sensitivity because the diffusion of permanent gases through the membrane was enhanced as the temperature was increased.

ANALYSIS OF PORPHYRINS USING AN ION TRAP MASS SPECTROMETER

Gary J. Van Berkel, Gary L. Glish, and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-8121

A major focus of our work with porphyrins is development of mass spectrometric analysis methods that provide more detailed structural information, and greater sensitivity and selectivity than obtainable from current mass spectrometric methods. We have found the ion trap mass spectrometer (ITMS) to be a promising tool in this effort due to its high sensitivity, multiple ionization modes, and MS^n capability. Using the ITMS, we have achieved a better understanding of the mass spectrometric behavior of porphyrins, thereby increasing the analytical utility of mass spectrometry for porphyrin analysis.

Electron ionization (EI) and chemical ionization (CI) in conjunction with multiple stages of mass analysis (i.e., MS^n, where $n \geq 2$) were investigated. The EI mass spectra obtained were very similar to those obtained on conventional instruments. For CI, common proton transfer reagent gases (CH_4, i-C_4H_{10}, and NH_3) and charge exchange reagent gases (N_2O and Ar) were used. In conventional CI, the mechanism of ionization and the extent of fragmentation can only be crudely controlled since several ions are often present to affect the mass spectrum. A particular reagent ion can be selected with the ITMS, however, allowing the mechanism and energetics of the ionization process to be more precisely controlled (Table 1). In conventional methane CI the major reagent ions present (CH_5^+ and $C_2H_5^+$) ionize the porphyrins <u>via</u> proton transfer and electron transfer respectively, complicating the molecular ion region of the spectrum. When CH_5^+ or $C_2H_5^+$ were selected to perform the ionization, the spectra were simplified producing only MH^+ or $M^{+\cdot}$, respectively. The degree of porphyrin fragmentation could be controlled by using charge exchange ionization via the recombination energy of the selected reagent ion. The ionization exothermicity was found to correlate with the degree of fragmentation.

MS/MS of porphyrin molecular ions and protonated molecules was used to determine the fragmentation pathways of alkylporphyrins (Figure 1). The MS/MS spectra contain a daughter ion characteristic of each substituent group of different mass on the macrocycle. The fragment characteristic of a particular substituent depends on the metallation state of the porphyrin and whether $M^{+\cdot}$ or MH^+ is analyzed. MS^n analysis was also used to investigate the nature of the substituent groups on the porphyrin macrocycle and the substituent group fragmentation pathways. MS^7 and MS^8 spectra were obtained.

The analytical utility of these ITMS techniques was demonstrated by the analysis of a complex vanadyl geoporphyrin mixture isolated from the New Albany Oil Shale Bitumen (Clark Co., IN). Using nitrous oxide (select $N_2O^{+\cdot}$) and ammonia (select NH_4^+) CI, the molecular ions and protonated molecules were produced, respectively, with no fragmentation (Figure 2a). The MS/MS spectra of each parent ion reveals the nature of the substituent groups on the porphyrins present at that mass (Figure 2b).

Selected reagent ion chemical ionization combined with multiple stages of mass analysis make the ITMS extremely useful for porphyrin identification, quantification, and structure determination. For example, "soft" ionization in combination with MS/MS could be of great utility in geoporphyrin mixture analysis. MS/MS spectra of all the porphyrins present in a mixture can provide a detailed substituent group "fingerprint" that might aid the use of porphyrins as biomarkers.

RAPID MICROORGANISM CHARACTERIZATION WITH PYROLYSIS, SHORT-COLUMN GC-ION TRAP MASS SPECTROMETRY

A. Peter Snyder
U.S. Army Chemical Research, Development and Engineering Center,
Aberdeen Proving Ground, Maryland 21010-5423

William H. McClennen and Henk L.C. Meuzelaar
Biomaterials Profiling Center, University of Utah,
Salt Lake City, Utah 84108

The analysis of complex compounds such as microorganisms is a formidable challenge, especially for the field of mass spectrometry (MS). The microbiological, medical and biotechnological communities have taken highly complex living systems and tailored the in-vivo/in situ experimental conditions to yield precise, yet trivial response characteristics, i.e., a go/no-go, present/absent or positive/negative analysis, expressed as a color (spectral) change as indicators of viability, process robustness and identification. Mass spectrometry, on the other hand, essentially uses abiological techniques in sample interrogation and must necessarily contend with analyzing parts and pieces of these large molecular weight entities. Lengthy extraction and derivatization of lipids from organisms with subsequent GC or GC/MS have provided an extensive database that accurately portrays their differentiation. Pyrolysis-short column GC-EI-ITMS is explored as a rapid (<6 min) and convenient means of producing information for generic and specific discrimination of microbes.

Microgram amounts of virulent (V) and low virulence (LV) B. anthracis (BA), B. licheniformis (BL) and F. tularensis (FT) were tested for strain response. The three species can be distinguished by a visual inspection of the TICs (Figure 1) and the latter part of each chromatogram was identified as the lipid TIC region. The microbiological literature attests to the diversity of lipid material in organisms, and extracted ion mass spectra were obtained (Figure 2) for a number of organisms including B. cereus (BC), B. thuringiensis (BT), B. subtilis (BS), L. pneumophila (LP), E. coli (EC) and S. aureus (SA). The mass spectral patterns are thought to represent the dehydrated diglyceride lipids. The possibility of discriminatory evidence between the virulent and low virulence strains of B. anthracis is noted in the reproducible differences associated with the extracted m/z 508, 522 and 536 mass spectra. This concept is of particular importance, and is a non-trivial exercise which requires a battery of plate growth and biochemical reaction tests for an accurate discrimination for virulence.

Figure 2 also shows distinct mass spectral differences as well as similarities within the Bacillus group, SA and Gram (-) organisms. Figure 3 presents a positive identification of the DNA/RNA nucleic acid and ATP adenine moiety, which is found in virtually all living systems, and is representative of all bacteria examined.

ANALYSIS OF FRAGRANCE MATERIALS USING AUTOMATIC REACTION CONTROL™ CHEMICAL IONIZATION ON THE ION TRAP DETECTOR™

P. R. Keller, G. J. Harvey and D. J. Foltz
The Procter and Gamble Company, Cincinnati, OH, 45241

Fragrances play an important role in the acceptance of many consumer products and thus, analytical characterization and quantitation of fragrance materials have become extremely important. Analytically, fragrances are challenging due to their complexity and the presence of numerous trace components. Chemical ionization has long been recognized as a useful tool for obtaining molecular weight information and selective/sensitive quantitation. For this application, the CI instrument should be capable of providing molecular weight information on trace components and quantitation of many components in a single GC run (i.e., good full scan sensitivity and dynamic range). With these considerations in mind, the chemical ionization capabilities (Automatic Reaction Control mode) of the Finnigan Ion Trap Detector (ITD) have been investigated for a number of common fragrance components.

Experimental

A 25 component perfume mixture was used to evaluate the CI capabilities of the ITD. The chromatographic separation was accomplished through the use of a 30 m DB–5 capillary column. The standard ITD open split interface was used throughout this work. Full scan data (100–300 Daltons) using the ARC CI scan function[1] was obtained for both qualitative (molecular weight determinations) and quantitative evaluations. Ammonia, isobutane and methane were all investigated as reagent gases. This perfume mixture was also analyzed on our Finnigan 4500 quadrupole mass spectrometer in order to obtain data for a direct comparison.

Molecular Weight Information

With the exception of one component, linalool, molecular weight information was obtained for each of the perfume components in the mixture with at least one of the reagent gases. High quality spectra were obtained in the low picogram range for most components. Linalool, a tertiary alcohol of molecular weight 154 Daltons, exhibited a major ion at m/z 137. This loss of water was also evident in the quadrupole CI spectra. Only ammonia CI on the quadrupole produced any ions with mass higher than the molecular weight (M+H, M+18, and M+35). In general, the CI spectra obtained on the ITD were similar to those obtained on our quadrupole MS (see Figure 1). The differences that were observed were in the areas of fragmentation and adduct ion formation. The ITD CI spectra exhibited somewhat more fragmentation than those obtained on our quadrupole. This increased fragmentation is likely due to the longer residence time (milliseconds vs. microseconds) for ions in the ITD vs. a beam instrument. With respect to adduct ions, the ITD spectra exhibited less adduct ion formation than our quadrupole. No methane adduct ions (M+29, M+41) were observed in any of the ITD spectra. However, ammonia CI did yield some adduct ion formation (M+18), although no higher adducts (M+35) were observed. It was generally observed that ammonia adducts were produced with molecules that were not stable to protonation.

Quantitation

The quantitative capabilities of ARC CI were evaluated by obtaining full scan data as above, followed by selected ion quantitation. Typically, the protonated molecular ion, an adduct ion, or the largest fragment ion was used for the quantitation. Isobutane was found to provide the best detection limits. This superiority is likely due to the minimal fragmentation induced by this reagent gas and the higher RF levels (i.e., higher trapping efficiencies) that are used with isobutane. Detection limits, using isobutane were in the 5 to 50 picogram range (injected). The linear dynamic range extends from the detection limits up to at least 100 nanograms, the highest level employed in

the experiment. This full scan sensitivity makes it possible to quantitate, at picogram levels, a large number of perfume components (20–60) in a single GC run.

TRACE ANALYSIS OF ORGANIC COMPOUNDS IN AQUEOUS SOLUTIONS USING A MEMBRANE PROBE AND A QUADRUPOLE ION TRAP

Anita K. Lister, R. Graham Cooks,
Purdue University
West Lafayette, IN 47907

Trace analysis of organic molecules directly from water poses many problems. Liquid chromatography/mass spectrometry and semipermeable membranes have been developed to allow fluid samples to be introduced into a mass spectrometer. Membrane probes have been interfaced to a triple quadrupole mass spectrometer for the analysis of organics in blood (1), for reaction monitoring and environmental analysis (2), and for off-line analysis of fermentation broths. Here, a membrane probe is interfaced to an Ion Trap Detector for the qualitative and quantitative analysis of organics directly from water.

Experimental:

A modified Finnigan 700 Ion Trap Detector (ITD) is used in this experiment (Figure 1). The software used is a special version of the standard ITD software supplied by the manufacturer.

Aqueous samples are introduced into the ITD through a simple membrane probe via the Granville-Phillips valve. The small amount of water which permeates the membrane is used as the chemical ionization reagent gas.

The membrane probe is constructed from Dow Corning silicon capillary tubing which is fashioned in a loop and sealed to a metal tube with vacuum epoxy (Figure 2). The probe is coupled to the ITD via a Granville-Phillips valve.

Results:

Ten organic compounds in the ppb to low ppm concentration range are analyzed directly from water. All solutions are analyzed with no sample preconcentration, and the most abundant ion in the $CI(H_2O)$ mass spectrum, typically $(M+H)^+$, is used for quantitation.

The detection limit for these compounds is established when the signal-to-noise ratio for the monitored ion is 2. Table 1 summarizes the monitored ion and the detection limit for each compound. Note that N,N-dimethylformamide is the only compound not detected in the concentration range of interest.

The linearity of the ion intensity over this concentration range is illustrated by the response curve of toluene (Figure 3). The rise time of most of the compounds is less than 60 seconds, and the fall times are generally less than 120 seconds (Table 2). Thus, analysis of a sample is complete within minutes.

Aqueous solutions of these compounds have also been analyzed using a triple quadrupole mass spectrometer. The chemical ionization mass spectra obtained on both instruments are similar.

One application of this technique is the analysis of mixtures. In two test mixtures containing three components, the response of each compound in the mixture appears to be unaffected by the presence of the other components. Table 3 summarizes the results of one of the mixtures.

Conclusion:

A membrane probe has been successfully interfaced to an ITD. The membrane/ITD combination is capable of rapidly detecting ppb levels of organics directly from water with no sample preconcentration.

REMEASUREMENT AND DETECTION OF HIGH MASS IONS IN FOURIER TRANSFORM MASS SPECTROMETRY

E. R. Williams, B. H. Wang, J. A. Loo, K. D. Henry,
and F. W. McLafferty
Chemistry Department, Cornell University, Ithaca, NY 14853-1301

Fourier transform mass spectrometry (FTMS) has numerous advantages in the analysis of larger molecules, including multichannel detection, high resolution, and extensive MS/MS capabilities. However, FTMS requires a minimum of about 10 ions to produce a detectable signal with a single measurement [1], a severe disadvantage over other detection methods, i.e., electron multipliers, capable of single ion detection. We now offer evidence for repeated FTMS measurements of the same ions resulting in substantial gains in sensitivity.

A 50 μCi ^{252}Cf source and a 60+ keV μMEVVA (MEtal-Vapor Vacuum Arc) SIMS gun in conjunction with a prototype FTMS-2000 provide continuous [2,3] and pulsed ion sources respectively [4]. Removal of the conductance limit and doubling the length of the cell improves the pumping capability but has negligible effect on sensitivity and resolution. However, elimination of the quench pulse can result in greater than 35 times increased signal for high mass ions measured with 40 scans (figure 1) and over 100 times with 800 scans. Collisional relaxation of large ions back to the center of their orbits makes these ions available for subsequent redetection. For gramicidin S (MW 1140.7) molecular ion species at 2 x 10^{-9} torr, the efficiency of relaxation is nearly 100% after approximately 180 sec. Higher pressures decrease the time necessary for relaxation; lower mass ions increase the relaxation time, consistent with the corresponding decreased collisional cross section. In addition, increasing the excitation power thereby increasing the ion orbit results in longer relaxation times. The high efficiency for ion relaxation is confirmed using a pulsed SIMS gun. Excitation of ions 2 times before the excite/detect sequence results in little loss of ion signal provided an adequate delay is allowed after both excite events to allow the ions to relax down to the center of their orbits.

Decreasing the system pressure through the use of an ion pump results in longer relaxation times and also longer RF transient lengths making possible high resolution measurements with plasma desorption (PD) (figure 2). The much shorter transients of large organic ions can provide useful mass spectral data by using special methods. In this regard the Hankel matrix singular value decomposition of Barkhuijsen and de Beer appears particularly promising.

CROSSED-BEAM STUDIES OF ENERGY TRANSFER IN LOW ENERGY ION-MOLECULE COLLISIONS

S. Howard, A. Shukla, K. Birkinshaw, J. Wang, and J. Futrell
Department of Chemistry, University of Delaware, Newark, DE 19716

The crossed molecular beam method was used to investigate energy transfer in ion molecule collisions. The measurement of angular scattering along with translational energy exchange in these systems provide detailed information on energy transfer during the collision. The basic mechanisms for energy transfer in low energy collisions have been a subject of debate for several years. The role of short-range repulsive interactions, transient complexes,[1] or the effects of a forced harmonic oscillator[2] are some of the possibilities for discussion. The reaction of oxygen ions with methane has received much study[1,3] as has the reaction of argon ions with nitrogen.[4]

Ion molecule reaction studies using well-defined beams are favorable for reaction dynamics investigations since they provide the possibility to examine the transfer of translational and internal energies in an elementary process. The basis for analyzing the dynamics of these studies lies in the expressions connected with conservation of energy, as discussed in more detail elsewhere.[5]

The crossed beam apparatus used in this study has been described in detail elsewhere.[6] Key features for present investigation include: a mass-selected ion beam decelerated to the chosen collision energy, a neutral beam generated by a supersonic expansion, and a detector capable of mass, energy and angular analysis.

