These results can explain why the Mn^+ produced by electron impact on $Mn_2(CO)_{10}$ did not react with alkanes even though there is evidence for the presence of excited states which are expected to react with the alkanes efficiently. Evidently reaction cannot compete with the de-excitation process.

GAS-PHASE REACTIONS OF BIS(CYCLOPENTADIENYL)METHYL-ZIRCONIUM(1+) WITH UNSATURATED HYDROCARBONS

Christ, Jr. C.S.;Eyler, J.R.;Richardson, D.E.
University of Florida, Gainesville, FL

Recently the solution phase investigation of electron deficient transition metal complexes such as $Cp_2ZrCH_3(L)_n^+$ (n=1,2)[1,2] and $Cp^*_2ScCH_3$[3,4] has revealed a high reactivity toward hydrocarbon and nitrogen containing hydrocarbon substrates. A similar reactivity can be observed in the gas-phase for the d^0 complex $Cp_2ZrCH_3^+$ (1), allowing a direct comparison. Our work with alkenes and nitriles shows products observed in solution reactions are in many cases intermediates in gas phase reactions whereas products of the analogous gas phase reactions may provide insight into thermally accessible higher energy products or intermediates in solution.

We applied Fourier Transform Ion Cyclotron Resonance Mass Spectrometry to study the gas-phase reactions of $[Cp_2ZrCH_3]^+$ (1, Cp=cyclopentadienyl). Collision induced dissociation (CID) experiments on 1 show the loss of CH_3, strongly implying a metal-methyl structure. No evidence was found for the involvement of the Cp rings in the reactions examined, therefore the transformations below are assumed to retain the Cp_2Zr unit.

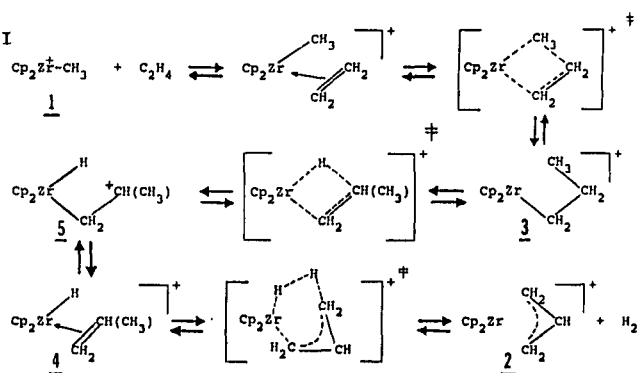
Jordan, et al.,[1] have observed ethylene polymerization by $[Cp_2ZrCH_3(THF)]^+$ in CH_2Cl_2 solution, but polymerization of ethylene by the solvent-free ion 1 is not observed in the gas phase. Instead, the energy released upon formation of $[Cp_2Zr(n\text{-}C_3H_7)]^+$ causes an intramolecular decomposition of the insertion product and produces a metal-allyl complex, $[Cp_2ZrC_3H_5]^+$(2), and H_2 (eq 1). CID experiments performed on 2 are consistent with allyl formation,as fragments corresponding only to the loss of one and two molecules of H_2 as well as C_3H_5 are produced. Reaction of 1 with ethylene

$$Cp_2ZrCH_3^+ + C_2H_4 \longrightarrow Cp_2ZrC_3H_5^+ + H_2 \qquad (1)$$

does not produce $[Cp_2ZrH]^+$, thus B-hydride abstraction followed by alkene elimination[5] is not observed in the gas-phase.

An investigation of mechanistic aspects of the ethylene reaction by using C_2D_4 shows a significant amount of hydrogen-deuterium scrambling, eliminating 11% D_2, 74% HD, and 15% H_2, which is somewhat different from the statistical distribution of 28.6% D_2, 57.1% HD, 14.3% H_2. A possible mechanism for the reaction of 1 with ethylene to produce 2 is given in Scheme I. Scrambling probably occurs during interconversion of the insertion product (3) and hydride intermediate (4) via successive hydride shifts along the three carbon framework of intermediate (5).

Scheme I



In the gas-phase rapid insertion of CD_3CN and elimination of CH_3CN occurs before the mono-adduct $Cp_2Zr(CH_3)(CD_3CN)^+$ is observed (eq 2).

$$Cp_2ZrCH_3^+ \ (1) \ + \ CD_3CN \longrightarrow Cp_2ZrCD_3^+ \ + \ CH_3CN \quad (2)$$

The insertion/elimination process yields products with no H-D scrambling observed implying an intact transfer of CD_3.

$Cp_2ZrCH_3^+$ (1) adds one molecule of acetonitrile yielding two isomers (m/z 276), $Cp_2ZrCH_3(NCCH_3)^+$ (6) and $Cp_2Zr(NC(CH_3)_2)^+$ (7) (eq. 3,4). Only (7) is reactive to coordination of a second acetonitrile molecule (eq 5).

$$Cp_2ZrCH_3^+ \ (1) + CH_3CN \longrightarrow Cp_2ZrCH_3(CH_3CN)^+ \ (6) \quad (3)$$

$$Cp_2ZrCH_3^+ \ (1) + CH_3CN \longrightarrow Cp_2Zr(NC(CH_3)_2)^+ \ (7) \quad (4)$$

$$Cp_2Zr(NC(CH_3)_2)^+ \ (7) + CH_3CN \longrightarrow Cp_2Zr(NC(CH_3)_2)(CH_3CN)^+ \ (8) \quad (5)$$

Structures were assigned to the isomers, (6) and (7), based on known solution structures and our gas-phase experimental results. Jordan et al. have reported similar product formation, i.e. the isolation of $Cp_2ZrCH_3(CH_3CN)^+$ as a salt of BPh_4^- and the observation of $Cp_2Zr(NC(CH_3)_2)(CH_3CN)^+$ detected by nmr after irreversible acetonitrile insertion.[2] Several experimental facts support the assignment of structurally isomeric products (6) and (7). Coordination of a second acetonitrile molecule to (m/z 276) occurs initially producing (m/z 317), however the addition stops leaving only the inert isomer (6) (m/z 276). The inert isomer (6) may be isolated and translationally excited; upon collision a rearrangement occurs forming the reactive isomer (7) and after an appropriate reaction time coordination of acetonitrile takes place producing $Cp_2Zr(NC(CH_3)_2)(NCCH_3)^+$, (8). Experiments to determine the effect of acetonitrile pressure have also been performed and indicate that an approach to equilibrium is not a reasonable explaination for the decrease in the rate of conversion of the (m/z 276) to (m/z 317).

Our observations suggest that intermediates of polymerization and metathesis reactions also occur in the solvent-free reactions of electron deficient d^0 transition-metal complex ions. Complexes formed following elimination of H_2 from these chemically activated gas-phase intermediates are possible products of chain termination in the polymerization of alkenes by solvated d^0f^n transition-metal catalysts. In addition, the formation of allyl species in solution and the possible role of this process in introducing unsaturation into polymers warrants further investigation. Reactions of acetonitrile are consistent with mechanisms proposed for analogous reactions in solution. This implies similar mechanisms may be used to understand these and related reactions in the gas-phase.

AN FTMS STUDY OF THE GAS-PHASE CHEMISTRY OF THE METAL DIMER $ScFe^+$

Leo M. Lech and Ben S. Freiser
Department of Chemistry
Purdue University
West Lafayette, IN 47907

The interest in both ionic and neutral metal clusters has increased tremendously in the past decade. Our laboratory has been actively studying the chemistry of various metal dimers. In one of these studies it was determined that the Sc^+-Fe bond strength was the lowest of a series of MFe^+ bond strengths (M = Ti, V, Cr, Fe, Co, Ni, Cu, Nb, Ta). The focus of this work was to determine if this weak dimer bond strength resulted in any unique chemistry between the dimer and various small organics. Reactions of $ScFe^+$ with both the linear butenes and isobutene reflect the weak cluster bond strength as do virtually all of the collision-induced dissociation (CID) spectra of various $ScFe^+$-ligand species.

The $ScFe^+$ dimer was generated and isolated in the gas-phase using Fourier transform mass spectrometry (FTMS), equation 1.

$$Sc^+ + Fe(CO)_5 \longrightarrow ScFe(CO)_3^+ \xrightarrow{CID} ScFe^+ \qquad (1)$$

By trapping the dimer in the presence of an organic, we can study the chemistry of $ScFe^+$. As expected, the observed chemistry of $ScFe^+$ is significantly different from the chemistry of the bare metal ions Sc^+ and Fe^+. There are much fewer reactive processes seen for the dimer and, when these reactive processes are observed, they involve predominantly, activation of C-H bonds. The single metal ions on the other hand are more reactive and have a higher affinity for C-C bond activation, especially in the case of Fe^+. One of the most interesting reactions observed for $ScFe^+$ is with the butenes. For example, in the reactions with 1-butene, Fe is displaced from the cluster generating the stable Sc^+-butadiene, equation 2. The Sc^+-butadiene can react with a second butene generating $Sc(C_4H_6)_2^+$ which is

$$ScFe^+ + C_4H_8 \longrightarrow ScC_4H_6^+ + FeH_2 \qquad (2)$$

isobaric with $ScFe(C_4H_4)^+$, a possible double dehydrogenation product of butene by $ScFe^+$, equation (3). The positive identification of this ion was obtained by implementing two different experiments. First, double resonance

$$ScFe^+ + C_4H_8 \longrightarrow ScFe(C_4H_4)^+ + 2H_2 \qquad (3)$$

ejection was used, Figure 1. When $Sc(C_4H_6)^+$ was continuously ejected during the reaction period, the product ion was not formed thus indicating that it arises directly from $Sc(C_4H_6)^+$. Also, when the product ion was collisionally activated, it lost a fragment corresponding to 54 a.m.u. which would not be possible if the ion was $ScFe(C_4H_4)^+$, equation 4.

$$Sc(C_4H_6)_2^+ \xrightarrow{CID} Sc(C_4H_6)^+ + C_4H_6 \quad (4)$$

$$ScFe(C_4H_4)^+ \xrightarrow{CID} \text{can not lose 54 a.m.u.}$$

The other reactions of $ScFe^+$ with alkenes show almost exclusive dehydrogenations. The weak nature of the cluster bond is again observed when the $ScFe^+$-ligand product ions from these reactions are collisionally activated. In virtually all of the CID processes observed, the cluster is broken apart resulting in a neutral loss of Fe,FeH, or FeH_2 implying in general that $D^\circ(Sc^+\text{-ligand}) > D^\circ(Sc^+\text{-Fe})$.

BIMOLECULAR REACTIONS OF DOUBLY CHARGED METAL IONS IN THE GAS PHASE

S.W. Buckner, T.J. MacMahon, Y. Huang, J.R. Gord, and B.S. Freiser
Department of Chemistry
Purdue University
West Lafayette, IN 47907

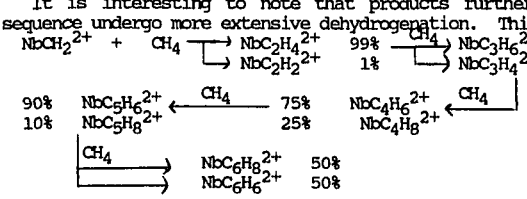
There has been much interest in the reactivity of gas-phase metal ions with small organic molecules as seen in the extensive literature relating to this topic. Multiply charged metal ions have not received much attention, however, due in part to the belief that rapid charge exchange would occur exclusively. In a very interesting recent paper, Tonkyn and Weisshaar [1] have observed clustering reactions of Ti^{2+} with methane and hydride abstraction from ethane in a flowing afterglow. This has prompted us to look at some bimolecular reactions of doubly charged early transition metals with various organic molecules under low pressure conditions in a Fourier transform mass spectrometer (FTMS). In this paper we present a "progress report" on our efforts in this area, including some recent results on (i) the reactions of M^{2+} (M = Nb, La, Zr, Ta) with methane, ethane and propane; (ii) the formation and reactions of the first doubly charged heteronuclear dimer species $LaFe^{2+}$; and (iii) the determination of kinetic energy release in the charge transfer reaction $M^{2+} + A \rightarrow M^{+} + A^{+}$ using FTMS methods.

Nb^{2+}, Zr^{2+} and Ta^{2+} are observed to react via other routes besides charge exchange, as in reactions 1 and 2 with methane. La^{2+}, however, is

$$M^{2+} + CH_4 \rightarrow \begin{cases} MCH_2^{2+} + H_2 & (1) \\ MH^{+} + CH_3^{+} & (2) \\ M^{+} + CH_4^{+} & (3) \end{cases}$$

unreactive with methane. Observation of MCH_2^{2+} from methane implies $D(M^{2+}-CH_2) > 112$ kcal/mol. In fact, we have assigned $D(Nb^{2+}-CH_2) = 197 \pm 10$ kcal/mol which can be compared to $D(Nb^{+}-CH_2) = 109 \pm 7$ kcal/mol [2].

$NbCH_2^{2+}$, $ZrCH_2^{2+}$ and $TaCH_2^{2+}$ all react further with CH_4. For example, $NbCH_2^{2+}$ reacts sequentially with CH_4, reaction 4, generating a variety of products. It is interesting to note that products further along in the reaction sequence undergo more extensive dehydrogenation. This may be



(4)

indicative of ligand coupling, as would be expected in a reaction which incorporates six separate C_1 units. Nb^{2+} reacts with C_2H_6 at least three times, reactions 5-11.

$$Nb^{2+} + C_2H_6 \rightarrow NbCH_2^{2+} + CH_4 \quad (5)$$
$$\rightarrow NbC_2H_2^{2+} + 2H_2 \quad (6)$$
$$\rightarrow NbC_2H_4^{2+} + H_2 \quad (7)$$
$$\rightarrow Nb^{+} + C_2H_6^{+} \quad (8)$$
$$\rightarrow NbH^{+} + C_2H_5^{+} \quad (9)$$

$$NbCH_2^{2+} + C_2H_6 \rightarrow NbC_3H_4^{2+} \xrightarrow{C_2H_6} NbC_5H_6^{+} \quad (10)$$

$$NbC_2H_2^{2+} + C_2H_6 \rightarrow NbC_4H_4^{2+} \; 75\% \xrightarrow{C_2H_6} NbC_6H_6^{2+} \quad (11)$$
$$\rightarrow NbC_4H_6^{2+} \; 25\%$$

A natural extension of this work is the study of doubly charged cluster ions. Recently, Tsong and coworkers [3] provided evidence for the first reported doubly charged metal dimer species, Mo_2^{2+}. The lifetime of this species was given a lower limit of several tens of nanoseconds, and it was not clear whether or not the species was metastable. We have successfully generated $LaFe^{2+}$ and shown it to be stable for at least on the order of seconds. The $LaFe^{2+}$ was generated <u>in situ</u> by collision-induced dissociation on $LaFe(CO)_2^{2+}$, which was formed from the reaction of La^{2+} with $Fe(CO)_5$. This method may be generalized to other systems, and, for example, we have generated YFe^{2+} in a similar manner. Nb^{2+} and Ta^{2+} react with $Fe(CO)_5$ only by charge transfer, and, thus, the corresponding dimers could not be synthesized. The nature of the bonding in $LaFe^{2+}$ is of real interest and calculations are underway in collaboration with Dr. Bauschlicher at NASA-Ames. Preliminary results indicate that the bonding is somewhere between the two possibilities La^{2+}-Fe and La^{+}-Fe^{+}, i.e. with La having most but not all of the charge.

Finally, in order to obtain additional information on the thermochemistry and reaction dynamics of these species, we have successfully transferred the methodology of Marx [4] and Bowers [5] to our FTMS to determine the kinetic energy released when a doubly charged ion undergoes charge exchange (or abstracts a negatively charged fragment) with a neutral to form two singly charged ions, which subsequently repel each other. As a model system, the reaction of Nb^{2+} with benzene to form Nb^{+} and $C_6H_6^{+}$ has been studied. Not surprisingly, a range of kinetic energies is observed indicating that the products are generated with a variety of internal energies.

CLUSTERING REACTIONS AND THERMOCHEMISTRY OF LASER ABLATED METAL IONS

F. Bouchard, J.W. Hepburn and T.B. McMahon,
Department of Chemistry, University of Waterloo, Waterloo, Ont.,Canada, N2L 3G1

In this experiment, we are using a conventionnal High Pressure Mass Spectrometer(1) suitably modified to allow a laser beam to penetrate the high pressure region(Fig. 1). A metal target located inside is the source for laser generated metal ions. Those ions diffuse randomly, undergoing thousands of collisions which efficiently cool them to the temperature of the gas. Furthermore, they can react in the bath with ligands of interest, cluster and equilibriate. The ions can diffuse freely through a small aperture of about 100 μm into a low vacuum region. They are then extracted, separated with a magnetic sector mass spectrometer and detected using a multichannel technique which provides a time profile of each ion. The entire experiment is pulsed.

The scope of our experiment is to generate metal ions in the HPMS using an excimer laser(308 nm) and to look at clustering equilibria between the metal ions and the ligand of interest. Up to now, $[Cu(X)_n]^+$ was observed for n=1 to 2 for X = Ar and Ne, n=1 to 3 for Xe and Kr and n = 1 to 4 for H_2O, N_2, CH_3OCH_3 , CO, CO_2, N_2O, CS_2 and CH_3OH. We have also observed various clusters containing aluminum, platinum or iron as the metal ion.

Under conditions of a mild supersonic expansion which is achieved by using 1 mm apertures, equilibrium time profiles were obtained when a xenon bath (5 torr) was allowed to react with copper ions (Fig. 2).

Using a gas tight source (100 μm apertures), water-copper ion equilibria have been observed and studied. Laser generated ions were allowed to react with 0,06 torr of H_2O in ≈ 4 torr of N_2. The ion time profiles are shown on Figure 3. For the first equilibrium: $Cu^+ + H_2O \leftrightarrow [Cu(H_2O)]^+$, the equilibrium constant is 1900 at 300K. This yields a ΔG value of 4,5 kcal/mol. Estimating ΔS to be about 20 cal/molK, we find ΔH to be 10.5 kcal/mol. In the case of the second equilibrium, $[Cu(H_2O)]^+ + H_2O \leftrightarrow [Cu(H_2O)_2]^+$, K is $1x10^6$, ΔG is 8,2 kcal/mol. Taking ΔS to be 25 cal/molK, ΔH is thus 15.7 kcal/mol for the second water-copper bond.

In the near future, temperature dependent studies will be conducted to definitely assess the bond energies and entropy changes involved in the clustering of water onto copper. Furthermore, other metals and others ligands will be studied. A cooled source is also being constructed. This source will allow the determination of the energetics of rare gases attachement onto metal ions.

TRANSITION METAL CATION MEDIATED CARBON-CARBON BOND FORMATION IN A MULTIQUADRUPOLE MS/MS/MS INSTRUMENT

Claude Beaugrand,
Nermag, 49 quai du Halage, 92500 Rueil-Malmaison, France
Hélène Mestdagh, Nicole Morin and Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75005 Paris, France

Most of the known reactions of transition metal cations with organic molecules involve chemical bond cleavage. For instance 2-methylpropane reacts with Fe^+ or Ni^+ by dehydrogenation or methane loss. For an organic chemist carbon-carbon bond formation looks more exciting ! We report here that reactive alkyl halides can be coupled by iron carbonyl cations ; typically allyl chloride leads to the formation of hexadiene radical cation :

$$Fe(CO)_n^+ + C_3H_5Cl \longrightarrow C_6H_{10}^{+\cdot} + n\ CO + FeCl_2$$

$Fe(CO)_n^+$ ions were generated in source by electron impact on $Fe(CO)_5$, mass selected using the first quadrupolar analyzer, and reacted with allyl chloride (1 mtorr) in the first RF-only collision cell. After mass selection by the second analyzer, the reaction products could be submitted to CAD (or to new reaction) in the second RF-only collision cell. The resulting fragments were finally scanned in the third analyzer.

Whereas bare Fe^+ leads mainly to $C_3H_5^+$ ion, which reacts further with allyl chloride, the presence of CO ligands allows fixation of the elements of allyl chloride on the transition metal ion, as indicated by the following major reaction pathways :

$$Fe^+ + C_3H_5Cl \longrightarrow C_3H_5^+ + FeCl \xrightarrow{C_3H_5Cl} C_6H_9^+,\ C_6H_7^+$$

$$Fe(CO)_2^+ + C_3H_5Cl \longrightarrow FeC_3H_5Cl^+ + 2CO$$

$$Fe(CO)_4^+ + 2C_3H_5Cl \longrightarrow FeC_6H_{10}Cl_2^+ + 4CO$$

$Fe(CO)^+$ and $Fe(CO)_3^+$ give intermediate results. $Fe(CO)_5^+$ is less reactive and undergoes mainly CO loss.

Ion $C_6H_{10}^{+\cdot}$, corresponding to the coupling of two allyl units, was found among the reaction products for n>2. Its CAD spectrum was very similar to the fragmentation pattern of hexadiene radical ions. CAD of $FeC_3H_5Cl^+$ ion gives mainly the following products, suggesting structure 1 :

$$FeC_3H_5Cl^+ \longrightarrow FeCl^+ + C_3H_5 \text{ (favored by high collision energy)}$$
$$\searrow FeC_3H_4^+ + HCl \text{ (favored by low collision energy)}$$

CAD of $FeC_6H_{10}Cl_2^+$ ion shows that it is the actual precursor of $C_6H_{10}^{+\cdot}$ ion :

$$FeC_6H_{10}Cl_2^+ \longrightarrow C_6H_{10}^{+\cdot} + FeCl_2$$
$$\searrow FeC_3H_5Cl^+ + C_3H_5Cl$$

A mixture of structures 2 and 3 would account for both fragmentation pathways of $FeC_6H_{10}Cl_2^+$ ion. Ligand exchange experiments confirmed this hypothesis : when $FeC_6H_{10}Cl_2$ was submitted to reaction with methallyl chloride C_4H_7Cl in the second collision cell (a variable reaction time was allowed, using ion confinement technique), replacement of one C_3H_5Cl ligand by one C_4H_7Cl ligand, expected to take place on structure 3, occurred at first very rapidly, but remained incomplete.

The coupling reaction occurring within the $FeC_6H_{10}Cl_2^+$ complex and leading to $C_6H_{10}^{+\cdot}$ ion is analogous to the transition metal promoted coupling of allylic halides in solution (Corey reaction). As in solution it does not occur on saturated alkyl halides. These results also show the key role of the CO ligands for the formation of the intermediate iron complex in the coupling reaction.

EXPERIMENTAL AND THEORETICAL INVESTIGATIONS INTO CHAINLENGTH EFFECTS IN THE CHEMISTRY OF TRANSITION METAL IONS WITH ORGANIC MOLECULES; John Allison, Deborah J. Hankinson, Cliff B. Miller, Eric J. Hooper, Anthony Tsarbopoulos, Tammy L. Wyatt, Department of Chemistry, Michigan State University, East Lansing, MI 48824

We have been using a simple electrostatic calculation to model possible interactions that occur between a metal ion and an organic molecule "before the chemistry starts". These interactions are being investigated to determine whether early events can be correlated to final product distributions. We have proposed the following: Initial ion/molecule interactions are largely electrostatic in nature. Such interactions will create "hot spots" - sites within the molecule that are highly attractive to a transition metal ion. The hot spots that correspond to the deepest potential wells represent those parts of the molecule about which the ion may reside, and hence positions from which chemistry (i.e., M^+ insertion into a bond) may occur. In the model used here, we consider interactions of the ion with each bond (using a bond-polarizability model), and with each atom (considering both partial charges on the atoms, and repulsive interactions).

In previous ASMS meetings[1], we have discussed these calculations for Cr^+ interacting with butane and butyl chloride. In the case of butane, it was found that positions about the interior C-C bond were more attractive than those in close proximity to the terminal C-C bond. This correlates with the observation that first row transition metal ions (M^+) form the product $MC_2H_4^+$ to a greater extent than the product $MC_3H_6^+$. In the case of butyl chloride, the most attractive molecular environment was atop the C-Cl bond, which again correlates with the observed chemistry, which is dominated by attack of that bond.

Here we report preliminary results for chlorohexane. The interaction of Cr^+ with a number of configurations of chlorohexane have been studied. The molecule is sufficiently large that hot spots analogous to those found in both butane and butyl chloride are present. The unique feature of these larger molecules is their ability to participate in multiple interactions with the metal ion. We had previously proposed[2] that when M^+ reacts with a molecule such as chlorohexane, the first interaction is with the electronegative Cl- end. Then, if the complex is sufficiently long-lived, parts of the alkyl chain can be accessed by M^+ via 5- and 6-membered rings. Through such multiple interactions, parts of the alkyl chain far from the functional group can be brought close to the metal ion, and thus become candidates for insertion to occur. In the electrostatic model presented here, the potential energies associated with such 5- and 6-membered ring intermediates are larger than those for simpler interactions.

If one considers attractive potentials close to the molecule, it appears that M^+ could access every bond, although this is not observed experimentally. However we find that, for molecules possessing permanent dipole moments, regions of positive potential exist at longer range about some parts of the alkyl group (e.g., close to the methylene unit adjacent to the Cl-, since this carries a substantial positive charge). These repulsive regions may prevent access of the attractive regions that lie closer to the atoms in the molecule.

The figure shows a family of potential curves for the Cr^+/chlorohexane system, for one of the configurations that we have studied. The points on the curve marked -10 kcal/mol indicate those positions where Cr^+ could be placed to yield this interaction energy. While the actual energies determined by this simple model appear to be higher than those determined experimentally, we have found the relative values to be extremely useful in suggesting the relative importance of the various molecular environments that the molecule presents to an incoming metal ion.

Shown above is a family of potential curves about a configuration of chlorohexane, as it interacts with Cr^+. This configuration was selected to investigate the relative stability of a 5-membered ring type of intermediate, in which the Cr^+ interacts with both the chlorine and a methylene unit in the hexyl group. This creates a region in space that is more attractive than any other "hot spot" about the molecular framework.

THE GAS PHASE CHEMISTRY OF NICKEL AND NICKEL-CONTAINING IONS WITH AROMATIC COMPOUNDS; Richard M. Stepnowski, John Allison, Department of chemistry, Michigan State University, East Lansing, MI 48824

The gas phase chemistry of transition metal ions with organic molecules has been extensively studied in recent years, using ion cyclotron resonance (ICR) and ion beam techniques. The organic molecules that have been studied include alkanes, as well as molecules that contain the basic alkyl structural features (straight chain, cyclic, branched) and functional groups of organic chemistry (halogens, alcohols, acids, esters, ketones, ethers, amines, nitro-compounds and nitriles)[1]. Some multifunctional compounds have also been studied.[2,3] The major reaction mechanisms have been discussed and reviewed.[1]

For small compounds such as alkyl halides (RX)[4], reaction products appear to be formed via a series of elementary steps. First, a transition metal ion such as Fe^+ inserts into the C-X bond to yield the intermediate $R\text{-}Fe^+\text{-}X$. If the R- group is an ethyl group or larger, a β-H shifts to yield a complex of the form $(C_nH_{2n})Fe^+(HX)$. The complex dissociates in a competitive ligand loss step.[3] For more complex functional groups (e.g., carboxylic acids), insertion into bonds within the functional group can also be important.[5,6]

This study involves the reactions of Ni^+, $NiCO^+$, $NiPF_3$, and $NiCp^+$ with a variety of aromatic compounds, including phenyl, benzyl, and aromatic carbonyl compounds. Reaction products and pathways were determined by Ion Cyclotron Resonance (ICR) Mass Spectrometry.

The phenyl group in some aspects behaves chemically intermediate to the methyl and ethyl groups. H transfer from the phenyl group is a high energy process, closer to the energy required for H transfer from a methyl group than an ethyl group. Nonetheless, reactions such as:

$$Ni^+ + C_6H_5X \rightarrow NiC_6H_4^+ + HX$$

are observed. The formation of a strong benzyne-Ni^+ bond makes this reaction possible in a few cases. When other pathways are open, such as the elimination of a small neutral molecule from the functional group, this pathway is preferred. For example, nitrobenzene reacts with Ni^+ via a nitro to nitrile isomerization[6] to first lose NO, then CO, leaving C_5H_5 retained by the metal ion:

$$Ni^+ + C_6H_5NO_2 \rightarrow NiC_5H_5^+ + NO + CO$$

A major effect of the phenyl group is its inductive effect. This can be seen in reactions of substituted benzyl compounds. The weak $C_6H_5CH_2\text{-}X$ bond plays an important role in these reactions. This bond is the only bond attacked for most of the benzyl compounds studied. Charge transfer to the $C_6H_5CH_2$ moiety following insertion into this bond occurs for benzyl chloride, benzyl bromide, and benzyl alcohol, due to the low ionization potential of the benzyl radical.

Most of the trends in reactivity can be explained by the steric effects of the ligand. By size, Cp > PF_3 > CO. This is also the same order as for the metal-ligand bond energies. The reactivity of the ligated metal ions $NiCO^+$, $NiPF_3^+$, and $NiCp^+$ may be related to both these factors. The NiL^+ ions often insert into bonds where steric interactions will be minimized in the insertion imtermediate.

The reactions of $NiPF_3^+$ follow closely the reactions of $NiCO^+$, with slightly less reactivity observed for the $NiPF_3^+$ ion. The bonding of the ligand in $NiCO^+$ and $NiPF_3^+$ is similar (primarily electrostatic, according to recent theoretical studies[7]) so this is not surprising. The slightly less reactivity of $NiPF_3^+$ reflects the steric crowding involved for insertion produced by this larger ligand. Much of the chemistry of the NiL^+ ions can be explained by the formation of intermediates with low steric interactions. The reactivity of $NiCp^+$ with the halobenzenes indicate that the Cp ligand affects the metal ion much differently than either CO or PF_3. Charge transfer to the cyclopentadienyl group may occur, to increase its aromatic character (giving it 6 π electrons) explaining why this ion is more reactive than the other NiL^+ species in some cases. In other cases, such as the aromatic carbonyls the steric hindrance of the bulky Cp group appears to prohibit reactions from occuring.

We also observed that Ni^+, produced by 70 eV electron ionization on the organometallic compounds $Ni(CO)_4$, $Ni(PF_3)_4$, and NiCpNO, have somewhat different reactivity. For example, Ni^+ produced from NiCpNO reacts with iodobenzene to form only the adduct $NiC_6H_5I^+$, while Ni^+ produced from $Ni(CO)_4$ and $Ni(PF_3)_4$ reacts according to:

$$Ni^+ + C_6H_5I \rightarrow NiC_6H_4^+ + HI \quad (1)$$

$$Ni^+ + C_6H_5I \rightarrow NiC_6H_5^+ + I \quad (2)$$

The ratio of products 1 and 2 is 1:1 for Ni^+ produced from $Ni(CO)_4$ and 1:2 for Ni^+ produced from $Ni(PF_3)_4$. Future work in our lab will determine if the Ni^+ ions, produced from different precursor molecules, are formed in excited states and what the relative population of those states are.

TIME-RESOLVED METASTABLE FRAGMENTATIONS OF METHYL ACETATE IONS

R. Arakawa
Institute of Chemistry, College of General Education,
Osaka University, Toyonaka 560, Japan

The unimolecular gas-phase chemistry of ionized methyl acetate has been the subject of a number of studies.[1-5]

$$CH_3COOCH_3^{+\cdot} \longrightarrow CH_3CO^+ + COH_3^{\cdot} \qquad (1)$$

The main interest consists in what configuration is a reacting precursor in complexity of isomerization/dissociation paths. Extensive labeling experiments[2,4] on methyl acetate and its enol isomer have proposed that the distonic ion, $CH_3\overset{+}{C}(OH)O\dot{C}H_2$, in which the charge and radical site are separated by more than one atom, is a key intermediate. This intermediate accounts for the considerable loss of positional identity of H and D atoms in the labeled isomers. However, the time-resolved mass spectra of ionized methyl acetate[4] indicated that the isomerization of methyl acetate ion is a rate-determining step in a μsec time-frame. On the other hand, ab initio calculations showed that the hydrogen-bridged ion/dipole complex, $CH_3CO\text{-}H\text{-}OCH_2^{+\cdot}$ is probably a precursor ion decomposing to CH_3CO^+ and $\dot{C}H_2OH$.[5] In this way, the reaction path of ionized methyl acetate is still an unsettled problem.

The reaction (1) has a strong metastable peak in a μsec time-frame. The apparent appearance energy is only 0.7 eV higher than ionization energy, and thus RRKM theory predicts no metastably slow rate. One way of accounting for such unusual characteristics is to assume a mechanism that the reaction path involves isomerization to a more stable structure prior to the dissociation.[6] We have investigated which isomer serves as the intermediate precursor, when assuming the prior isomerization mechanism, so as to explain the experimental time-resolved metastable fragmentation. The metastable ion intensities were measured as a function of ion-source-residence time by trapped ion mass spectrometry[7].

Figure 1 shows the metastable-to-main beam intensity ratio against the ion-residence time at electron impact energy of 40eV. The decay of metastable ion is principally dependent on rate vs. energy. Along a potential energy profile (Fig. 2) obtained by Heinrich et el.[5] using a high level of ab initio calculations, we suppose two prior isomerization models accounting for the unimolecular dissociation rate; the distonic ion and the hydrogen-bridged complex serve as a precursor ion. The vibrational frequencies for RRKM calculations are obtained from a

vibrational analysis for the assumed geometries and approximate simple valence fields. The experimental results are well reproduced by the distonic ion model(———) compared with the hydrogen-bridged complex model(----). The prior isomerization can yield slow dissociation rates($\lesssim 10^5$ s^{-1}). This is because the distonic ion model exhibits the high activation energy, and the hydrogen-bridged complex model has a loose structure in spite of low activation energy. Both models provide the higher state-density of the reactant at threshold energy. Finally, it is suggested from the present results of time-resolved metastable fragmentations that the distonic structure among the several isomers is the plausible precursor decomposing metastably to CH_3CO^+ and $\dot{C}H_2OH$.

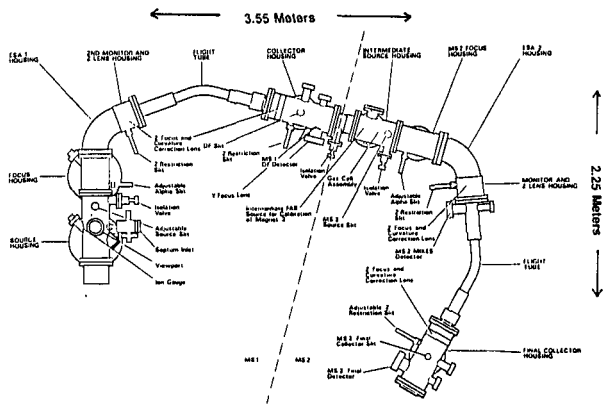
USE OF A VG 70-4SE TANDEM FOUR-SECTOR MASS SPECTROMETER IN STRUCTURAL STUDIES

R.M. Milberg*, J.M. Curtis, L.S. Rong, and K.L. Rinehart, School of Chemical Sciences, University of Illinois, Urbana,IL 61801; R.H. Bateman, B.N. Green, and G.W.T. Lee, VG Analytical Ltd., Floats Road, Wythenshawe, Manchester, M23 9LE, United Kingdom.

Introduction

The VG Instruments 70-4SE, a new double focusing, four-sector tandem mass spectrometer of E-B-E-B geometry (mass range to 3000 amu at 8-kV accelerating potential), has been in use since November 1987 at the University of Illinois. The MS1 section of the instrument is a standard VG 70-SE and meets all of the 70-SE performance specifications. The MS2 section is a modified 70-SE. The 70-4SE has a calibration-only FAB ion source and a high efficiency gas collision cell between MS1 and MS2. MS1 is used for EI and CI GC-MS and probe sample service work in our laboratory. The 70-4SE is interfaced to a VG 11-250J data system which provides control for MS/MS measurements. The four-sector tandem FAB sensitivity is greater than 6 x 10^{-9} amp for the m/z 133 ion of CsI at the MS2 detector for ions from MS1 and the CID collection efficiency is greater than 10% for the daughter ions of the m/z 142 precursor ion of n-decane from MS1 in the EI mode with the gas cell grounded.



VG 70-4SE

Results

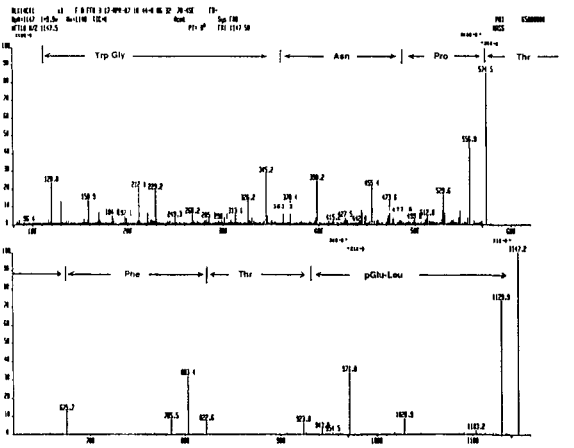
We have employed the 70-4SE for the study of the fragmentation of a number of peptides, marine natural products, and antibiotics, employing samples as small as 300 ng.