Laboratory angular and energy distributions were taken at a series of angles from 0° to 90° for the product ion. These data were graphically transformed into Cartesian probability densities, $P_c(u_1,u_2,u_3)$, required to construct scattering diagrams.[7]

At energies near 1 eV, the scattering diagram for oxygen ions scattering from methane (Figure 1) shows that scattering is approaching the isotropic distribution predicted by the transient complex model by Ferguson et al.[1] This diagram is the first to our knowledge which has a neutral velocity greater than the ion velocity. The diagram suggests that the excited a $^4\Pi_u$ state contributes to the overall scattering in addition to the vibrationally excited (v = 2) ground state. Ground-state oxygen quite effectively transferred between 0.2 and 0.9 eV translational energy to methane.

The absence of signal at the location where product would be found from initially $O_2^+(X^2\Pi_g)$ could be interpreted as reaction competing effectively with energy transfer. If this reaction occurs, product ions of different mass would be formed (the second mass analyzer was set to transmit only m/e = 32 ions). Tanaka et al.[3] have shown that reactive channels can be vibrationally enhanced for this system.

The reaction of $Ar^+(^2P_{3/2})$ with oxygen at 2.2 eV CM as shown in Figure 2 shows that charge transfer can also transfer both electronic and vibrational energy. Product oxygen ions are formed both in highly vibrationally excited ground states and in electronically excited states. Charge transfer can, therefore, be very effective in transferring energy during ion molecule collisions.

The Kinetic Energy Dependences of the Rate Constants for the Reactions of O^- with CH_4, N_2O, and SO_2 at Several Temperatures: Deriving Rotational Energy Dependences

A.A. Viggiano, Robert A. Morris, John F. Paulson, and F. Dale
Air Force Geophysics Laboratory, Ionospheric Interactions Branch
Hanscom AFB MA 01731-5000

The kinetic energy dependences of the rate constants for the reactions of O^- with CH_4, N_2O, and SO_2 have been measured at several temperatures over the range 85-500 K. The main ionic products are OH^-, NO^-, and e^-, respectively. The rate constants were measured in a selected ion flow drift tube. A similar apparatus has been described in detail[1] and will not be discussed here.

Figures 1-3 show the kinetic energy dependences of the rate constants for the reactions of O^- with CH_4, N_2O, and SO_2, respectively. The reactions of O^- with N_2O and SO_2 show little dependence of the rate constant on temperature, although there are appreciable kinetic energy dependences. The reaction of O^- with CH_4 is in contrast to this behavior, and the rate constants show substantially different kinetic energy dependences at various temperatures.

The data can be used to derive rotational temperature dependences of the rate constants for the reactions. When a reaction involving a monatomic ion is studied in the drift tube, varying the electric field results only in changing the ion translational energy and therefore the center of mass kinetic energy (which depends both on the electric field and temperature). Thus, the translational energy dependence of the rate constant at a particular temperature of the reactant neutral is obtained. The temperature of the reactant neutral is equal to the bath gas temperature, defining the internal temperature of the neutral. For neutral species with vibrational modes not appreciably excited at the temperatures used in the experiment, the only significant internal energy is that of rotation. By comparing rate constants measured at a particular kinetic energy at several temperatures, we obtain the dependence of the rate constant on the rotational (or internal) temperature of the neutral.

The data in Fig. 1-3 indicate that, for the three reactions in this study, only for the reaction of O^- plus CH_4 does the rate constant have a substantial dependence on internal temperature of the reactant neutral . The other two reactions have rate constants that depend only slightly on the internal temperature of the reactant. The vibrational frequencies of CH_4 are sufficiently high that the CH_4 in our experiments is mainly in the ground vibrational state, and the internal energy dependence therefore corresponds to a purely rotational effect. The rotational temperature dependence of this reaction is shown in Fig. 4 at 0.06 and 0.25 eV center of mass kinetic energy. The temperature dependence of the rate constant for this reaction was found to be $T^{-0.56}$ at 0.06 eV and $T^{-0.40}$ at 0.25 eV. The rate constants vary by a factor of 2.7 and 2.0 over the temperature range 85 to 500 K at 0.06 and 0.25 eV, respectively. To the best of our knowledge these represent the first measurements of the dependence of an ion-molecule rate constant on the rotational temperature of the neutral.

RATE CONSTANTS FOR ION-MOLECULE REACTIONS OF ATMOSPERIC SULFUR COMPOUNDS

T.F. Thomas, Dept. of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110; A.A. Viggiano, F. Dale, J.F. Paulson, Air Force Geophysics Laboratory, Hanscom AFB, MA 01731

In an effort to better understand the role of sulfur-compounds in the ion chemistry of the stratosphere rate constants for 24 reactions have been measured on the Selected Ion Flow Tube at AFGL. Figure 1 shows typical-looking data in the atypical case of an endothermic reaction (presumably due to many SO_2^+ ions retaining their vibrational excitation during their passage down the SIFT). Table I shows the rate constants obtained at 298°K for some of charge transfer reactions studied (only the major product formed is shown).

Table I. Rate Constants for Charge Transfer.

Reaction	$10^{10} \times k_{exp}$ ($cm^3 \cdot s^{-1}$)	$10^{10} \times k_{lit}$ ($cm^3 \cdot s^{-1}$)	ΔH (ev)
$SO_2^+ + NO \rightarrow NO^+ + SO_2$	1.0	0.7[1]	-3.0
$SO_2^+ + NO_2 \rightarrow NO_2^+ + SO_2$	3.6	-----	-2.7
$OCS^+ + NO \rightarrow NO^+ + OCS$	1.0	0.7[2]	-1.9
$OCS^+ + NO_2 \rightarrow NO_2^+ + OCS$	1.6	-----	-1.6
$O_2^+ + OCS \rightarrow OCS^+ + O_2$	11.0	10.[3]	-0.9
$H_2O^+ + SO_2 \rightarrow SO_2^+ + H_2O$	28.	-----	-0.3
$SO_2 + H_2O \rightarrow H_2O^+ + SO_2$	12.	-----	+0.3

Figure 2 displays the dependence of our measured rate constants for charge transfer, relative to theoretical values calculated by the method of Su and Chesnavich,[4] upon the enthalpy of reaction (ΔH). The data suggest a near-resonance condition $0 \leq -\Delta H \leq 1$ev for efficient charge transfer, which is a special case of energy transfer from an electronically excited molecule.

Some of the results obtained for clustering reactions at 298°K are shown in Table II.

Table II. Rate Constants for Clustering Reactions.

Reaction	$10^{-16} \times N_{He}$ (cm^{-3})	$10^{27} \times k_{ter}$ ($cm^6 \cdot s^{-1}$)	$10^{10} \times \tau$ (s)
$SO_3^+ + H_2O \rightarrow H_2SO_4^+$	1.14-1.70	4.5	36
$SO_2^+ + SO_2 \rightarrow S_2O_4^+$	1.30	2.1	24
$SO^+ + SO_2 \rightarrow S_2O_3^+$	1.30	1.0	10.5
$OCS^+ + H_2O \rightarrow H_2CO_2S^+$	1.29-1.85	1.2	9.0

In Table II $k_{ter} = k_{exp}/N_{he}$ and τ is the calculated lifetime of the ion-neutral collision complex in the usual mechanism for a termolecular reaction.

EMPIRICAL AND *AB INITIO* ESTIMATES OF THE STABILITIES OF FLUORINE-CONTAINING CATIONS

Dion A. Stams,[a] T. Darrah Thomas,[b] Duncan C. MacLaren,[b] De Ji[b] and Thomas Hellman Morton[a]

[a]Department of Chemistry, University of California, Riverside, CA 92521
[b]Department of Chemistry, Oregon State University, Corvallis, OR 97331

Since its introduction in 1970,[1] the concept of the isodesmic process has been proved as a useful way to analyze *ab initio* calculations and to compare them with experiment. In 1977 Jolly and Gin introduced the method of equivalent cores, which is a fully empirical approach for extracting thermochemical information from isodesmic processes involving positive ions.[2] The metathesis shown in equation 1 represents a hypothetical reaction that corresponds to an isodesmic process. The experimental value for ΔH, based on the gas phase heats of formation of the reactants and products, is 68 kJ/mol, with an experimental uncertainty on the order of ±8 kJ/mol.

$$(CH_3)_2C{=}O \quad + \quad CH_3CHO \quad \rightarrow \quad (CH_3)_2C{=}O \quad + \quad CH_3CHF^+ \qquad (1)$$

The method of equivalent cores equates ΔH of equation 1 to that of equation 2 estimated from ESCA core ionization energies. Since the O_{1s} core ionization energy of acetone is reported to be 0.66 eV lower than that of acetaldehyde, the value of ΔE_{ESCA} for equation 2 is 64 kJ/mol.

$$(CH_3)_2CO^{\cdot+}(1s) + CH_3CHO \rightarrow (CH_3)_2CO + CH_3CHO^{\cdot+}(1s) \qquad (2)$$

The implicit assumptions of the method of equivalent cores include the following shortcoming, which should be viewed as a caveat to its application:

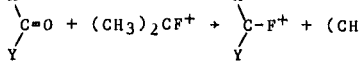
(i) The ion may have bond lengths and bond angles different from its isoelectronic, electrically uncharged analogue. For example, constraining the ions in equation 1 to the geometries of the corresponding carbonyl compounds may involve different energetic costs on the two sides of the equation.

Additional caveats that apply to the method of equivalent cores are not implicit in its underlying assumptions:

(ii) The ion may have a different conformational minimum than does its isoelectronic, electrically uncharged analogue;

(iii) Covalent or hydrogen bonds in the isoelectronic, electrically uncharged analogue may be absent in the ion (or vice-versa).

To examine these effects more deeply we have combined empirical and *ab initio* approaches for α-fluoro carbocations (equation 3) and fluoronium ions (equation 4).



$$\text{X,Y}{=}C{=}O + (CH_3)_2CF^+ \rightarrow \text{X,Y}{-}C{-}F^+ + (CH_3)_2C{=}O \qquad (3)$$

Equation 3 is a generalized example of equation 1 (the *ab initio* value for whose ΔH is 67 kJ/mol). Additional equivalent cores estimates for different choices of X and Y are given in the table. The *ab initio* changes in electronic energy are in good agreement with the empirical estimates, ΔE_{ESCA}.

$$R_1OR_2 + (CH_3)_2F^+ \rightarrow R_1F^+R_2 + (CH_3)_2O \qquad (4)$$

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Empirical (method of equivalent cores) and *ab initio* (6-31G**//6-31G**) estimates of energy changes (in kJ/mol) for equations 3 and 4.

Equation 3			*ab initio*	Equation 4			*ab initio*
X	Y	ΔE_{ESCA}	ΔE	R_1	R_2	ΔE_{ESCA}	ΔE
CH_3	H	+64	+67		$-CH_2CH_2-$	+24	+17
					$-CH_2CH_2CH_2-$	-53	-56
$-CH_2-$		+218	+238	CH_3	$CH_2=CH$	+38	+38
H_2N	H	-23	-39	CH_3	$CH_2=CCH_3$	+22	+7
					$-CH(CH_3)CH_2^-$	-16	-91
CH_3	Cl	+107	+101	$CH_2=CHCH_2$	H	+16	-86

Dialkyl fluoronium ions, $F_1FR_2^+$, can be expected to manifest substantial distortions relative to their isoelectric oxygen analogues. As we have previously discussed,[3] the two bonds to fluorine often have widely different heterolytic dissociation energies when $R_1 \neq R_2$. Only when $R_1 = R_2$ or when the two C-F bond strengths happen to be nearly the same should agreement between equivalent cores and *ab initio* estimates be anticipated.

For equation 4 the *ab initio* ΔE is within experimental uncertainty of ΔE_{ESCA} for oxirane and oxetane and their isoelectronic fluoronium ions, fluoriranium and fluoretanium. All are calculated to have symmetrical, planar geometries (even though no such constraints were imposed upon the geometry optimization). For methyl vinylfluoronium ions the heterolytic C-F bond dissociation energies are close to one another. Equivalent cores and *ab initio* estimates are in good agreement here, as well. The conformational minima for the methyl vinyl ethers (planar *s*-cis geometry) correspond to local maxima for the isoelectronic dialkyl fluoronium ions. The conformational energy barriers are not large, however, and it is not surprising that caveat ii does not lead to a large discrepancy in these instances.

In the last two cases summarized in the table, bond distortions are severe enough to correspond to caveat iii. The fluoronium ion that is isoelectronic to propylene oxide (which was calculated to possess a stable bridged geometry at 3-21G[3]) adopts a planar, acyclic *s*-cis conformation when the geometry is optimized using Hartree-Fock calculations with the 6-31G** basis set. Therefore ΔE_{ESCA} underestimates the stability of $CH_3CH^+CH_2F$ by 75 kJ/mol relative to the *ab initio* computation. A similar distortion is seen in the fluoronium ion that is isoelectronic with allyl alcohol. Here the fluoronium ion becomes an ion-molecule complex of allyl cation plus hydrogen fluoride, which is calculated to be >100 kJ/mol more stable than estimated by ΔE_{ESCA}. The discrepancies between empirical and *ab initio* estimates due to caveat iii can therefore be quite large.

THERMOCHEMISTRY AND GAS-PHASE ION/MOLECULE REACTIONS OF BOROHYDRIDE IONS

Derek B. Workman and Robert R. Squires
Department of Chemistry, Purdue University, West Lafayette, IN 47907

The properties and reactivity of borohydride negative ions have been investigated with a flowing afterglow - triple quadrupole apparatus.[1] Borohydride ion (BH_4^-), substituted borohydride ions (XBH_3^- and HBR_3^-), and polyborohydride cluster ions (ie., $B_2H_7^-$, $B_3H_8^-$, etc.) are generated in a helium flow reactor at 298K, 0.4 torr by ion/molecule reactions with the volatile borane complex Me_2S^+-BH_3^- ("BMS") (eq 1), or by hydride transfer to neutral boranes (eq 2). Trimethoxyborohydride ($HB(OMe)_3^-$) can be

$$(1) \qquad X^- \xrightarrow{BMS} XBH_3^- \xrightarrow{BMS} BH_4^- \xrightarrow{BMS} B_2H_7^-,\ B_3H_8^- \ldots$$

$$(2) \qquad H^- \xrightarrow{BuSiH_3} BuSiH_4^- \xrightarrow{BEt_3} HBEt_3^-$$

produced from the sequence of ion/molecule reactions accompanying direct electron ionization of $B(OMe)_3$ (eq 3).

$$(3) \qquad B(OMe)_3 \xrightarrow{e^-} (CH_3O^-)^* \xrightarrow{B(OMe)_3} HB(OMe)_3^- + CH_2O$$

The BH_4^- and $B_2H_7^-$ ions, and most all of the substituted borohydride ions are completely unreactive in the presence of simple aliphatic carbonyl compounds[2], substituted olefins, CO_2 and other potential H^- acceptor reagents. Neither H^- transfer nor adduct formation can be observed. Furthermore, reactions between neutral, monomeric boranes such as BEt_3 or $B(OMe)_3$ and potential hydride donor anions such as CH_3O^-[3] and c-$C_6H_7^-$[4] produce mainly or exclusively the corresponding adduct ions by efficient termolecular association. This behavior precludes the use of conventional ion/molecule equilibrium and bracketing experiments for determining the relative hydride affinities (HA) of neutral boranes under flowing afterglow conditions. However, we have found that endothermic hydride transfer reactions between mass-selected, translationally-excited borohydride ions and CO_2 (HA = 51.6 ± 2.5 kcal/mol)[5] can be observed in the triple quadrupole collision cell. From careful analysis of the energy thresholds for appearance of HCO_2^-, estimates of hydride binding energies of the borohydride reactant ions can be obtained.

Table 1 presents a summary of the resulting thermochemical data for five borohydride ions. The apparent differences are consistent with expected substituent effects,[6] high-level ab initio calculations,[7] and the known reducing activities of these species in solution.[8]

The hydride affinities of simple aliphatic ketones and aldehydes are ca 30-40 kcal/mol less than HA(BH_3) = 74.2 kcal/mol.[5] Thus, H^- transfer from BH_4^- to these compounds is strongly endothermic. The well-known facility with which borohydride reagents reduce ketones in alcohol solution suggests a pivotal role of the solvent and (alkali metal) counter-ion in the reduction mechanism. We have examined the effects of partial solvation of BH_4^- on its reactions with simple ketones in the gas phase. Solvated borohydride ions can be formed in the flow reactor by termolecular association of BH_4^- with H_2O, alcohols, and carboxylic acids (eq 4). The

$$(4) \qquad BH_4^- + HX \xrightarrow[\text{[He]}]{} BH_4^-(HX)$$

$$HX = H_2O,\ MeOH,\ CH_3CO_2H \quad \text{etc.}$$

$BH_4^-(MeOH)$ cluster ion reacts with acetone to yield an apparent switching product (eq 5) The observed reactivity of this product ion clearly shows

$$(5) \qquad BH_4^-(MeOH) + (CH_3)_2CO \longrightarrow BH_4^-((CH_3)_2CO) + MeOH$$

it to be a simple electrostatically-bonded cluster ion, rather than the lower energy $^iPrOBH_3^-$ form in which reduction of the ketone has occurred. We therefore conclude that one alcohol solvent molecule is insufficient to catalyze the strongly exothermic addition of the borohydride ion to the carbonyl group.

TEMPERATURE AND METHYL H3/D3 ISOTOPE EFFECTS ON THE ENTHALPY AND ENTROPY CHANGES OF METHYLATED ACETONE ONTO ACETONE AND DIMETHYL ETHER.

J.E. SZULEJKO AND T.B. McMAHON
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF WATERLOO, WATERLOO, ONTARIO, CANADA. N2L 3G1

EQUILIBRIUM ISOTOPE EFFECTS [EIE] HAVE BEEN OBSERVED FOR IONS IN SOLUTION [1] AND IN THE GAS PHASE [2-4.] MOST OF THE PREVIOUSLY REPORTED WORK WAS OBTAINED BY ICR MS [2,3]. SOME EIE HAS BEEN OBTAINED BY PULSED ELECTRON BEAM HIGH PRESSURE MASS SPECTROMETRY [HPMS] [4.] LITTLE OR NO TERMOLECULAR ION CLUSTERING EIE HAS BEEN REPORTED BY HPMS.

THE EXPERIMENTS WERE CONDUCTED ON A HPMS [5]. TYPICAL SAMPLE COMPOSITIONS USED WERE; (A) CH4 (OR N2) 700 τ, CH3Cl (OR CH3F) 5-15 τ, ACETONE 0.5-10 τ AND DIMETHYL ETHER 5-200 τ; OR (B) CH4 700τ, ACETONE 1-50 τ AND 2,2 DIMETHOXYPROPANE 2-5 τ.

THE FOLLOWING CLUSTERING REACTIONS WERE STUDIED AND THE DATA SUMMARIZED IN TABLE 1. Van't HOFF PLOTS ARE SHOWN IN FIGS 1 AND 2 FOR REACTIONS (1) IN FIG1; AND (5), (6), (7) IN FIG.2.

(CH3)2COCH3+ + (CH3)2CO		(1)
(CH3)2COCH3+ + (CH3)2CO		(2)
(CD3)2COCH3+ + (CD3)2CO		(3)
(CH3)2COCD3+ + (CH3)2CO		(4)
(CH3)2COCH3+ + (CH3)2O		(5)
(CD3)2COCH3+ + (CH3)2O		(6)
(CH3)2COCH3+ + (CD3)2O		(7)
(CH3)2COCH3+ + CH3OCD3		(8)

TWO SALIENT FEATURES ARE READILY OBSERVED FROM THE van't HOFF PLOTS; (1) SIGNIFICANT EIE AT LOW TEMPERATURES WITH LARGE ΔH AND ΔS AND AT HIGHER TEMPERATURES SMALLER ΔH AND ΔS VALUES. THE TWO LINES CROSSED AT Tc WHICH IS DETERMINED WHEN ΔG FOR THE TWO ISOMERIC CLUSTER IONS BECOME EQUAL. THE HIGH TEMPERATURE REGION HAS LITTLE EIE EXCEPT FOR (7). THE 2 ISOMERIC FORMS ARE PROPOSED TO HAVE (1) A COVALENTLY BONDED CLOSELY PACKED CONGESTED STRUCTURE AS REVEALED BY SPACE FILLING MODELS WITH MOST OF THE INTERNAL ROTORS SEVERELY RESTRICTED [6] AND THE OTHER (2) IS A LOOSELY BOUND CH3+ BRIDGED STRUCTURE [7]. THE EIE CAN BE RATIONALIZED IN TERMS OF THE GREATER ROTATIONAL ENTROPY OF A -CD3 OVER A -CH3 ROTORS (CIRCA 0.8 EU). THE ΔS OBSERVED WITH ACETONE AS THE NEUTRAL IS MUCH LESS THAN FOR DIMETHYL ETHER DUE TO A LESS CONGESTED FORM.

IN CONCLUSION, IT HAS BEEN DEMONSTRATED BY HPMS, TERMOLECULAR CLUSTERING EIE AND ISOMER DIFFERENTIATION. THE C2H5+ + H2 CLUSTERING (BY HPMS) HAS 2 ISOMERS [8].

GAS-PHASE ACIDITIES FROM ENDOTHERMIC REACTIONS

Susan T. Graul and Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN

The gas-phase acidity of a compound is defined as the heat of reaction H (or free energy G) for deprotonation (eq.1). This fundamental property is

$$RH \quad R^- + H^+ \quad H_{acid}(RH) \tag{1}$$

useful index of reactivity and has been measured for a variety of species. Well-established experimental techniques for determining acidities include bimolecular ion/molecule proton transfer equilibrium measurements or acidity bracketing and collision-induced dissociation (CID) of cluster ions, as well as electron affinity measurements (corresponding to R^-). Although these methods are widely applicable, there are certain limitations that restrict their usage. For example, proton transfer reactions are selective for the most acidic proton in the substrate. Moreover, the most basic of the readily available reagent anions is H_2N^- ($H_{acid}(NH_3)$ = 403.6 kcal/mol), but even this anion fails at thermal energy to deprotonate weak acids such as ethylene and cyclopropane. Thus, it is a worthwhile endeavor to develop experimental techniques that provide data for a specific proton in a given substrate, and that can be applied to even the weakest acids.

We recently introduced a method that allowed us to estimate gas-phase acidities for specific protons in a substrate(1). The acidity is derived by way of a simple thermochemical cycle from an experimental threshold energy for a decarboxylation reaction leading to the anion of interest (eq. 2).

$$RCO_2^- \quad R^- + CO_2 \tag{2}$$

$$H_{acid}(RH) = E_T + H_f(RCO_2H) - H_f(RH) - H_f(CO_2) + H_{acid}(RCO_2H) \tag{3}$$

We have applied this method to a number of anions with known proton affinities (note $PA(R^-) = H_{acid}(RH)$), and found in most cases very good agreement with accepted literature values(1). In the course of these studies, we had occasion to observe that the anions formed by decarboxylation of RCO_2^- could also be generated by CID of the appropriate alkoxide anion, e.g., RCH_2O^- (eq. 4).

$$RCH_2O^- \quad CID \quad R^- + CH_2O \tag{4}$$

Therefore, we undertook to extend the methods to estimate proton affinities for several previously unknown anions.

Our experiments are carried out in a flowing afterglow-triple quadrupole instrument. The precursor anion is generated by ion/molecule reactions in the flow tube and mass-selected at the first quadrupole (Q1). CID is effected in the second quadrupole (Q2) at single-collision conditions. By monitoring the intensity of a given fragment ion as a function of collision energy, we obtain a first-order estimate for the appearance energy of that fragment. This value is corrected for Doppler broadening due to thermal motion of the target gas to give our final CID threshold energy.

As an example of these techniques, we have observed the methyl anion CH_3^- resulting from CID of $CH_3CO_2^-$, $CH_3CH_2O^-$, $(CH_3)_2CHO^-$, and $(CH_3)_3CO^-$. Table I lists the observed threshold energies for these species and the resulting acidity for methane. The average value (417 kcal/mol) is in excellent agreement with the established literature value of 416.6 kcal/mol (2). We have estimated acidities for several other species; these results are shown in Table II.

We have augmented these activated unimolecular reactions with bimolecular reactions. One of these methods is a proton transfer reaction,

and like the thermal energy proton transfers, this method is selective for the most acidic proton. However, unlike the thermal energy counterparts, the technique is not limited to species that are more acidic than NH_3. This limitation is removed by balancing the energy deficit with kinetic energy. The reference base B^- is generated in the flow tube and accelerated into Q2 where it collides with and can deprotonate the reactive collision gas AH. By monitoring the intensity of A^- as a function of the collision energy, an appearance energy is obtained that can be related to the acidity of AH:

$$H_{acid}(AH) = H_{acid}(BH) + E_T \quad (5)$$

This method was applied to measuring the acidity of ethylene and methyl fluoride and yielded values of $H_{acid}(C_2H_4) = 406 \pm 2$ kcal/mol and $H_{acid}(CH_3F) = 407 \pm 3$ kcal/mol, in good agreement with values derived from decarboxylation thresholds and from CID of alkoxides.

The second bimolecular reaction is related to a method developed by DePuy, Bierbaum, and Damrauer (3) for estimating gas-phase acidities, in which the branching ratio for loss of CH_4 and RH from the addition/elimination reaction of OH^- with $RSiMe_3$ was correlated to the relative acidities. We used vinyltrimethylsilane as the collision gas, and Cl^- generated in the flow tube was accelerated into the collision chamber. Both CH_3^- and $C_2H_3^-$ can be detected, but their appearance energies are significantly higher (by 0.5 to 1.5 eV) than would be expected on the basis of simple thermochemistry. Moreover, the yield is low and the ion signals are weak, making accurate measurements difficult. Analogous reactions with other nucleophiles and silanes (e.g., CH_3O^- with Me_3SiPh) were attempted, but the energetics of displacement did not reflect thermochemistry. When the adduct of F^- with vinyltrimethylsilane is formed in the flow tube and subjected to CID, fragmentation results in loss of CH_4 and C_2H_4 and formation of $C_2H_3^-$. The $H_{acid}(C_2H_4)$ derived from the threshold energy for $C_2H_3^-$ is in fair agreement with our other measurements, although it is lower than expected. These silane-based methods proved more difficult to implement than the others discussed here due to low signal intensities.

Π-BOND STRENGTHS IN FLUORO, METHYL SILAETHYLENES

C.E. Allison and T.B. McMahon.
Department of Chemistry, University of Waterloo.
Waterloo, Ontario, CANADA N2L 3G1.

The strength of the Si=C double bond (E(Π)) in substituted silaethylenes has been investigated using Fourier transform ion cyclotron resonance (Spectrospin CMS-47). Proton transfer and fluoride transfer reactions from appropriately substituted silane precursors yielded proton affinities, fluoride affinities and the Π-bond strengths for the silaethylenes I, II and III.

Previous estimates of E(Π) in I have ranged from 38 kcal mol^{-1} (ICR bracketing) **[1]** to 47 kcal mol^{-1} (*ab-initio* calculation) **[2]**. Using the proton affinities measured in this work for I, II and III (Table) and other thermochemical quantities, E(Π) for I, II and III were calculated to be 43, 68 and 54 kcal mol^{-1} respectively (see Schemes). Using the fluoride affinities (Table), values of 51, 57 and 63 kcal mol^{-1} were obtained for E(Π). The disagreement between E(Π) obtained using the two approaches can be rationalized using a new value for the Si-F bond strength (134 kcal mol^{-1} - required in the calculation of E(Π) using the measured fluoride affinities - literature : 142 kcal mol^{-1} **[3]**) to give 43, 49 and 55 kcal mol^{-1} for I, II and III respectively. The two approaches then agree for I and III but provide vastly different estimates for the value of E(Π) in II.

Ab-initio calculations **[4]** indicate I and III are more stable than the isomeric silylene structures (Ia and IIIa) by 12 kcal mol^{-1} and by 37 kcal mol^{-1}, whereas II is 55 kcal mol-1 more stable then the methyl, fluoromethyl silylene (IIa), but 5 kcal mol^{-1} <u>less</u> stable than the fluoro, ethyl silylene (IIb). This arises from the stabilizing effects of both methyl and fluoro at the silicon and carbon centres **[5]**. Both groups have stabilizing effects, but the effects due to having fluorine on silicon and methyl at the carbon stabilizes the fluoro, ethyl silylene to a greater extent. (Methyl on silicon and fluorine on carbon destabilizes the silylene.) Where the substitution is for the same species (I and III) the stabilization is greatest for the silaethylene isomer. This indicates that the disagreement between the two approaches to E(Π) for II arises from the stability of the silylene isomer IIb. The proton affinity measured for II is thus that of the more stable species - the silylene. Using this information it is possible to estimate the proton affinity for II by using the value of E(Π) calculated from the fluoride affinity measurements. This gives a revised value of **206** kcal mol^{-1} for the proton affinity of II.

Structural Factors That Effect The Extent Of Deuterium Exchange When Using ND_3 As A CI Reagent Gas:

Killmer,L. SK&F R&D Laboratories, King of Prussia, PA 19406-0939

Introduction:

For most organic compounds, ND_3/CI/MS is an easy and unambiguous technique for determining the number of exchangeable (active) hydrogens. ND_3/CI/MS can also be used to support the proposed structures of unknowns and fragment ion assignments.

Theory:

H/D exchanges results from the collisions of the sample ions with the ND_3 reagent gas neutrals in the CI ion source. At typical ND_3/CI source pressures, each sample ion undergoes several hundred collisions before exiting the ion source. Multiple collisions between sample molecules and ND_3 reagent gas ions are highly unlikely due to their relatively low concentration in the ion source. $[M+D]^+$ and $[M+ND4]^+$ are the typical molecular ion species observed when using ND_3 as the CI reagent gas.

Experimental Conditions:

All of the mass spectra were obtained using either a Finnigan/MAT model 3625 or 4610 quadrupole mass spectrometer. The ND_3 (99.5%) was purchased from Cambridge Isotope Laboratories (CIL) Woburn,MA 01801. The source pressure was 450-475 microns and was measured using a Datameterics Model 1400 Barocel manometer. The source temperature was 150-175° C. All of the mass spectra were generated using a DCI or direct probe. When determining the number of active hydrogens in organic compounds it is critical to evaluate the compound first using NH_3 , then using ND_3. This technique makes determining the number of exchangeable hydrogens and fragment ion structure assignments an easier task.

Results:

1. Polyhydric Aromatic Compounds:

Hydroxyl groups are strongly activating ortho para directors. Aromatic ring hydrogens can be exchanged if they are activated by more then one OH group. Table #1 lists the number of exchangeable hydrogens for a series of aromatic diols and triols.

TABLE #1

COMPOUND	ACTIVE HYDROGENS	DEUTERIUM EXCHANGES
Catechol(1,2)	2-OH	2D (100.0%)
Resorcinol(1,3)	2-OH	2D (100.0%)
Hydroquinone(1,4)	2-OH	2D (100.0%)
Pyrogallol(1,2,3)	3-OH	3D (100.0%)
Hydroxyhydroquinone	3-OH	3D (77.6%)
(1,2,5)	1-H	4D (22.4%)
Phloroglucinol(1,3,5)	3-OH	3D (11.6%)
	3-H	4D (19.0%)
		5D (28.4%)
		6D (52.6%)

Note: In the case of phloroglucinol, each of the ring hydrogens are activated by all three OH groups.