A neuroactive decapeptide, HTF-II, was isolated from Carausius morosus, an Indian stick insect. From FABMS, FAB-MS/MS, and amino acid analysis the sequence below was determined:

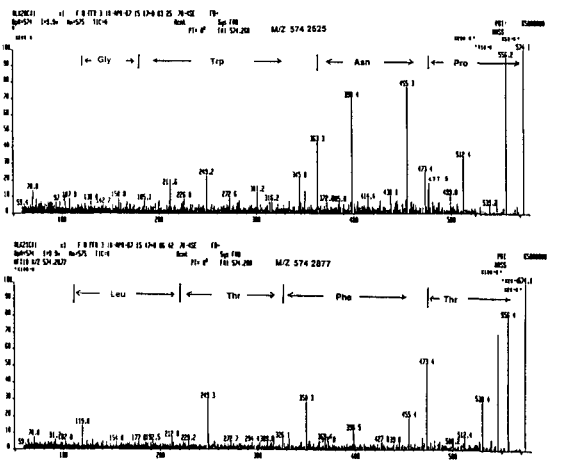
pGlu-Leu-Thr-Phe-Thr-Pro-Asn-Trp-Gly-Thr-NH_2

The analog HFT10 (with a hydroxyl C-terminus) was then generated on a peptide synthesizer in a structure-activity realationship study. The FABMS spectrum of HFT10 has a (M+H) peak at m/z 1147.5 and a large fragment at m/z 574.2. The MS/MS spectra of m/z 1147.5, shown below, has a large daughter ion at m/z 574. High resolution FABMS measurements found that the m/z 574 peak was a doublet at 574.2877 and 574.2625. The MS1 section was tuned to 15,000 resolution (10% valley) and MS/MS spectra,

shown below, were obtained of the two isobaric peaks. The data indicate that the daughters of m/z 574.2877 are derived from the C-terminal pentapeptide sequence and the daughters of m/z 574.2625 are derived from the N-terminal pentapeptide sequence.



MS/MS of HFT10



MS/MS of Peaks at m/z 574

Conclusions

The VG 70-4SE is a versatile tandem mass spectrometer which occupies the same floor space as a VG ZAB-SE instrument. The 70-4SE is used for routine probe and GC/MS service work employing EI and CI as well as performing MS/MS studies using FAB and EI.

AN EXPERIMENTAL INVESTIGATION OF FACTORS AFFECTING THE EFFICIENCY OF COLLISION-INDUCED DISSOCIATION OF PROTONATED PEPTIDE IONS.*

A.J.Alexander and P.Thibault**
National Research Council of Canada, 1411 Oxford St., Halifax, Nova Scotia, Canada B3H 3Z1; ** 6100 Royalmount Avenue, Montreal, Quebec, Canada H4P 2R2.

Tandem mass spectrometry under high (1) and low (2) collision energy regimes is a powerful tool in the characterization of peptides. Tandem sector instruments have proved more successful at generating diagnostically useful fragments from higher mass precursor ions (>1000 Da), and such MS/MS spectra are less dependent on instrumental parameters than those generated using XqQ instruments. In the latter the collision energy E(Lab), the amplitude of the RF power in q, the type of target gas (Tg) and its thickness P(Tg) are some of the parameters influencing the quality of the spectra (3).

Results from a study of Leu-Enkephalin (Tyr-Gly-Gly-Phe-Leu, MH+ 556), using an instrument of BEqQ geometry, show that different combinations of E(Lab) and P(Tg) with either argon or xenon target gas can be used to generate comparable daughter ion spectra (4), e.g. very similar MS/MS spectra were obtained with argon or xenon using E(Lab) values of 40 or 20 eV respectively, and 20% attenuation of the precursor ion. The degree of collisional activation in q could be easily controlled via changes in either E(Lab), P(Tg) or Tg. Xenon was more efficient than argon for generation of fragment ions at a given value of E(Lab), under both single and multiple collision conditions.

The combined influence of the RF amplitude and E(Lab) on the transmission of both precursor and fragment ions through q were in accord with established principles, given the significantly higher mass of the precursor ion studied here than in previous evaluations of the performance of XqQ tandem instruments.

However, studies on a series of Dynorphin peptide fragments (Leu-Enkephalin plus n residues, where n = 1,2 and 3) showed that with increasing precursor ion mass it becomes more difficult to obtain useful spectra for CID reactions conducted at low values of E(Lab) in q (Figure 1). This is only in part due to the fall-off in transmission of the deceleration lens/qQ assembly. The change in amino acid content also contributes to the observed change in fragmentation behaviour. For example Leu-Enkephalin-Arg and Leu-Enkephalin-Lys were found to exhibit quite different unimolecular and CID fragment ion spectra.

The exceptions observed thus far to this trend of lower efficiency CID with increasing mass (e.g protonated Gramacidin S, m/z MH+ 1141) have in common one significant feature, viz. an intense spectrum under unimolecular conditions (Figure 2). This suggests that collisional activation of large ions (MH+ approximately 800 Da or higher) at E(Lab) values less than 120 eV or so results in only a small <u>fractional</u> increase in the internal energy of the precursor. Under such conditions the pre-collision internal energy, assessed by the extent of unimolecular dissociation, largely determines the quality of the fragment ion spectrum generated by CID. This disparity between pre-collision internal energy and additional energy gained from the collision will increase as the mass (and thus number of vibrational modes) of the precursor ion increases.

A New Totally Automated Hybrid MS/MS System

M.R. Clench, R.Owen, V.C. Parr and D. Wood
VG Tritech Ltd., Crewe Rd., Wythenshawe, Manchester, England

Objective

To design a hybrid MS/MS system which offers a comprehensive set of MS/MS experiments at both high and low collision energies. Parent ion resolutions of up to 7500 should be achieved.

In addition the instrument control system should offer total flexibilty in choice of conditions without being overly complicated.

Introduction

The TS-250, with its air cored magnet [1] has become accepted as a flexible and easy to use general purpose GC/LC-MS instrument. Only in the field of MS/MS are there limitations in the available performance. This area has been addressed by TRIBRID, a unique MS/MS workstation based upon the successful TS-250 design. It has three collision cells and three analysers to allow complete freedom of choice of collision energies and modes of analysis.

This paper illustrates the implementation of this concept into an integrated system design.

Background

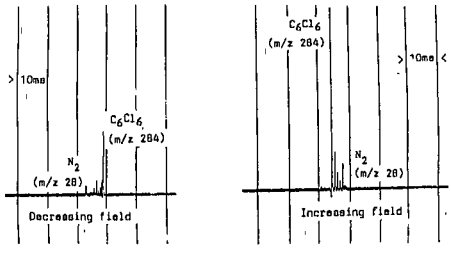
The TS-250 double focussing mass spectrometer uses a unique air cored electromagnet capable of rapid scanning (< 7 ms/decade ultimate) and switching. Also, by virtue of its air core, it does not suffer from magnetic hysteresis. This allows masses to be predicted and set by reference to the equation below.

$$m = k (I - dI)^2$$

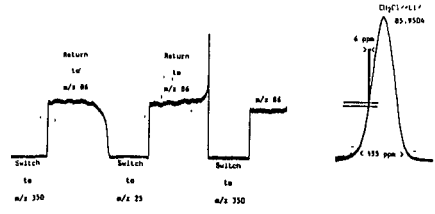
where:

k is a constant of proportionality, I is the coil current, dI is an offset.

The basic performance of the electromagnet system is illustrated by the figures below. The ultimate scan speed of less than 7 ms/decade is some ten times faster than for any other commercially available sector mass spectrometer. The switching example illustrates the absence of hysteresis in the system. These two features will allow fast and predictable parent ion selection, even at elevated resolving powers.



Maximum magnetic field rise and decay rates

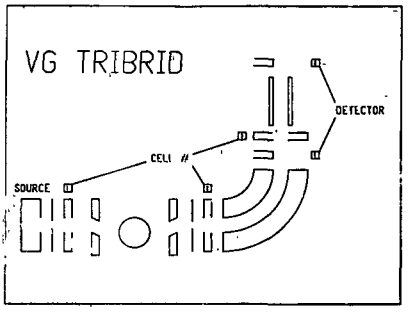


Magnet hysteresis at mass 86

The TRIBRID comprises a standard TS-250 analyser system (MS1) followed by a high energy collision cell and ESA for MIKES analysis. This is followed by retardation and beam shaping lenses which introduce the ions into an RF only collision quadrupole with energies selectable from 0 to 250 electron volts. A high performance quadrupole with 2-2000 dalton mass range and better than unit mass resolution characteristics analyses the daughter ions produced.

Because of the predictability of the analysers the scan functions for daughter, parent, mass loss and reaction monitoring can simply be programmed from a microprocessor control system in accordance with theory.

The analyser configuration is illustrated in the next figure.



The performance in each of the three cells is summarised below

	Cell 1	Cell 2	Cell 3
Parent R.P.	- 100	up to 7500	up to 7500
Daughter R.P.	2-500	- 50	unit mass
collision energy	high	high	0 to 250 eV

The control system adopted for the system is based upon a VME bus supporting three 68000 series micro's. Communication to a Vaxstation™ 2000 host is via a thinwire ethernet. Peak display for tuning is generated in a "scope" window on the VS2000 screen. The particular cell used and the collision conditions are illustrated in the "system visual". This is an interactive display which not only informs the operator of the current experiment, but also allows him to change the method by simply using the mouse to "click" on the appropriate cell or detector. Any sequence of experiments can be pre-programmed, although manual intervention can take place at any time.

Conclusion

A system has been developed which allows selection of any one of a wide menu of MS/MS experiments via interactive control from a Vaxstation 2000 workstation. Software aides such as the SMILES graphical structure system allow the MS/MS data generated to be interpreted more easilly. The use of both high and low collision energies offers structural information and selectivity for a wide range of applications.

STRUCTURAL STUDIES OF OLIGOMERIC AND POLYMERIC AROMATIC SYSTEMS BY TANDEM MASS SPECTROMETRY

T G Blease, J H Scrivens, ICI PLC, Wilton, Cleveland, UK, TS68JE
J J Monaghan, W E Morden, ICI PLC, Runcorn, Cheshire, UK, WA7 4QD

The use of MS in the characterisation of synthetic oligomeric and polymeric systems has, until recently, been limited to monomer purity studies and pyrolysis (either direct py-MS or py-GC-MS). These areas have given important results but their applicability is limited.

The advent of new types of high performance materials utilising poly aryl ethers, ketones, sulphones and sulphides has highlighted the need for MS methods capable of fully characterising these polymeric species. Specifically these methods should enable us to

1 obtain an accurate mol wt distribution of any synthetic polymer species, and
2 carry out detailed sequencing of the individual monomers which make up such a polymer.

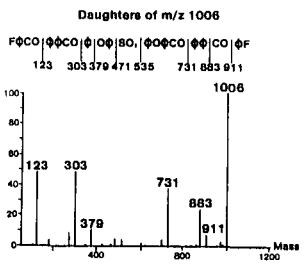
Characterisation of these non-polar, highly involatile, relatively intractable materials is difficult using conventional methods. However, high temperature (>600°C) direct probe EI MS has enabled us to obtain spectra of oligomers of these materials up to >1200 Daltons in mass.

MS-MS daughter ion spectra have been obtained, using a VG ZAB-HSQ hybrid mass spectrometer, from molecular ions of these oligomers and detailed sequencing information has been derived from these spectra.

Compounds of general structure  have been studied in detail and the effects of variation of the end group (phenyl, F, Cl) on the direction and ease of the fragmentation noted.

Fig 1 shows the sequence information available from the daughter ion spectrum of an oligomer of mol wt 1006 containing ether, ketone and sulphone linkages. As can be seen from the spectrum, complete sequencing is relatively straightforward with cleavages occurring preferentially at the carbonyl groups followed by the ether and sulphone linkages.

FIG 1



The sequencing rules derived from the study of such model compounds have enabled us to obtain structural information from the components of oligomeric synthetic reactions. From the reaction shown in Fig 2, two major products were obtained of mol wt 926 and 730 respectively. Application of the sequencing rules to the daughter ion spectra of m/z 926 (Fig 3) and m/z 730 (Fig 4) enabled us to determine the structures of both products unequivocally.

FIG 2

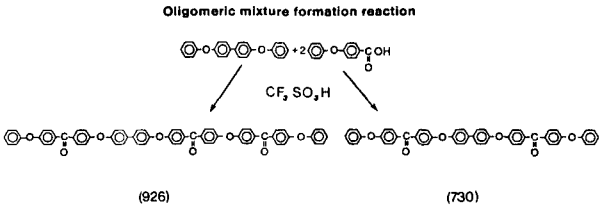


FIG 3

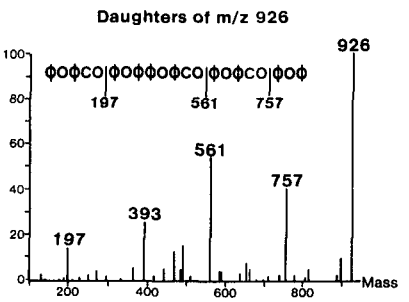

FIG 4

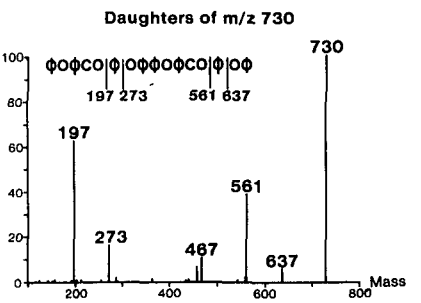

Thus high temperature direct probe EI-MS-MS has been shown to provide useful structural information on the components of synthetic oligomeric reaction mixtures.

It becomes increasingly difficult, however, at higher mol wts to obtain EI spectra of these aromatic materials and alternative ionisation techniques are needed to permit the study of such species. As part of our MS study of these materials we have used Field Desorption (FD) to study several typical aryl polymers. These FD spectra have enabled us to study related oligomeric species of the type $ClØSO_2(ØSØSO_2)_nØCl$. As well as clearly indicating the monomer spacing and differences in mol wt distribution between the samples, the spectra also show the presence in one of the samples of additional end groups, shown by satellite peaks corresponding to the replacement of Cl by F and OH.

Daughter ion spectra of these ions could easily be obtained so confirming these theories and giving detailed structural information.

We have also obtained FD spectra of similar aryl polymers showing a mol wt distribution up to 9000 Daltons.

Thus these non-polar, highly involatile, novel high performance species can be characterised by FD. Use of a high mass range FD MS-MS instrument should enable good sequence information to be obtained from such materials.

Molecular Orbital Study of Remote Charge Site Decompositions in the Collision Induced Decomposition Mass Spectra of Fatty Acid Carboxylate Anions

Marshall M Siegel* and Norman B. Colthup

American Cyanamid Company, Medical Research Division,
Lederle Laboratories, Pearl River, NY 10965

INTRODUCTION

In a series of papers, Gross, Tomer, Jenson and co-workers [1] demonstrated that a new class of decomposition ions is produced when closed shell positive and negative ions undergo collision induced decomposition (CID). The decomposition ions are formed remote from the charge site and are related to ions produced by thermal decomposition processes

The earliest observations of remote charge site decompositions were in FAB CID mass spectra of saturated and unsaturated fatty acid carboxylate anions [2] Similiar observations were made by Bambagiotti and co-workers [3] in CI CID mass spectra of saturated and mono-unsaturated fatty acid anions. Four major observations in the FAB and CI CID mass spectra of saturated fatty acid carboxylate anions were: (1) a characteristic homologous series of olefin carboxylate anions of moderate abundance, (2) an homologous series of radical anions of lower abundance, (3) losses of methane and (4) water from the fatty acid carboxylate anion. Semi-empirical molecular orbital (MO) calculations were performed in order to obtain a greater in depth understanding of the energetics involved in the four types of decomposition reactions thought to be involved in the production of these CID mass spectra.

RESULTS AND DISCUSSION

A) Formation of Terminally Unsaturated Fatty Acid Carboxylate Anions. Main Anion Decomposition Series

Reaction mechanism 1 was modeled using MO calculations with lauric acid carboxylate anion, $CH_3(CH_2)_{10}CO_2^-$. In order for reaction mechanism 1 to proceed, a CCCC segment of the molecule must be in the *gauche* configuration and distorted, as illustrated in Figure 1, where the central C-C bond length is stretched and the two C-H bond lengths are equally stretched. MO calculations were performed for a series of C_5-C_6 , C_4-H and C_7-H bond lengths, where the two C-H bond lengths were kept equal. The rest of the molecule was optimized for minimum MO energy The potential energy surface exhibited a saddle point 92 4 kcal/mol above the minimum energy *gauche* structure for lauric acid carboxylate anion. This energy corresponds to the calculated activation energy for reaction mechanism 1. The structure at the saddle point for the reactive segment of the hydrocarbon backbone is illustrated in Figure 1

B) Formation of Radical Anions by Cleavage of C-C Bonds of Fatty Acid Carboxylate Anions

Unlike the *gauche* case, the *anti* configuration for the hydrocarbon backbone of the lauric acid anion cannot lose a hydrogen molecule. If given sufficient energy, the C-C bonds will cleave to give two radical fragments. However, the high energy required for cleavage by this mechanism, calculated to be ~140 kcal/mol, compared to 92.4 kcal/mol for reaction mechanism 1, suggests that it should generate FAB CID ions of lower abundance FAB CID anions at m/z 58, 86 and 100 are of low abundance and are only seen because the main decomposition ion series becomes weak in this region It is suggested that all the CCCC *anti* segments can undergo homolytic cleavage, but that most of the peaks are too weak to be seen. These types of ions are observed at higher mass in the CI CID spectra of carboxylate anions [3], generated under higher resolution than the FAB CID experiments.

C) Methane Loss from Fatty Acid Carboxylate Anions

Figure 2A shows the optimized structure for the high energy intermediate for the terminal hydrocarbon segment of lauric acid carboxylate anion undergoing methane loss via mechanism 2. Figure 2B shows what happens when this $C_{1'}$-H distance is reduced to 1.45 Å, which is just past the high energy intermediate point. The methyl group rotates sharply, breaking the $C_{1'}$-$C_{2'}$ and the $C_{3'}$-H bonds, forming the $C_{1'}$-H bond to produce methane. These results show that reaction mechanism 2 is a plausable explanation for the $C_{1'}$-$C_{2'}$ bond cleavage. The calculated activation energy for this reaction is 119.0 kcal/mol indicating that this reaction is not forbidden. Figure 2 suggests why mechanism 2 is not a suitable mechanism for non-terminal C-C bond cleavages. In

order to form methane by mechanism 2, the methyl group must rotate sharply. The methyl group has a low moment of inertia and can rotate easily However, if a methyl hydrogen atom is replaced by a carbon chain, the molecule has a considerably lower probability for achieving the proper geometric configurations required for cleaving non-terminal C-C bonds, thereby, effectively preventing reactions by mechanism 2

D) Water Loss from Fatty Acid Carboxylate Anions

The m/z 237 anion in the FAB CID mass spectrum of palmitic acid is assigned to be the dehydration product of the parent carboxylate anion [2]. Jenson, *et al* [2] determined by deuterium substitution studies that both hydrogen atoms which form H_2O come from a single CH_2 group which is either α or β from the carboxylate carbon. MO calculations show that the two hydrogens are most likely removed from the α carbon.

AIM: To Investigate the Formation of Chemical Ionization Peaks in a Finnigan Ion Trap Detector and to Determine Inhibition of the McLafferty Rearrangement During Collisional Activation.

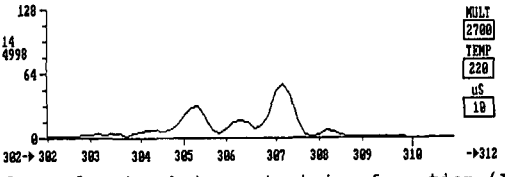
HISTORY: Those familiar with the Ion Trap detector will be aware of the existence in routine EI spectra of M+1 ions in the parent ion region. A recent communication (Eichelberger, Budde and Slivon, Anal. Chem 1987, 59, 2732-2734) examined this problem using anthracene. By observing real time ion profiles of the eluting peaks, they concluded that this phenomenon resulted from ion-ion repulsions in an overloaded orbit within the trap. However this explanation did not adequately account for our observations of M/M+1 ratios in relatively small peaks on a typical chromatogram using the AGC programs. Furthermore, it appeared that only the parent ion showed this effect, and fragment ions which were considerable more intense, did not show any abnormal carbon-13 isotope peaks. We decided to investigate this phenomenon further after repeating their experiment on a related compound.

EXPERIMENTAL: Normal mass spectra were acquired on both a Finnigan Ion Trap Detector (ITD) and on a Finnigan Ion Trap Mass Spectrometer (ITMS). Results were the same on both instruments. The ion trapping experiments were performed only on the ITMS. Except where otherwise noted, the samples were run in "AGC OFF" mode. Quantities noted on plots were actual amounts reaching the Trap. Deuterated compounds were obtained from Cambridge Isotope Laboratories in Woburn, Massachusetts. The methyl palmitate originated from Chem Service, West Chester, Pennsylvania.

OBSERVATIONS: Perdeuterio-naphthalene: This compound was chosen to relate closely to the experiments of Eichelberger, et al. When 77ng was injected onto the column with a filament "on" time of 1 microsecond, the parent ion at m/z 136 exhibited only a normal M+1 ratio. Even with ten times the ionization time, there was little if any change observed. However, with a B time of 25000, the M+1 ion dominated the spectrum. The prediction that this is "self-CI" was ruled out by Eichelberger, et al. on two accounts: first one would expect that the ion formed by "self-CI" would be an M+2 as the only source of protons must be the compound itself and the perdeuterio-naphthalene was nearly completely deuterated; second, an examination of the ion profiles showed that the M+1 resulted from poorly shaped ion peaks. We observed a similar result in that 77ng of perdeuterio-naphthalene with a filament time of 25 microseconds gave a good ion profile at the start of the peak but showed no integer resolution at the chromatographic peak apex. Therefore for these observations it seems easy to interpret the results in terms of overloaded ion orbits in the Ion Trap and certainly this is also true in our experiments run at very high sample ionization levels.

Contrary to this, however, we have observed that compounds which show considerable fragmentation in the EI spectra (in contrast to those used by Eichelberger et al.) tended to be the best candidates for M+1 formation. Following this idea we decided to investigate the spectra of fatty acid methyl esters and chose methyl palmitate (molecular weight 270) for this study. In a typical spectrum of methyl palmitate with increased parent ion + 1, the M+1 ratio of the fragment ions is not changed so the M+1 peak of the parent ion does not result from peak assymetry due to overloaded ion orbits. Furthermore, as the Ion Trap scans masses out of the trap from low mass to high mass, those ions most likely to be effected by space-charge saturation are indeed the lower masses. If the source of the M+1 is an ion-molecule reaction then we would expect perdeuterio-methyl palmitate to show M+2 instead of M+1. With 6ng of d34-methyl palmitate (m/z 304) only

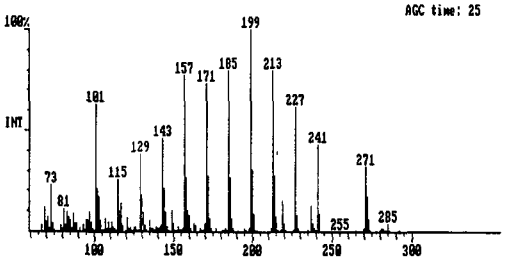
an ion at 304 is present accompanied by fragment ions. However at 12ng, the ion at m/z 306 is as high as the parent ion and at 24ng, the M+2 dominates. As there is no large change to the M+1 and M+3 ratios, the explanation must be that the effect results from "self-CI", ie. an ion-molecule reaction. With an injection of 48ng of d34-palmitic acid, the ion profile was observed and it clearly showed resolved peaks and not a broadened hump as was observed in the overloaded case with naphthalene.



With increased sample size but constant ion formation (AGC ON), we found that the amount of M+2 increased and this led to the hypothesis that this was a reaction between ions in the trap and the neutral compound which is continually eluting into the trap during the analysis section of the trap cycle.

Some aditional experiments were run on the ITMS which involved the "trapping" of individual ions in the mass spectrum of methyl palmitate. The ions chosen were the parent ion at 270 and fragment ions at 143, 87 and 74. In separate experiments, all ions other than the ion of interest were ejected from the trap with a combination of RF and DC fields. The selected ion was then held in the trap for a period of 20 milliseconds before being scanned out. All fragment ions did show protonated molecular ion formation with m/z 74 being the best. Therefore, the fragment ions DO react with the neutral molecule to give M+H as an ion-molecule reaction product. However no such product was observed from the storage of the parent ion itself at m/z 270; instead a protonated dimer ion was observed at m/z 541.

MC LAFFERTY REARRANGEMENT WITH ION TRAP MS/MS: During these experiments, we also examined the ms/ms of the parent ion (m/z 270). After sweeping out all other ions, the collisionally activated ion produced the fragments shown below. We were suprised to note that the McLafferty rearrangement ion at m/z 74 was completely absent. Presumably this ion results from a more short-lived species formed during ordinary electron impact mass spectrometric conditions. This phenomenon is currently being investigated with other species such as ketones.



SUMMARY: "Self-CI" does occur in the Ion Trap mass spectrometer as a result of fragment ions reacting with the neutral molecule entering the trap during the storage and analysis phase. It appears that this only occurs with fragment ions and not with the parent ion. Hence in the previously reported results of Eichelberger, Budde and Slivon, no "self-CI" was observed because the compound gave few fragment ions. With such compounds, ion saturation occurs and causes broadened peaks which are interpreted by the software as higher mass ions. In our hands, we have only observed a changed C-13 isotope ratio for a non parent ion in a compound where facile loss of water occurred. Here the M-water ion also showed an increased isotope ratio.

Mass Spectrometry and Structural Biology - An Exciting Symbiosis

A.L. Burlingame
Department of Pharmaceutical Chemistry and the Liver Center, University of California, San Francisco, CA 94143-0446

Present challenges in protein biochemistry, rational drug design and biotechnology involve the need for determination of structurally precise structure-function relationships at the picomole sample level. Often the unavailability of sufficient quantities of protein or protein crystals precludes use of 2-d NMR and X-ray crystallographic methods. Immunochemical methods are sufficiently sensitive, but structurally imprecise.

Many of these problems in structural biology may be solved by concerted use of a variety of new mass spectrometric-based technologies in conjunction with micro methods of protein sample handling, viz. the isolation, e.g. 2-d gel electrophoresis, enzymic digestion and microbore HPLC. Success in integrating these methods requires picomole sensitivities for all of the steps in the overall structural characterization and sequencing strategy.

In this laboratory we have invested considerable effort in development of both sample handling and mass spectrometric technologies to meet these goals. We have now achieved an operational ability to solve sequencing, structural and topographic issues in protein and glycoprotein problems at the subnanomole to picomole level.

We are studying three classes of proteins which represent the types of structural and topographic issues which must be tackled: 1) cytosolically soluble, 2) amphipathic, and 3) integral membrane proteins. We have illustrated our strategy on sequence revision studies of rat heart fatty acid binding protein [1] using 100-500 pmol total sample. Mapping molecular weights of proteolytic digest HPLC fractions was carried out using the wide mass range zoom capabilities and subpicomole sensitivity of the Wien mass spectrometer [2]. Peptide sequencing was carried out by ultra-high sensitivity 4-sector MS-MS using the Kratos Concept with 35 Kev cesium liquid sputtering ion source and computer-controlled electro-optical multi-channel array detection system [3]. For example, correction of the published sequence of peptide 45-52 [4] was verified using a high energy CID spectrum of MH^+ 861, which coeluted with another peptide of MH^+ 875.

Figure 1a illustrates the quality of high energy CID-array spectra yielding full sequence information obtained on one compound of this mixture using only 10 pmol of sample. Previous 4-sector results without cesium source and array detection required 700 pmol in the case of the N-terminally blocked peptide MH^+ 1036 [1]. Figure 1b illustrates the sensitivity of the Kratos 4-sector array detection instrumentation using 10 pmol of substance P to obtain a high energy CID spectrum and full sequence. Previous results using a Jeol 4-sector instrument without array detection required 1-2 nmol of substance P [5], while recent results on the same instrument with array detection required 0.2 nmol of substance P [6] to obtain the entire CID spectrum.

Studies are in progress on the mapping of colicin 1a, a model amphipathic protein [7]. We will use 4-sector CID spectra to study photoaffinity binding to the integral membrane form of this protein to ascertain topographic information with respect to the membrane.

Studies of the nicotinic acetylcholine receptor have been carried out to delineate post-translational modifications, i.e. glycosylation and phosphorylation, and obtain topographic information [8]. Results on photoaffinity labelling of colicin 1a will be used to guide analogous studies of the acetylcholine receptor.

CONTINUOUS-FLOW FABMS - AN OVERVIEW

Richard M. Caprioli
The University of Texas Medical School
Houston, TX 77030

Continuous-flow (CF) FAB provides a means for the analysis of polar compounds in aqueous solution without the need for glycerol in the sample (1). Low concentrations (about 5%) of glycerol or other viscous liquid present in the carrier solution are adequate to provide a fluid stage for the bombardment process. The ability to continuously feed samples and solutions into the ion source of a mass spectrometer opens up many areas for the mass specific analysis of compounds. The use of CF-FAB provides some significant advantages over standard FAB techniques, including higher sensitivity and lower limit of detection due to the decreased background chemical noise and decreased ion suppression effects. In addition, it provides a means for the rapid analysis of large numbers of samples present in aqueous solutions as well as those dissolved in volatile organic solvents such as acetonitrile or methanol.

The CF-FAB probe has been used in this laboratory on three different instruments; a Finnigan MAT 90 high field magnetic instrument, a Finnigan MAT TSQ 70 MS/MS instrument, and a Kratos MS50RF high field instrument. The technique was found to perform essentially the same on these instruments although each device is somewhat different and has minor advantages. However, a significant advantage of the probe for the MAT 90 is the incorporation of a mechanism to allow the capillary to be moved while in the ion source and also the placement of a small filter pad below the probe tip which acts as a wick to remove solution from the tip and provide a thin surface and smooth flow. The filter pad has the additional advantage of allowing the recovery of a sample if necessary through removal and extraction of the pad.

We have used CF-FAB for the analysis of compounds from a wide array of applications in the field of biological chemistry. These include on-line monitoring techniques for the analysis of drugs directly in the bloodstream of live animals using microdialysis methods, direct injection of aqueous samples and urine using MS/MS methods for drug analyses, enzymic reaction analysis to determine kinetic parameters, and LC/MS applications.

The on-line reaction monitoring application is illustrated for the tryptic digest of a solution containing 11 different peptides in a study aimed at the investigation of the catalytic properties of trypsin. The relative rates of cleavage of the peptides were of interest as the specific reaction conditions were altered. The CF-FAB system was operated in the flow-injection mode whereby a micro-autoinjection valve was used to constantly inject sub-microliter samples of the aqueous enzymic reaction into a carrier flow solvent. This solvent is typically composed of 95% water, 5% glycerol, and 0.1% TFA. The reaction solution contained 100 pmol of each of eleven peptides, 50 mM Tris (pH 8.4), and trypsin in a substrate: trypsin ratio of 200 : 1 (w/w). As the reaction proceeded, individual molecular species were monitored, i. e., the decrease in the $(M+H)^+$ of the reactants and increase in that of the products was followed over a period of about 50 min. Figure 1 shows the selected ion chromatograms for the molecular species of physaleamin at m/z 1265 and its tryptic fragment at m/z 629. The relative rate curves for the hydrolysis of this peptide as well as several others are shown in Figure 2.

We have used CF-FAB for the microbore LC/MS analysis of peptide mixtures. This is illustrated for the analysis of the tryptic digest of β-lactoglobulin A. An Applied Biosystems model 130A microbore LC system was linked to a Finnigan MAT 90 mass spectrometer through the CF-FAB probe as an interface. The LC was fitted with a Brownlee RP-300 1x50 mm column which was eluted at a rate of 25 μL/min with 0-60% acetonitrile gradient. The eluate was split 4:1 to the UV and MS detectors, respectively. The MS was continuously scanned from m/z 600-2900 at 10 sec/scan in the analysis

of 40 pmol of the digested protein. Individual ion searches were used to locate peptides in the total ion chromatogram. In all, fifteen peptides were identified in this single analysis. Simultaneous UV detection and sample collection of the effluent permits additional sample work-up on the mass identified peak fractions. Other aspects of the use of CF-FAB as an LC/MS interface are described in the paper by W. T. Moore et al. in this volume.

The direct sampling of blood in a live rat using a microo[illegible] probe implanted in the jugular vein and connected to the CF-FAB probe in a TSQ 70 MS/MS instrument permitted pharmacokinetic measurements to be obtained directly and on-line. Negative ion MS/MS techniques together with on-line sample enrichment methods provided the required sensitivity and selectivity to perform the analysis in the perfusate without the need for extraction and derivatization steps or other sample handling. Additional details of this application are found in the paper by S. Lin and R. M. Caprioli in this volume.

Direct analysis of drugs and drug metabolites in aqueous solution including urine have been demonstrated using CF-FAB and MS/MS techniques. The compounds analyzed include cocaine, benzoylecognine, phentolamine, penicillin G, THC, morphine and phenobarbital. The high sensitivity of the procedure was demonstrated, for example, with the analysis of phentolamine at 50 pg injected into the spectrometer. Additional details of this work can be found in the paper by W. E. Seifert et al. in this volume.

CF-FAB has been shown to be an effective means to introduce samples in volatile liquids into a FAB mass spectrometer. It is amenable to on-line operation for the analysis of batch reactions and also for a wide variety of applications where a continuous analysis is required. In this regard, it serves as an efficient and effective interface for microbore LC/MS applications.

QUANTITATION BY LC/MS OF ENDOGENOUS NEUROPEPTIDES ISOLATED BY IMMUNOAFFINITY CHROMATOGRAPHY

C.A. Lisek, T.L. Yaksh and I. Jardine

Depts. of Pharmacology and Neurologic Surgery
Mayo Clinic, Rochester, MN 55905

Neuropeptides are important biologically active molecules which function as intracellular messengers, i.e. neurotransmitters, in the nervous system. Neurotransmitters are usually quantitated by radioimmunoassay (RIA), an immunological method which affords high sensitivity (fmol range) of analysis but lacks complete specificity. We have developed a strategy (Figure 1) for the quantitative analysis of neuropeptides which combines immunological methods with the sensitivity and specificity of LC/selected ion monitoring (SIM) mass spectrometry. This strategy is detailed below.

Cat spinal cords were boiled in 0.1 N HCl, homogenized, concentrated in vacuo, then dissolved in phosphate-buffered saline (PBS) solution (0.5 M KH_2PO_4, 0.9% NaCl, pH 6.5). An aliquot of the PBS solution of the extract was assayed for neuropeptide activity by RIA using the I^{125}-analog of the neuropeptide (recoveries: 85-91% for authentic methionine enkephalin, substance P, and VIP). For substance P, the rest of the extract was then applied to an immunoaffinity column containing rabbit polyclonal antibodies (IgG fraction) immobilized on cyanogen bromide-activated Sepharose 4B. Substance P was eluted with 20% aqueous formic acid. The formic acid fractions from several runs were pooled and lyophilized, and a small aliquot was assayed by RIA for SP activity (yield: 100 pmol). A second SP extract (126 pmol) was subjected to the above immunoaffinity purification in the presence of a 10-fold molar excess (1260 pmol) of deuterated (d_8-Phe^8) substance P as internal standard (yield: 40.7 pmol d_0-SP).

Standard solutions of d_0- and (d_0 + d_8)- methionine enkephalin (MW 573.7) and substance P (MW 1347.6) were analyzed by combined HPLC/thermospray mass spectrometry. The MH^+ and MNa^+ ions were selectively monitored. The limit of detection was 100 pmol. In contrast, analysis of standard solutions of d_0-SP by dynamic FAB SIM MS (Figure 2) resulted in a limit of detection of 0.1 pmol.

The immunoaffinity purified endogenous substance P samples were desalted on a C4 wide pore (40 μm) disposable filtration column, then quantitated by microcolumn LC/dynamic FAB SIM MS. An aliquot (0.1 or 0.5 μL) of sample was injected onto a C18 packed fused silica microcolumn (0.32 mm ID) fitted to a VG 30-253 quadrupole mass spectrometer dynamic FAB-MS inlet. The mobile phase was 0.1% TFA and 5% glycerol in 75:25 MeOH:H_2O and the flow rate was 5 μL/min. The protonated molecular ions of d_0- and d_8-SP were selectively monitored.

A comparison of the results from the analysis of one immunoaffinity purified endogenous sample (40.7 pmol by RIA) with those results from standard solutions of (d_0 + d_8)-SP is depicted in Figure 3. From the d_0/d_8 ratios obtained from the standard solutions, a response curve (Figure 4) was generated. The d_0/d_8 ratio for the endogenous sample corresponds to 39.0 pmol of d_0-substance P, which is in agreement with that value (40.7 pmol) determined by RIA. Quantitation of the second immunoaffinity purified endogenous SP sample (100 pmol) also gave results complementary to the RIA results.

In conclusion, (1) endogenous substance P was quantitated by combined microcolumn LC/dynamic FAB SIM MS; (2) the dynamic FAB SIM MS results for substance P were in agreement with those determined by RIA; (3) the limit of detection of substance P by dynamic FAB SIM MS was three orders of magnitude lower than that obtained by thermospray SIM MS and (4) the combination of immunoaffinity chromatography with both RIA and microcolumn LC/dynamic FAB SIM MS detection provides an optimal analytical methodology for endogenous neuropeptides.

CONTINUOUS FLOW FAST ATOM BOMBARDMENT MASS SPECTROMETRY OF PEPTIDES AND PEPTIDE DIGESTS

Keith R Jennings, David W Hutchinson and Adrian R Woolfitt
University of Warwick, Coventry, England.

The analysis of peptides and peptide digests by continuous flow fast atom bombardment (CF-FAB) ionisation offers a number of advantages over static FAB. Following preliminary work at Kratos [1] using Dipeptidyl Peptidase (DPP) I and IV for cleaving dipeptides from the N-terminus end of peptides, CF-FAB has been implemented on the MS50 instrument at Warwick during the past year. Investigations have been concentrated on the widely dispersed peptide ubiquitin which is unusual in that all ubiquitin extracted from animal sources has an identical sequence whereas that derived from plant sources shows very slight changes in the residues present. Ubiquitin has a RMM of 8560.6 and comprises 76 amino-acid residues (Fig.1). It has recently been shown [2] that it may be denatured in 6M urea and that under these conditions, a tryptic digest will yield approximately 12 smaller peptides ranging in mass from m/z 133 to m/z 1788 which can be separated off-line by means of reverse-phase HPLC.