Polyhydric aromatic compounds are the most difficult class of compounds to determine the number of exchangeable hydrogens when using ND_3. Catechin provides an example of the problems that one can encounter with polyhydric aromatic compounds. Catechin has 5 OH groups but exchanged 7 rather then 5 deuteriums since two of the aromatic ring hydrogens were also exchanged.

2. Polyamino Aromatic Compounds:

   Like OH groups, NH_2 groups are strongly activating ortho para directors. If an aromatic ring hydrogen is activated by more then one NH_2 group it can be exchanged. Table #2 details the extent of deuterium exchange for a group of di and triamino benzenes and aminophenols.

TABLE #2

COMPOUND	ACTIVE HYDROGENS	DEUTERIUM EXCHANGES
1,2 Benzenediamine	2-NH2	4D 100.0%
1,3 Benzenediamine	2-NH2	4D 52.0%
	2-H	5D 26.4%
		6D 21.6%
1,4 Benzenediamine	2-NH2	4D 100.0%
1,2,4 Benzenetriamine	3-NH2	6D 75.0%
	1-H	7D 25.0%
2-aminophenol	1-OH	3D 100.0%
	1-NH2	
3-aminophenol	1-OH	3D 52.7%
	1-NH2	4D 35.7%
	2-H	5D 11.6%
4-aminophenol	1-OH	3D 100.0%
	1-NH2	

3. Alkynes:

   Alkynes with the triple bond at the end of a chain are very weak acids. In the presence of ND_3 many terminal alkynes will undergo H/D exchange.

4. Keto-Enol Tautomers:

   Since the two forms of these tautomers differ by one exchangeable hydrogen, each form of the keto-enol equilibrium can be observed via ND_3/CI/MS.

5. ß-Diketones:

   The methylene hydrogens in ß-diketones are acidic and therefore exchangeable. The H/D exchange for ß-diketones is a two step process.. The addition of the second deuterium is a function of probe temperature and reaction time within the ion source.

6. Negative Ion Deuterium Exchange:

   ND_3 can be used to determine the number of active hydrogens in the negative in the negative ion mode. The main advantage of ND_3 in the negative ion mode is that the deuterium exchange tends not to involve aromatic ring hydrogens. This in turn generates simpler spectra that can be easily interpreted.

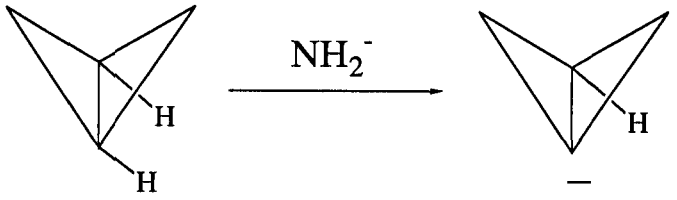
THE BICYCLOBUTYL ANION: AN ALKYL CARBANION

Phillip Chou and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

Alkyl anions are extremely rare in the gas phase. They are extremely basic and many are thought to have negative electron affinities.[1] It therefore is not surprising that only a few alkyl anions, methyl, cyclopropyl, methylcyclopropyl and neopentyl have been reported to date.[2] None of them have been produced by proton abstraction from the parent alkane. In fact, methyl anion has the largest known proton affinity, 416.6 ± 0.9 kcal/mole.[3]

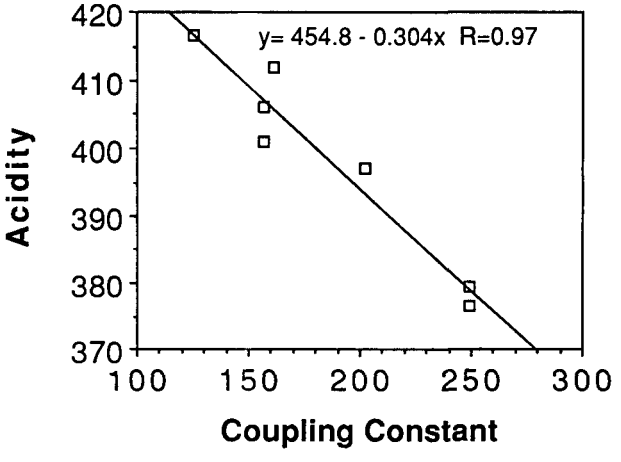
We have recently generated a new alkyl anion derived from bicyclobutane. This hydrocarbon is highly strained but thermally quite stable. The rigid ring system results in the bridgehead carbon-hydrogen bonds having a high degree of s-character (~$sp^{1.5}$) thereby enhancing their acidity. As a result, we have been able to deprotonate an alkane for the first time.

Proton abstraction from bicyclobutane affords the 1-bicyclobutyl anion and does not lead to any ring opening (eqn. 1). The proton affinity (397 ± 4 kcal/mole) and electron affinity (0.77 ± .34 eV) were measured and the reactivity of this novel ion with reagents such as O_2, CS_2 and N_2O was explored.



1)

In the process of carrying out this work it was noted that there is a correlation between gas phase acidity and ^{13}C-^{1}H NMR coupling constants (figure 1). This observation leads to the prediction that other strained hydrocarbons, such as bicyclo(2.1.0)pentane, should be suitable precursors for the generation of alkyl anions. Further investigations are in progress



Compounds	ΔHAcid (kcal/mole)	J (Hz)
Methane	416.6	125
Ethylene	406	157
Benzene	401	157
Cyclopropane	412	161
Acetylene	379.6	249
Methylacetylene	376.7	249
Bicyclobutane	397	202

The Detection of Neutral Products of Chemical Ionization Reactions

Charles Allgood and Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware
Newark Delaware 19716

The neutral products formed in chemical ionization reactions can be detected and provide additional information to that obtained in a conventional CI mass spectrometry experiment.

Initial experiments were carried out with bibenzyl, $C_6H_5CH_2CH_2C_6H_5$ which has a simple CH_4 CI mass spectrum: the base peak at m/z 105 and an abundant MH^+ at m/z 183. In agreement with previous experiments[1] the neutral product of benzene could be detected by the increase with increasing electron current of the ratio of ion currents, $C_6H_7^+/C_8H_9^+$, according to the following reactions:

$$CH_5^+ + C_6H_5CH_2CH_2C_6H_5 \longrightarrow C_8H_9^+ + C_6H_6 + CH_4$$

$$CH_5^+ + C_6H_6 \longrightarrow C_6H_7^+ + CH_4$$

The ratio of ion currents I(183)/I(105), or $[MH^+]/[C_8H_9^+]$, was independent of variations in electron current, as one would expect for two ions which were formed by competing bimolecular reactions of CH_5^+ and $C_2H_5^+$ ions with the sample.

The ratio of I(79)/I(105) was observed to increase as expected while the ratio I(183)/I(105) remained essentially constant as the reaction time increased with increasing source pressure.

The CH_4 CI mass spectrum of p,p'-DDT contains fragment ions corresponding to the loss of C_6H_5Cl, HCl, and $CHCl_3$ molecules from the protonated molecule.[2] The neutral product of chlorobenzene is easily detected as the MH^+ ion at m/z 113 and the $(M+C_2H_5^+)$ ion at m/z 141. The relative intensities show the characteristic dependence on electron current.

Small amounts of CCl_3^+, the dominant ion in the CH_4 CI spectrum of chloroform, were also detected in the spectra of DDT but only at the highest electron currents used in these experiments.

The neutral product from the other major fragmentation reaction of DDT is HCl; however, no significant amounts of H_2Cl^+ are observed under any conditions. We presume that the HCl reacts rapidly with the walls of the source of the mass spectrometer. The dominant ionic products in the CH_4 CI mass spectra of aliphatic chlorides are $(M+H-HCl)^+$ ions; however, no significant amounts of H_2Cl^+ were detected with these compounds either.

Ratios of other primary fragment ions in p,p'-DDT as well as chlorine isotopic peaks are independent of electron current consistent with the proposed mechanism of formation.

For benzil, $C_6H_5COCOC_6H_5$, the CH_4 CI mass spectrum contains predominantly $C_6H_5CO^+$ at m/z 105 which can be formed by two equally reasonable mechanisms that cannot be differentiated from the ionic species formed:

$$\text{---> } C_6H_5CO^+ + C_6H_5CHO$$

$$C_6H_5COCOC_6H_5 + CH_5^+ \text{ --}$$

$$\text{---> } C_6H_5CO^+ + C_6H_6 + CO$$

The correct mechanism can be determined by detecting the neutral products by subsequent reaction with methane reagent ions, either benzaldehyde or benzene and carbon monoxide.

The experimental results clearly show that formation of benzaldehyde is the correct pathway as the ionic ratio $C_6H_5CHOH^+/C_6H_5CO^+$ or I(107)/I(105) increases with increasing electron current while only very small amounts of protonated benzene are detected at m/z 79 and the ratio I(79)/I(105) is independent of electron current. Protonated carbon monoxide, HCO^+ cannot be detected at m/z 29 due to interference from a methane reagent ion, $C_2H_5^+$.

In conclusion it appears that this two step mechanism is occuring to some extent in forming ions for these samples under chemical ionization conditions. The detection of these neutral products may be useful in structure confirmation as well as in studies of the mechanisms of chemical ionization reactions.

THE REACTION OF THE BUTADIENE RADICAL CATION AND METHYL VINYL KETONE: a GAS PHASE ANALOGOUE OF A [4 + 2] CYCLOADDITION

L.W. Castle, and M.L. Gross, Midewest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE 68588

The ability of tandem mass spectrometry to moniter a single ion for collisional activation (CAD) makes it an effective tool for studying bimolecular gas-phase reactions. Using a chemical ionization (CI) source as a reaction vessel. An adduct can be generated and then its structure determined by measuring its CAD mass spectrum. In order to determine possible changes in an adduct structure over time, we can conduct the reaction in an FTMS. With these two complimentary tools we are able to obtain structural and kinetic information concerning the reaction products and intermediates.[1,2]

We have used this strategy to study the reaction between the butadiene radical cation and methyl vinyl ketone. Assignment of adduct structures were based on the comparison of adduct CAD spectra with those of appropriate model compounds. Due to interference at the exact mass from a competing adduct we have generated specifically labeled adducts at masses free from interference by other ions.

The reaction of D_6-butadien radical cation plus methyl vinyl ketone gives an adduct at m/z 130 which fragments to generate ions of m/z 43, m/z 60, m/z 87, m/z 113 and 115. The ion of m/z 43 corresponds to $[CH_3 - C = O]^+$ which is a loss of $[C_6H_3D_6\cdot]$. The peak at m/z 60 corresponds to $C_4D_6^{+\cdot}$ which is D_6-butadiene; or reversion to starting material. The ion of m/z 87 corresponds to $[C_6D_6H_3]^+$. The peaks at m/z 115, and 113 correspond to losses of methyl; m/z 115 is loss of CH_3; and m/z 113 is loss of $CD_2H\cdot$, respectively. The fragments m/z 113 and 115 occur in almost identical proportion. These fragments can be explained when the (CAD) spectra of certain model compounds CAD spectra are used for comparison. The model of 1(3-cyclohexenyl)-ethanone fragment. to give m/z 43, m/z 81, and m/z 109 as its major fragments. The model compounds of 1-(3-cyclohexenyl) ethanone fragments to form m/z 43, m/z 81, and m/z 109 as its major fragments. The ion of m/z 43 corresponds to $[CH_3CO]^+$ in both the adduct and the model compound; the ion of m/z 81 is $[C_6H_9]^+$ whereas the adduct gives m/z 87 which is $[C_6D_6H_3]^+$; the ion of m/z 109 corresponds to loss of methyl, the adduct forms m/z 115 and 113 which is the loss of $CH_3\cdot$ and $CD_2H\cdot$, respectively. The ratio of these fragments to each other in the model compound, and in the adduct, are very close suggesting thay they are generated from the same structure.

However, there is one fragment peak unaccounted for by this model compound; i.e., m/z 60, which corresponds to $[C_4D_6]^{+\cdot}$ and is a reversion to starting materal. The only model compound which we found to give rise to m/z 54 $[C_6H_6]^{+\cdot}$ was 2 ethenyl 3,4-dihydro pyran via the retro Diels Alder (RDA) reaction. It is known that ethenyl 3,4 dihydro pyran systems can isomerize to form 4-cyclohexen substitude aldehydes or ketones dependant on the substitution at the six position.[3,4]

From this information we propose that D-6-Butadiene radical cation reacts with methyl vinyl ketone to form 2 ethenyl 3,4-dihydro 6-methyl pyran radical cation this then can decompose by two paths; either the (RDA) to generate m/z 60 or the Claisen rearrangement to form 1-(3-cyclohexene) ethanone which can then fragment to form ions of m/z 43, m/z 87, m/z 115 and 113.

We were able to establish by appropriate double resonance experiments in FTMS that the reactant species is the butadiene radical cation in the butadiene/methyl vinyl ketone system. In the FTMS we were able to adjust reation conditions (i.e., ionization voltage, and partial pressures of reactants) in such a way as to favor the butadiene/methyl vinyl keton reactions over methyl vinyl keton/methyl vinyl ketone reaction. With this obstacle overcome we were able to use unlabeled butadiene plus methyl vinyl ketone. We then did the reaction as a function of delay time between

ionization and detection, starting at 50 mS and ending at 600 mS. We monitered the ion of m/z 54 (butadiene radical cation) and the ions of m/z 43, m/z 81, and m/z 109 which correspond to fragments of 1-(3-cyclohexenyl) ethanone. We also mointored the methyl vinyl ketone radical cation (m/z 70).

When the data is plotted with time in mS versus relative abundance we find that the ion of m/z 54 declines linearly while m/z 43, 81, and 109 all increase steadily from 50 mS to 600 mS. It was noted that the ion of m/z 70 is only present in low abundance during the first two data points (i.e., 50 and 100 mS).

The conclusion then is that a [3 + 2] cycloaddition is occuring; furthermore, the reaction has first order rate kinetic with respect to the butadiene radical cation.

Gas-Phase Ion Chemistry of Benzene Radical Cation and Cyclic Ethers

Charles D. Warner, Dept. of Chemistry, Hastings College, Hastings, NE 68901;
R. W. Holman and M. L. Gross, Midwest Center for Mass Spectrometry, Univ. of Nebraska-Lincoln, Lincoln, NE 68588

The principle aim of this study is to investigate whether gas-phase ion molecule reactions take place between benzene radical cation and cyclic ethers, and if so characterize the adducts. These reactions are of interest because the adduct formed may initially exist as a distonic radical cation (charge-radical site separate radical cations). Previous work showed that benzene radical cation formed distonic ions when reacted with dienes[1], alkenes[2], and cyclic alkanes[3]. In addition, these reactions may serve to further the understanding of the nature of radical cation adducts, and add to the growing body of bimolecular radical cation reactions.

When the reaction of an unionized mixture of benzene and either ethylene oxide, oxetane, or tetrahydrofuran (THF) is conducted in the high pressure source of a tandem mass spectrometer (Kratos MS-50 TA), adduct ions are formed. In these reactions it is benzene that reacts as the radical cation (proven by FTMS pulsed valve experiments).

The efficiency of adduct formation for the reaction of benzene radical cation with each of the neutral cyclic ethers was determined semiquantitatively so that relative reaction efficiency could be assigned. The following reaction efficiency order is obtained:

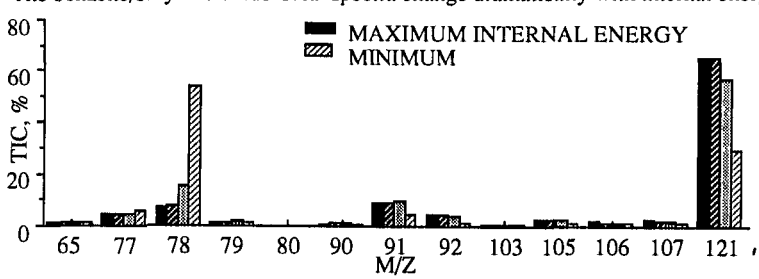
Table 1

	Ethylene oxide		Oxetane		THF
$(Adduct^{+\cdot}/C_6H_6^{+\cdot})$	6	:	1	:	~ 0

This relatively small differential in relative reactivity between ethylene oxide and oxetane contrasts sharply with the 100:1 differential in reactivity observed when comparing the reaction of the benzene radical cation with cyclopropane versus that with cyclobutane. The relatively small differential in reactivity for the cyclic alkanes must mean that oxygen coordination must take place (at least in part) in the formation of adduct ions.

To test further the nature of the bonding in these adduct ions the CAD spectra of the various benzene radical cation/cyclic ether adducts were obtained as a function of internal energy. The methodology employed to study bimolecular reactions as a function of internal energy involves conducting the reaction in the high pressure source with variable partial pressure of a third body collision gas, in this case, CS_2. By incrementing the partial pressure of the third body the degree of collisional stabilization of the adduct becomes greater, and hence average internal energy lower.

The benzene/ethylene oxide CAD spectra change dramatically with internal energy.



For low internal energy adducts the predominant process is either return to starting material or charge exchange.

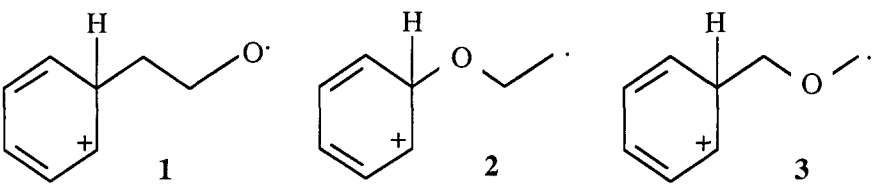
Table 2:

$$\text{Benzene}^{+\cdot} + C_nH_{2n}O \longrightarrow C_nH_{2n}O\text{-}C_6H_6^{+\cdot}$$

$C_nH_{2n}O$	$C_nH_{2n}O^+/C_6H_6^{+\cdot}$	Ionization Potential
ethylene oxide	0.011	10.57
oxetane	0.1	10.26
THF	2.1	9.63

The extent of charge exchange parallels the ionization potential of the various cyclic ethers. It is concluded that the low energy benzene radical cation/cyclic ether adduct ions are predominantly ion-dipole complexes (possibly involving oxygen coordination). For high internal energy adducts the contribution from ion-dipole complexes is greatly reduced as evidenced by only minor $C_6H_6^{+\cdot}$ or $C_2H_2O^{+\cdot}$ formation. The predominant dissociation pathways for the high energy adduct is to form $C_7H_7^{+\cdot}$, $C_7H_8^{+\cdot}$, and $C_6H_5C_2H_2O^{+\cdot}$ at m/z 91, 92, and 121, respectively. Hence, the high internal energy adducts are predominantly covalent species.

The structure of the initial covalent benzene radical cation/ethylene oxide adduct may be either structure 1, 2, or 3 (see figure 2). A comparison of the initial CAD mass spectra of appropriate model compounds with that of the adduct can be



used to elucidate the structure. The model compounds studied include the phenyl ethyl ether radical cation and phenylethanol radical cation. The CAD spectra of the model compounds do not match well with the spectrum of the adduct, and hence it is unlikely that the adduct that is collisionally activated is linear. This is not surprising since rearrangements such as from 1, 2, and 3 are quite fast.

Two processes account for the spectra obtained from the reaction of benzene radical cation and cyclic ethers. At low internal energy, the initially formed ion-dipole complex is the dominant process. This complex either dissociates to benzene radical cation or, if the IP of the ether is low, charge exchange occurs and the radical cation of the ether dissociates from the complex. At higher internal energy and to a certain extent at lower energy, a covalent adduct is formed. This adduct rearranges to a structure for which the dominant process is loss of H. The structure which reaches the collision cell does not appear to be a linear structure such as 1, 2, or 3.

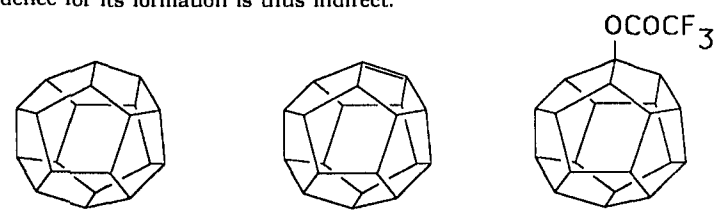
GAS PHASE SYNTHESIS OF DODECAHEDRENE AND DETERMINATION OF ITS DOUBLE BOND ENERGY

Jeffrey P. Kiplinger, Alan G. Marshall, Tomoshige Kobayashi, and Leo A. Paquette

Departments of Chemistry and Biochemistry
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

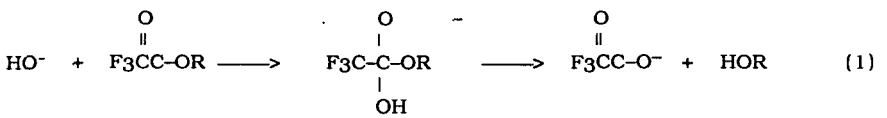
The synthesis of dodecahedrane (**1**, $C_{20}H_{20}$) in 1982[1] generated a great deal of interest in highly symmetric and strained hydrocarbons. We have recently synthesized dodecahedrene (**2**, $C_{20}H_{18}$) in the gas phase. This molecule is the neutral product of an ion-molecule reaction carried out in a Nicolet FTMS-2000 FT-ICR spectrometer, and our evidence for its formation is thus indirect.



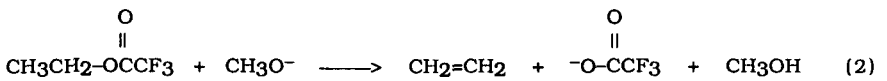
1 **2** **3**

Dodecahedrene is produced as the product of a gas-phase β-elimination reaction when trifluoroacetoxydodecahedrane (**3**) reacts with strong bases (e.g., hydroxide ion). The observed ionic product of this reaction is trifluoroacetate ion, m/e 113^-. Trifluoroacetate is also produced in small quantities on impact of near-thermal electrons, but not on impact of the 5.3 eV electrons used to produce hydroxide from water. In addition, prior ejection of the anionic base produces a >90% reduction in the abundance of m/e 113^- ions.

Reaction of hydroxide ion with **3** to produce trifluoroacetate may take place via a different mechanism, however. Bimolecular substitution is indistinguishable from elimination in the FT-ICR spectrometer since both produce the same ionic product, but in the case of the dodecahedrane system this reaction is sterically unreasonable due to the impossibility of backside attack by the base. Trifluoroacetate may also be produced via a $B_{AC}2$ mechanism, as illustrated in Equation 1. The activated tetrahedral intermediate formed would decompose preferentially to yield trifluoroacetate rather than the dodecahedrane alkoxide due to the greater acidity of trifluoroacetic acid. Reaction of **3** with $^{18}OH^-$ produced from labeled water allows us to differentiate between this mechanism and β-elimination, since the former incorporates the oxygen label into the product ion while the latter does not. The ratio of 113^- to 115^- produced in this experiment is approximately 2.5:1, and this ratio is a direct measurement of the branching ratio for elimination vs. $B_{AC}2$ pathways. Elimination is therefore the preferred pathway, and dodecahedrene is the reasonable neutral product.



(1)



(2)

Examination of the thermochemistry involved in this reaction yields a measurement of the amount of energy necessary to incorporate the strained double bond into this molecule. The elimination reaction takes place easily and with comparable rate constants with the bases hydroxide and methoxide, but does not take place even at very long ion trapping times with ethoxide, which is 13 kJ/mol less basic in the gas phase than methoxide. Such a dramatic change in kinetics with a relatively small change in thermochemistry suggests a kinetically facile mechanism with a small barrier, and allows us to assign a thermochemical threshold for the reaction with confidence. The 1,2 elimination of trifluoroacetate from its ethyl ester (Eq. 2) is calculated[2] to be 174 kJ/mol exothermic with methoxide and 161 kJ/mol exothermic with ethoxide as base. The increased endothermicity involved in the dodecahedrane system represents the extra energy (relative to ethene) necessary to form the strained olefin; our measurement allows a bracketing of this "strain energy" at 168 +/- 12 kJ/mol. This is the additional energy cost of the pyramidalized π-system, and is similar to the energy associated with other strained π bonds.[3]

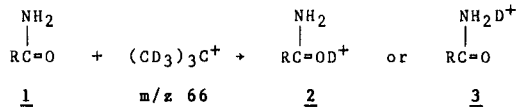
ACIDIFICATION-NEUTRALIZATION OF CARBONYL COMPOUNDS IN THE GAS PHASE

Thomas A. Shaler and Thomas Hellman Morton
Department of Chemistry
University of California
Riverside, CA 92521

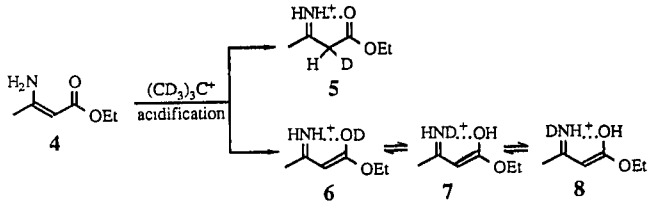
The Brønsted basicity of carbonyl compounds strongly influences their reactivity in a wide range of organic reactions. In many cases protonation on oxygen predominates over protonation at other basic sites. We have investigated this using acidification-neutralization in the FTMS. A neutral molecule, M, is deuterated with a D^+ donor to prepare the [M+2] conjugate acid. Hydron is subsequently removed by reaction with a Brønsted base, B, and the BH^+/BD^+ intensity ratio is measured to assess the degree of isotopic scrambling that must have taken place within the [M+2] conjugate acid. In favorable instances we can detect isomeric conjugate acids and assess which is thermodynamically favored.



(1)

If the nitrogen of simple amides were deuteronated, 1 → 3 in reaction 1, then one deuterium would become equivalent with two hydrogens. Subsequent removal of hydron from the [M+2] conjugate acid with a Brønsted base (B:) would yield approximately twice as much proton transfer as deuteron transfer. Under typical experimental conditions, the d_9-t-butyl cation (m/z 66, prepared by electron impact on d_{12}-neopentane) reacts with acetamide (1, R=CH_3) to form [M+2] conjugate acid, which yields predominantly BD^+ when a pulse of base is added after trapping. This implies that the [M+2] conjugate acid is O-protonated (structure 2), in accord with what is known for amides in solution. When a mixture of pyridine is used to dehydronate a 4.0:1 mixture of [M+2]:[M+1] from acetamide, the BD^+:BH^+ ratio is 2.8:1 for B = pyridine and 3.6:1 for B = N,N-dimethylacetamide. After correction for the presence of [M+1], this means the 92% of the product of reaction 2 is BD^+ for the former base and 98% is BD^+ for the latter.

Vinylogous carbamate 4 has a basic carbon atom as well as basic heteroatoms. From gas phase equilibrium measurements we find that 4 is more basic than pyridine and less basic than 2-methoxypyridine. Tautomeric [M+2] conjugate acids are shown in reaction 3. Deuteronation on carbon yields 5, in which it scrambles with one hydrogen. Deposition on oxygen yields 6, which, if equilibration proceeds among internally hydrogen-bound species, scrambles one deuterium with two hydrogens via 7 and 8.



(3)

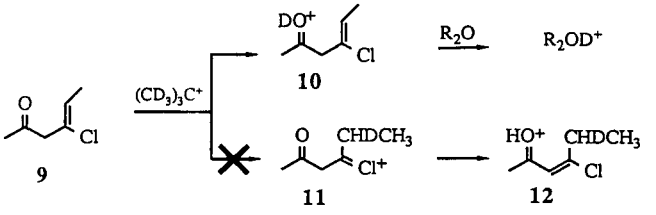
June 5-10, 1988, San Francisco, CA



(4)

The results for a 4.9:1 mixture of [M+2]:[M+1] from 4 (vapor from the crystalline Z-isomer) yield more BH^+ than BD^+. The [M+1] conjugate acid from the bimolecular reaction between $M^{+\cdot}$ and M does not react with N,N-dimethylacetamide, while both [M+1] and [M+2] react with 2-methoxypyridine. If the conjugate acids are dehydronated by a 50:1 N,N-dimethylacetamide:pyridine, mixture the BD^+:BH^+ ratio from 2-methoxypyridine is 0.39:1, while the ratio from N,N-dimethylacetamide is 0.93:1. Since neither base is much stronger than 4, reaction of any of the ions in reaction 3 must return it to 4. The most parsimonious explanation of our result is that the [M+2] conjugate acid of 4 consists of a mixture of tautomers 5-8, with 5 less than the others. 2-Methoxypyridine is a strong enough base to dehydronate all of the tautomers, while N,N-dimethylacetamide (which is 4 kcal/mol weaker) only reacts with the high energy tautomer. Since the BD^+:BH^+ ratio is close to unity for the less stable [M+2] conjugate base, we conclude that this must be 5. Therefore deuteronation on carbon occurs, but it is neither kinetically nor thermodynamically favored. This contrasts to the solution phase result, in which we confirm the previously reported observation by Witkop that 4 protonates solely on carbon in $CDCl_3$.

In CD_3OH/HCl solution the ^1H NMR spectrum is much more complex, as a number of species appear to be present. These could be due to the presence of heteroatom-protonated forms, although no assignments are yet conclusive.

Finally we turn to the β,γ-unsaturated chlorohexenone 9. We prepare this with high regio- and stereoselectivity by an "ene" reaction of acetyl chloride/$AlCl_3$ with 2-chloro-1-butene. Three tautomers of the [M+2] conjugate acid are shown in reaction 7. If internal proton transfer were facile, interconversion of 10 with 11 would scramble the deuterium with a hydrogen. Further internal transfer could convert 11 to 12, which might transfer only protons to base. Experimentally, however, we find that the [M+2] conjugate acid of 9 gives ≥95% BD^+ when B = diethyl ether. Therefore 10 is formed and does not interconvert with 11. The sort of transfer that occurs rapidly between oxygen and nitrogen (e.g. 6 ⇄ 7 ⇄ 8) does not readily take place between oxygen and carbon. Reaction of 9 with D_3O^+ in solution leads eventually to exchange of the α-hydrogens for deuterium with no detectable isomerization.

Acknowledgment. We are grateful to Dr. Robert Brown and Ms. Lydia M. Nuwaysir for assistance in writing the FTMS pulse sequence. This work was supported by NSF Grant CHE85-09557.

FOURIER TRANSFORM MASS SPECTROMETRIC GENERATION AND STUDIES OF CARBOETOXY RADICAL ANION, EtOCOCH·⁻

A. Kasem Chowdhury and Charles Wilkins
Department of Chemistry
University of California, Riverside
Riverside, CA 92521

Introduction:

In contrast to results from Flowing afterglow studies[1], we report here that ethyl- diazo acetate undergoes dissociative electron attatchment under low pressure FTMS conditions, yielding abundant carboethoxy radical ion, EtOCOCH·⁻ (1). In addition to qualitative characterization of its reactions, proton affinity (PA), H atom affinity, and heats of formation of (1) are reported.