To date, 9 of the expected 12 peptides have been recognised using CF-FAB. Those of m/z 133 and m/z 1788 were outside the calibrated mass range and the fragment ALA-LYS with a Bull and Breeze index of 535 would be difficult to detect. In a number of cases, it was noticed that after several runs in which the MH^+ ions of a peptide dominated the spectrum, the peak was replaced by one which was 62 amu higher in mass. This was attributed to the replacement of H by Cu which would occur only after the peptide had flowed beyond the stainless steel central section of the probe tip to the copper surrounding this section. Further confirmation of the identity of peaks ascribed to peptide ions was obtained by treating the fraction of the digest with acetic anhydride which adds 42 amu to the mass of the MH^+ ion, readily distinguishing between peaks arising from peptides and those due to the background (Fig. 2). Two unexpected peptides were observed but could be interpreted as being due to tryptic peptides 11+12 and 5+6, the bonds between these pairs being somewhat resistant to tryptic cleavage.

It is important positively to identify each tryptic peptide appearing in the mass spectra of the HPLC fractions. The products of collision-induced decomposition of each of the peptides will be investigated using tandem mass spectrometry in the near future but valuable information may be gained by investigating the products of various secondary enzyme digests. Chymotryptic digests of 3 HPLC fractions have been carried so far and additional information on the sequence of amino-acid residues has been obtained (Fig. 3); DPPI has also been used to obtain information on the peptide believed to be due to tryptic digests 5+6.

In summary, considerable progress has been made using CF-FAB in obtaining sequence information for the peptide ubiquitin. The sensitivity of the technique has not yet been established for these peptides but in the case of bradykinin, it is in the picomole range. Further work on enzyme digests is in progress and it is planned to investigate ubiquitin isolated from plant sources with a view to searching for the slight variations in amino-acid sequences which have been reported.

ANALYSIS OF PERMETHYL-OLIGOSACCHARIDES BY CONTINUOUS-FLOW FAB-MS AND BY COUPLING LC-MS WITH CONTINUOUS-FLOW FAB AS INTERFACE

Bernard FOURNET,* Yves LEROY,* Guy RICART,§ and Jean MONTREUIL*
*Laboratoire de Chimie Biologique de l'Université des Sciences et Techniques de Lille Flandres-Artois (UA du CNRS No 217), 59655 Villeneuve d'Ascq Cedex, France; §Laboratoire de Spectrométrie de Masse de l'Université des Sciences et Techniques de Lille Flandres-Artois, 59655 Villeneuve d'Ascq Cedex, France

Conventional positive fast atom bombardment (FAB) and continuous-flow FAB analysis were carried out with permethylated lacto-N-tetraose. This latter method, a new approach, has been used to analyse a mixture of permethylated oligosaccharides by liquid chromatography-mass spectrometry (LC-MS) with a packed capillary fused-silica column and the continuous-flow probe as interface. Under these conditions, we found the continuous-flow probe to be superior to the conventional probe because its low matrix level increased the signal-to-noise ratio. The analysis of the mixture of permethylated oligosaccharide alditols obtained from hen ovomucoid by LC-MS using the continuous-flow probe as interface is described.

EXPERIMENTAL

Mass spectrometer. A Kratos MS 50 RF equipped with a DS 90 data system was used in these studies. The mass spectrometer was operated at a 8 keV accelerating potential. An Ion Tech fast atom source was used with xenon (7.3 kV, 1.2 mA). For classical FAB analysis, permethylated lacto-N-tetraose dissolved in methanol was introduced with a Rheodyne Model 7520 injection valve. The solvent, methanol:thioglycerol:water, (90:10:5, v/v/v) was delivered by a Brownlee syringe pump operated at 5 µl/min. The continuous-flow probe is described in Ref.(1). For the analysis of the permethylated lacto-N-tetraose, the mass range 1000 to 200 was scanned at 10 s/decade with a mass resolution of 3000. For the LC-MS analysis of the permethylated oligosaccharide alditols from ovomucoid, the mass range 3200 to 900 was scanned at 10 s/decade with a mass resolution of 3000.

Micro-LC with a packed fused-silica column. The microdelivery system consists of a Brownlee syringe pump equipped with a 60-nl Valco injection valve. The analysis of permethylated oligosaccharides from hen ovomucoid (4.5 µg) was performed on a fused-silica micro-LC column (250 X 0.32 mm) packed with 5 µm RoSil C 18D (RSL/Alltech). the flow rate was 5 µl/min. The column was connected directly to the capillary of the continuous-flow probe. The elution was carried out with the following gradient: 80% of solvent A (methanol:thioglycerol:water, 90:10:5, v/v/v) and 20% of solvent B (thioglycerol:water, 10:90, v/v) to 100% of solvent A in 20 min followed by isocratic conditions for 1 h.

RESULTS AND DISCUSSION

Positive FAB analysis of permethylated lacto-N-tetraose clearly shows that for detection of $(MH)^+$ in permethylated LNT, continuous-flow FAB is 1.5 times more sensitive with 0.1 µg and 3.4 times more sensitive with 1µg than conventional FAB. The quality of the separation by micro-LC coupled to FAB-MS (Fig.1) is illustrated by the very slight deformation of peaks due to the suitability of the probe and the good separation of a mixture of permethylated oligosaccharide alditols from hen ovomucoid and characterizes oligosaccharides 1, 7, 11, and 14 (2). In Fig. 2, we give the LC-MS continuous-flow FAB mass spectra of oligosaccharides 7 and 14.
These first results obtained by using the packed capillary LC-FAB-MS with continuous-flow probe as interface are very promissing. indeed, the good resolution of a packed capillary column allows the analysis of microquantities of very complex mixtures of oligosaccharides (less than 200 ng per peak) with a suitable intensity of molecular ion.

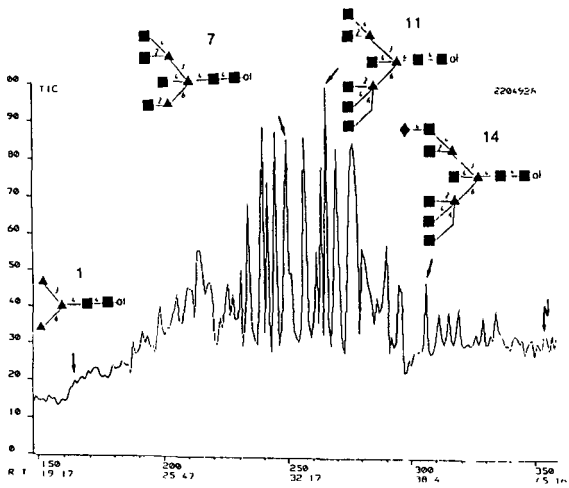

Fig. 1. Total ionic current of the permethylated oligosaccharides from hen ovomucoid on a packed fused-silica capillary column. Oligosaccharides 1, 7, 11, and 14 are localized and their structures are shown. (■) GlcNAc, (▲) Man, (♦) Gal.

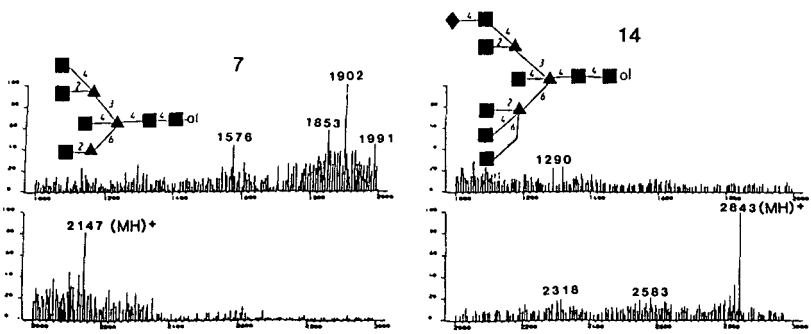

Fig. 2. Positive FAB mass spectra of oligosaccharides 7 $(MH)^+$ m/z 2147 and 14 $(MH)^+$ m/z 2843.

TANDEM MASS SPECTROMETRY OF BIOMOLECULES BY USING CONTINUOUS FLOW FAB.

R.L. Cerny, R.N. Hayes and M.L. Gross, Midwest Center for Mass Spectrometry Dept. of Chemistry, University of Nebraska, Lincon, NE 68588

One problem encountered in using FAB has been the generally poor sensitivities obtainable as compared to those achieved for samples amenable to EI. A major contribution to this problem has been the level of chemical noise due to the matrix background. Another characteristic of FAB is the short-lived ion currents obtained when small amounts of sample are used. This can be problematic when FAB is used in conjunction with tandem mass spectrometry (MS/MS).

Continuous flow FAB[1] reduces the amount of background chemical noise present and thus leads to increased sensitivity for the molecular species. In addition, continuous introduction of the analyte leads to steady production of these ions for long periods of time. As in conventional FAB, however, few structurally informative fragments are produced. FAB combined with tandem mass spectrometry has been shown to be a powerful tool in the structure elucidation of biomolecules such as peptides and oligonucleotides. CF FAB and MS/MS are now combined to exploit the advantages of the individual methods. Of major interest are the importance of factors such as reduced chemical background and the continuous sample introduction to success of the MS/MS experiment.

For MS/MS studies, it is desirable to produce stable ion current for long periods of time for the species of interest. This allows improved S/N through either signal averaging or long scan times with high filtering. In these experiments the mass is known; the most important aspect is the ion yield for a given amount of material. A comparison of the ion currents for the $(M + H)^+$ species produced from 10 ng of Leu-Enkephalin by the direct probe method and by CF FAB is shown in Fig. 1.

For the direct probe experiments, 1 µl of a 10 ng/µl solution of the peptide in methanol was placed on the probe with 1 ul of DTE/DTT matrix. The CF-FAB experiments used a solution of 5% DTE/DTT in water with .1% TFA added. The analyte was present at a level where 10 ng would be delivered to the probe over 6 min at a flow rate of 3 µl/min.

As expected, the initial ion production in the probe experiment is higher. This tails off as the sample is depleted. In the CF FAB experiments a lower but more stable ion production is observed. The integrated ion current is greater for the probe experiment than for CF FAB; it is likely that conditions are not yet optimized for the CF FAB experiments. These preliminary results, however, hold promise for increased ion production by using CF-FAB.

For higher mw peptides we have observed > an order of magnitude increase in sensitivity in MS/MS experiments incorporating CF FAB (see Fig. 2). As shown in this example, a characteristic spectrum of Gramicidin S can be obtained for as little as 200 p mole of the peptide with CF FAB.

The reduction of chemical interferences is most important when studying a low abundance species in the presence of others with much greater abundance. Such a situation arises when using naturally occuring isotopic abundances as sources of "labeling experiments" in mechanistic studies. This practice is common with EI and CI ionization but not with FAB.

In the MS/MS spectra of cationized peptides, the most abundant fragment involves the C-terminus amino acid. Two different mechanisms can be postulated which include the loss of either O and NH_2 or 2 O. This could be resolved by MS/MS of the ^{18}O containing species. Background interferences preclude this experiment using conventional FAB (see Fig. 3). CF FAB produces much less interference.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Shown in Fig. 4 is the MS/MS spectrum in the mass range of the fragmentation under study. For the monoisotopic species (^{16}O containing) a singlet is observed of m/z 82. The MS/MS spectrum of the ^{18}O-containing isotope consists of a doublet of m/z 82 and 84. The peptide studied contains three oxygens; if the mechanism involves loss of 2 oxygens the ratio of 82:84 should be 2:1 - if only 1 oxygen is lost the ratio should be 1:2.

Although the S/N is low; it is evident that the observed ratio favors the mechanism which involves elimination of only one oxygen.

QUANTITATIVE ANALYSIS OF POLAR COMPOUNDS BY CONTINUOUS FLOW FAB

S.P. Markey, T.-C.L. Wang, M. Shih, R. Boni, M. Duncan, S.-C. Yang
Laboratory of Clinical Science, NIMH, Bethesda, MD 20892 and
D.C. Bradford, Finnigan MAT, San Jose, CA 95134

Ease of analysis and achievement of accuracy in the quantification of polar biologicals can be realized best without chemical transformation. For example, the norepinephrine metabolite MHPG (3-methoxy-4-hydroxyphenylethylene glycol) is found as a sulfate ester, a glucuronide, or as the free compound in biological fluids. The high precision attainable within a laboratory using GC/MS to quantify MHPG after hydrolysis of the conjugates highlights the systematic discrepencies in the literature regarding interlaboratory differences for normal versus clinically different diagnostic groups. One means of addressing the accuracy issue is direct analysis of each conjugate by continuous flow-FAB (CF-FAB). In the process of testing a prototype Finnigan Bioprobe system on a triple quadrupole mass spectrometer, we have determined this system's general applicability to a variety of analytical problems.

Our system uses a pulse-dampened HPLC pump to deliver a 20% glycerol/-water solution to a 0.5 µL loop injector and then through 75 micron i.d. fused silica tubing into the ion source region through a flange on the side of the vacuum manifold. The fused silica tubing is guided through a temperature controlled aluminum cylinder in the ion source, from which a 3-6 mm portion protrudes to make contact with a standard static FAB probe tip. The liquid emerging from the fused silica wets the congruent surface of the copper FAB tip, and mechanical adjustment is monitored optically in order to maintain a stable film. Typically, with the chamber and source block at ambient temperature, a stable film is obtained at 5.5-6.5 µL/min. Important factors effecting stability and sensitivity include maintaining thermal contact to the fused silica near to the region of evaporative cooling; orientation of the probe tip relative to the capillary (Fig. 1); composition of the sample with regard to surface tension; and film thickness or flow rate (Fig. 2).

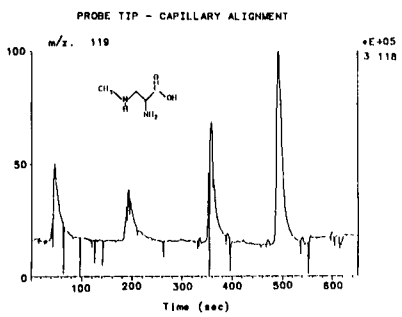

Fig. 1. Small rotational changes of the probe tip influence the flow of sample and the secondary ions, altering both peak shape and sensitivity as indicated by repetitive injections of BMAA.

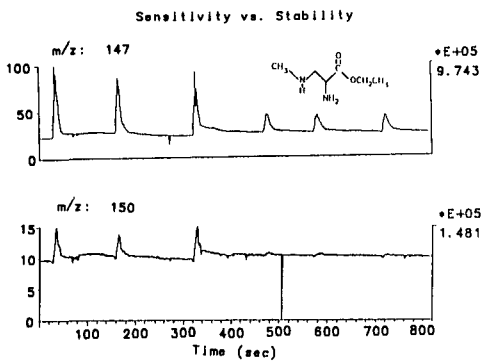

Fig. 2. Repetitive injections of BMAA-Et made while increasing glycerol-water flow rate from 6 to 6.5 µL/min show that higher sensitivity as indicated for m/z 147 (MH^+) is due to film instability evidenced by spurious baseline rise detected at m/z 150. At higher flow, signal at m/z 147 is less intense, but baseline at m/z 150 is stable.

Repeated injections (n = 10) of standards of 1-methyl-4-phenylpyridine (mw 170) and its $^2H_3$-isotopomer (mw 173) demonstrate the consistent reproducibility of the system (Fig. 3). The sample peaks were 50 sec wide at baseline, 15 sec wide at half-height, allowing sample introduction every 2 min. Routine chromatographic data processing was applied, including background subtraction and peak ratio analyses so that CF-FAB combines the benefits of liquid chromatography with the power of fast atom bombardment ionization even at low m/z. The mean ratio of m/z 170/173 integrated ion current peak areas was 0.3983 ± 0.002 S.D. with a range of 0.3955-0.4011.

Other examples to which we have applied CF-FAB include: quantitative tryptophan analysis from 5-500 ng; sensitive MHPG-sulfate detection in negative ion mode, (5 ng/sample); and the quantification of β-N-methylamino-alanine (BMAA) in plant extracts by CF-FAB MS/MS. For the latter problem, we compared the results of a capillary GC-selected ion assay of derivatized BMAA with a direct CF-FAB analysis of crude plant extracts. As expected, the CF-FAB-MS did not exhibit sufficient selectivity when ions at m/z 119 were monitored with respect to the $^2H_3$ isotopomer at m/z 122. Two steps were added to provide the requisite selectivity and sample concentration prior to CF-FAB MS/MS. Formation of BMAA-ethylester (mw 147) permitted acid-base extraction as well as concentration in chloroform prior to drying and dissolution in glycerol-water. Subsequently, excellent selective and quantitative results (Fig. 4) were obtained from plant extracts which contain BMAA (Cycas spp.) in contrast to those which do not (Macrozamia spp.) by monitoring alternately m/z 147 fragmenting to 44 and the $^2H_3$ isotopomer m/z 150 to 47.

Areas of active research in CF-FAB include focussing a cesium ion beam to maximize liquid-SIMS performance; improvement of liquid film stability by providing a better wetting mechanism; and design of an alternative and rugged probe assembly.

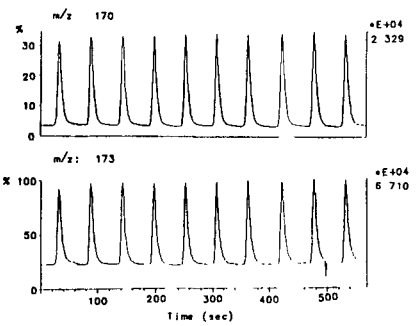

Fig. 3. Repetitive injections of MPP^+ and $^2H_3$-MPP mixtures indicate system stability for repeated measures.

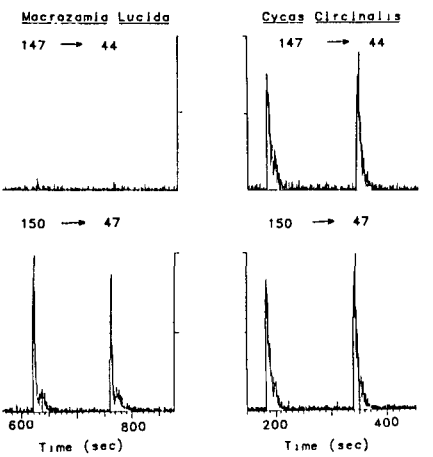

Fig. 4. CF-FAB MS/MS of plant extracts indicate the absence of BMAA-Et in Macrozamia relative to the amount detected in Cycas, both having been spiked with identical amounts of $^2H_3$-BMAA.

AN RRKM EXPLORATION OF WHETHER THE MCLAFFERTY REARRANGEMENT OF IONIZED N-BUTANAL IS STEPWISE OR CONCERTED: Lawrence L. Griffin,[a] David J. McAdoo[b] and Charles E. Hudson[b]
[a]Department of Marine Sciences, Texas A&M University at Galveston, Galveston, Texas 77553,
[b]Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550.

A long-standing issue in gas phase ion chemistry is whether the McLafferty rearrangement is stepwise or concerted [1]. Hydrogen/deuterium exchange accompanying this reaction at low energies has been taken to prove a stepwise mechanism [1,2]. A belief has since developed that reactions of ions in the gas phase are in general stepwise [3]. However, recent ab initio calculations by Ha and coworkers [3] gave a critical energy for concerted loss of ethene from ionized n-butanal (1) lower than that for loss of ethene from $^{\cdot}CH_2CH_2CH_2CH{=}OH^+$ (2), the intermediate in the stepwise process. They concluded that the reaction is concerted. Also, the critical energy calculated by Ha et al [4] for hydrogen exchange by $1 \rightleftharpoons 2$ is considerably lower than the barrier to decomposition by either concerted or stepwise processes. Therefore this hydrogen exchange might precede either stepwise or concerted decomposition. This reopens the issue of whether the McLafferty Rearrangement is stepwise or concerted. To further explore this, we carried out RRKM calculations (program of Bunker and Hass [5]) utilizing the potential surface of Ha et al. [4], and one modified based on our own ab initio calculations [6].

Our calculations indicated no reverse activation energy for $2 \rightarrow 3$, in contrast to those of Ha et al [4]. Their transition state was constrained to have a plane of symmetry; ours was not.

SPECIES	RATE CONSTANTS	RELATIVE ENERGIES (KCAL/MOL^{-1})	
		Ha et al. [4]	This work
$CH_2CH_2CH_2CHO^{+\cdot}$ (1)		0.0	0.0
$^{\cdot}CH_2CH_2CH_2CH{=}OH^+$ (2)		-3.6	-3.6
$CH_2{=}CH_2 + CH_2{=}CHOH^{+\cdot}$ (3)		16.9	16.9
TS($1 \rightarrow 2$) (B)	k_1, k_2	8.5	8.5
TS($2 \rightarrow 3$) (F)	k_3	37.6	16.9
TS($1 \rightarrow 3$) (H)	k_4	31.5	31.5
TS($2 \rightarrow 3$) (B,H)	k_5	37.6	

In most calculations vibrational frequencies were taken to be similar to those of the corresponding groups in other molecules. RRKM calculations utilizing harmonic frequencies for 1 obtained with Gaussian 86 [6] at the 3-21 level gave results only slightly different from ones obtained using estimated frequencies. The following table gives RRKM-calculated rate constants as a function of energy in the ion.

ENERGY	LOG(K1)	LOG(K2)	LOG(K3)		LOG(K4)	LOG(K5)
			Ha et al	This work		
8.6	7.37	5.55				
9.1	7.63	5.99				
16.6	9.18	7.91				
17.1	9.23	7.97		4.97		
17.6	9.29	8.04		5.39		
19.10	9.44	8.22		6.13		
31.1	10.25	9.18		8.44		
31.6	10.28	9.21		8.49	3.72	2.59
32.1	10.30	9.23		8.55	4.05	3.10
37.1	10.52	9.48		9.00	5.99	5.33
37.6	10.54	9.51		9.04	6.12	5.45
38.1	10.55	9.53	1.55	9.08	6.25	5.59
38.6	10.57	9.55	1.90	9.12	6.38	5.72
48.1	10.88	9.91	4.81	9.71	8.08	7.48
58.1	11.13	10.19	6.25	10.15	9.18	8.60

On the surface of Ha and coworkers [5], the calculated rates predict concerted decomposition (1 → H → 3 and 2 → B,H → 3) to be much faster than stepwise decomposition, and gamma hydrogen exchange to be much faster than either. Thus hydrogen exchange is not necessarily proof of a stepwise process. Assuming that 1 and 2 reach a steady state (a plausible assumption at long times) yields a relative concentration of 2 an order of magnitude greater than that of 1. Concerted 1 → 3 and 2 → 3 would be the dominant decompositions of Ha's surface. However, in our model 2 → 3 becomes orders of magnitude more frequent than concerted 1 → 3 and 2 → 3. We believe our model to be closer to reality, and hence conclude that the decomposition of 1 via the McLafferty rearrangement is stepwise.

COMPETING REACTIONS OF THE ACETONE CATION-RADICAL, RRKM-QET CALCULATIONS ON AN *AB INITIO* POTENTIAL ENERGY SURFACE

Chava Lifshitz and Frank Louage
Department of Physical Chemistry and
The Fritz Haber Center for Molecular Dynamics
The Hebrew University of Jerusalem, Jerusalem 91904, Israel

and

Nikolaus Heinrich and Helmut Schwarz
Department of Chemistry
Technical University, D-1000 Berlin 12, W. Germany

We have employed, for the first time in RRKM-QET calculations, sets of reactant and transition state frequencies as well as energetics based on *ab initio* calculations of a reaction potential energy profile The reaction system involves two parallel dissociations of the acetone cation radical

$$CH_3COCH_3^{+\cdot} \xrightarrow{(1)} CH_2CO^{+\cdot} + CH_4$$
$$CH_3COCH_3^{+\cdot} \xrightarrow{(2)} CH_3CO^{+} + CH_3$$

Ab initio calculations demonstrate the intermediate existence of a hydrogen-bridged $[CH_3CO^+/CH_3]$ complex for both reactions Assumptions made and data used in the RRKM calculations are as follows: 1) Dissociation takes place from the acetone cation radical potential well, i.e., the reactant, even if going through the H-bridged complex, has available to it the high density of states of the acetone well. 2) The energetics of the dissociations conform to those of the highest level *ab initio* calculations, MP3/6-31G(d,p)//6-31G(d) + ZPVE. 3) Reaction (1) can take place at its endothermic threshold by quantum-mechanical tunneling through the barrier. An unsymmetrical Eckart barrier has been assumed with tunneling taking place between the H-bridged complex and a ketene ion/methane complex. By invoking tunneling in the first unimolecular reaction channel (CH_4 elimination) we were able to reproduce several experimental observations: (a) Reaction channel (1) is the major channel for so-called "metastable ion" fragmentations in the microsecond lifetime range; (b) Channel (2) becomes the major reaction channel at high internal energies of the reactant ion. Photoionization efficiency (PIE) curves for the two competing channels calculated on the basis of RRKM-QET microcanonical rate coefficients k(E) reproduce experimental results[1] rather well (see Figure 1).

The reaction system is a quite general example in mass spectrometry for two parallel reaction paths with slightly different critical energies and different activation entropies. The special interest in this system is two-fold: The formation of a single intermediate through which both reaction paths proceed, and the possibility of tunneling through a barrier other than a centrifugal one.

THE UNIMOLECULAR DISSOCIATION MECHANISM OF METHYLNITRITE

Qingmei Zha, R. N. Hayes, M. L. Gross and G. G. Meisels
Department of Chemistry, University of Nebraska-Lincoln
Lincoln NE 68588-0312

The fragmentation mechanism of methylnitrite ion has been the subject of considerable interest, especially with regard to the formation of the ion at 31 daltons. Gilman et al[1] investigated this process by TPEPICO and reported that the fragmentation of the parent ion at a constant internal energy produced ions at 30 and 31 daltons at greatly different rates, with that for the production of the latter ion much too slow to be accounted for by single-state statistical theories (RRKM/QET). They suggested therefore that this ion was formed by a state-specific channel. They also suggested that the ion at 31 daltons might be CH_3O^+. Burgers and Holmes[2] measured kinetic energy release accompanying metastable ion formation in methylnitrite, and concluded that the ion at 31 daltons is CH_2OH^+ and is formed by a hidden hydrogen migration. Baer and Hass[3] attempted to account for the difference in rate constants of the formation of ions at 30 and 31 daltons by proposing that a stable isomeric structure $HNC(OH)_2^+$ is formed prior to dissociation of the molecular ion at low internal energies. The product ion would also have the structure CH_2OH^+. The assumption of the intermediate, stable isomeric ion allowed statistical calculations to be brought into agreement with observations. However, Ferguson[4] noted that the formation of the proposed intermediate required the simultaneous breaking and re-making of five bonds and was therefore probably energetically not feasible.

We have reexamined the mechanism of methylnitrite dissociation using a triple-sector Kratos MS50TA tandem mass spectrometer by analyzing the isotopic composition of reaction products resulting from the metastable dissociation of CH_3ONO^+ and specifically labeled $CH_3{}^{18}ONO^+$. The latter was prepared from $CH_3{}^{18}OH$ and $NaNO_2{}^1$.

The major peaks in the metastable mass spectrum of CH_3ONO (Figure 1) are at 60 (CH_2ONO^+), 31 (CH_3O^+ or CH_2OH^+), 30 (NO^+) and 29 (HCO^+) daltons. A precursor ion spectrum of HCO^+ indicates that its predominant precursor is the ion at 31 daltons. The ratio of the peaks at 31 and 29 daltons, respectively, is about 14:1.

If a long lived intermediate of structure $HNC(OH)_2^+$ were the only precursor of the ion at 31 daltons, one would expect that the two oxygen atoms would be equivalent and that either the labeled or unlabeled oxygen would be lost with equal probability, and the peak at 31 daltons in the unlabeled methylnitrite should split into ions at 31

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

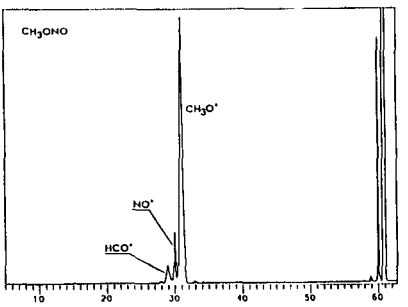

Figure 1.

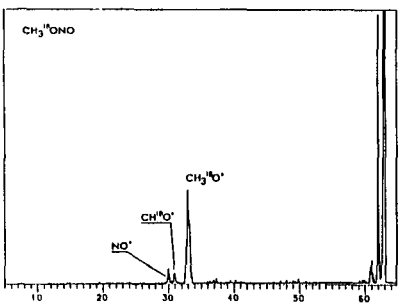

Figure 2.

and 33 daltons with approximately equal intensities. Similarly, the peak at 29 daltons in the unlabeled compound should lead to ions at 29 and 31 daltons in approximately equal intensities.

The metastable mass spectrum of $CH_3{}^{18}ONO$ (Figure 2) does not show such behavior. The peak at 29 daltons in CH_3ONO essentially disappears and is presumably shifted to 31 daltons. The new peak at 33 daltons becomes the major peak (other than for unchanged NO^+); the ratio of the peaks at 33 and 31 daltons is about 10:1. After correction for the contribution of $CH_3{}^{18}O^+$ to the peak at 31 daltons, not more than 6 % of the CH_3O^+ peak could have been formed via an intermediate structure in which the two oxygen atoms are equivalent. This suggests strongly that there is very little if any scrambling and certainly that in the dominant dissociation process the two oxygen atoms have not become equivalent.

We note here also that the formation of 31 daltons occurs only over a very narrow range of about 0.5 eV[1]. Hence, the ion is not formed with more than 0.5 eV excess internal energy above ionization threshold. Since a MIKE investigation has reported the kinetic energy release to be measured to be 0.3 eV[2], kinetic energy release would be about 60 % if the nascent fragment ion had the CH_3O^+ structure. Direct dissociation without participation of internal modes would predict a kinetic energy release of 68 %. This would be consistent with a similarly high proportion of excess energy appearing as kinetic energy reported in the dissociation of dimethyl ether[5].

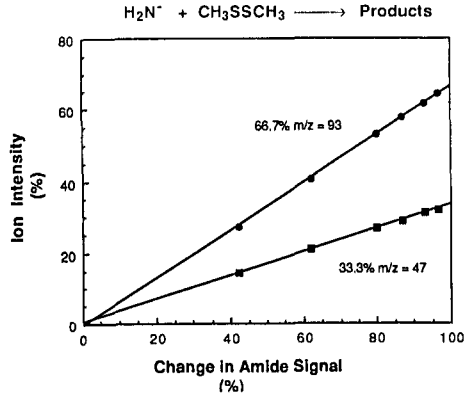
SELECTIVITY IN THE REACTIONS OF ANIONS WITH DIMETHYLDISULFIDE

Joseph J. Grabowski and Lijian Zhang
Department of Chemistry, Harvard University
Cambridge, MA 02138

The importance of sulfur, demonstrated by the existence of a vast literature, is due to the variety of valence states for sulfur and sulfur's widespread occurrence in chemistry, in biology, in industry, in agriculture and in air pollution among others. It appeared to us that a gas phase ion-molecule investigation into the intrinsic chemistry displayed by unsolvated, uncomplexed anions reacting with unsolvated, unaggregated reduced sulfur systems would make an important contribution to efforts to thoroughly understand the chemistry of sulfur in all its applications. In the study reported here, we have allowed a series of anions to react with dimethyldisulfide in the gas phase, under thermally-equilibrated (300K) reaction conditions. The results presented below were obtained utilizing the flowing afterglow technique, in 0.3 Torr of helium buffer gas.

A sample branching ratio plot for the reaction of H_2N^- with CH_3SSCH_3 is shown in the first figure below, while the data from repeated measurements is summarized in eq 1.



$$H_2N^- + CH_3SSCH_3 \longrightarrow 34\%\ CH_3S^- + [CH_5NS] \quad (1a)$$
m/z = 16 m/z = 47

$$H_2N^- + CH_3SSCH_3 \longrightarrow 66\%\ (C_2H_5S_2)^- + NH_3 \quad (1b)$$
m/z = 16 m/z = 93

While there can be no doubt as to the structure of the ion at m/z = 47 or the chemical composition of the ion at m/z = 93, the structure of the latter ion is not obvious from this one experiment. Based on an extensive series of experiments that examined the chemical reactivity of the m/z = 93 ion synthesized by amide (and by other reagent ions with dimethyldisulfide) and compared to the reactivity of model anions of known chemical structure, we were able to show that the m/z = 93 ion has the thiolate ion structure, $CH_3SCH_2S^-$. The data from a number of analogous reactions are summarized in the Table.

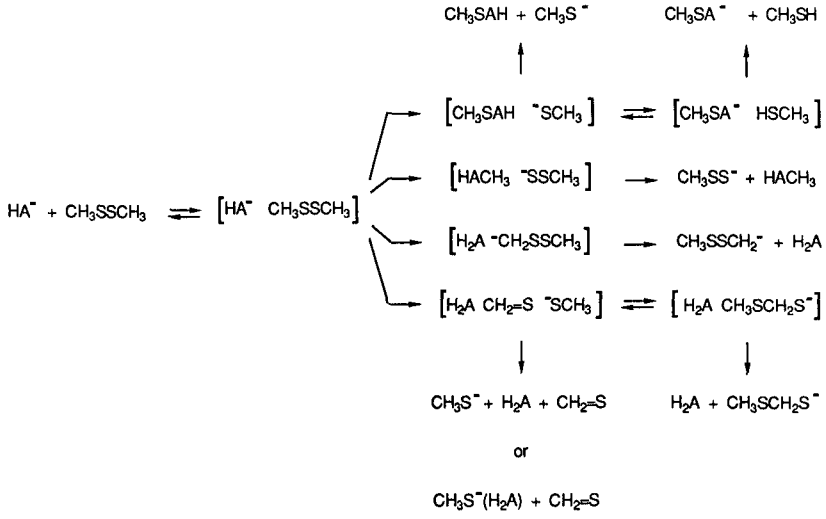
$HA^- + CH_3SSCH_3 \longrightarrow$

PA (kcal/mole)	HA^-	CH_3SA^-	CH_3S^-	$CH_3SCH_2S^-$
356 4	$CH_2NO_2^-$	100%	0%	0%
369 1	$H_3C\text{-}\overset{O^-}{\overset{\vert}{C}}{=}CH_2$	82%	18%	0%
373 9	CH_2CN^-	75%	25%	0%
379 8		0%	99%	1%
390 7	$H_2C{=}CH\text{-}CH_2^-$	0%	94%	6%
403 6	H_2N^-	34%	0%	66%
390 7	HO^-	36%	7%	57%
380 6	CH_3O^-	13%	11%	76%



In general, we find that anions react with dimethyldisulfide either by displacement at sulfur or by elimination across a carbon sulfur bond. Anions which can be described as being localized in nature appear to react principally (if not exclusive) by elimination (bottom pathway of general scheme) while anions that are best described as being delocalized react almost entirely by displacement at sulfur (top pathway of general scheme). The reaction pathway selected for any particular ion appears to depend solely on the structure of the ion and not the energetics (e.g., compare reactivity of hydroxide and allyl anions; both reactions proceed at near the collision efficiency). Displacement at carbon to yield the disulfide anion and proton abstraction to yield the stable conjugate base of dimethyldisulfide was not observed for any anion examined.

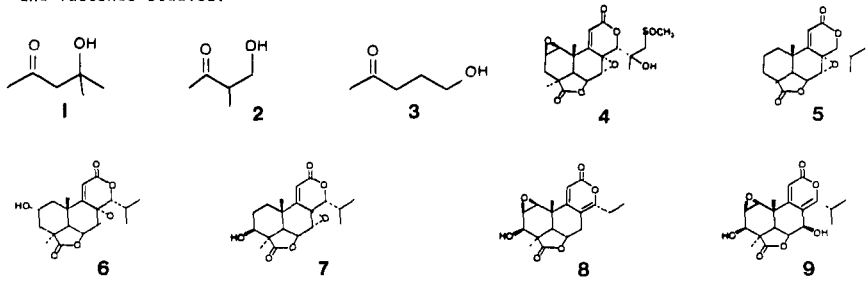
Ion-Molecule Reactions of Ethyl Vinyl Ether With Various Oxygen-Containing Cations in a Triple Quadrupole Mass Spectrometer and a Quadrupole Ion Trap

H.I. Kenttämaa and R.G. Cooks
Purdue University
West Lafayette, IN 47907

Gas-phase reactions of ethyl and methyl vinyl ether with different oxygen containing cations were examined by employing a triple quadrupole tandem mass spectrometer, and a quadrupole ion trap capable of tandem experiments. A product ion which formally corresponds to exchange of a proton of the reactant ion to a vinyl group (loss of ethanol/methanol from the ion-molecule complex with ethyl vinyl ether/methyl vinyl ether) is of special interest. An abundant vinylation product was obtained in both instruments for ions which contain a protonated carbonyl group and a hydroxy group in close proximity (e.g., 1 and 2; 3 to a minor extent). The reaction seems to be specific to this combination of oxygen-containing functional groups; no vinylation product was observed for various protonated ethers, epoxides, aldehydes, ketones, esters and lactones studied.



The general behavior described above applies to complex polyfunctional molecules, as well. After protonation, the molecules 4-9 were allowed to collide with ethyl vinyl ether in the center quadrupole of the triple quadrupole mass spectrometer. While an abundant vinylated molecule was observed for 7-8 which have a hydroxy group close to the lactone ring, protonated 4-6 do not give the corresponding product ion (Figure 1).

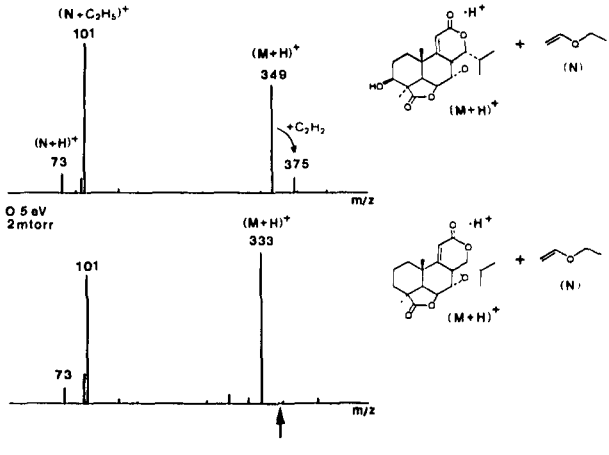


Figure 1

Studies employing various ionic reagents indicate that the reactant ion is the protonated carbonyl compound and not the protonated ether. The yield of the reaction (Figure 2) appears to be first order with respect to ethyl vinyl ether at pressures below 2 mtorr in the triple quadrupole mass spectrometer. The reactions of simple ions as well as complex polyfunctional ions show a negative kinetic energy dependence which indicates that the reaction is exothermic, and that it has no significant energy barriers in the cases studied.

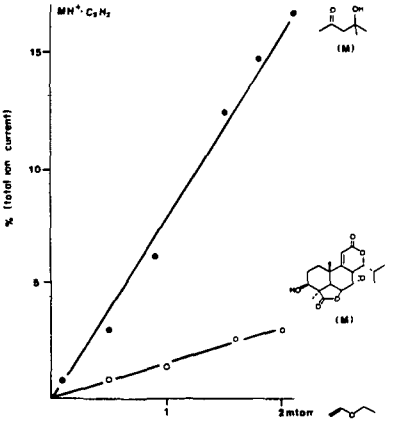

Figure 2

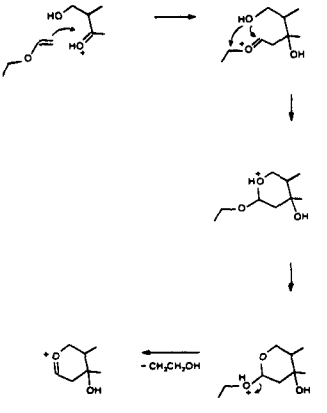

Figure 3

A mechanism unified with the experimental results is presented in Figure 3. Results obtained by deuterium labelling experiments, and MS/MS/MS employing collision-activated dissociation of the product ion (major loss of acetaldehyde) in the ion trap provide support for the proposed product ion structure.

THE STRUCTURE OF IONIZED n-PROPANOL PRECEDING THE LOSS OF WATER

Qingmei Zha and G. G. Meisels
Department of Chemistry University of Nebraska-Lincoln Lincoln NE 68588
T. Nishimura
Control Spectroscopy Development The Upjohn Co. Kalamazoo MI 49001

The unimolecular dissociation of energy-selected normal propanol ion was investigated by photoelectron photoion coincidence (TPEPICO) mass spectrometry. Asymmetric time-of-flight (TOF) distributions were observed for the formation of cyclopropane ion resulting from the loss of H_2O. The observed rate constants were about 10^6 s^{-1} at threshold.

There are two possible isomeric structures of ionized n-propanol. Holmes et al[1] concluded that the distonic radical cation ($\cdot CH_2CH_2CH_2OH_2^+$) is the proper reacting configuration for dissociation leading to the loss of H_2O at low internal energies. The heat of formation for this structure was determined to be 714 ± 5 kJ mol^{-1}, 17 kJ mol^{-1} lower than that of the molecular ion. Shao, Baer et al[2] suggested that the stable isomeric structure is the ion-dipole complex ($c\text{-}C_3H_6^{+\cdot}\text{---}OH_2$), and that the heat of formation of this complex can be taken to be the same as that of the distonic radical.

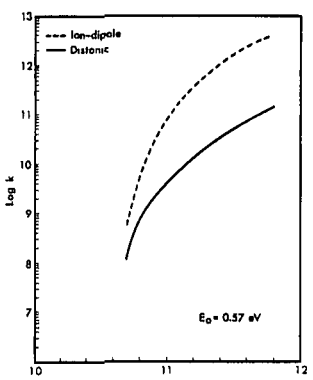

Fig. 1.

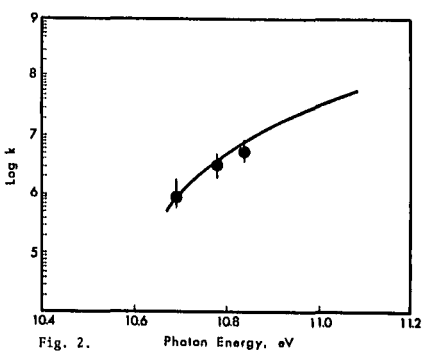

Fig. 2.

The results of RRKM/QET rate calculations are shown in Fig. 1. The calculated rate constants for ion-dipole assumption are of the magnitude of 10^9 s^{-1}, much higher than observed experimentally. This is also higher than the calculated rate constants of an order based on the distonic radical as the assumed intermediate.

However, the latter calculation still leads to calculated rates higher than those

observed. A modification of the calculation was attempted by multiplying the vibrational frequencies of the reactant by a reactant frequency factor R ($R < 1$). The result is shown in Fig. 2, where factor R was taken as 0.7 at the same activation energy of 0.57 eV.

The relationship between R and the minimum rate constant k_{min} at threshold can be derived from the rate expression:

$$\frac{[k_{min}]_o}{[k_{min}]_r} = \frac{[N(E_o)]_r}{[N(E_o)]_o} \approx \frac{1}{R^v}$$

where subscripts o and r represent the situations without and with adopting R factor, $N(E_o)$ is the density of states of reactant with energy between critical energy E_o and E_o+dE, and v is the number of independent oscillators for a given reactant.

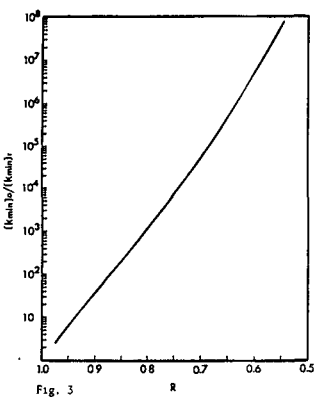

Fig. 3

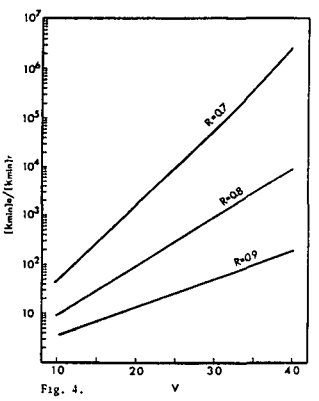

Fig. 4.

Fig. 3 shows the ratio of $[k_{min}]_o$ / $[k_{min}]_r$ vs. R for n-propanol ion in which v is 30. When R is taken as 0.7, k_{min} is reduced by about 10^4. This corresponds to an increase in the state density of the reacting ion as shown in the above equation. The relationship between the ratio of $[k_{min}]_o$ / $[k_{min}]_r$ and molecular complexity is shown in Fig. 4 where R is fixed while the variable is the number of independent oscillators v. The ratio of $[k_{min}]_o$ / $[k_{min}]_r$ increases greatly for large number of v, i.e. big molecules. The need for the reduction of vibrational frequencies may reflect the involvement of an isomerization process in the unimolecular dissociation.

SEPARATION OF PHOTOOXIDATION PRODUCTS OF TOLUENE BY MEDIUM RESOLUTION ATMOSPHERIC PRESSURE IONIZATION MASS SPECTROMETRY

Andrew H. Grange, Oregon Graduate Center, Beaverton, OR 97006
Robert J. O'Brien, Portland State University, Portland, OR 97207
Douglas F. Barofsky, Oregon State University, Corvallis, OR 97331

Atmospheric photooxidation of toluene, an important industrial solvent and a major component of gasoline, contributes to the severity of smog episodes. Recent studies have utilized GC/MS, CI tandem MS, or atmospheric pressure ionization (API) MS to identify photooxidation products of toluene generated in simulated atmospheres. The resolution provided by the quadrupole mass filters used was insufficient to distinguish between ring fragmentation products differing in composition by a -C=O vs a -CH2CH2- group. Identities of several products remain uncertain.

Of the aforementioned mass spectrometric techniques, only APIMS has sufficient sensitivity to detect photooxidation products generated in simulated atmospheres without prior separation or concentration steps, which have altered products in past studies. To analyze these products directly and to enhance resolution we built a corona discharge, API source for a VG 7070E-HF double focusing mass spectrometer.[1,2] Operating with a resolution of 2,800 (m/z 101, <1% valley, 1/6 maximum transmission) multiple peaks were resolved at numerous nominal masses. Three species were resolved at both m/z 97 and m/z 99 (Figure 1). The different kinetic behavior of each peak allows them to be distinguished as photoproducts and two types of background components.

Table 1 lists experimentally determined masses for these peaks and the computed masses for molecular formulae containing C, H, O, or N that are chemically reasonable and whose exact masses agree to within two standard deviations (peak a3 is the lone exception to the latter criterion). The errors associated with experimental masses of peaks a1, b1, and b3 are nearly small enough to establish the elemental compositions of the corresponding ions without invoking supplementary information. For peaks a2 and b2 the first molecular formulae listed are most likely since compounds containing N are inconsistent with the known photochemistry of toluene. The products identified in other studies listed in the right column have the molecular formulae determined in our study.

In normal operation, a small potential is applied across the differentially pumped region in the API source to maximize the signal from molecular ions by dehydrating molecular ions associated with water molecules. Figure 2 illustrates an additional use of the CID potential to clarify the structure of the compound producing the principal peak at m/z 103. Both 1,4-butenedial and hydroxy-3-oxobutanal have been identified as toluene photooxidation products in past studies. This peak could arise from protonated hydroxy-3-oxobutanal or from protonated, monohydrated 1,4-butenedial. A modest increase in the CID potential, insufficient to induce significant fragmentation of molecular ions, (row three) substantially diminished the principal peak at m/z 103, while the peaks due to non-hydrated ions at m/z 99 showed little change. Hence, the majority of this peak's ion abundance is due to the hydrated ion.

FAST ATOM BOMBARDMENT MASS SPECTROMETRY AS A PROBE FOR THE ANALYSIS OF SHORT LIVED REACTION INTERMEDIATES

Larry M. Mallis[1] and William J. Scott

[1]High Resolution Mass Spectrometry Facility
and Department of Chemistry
The University of Iowa
Iowa City, Iowa 52242

A growing body of synthetic methodology has been developed in the last two to three decades which involves the use of stoichiometric or catalytic amounts of transition metals to mediate carbon-carbon bond forming reactions. In this paper, we report on a palladium catalyzed coupling reaction of 4-*tert*-butyl-cyclohexenyl triflate with vinyltributylstannane in the presence of tetrakis(triphenylphosphine)palladium(0) [$Pd(PPh_3)_4$] and lithium chloride to give 1-vinyl-4-*tert*-butylcyclohexene. While there is precedent in the literature for each step of the mechanism for this reaction there remains no direct evidence for the formation of many of the postulated palladium(II) intermediates.[2]

Recently, Daves and co-workers showed that fast atom bombardment mass spectrometry (FAB-MS) could be used to probe the short lived intermediates involved in the Pd(II) catalyzed olefination of organomercury compounds.[3] Thus, to better understand the mechanism of the Pd(0) catalyzed coupling reactions with electrophiles the reaction was performed on a standard FAB probe tip.

A suitable FAB matrix for this reaction had to be inert with respect to the components of the reaction mixture yet be able to aid in ionization of the reaction intermediates being studied. Triethanolamine was the only matrix compound tried that produced PdL_n^+ ions while inhibiting the decomposition product ions $Pd_nL_n^+$ observed for all other matrix compounds.

The first step of the catalytic reaction is an oxidative addition of tert-butylcyclohexene to $Pd(0)L_n$ in the presence of LiCl to form an organoPd(II) chloride species (Figure 1). An ion at m/z 958 is observed in the catalytic reaction and assigned as organoPdL_2Cl·LiOTf, an intermediate in the oxidative addition process (see Figure 3). In addition, an ion at m/z 767, shown under stoichiometric conditions to be organoPdL_2, was observed in the catalytic process. It is interesting to note that an ion at m/z 399 corresponding to $RPPh_3$ was observed only in the presence of palladium. Further studies to elucidate the mechanism of the transmetallation step are currently under way.

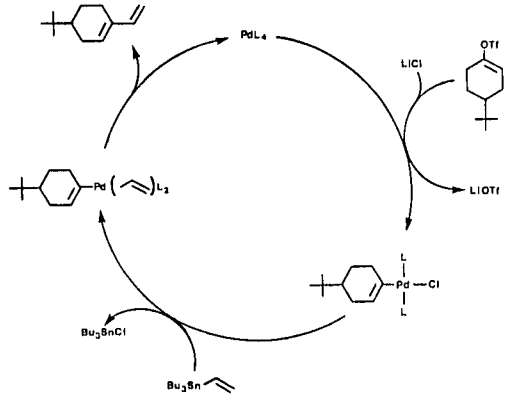

Figure 1. Schematic representation of the palladium catalyzed reaction pathway. Although the mechanism is generally accepted, reaction intermediates have not been fully elucidated.

CLUSTER IONS AS A PROBE FOR BIMOLECULAR SUBSTITUTION REACTIONS UNDER SIMS CONDITIONS--CHOLINES--

Mamoru Ohashi, Takashi Iino, and Takeshi Tani
Department of Applied Physics and Chemistry, The University of Electro-Communications, Chofu, Tokyo 182 Japan

Recently particle bombardment-induced reactions in a matrix under SIMS conditions attract considerable attention. Because of the widespread use of desorption ionization methods, it must be essential to clarify the scope and limitation of those reactions. This paper deals with the particle bombardment-induced intermolecular reactions of choline and acetylcholine halides under SIMS conditions. Structures of the reaction products contained in cluster ions were characterized by means of linked scannings at constant B/E and B^2/E.

As an example, dry SIMS and liquid SIMS(glycerol matrix) spectra of choline bromide(C^+(a) Br^-) are shown in Fig. 1A and 1B, respectively. In Fig. 1A the peak corresponding to transmethylation product at m/z 118 is prominent and the linked scanning at B/E constant showed its daughter ions at m/z 90, 74, 60, 59, 58, and 42, which clearly indicated its structure as the transmethylation product $MeOCH_2CH_2\overset{+}{N}Me_3$(b). On the other hand, Fig. 1B exhibits many cluster ions whose structures were characterized as (C^++nM, where M=C^+X^-); m/z 104, (287 and 289), (470, 472 and 474), (653, 655, 657 and 659): (b)+nM; m/z 118, (301 and 303): $Me_3\overset{+}{N}CH_2CH_2O^-$ (c) $Me_3\overset{+}{N}CH_2CH_2OH$ +nM; m/z 207, (390 and 392), (573, 575 and 577): $^-BrCH_2CH_2\overset{+}{N}Me_3$(d)+nM; m/z(166 and 168), (349, 351 and 353), (532, 534, 536 and 538), (715, etc.). Comparison of these two spectra lead us to conclude that transmethylation is more favorable under dry conditions than in glycerol, and that the brominated compound was detected only in glycerol. In the cases of choline chloride, transmethylation occurs in a similar tendency, but the chlorinated cation corresponding to (d) was not detected even in glycerol. Cluster ions of (a),(b) and (c) were also observed on liquid SIMS of choline chloride but not on dry SIMS.

On the liquid SIMS spectra of acetylcholine halides(C^+X^- X=Cl, Br, I) the following cluster ions were characterized in commom with the use of linked scannings; in the case of chloride: C^+(e)+nM; m/z 146, 327, 508, 689 and 872: $HOCH_2CH_2\overset{+}{N}Me_3$(a)+nM; m/z 104, 285, 446, 647 and 830: $CH_2{=}CH\overset{+}{N}Me_3$(f)+nM; m/z 267, 448, 629 and 813. While on the dry SIMS spectra of acetylcholine chloride, a transmethylation product(g, m/z 160) but not (f) was observed. In the case of benzoylcholine iodide, a series of peaks due to C^+ +nG(G; glycerol molecule, MW 92), m/z 208, 300, 392, 484, 576, 668, 760, 852 and 944, have been observed besides the C^++nM(m/z 208, 543, 878).

In summary, ions indicating the following reaction products of choline and acetylcholine halides have been recognized under liquid SIMS conditions;

1) $2HOCH_2CH_2N^+Me_3$(a) ⟶ $MeOCH_2CH_2N^+Me_3$(b) + $HOCH_2CH_2NMe_2$

2) $HOCH_2CH_2N^+Me_3\ X^-$ ⟶ $^-OCH_2CH_2N^+Me_3$(c) + HX

3) $HOCH_2CH_2N^+Me_3\ Br^-$ ⟶ $BrCH_2CH_2N^+Me_3$(d)

4) $AcOCH_2CH_2N^+Me_3$(e) ⟶ $CH_2{=}CHN^+Me_3$(f) + AcOH

5) $2AcOCH_2CH_2N^+Me_3\ X^-$ ⟶ ($CH_2{=}C(OMe)OCH_2CH_2N^+Me_3$(g)) + $AcOCH_2CH_2NMe_2$

6) $AcOCH_2CH_2N^+Me_3$ ⟶ $HOCH_2CH_2N^+Me_3$

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Although all processes from the molecular cations(C^+) to fragment ions(F^+) were confirmed by linked scan techniques, no metastable transitions from (C^++nM) to (F^++nM) in the first field free region have been observed except for reaction 2. This means that transmethylation occurs mainly in the liquid phase but scarcely in the cluster ion forms in the vapor phase. Commercial samples of choline halides we used turned out to contain a small amount of $HOCH_2CH_2OCH_2CH_2\overset{+}{N}Me_3$ cation whose structure has been confirmed by liquid SIMS linked scannings.

Figure 1. SIMS spectra of choline bromide, 1A; dry SIMS, 1B; liquid SIMS(glycerol).

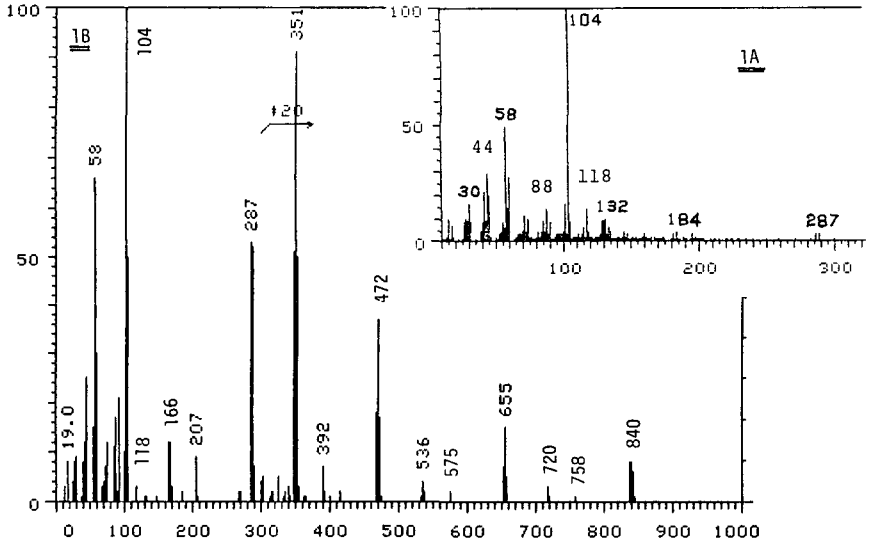

Figure 2. SIMS spectra of choline chloride, 2A; dry SIMS, 2B: liquid SIMS(glycerol).

Mass Spectrometric Measurement of Isotopic Oxygen Abundances Occurring within Transient Products Generated from Hot $^{18}O(^3P)$ Atom Reactions with Formaldehyde

Richard A. Ferrieri and Alfred P. Wolf

Brookhaven National Laboratory, Department of Chemistry,
Upton, New York 11973.

Our recent interest in the reactions of translationally hot ground-state (^3P) oxygen atoms with aldehydes, and other related compounds, stems from the realization that high temperature OH radical formation from such systems remains as one of the fundamental aspects of oxygen atom chemistry not clearly understood.(1) However, the major role these processes play in the many facets of today's growing technology, such as in combustion, laser chemistry, rocket propulsion, atmospheric chemistry and in space materials research, creates practical problems that require solutions as well.

Within the last two years, we have developed a novel oxygen atom source that is well-suited for conducting high energy chemical studies of this nature.(2) This source relies on kilovolt atomic ion sputtering for the generation of macroscopic concentrations of oxygen atoms sputtered from appropriate metal oxide targets through one or more mechanisms.(3) By virtue of the nature of this sputtering mechanism, some degree of control can be affected over the state and energy of the sputtered atom. For example, low mass-medium energy (<100 KeV) atomic ion sputtering of a Ta_2O_5 target yields a clean source of neutral ground-state oxygen atoms that possess a distribution of translational energies centered about 6 eV. This behavior was shown to be characteristic of a sputtering mechanism dominated by linear collision cascades where nuclear stopping of the impinging ion beam was important. However, these characteristics could have been altered by promoting a different mechanism through retuning the impinging ion beam to a different mass and energy, or by selecting a different target material that exhibited different surface binding properties.

Surrounding the above source was a high vacuum chamber that permitted the controlled introduction of substrate gases over a broad range of pressures. Also attached to this chamber in an orientation 90° to the axis of the impinging ion beam was a differentially pumped quadrupole mass spectrometer equipped with an electron impact ionizer and electron multiplier detector. This system enabled the measurement of both transient and stable products that could be related to primary reactions involving the hot atom and the substrate molecule. In operating this detector, background signals from the substrate gas were minimized by modulating the oxygen atom source through chopping the incident ion beam. A difference in the product ion signal was then measured from this modulation sequence and was equated to reactive channel contributions and background beam scatter contributions within the chamber. The latter was removed through separate background calibrations.

Most recently, we investigated the reactions of hot $^{18}O(^3P)$ atoms with formaldehyde containing oxygen-16. Formaldehyde represents the smallest homolog of the aldehyde class. The isotopically enriched atomic source, generated by sputtering oxygen-18 from $Ta_2{}^{18}O_5$, enabled us to probe the mechanisms for OH radical formation through mass spectrometric measurement of the isotopic oxygen abundances in transient and stable products. Near-single collision conditions were achieved, in part by conducting the studies at 1×10^{-5} Torr, and in part by acquiring reactive ion signals on a 4 msec time basis.

It is generally accepted that abstraction of the weak aldehydic hydrogen atom of formaldehyde is the only important reaction at thermal energy.(4) Under these circumstances, we would expect no isotopic mixing to occur in the OH and HCO radical products.

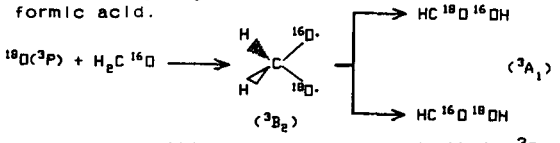
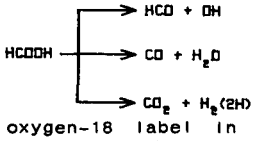
$$^{18}O(^3P) + H_2C^{16}O \longrightarrow {}^{18}OH + HC^{16}O$$

However, atom attachment to the carbonyl double bond may be of sufficient importance to be seen as a reaction channel (5), if sufficient energy could be deposited within the newly formed triplet dioxymethylene intermediate to promote migration of a hydrogen atom across one of the two C-O bonds and yield triplet formic acid.



Although a recent ab initio study suggested that $^3B_2$ dioxymethylene isomerization to $^3A_1$ formic acid would require at least 30 kcal/mol (6), this energy restriction may not apply here.

Once formed, the excited acid will unimolecularly dissociate by one of several pathways--one in particular yielding HCO and OH radicals.(7)



The distribution of the oxygen-18 label in these products would then reflect its' position in the excited acid.

Results from our mass spectrometric measurements showed that the intermediate migration pathway to OH formation was not only operative at these high kinetic energies, but also accounted for a major portion of those radicals detected. Similiar pathways have been proposed by us for this species formation when hot $O(^3P)$ atoms react with alkenes.(2b,8)

Research carried out at Brookhaven National Laboratory under contract with the U.S. Department of Energy and supported by its Office of Basic Energy Sciences.

CALCULATED ION STRUCTURES FOR SMALL COPPER- AND SILVER-CONTAINING IONS: COMPARISON WITH RESULTS FROM MS/MS EXPERIMENTS. R. A. Flurer and K. L. Busch; Department of Chemistry, Indiana University, Bloomington, Indiana 47405

Busch et al. [1] have recorded the daughter and parent ion MS/MS spectra of several small silver-containing ions formed from silver carboxylates. On the basis of the observed fragmentation pathways, it was concluded that certain of the fragment ions contained metal-metal bonds and others did not, based on the distribution of parent ions of the Ag_2^+ dimer ion. Specifically, it was concluded that $Ag_2CH_3^+$, Ag_2O^+, and Ag_2CO^+ probably contain metal-metal bonds to some degree, and that Ag_2H^+ does not.

DeKock et al. [2] have recently calculated the equilibrium geometries and fragmentation energies of the Ag_2H^+ and $Ag_2CH_3^+$ species using the Hartree-Fock-Slater method. They concluded that both of these species should have a bent geometry and contain metal-metal bonds. Gaspar and Tamassy-Lentei [3] have also investigated the Ag_2H^+ species using a simple pseudopotential method and have also predicted that this species should have a bent equilibrium geometry, but do not speculate on the presence or absence of a metal-metal bond. The present work applies the Hartree-Fock SCF method with effective core potentials to the calculation of the equilibrium geometries and dissociation energies of several copper- and silver-containing species observed in the electron ionization mass spectra of copper(II) propionate and silver propionate.

Calculations have been carried out for the following copper- and silver-containing species: Ag_2, AgH, Ag_2H^+, Ag_2O^+, AgO, $Ag_2CH_3^+$, Cu_2, CuH, and Cu_2H^+. Full geometry optimizations were carried out for all species at the Hartree-Fock SCF level of theory using relativistic effective core potentials for the silver-containing species and non-relativistic effective core potentials for the copper-containing species. For all species, the outer core orbitals on silver (4s and 4p) and copper (3s and 3p) were not included in the effective core potential, but were treated explicitly in the HF SCF calculations. The basis set used on copper consisted of a (5s5p/5s3p5d) basis contracted to [1s1p/3s2p3d], and for silver a (5s5p/5s3p4d) basis contracted to [1s1p/3s3p3d] was used. The basis sets for carbon and oxygen were STO4-31G*, and the basis set used for hydrogen was STO6-31G**. The calculated equilibrium geometries for all species studied are shown in Figure 1. The experimental geometries for the diatomic species are listed in parentheses for comparison.

The Ag_2H^+ and Cu_2H^+ species are predicted to be linear, and therefore not to contain metal-metal bonds, by calculation, which is consistent with the absence of these two species in the corresponding parent ion spectra of the metal dimer ion. In contrast, DeKock et al. predict the Ag_2H^+ species to have a bent geometry, and thus the possible presence of a metal-metal bond, which is not consistent with the fact that this species does not appear in the parent ion spectrum of the silver dimer ion. The authors cite several possible reasons for this discrepancy in their conclusions; however, none of them is really satisfying. The Ag_2O^+ species is also predicted to have a linear geometry, and therefore not to contain a metal-metal bond; however, this is not consistent with the presence of this ion in the parent ion spectrum of the silver dimer ion, which suggests that either this species has a much lower barrier for fragmentation to the dimer ion than do the Ag_2H^+ and Cu_2H^+ species or that the calculated results are not trustworthy for this particular species. However, the calculations do predict a significantly lower dissociation energy for the Ag_2O^+ species (28 kcal/mole) relative to the Ag_2H^+ (44 kcal/mole) and Cu_2H^+ (54 kcal/mole)species, a trend that is at least in agreement with the MS/MS results. These dissociation energies should not, however, be taken as quantitative due to the fact that electron correlation has not been included in the computations. The calculated geometries for the diatomic species AgO and CuH suggest that this computational method generally predicts bond lengths to be somewhat too long; this could probably be corrected to a large extent by including the effects of electron correlation in the computations by perturbation theory [4].

As shown in Figure 1, the $Ag_2CH_3^+$ species is predicted to have a bent Ag-C-Ag framework and thus a metal-metal bond to some degree, which is consistent with the presence of this species in the parent ion spectrum of the Ag_2^+ dimer ion. This is also consistent with the results of DeKock et al., which also predict a bent Ag-C-Ag framework with a Ag-C-Ag bond angle of 77 degrees. However, the present calculations predict a Ag-Ag distance that is 0.22 angstroms longer than that calculated by DeKock et al. This notwithstanding, it still seems possible that a metal-metal bond could be present in this species.

In summary, it can be stated that in general the Hartree-Fock method using effective core potentials provides geometric predictions for ionic species, which contain transition metal atoms, that are consistent with the results of MS/MS experiments. However, it appears that in some cases (the Ag_2O^+ species), transition state calculations that yield barrier heights for chemical processes, are necessary to obtain a full understanding of the gas-phase ion chemistry of transition metal containing species.

PLASMA DESORPTION MASS SPECTROMETRY OF SUCROSE POLYESTERS, T. Keough, M. Lacey, R. A. Sanders and D. R. Gardner, Winton Hill Technical Center, 6071 Center Hill Road, Cincinnati, OH 45224

Introduction: Molecular weight determination of large non-polar molecules is a continuing challenge of interest to lipid chemists. Techniques such as fast atom bombardment (FAB) and field desorption (FD) are most applicable to polar or ionic species. Non-polar lipids are ionized with low efficiency or not at all so that very little molecular weight information is obtained. The goal of this work was to investigate the applicability of plasma desorption mass spectrometry to molecular weight determination of non-polar lipids, especially sucrose polyesters.

A sucrose polyester structure is shown in Figure 1. When the C-C double bond is cis 9, this is sucrose octaoleate. Such sucrose polyesters have properties similar to triglycerides in food products. Mass spectral applications to sucrose polyesters include verification of identity and characterization of lower esters, such as hepta or hexaesters.

FAB and FD have been applied to sucrose polyesters with substantial success(1,2). FD of sucrose octaoleate produces a protonated molecule containing one C-13 as the most abundant ion in the molecular weight region. Though this was a significant breakthrough that allowed acquisition of mass spectra from sucrose polyesters for the first time, the approach was only applicable, for sensitivity reasons, to relatively simple, one or two component systems. And, the transient nature of the signal precluded observation over the wide mass range necessary for determining ester distributions. This latter problem was largely solved by using fast atom bombardment. In a DTT/DTE matrix, with approximately 1 ppm NaI, sucrose polyesters give interpretable FAB spectra in which Na adduct ions provide the required molecular weight information. Though S/N is no better, the persistent signal allows semi-quantitative ester distribution measurement and the use of MS/MS techniques. However, the sensitivity is such that large amounts of pure samples are required -- making it difficult to characterize isolates from HPLC. In particular, we were unable to obtain molecular weight information on minor components (suspected to be sucrose polyester dimers formed in heated samples) in the 4000-5000 molecular weight range as estimated from size-exclusion chromatography retention data.

Experimental: The plasma desorption (PD) data reported were obtained through the use of a Bio Ion 20 PD mass spectrometer. The nitrocellulose substrate was treated with NaI by evaporation from aqueous solution (10 uL of a 75 ug/mL solution). The 1-10 nmoles of sucrose polyester were deposited on the foil from solution in a 70/30 hexane/benzene mixture.

Results and Discussion: Figure 2 displays a PD spectrum of sucrose octalaurate (C12 fatty acid with no C-C double bonds). The parent + 23 peak at 1824 defines the molecular weight (nominal mass 1798 + 23 + 2 for H mass defect + 1 for C13) and the fragment at 893 corresponds to cleavage at the oxygen between the glucose and fructose rings. When a mixture of fatty acids is used and when hepta and hexaesters exist, a spectrum like the one shown in Figure 3 is obtained. The fatty acids are C16 and C18 with 0, 1 or 2 C-C double bonds. The peaks at approximately 2466, 2203 and 1940 daltons are parent + 23 for octa, hepta and hexaesters, respectively. Cleavage between the sucrose rings is observed as before -- peaks at approximately 1200 and 900 daltons corresponding to tetraester and triester, respectively. An expanded view of the molecular ion region of a similar mixture is shown in Figure 4. It is clear that the hexa, hepta and octaester peaks are split into components that differ in molecular weight due to the different numbers of carbons in the fatty acids. The highest mass octa component corresponds to eight C18 fatty acids; the next highest contains one C16 fatty acid, etc. Compared to FAB data on similar samples, PD suffers in terms of mass resolution. It is not possible to distinguish species which differ only in degree of unsaturation by PD. However, better S/N is achievable on lower levels (10 nmoles were required for this analysis) making it more applicable to HPLC and TLC isolates. Figure 5 shows the PD spectrum of a heptaester LC fraction from a sucrose polyester mixture very similar to the one analyzed above. The S/N is substantially better than that achievable by FAB and the sample preparation is more straightforward. The requirement of sample solubility in the FAB matrix was quite restrictive in the FAB approach; the PD approach only requires solubility in a non-chlorinated solvent (we found that chlorinated solvents disrupted the nitrocellulose surface).

Another advantage of the PD approach to sucrose polyester analysis parallels its advantage over FAB for high-mass, polar compounds. We have been able to obtain molecular weight information, for the first time, on dimeric sucrose polyester species isolated from heated samples by size-exclusion chromatography. Figure 6 shows the PD spectrum of this dimer. Peaks in the 2400 region are due to the monomer, which is not completely resolved by the chromatography. Components in the 4800 region are parent + 23 peaks for dimers. The peaks in the 3600 region are dimer fragments at the ring-joining oxygen, analogous to those fragments observed in the 1200 dalton region of the monomer.

Conclusion: Plasma desorption mass spectrometry offers the advantages of better high mass sensitivity as well as simpler and more universal sample preparation when compared to fast atom bombardment of sucrose polyesters. These come at the expense of mass resolution and accuracy. A combination of both techniques, applied in the appropriate circumstances, is recommended.

COMPARISON OF FAB WITH CI USING GLYCEROL AS A REAGENT GAS: K.L. Duffin and K.L. Busch; Department of Chemistry, Indiana University, Bloomington, IN, 47405.

Positive ion mass spectra generated by fast atom bombardment mass spectrometry using glycerol as a liquid matrix are compared to mass spectra recorded with chemical ionization using glycerol as a reagent gas. Comparison of mass spectra and daughter ion MS/MS spectra of protonated molecules suggest both similarities and differences in the mechanisms underlying these two ionization methods. In the first part of this study, FAB and CI mass spectra of leucine and glutamine are compared. When the glycerol vapor pressure is sufficiently high, CI mass spectra of these two compounds are very similar to the corresponding FAB mass spectra [Figure 1]. At these pressures, glycerol dimer ions are also present in the mass spectra. Adjustment of the reagent gas pressure to yield fragment and dimer ion abundances similar to those observed in FAB mass spectra provides a pressure reading of 2-5 Torr. However, even at these high CI gas pressures, glycerol cluster ions greater than n=2 are not observed. As expected, CI spectra also do not contain the chemical noise at every mass unit that is common in FAB mass spectra and has been attributed to radiation chemistry resulting from bombardment by the primary fast atom beam [1].

Energy-resolved daughter ion MS/MS spectra of the $(M+H)^+$ ethopropazine obtained at different CI gas pressures indicate that the relative abundances of the respective daughter ions depends dramatically on the source pressure at which the protonated molecule is initially formed and, to a much lesser extent, on the parent ion collision energy. At low CI reagent gas pressures (<0.5 Torr), daughter ions of protonated ethopropazine are produced in high abundance at m/z 100 and 214, corresponding to cleavage of a carbon-carbon bond [Figures 2 and 3]. However, at high CI reagent gas pressures (>2 Torr), daughter ion MS/MS spectra obtained at the same collision energy contain ions at m/z 114, 198, and 240, corresponding to cleavage of carbon-nitrogen bonds. Collisional stabilization at higher source pressures appears to make cleavage of a carbon-carbon bond inaccessible, whereas large internal energy deposition at low source pressures favors cleavage of the carbon-carbon bond to yield different daughter ions. Correlation of the daughter ion MS/MS spectra obtained by fast atom bombardment ionization from a glycerol matrix and by chemical ionization using glycerol reagent gas [Figure 3] independently confirms that fast atom bombardment ionization simulates high pressure chemical ionization. Daughter ion MS/MS spectra of protonated ethopropazine are also obtained using methane, ammonia, water, and triethanolamine as CI reagent gases, and thioglycerol and triethanolamine as FAB matrices. In general, small differences in the daughter ion MS/MS spectra can be correlated to differences in exothermicities of protonation of the various reagent and matrix compounds [2]. However, this effect is far outweighed by changes in source pressure. Deuterated ethopropazine obtained by using deuterated glycerol as a FAB matrix helped confirm daughter ion assignments. In conclusion, the occurrence of high pressure gas phase protonation reactions in FAB is confirmed, and further, it is shown that source conditions can have a dramatic effect on daughter ion MS/MS spectra.