Experimental:

All experiments were performed on a Nicolet FTMS-1000 Fourier transform mass spectrometer equipped with a 4.76 cm^3 cell and 3.0 tesla superconducting magnet. A potential of -0.7V was applied to the trap plates to retain negative ions in the cell. Carboethoxy radical anion was generated by a 200 ms beam of 0.199 eV electrons with a filament emission current of approximately 1-2 uA. The anions were trapped in the cell for variable times (from a few millisecond to 1 second) to allow ion-molecule reactions with selected neutral reagent gas.

Results and Discussion:

Dissociative electron attatchment with EtOCOCHN2 in the FTMS yields abundant carboethoxy radical anion (reaction 1). This is in contrast to high pressure FA results where formation of molecular diazo anion was observed[1]. Flowing afterglow systems operate at relatively high pressure (0.3 - 1.0 torr), the electron energy distribution is significantly broader, and fragmentation of molecular ion is less evident. Furthermore, multiple collisions with He buffer gas also contribute to collisionally stabilize vibrationally excited molecular ions. Such collisional stabilization, however, is inefficient in the low pressure FTMS system and the fragmentation of molecular ion is more likely.

$$\text{EtOCOCHN2} \xrightarrow{e^-} [\text{EtOCOCHN}_2^-] \longrightarrow \text{EtOCOCH}^{\cdot -} + N_2 \qquad (1)$$

Upon collision induced dissociation, EtOCOCH·⁻ appears to eliminate C_2H_4 via a six membered transition state, yielding m/z 58. The reaction of EtOCOCH·⁻ with the neutral diazoester produces EtOCOCHCHCO2Et⁻ anion (m/z 172) by attacking at C1, with subsequent loss of N_2 (reaction 2).

$$EtOCOCH^{\cdot -} + EtOCOCHN_2 \rightarrow \begin{cases} EtOCOCHCHCO_2Et^- + N_2 \\ m/z\ 172 \\ EtOCOCN_2^- + EtOCOCH_2^{\cdot} \\ m/z\ 113 \end{cases} \quad (2)$$

The product with m/z 113 is the result of proton abstraction from the diazo ester.

To determine the PA of (1), the reactions of $EtOCOCH^{\cdot -}$ with a series of potential proton donors of known gas phase acidity were investigated. Thus, the PA of $EtOCOCH^{\cdot -}$ was bracketed between the ΔH_{acid}'s of C_2H_5OH and CH_3OH giving PA ($EtOCOCH^{\cdot -}$) = 377.7 ± 2 kcal/mol. By relating the PA with other thermochemical data, ΔH_f ($EtOCOCH^{\cdot -}$) = 48.5 ± 3 kcal/mol was calculated[2]. As a free radical $EtOCOCH^{\cdot -}$ abstracts H· atom from potential H· atom donors. Bracketing such reactions yielded D(EtOCOC-H $^-$) = 104 ± 4 kcal/mol.

Both $CF_3CO_2CH_3$ and $CF_3CO_2C_2H_5$ react rapidly with $EtOCOCH^{\cdot -}$, yielding two products (reaction 3).

$$EtOCOCH^{\cdot -} + CF_3CO_2R \rightarrow \begin{cases} 0.99 & EtOCOCHCOCF_3^- + \cdot OR \\ 0.01 & EtOCOCHCO_2R^- + \cdot CF_3 \end{cases} \quad (3)$$

The major reaction channel is considered to be the product of carbonyl addition followed by radical β-fragmentation of the alkoxy radical. The minor product appears to be formed via loss of $\cdot CF_3$ radical from the tetrahedral intermediate produced by carbonyl attack. Although no reaction was observed with O_2 and N_2O, $EtOCOCH^{\cdot -}$ reacted rapidly with CS_2 via S atom abstraction to yield $EtOCOCHS^-$.

ION/MOLECULE REACTIONS OF $C_5H_3^+$ AND $C_7H_7^+$ IN THE GAS PHASE

F. Ozturk and J. R. Eyler
Department of Chemistry
University of Florida
Gainesville, Florida 32611

Introduction:

The $C_5H_3^+$ and $C_7H_7^+$ ions have been proposed as two species involved in an ion/molecule mechanism of soot formation.[1,2] Results of previous experimental work suggested[3] two different linear structures for the $C_5H_3^+$ ion, each produced from a different precursor. Previous experimental studies[4] on structural characterization of $C_7H_7^+$ ions indicated that these ions exist in the gas phase with at least two structures; tropylium, and benzyl, which were also identified as the two most stable structures by theoretical studies.[5] Unreactive and reactive $C_7H_7^+$ observed in ion/molecule reactions have been attributed[6] to tropylium and benzyl structures respectively.

Experimental:

A Nicolet FTMS-1000 Fourier transform ion cyclotron resonance (FTICR) mass spectrometer was used. Reaction pathways were delineated using the ejection capabilities of FTICR which make it possible to eject one ion from a complicated reaction mixture to determine its contribution to the mass spectrum of all the other ions. Reaction rate coefficients were determined by monitoring the intensity of the $C_5H_3^+$ and $C_7H_7^+$ ions as a function of time after ejection of all other ions from the analyzer cell. $C_5H_3^+$ ions were produced by 50 eV electron ionization of 2,4-hexadiyne and by the reaction of $C_3H_3^+$ with diacetylene. $C_7H_7^+$ ions were produced from toluene, cycloheptatriene and norbornadiene by dissociative chemical ionization using different charge transfer agents ($C_4H_2^+$, Xe^+, Kr^+, and Ar^+).

Results:

$C_5H_3^+$ Reactions with Acetylene and Diacetylene: Although almost all of the $C_5H_3^+$ ions produced from 2,4-hexadiyne reacted with the neutral precursor, no reaction of these ions was observed with either C_2H_2 or C_4H_2. $C_5H_3^+$ ions produced as products of the reaction of $C_3H_3^+ + C_4H_2$ were 100% reactive with both propargyl iodide and diacetylene (the neutrals present in the reaction medium). The rate coefficient for the reaction of $C_5H_3^+$ with diacetylene was found to be $(5.6 \pm 1.7) \times 10^{-10}$ cm^3/s.

$C_7H_7^+$ Reactions with Acetylene and Diacetylene: $C_7H_7^+$ ions produced from different precursors had both reactive and unreactive populations. While $C_7H_7^+$ produced from cycloheptatriene and norbornadiene reacted with acetylene with rate constants in the range of $(1\text{-}4) \times 10^{-11}$ cm^3/s to form $C_9H_9^+$, no reaction was observed with $C_7H_7^+$ ions produced from toluene. $C_7H_7^+$ ions produced from different precursors reacted with diacetylene with different rate coefficients.

Discussion:

$C_5H_3^+$: Higher reactivity of $C_5H_3^+$ ions produced by the $C_3H_3^+ + C_4H_2$ reaction compared to those produced by electron ionization of 2,4-hexadiyne suggests that the former has a higher heat of formation with a stable structure <u>different</u> from those reported earlier for $C_5H_3^+$ ions from both 2,4-hexadiyne <u>and 1,3-pentadiyne</u>. Although no structural assignment can be made for the $C_5H_3^+$ ion produced by reacting $\ell\text{-}C_3H_3^+$ with diacetylene based on the results of this study, several structures can be considered possible on the basis of initial charge distribution on $\ell\text{-}C_3H_3^+$. Thus, reaction of the propargylium cation with diacetylene with resultant loss of acetylene, might proceed according to either Scheme I or Scheme II leading to the formation of three different $C_5H_3^+$ ion structures.

Scheme II

$C_7H_7^+$: Based on the differences in behavior observed in this study of $C_7H_7^+$ ions produced from three precursors, the possibility of stable structure(s) other than benzyl and tropylium must be considered. As suggested by AM1 calculations for the $C_7H_7^+/C_7H_8^+$ surface,[7] the ion produced by hydrogen loss from the bicyclo [3.2.0] heptadiene radical cation is a stable $C_7H_7^+$ isomer accessible at about 2.8 eV above the appearance potential of tropylium from cycloheptatriene. Table I summarizes the proposed $C_7H_7^+$ structures for different precursors on the basis of previous and present studies.

Table I.

Precursor of $C_7H_7^+$	Unreactive Structure (ΔH_f = 207 kcal/mole)	Reactive Structure	ΔH_f (kcal/mole)
Toluene	Tropylium$^+$	Benzyl$^+$	211 (Ref. 8)
Cyclohpetatriene	Tropylium$^+$	(BCH-H)$^{+a}$	271 (Ref. 7)
Norbornadiene	Tropylium$^+$	(MCH-H)$^{+b}$	?(236) (Ref. 5)

[a] Structure produced by hydrogen loss from bicyclo[3.2.0]heptadiene radical cation.
[b] Structure produced by hydrogen loss from 5-methylene-1,3-cyclo hexadiene ion.

ION-MOLECULE REACTIONS OF ISOMERIC TERPENE DERIVATIVES UNDER POSITIVE AMMONIA CI: STUDY OF STEREOCHEMICAL EFFECTS

Richard B. Cole, Chantal Prevost and Jean-Claude Tabet*

Laboratoire de Chimie Organique Structurale, U.A. 455, Université Pierre et Marie Curie, 75230 Paris Cedex 05 and Laboratoire de Synthèse Organique, Ecole Polytechnique, 91128 Palaiseau, FRANCE

The following epimeric 16-hydroxy-13-ketal modified tetracyclic terpene derivatives (exo 1a and endo 1b) undergo competitive ion-molecule reactions in a high pressure chemical ionization (> 10^{-1} torr ammonia) source of a Triple Quadrupole (Nermag R30-10). Among the predominating processes (Fig. 1) are protonation and aminolysis of the ketal group to form MH^+ (m/z 335), as the proton affinity of the ketal group is superior to that of ammonia, and $(M+NH_4-C_2H_4O)^+$ (m/z 308, denoted MaH^+), respectively.

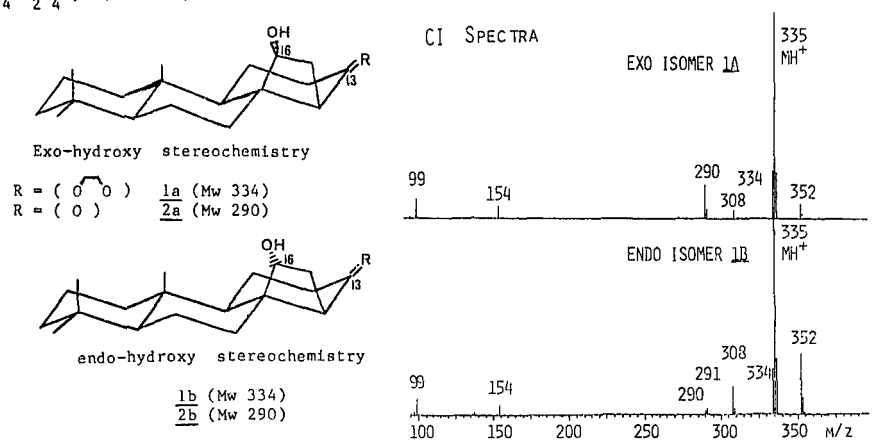

Figure 1

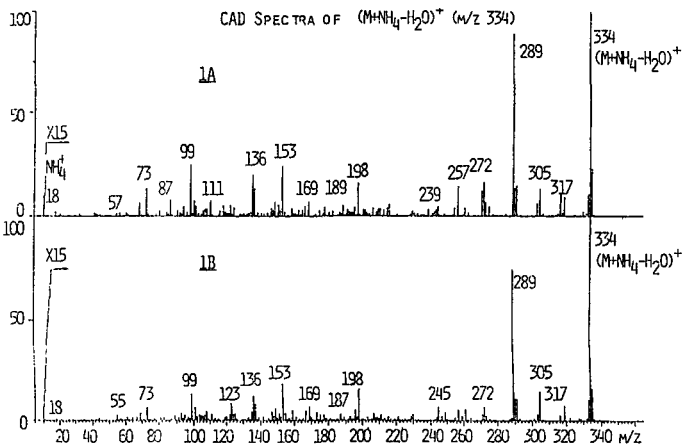
Comparison of low-energy (10 eV lab.) CAD spectra of MaH^+ ions with those of ammonia adducts of the corresponding hydroxy-ketone isomeric forms (i.e., a carbonyl group at C_{13} in place of the ketal group) reveals identical structures for each pair of ions with the same hydroxyl spatial orientation. This confirms that the stereochemistry of the hydroxyl group is not affected by the aminolysis reaction. A solvated adduct structure appears to be involved in preference to geminal hydroxyl and ammonium groups at C_{13}. Under higher collision energy (60 eV lab.), the CAD spectra are superimposable at low m/z values indicating that the polycyclic skeleton is preserved intact in all cases. The MaH^+ ion is most likely produced by ammonia solvation of the protonated ketone fragment ion in the ion source and not by direct ammonia attack upon the m/z 352 adduct ion.

In comparing the fragment ions at m/z 290, produced from hydroxy-ketal $(M+NH_4-C_2H_6O_2)^+$ and hydroxy-ketone (mol. wt. 290) stereoisomers, structural differences involve more than just hydroxyl stereochemistry. From ketal isomers, m/z 290 is characterized by immonium (as

opposed to ammonium) ion structures. The immonium ion could be produced from an opened-ring form of the ketal adduct ion which reacts with NH_3 leading to aminolysis. In contrast, for the hydroxy-ketone, a direct nucleophilic substitution occurs at the hydroxylic site to form m/z 290. This reaction is favored because the proton affinity of the hydroxyl group is lower than that of ammonia. Consequently, formation of MH^+ from an adduct form where the hydroxyl group solvates NH_4^+, is endothermic. Exothermic nucleophilic substitution thus occurs preferentially. Similarly, nucleophilic substitution also occurs to a minor extent at the C_{16} hydroxyl group of hydroxy-ketal derivatives to form $(M+NH_4-H_2O)^+$, m/z 334 denoted MsH^+. Low-energy (30 eV lab.) CAD spectra (below) reveal that the structure of this substituted MsH^+ ion is the same for both reactant stereoisomers and corresponds to an exo ammonium form.

Figure 2.



This indicates that the substitution reaction is bimolecular (S_N2) with inversion of configuration for the endo isomer (1b+NH_4)$^+$; for the exo isomer (1a+NH_4)$^+$, steric constraints on the NH_3 approach (endo side) permit only intramolecular (S_Ni) reaction with retention of configuration.

ENERGY DEPOSITION VIA COLLISIONALLY INDUCED DISSOCIATION IN A HYBRID MASS SPECTROMETER

T G Blease, J H Scrivens, ICI PLC, Wilton, Cleveland, UK, TS6 8JE
J J Monaghan, ICI PLC, Runcorn, Cheshire, UK, WA7 4QD
E Schöder, Finnigan MAT, 2800 Bremen, FRG

In MS-MS various methods of inducing a selected ion to fragment have been proposed. These include collision induced dissociation (CID), photodissociation, surface induced dissociation (SID) and electron induced dissociation. Of these, CID has proven of widest utility due to the relatively large cross-sections for excitation and subsequent dissociation and the ability to vary the density of the target gas readily.

The fragmentation induced by CID in a low energy MS-MS experiment has been found to depend on the number of collisions in the collision region (gas pressure), the collision energy of the parent ion, the energy level of the collision quadrupole with respect to the analysing quadrupole, the nature of the target gas, the design parameters of the collision quadrupole (including interquadrupole apertures and rf level) and the type of detector used.

In addition to fragmentation efficiency and CID efficiency, recent literature discussions have highlighted another important parameter affecting CID performance, namely the internal energy deposition of the selected ion after activation. Cooks and co-workers have outlined an objective approach to the measurement of this parameter. This involves the study of compounds that undergo consecutive fragmentations of known activation energies.

We have used this approach with tetraethylsilane to characterise energy deposition in a Finnigan HSQ30 hybrid mass spectrometer of geometry BEQQ. We have found that the Finnigan instrument allows access to significantly higher energy transfer conditions than other hybrids. Since these conditions are only analytical useful if adequate sensitivity is available, we have compared results obtained previously on a VG ZAB HSQ instrument for the detection of alkyl sultones in detergent formulations (1) with those obtained on the Finnigan instrument under these high energy transfer conditions.

The decomposition/appearance potentials for tetraethylsilane are well established: $SiEt_4^+$ (m/z 144, 10.5eV), $SiEt_3^+$ (m/z 115, 11.0eV), $HSiEt_2^+$ (m/z 87, 12.5 eV), H_2SiEt^+ (m/z 59, 14.0 eV), SiH_3^+ (m/z 31, 20.6 eV), $SiEt^+$ (m/z 57, 19.4 eV), SiH^+ (m/z 29, 26.8 eV), and serve as a useful indicator of the energy transfer possible in any instrument.

Fig 1 shows the daughter ion spectrum of m/z 144 obtained using the Finnigan HSQ30 with 3mTorr of argon and 30 eV collision energy. This corresponds to multiple collision conditions and, by increasing the target gas pressure and thus the average number of collisions experienced, more energy may be transferred. Fig 2 shows the spectrum obtained at 30mTorr of argon and 30 eV. As can be seen, very significantly more energy is transferred. Fig 3 shows the effect of increasing the collision energy to 100 eV when extensive fragmentation is observed.

Fig 4 gives the variation of fragment ion intensities obtained from 0-100 eV collision energy at an argon gas pressure of 30mTorr. These may be compared with Cooks' results (Fig 5) obtained from the same molecule using SID. Very similar results are obtained although the absence of m/z 57 from our CID results is interesting.

FIG 1

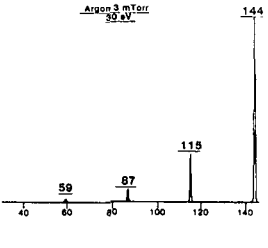

FIG 2

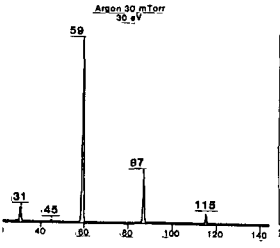

FIG 3

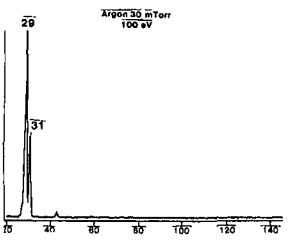

FIG 4

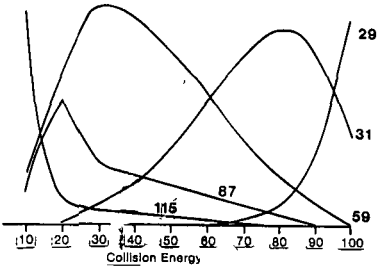

FIG 5

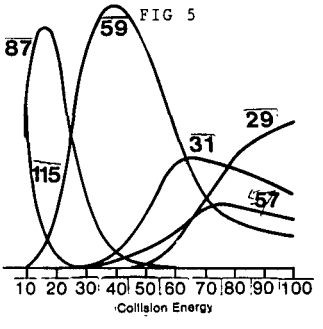

Although these results indicate that, under experimentally extreme collision conditions, energy transfer may be induced beyond that normally obtained with low energy CID, it is important to achieve adequate sensitivity using a well characterised sample.

The analysis of 1,3 and 1,4 alkyl sultones in an anionic surfactant matrix, $RO(CH_2CH_2O)_n\ SO_3^-Na^+$ where n = average of 3, using hybrid MS has been described earlier (1). Negative CI using ammonia is used to discriminate in favour of the uncharged sultone species which give $(M-H)^-$ ions for the 1,3 species and M^- ions for the 1,4 sultones.

Using a VG ZAB HSQ hybrid mass spectrometer, a daughter ion spectrum of $(M-H)^-$ from hexadecane 1,4 sultone (m/z 303) gave a detection limit of <1 ppm for the sultone in the surfactant matrix.

Using the HSQ30 under these high energy transfer conditions, at least equivalent sensitivity to the lower pressure data is obtained for the detection of the sultone in the matrix. Subsequent work using the parents of m/z 80 (SO_3^-) as a general analysis for both 1,3 and 1,4 sultones yielded the required sensitivity.

The use of collision cell pressures of 30mTorr of argon and collision energies of 100 eV can, with suitable instrumentation, result in a combination of high energy transfer via multiple collisions and adequate analytical sensitivity. This increased range of energy transfer will improve the applicability of MS-MS approaches in areas where stable ions are involved or where greater flexibility in directed fragmentation is required.

A COMPARISON OF THEORETICAL AND EXPERIMENTAL RELATIVE SENSITIVITIES IN GAS CHROMATOGRAPHY/CHEMICAL IONIZATION MASS SPECTROMETRY

Ron Orlando and Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware
Newark, Delaware 19716

One problem in the quantitation of complex mixtures by any technique is the availability of the standards which are needed to establish either the sensitivities or the relative sensitivities of the compounds in the mixtures. The more complex the mixture, the more difficult it becomes to obtain all of the compounds. Therefore, methods of predicting relative sensitivities of compounds or correlating sensitivities with molecular structures are of great importance in reducing the necessary number of standardization experiments.

In chemical ionization mass spectrometry, the sample ions are produced by ion/molecule reactions of the reagent ions with the sample molecules; consequently, the sensitivities (or calibration factors) are proportional to the rate constants for these ion/molecule reactions.[1] The rate constants (or collision frequencies) for these reactions can be calculated either from the Langevin theory which uses only the molecular polarizabilities[2], or from another theoretical model which includes both the molecular polarizabilities and dipole moments.[3] The relative sensitivities, based on total sample ionization, can then be calculated for all compounds from the ratios of these rate constants.

The relative sensitivities for a number of compounds in chemical ionization mass spectrometry with tetramethylsilane (TMS) as the reagent gas have been accurately represented by the ratios of calculated rate constants. The agreement between the calculated and experimental relative sensitivities is good for both theoretical models for a diverse set of compounds (ketones, phenols, aliphatic alcohols, di-alkyl ethers, cyclic ethers, sulfides, and thiols). The average difference between the calculated and experimental relative sensitivities is 9.2% for the Langevin model and 5.8% for the Su and Chesnavich model. These errors are slightly smaller than the sum of the errors in the experiments, and the calculated values usually lie within one standard deviation of the experimental value. However, it is apparent that the relative sensitivities calculated from the Su and Chesnavich model (which includes a contribution from the dipole moment) are in much better agreement with the experimental data for the ketones than the relative sensitivities calculated on the basis of the Langevin theory (polarizabilities only).

The deviation between the two models decreases with decreasing dipole moment and with increasing polarizability (molecular weight) of the sample molecules. Plots of the relative deviation, [k(exp) - k(L)]/k(L), as functions of molecular weight for different compounds with various values of dipole moments are in excellent agreement with the theoretical curves for the calculated relative deviations, [k(SC) - k(L)]/k(L), using the appropriate dipole moment[4] for each individual compound. k(SC) refers to the rate constant calculated from the Su and Chesnavich model[3] and k(L), from the Langevin model,[2] both relative to 1-hexanol. Even for very polar species, the relative sensitivities calculated with the two models differ by no more than 10% for compounds with molecular weights greater than 200. In addition, for compounds of the same type, the deviations between these two models change very slowly with increasing molecular weight above 200;

consequently, the ratio of rate constants or the relative sensitivity for two compounds, k_2/k_1, will be approximately the same when calculated using the Su and Chesnavich or the Langevin model.

The TMS CI spectra of the primary, secondary, and tertiary alcohols are very different and show strikingly different variations with sample size because of different sample ion/sample molecule reactions.[5] However, the sensitivities, which are determined by the reactions of $(CH_3)_3Si^+$ with compounds of the same polarizabilities and nearly identical dipole moments, are essentially identical.

One possible problem with this procedure for calculating relative sensitivities results from different mechanisms for the formation of sample ions for different compounds. These different mechanisms lead to different temperature dependences of the relative sensitivities. It was shown earlier that the relative sensitivities of aliphatic alcohols and ethers which undergo dissociative addition reactions with $(CH_3)_3Si^+$, are independent of temperature.[5,6] The Si-containing ions, produced in the primary reactions, have been shown to react by trimethylsilyl ion transfer with a second sample molecule to form the adduct ion, $(M+73)^+$. However, the relative sensitivities for those compounds which form adduct ions by collisionally stabilized addition, have strong negative temperature coefficients, in agreement with earlier work on association reactions on simple system[7]. Consequently, the calculated relative sensitivities for these compounds will be reliable only at relatively low temperatures when the rate of sample ion formation is determined by the rate of collisions of the trimethylsilyl ion with the samples.

Additional problems may be encountered because the relative sensitivities may not be independent of the source configuration, although this would not effect the rate constants. More experimentation with different instruments is needed to test this possible source of error.

Because the relative rate constants can be calculated for the reactant ions from any CI reagent gas, we would like to suggest the use of this method for other systems.

To be published in Analytical Chemistry, 1988.

ION MOLECULE REACTIONS OBSERVED FOR NITRO AROMATIC COMPOUNDS IN NEGATIVE ION FAST ATOM BOMBARDMENT MASS SPECTROMETRY

K. Balasanmugam[1], J. M. Miller[1], and R. W. Smith[2]

[1] Dept. of Chemistry, Brock University, St. Catherines, Ont., L2S 3A1, Canada

[2] McMaster Regional Centre for Mass Spectrometry, Dept. of Chemistry, McMaster University, 1280 Main St. W., Hamilton, Ont., L8S 4M1, Canada.

Nitro aromatic compounds (NACs) have been identified in various environmental samples such as air particulates, diesel exhaust paricles and carbon black. Since NACs have been characterized as direct mutagens there is considerable interest in their identification. Consequently, NACs have been extensively investigated using mass spectrometric techniques such as electron impact, electron capture negative ion chemical ionization, high pressure mass spectrometry, and atmospheric pressure ionization mass spectrometry. More recently, laser mass spectrometry (LMS) has been employed to characerize NACs[1]. In this study[1] an interesting ion-molecule reaction was observed (a).

$$NAC + NO_2^- \longrightarrow (NAC + O\text{-}H)^- + HNO \quad (a)$$

In this paper we have studied a series of twenty NACs by positive and negative ion fast atom bombardment mass spectrometry (FAB) in an attempt to assess the potential of the technique both as a means to characterize NACs and to detect any ion-molecule reactions that may be occurring during the FAB ionization process. All experiments were performed on a VG ZAB-E mass spectrometer. Xenon was used as the primary atom beam and the FAB gun was operated at 8keV/mA. Depending on the solubility of the samples, either 3-nitrobenzyl alcohol (NBA) or 2-nitrophenyl octyl ether (NPOE) were used as the matrices. Samples were dissolved in the matrix (10-15 mg/ml) and, in some cases, a small amount of dimethyl sulphoxide was used to enhance solubility. All spectra presented are the average of at least 10 scans. The variation in peak intensities from scan to scan is on the order of 6-10%.

In general, the negative ion FAB spectra of the NACs studied are more useful than the positive ion spectra for compound characterization. The negative ion spectra (Table 1) all exhibit ions corresponding to $M^{-\cdot}$ and/or $(M\text{-}H)^-$ except for compounds 8 and 13. Compounds 7, 16, and 17 undergo hydrolysis in these experiments, for example, 4-nitrobenzyl bromide yields a very weak molecular anion in NBA matrix. The spectrum is dominated by ions characterized as Br^-, $(NBA+Br)^-$, and $(2NBA+Br)^-$. Interestingly, an ion-molecule reaction seems to be occurring between the Br^- ion and the matrix. Some of the NACs studied yield ions corresponding to $(M+NO_2)^-$ and/or $(M+O\text{-}H)^-$ (Table 1). Formation of the molecular anion, $M^{-\cdot}$, is presumeably by electron exchange with the NO_2^- ion whilst the $(M\text{-}H)^-$ ion is formed by proton abstraction by the NO_2^- ionic species. In positive ion FAB, only compounds 1-6, 8, 14, and 15 yielded ions indicative of structure. In these cases, $(M+H)^+$ ions dominate although $M^{+\cdot}$ ions are also observed. Formation of the $M^{+\cdot}$ ions, again by electron exchange, only occurs for those samples with ionization potentials less than 9eV.

The linked scan and CID spectra of the ion at m/z 199 $(M+NO_2)^-$ in the spectrum of NBA shows that the ions characterized as $(M+O\text{-}H)^-$ m/z 168, $M^{-\cdot}$ m/z 153, $(M\text{-}H)^-$ m/z 152, $(M\text{-}2H)^{-\cdot}$ m/z 151, and $(C_6H_4NO_2)^-$ m/z 122 are formed in part from the ion-molecule adduct (Figure 1). Addition of an NO_2^- source to the matrix (eg. 1,3,5-trinitrobenzene) increases the intensity of all ions associated with NO_2^- formation. This observation further supports the contention that the $(M+NO_2)^-$ ion is formed through an ion-molecule reaction.

Table 1 Negative ion FAB mass spectra of compounds studied

	COMPOUND (MW)	M /(M H)	(M+NO_2) / (M+O-H)	NO_2	OTHER IMPORTANT IONS (M/Z, RELATIVE INTENSITIES)[b]
1	2-(4-nitrobenzyl) pyridine[a] (214)	33.5/27.9	0/3.4	82.1	
2	4-nitrobenzamide (166)	100/69	21.4/7.1	70.0	(M - $CONH_2$) (122, 11.9), (M+NO_2) (212, 2.4)
3	2,4-dinitrodiphenylamine (259)	79.1/60.9	35.6/2.7	81.4	$NO_2C_6H_3NH^-$ (136, 8.5), $(NO_2)_2C_6H_4^-$ (168, 11.9) $(NO_2)_2C_6H_4$- NH (182, 3.3)
4	2,4-dinitrophenylhydrazine (198)	41.6/95.7	4.4/1.3	99.5	$(NO_2)_2C_6H_4NH^-$ (182, 11.5) $NO_2C_6H_3NH^-$ (136, 11.5) $C_6H_5NH^-$ (92, 5.3)
5	3-methyl 2-nitrobenzoic acid (181)	37.6/100	0/2.1	20.2	(M - NO_2) (135, 3.4) (M - H - CO_2) (136, 24.0)
6	3-nitrophthalic acid (211)	33.7/100	0/0	17.2	(M - H - $2CO_2$) [c] (122, 35.5), (M - H - CO_2) (166, 58.6)
7	3-nitrophthalic anhydride[d] (193)	34/100	0/0	10.0	(M - H - $2CO_2$) [c] (122, 34), (M - H - CO_2) (166, 39.1)
8	4-nitrophenylphosphate (227)	100/0	0/12.0	56.8	
9	1,3-dinitrobenzene (168)	100/6.9	0/6.6	38.5	
10	1,3-dinitrobenzoylchloride[a] (151)	56.6/4.7	0/3.2	76.8	
11	4-nitrophenylacetonitrile (162)	35.7/100	1.2/4.8	70.0	
12	4-nitrobenzonitrile[a] (148)	85.5/6.9	0/6.6	79.1	
13	4-chloronitrobenzene[a] (157)	39.1/0	0/0	70.7	
14	2-nitrophenyl octyl ether (251)	81.7/20.1	5.7/16.7	73.1	$NO_2C_6H_4O^-$ (138, 100)
15	3-nitrobenzyl alcohol (153)	100/55	31.2/23.5	50.4	(2M + NO_2) (152, 3.7) 4M (612, 1.2) 3M (459, 7.5) (M - H_2) (151, 50.7)
16	4-nitrobenzyl chloride[a] (171)	51.0/12.8	0/0	78.6	$O_2NC_6H_4CH_2OH^-$ (153, 7.4) Cl (35, 80.6)
17	4-nitrobenzyl bromide[a] (215)	4.8/4.5	0/0	45.8	$NO_2C_6H_4CH_2OH^-$ (153, 16.8), $(O_2NC_6H_4CH_2OH + NO_2^-)$ (199, 4.2) $(O_2NC_6H_4CH_2OH + Br)$ (232, 20.6) Br (79, 100)
18	2-nitrobenzoic acid[b] (167)	60.0/94.9	5.0/1.8	58.2	(M - H - CO_2) (122, 48.1) (M - CO_2) (123, 8.9)
19	3-nitrobenzoic acid (167)	20.2/100	3.8/6.3	24.0	(M - H - CO_2) (122, 22.8) (M - CO_2) (123, 3.8)
20	4-nitrobenzoic acid[b] (167)	24.0/62.0	2.5/2.5	40.5	(M - H - CO_2) (122, 37.9) (M - CO_2)$^-$ (123, 8.7)

a. matrix used in these cases is NPOE where ions corresponding to $NO_2C_6H_4O^-$ (m/z = 138, 100%) from the matrix dominate the spectra. NBA is used for all other cases with the NBA (m/z = 153) ion dominating the spectra of 3 and 4

b. ions corresponding 2M - (2M - H) (M + NBA) (M + NBA - H) (M - O) and $O_2NC_6H_4^-$ are generally observed in majority (molecular cluster ions are absent for 10, 12, 13, 16 and 17) of the examples studied

c. includes a small contribution from the matrix peaks.