GAS-PHASE ION-MOLECULE AND SURFACE-CATALYZED OXIDATION REACTIONS OF PAH UNDER NEGATIVE ION CHEMICAL IONIZATION CONDITIONS*

M.V. Buchanan and E.A. Stemmler
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

The negative ion chemical ionization (NICI) mass spectra of polycyclic aromatic hydrocarbons (PAH) often show unusual ions that can be used for isomeric differentiation. One such ion appears at $[M+14]^-$ in the spectra of PAH with an exposed methylene group, such as fluorene (1). Previous studies in this laboratory using deuterium labelled analogues, isotopically labelled buffer gases, Fourier transform mass spectrometry (FTMS), and MS/MS showed that the $[M+14]^-$ ion corresponds to $[M+O-2H]^-$, where oxygen substitution occurs at the 9-carbon and the anion structure resembles the molecular anion of 9-fluorenone (1).

One question regarding formation of the $[M+O-2H]^-$ ion that remained unanswered resulted from the inability to identify ionic precursors to this ion using swept double resonance (SDR) experiments on the FTMS. Additional experiments were conducted on a quadrupole instrument to determine the source of oxygen in the $[M+O-2H]^-$ ion. Fluorene was introduced through a gas chromatograph and oxygen containing reagents, including H_2O and O_2, were doped into the N_2 buffer gas. The addition of H_2O enhanced the $[M-H]^-$ ion from fluorene; however, $[M+O-2H]^-$ was enhanced by the addition of O_2. Experiments with ^{18}O-labelled O_2 verified that oxygen was being incorporated in the $[M+O-2H]^-$ ion; however, the degree of incorporation was lower than expected from the ^{18}O enrichment.

During the course of these studies, it was found that ion chromatograms corresponding to the $[M+O-2H]^-$ ion tailed relative to those observed for the $[M-H]^-$ ion (see Figure 1). It was also found that elevation of the ion source temperature increased the abundance of the $[M+O-2H]^-$ ion, and reduced the degree of chromatographic peak tailing exhibited by this ion (see Figure 2). In contrast, the peak shape for the $[M-H]^-$ ion showed no variation as a function of ion source temperature. Recent reports (2) have indicated that tailing ion chromatograms in NICI mass spectra are associated with solute-surface interactions in the ion source region that are followed by electron capture ionization. Our experiments indicate that the formation of 9-fluorenone from fluorene proceeds by a surface-catalyzed reaction with oxygen that occurs after fluorene elutes from the chromatographic column (see Scheme 1). Further results that support this conclusion come from experiments made under positive chemical ionization (PCI) conditions. The O_2/N_2 PCI mass spectrum of fluorene shows the expected ions at M^+ and $[M+H]^+$, which exhibit normal chromatographic peak shapes. Ions at $[M+14]^+$ and $[M-14]^+$ are also observed, and correspond to the M^+ and $[M-CO]^+$ from 9-fluorenone. Both of these ions exhibit tailing chromatographic peaks.

Additional studies were conducted to determine if similar reactions occur for other PAH, such as anthracene. In addition to the formation of M^-, anthracene was found to undergo various ion-molecule reactions in the presence of oxygenated compounds such as H_2O, N_2O and O_2. For example, $[M-2H]^-$ and $[M+O-H]^-$ were observed in the FTMS spectra of anthracene using N_2O, and were found to be linked to O^- by SDR experiments. In addition, SDR experiments indicated that ions corresponding to $[M-H]^-$ resulted from reactions with OH^-.

Using the quadrupole system, the $[M-H]^-$ from anthracene was enhanced by the addition of water to generate OH^-, and an ion at $[M+OH]^-$ was also

observed. Upon addition of N_2O, the ion at $[M+O-H]^-$ was enhanced. When oxygen was added to the reagent gas at low ion source temperatures, an ion at $[M+O_2]^-$ was formed. All four of these ions gave normal chromatographic peak shapes and ion formation was attributed to gas-phase ion-molecule reactions. In contrast, the O_2/N_2 NICI mass spectrum of anthracene, measured with the ion source temperature at 300° C, showed an ion at $[M+30]^-$ that exhibited a tailing chromatographic profile. Upon addition of $^{18}O_2$, incorporation of two oxygen atoms was indicated. These results, in conjunction with experiments using fully deuterated anthracene, showed that the $[M+30]^-$ ion resulted from $[M+2O-2H]^-$. This ion corresponds to the M^- ion of anthraquinone, where anthraquinone is formed by a surface-catalyzed oxidation reaction. This assignment is supported by measurements made in the PCI mode, where ions corresponding to the M^+, $[M-CO]^+$, and $[M-2CO]^+$ ions from anthraquinone appeared in the spectrum of anthracene.

These studies have shown that PAH undergo gas-phase electron-capture and ion-molecule reactions, in addition to surface-catalyzed oxidation reactions. These latter reactions are enhanced by addition of O_2 and elevation of the ion source temperature. The oxidized products, such as ketones and quinones, appear in the NICI mass spectra when they are ionized by electron-capture reactions.

ISOMERIC DIFFERENTIATION OF PAH AND METHYL-PAH USING SURFACE-CATALYZED OXIDATION REACTIONS*

E.A. Stemmler and M.V. Buchanan
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Recent studies have shown that surface-catalyzed oxidation reactions followed by electron-capture ionization produce unusual ions that dominate the O_2/N_2 negative ion chemical ionization (NICI) mass spectra of polycyclic aromatic hydrocarbons (PAH) at an ion source temperature of 300° C. These oxidation reactions yield products that can be used to differentiate isomeric PAH.

The spectra of unsubstituted PAH show three types of oxidized products. Compounds with methylene groups, like fluorene, undergo $-CH_2-$ to $-CO-$ conversion giving an $[M+O-2H]^-$ ion that appears at $[M+14]^-$. Ring oxidation reactions produce quinones and anhydrides. Most PAH undergo ring oxidation to give an $[M+2O-2H]^-$ ion that appears at $[M+30]^-$ (see Scheme 1A). PAH with an exposed ethene group undergo a unique oxidation reaction to give an $[M+3O-2H]^-$ ion that appears at $[M+46]^-$ (see Scheme 1B). These ring oxidation reactions permit differentiation of isomeric PAH such as benzo[ghi]fluoranthene, which gives an $[M+30]^-$ ion, from cyclopenta[cd]pyrene, which has an exposed ethene bridge and gives an $[M+46]^-$ ion. PAH also undergo oxidative ring cleavage reactions that produce anhydrides and ketones. Anhydride formation is observed when oxidation occurs in conjunction with loss of part of the aromatic ring. For example, naphthalene oxidizes to give an ion at m/z 148 that corresponds to phthalic anhydride. This reaction can be used to determine the number of methyl substituents on each aromatic ring of dimethylnaphthalenes because the isomers with methyl groups substituted on both aromatic rings give a single ion at m/z 162 (corresponding to methyl-substituted phthalic anhydride), while the isomers with both methyl groups substituted on the same ring give two ions at m/z 148 and 176 (corresponding to phthalic and dimethylphthalic anhydride, respectively). Ketone formation occurs in conjunction with loss of CH_2 to give an ion at $[M+2]^-$. The fact that these reactions occur to different a different extent for isomeric PAH with different structures permits differentiation of isomers, such as benz[a]anthracene, chrysene, and triphenylene (see Figure 1).

Methyl-substituted PAH undergo a variety of oxidation reactions involving oxidation of the methyl group, displacement of the methyl group during ring oxidation, and proximity reactions that take place between the methyl group and the aromatic ring or another methyl group. Methyl group oxidation involves conversion of the methyl group to an aldehyde to give an $[M+O-2H]^-$ ion that appears at $[M+14]^-$. Ring oxidation gives an ion at $[M+30]^-$ if the methyl group is not substituted at the site of oxidation. When methyl group and ring oxidation both occur, an ion at $[M+3O-4H]^-$ appears at $[M+44]^-$. These ions are all observed in the spectrum of 2-methylanthracene (see Scheme 2). If a methyl group is substituted at the site of ring oxidation, methyl group displacement occurs. For example, the spectrum of 9-methylanthracene is dominated by an ion at $[M+16]^-$, which corresponds to $[M+2O-CH_3-H]^-$ (see Scheme 3). In the case of 9,10-dimethylanthracene, the spectrum is dominated by an ion at $[M+2]^-$, which corresponds to $[M+2O-2CH_3]^-$. These reactions can be used to differentiate positional isomers of methyl-PAH. For example, 3,9-dimethylbenz[a]anthracene can be differentiated from the 7,12-isomer because of the $[M+2]^-$ ion that appears in the spectrum of the latter compound (see Figure 2). Ions are also observed that result from interactions of between the methyl group and the aromatic ring. For example, the spectrum of 4-methylchrysene is dominated by an ion at $[M+12]^-$, which is not observed in the spectra of the 1-, 2-, 3-, or 6-methyl isomers. This ion corresponds to $[M+O-4H]^-$ and would result from an oxidative ring closure to produce a cyclopentenone ring. This reaction, in conjunction with methyl group oxidation, accounts for the $[M+26]^-$ ion observed in the spectrum of 7,12-dimethylbenz[a]anthracene.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

In summary, the O_2/N_2 NICI mass spectra of PAH and methyl-substituted PAH, measured with an ion source temperature of 300° C, are dominated by unusual ions that result from surface-catalyzed oxidation reactions, followed by electron-capture ionization. These reactions yield products that can be used to distinguish isomeric PAH and help determine the position of substitution for methyl-PAH.

ELECTROSPRAY IONIZATION OF SOME POLYPEPTIDES AND SMALL PROTEINS

Chin Kai Meng, Matthias Mann and John B. Fenn
Department of Chemical Engineering
Yale University, New Haven, CT 06520-2159

Previously we have reported results obtained with Electrospray (ES) mass spectrometry of poly ethylene glycols (PEG) having nominal values of Molecular Weight (M) from 400 to 17,500. At M greater than about 4000 there were so many combinations of m and z within a small interval of m/z that our analyzer was unable to resolve the individual peaks because the spectra were so congested. Even so, the results indicated that the largest of the oligomers (M = 20,000) could accommodate as many as 23 charges (Na^+). (1) Such multiple charging is most attractive because it can substantially extend the effective mass range of any analyzer. Consequently, we have extended our studies and report here some of the results obtained by ES ionization of polypeptides and small proteins with M up to about 40,000.

The ES mass spectrometer was the same one used in the PEG studies and has been previously described (1,2). Samples of varying purity were obtained from various sources. Solvents usually comprised a mixture of methanol, acetonitrile and water but sometimes a propanol water mixture was used. Acidification with small quantities of acetic acid (HAc) or trifluoro acetic (TFA) acid was most helpful. Solutions at sample concentrations ranging from 0.05 to 2.0 mg/ml were introduced at a uniform flow rate of 8 ul/min.

The results are conveniently summarized in the accompanying figures showing illustrative examples of the spectra that were obtained. Each spectrum is the result of a single 30 second scan over the indicated range of m/z values and comprised a family of peaks in which adjacent members differ by one in the number of charges, each of which is an H^+ in these experiments. This number of charges per ion, shown for two peaks in each spectrum, reaches a value of at least 46 in the case of alcohol dehydrogenase from equine liver which has an M of about 40,000 and is the largest species we have yet run successfully. In this case, as for some other large species, the individual peaks seem to be too broad to be completely resolved. We do not yet fully understand why this broadening occurs in but we are fairly certain that it is not due to internal excitation as has been found to be the case when similar species have been ionized by bombardment with 35 kV cesium ions. Photo-Assisted Fragmentation Spectroscopy by Neutralization-Reionization Mass Specroscopy

Susan F. Selgren and Gregory I. Gellene
Department of Chemistry
University of Notre Dame
Notre Dame, IN 46556

A new technique where by the high resolution absorption spectrum of unusual metastable radicals in a high velocity beam can be obtained by monitoring photoinduced changes in their neutralization-reionization mass spectra has been developed. H_3^* radicals can be produced in an unusual metastable ($2p^2A''_2$, N=K=0, where N and K are the rotational quantum numbers of a symmetric top molecule) by an H_3^+/K electron transfer reaction. These radicals have lifetimes in excess of 10μs and can be collisionally reionized to give rise to the neutralization-reionization mass spectra in Fig. 1.

The integrated intensity of the parent ion signal in the secondary mass spectrum is a direct indication of the extent to which the neutral H_3^* molecules survived the transit time from the neutalization to the reionization chamber. In the present experiment, the stability of H_3^* in this region is affected by photo-assisted fragmentation (PAF) induced by the resonant absortion of a photon provided by tunable dye laser system using a modified version of the apparatus as shown in Fig. 2. The laser is chopped at a frequency of about 100Hz, allowing secondary ions to be counted alternately with the laser on (N_{on}) and (N_{off}). The ion counting data is used in the relationship: $A=1-N_{on}/N_{off}$ to provide a normalized measure of the effect of laser radiation on the mass resolved secondary ion signal.

Figure 3 shows a plot of A vs. photon energy for secondary H_3^+ ions. The peak at 16694.96 cm^{-1} is the previously known $R_0(0)$ transition of the $3s^2A'_1 \leftarrow 2p^2A''_2$ band. The result is readily understood in terms of a metastable H_3^* radical absorbing a photon, making a transition to the $3s^2A'_1$, N'=1, K'=0 state which then fluoresces back to the $2p^2A''_2$ electronic state branching between the (N",K")=(0,0) and (2,0) rotational levels in a 1:2 ratio. Although those molecules returning to the N"=K"=0 level are again metastable, those in the N"=2,K"=0 level predissociate with a lifetime of about $2x10^{-11}$s. Thus at least two thirds of the H_3^* radicals which undergo the optical absorption dissociate following fluorescence, but because the upper state is spectroscopically long-lived, the lifetime broadening of the transition, determined by the molecular transit time through the radiation field, is less than $2x10^{-4}$ cm^{-1}.

Although application of this technique would appear to be limited, all that is actually required is a lower state having a greatly decreased lifetime with increased internal energy and an upper state which is radiatively stable. These stability characteristics have been identified theoretically and experimentally for the second row hypervalent hydrides, NH_4, H_3O, H_2F, NeH, which will be the focus of future PAF spectroscopic investigations in this laboratory

Laser Ionization Spectroscopy of Amino Acids and Peptides Using Supersonic Jet Injection Into a Time-of-Flight Mass Spectrometer

David M. Lubman and Liang Li
Department of Chemistry
University of Michigan
Ann Arbor, MI 48109-1055

Resonant two-photon ionization (R2PI) spectroscopy has been shown to be a means of preselecting ions for mass spectrometry. Although ions are produced as the final product of R2PI, the ionization cross-section as a function of wavelength reflects the absorption-excitation spectrum of the $S_0 \rightarrow S_1$ transition of a molecule. Thus by tuning the laser frequency to a given rovibronic transition, one can in principle selectively excite a target molecule in a complicated mixture. The problem here is that the UV-VIS spectra of most large polyatomics consists of an unresolvable contour due to a broad thermal congestion of unresolvable rotational lines in the electronic transition. We therefore use the supersonic jet technique to provide ultracold molecules with sharp spectral features for selective chemical analysis.

The above combination of techniques has generally been limited to reasonably volatile molecules. In this work we use pulsed laser desorption as a means of volatilizing nonvolatile and thermally labile molecules for entrainment into a supersonic jet expansion. A relatively low-powered CO_2 laser (~ 10^6 W/cm^2) is used to desorb neutral molecules without decomposition. The resulting plume is synchronized with a pulsed supersonic flow of Ar or CO_2 and carried into a time-of-flight device where the molecules are detected using R2PI spectroscopy. This desorption technique provides a simple repetitive method for obtaining cold biological molecules in a supersonic jet for spectroscopic scanning purposes. Using this method we demonstrate the ability to obtain cold, sharp spectral features using R2PI spectroscopy in a TOFMS for tyrosine, tryptophan, catecholamines and their related analogs as well as several dipeptides as shown in Figure 1.

The key to this method is that R2PI spectroscopy serves as a sensitive probe, revealing small differences in molecular structure (Figure 2). This figure shows R2PI spectra of octopamine and synephrine obtained by monitoring only the molecular ion as a function of wavelength. These two compounds are very similar in structure, the difference being an extra $-CH_3$ group attached to the linear substituent chain. Nevertheless, each spectrum has distinctive sharp spectral features which are shifted by several tenths of a nm relative to one another, but which can clearly be resolved by the laser. In combination with the mass spectrometer, this technique provides a powerful tandem method of discriminating molecules. This capability is demonstrated in Figure 3 which illustrates the mass spectrum of a 1:1 mixture of tryptophol:tryptamine dissolved in a glycerol matrix and desorbed from the probe using pulsed laser desorption. The relative abundance of the mass peaks corresponding to the compounds are monitored as a function of wavelength at (Figure 3): (a) 286.30 nm, (b) 285.27 nm, and (c) 285.59 nm. Using this method, an optical discrimination of 1:100 of tryptamine in tryptophol has been demonstrated. A series of mixtures of tryptamine in tyramine were also examined at 286.30 nm and an optical discrimination of $1:10^5$ was achieved since cold tyramine does not absorb radiation at this wavelength.

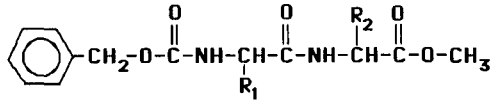
Sequence Specific Fragmentation of Derivitized Dipeptides Using Resonance Enhanced Multiphoton Ionization

Kimberly R. Segar and Murray V. Johnston; C.I.R.E.S. and Department of Chemistry and Biochemistry
University of Colorado, Boulder, Colorado, 80309-0215

We have studied the REMPI fragmentation at 266 nm of benzyloxycarbonyl (CBZ) derivatized dipeptide methyl esters of nonaromatic amino acids:



These compounds represent simple examples of chromophore derivatives of nonabsorbing compounds that permit detection by REMPI. If chromophore derivatization is to be of use in REMPI, it will be important to understand how the chromophore perturbs the fragmentation processes of the underivatized compound and whether or not the information content of the mass spectrum is enhanced or diminished.

<u>Types of Fragment Ions Observed in REMPI</u> Prominent ions in the REMPI mass spectra of all of the CBZ dipeptides are given in Table 1. Ions present at low laser intensities are the parent ion ($M^{+\cdot}$), ions corresponding to the loss of the amino acid side chains ($M-R_i^{+\cdot}$), ions corresponding to the N-terminal type A and A+H sequence ions, and $C_7H_7^+$ (m/z 91) corresponding to fragmentation of the CBZ moiety. The mass spectra taken with higher laser pulse energies exhibit increased abundance of m/z 91 and additional fragment ions identified as $A-C_7H_6^+$, $A-CO_2^+$ and $A-C_7H_6-CO_2^+$. Many of the dipeptides also give a weak Y sequence ions as well.

<u>REMPI Fragmentation Mechanisms</u> To understand the mechanism of ion formation in REMPI, one would like to determine the number of photons required to produce a given ion and whether or not all ions arise from ionization/dissociation of the same neutral precurser. An indication of the number of photons required to produce a given ion can be obtained from the dependence of the ion current on laser pulse energy. The number of photons involved in fragment ion formation can be obtained by plotting the ratio of the fragment ion to parent ion current vs. laser pulse energy. From such power dependent studies we have found that the parent ion is created by resonant two photon ionization (R2PI). Power dependent studies have also allowed us to classify the fragment ions observed as being produced by either a 2+0 or 2+1 photon process. A 2+0 fragmentation mechanism is defined as R2PI of the neutral molecule to form the parent ion with sufficient internal energy to cause spontaneous decomposition to the 2+0, low appearance energy , fragments ions. $A^+/A+H^+$ and $M-R_i^{+\cdot}$ are examples of 2+0 fragments. High energy fragments such as m/z 91, $A-CO_2^+$, $A-C_7H_6^+$ and $A-C_7H_6-CO_2^+$, were found to be formed by a 2+1 photon mechanism, one photon dissociation of the parent ion which was previously created by resonant two photon ionization. A summary of the mechanisms of ion formation for all compounds studied is given in Table 1. Relative abundancies of the ions are also given in Table 1. At low laser intensities both the molecular ion and the A type sequence ion are produced in large amounts. The molecular ion is usually the base peak (never lower than 20 % relative abundance) while the intensity of the sequence ion ranges from 8% to 86% of the base peak (usually averaging <50% relative abundance). This contrasts with 70 eV electron impact (EI) data of these compounds. Although the same types of fragment ions are observed in both the REMPI and EI mass spectra the relative intensities vary greatly. For 70 eV EI the parent and the sequence ions are

seldom greater than 3% and 20% respectively of the base peak. The base peak in the EI mass spectra for all the CBZ dipeptides is m/z 91which is due to fragmentation of the chromophore and provides no sequence information.

Isomer Differentiation From our work we have determined that the isomers CBZ-ile-ala-OCH_3 and CBZ-leu-ala-OCH_3 can be distinguished by their REMPI mass spectra shown in Figure 1. It is evident from the REMPI mass spectra that the peak ratios for m/z 220 to 294 ($A^+/M\text{-}R_1^{+\cdot}$) are different and could be used to differentiate between the two isomers. The 70 eV EI spectra for these isomers are identical.

Table 1

Assignment	Ala-Gly	Ala-Val	Val-Gly	Val-Ala	Val-Leu	Ile-Ala	Leu-Ala	Leu-Leu
			(2 + 0) FRAGMENTATION MECHANISM					
$M^{+\cdot}$	100(294)	100(336)	100(322)	100(336)	69(378)	25(350)	20(350)	25(392)

LITHIUM METAL PROBE TIP: PRODUCTION OF LITHIUM CATIONS AND LITHIATION OF NEUTRAL MOLECULES DURING FABMS

Julie A. Leary and Emirgul Tolun

Chemistry Dept., University of California, Berkeley

We have developed a lithium probe tip from which a continuous lithium bean can be generated by bombarding the metal surface with 8 keV Xenon atoms. This beam provides a mechanism whereby lithium can efficiently cationize neutral organic molecules thereby generating positively charged ions. Our results with a series of symmetrical and unsymmetrical vicinal diols (Table 1) show that lithiated molecular ions (MLi+) are obtained when crystals of the sample are impregnated into the lithium metal tip. The spectra are then recorded without the use of a liquid matrix. These vicinal diols do not give molecular ions using conventional EI or FAB techniques but instead the molecular ion minus water is seen.

Construction of the lithium tip and all sample preparation and deposition onto the tip was done under inert atmosphere in a dry box using argon. A uniform layer of lithium metal shavings are deposited onto the stainless steel tip in much the same way as putty is applied to surfaces. A few crystals of the sample are then placed into indentations made in the lithium metal. Although spectra generated from the litium tip have a tendency to show only MLi+ and no fragment information (Fig. 1), we have been able to show that subsequent BEQQ scans provide structural detail (Fig.2). These data clearly show that a matrix is not required when desorption and ionization take place from a lithium surface, and may be beneficial in cases where samples either react with or do not dissolve in the available solvents used as FAB matrices.

NONLINEAR SECONDARY ION YIELD ENHANCEMENT WITH FAST INCIDENT MOLECULAR IONS*:

Mehran Salehpour, Derry Fishel and Jerry Hunt, Chemistry Division, Argonne National Laboratory, 9700 South Cass Avenue, Argonne, Illinois 60439, U. S. A.

Incident ions with velocities greater than the Bohr velocity ($v_o \approx 0.2$cm/ns), referred to here as fast ions, interact mainly with the electrons of the medium in which they are traversing. This distinguishes the mechanism from the low energy processes such as those observed in conventional SIMS (Secondary Ion Mass Spectrometry) and FAB (Fast Atom Bombardment). From an application point-of-view, the use of fast ions has been very successful in the high molecular weight mass spectrometry. Plasma Desorption Mass Spectrometry has been responsible for detection of intact protein molecular ions such as pepsin (MW≈34000) [1]. The use of high energy accelerators (≈ 1MeV/nucleon) has facilitated more insight into the physics of the desorption process. All experiments, until recently, had concerned incident atomic ions. Thomas et al. has reported measurements with H_n^+ clusters in a velocity region around v_o [2].

The yield is defined as the number of detected secondary ions per incident ion. The experimental details are explained elsewhere [3]. A 4.5 MV dynamitron accelerator at the physics division, Argonne National Laboratory has been used to accelerate the incident ions. Measurements on the secondary ions are performed using a time-of-flight technique. The yield of valine molecular ions, $(M-H)^-$, has been measured as a function of the velocity of a number of different incident atomic and molecular ions.

Figure 1 shows the yield of valine molecular ions as a function of the velocity of C^+, O^+, CO^+, O_2^+ and CO_2^+ incident ions. Let Y(X) be the yield of the valine secondary molecular ions for an incident ion X. The inherent nonlinearity of the desorption process can be seen in comparing $Y(C^+)$ and $Y(O^+)$ to the molecular ions, $Y(CO^+)$ and $Y(O_2^+)$, i.e., $Y(O_2^+) >> 2 \cdot Y(O^+)$ and $Y(CO^+) >> Y(C^+) + Y(O^+)$. Desorption by atomic ions in this velocity region varies with the square of the electronic stopping power [3]. However, the yield enhancements with incident molecular ions can not be solely explained on the basis of a quadratic dependence of the yield on the electronic stopping power. Thus, collective effects exist for incident molecular ions which are due to the vicinage of the moving charges in the medium. Spatially and temporally correlated fast moving charges in solids have been experimentally shown to display collective effects in the form of enhancement in the electronic stopping power per atom [4]. Another interesting feature is the high yield due to incident CO_2^+ ions.

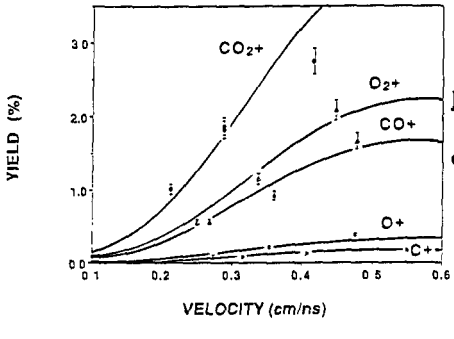

Figure 1. The yield of valine molecular ions, $(M-H)^-$, as a function of the velocity of C^+, O^+, CO^+, O_2^+ and CO_2^+ incident ions.

Figure 2 shows the yield of valine (amino acid, MW=117) molecular ions as a function of the velocity of incident C^+, CF^+, CF_3^+, $C_3F_5^+$ and $C_4F_7^+$ ions. As with the ions discussed above, collective molecular effects exist for all the incident ions. From an applied point-of-view, it is interesting to note that strong yield enhancements are measured with the heavy incident molecular ions such as $C_3F_5^+$ and $C_4F_7^+$. The absolute value of $Y(C_4F_7^+)$ is about 5% which is comparable to yield obtained with fission fragments from a ^{252}Cf. In fact this particular sample was removed from vacuum repeatedly due to unavoidable experimental problems prior to the start of the measurements. Thus, the yield from a fresh sample could be an order of magnitude higher.

For heavy molecular ions such as $C_3F_5^+$ and $C_4F_7^+$, comparison to incident C^+ at the same velocity is not possible, however, we can compare to the C^+ data point at the lowest velocity. Results shows that $Y(C_4F_7^+) > 60 \cdot Y(C^+)$. Such dramatic enhancements in the secondary ion yield are very important for mass spectrometry of large organic molecules. Håkansson et al. [5] have shown that the inherent nonlinearity in desorption with atomic ions, becomes more pronounced for larger secondary ions. This makes it very important to utilize projectiles with high electronic stopping powers. The use of incident molecular ions, as shown here, could prove to be very important in mass spectrometry.

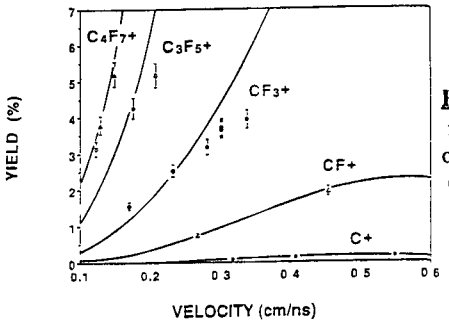

Figure 2. The yield of valine molecular ions, $(M-H)^-$, as a function of the velocity of incident C^+, CF^+, CF_3^+, $C_3F_5^+$ and $C_4F_7^+$ ions.

A ROBOTIC BASED SAMPLE PREPARATION AND INTRODUCTION SYSTEM FOR AUTOMATED EI AND CI PROBE ANALYSIS

D.C. Smith, V. Gould, M.J. Hammond and D.E. Todd*.

VG MassLab Ltd., Tudor Road, Altrincham, WA14 5RZ, UK. Phone 061 941 3552. Tlx 669964. *Zymark Ltd., The Genesis Centre, Science Park South, Birchwood, Warrington, WA3 78H. Phone 0925 826600. Tlx 629343.

A high throughput of routine samples is a common feature of many laboratories such as those in the pharmaceutical industry. Sample preparation and injection onto a probe and introduction of the probe into a mass spectrometer is generally a repetitive process involving very little operator skill. As such the process is ideally suited to some form of automation.

We have developed an integrated robot-MS-DS instrument capable of performing complete analyses on a series of such samples.

A laboratory robot is used to prepare the sample prior to injection. The robot is fed with screw topped sample bottles placed in a rack. Samples may be dry or already in solution. The robot will automatically perform a number of functions such as screw cap removal, addition of solvent, ultrasonic agitation and injection. Sample workup can easily be extended to include extraction, purification and derivatisation steps. Internal standards may also be added. Programming of the robot is through a high level language so the operator can readily change the preparation stages.

If sample workup is not required, the laboratory robot can be replaced by a conventional GC autosampler. Each sample bottle in turn is transferred to the injection station from the 100 position rack. After injection normal syringe washing routines are performed and the sample bottle is returned to the rack.

The sample insertion probe is automatically admitted to and withdrawn from the ion source using a pneumatically driven multi-position linear actuator. Sample is injected onto a coil of platinum wire mounted at the tip of the probe. The coil can be heated to aid sample desorption and, after completion of the analysis, to eliminate memory effects.

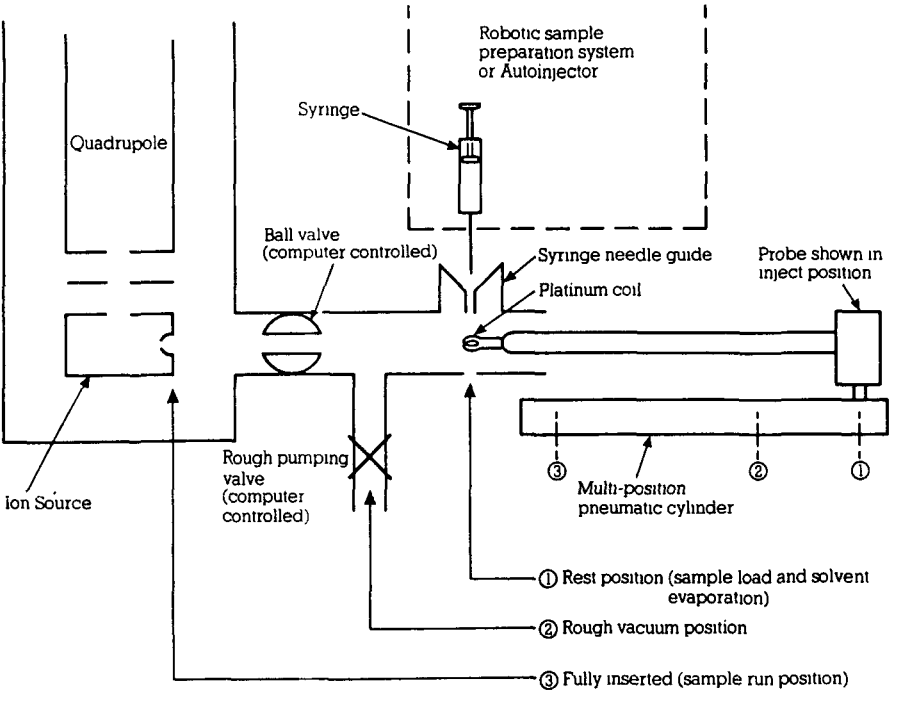
The introduction lock is of conventional design. The ball valve is pneumatically operated and the rough pumping is controlled by a solenoid valve. The complete system has been designed to be fitted permanently to the mass spectrometer without interfering with other inlets.

All operations are controlled automatically by the mass spectrometer datasystem, although an override facility has been incorporated for manual control. Valve and probe operations are governed by the vacuum system interlock.

If desired, sample heating may be regulated by feedback of the total ion current signal to give a controlled evaporation profile.

Operation is fully compatible with normal datasystem functions such as spectral acquisition, library searching and output.

Spectra may be acquired in either the EI or CI mode. When fitted to an instrument equipped with the ACE facility, alternate EI and CI spectra may be acquired.



The sequence of operation following syringe loading is as follows:

1. 1 microlitre of dissolved sample is injected onto the probe tip. Sufficient time is allowed for solvent evaporation.
2. The probe moves to the first stage of the vacuum lock and the roughing valve opens.
3. When the roughing pressure is sufficiently low the ball valve opens. The probe moves into the ion source.
4. The sample is desorbed, and data is acquired in the normal manner.
5. The heating current is increased to 1.5 Amps to clean the coil.
6. The probe is withdrawn to the intermediate position and then, after the valves have closed, to the inject position ready for the next sample.

The cycle time for the above sequence is typically three minutes.

The robot MS-DS system described above allows repetitive, routine sampling to be carried out automatically, leaving the operator free to concentrate upon evaluating the results. In addition to relieving the tedium of manual probe operation, laboratory productivity can be significantly improved.

A NEW DEVICE FOR PYROLYSIS MASS SPECTROMETRY OF BIOLOGICAL MATERIALS

William M. Lagna
U.S. Army Chemical Research, Development and Engineering Center (SMCCR-DDT)
Aberdeen Proving Ground, Maryland 21010-5423.

Pyrolysis mass spectrometry has been utilized as an analytical technique for the profiling of biological materials which are well beyond the mass range associated with traditional mass spectrometry. The biomaterials, which include fungus, pollen, bacteria and viruses, are pyrolyzed for the release of characteristic compounds or groups of compounds. These chemical signatures can be used as the basis for identification of the compounds.

Recently, a pyrolysis device based on infrared heating has been integrated with a mass spectrometer and successfully implemented as an experimental biological sample processing system. As an extension of this technology, a low cost version of this pyrolyser was constructed using commercially available components (Figure 1). The new device was designed with provisions for batch sample introduction, interface to an aerosol sampling device or for direct sampling of airborne biomaterials within the pyrolyser volume. A programmable temperature controller is used for either isothermal or temperature-ramped heating and is programmed through the serial communications adapter of the data system of the mass analyzer. A section of quartz tubing is used for the construction of the pyrolysis cell. Quartz wool is placed within the cell and acts as the pyrolysis surface for batch samples, or as a filter when the device is interfaced with an aerosol sampler. The cell is wound with either platinum or nichrome wire and mounted within a larger quartz tube. A four-way tee is used to connect the unit to the capillary inlet of the gas chromatograph or mass spectrometer. The heater and thermocouple leads are passed through the connector with a feedthrough designed for such purposes, and a small vacuum pump is connected to the tee. The unit can be placed within the oven of a gas chromatograph, or insulated for stand-alone applications. A three way-tee on the opposite end can be used as an inlet for helium, as an interface to the capillary output line of an aerosol sampler or deleted for oxidative pyrolysis.

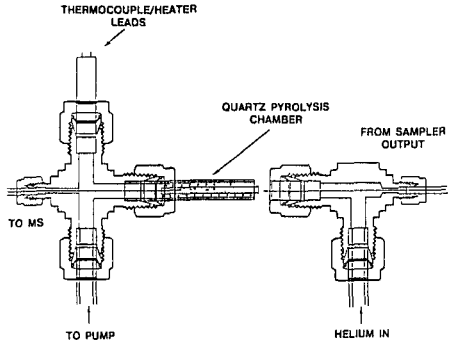

FIGURE 1
CUTAWAY VIEW OF THE NEW PYROLYSIS DEVICE

Initial runs were performed on batch introduced samples in a temperature programmed pyrolysis mode. The output was initially profiled on a flame ionization detector. Full gas chromatographed mass

spectrometry (GC/MS) was performed to determine if the nature of the pyrolysates were unique to each group. Mass spectra were acquired on a Finnegan Ion Trap detector using electron impact ionization.

Results in the batch introduction mode from samples of bee pollen, brewer's yeast, Acidophilus milk culture bacteria and urban particulate dust indicate that the temperature programmed pyrolytic signatures are reproducible and visually differentiable (Figure 2). Examination of the GC/MS data revealed that the pyrolytic components correlate well with the published data obtained using other pyrolytic methods on related materials (Figure 3). In addition, the lower temperature (up to 240 ^{o}C) pyrolysis data included a large number of higher molecular weight compounds.

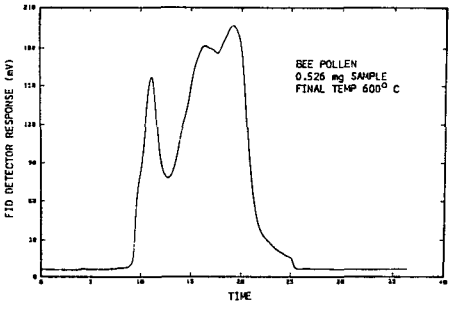

FIGURE 2
PYROGRAM OF BEE POLLEN

When interfaced with a virtual impaction aerosol sampler, isothermal operation of the pyrolyser resulted in signatures which appeared to vary with ambient conditions. The complex data sets require statistical analysis for interpretation. With the device connected to a small vacuum pump, very slow sample acquisition precludes simultaneous isothermal operation of the pyrolyser. In this mode, sample is collected for an extended period into the pyrolyser cell which is then heated in a temperature programmed mode. The resulting spectra are similar to those observed using the batch introduction method. However, substantial interferences from larger background particulates are observed and tend to mask the presence of the lower level biological materials. A coarse prefilter appears necessary to establish an upper-limit size cutoff and MS/MS could be utilized to increase the specificity of the method.

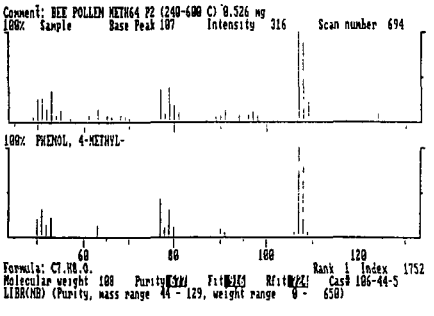

FIGURE 3
UPPER FIGURE IS A SAMPLE SPECTRA OF ONE OF THE PRINCIPAL PYROLYTIC COMPONENTS OF BEE POLLEN. LOWER FIGURE IS COMPUTER SEARCH LIBRARY MATCHED SPECTRA.

In conclusion, this device appears useful for general pyrolysis mass spectrometry applications on biological materials. The direct aerosol sampling method, although non-specific in nature, requires a minimal amount of sample preparation and could be used as a fast method of classifying airborne biological materials.

DEVELOPMENT OF A SELECTIVE SECONDARY ION ENHANCER FOR SIMS

M. Inoue, Y. Sugiyama, S. Nishigaki and T. Noda

Toyohashi University of Technology, Toyohashi 440, JAPAN

In SIMS (Secondary Ion Mass Spectrometry) measurements, it is well known that the detection sensitivity for positive or negative element is enhanced by flooding oxygen or cesium on the specimen surface. Therefore, oxygen or cesium ions have often been used as the primary ion. This method has a merit that the surface concentration of dosed elements is dependent only on the sputtering yield and not affected by the fluctuation of the beam current density. Contrary speaking, however, this method has a demerit that the concentration of dosed elements is hardly variable and the optimum condition is not usually established. Furthermore, in-situ detection of positive and negative elements is difficult because different ion guns are required. In the present study, we developed a compact secondary ion enhancement hardware that allows us to conveniently dose proper amount of oxygen gas and/or cesium vapor selectively onto the specimen surface, while retaining the same ion gun in operation. In this method, the surface concentration of dosed elements is easily controlled by varying the dose rate.

Since the secondary ion yield is very sensitive to the amount of dosed elements on the surface, it is important to monitor the elemental composition at the sputtering front under the ion bombardment for the reproducible SIMS measurement. ISS (Ion Scattering Spectroscopy) is, as well known as a very sensitive technique for outermost atomic layers, particularly adequate for this purpose. We recently developed a new technique for the sequential SIMS-ISS measurement[1)] by means of a double focusing mass analyzer of a commercial SIMS instrument operated with B^2/E linked scan method and AC modulation for the magnetic field B.

Figure 1 shows the construction of the newly developed O_2/Cs flooder. Oxygen gas is introduced into an experimental chamber through a variable leak valve and a stop valve, and then flooded onto the specimen surface through a capillary. The dose rate of oxygen was controlled with valve manipulation so

as to maintain the oxygen pressure unchanged. Actual oxygen pressure at the specimen surface was nearly three times of that indicated on a pressure gauge for the experimental chamber.

Cesium vapor is obtained by heating a powder mixture of Cs_2CrO_4 and Si in a crucible made of boron nitride. The dose rate of cesium was stabilized by feedback control of the crucible temperature. Figure 2 shows variations of the temperature and the ISS signal intensity from cesium on the specimen surface with time. It is obvious that the preset temperature is attainable within 20 seconds, and that the cesium concentration at the surface reaches stationary within a minute. It is thus concluded that enhanced measurement in SIMS can reproducibly be established by means of this O_2/Cs flooder unit in combination with the ISS technique.

AN AUTOMATED REDUCED-PRESSURE INTERFACE DEVICE FOR THE HEWLETT-PACKARD MASS SELECTIVE DETECTOR. Patrick W. Langvardt, Michael J. Bartels, The Dow Chemical Company, Midland, Michigan, 48674.

An automated reduced-pressure interface device (RPID) has been developed for the Hewlett-Packard 5970 Mass Selective Detector (MSD). Because the MSD has no interface oven, considerable modifications of the original RPID design(1) were necessary. The result was a device that has all of the characteristics of the original RPID: chromatographically efficient, inert, complete analyte transfer, suppression of unwanted sample components, rapid column changing, pressure control at end of analytical column, low maintenance, and inexpensive.

The MSD design required that the interface be positioned in the oven of the gas chromatograph (see diagram). A custom-built (Scientific Glass Engineering, Austin, TX) glass-lined tee connects directly to the transfer line of the MSD. The MS restrictor tube (150 μ x 35 cm) determines the ratio of column effluent that can be diverted. The GC restrictor (120 μ x 40 cm) provides a 15 psi pressure drop such that the end of the analytical column is near atmospheric while the tee operates at reduced pressure at all times. It is important that the 1/16 inch tubing leading from the tee to the divert valve is coiled to provide a tightening of the seal to the MSD.

In operation, analytical columns can be changed in minutes by diverting gases away from the ion source. Ion gauge pressures of 10^{-6} torr are typical during that procedure. Analytical columns (0.18 to 0.53 mm id) are threaded over the protruding GC restrictor and butted inside the column connector.

The divert solenoid valve is powered by the GC injector A purge control circuitry and can be controlled manually from the GC front panel or by entries in the MSD computer Run Table via an optional A111 control board. Thus, the ion source is protected from unwanted sample components and column bleed, considerably reducing source maintenance.

The described MSD RPID has been installed on four instruments in our organization for several months. The devices have been applied primarily to automated trace analyses of complex matrices and have operated with little maintenance efforts. The RPID is a universal device for coupling capillary gas chromatography with mass spectrometry.

DYNAMIC FAB WITH A DIP GUN

Julius Perel and John F. Mahoney
Phrasor Scientific, Inc.
Duarte, CA 91010

INTRODUCTION

Continuous flow systems allow for the delivery of aqueous solutions with buffers and samples to a FAB sample target in a mass spectrometer at controlled rates [1]. To retain a thin liquid coating, flow and evaporation balance are achieved by control of the flow rate and the target temperature. The continuous flow system may be used as an LC interface or a batch load inlet for separate samples. It can also be used to monitor selected ions reflecting the progress of a biochemical reaction, and has been shown to greatly reduce chemical noise often observed with regular FAB.

A new device combining these advantages with those of a DIP Gun [2] used for FAB has been developed. The DIP Gun, which combines the ion gun and the sample target onto a single probe, offers several advantages over other designs. It requires only a single vacuum inlet part, rather than two. The gun-to-target distance is small (increasing flux), and alignment is fixed (facilitating alignment). The probe can be used with an EI source, allowing instantaneous calibration and molecular ion fragmentation. Furthermore, enhanced signal-to-noise has been found with the DIP Gun used on quadrupoles, evidently due to a reduction in fast particle scatter noise [3].

The DynaFAB Probe, a DIP Gun modified to accommodate continuous flow FAB, has all of the above advantages and is also capable of performing both dynamic and static FAB. A single probe replaces the FAB gun, the dynamic probe and the static FAB probe.

DynaFAB CONFIGURATION

A DIP Gun was modified to include a fused silica capillary (0.075 mm I.D. x 700 mm long) to deliver solution to the target. The capillary is brought into the probe shaft through an LC fitting using a special adapter, which is the major modification of a regular DIP Gun (see Fig. 1). The capillary traverses the shaft between the Teflon insulation and the inside of the shaft wall and passes through the extractor button about 3 mm from the Capillaritron nozzle. It threads through the inside of the sample tip and terminates at the target.

TEST RESULTS

The prototype DynaFAB Probe described above was tested on an HP5982 mass spectrometer using a solution containing 80% H_2O, 20% glycerol and 0.1 M ammonium acetate. A flow rate of 4.7 μℓ/min. was attained using atmospheric pressure to feed the solution in reasonable agreement with calculation for Pousille flow.

When the target was rotated to face 90° or 180° from the analyzer axis, fewer fast beam particles were scattered toward the detector, but the slow desorbed sample ions were still effectively collected for analysis by means of repeller and draw out fields in the source. While the sample signal was attenuated slightly, the scatter noise was greatly reduced by this rotation and the signal-to-noise ratio was greatly enhanced consistant with results for the unmodified DIP Gun [3].

Spectra were measured to demonstrate use of the probe in the various FAB modes. In the static mode the results showed no discernable difference from those obtained using a regular DIP Gun. A dynamic FAB spectrum of Stateze, a surfactant with a molecular weight of 256 amu, is shown in Fig. 2. The ionization source was maintained at 80°C and only minimal effort was made to optimize the temperature/flow relationship. Fig. 3 shows the spectrum of the same sample in the filament on (EI mode), thus showing glycerol peaks which could be useful for calibration.

Future tests are planned to optimize the operating variables and to allow for the direct and simple threading of the capillary tubing into the DynaFAB Probe.

Design and Characterization of a Continuous Flow FAB Probe and an Ion Source Modified for Dynamic Sample Introduction

Mark R. Bauer and Mark F. Yancey

Battelle Columbus Division, Columbus, Ohio 43201

A simple, inexpensive continuous flow FAB probe was designed and tested which obviates several of the physical short comings of standard probe techniques. The new probe, which fits into a conventional VG FAB source, uses a 50 μm i.d. fused silica capillary column to deliver a constant flow of analyte and matrix to the probe tip for continuous analysis.

The probe, shown in Figure 1, is constructed from a 22 inch length of 1/2 inch stainless steel tubing. One end is threaded to accept a bullet-shaped polished copper tip, separated from the probe body with a hollow teflon insulator. A piece of 50 μm i.d. fused silica tubing runs inside the probe and extends about 0.1 mm through a 0.060 inch hole in the copper tip. The capillary is held in place by a septum sandwiched between the insulator and the inside of the copper tip. A 1/16 inch swagelock fitting is soldered to the other end of the probe to provide the vacuum seal.

The probe design mandated several modifications to the existing FAB source block so heat could be applied to the probe. These modifications are shown in Figure 2. Two holes were drilled through the block to accommodate EI-style cartridge heaters. To prevent the heater connections from protruding into other interfaces present in the source chamber, two 5x7 mm slots were milled into the bottom of the source block, thus allowing the heater connections to be made underneath the block.

There are no provisions in the conventional FAB source for heater or thermocouple connections. These connections, which are available for the EI source, were added by installing the appropriate leads to the FAB mounting plate and utilizing the EI control electronics. Figure 3 shows the positions of the connections added to the mounting plate. Because the FAB source block is held at the repeller potential, the thermocouple must be isolated from the block with ceramic insulators. The thermocouple is floated at the accelerating voltage by adding a short to the source potential feedthrough. These modifications to the source do not interfere with using the source in the conventional manner.

A variety of FAB applications may be accomplished with this new probe. The capillary which carries analyte to the probe tip can simply be dipped into the sample. Analyte can be continually introduced into the source using this "dip-and-suck" method. Dip-and-suck is typically accomplished by dissolving the analyte in a 5% glycerol in water solution, dipping the capillary into the sample and allowing the vacuum to aspirate the sample into the source. The flow rate is controlled by adjusting the length or diameter of capillary tubing used. A flow rate of 1 μL/min is typically achieved with a 1 meter, 50 μm i.d. capillary.

This mode of operation is especially useful for long experiments and MS/MS work which require the analyte signal to be present for extended periods. Dip-and-suck is also useful when analyzing many consecutive samples; it eliminates the constant insertion and removal of the probe. Kinetic and other dynamic experiments can easily be monitored, as there is always a fresh supply of the reaction mixture to the ionization surface. An HPLC loop injector can also be added to improve the reproducibility of small volume injections.

Chromatographic separations can be accomplished inside the probe by replacing the 50 μm tubing with a 250 μm i.d. packed capillary column filled with 3-5 μm packing material. By placing the column inside the probe, only a 2 cm length of 50 μm tubing is needed as an interface to the probe tip.

The short interface results in a minimum amount of peak broadening. Due to backpressure of the column, a pump is required to deliver a flow of about 1 μL/min. Figure 4 shows a selected ion chromatogram of the protonated molecular ion from pyridostigmine generated using the packed capillary interface. The mobile phase used was 100% acetonitrile; no glycerol was added.

THERMOELECTRICALLY COOLED SAMPLE PROBE FOR FABMS (LSIMS)

S.A. Martin*, J.A. Hill, K. Biemann
Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge,MA 02139
*on leave of absence Dept. Pharmacology, Med. Univ. of South Carolina

Since the introduction of FAB the effect of temperature on the secondary ion yield of samples has been noted (1) and recently the design and construction of a chilled probe employing freon was described (2). We report here the design, construction and operation of a thermoelectric (Peltier) cooler in which surface temperature, above or below ambient, is precisely regulated by applied current.

In a thermoelectric (Peltier) cooler, current is applied to semiconductor junctions between two layers of beryllium oxide which results in the cooling of one surface and the heating of the other. These devices are commercially available and can be obtained in sizes small enough to be incorporated in the tip of a sample probe that fits through the normal vacuum lock of a FAB probe.

The ability to cool the matrix has several advantages. First, it allows the use of a wider variety of matrices because their vapor pressure can be reduced to the point that the evaporation rate is sufficiently slow to obtain a long lasting secondary ion current. Second, the Peltier cooler has a reproducible current *vs.* temperature curve which allows reproducible fast attainment of surface temperatures. Third, by reversing the potential, the probe tip can be heated and thus permits the use of low melting matrices. Such a system is more convenient to use and more reliable than chilled probes operating with cold gases or low boiling liquids (Freon).

We have built and tested such a thermoelectrically cooled sample probe (Fig. 1) and use it routinely on our JEOL HX110/HX110 tandem mass spectrometer (EBEB). The thermoelectric heat pump modules are purchased from MELCOR Corp, Trenton, NJ 08648, part no. FC0.45-4-05L. The thermoelectric sample probe is calibrated for cooling (Fig. 2) and heating (Fig. 3) by recording the sample surface temperature under vacuum as a function of applied current. As a test case, the ion current of of the $(M+H)^+$ isotope cluster of aprotinin (MW 6507.0) in thioglycerol kept at -4 °C showed a twentyfold increase in ion current as compared to operation at ambient temperature. It also lasted for more than 6 min as compared to less than 2 min. The S/N of the data is also improved by the lower temperature. Measurements have also been made of the secondary ion yield of various matrices at various temperatures. A comparative study of the relationship of the secondary ion yield of various peptides and small proteins *vs.* probe tip temperature has been carried out.

The thermoelectric temperature regulated sample probe was inexpensive to build and has been in routine use in our laboratory for more than 8 months with only a single structural failure. During this period its applications have ranged from two sector high mass to negative ion MS/MS studies providing longer lasting secondary ion signals and a wider range of matrix options.

STUDIES WITH FAST ATOM BOMBARDMENT PROBE TARGETS

Marshall M. Siegel*, Rushung Tsao, William Boulay

American Cyanamid Company, Medical Research Division,
Lederle Laboratories, Pearl River, NY 10965

1) ENCLOSURES FOR PLANAR AND ARTICULATED FAB PROBE TARGETS

Sputtering and splattering of both the FAB matrix and sample from a planar FAB probe target often occurs at an excessive rate resulting in short sample lifetime, source contamination and losses in sensitivity and resolution. When using an articulated FAB probe target for exact mass measurements, the uncontrolled sputtering and splattering occasionally quench the signal of the unknown or reference compound.

To alleviate the above problems, a variety of enclosures were designed for the planar and articulated FAB probe targets. FAB target styles I and II were found to enhance sample lifetime and reduce source contamination. Style I is effectively a three walled enclosure about the planar FAB target where the top is opened and the fourth side is absent enabling the fast atom beam to strike the sample. Style II is similar to style I except that the top is covered and a slit is provided for the exit of the ion beam. Dimensions for these probe targets when used on a VG ZAB-SE FAB source are: length - 0.25", width - 0.08" (0.18"), height - 0.13" (0.25") and slit width - 0.015".

The effect of sample lifetime was studied for a variety of FAB targets of similar dimensions on which was applied 5.0 ul of sulfolane, a more volatile FAB matrix. The sample lifetime was about two times longer with target style IA vs. the planar target. The sample lifetime was about four times longer for target style IIA vs. the planar target, the initial total ion current was reduced by a factor of about four times and the net resolution increased from 1000 to 1500. (The beam from the FAB gun must be alligned with the opening on the side of the style II target for optimum ionization of the sample. The ions can then exit through the slit on the cover of the FAB target.)

The use of especially style IA FAB target in our laboratory has enabled us to use volatile matrices, run large numbers of routine samples with reduced source contamination and arcing, and enhance the lifetime of samples for nominal and exact mass measurements. With the targets, polyethylene glycols and their derivatives (neutral surfactants adulterated with potassium ions) which seriously contaminate the FAB source, can be used with minimal source contamination as internal standards for exact mass measurements. The behaviour of the FAB target enclosure mimics some of the characteristics of commercially available exchangeable ion volumes for FAB sources.

2) PROBE TARGET DESIGNED FOR DYNAMIC FAB

Target style III was designed for dynamic FAB based upon the three sided enclosure of the style I target. The sample is confined to flow in a recessed narrow region of the target (depth - 0.05", length - 0.10", width - 0.05") in order to achieve optimum sensitivity and minimization of sputtering and splattering of the liquid sample so as to control the sample lifetime. The collar around the target serves to shield the bottom surface of the inner dynamic FAB target from the fast atom beam, thereby, minimizing memory effects. It also serves to trap any liquid which may acculmulate, after flowing over the dynamic FAB target, and to channel it away from the fast atom beam to the drain hole.

3) HEATED FAB PROBE TARGETS

Heated FAB targets were fabricated utilizing nichrome wire (0.010" and 0.004" diameter) as the heating element. The VG DCI power supply was used to generate the heating current. Style IV heated FAB target consists of a heater coil which coaxially surrounded the planar FAB target upon which the sample is placed. Style V heated FAB target consists of nichrome wire folded to form a plane upon which the sample resided so as to be heated directly by the nichrome wire. Style VI heated FAB target is a nichrome coil mounted inside a FAB target enclosure. The matrices evaluated were mannose, polyphenyl ether and fomblin oil. The properties of the latter two materials, viz., high

boiling points, very low vapor pressures and high thermal stabilities, enable samples to be analyzed in these liquids at relatively high temperatures.

Figure 1A illustrates the FAB mass spectrum of tri-tyrosine methyl ester acquired at room temperature with "magic bullet" matrix and Figure 1B illustrates the spectrum at elevated temperature with style IV target and mannose as the matrix. In the high temperature spectrum, note the absence of matrix ions and the additional fragmentation relative to the room temperature spectrum. For the model compounds studied to date, no significant spectral differences were observed at elevated temperatures as a function of tip style or high temperature FAB matrix. These observations are similar to those reported by Ackermann et al [1,2]

[4] INSERT FOR THE VG EI/CI DIRECT PROBE

A stainless steel insert was fabricated and placed within the boron nitride sample holder assembly of the VG EI/CI direct probe. This insert provides for rapid heat transfer to the sample cup from the heatable/water cooled end of the direct probe.]

MINIATURIZED SOLID-STATE EI/FI ION SOURCE

Steve Young and Michael J. Coggiola
SRI International, Menlo Park CA, 94025

A miniaturized ion source has been developed and tested that is capable of performing either electron impact or field ionization depending on the polarity of the voltage applied across the device. The basis for this source is a solid-state, micromachined structure that is fabricated using techniques similar to those employed for integrated circuit fabrication. The device consists of an array of 10,000 2 μm diameter wells etched in silicon dioxide on a silicon substrate. Each well contains a molybdenum cone whose tip is coplanar with a molybdenum gate film deposited on the top of the silicon dioxide. Th application of a modest voltage (50-150 volts) between the tips and the gate film produces very high (10^8 v/cm) local electric fields. As originally developed, these devices were designed as cold electron sources producing electrons via field emission. However, by reversing the polarity of this voltage, the high field can also produce positive ions via field ionization.

A compact ion source was designed and built by placing the 1x1 mm emitter array in an enclosed volume of 1 cc, opposite to an ion extraction aperture. Sample gas was admitted directly into the source volume. A number of source designs were investigated using ion trajectory simulations (SIMION) and the optimum configuration was selected for fabrication. For test purposes, the source was mounted on an Extrel quadrupole, and electrically floated so that the ion energy could be established between 10 and 100 volts. The emitter tips were driven in a pulsed mode with 60 Hz half wave rectified ac of variable amplitude.

When operated in the EI mode, typical electron currents were 10-20 μA. Organic vapor samples exhibited mass spectra very similar to standard electron impact spectra. Some small differences were noted, however, these are likely due to differences in the electron energy and the source temperature. With the polarity across the emitter array reversed, characteristic positive FI mass spectra were observed consisting primarily of organic sample parent ions. Because of the very small dimensions of the active field emission sites, the voltages required to produce field ionization are very low. A typical plot of ion current as a function of the applied voltage is shown in Figure 1. It is noteworthy that a potential as low as 70 volts was able to generate an electric field strength sufficient to produce field ionization.

Sensitivity for this source was higher in the EI mode than the FI mode. Typical total ion signal levels for a 1 x 10^{-6} Torr sample pressure of n- propyl benzene were 400 kHz in the EI mode and 10 kHz in the FI mode. As a result of prolonged operation in the FI mode, it was observed that higher voltages were required to obtain the same ion currents. This behavior is most probably associated with the deposition of conductive organic polymers on the device. These materials lead to a leakage path between the emitter tips and the gate film, thus requiring higher potentials to establish the same local electric field strength. Even if a leakage path is localized to a few emitter cones, it will affect the entire array since all tips are electrically connected in parallel.

These preliminary studies have shown that a miniaturized EI/FI source can be based upon a microfacbricated, solid-state device. Such a source could potentially be made much smaller than the version described here since the active area of the array is only 1x1 mm. In addition, the low sensitivity of this source in the FI mode could be enhanced by improving the sample introduction method. At present, FI depends on the diffusion of sample vapors into the regions of high field strength near the emitter tips. A more efficient mechanism of sample delivery would thus improve the FI sensitivity.

A GAS TRAP FOR HEADSPACE GC/MS ANALYSIS.

Jia-shen Wang*, Avelina Qua, and Ira E. Rosenberg
Clairol Inc., Stamford, CT 06922

Headspace/gas chromatography (HS/GC) or headspace/gas chromatography/ mass spectrometry (HS/GC/MS) have been widely applied for the analysis of volatile compounds in the presence of non-volatile matrices. At Clairol we have constructed a gas trap which can be directly coupled with a Finnigan GC/MS system for headspace analysis. The advantages of this set-up are: the device is very easy to install and remove from the GC/MS system, will not effect the performance of the system, no modification of the GC inlet system is necessary, and the whole unit is very compact, inexpensive and easy to fabricate. The set-up is shown in Figure 1. The device can be divided into three portions: the desorber, the power and temperature control unit (P/T unit), and the

Figure 1. Gas Trap & GC Configuration

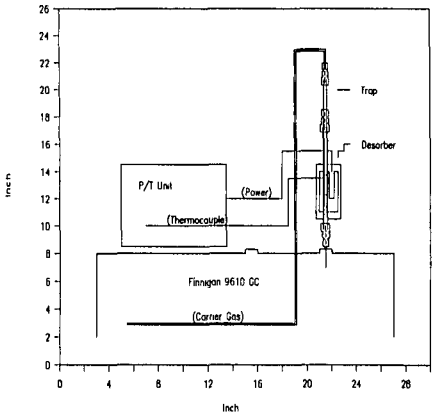

Figure 2. Desorber & Trap

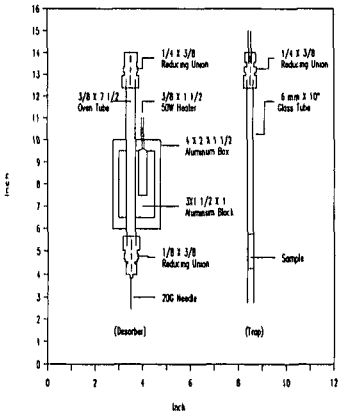

trap. The dimensions of the desorber are similar to that of Priestley's design[1]. Modifications, however, have been made to simplify construction and operation. The desorber and the trap are shown in Figure 2.

The desorber is made with a piece of 1"X1.5"X3" aluminum block and was enclosed with a 1.5"X2"X4" aluminum box. Glass wool was packed between the box and the block for insulation. A 3/8" i.d. hole was drilled through the block and the box for an oven tube. A 3/8" i.d. blind hole was drilled for a cartridge heater. The heater is a 3/8"X1.5" 50 watt cartridge heater. The oven is a 3/8" o.d. and 7.5" long stainless

steel tube. Two Swagelok reducing unions were attached at the ends of the tube. The center of the top union was enlarged to 1/4" in order for a trap to pass through. A 20 gauge needle surrounded with a piece of 1/8" o.d and 1/2" long copper tube was inserted into the 1/8" end of the lower union.

The trap was made of a 10" long 6 mm glass tube with one end attached to the 1/4" side of a 1/4 X 1/8 Swagelok reducing union. The 1/8" side of the union was connected with a piece of 1/8" o.d and 3" long copper tube which was then connected with a Tygon tube for carrier gas. Either the adsorbent or a sample should be packed near the end of the tube which would sit in the heating zone when a trap was fully inserted in the heating block.

The temperature of the heating block was controlled by the P/T unit. The J-type thermocouple was used for temperature mesurement. The P/T unit is a 10 ampere analog temperature controller (Thermon Manufacture Company) enclosed with a 6" X 8.5" X 9" metal box. A jack for the J-type thermocouple was mounted on the front of the box. A jack for the 120 v. power line was mounted on the side of the box.

The trap was operated in two modes: trapping and desorption. In the trapping mode, the glass column was packed with an adsorbent. In the other mode the column will be packed with sample only. In either case, once a tube was loaded, the subsequent procedure is the same. The sample end of the tube was inserted into the oven about 1". The other end was connected to a gas outlet of the GC which was used for measuring the carrier gas flow rate of the packed GC. The heating block was then connected to the GC by punching the needle into the injection port of the Packed GC. The next step is to set the GC in the carrier gas measuring mode. The carrier gas will enter into the trap and then into the GC. After 30 seconds (to remove the air in the trap), the trap was inserted into the oven tube totally and the GC/MS set to run. The volatiles were desorbed by heat. The carrier gas carried the volatiles into the GC for a GC/MS analysis.

This device in conjunction with the GC/MS system had been used to perform headspace analysis for malodorous samples (e.g. to detect the hardener in the plastic used to manufacture rollers). The device has also been used to analyze directly samples (0.2 gram of non-volatile) where the contaminats (volatiles) were in the range of fractions of ppm. Most important, however, is that the device enables us to analyze samples which are chemically unchanged prior to the MS analysis. Therefore, contamination due to sample preparation is minimal.

CONCEPTS AND APPLICATIONS OF SHORT OPEN TUBULAR COLUMNS IN GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Mark E. Hail, and Richard A. Yost, University of Florida,
Department of Chemistry, Gainesville, FL 32611.

The multidimensional information provided by mass spectrometry and tandem mass spectrometry reduces the necessity of chromatographic resolution for mixture analysis. The use of short (e.g. 3 meter) open tubular columns in GC/MS provides several notable advantages (1). Chromatographic theory predicts that optimum carrier gas velocities are higher when the column outlet is at vacuum, and with short open tubular columns higher flow velocities can be used without much loss of chromatographic efficiency. Analysis times are reduced by a factor of 30, if a 3 m column is used instead of a 30 m column, and both are operated at their optimum gas velocities. The reduced analysis times are due to the reduction of the column length by a factor of 10, as well as the increase in the optimum gas velocity by a factor of 3 for the shorter column. In addition, the resolution lost by a using a column that is 10 times shorter is only a factor of the square root of 10.

The increased optimum carrier gas velocities obtained with short columns with vacuum outlet is due to the reduction of the average column pressure. A better understanding of this phenomenon can be obtained by observing the effects of the outlet pressure on the calculated pressures at each point along a 3 m column, as shown in Figure 1. Figure 2 shows the theoretical dependence of the plate height on the average gas velocity for the same outlet pressures used in Figure 1. Note that the behavior is essentially the same for 100 Torr and 1 Torr outlet pressures. Thus, any GC detector which could be operated at the reduced outlet pressures would offer significant advantages in terms of speed of analysis.

The limitation is that short columns with vacuum outlet require sub-atmospheric inlet pressures, if optimum gas velocities are to be obtained. This is demonstrated in Figure 3 for both He and H_2 carrier gases. Most capillary GCs use pressure regulators, thus optimum velocities can not be obtained with short columns operated with reduced outlet pressures. Alternatively, a flow-controlled system can be used, as shown in Figure 4. This system allows the injection port to be operated at reduced pressures in the split or splitless mode. In particular, during splitless operation, the sample is injected at pressures slightly above atmospheric, and then the pressure is sharply reduced after a few seconds (i.e. after allowing all of the sample to be loaded onto the column).

Flow programming of the carrier gas has been evaluated as an alternative to temperature programming for use with chemical ionization (CI). In fact, exponential flow programming of the carrier gas results in peak distributions similar to those obtained with linear temperature programming (2). This is demonstrated in Figure 5, which shows a comparison of temperature and flow programmed runs. The sensitivity under electron ionization (EI) conditions decreases dramatically with increasing flow rates of carrier gas into the ion source. Thus, vacuum inlet pressures (and thus lower flow velocities) are preferred for the use of EI and short columns. However, studies have shown that carrier gas flow rates as high as 30 mL/min can be used without degrading CI mass spectra. Even when H_2 is used as a carrier gas and is present in the source at pressures of 0.5 Torr, methane CI spectra are unaffected. This is apparently due to the fact that the hydrogen reagent ions (H_3^+) are used in the protonation of methane gas, since methane has a higher proton affinity than hydrogen.

One advantage of flow rate programming is that lower temperatures can be used to separate thermally labile components. Another advantage is that a high sample throughput can be obtained, since column equilibration is accomplished by an essentially instaneous resetting of the column flow rate. These concepts are being applied toward the development of a compact GC, which utilizes short open tubular columns and is approximately the same size as a conventional direct insertion probe. Flow programming would be particularly attractive for isothermal operation of the probe-type GC, since it would not be necessary to cool the probe between injections.

CAPILLARY GC/MS FOR THE DETECTION OF ORGANIC FIREARMS DISCHARGE RESIDUE

Dean D. Fetterolf and Robert D. Koons
FBI Laboratory, Forensic Science Research Unit
FBI Academy, Quantico, Virginia 22135

The most common method to indicate the handling or discharging of a firearm involves the analysis of hand swabs for antimony, barium and/or lead, components of the primer mixture. Another popular method involves particle analysis of primer residue by scanning electron microscopy. Interpretation of the forensic significance of the elemental concentrations is compounded by their ubiquitous environmental presence. Particle analysis methods are time consuming.

The majority of firearms propellants are double-based composition; containing nitroglycerine (NG), nitrocellulose and stabilizers such as ethylcentralite or diphenylamine. Typical ammunition ranges from 10% to 40% by weight NG. Due to its limited usage, NG is not a common environmental contaminant. Attempts at determining the organic residue on hands has met with limited success and application. Most procedures involve the use of HPLC with reductive electrochemical detection.

Using solid phase extraction and GC/MS we have developed a rapid and simple procedure for the detection of NG on hand swabs. Cotton swabs moistened with methyl tertiary butyl ether (MTBE) are rubbed across the back of the hands of suspected shooters. NG is extracted from the swabs with 2 x 1 mL pentane washes. Sample clean-up is carried out using a preconditioned (pentane/ethyl acetate) disposable diol (Supelclean, LC-Diol) extraction column. Following a 1 ml pentane wash, the NG is eluted with 1 mL ethyl acetate into a silanized screw cap vial.

Results of recovery studies from various packing materials indicated that the diol or CN packing provided complete recovery from the column (100% and 98% respectively). Micropacked XAD-7 columns showed 62% recovery while SAX columns only 14%. Recovery of 92 ng NG from spiked swabs ranged from 80% to 90%. The effect of contamination on recovery was studied by spiking swabs with 92 ng NG along with 100 μL of contaminant. Recoveries from swabs contaminated with gasoline, hand lotion and floor sweepings were 80%, 85%, and 87% respectively.

Using cold on-column injection 1 μL of the eluant is chromatographed on a 0.1 micron film, 15M DB-5 x 0.25 mm ID capillary column temperature programmed from 100 C to 250 C. Using electron capture negative chemical ionization, the NG is detected by multiple ion detection at m/z 46 $(NO_2)^-$ and 62 $(NO_3)^-$ on a Finnigan-MAT TSQ-45 operated in the Q3 MS mode. Relative sensitivities observed for EI (m/z 46,76), PCI (m/z 46,76), and NCI (m/z 46,62) were 1.0, 1.6 and 352 respectively. A limit of detection of 0.3 pg NG has been obtained. This corresponds to 0.3 ng NG on the hand. Hand blanks from non-shooters showed no interference with the NG peak using the above procedure. Figure 1 shows the chromatographic results of the injection of a hand blank, swab extracts from a shooter after firing three shots with a Smith and Wesson (S&W) 38 Special and a 92 pg NG standard.

A number of studies relevant to the forensic utility and interpretation of the data are underway. Where is NG deposited on the hand? What are the effects of weapon choice and firing method? What effect does activity have on the recovery of NG from the shooter's hand?

The highest amounts of NG are typically recovered from the thumb-web-forefinger area of the shooting hand. Test firing a variety of weapons has shown NG deposition ranging from 1.2 ng to 1,600 ng. Some typical results from swabing the left and right backs of shooter's hands are shown in Figure 2. As expected, the choice of weapon (38 caliber Smith and Wesson vs. 22 caliber RG) and the firing method (right handed vs. 2 handed) effect NG deposition. In addition, no NG was recovered from the hand of a non-shooter moving throughout the firing range or from the hands of a person having fired 6 shots the previous day.

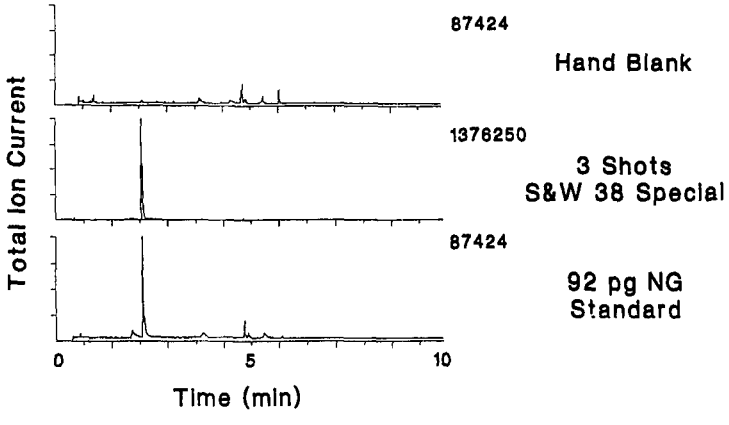

Figure 1. Chromatographic results for hand blank, 3 shots - Smith and Wesson 38 Special and 92 pg NG standard.

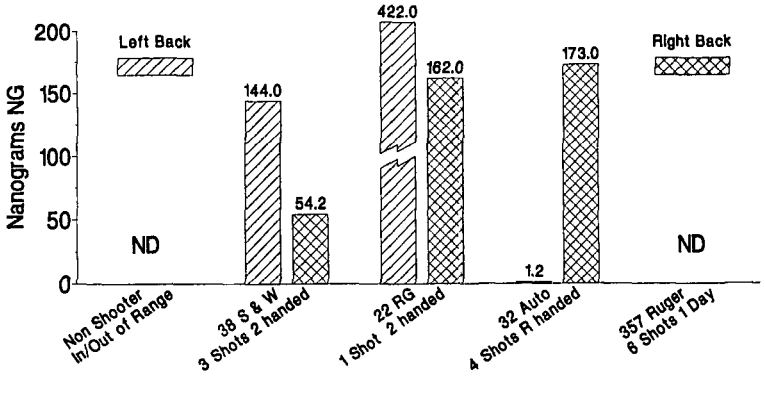

Figure 2. Typical results demonstrating effect of weapon, firing method and activity on NG deposition.

CAPILLARY SUPERCRITICAL FLUID CHROMATOGRAPHY NEGATIVE ION CI MASS SPECTROMETRY OF TRICHOTHECENE MYCOTOXINS

John A. G. Roach, Denis Andrzejewski and James A. Sphon, Damico MS Lab,
Division of Contaminants Chemistry, Food and Drug Administration,
Washington, DC 20204

Purpose

Trichothecene mycotoxins are produced by various fungi which attack agricultural products. These compounds can be detected in food extracts by mass spectrometry (MS) but they are difficult to gas chromatograph. Extensive sample preparation is usually required for combined gas chromatography/MS. Supercritical fluid chromatography (SFC) is an alternative to gas chromatography (GC). Thus, there are three purposes for this work:

(A) To determine if it is advantageous to use SFC rather than GC for trichothecene analyses.
(B) To design an SFC/MS interface and define parameters suitable for trichothecene analyses.
(C) To determine if SFC is compatible with negative ion MS of trichothecenes.

SFC/MS Interface Design Criteria

(A) SFC/MS interface would not impede GC/MS or probe analyses.
(B) Fabrication used existing equipment and available materials.
(C) Adequate control of interface and restrictor temperatures.

Need for SFC Restrictor Temperature Control

A restrictor is required at the end of the capillary column to maintain SFC conditions throughout the column. In an SFC/MS interface, the restrictor must separate the high vacuum of the MS from the high pressure of the SFC column and still permit the transmission of sample into the MS. The expansion of mobile phase at the exit of the column cools the tip. Therefore, heat must be added to the restrictor to assist in vaporization of the effluent.

Our interest in thermally labile samples caused us to use two heated zones in the SFC/MS interface. The tip of the restrictor is heated independently of the rest of the interface. The two zones permit the selection of interface temperatures which minimally heat the SFC effluent.