d. spectrum is identical to that of 3-nitrophthalic acid with respect to ion masses (m/z), where M refers to m/z = 211 rather than 193 (see text)

EFFECT OF COLLISION GAS PRESSURE AND ENERGY ON THE MASS SPECTRA OF SOME TRICHOTHECENES OBTAINED BY REACTIVE COLLISIONS WITH AMMONIA

R. Kostiainen

Finnish Research Project on Verification of Chemical Disarmament, Department of Chemistry, University of Helsinki, Vuorikatu 20, Helsinki 10, Finland

The use of reactive collisions with ammonia provides a highly specific method for the characterization of trichothecenes. In this method the trichothecenes are introduced to the ion source by direct exposure probe and ionized by isobutane CI. The protonated molecule is mass-selected by the first quadrupole and enters the collision chamber (quadrupole 2, Q2), where ammonia is used as neutral reagent instead of inert collision gas. Interaction of the protonated molecule with ammonia in Q2 produces not only ions formed by the collisionally activated dissociation (CAD) $[M+H-HX]^+$, but also ions formed by collisionally activated reactions (CAR): the adduct ion $[M+H+NH_3]^+$, ions formed by substitution reactions $[M+H+NH_3-HX]^+$, solvated ions $[M+H+(NH_3)_2]^+$ and $[M+H+(NH_3)_2-HX]^+$ (1). The ions formed by the collisionally activated reaction (CAR) process provide additional information for structural characterization and can also be used for monitoring (2). Figure 1. shows, as an example, collisionally activated reaction spectra of diacetoxyscirpenol (DAS) and deoxynivalenol (DON) using ammonia as a collision gas.

The collision pressure and energy have a great effect on the formation of ions in the reactive collisions. On the basis of the energy and pressure resolved curves, suitable collision conditions can be chosen for analytical purposes. The formations of adduct, substitution and solvated ions are favoured by high collision pressures and low collision energies, whereas the formation of CAD ions is favoured by high collision energy and pressure (Fig. 2). By choosing a relatively low collision energy and high collision pressure, the ions formed in the reactions between ammonia and protonated molecule and the ions formed by collisionally activated dissociation can be clearly detected.

GOLD CHEMICAL IONIZATION MASS SPECTRA OF ALKANES AND ALKENES USING FOURIER TRANSFORM MASS SPECTROMETRY

A. Kasem Chowdhury and Charles L. Wilkins
Department of Chemistry
University of California, Riverside
Riverside, CA 92521

Introduction:

Use of metals or metal complex ions as CI reagents is emerging as an area of active current research interest. In this report, we describe the results of our investigation on the utility of Au as reagents for obtaining chemical ionization mass spectra of alkanes and alkenes.

Experimental:

Experiments were carried out using a Nicolet FTMS-2000 Fourier transform mass spectrometer equipped with a dual 4.78 cm^3 cell and a 7 tesla superconducting solenoid magnet. Gold ions were generated by focussing the beam of a Tachisto 215G pulsed TEA CO_2 laser onto a gold foil. Following the ion formation laser pulse, gold ions were trapped in the cell for variable times to allow chemical ionization reactions with the selected neutral gases.

Results and Discussion:

Two fundamental processes, hydride abstraction and dehydrogenation, are involved in the reaction of gold ions with alkanes and alkenes. The processes are summarized in reactions 1-3.

$$Au^+ + \text{Alkane} \begin{cases} \text{Hydride abstraction} \longrightarrow [\text{Alkyl cation}] \longrightarrow (C_nH_{2n+1})^+ \\ \text{Dehydrogenation} \longrightarrow [Au + \text{Alkane} - nH_2]^+,\ n = 0\text{-}1 \end{cases} \quad (1)$$

$$Au^+ + \text{Alkene} \begin{cases} \text{Hydride abstraction} \longrightarrow [\text{Alkenyl cation}] \longrightarrow (C_nH_{2n-1})^+ \\ \text{Dehydrogenation} \longrightarrow [Au + \text{Alkene} - nH_2]^+,\ n = 0\text{-}1 \end{cases} \quad (2)$$

$$Au^+ + \text{Cycloalkane} \begin{cases} \text{Hydride abstraction} \longrightarrow [\text{Cycloalkyl cation}] \longrightarrow \text{no fragmentation} \\ \text{Dehydrogenation} \longrightarrow [Au + \text{cycloalkane} - nH_2]^+,\ n = 0\text{-}1 \end{cases} \quad (3)$$

Hydride abstraction by Au^+ produces excited alkyl cation which fragments to yield a series of ions (C_nH_{2n+1}) characteristic of alkanes. Figure 1 shows mass spectra of 2,2-dimethyl hexane and 2,5-dimethyl hexane which demonstrate the utility of Au^+ as a CI reagent to characterize branched isomers. In the presence of C_6F_6 (1×10^{-6} torr) in the FTMS system, all alkanes produce abundant (Au + alkane) ions to give molecular weight information. Figure 2 shows mass spectra of 1- and 3-heptene. In addition to characteristic alkene series, (CnH2n-1) ions and (Au + Alkene) ions the relative abundances of m/z 98, m/z 225, and m/z 253 clearly distiguish each isomer.

METHYLENE CHLORIDE - A USEFUL REAGENT FOR POSITIVE ION CI/MS OF ALCOHOLS, ALDEHYDES AND KETONES:

Harri G. Ramjit and Roger E. Powers;
Merck Sharp & Dohme Research Laboratories, West Point, Pennsylvania 19486

The potentials of negative ion CI/MS have been investigated using methylene chloride as the CI reagent; carboxylic acids, amino acids, amines, phenols and amides gave the $[M+Cl]^-$ ion as the base peak in most cases.(1) Yields of chlorine attachment have been explored as probes in HPLC/CI/MS, where methylene chloride has been added as mobile phase modifiers.(2) The effectiveness of chlorine attachment in the production of $[M+Cl]^-$ has been studied using mixed reagents such as methylene chloride/chloroform, carbon tetrachloride/methane.(3,4) However, Positive Ion Chemical Ionization using halogenated solvents has not been investigated. Accordingly, the object of this study was to assess the influence of methylene chloride as a CI reagent with primary, secondary and tertiary alcohols, aldehydes and ketones, employing the VG MM7035 mass spectrometer.

Methylene chloride CI mass spectra of the primary alcohols C_6-C_{12} show that protonation $(M+H)^+$ is a relatively insignificant reaction pathway, while deprotonation $(M-H)^+$ exhibits a well defined trend with increasing carbon number (Fig. 1). The intensities of $[M+H-H_2O]^+$ and $[M-H-H_2O]^+$ suggest that the $[M+H]^+$ and $[M-H]^+$ species are relatively unstable and readily dehydrate to give the carbonium ion R^+, and the alkenyl ion $[R'-CH=CH_2]^+$.

Secondary Alcohols: Alcohols such as 2-octanol and 4-heptanol exhibited $[M+H]^+$ ion intensities of less than 0.5% with $[M+H-H_2O]^+$ as the base peak; $[M-H]^+$ intensities were about 12% and $[M-H-H_2O]$ between 12 and 30%.

Tertiary Alcohols such as 3-ethyl-3-pentanol and t-butanol exhibited $[M+H]^+$ intensities at 0.1 and 0.7%, with $[M+H-H_2O]^+$ as the base peak. The $[M-H]^+$ was found to be between 4 and 9% with $[M-H-H_2O]^+$ at about 2 and 4% relative intensity.

Ketones: For the 2-ketones (C_6-C_{12}), $[M+H]^+$ increased in intensity between C_8 and C_{10}, then dropped off to about 42% at C_{12}, while the $[M-H]^+$ intensity increased somewhat linearly up to C_{10}, then formed the base peak at C_{11} and C_{12}. $[M+H-H_2O]$, on the other hand, formed the base peak up to C_9, then decreased linearly to 31% at C_{12}, while $[M-H-H_2O]^+$ plateaued between C_9 and C_{11} and decreased at C_{12} to 32% (Fig. 2). The ratio of $[M-H]^+/[M+H]^+$ (Fig. 3) shows a definite trend with increasing carbon number. This could be a reflection of keto-enol tautomerism prevalent in these compounds. The most interesting feature is the attachment of $[CHCl_2]^+$ to these ketones; the effectiveness of attachment increases from C_6 to C_{12} linearly (Fig. 2). This attachment process does not occur with the alcohols as illustrated in Fig. 4.

Aldehydes: The C_8, C_{10} and C_{12} aldehydes show $[M+H]^+$ with increasing intensity from 9% to 34%, while $[M-H]^+$ formed the base peak. Although chlorine-containing radicals yielded attachment products at intensities less than 5%, the most significant observation is the formation of the $[M-3H]^+$ species with intensities from 46 to 35%.

The reaction of methylene chloride under CI conditions with substrates such as alcohols, aldehydes and ketones where protonation, deprotonation and radical attachments are favored could be exemplified by the proposed mechanism Scheme 1.

We are currently evaluating other halogenated solvents such as chloroform and tetrachloroethylene on various classes of compounds. Our objectives accommodate such approaches as GC/MS/CI, HPLC/MS/CI and DCI. It is anticipated that qualitative and indeed quantitative procedures would be enhanced. These approaches are seen as complementary to negative ion CI studies using halogenated solvents.

PROPOSED MECHANISM FOR POSITIVE ION METHYLENE CHLORIDE CHEMICAL IONIZATION

Initiation Reaction

$CH_2Cl_2 + [CH_2Cl_2]^{\dagger} \rightarrow [CH_2Cl_3^{\bullet}]^+ + [CH_2Cl]^{\bullet}$ complex

$\rightarrow [CH_3Cl_2^{\bullet}]^+ + [CHCl_2]^{\bullet}$ complex

Product Formation

a. Attachments and Protonation

1. $M + [CH_2Cl_3^{\bullet}]^+ \rightarrow [M+CH_2Cl]^+ + Cl_2$
   $\rightarrow [M+CHCl_2]^+ + HCl$
   $\rightarrow [M+Cl]^+ + CH_2Cl_2$

2. $M + [CH_3Cl_2^{\bullet}]^+ \rightarrow [M + CHCl_2]^+ + H_2$
   $\rightarrow [M + CH_2Cl]^+ + HCl$
   $\rightarrow [M+H] + CH_2Cl_2$

b. Hyrdride Abstraction

1. $M + [CH_2Cl_3]^+ \rightarrow [M - CHCl_2^{\bullet}]^+ + HCl$
   $\downarrow$
   $[M-H]^+ + CH_2Cl_2$

2. $M + [CH_3Cl_2^{\bullet}]^+ \rightarrow [M - CH_2Cl]^+ + HCl$
   $[M-H]^+ + CH_3Cl$

REACTIVITY AND COLLISIONAL DE-EXCITATION OF ELECTRONICALLY EXCITED METAL IONS

Fred Strobel and D. P. Ridge
Department of Chemistry and Center for Catalytic Science and Technology
University of Delaware, Newark, DE 19716

Electron impact on $Mn_2(CO)_{10}$ produces electronically excited Mn^+. This electronically excited Mn^+ has a lifetime long enough to be studied under ICR conditions. The evidence for the electronically excited Mn^+ is the ratio of MnI^+ to $MnCl^+$ produced when Mn^+ reacts with ICl. Mn^+ produced by electron impact on $Mn_2(CO)_{10}$ gives 37±2% MnI^+. Mn^+ formed by surface ionization gives 19±3% MnI^+. Surface ionization presumably forms only ground state ions so the difference can be attributed to excited state ions produced by electron impact.

A measurement of the lifetime of the excited state was done on a Nicolet FTMS-2000. Mn^+ is formed in the source side by electron impact on $Mn_2(CO)_{10}$ and then is transferred to the analyzer side and isolated by ion ejections. The pressure in the analyzer side, $3X10^{-9}$Torr, assures a long mean free time between collisions. The Mn^+ was allowed to remain in this region for a variable length of time, T_d, before $Cr(CO)_6$ is pulsed into the analyzer side. The Mn^+ is allowed to react with the $Cr(CO)_6$ for 1 second before a spectrum is taken. One of the products observed is $Cr(CO)_6^+$, the result of charge transfer which is endotermic for the ground state species by .707eV. The intensity of the $Cr(CO)_6^+$ thus indicates the amount of electronically excited Mn^+ present after the variable delay T_d. A plot of ($Cr(CO)_6^+$/Total ion current) vs T_d. gives a exponential decay with a first order rate of $.17\pm.02s^{-1}$ which corresponds to a lifetime of 5.8±.7 seconds.

The lifetime that was measured may be a lower limit on the actual radiative lifetime since it is comparable to the time between collisions for Mn^+ and the background gas at $3X10^{-9}$ Torr. Dividing the unimolecular rate ($.17\ s^{-1}$) by the neutral number density gives a second order rate constant of $1.7X10^{-9}$molecules^{-1}cm^{3}s^{-1}. The background is hydrocarbons and as discussed below it is not unreasonable that the excited Mn^+ could be collisionaly relaxed by hydrocarbons at this rate constant.

The possibility that quenching of the electronically excited Mn^+ occurs was investigated by monitering the MnI^+ to $MnCl^+$ ratio for the reaction of Mn^+ produced by electron impact with ICl as N_2 and CH_4 are added to a drift cell ICR. The result indicates that N_2 is an inefficient quenching gas but CH_4 is very efficient(k_Q= $1.88\pm.35X10^{-9}$ molecules^{-1}cm^{3}s^{-1}).

A qualitative potential surface is shown in fig. 1 for the low lying states of Mn^+ reacting with CH_4. As indicated in the figure surface crossings will result if the ^5D surface is attractive. This provides the means for crossing to the repulsive ground state surface. Since the excited states are quintets and the ground state is a septet the quenching process implies that spin is not a good quantum number. The quenching process also substantiates that one of the excited states is attractive.