Component Parts of SFC/MS Interface

The fabricated parts of the interface are a block heater on the ion source, a hollow direct inlet probe and a flexible coupling between the probe and the SFC oven.

A standard porous frit supplied by the SFC manufacturer acts as the restrictor. The restrictor is coupled to the column with a zero dead volume butt connection and threaded through the interface until the frit is at the tip of the direct inlet probe. A swagelock tee in the handle of the probe supplies CI reagent gas coaxially to the source through the probe.

The major portion of the SFC/MS interface is maintained at or near the SFC oven temperature. The frit in the tip of the restrictor is independently heated by a block heater that replaces the standard ion source inlet adapter on the ion source.

Experimental

The trichothecene mycotoxins T-2 toxin, deoxynivalenol and roridin A were used to evaluate the effect of restrictor temperature and carbon dioxide mobile phase on the negative ion CI spectra of these compounds under electron capture, proton abstraction and chloride attachment conditions. The reagent gases employed were:

(A) methane - resonance electron capture CI
(B) methane/nitrous oxide - hydroxide ion CI
(C) methane/difluorodichloromethane - chloride CI

Split and splitless 0.2 ul injections were made. A 10:1 splitter was used for the split injections. An uncoated 40 cm length of 0.075 mm i.d. fused silica tubing was used to couple the injector valve to the 10 m x 0.050 mm i.d. fused silica methyl silicone capillary column for splitless injections.

Column temperature was maintained at 100 C. The width of each mycotoxin response narrowed as the temperature of the frit was raised to approximately 100 C above the published melting point of each mycotoxin. As examples: the width of a T-2 response was 50 sec at 225 C and 10 sec at 245 C; a roridin A response continued for 9 minutes at 245 C, but an equal amount of roridin A eluted in 20 sec at 295 C.

The negative ion mass spectra of the trichothecenes obtained by SFC/MS were comparable to those obtained by direct probe. No significant interferences were observed to arise from the carbon dioxide mobile phase. Repetitive scans of a 500 dalton window readily detected 40 ng of the trichothecenes using the 3 negative ion CI reagent species chosen for this study.

Conclusions

Combined SFC/MS can be used for the confirmation of trichothecene mycotoxins in the negative ion mode. Restrictor temperatures less than 100C above the melting point of the samples retard sample transfer into the MS, but neither restrictor temperature nor carbon dioxide mobile phase significantly affect negative ion CI conditions.

DESIGN AND PERFORMANCE OF A CONTINUOUS FLOW PROBE HPLC INTERFACE FOR A LIQUID SIMS TIME OF FLIGHT MASS SPECTROMETER

Kai-Hsien Chen, Peter Marcus, and Robert J Cotter
Department of Pharmacology, Johns Hopkins University, Baltimore, MD 21205

OBJECTIVES

We recently reported the design of a liquid SIMS time of flight mass spectrometer (1,2) which enables the use of liquid matrix with a high flux primary ion beam. With a grounded source and relatively low voltage extraction pulses, it was possible to incorporate with a TOF a continuous flow probe with a rather simple design. The objectives of this report are to describe the design of such a probe for the future development of LC-TOF and to detail our studies of the dynamic processes of LSIMS desorption with regard to ion yield, mass spectra and chromatogram performance.

EXPERIMENTS

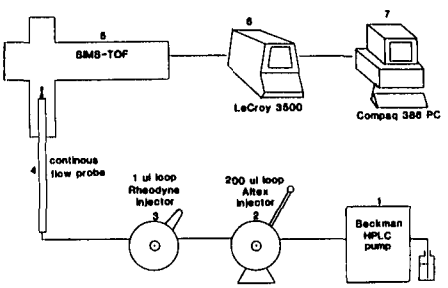

Figure 1 System setup

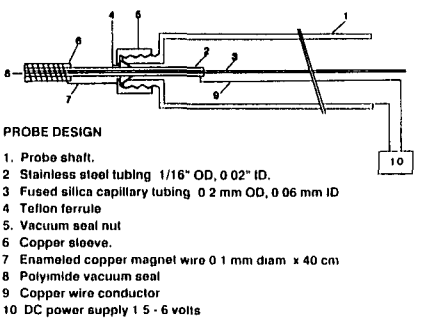

Figure 2 Probe design

The HPLC pump was operated at 1 - 3 ul/min, different solvents were injected into the 200 ul solvent loop, and the temperature of the probe was maintained at 30 - 40 C. After the pressure was stabilized in LSIMS-TOF, 1 ul of sample was injected into the system through the Rheodyne 7520 injector. The transient signals from the LSIMS were analyzed by a LeCroy 3500 wave form analyzer then transferred to a Compaq 386 PC for later processing.

RESULTS AND DISCUSSIONS

1. Low molecular weight ions were greatly suppressed by a longer primary ion pulse, while higher molecular weight ions were less affected (Table 1). This may indicate that, with the continuous flow probe, lower molecular weight species like the solvent and matrix leave the source faster under higher flux conditions prior to ion extraction. A longer primary ion pulse also resulted in less background and less memory effects in the selected ion chromatogram than when a shorter ion pulse was used (Fig. 4a, 4d). This may indicate that with a shorter ion pulse the sample on the probe surface was not completely removed by bombardment, thus a small amount of sample was deposited at the probe tip and resulted in the tailing seen on the chromatogram (fig. 4b, 4e).
2. Reducing the duty cycle of both the ion pulse and extraction pulse from 800 Hz to 400 Hz resulted in a small increase in the ion yield but greatly increased the tailing of the the selected ion chromatogram especially when shorter ion pulse was applied (Fig. 4b, 4e). Maintaining the extraction pulse at 400 Hz but increasing by ten times the frequency of the ion pulse greatly improved the chromatogram without losing the ion yield (Fig. 4e, 4f), while double the extraction duty to 800 and ion duty cycle to 8000 resulted in a good chromatogram but very low ion yield (Fig. 4b, 4c). These

results indicate that a proper balance between the duty cycle of the extraction and primary ion pulse and the width of the ion pulse is required for both good chromatogram and ion yield

CONCLUSION

The performance of continuous flow probe for LSIMS-TOF depends on a proper probe design and a combination of various proper controls such as probe temperature, flow rate, solvent compositions, extraction pulse duty cycles, ion pulse width, ion pulse duty cycle and vacuum pump evacuation rate. The selected ion chromatogram are highly reproducible as shown by multiple injection Thus, the design of this continuous flow probe is well adapted to our LSIMS-TOF and is a promising LC interface for high mass molecules analysis.

ION CONFINEMENT IN THE RF-ONLY QUADRUPOLE COLLISION CELL OF TANDEM QUADRUPOLE MASS SPECTROMETERS : ACCESS TO THERMODYNAMIC EQUILIBRIUM AND ION REJECTION

Claude Beaugrand and Gérard Devant,
Nermag, 49 quai du Halage, 92500 Rueil-Malmaison, France
Daniel Jaouen, Hélène Mestdagh and Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

We have shown last year that ion confinement in the RF-only collision cell of a tandem quadrupole instrument, using the entrance and exit lenses as electrostatic mirrors (Figure 1), is very efficient. The CAD efficiency under monocollision conditions was checked to depend only on the number of collisions, i.e. the product of confinement time and pressure, in a wide range of each parameter. We present here an important application of this device : access to thermodynamic equilibrium, and a new possibility : selective ion ejection.

Applied to ion-molecule reactions, the ion confinement technique allows for a variable interaction time, therefore for the measurement of kinetic and in some cases thermodynamic parameters of the reactions. The chemical system chosen for testing this method was the interaction of ammonium ion with a mixture of piperidine (Pi) and pyrrolidine (Py), involving the following successive steps :

- Kinetic protonation of the amines by NH_4^+ ion :

(k_1) $NH_4^+ + Py \longrightarrow PyH^+ + NH_3$; (k_2) $NH_4^+ + Pi \longrightarrow PiH^+ + NH_3$

- Proton exchange leading to acid-base equilibrium :

(k_3) $PyH^+ + Pi \rightleftharpoons PiH^+ + Py$ (k_{-3}) $K_3 = k_3/k_{-3}$

- Formation of proton-bound dimers :

$$PyH^+ + Py \longrightarrow PyHPy^+$$

$$PyH^+ + Pi \text{ or } PiH^+ + Py \longrightarrow PyHPi^+$$

$$PiH^+ + Pi \longrightarrow PiHPi^+$$

$$\begin{array}{ccc} Py & \rightleftarrows & Pi \end{array} \quad \text{fast equilibrium } (K_4)$$

$$\begin{array}{ccc} Py & \rightleftarrows & Pi \end{array} \quad \text{fast equilibrium } (K_5)$$

The variation of relative abundance of parent and fragment ions with confinement time was recorded for several reactant gas pressures (10^{-5} to 2.7 x 10^{-4} torr) in a wide time range (0.035 to 10 ms, up to 220 ms for one pressure). Figure 2 displays an example of these abundance curves. As shown in Figure 3, the PiH^+/PyH^+ ratio becomes constant for large enough reaction time and/or pressure, indicating that chemical equilibrium is actually reached for reaction [3]. This ratio corresponds to the equilibrium constant $K_3 = 3.5 \pm 0.5$, in agreement with literature values. Base-exchange equilibrium is rapidly achieved among the dimers (equilibrium constants K_4 = 2.3, K_5 = 0.38). Several rate constants were also measured. Figure 4 displays the linear variation of $\ln(NH_4^+)$ with confinement time for the different pressures used. As expected the slope of these curves is proportional to pressure, allowing to derive the rate constants k_1 and k_2 (2.3 x 10^{-9} and 2.1 x 10^{-9} s^{-1} molec.$^{-1}$ cm^3).Rate constants of other reactions involved were determined in a similar way : k^3 and k^{-3} = 2.8 x 10^{-10} and 8.1 x 10^{-11} s^{-1} molec.$^{-1}$ cm^3, k_d (total dimerization third-order rate constant) = 3.0 x 10^{-24} s^{-1} molec.$^{-2}$ cm^6.

Selective ion rejection from the collision cell can be effected using an auxiliary radiofrequency field applied on the RF-only quadrupole and tuned on the transverse frequency characteristic of the considered ion. The efficiency of this method was studied on a mixture of $Fe(CO)_n^+$ (n=0 to 5, m/z 54 to 196) ions confined (0.5 ms) in the collision cell. For instance, optimization of radiofrequency power allows nearly complete rejection of $^{56}Fe^+$ ion (intensity reduced to 2.5% of its initial value) with no distortion on other $Fe(CO)_n^+$ ions. The slight intensity decrease of the minor isotope $^{54}Fe^+$ ion (intensity reduced to 75% of its initial value) shows that the band width of ion ejection is in fact less than two mass units.

Figure 5 demonstrates the application of ion rejection to elucidation of reaction mechanisms in the case of Fe^+ ion-allyl chloride reaction. Excitation of ion $C_3H_5^+$ (m/z 41) leads to a large decrease not only of this ion, but also of m/z 55, 75, 79, 81, 89 ions,indicating that these ions are subsequent reaction products of $C_3H_5^+$ with allyl chloride. Ions which remain

unaffected (m/z 67, 76, 78, 82, 91, 93, 96, 132, 134) must be formed in another way.

In conclusion, use of variable confinement time, and its association with selective ion rejection, appear as powerful tools for studying complex ion-molecule processes.

CHARACTERIZATION OF MULTIPOLE FRAGMENTATION CHAMBERS USING COMPUTER SIMULATIONS OF ION TRAJECTORIES: Sherri-Sue Delbert and Chris G. Enke; Michigan State University, Department of Chemistry, East Lansing, MI 48824

Optimal characteristics for a reaction/fragmentation chamber include minimal gain of radial energy, efficient ion trapping and wide mass range. We have modified a lens analysis and design program called SIMION[1] to characterize a hexadecapole chamber. Program modifications include the application of a cosine function to the potential gradient, insertion of a frequency dependent, time-step size limit, insertion of a maximum integration time and implementation of a batch run capability.

Although analytical solutions are possible for the Mathieu equations representing the quadrupole system, they are not available for multipole systems[2,3] due to the coupling of the ion motion. Computer simulation is used to characterize "non-standard" multipole systems because it can represent the "real" features of the chamber; the rods can be any shape or size placed in any geometrical position.

Computer simulations of ion trajectories in rf-only quadrupole chambers have shown that ions can gain five to ten volts of radial energy due to the electric field potentials extending into the central region. Our simulations for the hexadecapole chamber indicate that, as the number of poles increases, the field potential becomes increasingly flat in the center. In addition we show that better ion containment can be achieved by increasing the applied voltage or decreasing the voltage rf. Thus, for tandem mass spectrometry applications, a multipole reaction chamber is expected to be superior to the now-standard quadrupole system.

According to the theory of quadrupoles, a stable ion trajectory occurs when the radial position remains finite as time approaches infinity. Thus, we have defined a stable trajectory as one in which the change in radial position over time remains constant or decreases. On the other hand, a transmitted ion is one which did not hit an electrode or escape from the chamber during the time it requires to travel the chamber length. As a result, there are four possible types of ion trajectories: transmitted/stable, transmitted/unstable, nontransmitted/stable and nontransmitted/unstable.

We have investigated the ion transmission/stability characteristics of a quadrupole and a hexadecapole system as a function of the ion's initial off-axis energy (Figs. 1 & 2). The boundaries between transmission and nontransmission for the quadrupole system are well defined as expected from the a,q diagram. However, the hexadecapole system does not exhibit clear boundaries for transmission or stability. This result is also expected considering the diffuseness of the a,q diagrams generated by Szabo[3] for various multipole systems.

SIMION has proved invaluable in the characterization of "non-standard" multipole chambers. We have also shown that quadrupole systems exhibit predictable transmission/stability characteristics while hexadecapole systems exhibit chaotic behavior. As a result of the chaotic behavior of hexadecapole systems at the transmission boundary, attempting to define the relationship between various instrumental/ ion parameters which will produce the best ion transmission in multipole chambers may be more complex than previously thought. However, because of the improvement in ion containment and the reduction of radial energy gain relative to the quadrupole system, multipole chambers are useful as ion/molecule or ion/photon reaction chambers.

LONGITUDINAL FIELD FAULTS IN QUADRUPOLE MASS FILTERS

P.H. DAWSON
NATIONAL RESEARCH COUNCIL, OTTAWA, CANADA

INTRODUCTION

Quadrupole mass filters may have longitudinal field faults (i.e. along the length) due to converging or diverging rod sets. A similar effect could be produced by very rapid scanning giving a varying q as the ions pass through the filter. A more complex longitudinal field fault is produced by rod sets that are bowed out or bent in at the centre. Using phase space techniques, it is shown how these faults can influence performance and produce non-ideal peak shapes. Even very small geometric deviations can have significant effects for slow ions under high resolution conditions.

METHOD OF CALCULATION

The $+r_0$ and $-r_0$ limits to oscillation at each zero phase of the rf field were transformed back to the quadrupole entrance in order to find the restrictions placed on ion entry conditions. The results are shown as superimposed plots on phase plane diagrams (transverse velocity versus transverse position).

The longitudinal field faults were included by inserting different a and q values along the length of the quadrupole. Where a,q values are quoted they refer to those at the entrance of the quadrupole.

For quadrupoles operating under analyser limited conditions peak shapes can be examined by multiplying together x and y acceptance areas and examining them as a function of q.

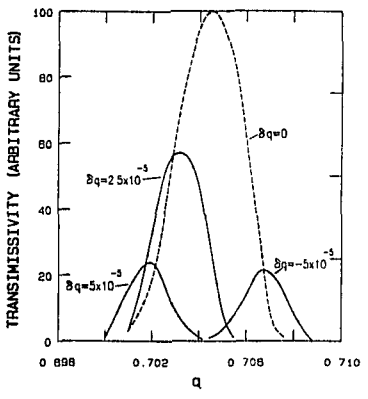
NOMENCLATURE

a and q are the Mathieu parameters.

n_0 is the number of rf cycles that the ions spend in the field.

δq is the change in q <u>per rf cycle</u> due to the field fault, e.g. for diverging or converging rods the total change in q will be $n_0\delta q$.

Note that $\delta q/q = -2\delta r_0/r_0$ where r_0 is the radius of the field.

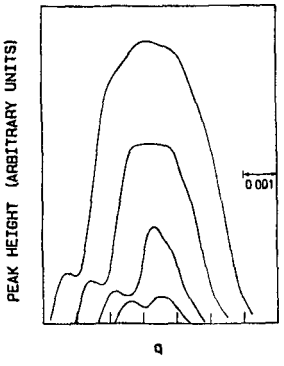


Converging rod sets give an increase in a and q as the ions pass through. A similar effect could be caused by very fast mass scanning.

For analyser limited transmission, peak shapes can be calculated. Examples are shown in the figure for δq positive. Note the tendency to produce a tail on the high mass side as the magnitude of the field fault increases.

Diverging rod sets give decreases in a and q as the ions pass through.

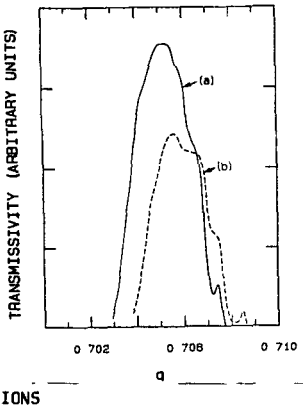
For analyser limited operational conditions, the resulting peak shape for 100 cycles in the field and $\delta q = 5\times10^{-5}$ is shown. This corresponds to a total fractional change in q (from entrance to exit) of 0.7% (or a fractional change in rod separation of 0.35%.
Note the asymmetry of the peak.



Peaks with differing resolution

For rod sets bent in at the centre

For a given field fault and 100 cycles in the field, the peak shapes vary with the resolution. At high resolutions the shoulder becomes dominant. With very large field faults, multiple structure can appear. $\delta q = 5\times10^{-5}$



For rod sets bowed out at the centre

Under analyser limited transmission conditions peak shapes can be calculated. Bowed rod sets lead to satellite structures on the high mass side. Even satellite peaks may be observed.
(a) $n = 100$ $\delta q = 2.5\times10^{-5}$
(b) $n = 100$ $\delta q = 5\times10^{-5}$

CONCLUSIONS

As quadrupole mass filter performance is pushed to high levels, peak shape problems due to non-parallel rod sets are likely to be observed.

The characteristics predicted for bent and bowed rod sets are very similar to certain features observed experimentally. i.e. shoulders or even satellite peaks that become more and more dominant as the resolution is increased and the main peak decreases in magnitude.

ISOBARIC DOUBLET ION SEPARATION ON QUADRUPOLAR SINGLE AND TANDEM MASS SPECTROMETERS

Frederic de Maack, Gérard Devant, Gérard Lepetit,
Nermag, 49 quai du Halage, 92500 Rueil-Malmaison, France
Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

Analytical experiments using a quadrupolar mass spectrometer are normally recorded with a constant peak width, typically 0.5 u at half height all over the mass range. This operating mode leads to a variable resolution R (R=M/ M) equal to 2M at mass M. A new method has been developed in order to improve the resolution of quadrupole analyzers. An electronic device called "Resolver™" has been developed to implement this new technique in analytical mass spectrometers. Using this method a peak width of 0.15 u at half height is obtained over the mass range of 10 to 1500 mass units;thus the higher achievable resolution is ten thousand. This improvement was obtained by association of the classical AC-DC resolving mode of the quadrupolar analyzer and a periodically over-resolving modulation.

Figure 1 shows the results obtained on the $[M - 19]^+$ isotopic ions of 2,4,6-tris(perfluorononyl)-1,3,5-triazine at m/z 1466. This resolution better than ten thousand at 50% valley, was obtained with a decrease in signal intensity less than a factor of ten from the normal operating conditions. Furthermore the isotopic ratio M + 1 to M that could be measured from this figure fits the theoretical value with a precision better than 1%.

Figure 2 shows the reconstructed ionic currents at m/z 253.19 and 253.29 obtained during the capillary GC/MS separation of a crude oil from Hungary. These data were obtained in multiple ion monitoring mode with a scanning rate of 200 ms per ion. Using the "Resolver™", isobaric doublet of aromatic (253.19) and aliphatic (253.29) hydrocarbons base peaks are cleanly separated; this increases the analysis specificity whithout any limitation of the fast scanning rate of quadrupole instruments.

Obviously this technique can be easily implemented on the first analyzer of a tandem quadrupole MS/MS instrument. The second analyzer works under more harder conditions due to kinetic energy spread after collision. In spite of these difficulties we demonstrate here that a medium resolution can also be obtained from CAD fragment ions. Figure 3 displays a part of the daughter spectrum of two isobaric parent ions from a mixture of diazepam (m/z 284.07) and hexachlorobenzene (m/z 283.87) introduced by the direct inlet probe. We used a "classical" resolution (c.a 500) on the first analyzer and a medium resolution (c.a 3000) on the second analyzer. The resolution of the second analyzer is such that even after collision with neutrals the common isobaric daughter doublet resulting from the loss of chlorine is cleanly separated.

These experimental results demonstrate that a medium resolution (c. a. peak width 0.15 u) on the entire mass range can be obtained on quadrupole analysers either in GC-MS or in tandem MS/MS instruments using the "Resolver™".

Improved Performance from a Hybrid Mass Spectrometer

J.J. Monaghan, I.C.I
B. Wright, Kratos Analytical

Introduction

RF-only quadrupoles have widespread applications including MS/MS (Triple Quadrupole[1] and Hybrid Mass Spectrometers), focusing elements for ICP/MS instruments and some quadrupole based GC/MS system[2]. The principal use of the RF-only quadrupole is in ion containment and focusing devices for obtaining collisionally induced dissociation spectra for MS/MS. They are still widely regarded as total ion transmission devices despite the lack of experimental data regarding the extent of mass discrimination. Miller and Bonner Denton[3] have recently pointed-out some of the problems associated with ion transmission through RF-only quadrupoles and our experimental work broadly agrees with their theoretical and experimental data.

We have constructed a new type of collision cell, utilising the strong focusing action of RF fields, which is capable of replacing the conventional quadrupole collision cell and which shows significant improvements in ion transmission properties.

Ion Transmission Efficiency

Ion transfer efficiencies in RFonly quadrupoles (after RF optimisation) can be made quite large (typically 50-90%) over a wide mass range. However, Miller and Bonner Denton[3] have shown that spatial focusing effects cause RF-only quadrupoles to exhibit mass discrimination effects of an oscillatory nature that are of importance even over a narrow mass range.

Ion intensity comparisons are frequently made by users of MS/MS instruments and, in such cases, the RF-only quadrupole should be operated under conditions such that both the flight time and the operating point of all ions in a,q space are the same. These restrictions impose difficult practical limitations on the users of such instruments. A more productive approach is to make an improved collision cell which is not subject to these restrictions.

New Collision Cell

Data for CsI was obtained using a FAB ion source. A parent ion of m/z 912 and a daughter ion of m/z 393 were chosen as representative examples. The mass spectrometer was a CONCEPT ISQ hybrid, produced by KRATOS ANALYTICAL, with an EBQQ configuration.

Figure 1 shows the effect of varying the applied RF voltage on the parent ion transmission in both the traditional quadrupole and the new collision cell. The overall shape[4] [5] and fine structure of the curve in the case of the collision quadrupole agrees with Miller and Bonner Denton[3]. Note the curve for the new collision cell is linear and the cell is capable of operating over a larger RF voltage range.

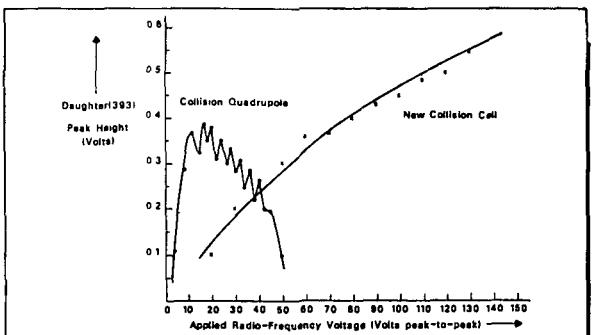

Fig.2 Effect of RF Voltage on Daughter Peak Height

Figure 2 shows the effect of varying the applied RF voltage on the daughter ion transmission. Note, in the collision quadrupole case, that the fine structure in the curve persists, but is reduced in amplitude. Again, the curve for the new collision cell is more linear over a wider voltage range.

Figure 3 shows the combined effects of Figures 1 and 2 by plotting the daughter/parent ion current ratio as a function of applied RF voltage.

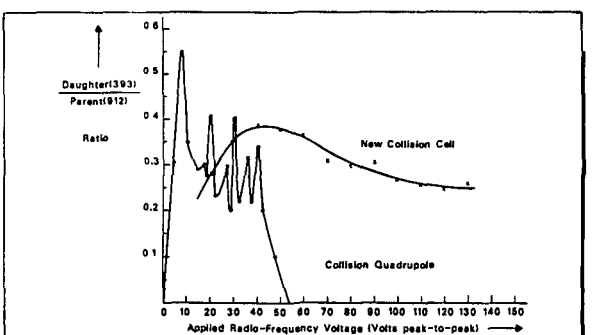

Fig.3 Effect of RF Voltage on Daughter/Parent Ratio

Conclusions

The new collision cell shows a far more stable daughter/parent relationship as the RF voltage is changed and indeed our best results have shown about a 10% relative change in ratio over the useful RF voltage range. In the future, it is hoped that the new collision cell will help in producing more precise daughter/daughter and daughter/parent ratios, so that such data may be conveniently used for instrument comparisons and quantitative applications.

Introduction

Normal FAB mass spectra of small peptides often do not contain sufficient sequence information to allow complete structural elucidation (1). Collisionally Induced Dissociation (CID) of the (M + H) species has been suggested as a *means to overcome this problem. Two collision regimes are available ie high* (kev) and low (ev) collision energies. In order to asses the usefullness of the technique we have chosen to investigate the daughter ion spectra generated from small peptides. For high energy collisions First Field Free Region collisions and Linked B/E scans were employed. Low energy collisions were generated by the use of a RF only quadrupole collision cell and mass analysed with a quadrupole mass filter.

Experimental

Spectra were obtained on a VG Tribrid mass spectrometer. Samples presented in a matrix of 2:1 thioglycerol/glycerol were ionised by Fast Ion Bombardment with an 11 kev Csi primary ion beam.

Result and Discussion

The data from high energy collisions along with a normal mass spectrum for Beta Casomorphin (YPFPGPI RMM 789) are shown in Figs (1-3). Data from a range of collision gas pressures was recorded, all data being obtained at 4kev collision energy. As can be seen the B/E scan combined with high energy CID generates good quality data containing a great deal of structual information. The relative instensity of specific ions in the spectrum as a function of collision gas pressure Fig. 6 shows the expected trends. The only effect of increasing collision gas pressure is to decrease the intensity of the higher mass ions relative to those at lower mass. At the high gas pressures beam scatter reduces all signal intensity. The low energy CID spectra Figs. 4 and 5 also show intense sequence ions at high mass however in this case it proved difficult to obtain good quality data containing both intense sequence and diagnostic immonium ions in one spectrum. For smaller peptides it was possible to produce a low energy collision regime that gave as much structural information as the high energy work. This work will be extended for peptides in the 1000 - 2000 moleular weight range.

Conclusion

The method of B/E linked scanning in conjunction with high energy CID offers an excellent method for structural analysis of small peptides.

SCAN MODES FOR HYBRID MASS SPECTROMETERS

Gary L. Glish and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831

Hybrid mass spectrometers consisting of a quadrupole combined with a magnetic and/or electric sector are becoming increasingly popular. One of the advantages of such instruments is that they have reaction regions in which high kinetic energy (3-10 keV) collision-induced dissociations (CID) can be performed and reaction regions in which low kinetic energy (5-500 eV) CID can be performed. However, to date, almost all the reported data has used the low collision energy reaction region. This is due in part to the fact that the scanning modes necessary to acquire such data are simple.

This paper describes the scanning modes necessary to acquire daughter ion, parent ion and neutral loss spectra from any reaction region in eight different hybrid mass spectrometers composed of a magnetic and/or electric sector followed by a quadrupole and vice versa. Several of these scans require scanning all three analyzers simultaneously and, in geometries in which the sector(s) precede the quadrupole, often also the decelerating voltage . The scan equations are listed in the tables below.

Table I. Scan equations for the EQ geometry.[a]

Reaction region	1 (E)	(decel) (Q)
Ion kinetic energy	keV	
Daughter ion scan	Q/E=C	
Parent ion scan	SCAN E	
Neutral loss scan	(Q/E)-Q=C

To use the keV reaction regions in the sector/quadrupole geometry instruments, the deceleration voltage must also be scanned with the sectors. Also, with these instruments, some type of crude energy filter has to be present to allow the reaction region between the last sector and the deceleration lens to be used. Otherwise, severe background and artifact peak problems will make these reaction regions useless. RR1 in the EBQ and BEQ provides no improvement to the as compared to using just the sectors and detecting prior to the deceleration. In fact, using the quadrupole is detrimental due to the reduced sensitivity from transmission losses.

In summary, no single instrument or geometry will be best for all applications. The sector/quadrupole instruments will have better parent ion resolution for reactions occurring at eV energies. This is the main advantage these instruments have over quadrupole/sector instruments for the basic MS/MS experiments. The latter will be less prone to artifact peaks, have higher daughter ion resolution for eV reactions and some keV reactions, and will not have to scan any lens voltages such as the deceleration voltage in the sector/quadrupole geometry instruments.

KINETIC ENERGY RELEASE EFFECTS ON RESOLUTION IN MS/MS

Gary L. Glish and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831

Artifact peaks occur in many types of MS/MS scans due to the fact that when an ion dissociates part of its internal energy is partitioned into energy of separation, the so-called kinetic energy release, which manifests itself as a change in ion velocity. Since sectors analyze properties which are a function of velocity (momentum or kinetic energy), scans which have velocity as a parameter are subject to artifact peaks and/or have decreased resolution. Such scans are performed with sector instruments and hybrid instruments (instruments with sector(s) and quadrupole(s)).

The effects of kinetic energy release can be grouped into two categories which cover all scans on sector and hybrid instruments. The first category is that in which the dissociation occurs prior to the last sector, which is also the last analyzer (i.e. quadrupole/sector geometry hybrid instruments). In this case, the kinetic energy release affects the daughter ion resolution. The second category is that in which the dissociating ion must pass through two or more analyzers before arriving at the detector. In such cases, the kinetic energy release leads to artifact peaks, which can be thought of as being due to a decrease in parent ion resolution.

For the daughter ion resolution case, the kinetic energy release (T), measured at some defined percentage of the peak maximum, necessary to cause a signal to be obtained at the centroid of the next mass can be calculated, to a close approximation, from the following equations for an electric sector and magnetic sector, respectively

$$T=V/4m_d m_n \qquad T=V/m_d m_n$$

where V is the accelerating voltage, m_d is the daughter ion mass and m_n is the neutral fragment mass. It can be seen from these equations that when kinetic energy release is the daughter ion resolution limiting factor that a magnetic sector will have four times the resolution of an electric sector.

For parent ion resolution, the same equation applies for both types of sectors. It is

$$T=m_d V/4m_p{}^2 m_n$$

From these equations, one can get the relationships between the various parameters and kinetic energy release. Six plots are shown on the next page.

A GRAND SCALE MASS SPECTROMETER "GEMMY" AT OSAKA UNIVERSITY

T. Matsuo, T. Sakurai, M. Morris, I. Katakuse, H. Matsuda.

INTRODUCTION

The advent of the soft ionisation techniques (FD, FAB, LSIMS, PD, LD) has opened the pathways for the mass spectrometric studies of high molecular weight compounds, such that the demand for accurate mass measurement of such heavy species has also increased. For such analysis, an instrument that satisfies the criteria for high mass range, high mass resolution and high sensitivity simultaneously is required. We know the four equations that determine the ion optical characteristics of a mass spectrometer: 1) Mass spectrometry equation, 2) Abbe's sine law. 3) Q-value concept, and 4) Theoretical mass resolution as expressed by the transfer matrix elements. A grand scale instrument is one of the solutions that satisfied the above requirements, a geometrically large size being essential. We have designed and constructed such a machine of QQBQE [1] arrangement GEMMY at Osaka University. The ion optical block diagram of GEMMY is shown in Fig. 1.

RESULTS AND DISCUSSION

First, a comparison of the theoretical and experimental mass resolutions was made using an EI source, and found to be 24,300 by experiment and 28,000 by theoretical calculation, both with a 100μm source slit width. This agreement is satisfactory. Second, the detectable mass range was examined using CsI and Ag clusters, and was found to be 50,000 daltons at 5kV. Third, the mass determination was assessed for each isotopically separated peak of an organic compound, and was found to be better than 0.2 mass units in routine measurement mode. We are concerned with the analysis of peptide mixtures, including mutants, which are obtained from enzymatic digestion of proteins. The molecular weights of the components of such a mixture are usually less than 5,000 daltons, and the present accuracy of GEMMY is adequate for this type of analysis. The mass spectrum of bovine insulin is shown in Fig. 2.
Our current project is concerned with the detection of heavy biomolecules (great than 10,000 daltons) in low resolution mode.

CALIBRATION AND OPTIMIZATION OF AN EBQQ SYSTEM FOR QUANTITATIVE ANALYSIS - A NOVEL APPROACH

Paul E. Farrow and Lauren M. Yelle, Arthur D. Little, Inc., Cambridge, MA 02140 and Gerald Dudek, Brandeis University, Waltham, MA.

OBJECTIVE

A large amount of our work involves trace analysis of specific analytes in complex matrices. The matrix may be a polymer, food, soil, sludge or slurry extract. MS/MS has proved very successful in our laboratories and others for this type of analysis (1,2,3). However, we, and others, have found that several key MS/MS parameters can cause significant changes in relative intensities of daughter ions obtained from XQQ systems (QQQ, BEQQ, EBQQ, etc.). The increasing need to carry out qualitative and quantitative experiments by GC/MS/MS and LC/MS/MS means that standardizing instrument set-up is critical for obtaining reproducible results. Our objective was to find a compound, or compounds, suitable for the standardization and fine tuning necessary to achieve such results.

INSTRUMENTATION

All experiments were carried out on a VG 70SEQ hybrid (EBQQ) mass spectrometer (VG Instruments, Inc., Danvers, MA). Typical operating conditions were:

Accelerating Voltage: 8kV
Source Temperature: 200° C
Emission Current: 200 A
Electron Energy: 70 eV
Solid Probe Temperature: 45°C

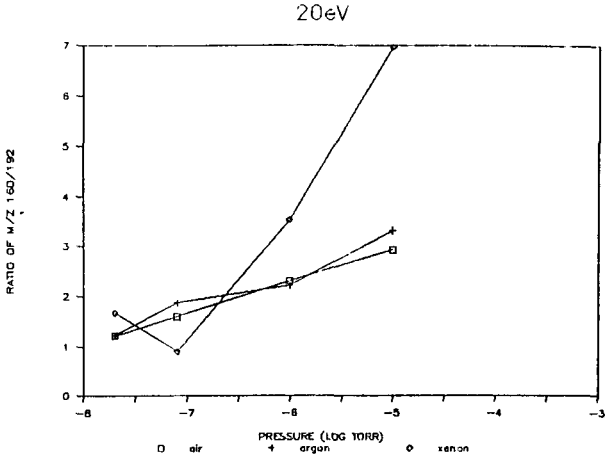
SUMMARY

The Electron Impact (EI) ionization of sulfur, S_8, gives an interesting spectrum. The successive losses of 32 amu (S^+) gives a repetitive fragmentation pattern ideal for linear calibration of a quadrupole system. In addition, the daughter ion spectrum is responsive to changes in the quadrupole system (e.g., gas type, pressure and collision energy). Sulfur is readily available, inexpensive and easy to handle (a solid). By controlling the solid probe temperature, a steady bleed of sulfur vapor is introduced into the ionization chamber.

The following figure demonstrates the relationship between gas pressure and relative response of two daughter ions in the sulfur spectra. We have arbitrarily chosen the relative response of m/z 160 to m/z 192 for these illustrations. Each plot shows the response for a given gas at varying pressure (log torr) with collision energy kept constant.

METHOD

Initially we obtain a standard daughter ion spectrum of the analyte(s) of interest. Parameters such as collision energy, collision gas type and gas pressure are optimized for the analyte. We then introduce sulfur into the system and record its daughter ion spectrum under these conditions. When the analysis is to be repeated, the conditions are optimized for the sulfur spectrum previously stored.



EXAMPLE

An example of data obtained by using this approach is the detection of a chlorophenol in a food extract. Interference rules out the identification and the desired quantification of this analyte.

The daughter ion spectrum of the chlorophenol was optimized and recorded along with the standard sulfur spectrum.

By selecting suitable daughter ion transitions, a MRM (multiple reaction monitoring) experiment was set up for this analysis. A positive identification was made and quantification in the ppb range was possible.

CONCLUSION

Whenever a compound is analyzed by MS/MS, we record a standard sulfur daughter ion spectrum along with the data and operating conditions. When the analysis is to be repeated, possibly months later, sulfur is used to fine tune the operating parameters (energy, gas, pressure) to give the same daughter ion spectrum as before. The system is then ready for the analysis without having to introduce a standard of the analyte again.

As a result of this work, we are able to obtain reproducible daughter ion spectra from one experiment to another. This has led to consistent detection limits and the ability to obtain quantitative data at the ppb level from MS/MS experiments.

Operation of a Hybrid Tandem Mass Spectrometer of BEqQ Configuration in Unlinked Scan Modes: Theory and Applications.

A.J.Alexander, R.K.Boyd, R.Guevremont, P.Thibault,
National Research Council of Canada, 1411 Oxford St., Halifax,
Nova Scotia, Canada B3H 3Z1.

Mass analyzed ion kinetic energy spectroscopy (MIKES) (1) is widely used for the study of collision induced dissociation (CID) at keV energy. Limitations of MIKES include (i) lack of mass resolution in the fragment ion spectrum, (ii) uncertainty in mass due to appreciable energy losses during collisional activation, and (iii) occurrence of artifact peaks. A hybrid tandem instrument of BEqQ configuration can provide unit-mass (Q-defined) fragment spectra for keV collisions, essentially artifact-free, via a linked-scan at constant E/Q. Problems (i) and (iii) are thus avoided. Unfortunately the linked E-Q scan does not solve problem (ii), and may introduce new problems such as drift (electronic) in the E/Q ratio with time, and inaccuracy in the q deceleration lens and the qQ float voltages.

The experiments reported here were conducted using a VG Analytical ZAB-EQ hybrid instrument. Changes to the instrumentation were made to permit selection of a series of operating states wherein the computer and the console could simultaneously retain control of different parts of the instrument; eg. the electric sector could remain under console control while the computer controlled the functions necessary for the acquisition of data using a normal Q scan (eg. MS/MS/MS,(2)).

All benefits of the linked E-Q scan may be retained, with minimization of electronic problems, if the scans of E and Q are uncoupled. In this mode E and Q are both scanned during acquisition, but the scan functions are unrelated. The quadrupole analyzer is scanned under computer control, to utilize existing capability of the system to collect data into a multichannel analyzer (MCA) file. The electric sector is scanned under console control. Although the E scan is completely uncoupled from the computer controlled quadrupole scan, a Quadrupole-resolved MIKES (QMIKES) spectrum is acquired. QMIKES is best described as mapping of the 2-dimensional E-Q space onto the Q axis. The areas of simultaneous transmission through E and Q fall on a line through E-Q space; the peaks are broad if viewed from the E axis, and narrow when viewed from the Q axis. Unlinked, random, scans of E and Q will eventually pass over every area of E-Q space. If all the quadrupole scan data is acquired into a MCA data file, this file will be a record of all occurrences of simultaneous transmission of ions through E and Q, and more important, the MCA data will be accurately mass analysed, with unit resolution. Fig.1 illustrates a comparison of MIKES and QMIKES spectra of the same group of fragment ions.

The unlinked E-Q scan is simple to implement, but inappropriate for scans over a wide mass range. A version of 'partially linked E-Q scans' has been designed to improve the efficiency of scans over a wider mass range, and to avoid the limitations of completely linked scans. This approach uses a small (50V) low frequency (100Hz) modulation of the electric sector added to a constant E/Q scan. Electronic deviations from the ideal E-Q link, and shifts of the MIKES peaks caused by kinetic energy (Derrick) effects, can be accommodated without loss in ion intensity. The electric sector will pass through the optimum energy of transmission of fragments during the course of the E modulation, even though the calculated E-Q link is slightly in error.

Fig.2 is a schematic representation of the modifications to the VG Analytical ZAB-EQ which enable operation in the 'partially linked E/Q' mode. The electric sector voltage is 'slaved' to the quadrupole analyzer scan so as to maintain constant E/Q ratio, and a modulation is added to the E voltage. The modulation is not coupled to the E-Q scan function. (The quadrupole float voltages remain 'slaved' to E.) In addition, these circuits drive the mass display unit and provide appropriate values to the quadrupole energy partition circuitry. During the operation of the

NRCC No . 9010

partially linked E/Q scans, the computer is allowed to control only the quadrupole scan; all other control remains with the console units and the circuits in Fig.2.

QMIKES and the partially linked E-Q scans have been used to identify artifact ions in MIKES spectra (Fig.3), obtain unit mass resolved MIKES spectra of isotope labelled compounds, and to assess the CID reactions of larger molecules(3) where a so-called Derrick shift (kinetic energy loss) can lead to uncertainty in the assigned masses of fragment ions (Fig.4).

A MODEL FOR MASS-INDEPENDENT SPACE AND ENERGY FOCUSING IN TIME-OF-FLIGHT MASS SPECTROMETRY USING DYNAMIC POST-SOURCE ACCELERATION

GEORGE E. YEFCHAK AND CHRISTIE G. ENKE
Department of Chemistry, Michigan State University, East Lansing, MI 48824

JOHN F. HOLLAND
Department of Biochemistry, Michigan State University, East Lansing, MI 48824

Conventional time-of-flight mass spectrometers suffer from poor resolving power with gaseous samples due to the initial spatial and kinetic energy distributions of ions at the time of their formation. It has been shown that mass-independent compensation for both the spatial and energy effects cannot be achieved concurrently using static acceleration fields [1]. Mass independent space and energy focusing is needed, however, to gain the advantage of monitoring the full spectrum of arrival times for each pulse of ions from the source.

Exploration into the use of non-static fields has resulted in techniques which incorporate dynamic acceleration either in the source [2] or in a region past the source [3]. To further develop dynamic post-source acceleration, a computer model has now been developed which incorporates all pertinent parameters including the extraction voltage, the accelerating and field-free region lengths, and the dynamic acceleration function. Analytical equations and ion flight-time simulations using this model have led to the development of a new post-source acceleration technique, *dynamic-field focusing* (DFF), which provides mass-independent space and energy focusing [4].

The DFF focusing principle is illustrated in Fig. 1. Ions are extracted from a single-field source and enter the first of two field-free regions (FF1). As the ions approach the space-focus plane, there is no simple relationship between their positions and velocities. Farther along the flight path, however, velocity becomes related to position in such a way that the velocity adjustment necessary to achieve simultaneous arrival at the detector (within the isomass packet) is a monotonic function of arrival time at the DFF region. Ions are accelerated as they pass through the DFF region and enter the second field-free region (FF2). The magnitude of this acceleration is a function of the ion's arrival time at the end of FF1; ions arriving later receive more energy than leading ions. Thus in FF2, the relationship between position and velocity is inverted (*i.e.*, within any isomass group, the leading ions are the *slowest*). The applied acceleration is tailored at each instant to make the trailing ions just catch up to the leading ones at the detector.

To obtain the functional form of the required dynamic acceleration, equations were derived which yield the voltage rise, dV/dt, needed to focus isomass ions. A separate equation was derived for each of three cases: Case **S** results from ions initially located away from the center of ionization; cases **E+** and **E-** result from ions having initial thermal motion directed toward or away from the detector, respectively. These three equations were reconciled by inspection, combined with simplex optimization of an "overall resolving power" response function, to yield instrument parameters which make dV/dt similar for the three cases. The resulting average dV/dt

function was then numerically integrated to yield the DFF voltage function. A Monte-Carlo simulation of DFF-TOFMS peak shapes for 1000 and 1001 u ions is shown in Fig. 2. Predicted resolving power as a function of mass for DFF-TOFMS is shown in Fig. 3. Unit resolving power is achieved for ions up to 2000 u.

INSTRUMENTATION FOR MASS SPECTROMETRY/COINCIDENT FRAGMENT DETECTION

D.E. Goeringer, S.A. McLuckey, and L.K. Bertram
Analytical Chemistry Division
Oak Ridge National Laboratory
P.O. Box 2009, Oak Ridge, TN 37831-8121

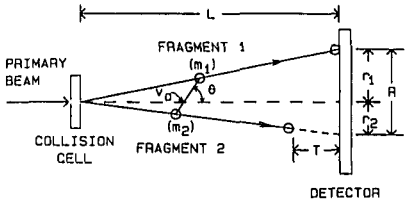
Mass spectrometers of various geometries are used to study the collision-induced dissociation (CID) of mass-selected molecular ions (M^+) into fragments (m_1^+, m_2), with the charged fragment subsequently mass/energy analyzed. However, much of the M^+ beam current in MS/MS instruments is lost via neutralization

$$M^+ + N \text{ ---> } M + N^+$$

or dissociative charge exchange (DCE)

$$M^+ + N \text{ ---> } M^* + N^+$$
$$\quad\quad\quad\quad\quad\quad\quad\quad \text{---> } m_1 + m_2$$

It seems likely that we can improve the detection of fragments in MS/MS by optimizing DCE and detecting the neutral fragments. Therefore, we propose to develop a new type of instrument for mass and energy analysis of neutral fragments.



The general experiment depicted above involves the measurement of time delay (T) and spatial separation (R) for the (nearly) coincident detector impacts of two neutral fragments resulting from the dissociation of a mass-selected molecule having center-of-mass velocity, v_0, and initial energy, E_0. For our instrument design, delay and position measurements must be made with a resolution of ~1 ns and ~200 μm, respectively. The experimentally determined time delay and spatial separation for the detector impacts can be used to calculate the kinetic energy release (ϵ) and recoil angle (θ) for the dissociation; because the precursor mass (M) is known, the masses of the fragments (m_1, m_2) can also be determined using the corresponding distances (r_1, r_2) from the center of the detector.

The proposed instrument consists of a first stage mass spectrometer (single magnetic sector) for mass selection of the parent molecular ion, a collision cell for DCE, deflection plates for removal of charged species, a flight tube (straight) for separation of the neutral fragments, and a two-dimensional detector for time and position measurements. The detector for the instrument is a dual microchannel plate (75 mm dia.) located in front of a specially designed anode consisting of two semicircular sections of concentric rings. The fragment impact positions are determined by charge division and the time delay by direct time measurement. The schematic diagram for the detector and the anode design is shown below.

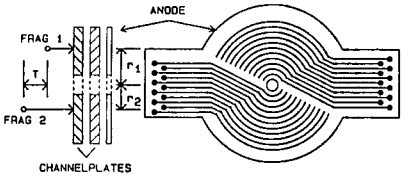
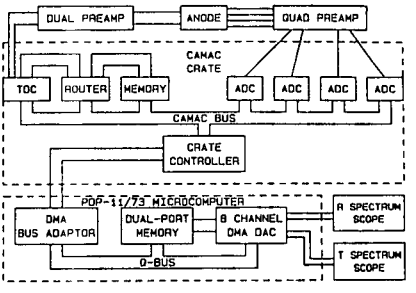
June 5-10, 1988, San Francisco, CA



The data acquisition system is based on the computer automated measurement and control (CAMAC) concept; a DEC LSI-11/73 microcomputer system is used to control four analog-to-digital converters (ADCs), a time-to-digital converter (TDC), and associated memory modules housed in a CAMAC crate. A schematic diagram for the data system is shown below.



Data acquisition for each dissociation event involves the coordination of four ADC conversions and one TDC conversion. It is possible for the CAMAC system to autonomously acquire such data in blocks of 5 x 1024 points (fragmentation events) at burst rates of 150 kHz. The data block is then transferred via direct memory access (DMA) to the microcomputer where it is histogrammed and displayed in near real-time while another block of data is being acquired via the CAMAC system. Special memory and digital-to-analog converter (DAC) boards, with private DMA interconnection, enable the data to be displayed without using microcomputer DMA cycles. Therefore, the DMA capability for the microcomputer is totally available for data transfer from the CAMAC system.

Because this technique can detect charged fragments from CID as well as neutral fragments from DCE, we will study CID of well-characterized molecular ions such as ionized acetone for proof-of-principle demonstrations. Following this, we will repeat experiments performed on a similar instrument by de Bruijn and Los (1) involving the DCE of H_2^+. We will then proceed to investigate the unimolecular chemistry of neutralized beams of larger polyatomics. The systems created via ion formation/neutralization could be very interesting and unusual, e.g. $MH^{\cdot}$ from MH^+ or other ions for which no stable neutral counterpart is known to exist. The instrument could also be very useful for fundamental studies of neutralization-reionization mass spectrometry (NRMS) since the charge exchange reaction is the first step in that process.

A Direct Comparison of Two-, Three-, and Four-Sector Mass Spectrometers for Measuring CID Spectra of Peptides

John T. Stults and John A. Chakel
Genentech, Inc.
460 Point San Bruno Blvd.
South San Francisco, CA 94080

Tandem mass spectrometry utilizing four-sector instruments represents one of the best means of obtaining sequence data for peptides by mass spectrometry. The mass range and resolving power permit reliable data to be obtained for a variety of peptides of up to about 25 residues in length. Newer techniques are pushing the mass range upward and reducing the amount of sample required. Typically 0.5-1.0 nmole of peptide is necessary for obtaining collision spectra with reasonable ion signal levels.

A successful MS/MS experiment is most dependent on the precursor ion intensity, so sample quantity, precursor mass, and instrument resolving power all play a role. When adequate precursor intensity is available, the EB-EB CID spectrum with unit resolution of both precursor and daughter ions is most desirable. Quite often, the desired quantity of sample is not available, particularly when the peptides are isolated from natural sources. With our present instrumentation, this necessitates reduction in resolving power to increase the signal. When the precursor ion intensity is less than desired, compromises in resolution need to be made.

Generally the resolution of MS1 is set to transmit only the ^{12}C isotope of the precursor. This value separates the peptide of interest from other peptides and matrix ions, and provides monoisotopic peaks in the daughter spectrum. Resolution in MS2 is normally set to resolve all daughter ion peaks. For compounds with mass <2000Da, available in >0.5nmole amounts, these conditions usually provide sequence-rich spectra. The resolution requirements are low and the ^{12}C isotope is the largest peak in the precursor ion cluster. Larger peptides typically fragment less efficiently, require greater resolving power, and display less intense ^{12}C isotope peaks. In these cases, and for smaller peptides which are available in low quantity, compromises in resolution may be necessary. However, the integrity of the sequence information must be preserved.

Several peptides of different masses have been examined to determine what operating conditions (including 2- and 3-sector operation) provide the best signal levels without sacrificing the sequence information content of the spectra. These peptides were:

FPTIPLSR, MH^+=979.5, 30pmole

DLEEGIQTLMGR, MH^+=1361.7, 30pmole

LHQLAFDTYQEFEEAYIPK, MH^+=2342.1, 1.2 nmole

<ELYSALANKCCHVGCTKRSLARFC, MH^+=2657.3, 1.3 nmole

The first three peptides were isolated from a tryptic digest of recombinant human Growth Hormone. The fourth peptide is the A-Chain of synthetic human Relaxin. Spectra were obtained with a JEOL JMS-HX110HF/HX110HF Tandem Double-Focusing Mass Spectrometer (E_1B_1-E_2B_2 configuration), equipped with a JEOL DA-5000 data system. Samples were dissolved in 0.1%TFA and 0.5ul of each mixed 1:1 on the probe tip with 0.5ul glycerol:DTT:DTE (6:5:1). Ionization was by fast atom bombardment using a JEOL FAB gun, 6keV Xe atoms, 10mA emission current. For EB-EB and EB-E experiments, precursor ions were selected with MS1 and fragmented by CID in the grounded collision cell-2 (10keV energy, 75% attenuation of the precursor beam with helium). For EB (constant B/E linked scan) measurements, ions were formed in the MS2 ion source; fragmentation by CID or metastable decomposition took place in collision cell-2.

Based on examination of the measured spectra, several conclusions can be drawn about the different modes of operation:

For precursor mass <~2000u:

EB-EB

Unit resolution of the precursor ^{12}C peak should be maintained. This yields monoisotopic daughter ion peaks and it is easy to achieve because MS1 resolution <1000 is required [S.A.Martin et al, 1987 ASMS, Denver, bound volume pp.78-79]. Reduction of MS2 resolution will give unresolved peaks only at the high mass end of the spectrum, but this is generally not a problem (except for z,z+1; a,a+1; etc.).

EB-E

Signal intensities for the three- and four-sector experiments are similar. The much poorer daughter ion resolution, and the observed translational energy release and translational energy loss make this mode of operation of little utility. A non-uniform baseline makes mass assignment by the data system difficult.

EB (B/E linked scan)

Signal intensities are 10-20 times larger than those observed in the four-sector experiments, and for precursor mass <1000, where the ^{13}C peaks are minimal, the spectra are readily interpretable. However, for low sample quantity, matrix ion interferences often mask the peptide daughter ions. Much of the matrix interference is due to metastable decompositions.

For precursor mass >~2000u:

EB-EB

When possible, maintain unit resolution in MS1. As the mass increases, however, unit resolution of the precursor becomes harder to achieve while yielding good daughter ion spectra. The precursor abundances are less, the ^{12}C isotope peak becomes increasingly smaller, the collision efficiency decreases, the total daughter ion intensity is spread over a larger number of ions, and the resolution required increases. Selection of the ^{13}C precursor peak or the isotope envelope produces daughter ion peaks that are weighted averages of the precursor isotopic components and require mass correction before interpretation. However, if the mass differences between peaks are used for interpretation [Scoble, Biller, and Biemann, Fresenius Z. Anal. Chem. **1987**, 327, 239-245], the mass shifts are not a problem. Reduction of MS2 resolution is acceptable if the ^{12}C precursor peak is selected. Low resolution in both MS1 and MS2 can be used for those sample where intensity is at a premium.

EB-E

The increased complexity of the spectra in addition to the reasons mentioned above make the three-sector mode of operation of limited value for peptides of this size.

EB (B/E linked scan)

The poor parent resolution inherent to two-sector B/E scans results in daughter ion masses that are weighted functions of the precursor isotopic envelope. However, the increase in signal is substantial and matrix contributions in this mass range are minimal. The metastable spectrum is strong and is simpler than the CID spectrum (no w ions), making it potentially useful for higher mass precursor ions.

Although two-sector B/E spectra provide useful data for low mass peptides (<1000Da) and higher mass peptides (>2000), data from the four-sector mode of operation give superior results in most cases, providing maximum sequence information with the best resolution. The ability of the four-sector mode of operation to eliminate artifact peaks and to utilize a floating collision cell also weigh in the comparison.

A FOUR SECTOR MASS SPECTROMETER FOR NEUTRALIZATION-REIONIZATION (NR) STUDIES

R. Feng, M. -Y. Zhang, C. Wesdemiotis, M. A. Baldwin, D. E. Drinkwater, B. Leyh, M. Marchetti, and F. W. McLafferty

Chemistry Department, Cornell University, Ithaca, NY 14853-1301

The prototype Cornell EBEB mass spectrometer has been modified to permit high performance neutralization-reionization (NR) experiments. Precursor ions, mass-selected by MS-I (EB), enter the interface region between MS-I and MS-II and undergo neutralizing collisions at collision cell I (Cls-I). A deflector electrode (Dfl-I) is situated immediately after Cls-I to remove unneutralized ions. Cls-II follows, and is used for reionization, or neutral dissociation. In the latter case, newly formed ions are removed by Dfl-II, and the neutral beam is reionized in Cls-III. Cls-I and Cls-II have differential pumping systems, with a 10" diffusion pump on the entire interface region. Cls-III can be replaced by a field ionization chamber for the selective reionization of neutrals in Rydberg states. NR spectra are detected after mass-analysis through ESA-II; alternatively, ESA-II can be used to mass-separate individual ions from the NR spectra for collisionally activated dissociation (CAD) at Cls-IV in the field-free region between ESA-II and Magnet-II. Fragment ions from such MS/MS/MS experiments are recorded after mass-analysis in the final magnet.

A new data system based on an IBM personal computer (PC/AT) is interfaced to the instrument. It enables accurate determination of absolute abundances for neutralization and reionization cross-section measurements.

He is the best target for CAD of neutral species. Spontaneous and extensive fragmentation of the neutrals produced can also be achieved by neutralization with targets of low ionization energy, such as Na or Cs. Individual neutral components in neutral mixtures can be detected selectively via reionization and CAD in Cls-IV. Closed-shell molecules are best made visible by cationization (NR^+) with O_2 or He, while for many radicals anionization (NR^-) with C_6H_6, Hg, or Na exhibits high relative efficiency. For example, extensive dissociation of 1- and 2-butene molecules is effected upon Na neutralization of their molecular cations; the resulting allylic radicals are selectively anionized with Na (Figure 1). As expected, 1-butene yields more abundant allyl anions (m/z 41) than 2-butene.

Field ionization conditions that produce $Ar^{+\cdot}$ ions from Rydberg Ar atoms fail to reionize $H_2Cl\cdot$, obtained via H_2Cl^+ neutralizaion with Hg, indicating that this hypervalent radical is not generated in a Rydberg state. Semiempirical calculations suggest that this radical has the structure H-H-Cl, formed in its ground state via vertical neutralization from the first triplet state of H_2Cl^+, for which the $H\text{-}H\text{-}Cl^+$ is more stable than the $H\text{-}Cl\text{-}H^+$ conformation.

Often, the structural identity of a molecular ion is hidden in the neutral CAD fragments. The He CAD spectra of the protonated molecules of N,N-dimethyl- and N-ethyl-β-phenylethylamine are identical within experimental error, showing intense $C_8H_9^+$ fragments (loss of C_2H_7N). However, the O_2 reionization spectra of their neutral dissociation products display structurally diagnostic differences (Figure 2): the appearance of intense ions at m/z 44 in the upper, and at m/z 30 in the lower spectrum are consistent with the presence of $(CH_3)_2NH$ and $CH_3CH_2NH_2$ in the corresponding neutral CAD beams.

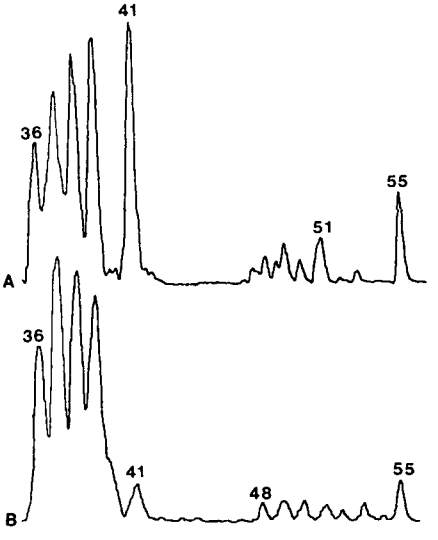

Figure 1. Na (30% Transmittance) NR^- spectra of the molecular cations of (A) 1-butene and (B) 2-butene.

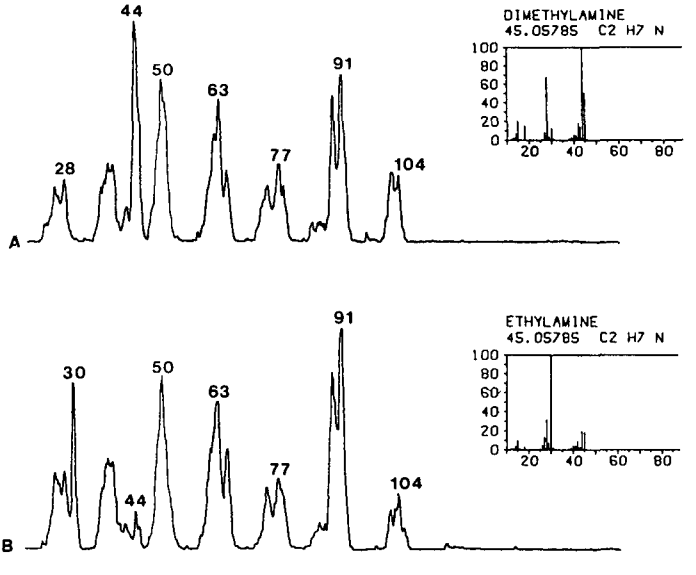

Figure 2. He (30% T)/O_2 (30% T) NR^+ spectra from the protonated molecular cations (methane chemical ionization) of (A) $C_6H_5CH_2CH_2N(CH_3)_2$ and (B) $C_6H_5CH_2CH_2NHCH_2CH_3$. Insets are the EI spectra of dimethylamine and ethylamine.

JEOL USA INC. 11 Dearborn Road, Peabody,MA 01960 USA

High resolution selected ion monitoring (HR/SIM) in GC/MS becomes regularly used[1] to advance detection limits in trace analysis. Furthermore, FAB/MS has been routinely used for the analysis of high molecular weight compounds. In both, a magnetic sector mass spectrometer is commonly utilized, and that under higher mass resolutions. However, a magnetic mass spectrometer has an inherent problem that sensitivity decreases proportionally when the main slit width is decreased for the purpose of increasing resolution.

We have designed and constructed a highly sensitive, medium sized double focusing mass spectrometer, the JMS-SX102, which allows for a wider main slit width than that on conventional instruments.

The ion optics of the JMS-SX102[2] is shown in Fig.1 and the major ion optical parameters are shown in Table 1. The $A\gamma/Ax$ ratio ($A\gamma$:mass dispersion, Ax:image magnification) is 5 times as large as that of ordinary optics($A\gamma/Ax$=1.0). This means that a wider main slit can be used not only under low resolution conditions but also under high resolution conditions. Fig.2 shows horizontal(X) and vertical(Y) ion trajectories. The pair of electrostatic quadrupole lenses(Q_1,Q_2) vertically focuses the ion beam so that it can be transmitted through the narrow magnet gap, and the third quadrupole lens(Q_3) refocuses the beam stigmatically at the collector slit. Consequently, high ion transmission is obtained.

Table 1 Ion Optical Parameters

deflection angle of magnetic field	40°
deflection angle of electric field	85°
image magnification(Ax)	0.20
mass dispersion($A\gamma$)	0.98
$A\gamma/Ax$	4.9

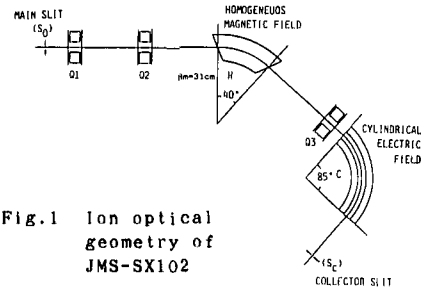

Fig.1 Ion optical geometry of JMS-SX102

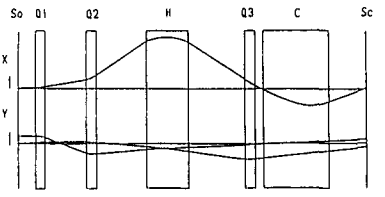

Fig.2 Horizontal(X) and vertical(Y) ion trajectories

Second- and third-order optical aberrations are minimized[2] using the computer code "TRIO"[3].
Fig.3 shows a high resolution spectrum of CH_2Cl_2 and $CDCl_2$ over 60,000 (The resolution required to separate the two peaks is R=54,260).
The main slit was set at 11μm which closely coincides with the calculated value of 13μm.

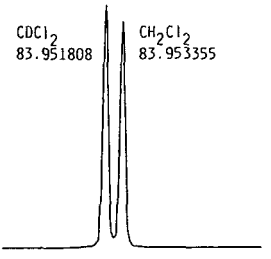

Fig.3 High resolution spectrum over 60,000

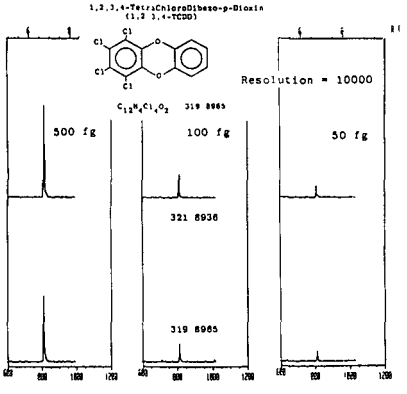

Fig.4 HR/SIM profile of 1,2,3,4-TCDD(m/z319.8965, 321.8936)

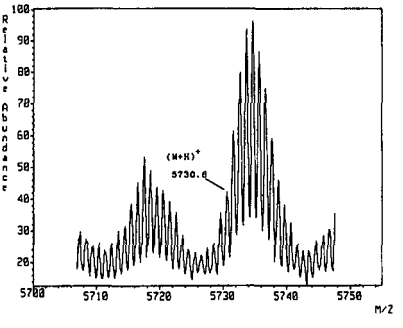

Fig.5 FAB spectrum of bovine insulin (moleculer ion region)

Fig.4 shows HR/SIM chromatograms of fentogram range TCDD. The resolution was set at R=10,000 which is enough to eliminate interferences from adjacent mass peaks.
Fig.5 shows the molecular region FAB spectrum of bovine insulin. The spectrum was obtained at 4KV accelerating voltage and with R=6,000.

These results show that the JMS-SX102 is extremely sensitive under even high resolution conditions and in any mass regions, compared to conventional instruments.

IMPROVEMENT IN HIGH MASS ION DETECTION OF A TANDEM QUADRUPOLE MASS SPECTROMETER USING A HIGH VOLTAGE POST-ACCELERATION DETECTOR

A.E. Schoen and John E.P. Syka, Finnigan MAT
355 River Oaks Parkway, San Jose, California 95134

Recent advances in quadrupole technology have enabled the use of soft ionization techniques such as liquid SIMS and thermospray to be utilized effectively on triple quadrupole instruments for the analysis of molecules larger than 2000u. However, these instruments suffer due to mass dependent detection efficiencies far less than unity. A new detector employing post analysis acceleration to 20 kilovolts of ion energy increases the detected analog signal at mass 4030 by more than a factor of twenty.

Detectors employing post analysis acceleration have been used in many mass spectrometers. Our goal was to design an implementation for a triple quadrupole system which allows investigation of higher conversion energies while reducing noise from field emission. The system uses a single, large, concave dynode mounted 90 degrees off axis from the beam exiting the final quadrupole. The entrance to the electron multiplier is directly opposite the dynode such that fast neutrals and photons may pass between the dynode and the multiplier without striking any surfaces.

The detector is similar to the one found on a sector field instrument. The difference is the nature of the ion beam. In sector instruments, the ion beam has a high kinetic energy at ground potential. Sector instruments without post acceleration detectors have a conversion energy equal to the difference between the ion source potential and the electron multiplier bias which has historically contributed to the observation of larger high mass peaks compared to peaks on quadrupole systems. The post acceleration detector eliminates this distinction between sector field and quadrupole mass spectrometers. In addition, this detector has essentially no dark current for dynode voltages up to 15 kilovolts and less than 20 ion counts per second at 20 kilovolts.

Figure 1 shows the gain in peak intensity as a function of mass for 10, 15, and 20 kilovolts relative to 5 kilovolts. The data is for cesium iodide and glucagon, however, other data for florinated reference compounds show indentical results. Not shown are results for a negative ion at mass 452 which exhibit a ninefold improvement when the dynode voltage is increased form 5kV to 20kV. SIMION was used to model the ion trajectories to the dynode and the collection of secondaries from the dynode. It was found that the high dynode voltage dominates the ion motion. Quadrupole exit conditions and lens settings have little effect.

Inspection of profile data acquired for daughters of substance P and the molecular cluster region of glucagon reveals an improvement in the subjective quality of data obtained while data taken at low mass shows no noticable change. Conversion efficiency alone cannot account for the improvement and overall detector gain should only affect peak height ratios. Indications that conversion efficiency does not increase as much as gain is contradicted by the obvious decrease in jitter on the peaks.

Since 20kV is insufficient to reach the threshold velocity for conversion efficiency to be greater than unity at mass 2000 (1), a statistical evaluation of the improvement was attempted. Measurements to compare the relative standard deviation of a measured ion signal at mass 502 as a function of dynode voltage revealed only a modest improvement in ion statistics. To determine whether the improved high mass detection is due to improved conversion efficiency or mass dependent gain, low ion flux was observed with a bandwidth of 23000Hz. At mass 1951, 32 ions are seen in 0.5 seconds at 5kV and 43 are seen at 20 kV. The conversion efficiency improves by a ratio of 1.34. The maximum pulse height increases by a factor of 6.33 to give a total gain of 1.34 x 6.33 = 8.48 which compares low to 11.1 as measured by conversion efficiency increase. Pulse pile up probably obscures some conversion efficiency increase and the relative pulse height distribution is slightly narrower at high voltage giving more gain compared to the ratio of maximum pulse heights.

The crude pulse height test confirms that most signal increase is due to mass dependent gain accompanied by a small improvement in the relative pulse height distribution and conversion efficiency. It should also be noted that for masses below 2000u, which can reach the threshold velocity, there are no breaks in the curves for the effect of dynode voltage on peak height.

The following conclusions may be drawn from these observations. Consistent with work by many others, higher conversion dynode voltage increases the detection of high mass ions relative to low mass ions. The improved high mass detection allows quadruople or other low energy instruments to yield spectra more similar to magnetic sector systems. The increase is due to a combination of increased conversion efficiency and mass dependent gain. An improvement in pulse height distribution may also contribute to better signal quality. Where detected noise is due to residual low mass ions or neutrals, the mass dependent gain will directly improve the signal to noise ratio. And finally, the simple dynode design eliminates most of the dynode noise from field emission expected with high voltage systems.

IMPROVING THE DETECTION SENSITIVITY FOR HIGH MASS IONS

J.F. Mahoney[1]*, J. Perel[1], T.D. Lee[2] and K. Legesse[2]

[1]Phrasor Scientific, Inc., 1536 Highland Ave., Duarte CA 91010
[2]Div. of Immunology, City of Hope, Duarte CA 91010

A needexists in mass spectrometry for a more sensitive method of detecting high mass ions of biologically important compounds. Conventional means for the detection of ions have relied on the production of secondary electrons released when incident ions impact an electron multiplier or post-acceleration dynode. Both methods are limited by an incident ion threshold velocity below which efficient ejection of secondaries is poor (1). In general, ion detection based on the kinetic ejection of secondary electrons becomes progressively more difficult to achieve with increasing ion mass. Recent approaches for improving detection sensitivity depend on post-dynode elements to achieve current amplification. This present study reports on the feasibility of improving the yield of secondary negative particles at the ion impacted dynode by forming a low work function overlayer on the dynode surface. Typically, low work function dynode surfaces are prepared by alternate or co-deposition of cesium and oxygen (2).

By forming a low work function, semiconducting photoemissive surface, the yields of secondary negative particles induced by impact of high molecular weight ions can be increased by several mechanisms. Sinceorganic ions undergo fragmentation after colliding with solid targets (3), enhanced yields of desorbed negative fragment ions can be achieved by establishing conditions at the dynode surface favorable for electron capture by the low mass, molecular fragments. These conditions are met by providing a low work function surface and molecular fragments having high electron affinities. Additionally, low energy ion-surface collisions can induce optical radiation (4). By irradiation of a thick cesium-oxide film with photons formed in the collisional interaction between incident biomolecular ions and a dynode surface, photoemissive electrons can be ejected. Photon emission can occur by excitation of backscattered ions, by excitation of adsorbed surface molecules and by excitation of fragmentation products. Thermionic emission arising from localized thermal spikes in low work function regions may also contribute to signal enhancement.

To examine the effects on increased ion detection sensitivity arising from the mechanisms described above, the apparatus shown in Fig.1 was constructed. A highly polished nickel dynode was machined to duplicate the dynode configuration supplied with a JEOL HX100 HF double focusing MS and mounted on a movable shaft. Retracted to the deposition position, the dynode was exposed to alternate doses of cesium supplied by a heated dispenser and oxygen was introduced through a leak valve. After each dosage, the activated dynode was re-positioned and FAB spectra acquired for melittin (MW=2846). The increase in sample ion intensity for the treated dynode over the bare nickel dynode is expressed as a ratio in Table I. For the last deposition condition (Cs+O+Cs+O+Cs), the sample ion intensity reached a value over 30 times that measured for the untreated dynode. Fig.2 illustrates the melittin spectra for the bare nickel singly, doubly and triply dosed dynode. Low mass, matrix ions show similar increases. In these studies the chemical background was proportionally amplified with the overall signal-to-noise remaining nearly constant. The Cs-O activated dynode exhibits higher cold emission or thermionic noise under applied voltage but remained below the chemical background. Quantification and discrimination involving the mechanisms postulated for the increases observed in signal enhancement are under investigation.

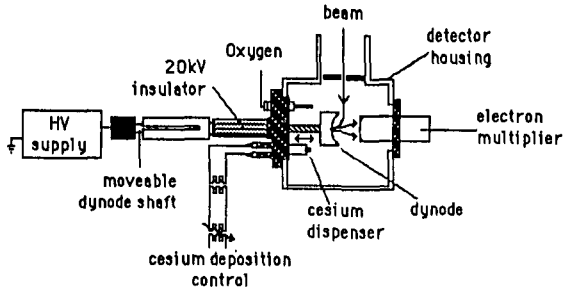

Fig. 1. Detector Test Configuration

Table 1. Sample Ion Intensity Ratio I/I_0 For Treated (I) vs. Standard Dynode (I_0).

Dynode Voltage			Deposition Condition
-10 kV	-15 kV	-19 kV	
1	1	1	Bare Nickel
12.3	13.3	12.8	Cs
32.3	21.5	21.9	Cs - O - Cs
37.4	34.4	---	Cs - O - Cs - O - Cs

Sample Ion (melittin, m/z 2846) intensities are the average of 10 scans. Standard Dynode = Bare Nickel

AN IMPROVED ^{252}Cf PLASMA DESORPTION MASS SPECTROMETER FOR LARGE BIOMOLECULES

P.D. Mudgett, J.C. Hill, and R.D. Macfarlane
Texas A&M University, College Station, TX 77843

^{252}Cf Plasma Desorption Mass Spectrometry (PDMS) has developed into a highly useful technique for the mass analysis of involatile biomolecules. It is, however, desirable to extend the sensitivity of the technique into the picomole to femtomole range [1]. There are many factors which determine the sensitivity of PDMS for large molecules, and the research in this area of PDMS involves determining the necessary conditions for detecting massive ions, as well as the sources of the large background associated with the PD mass spectra. A more complete understanding is necessary in the design of the instrumentation required for optimal sensitivity and mass accuracy for PDMS of high mass molecules. In this report, several sensitivity considerations will be discussed, and improvements to PDMS time-of-flight instrumentation presented along with spectrometric results using bovine insulin (m/z 5735) as a test molecule.

The analyte peaks of interest in a PDMS spectrum appear superimposed on the background continuum which affects the mass assignment. It is thus desirable to "decouple" in real time the peak from the background via the hardware. The background continuum generally increases in relative intensity with mass and is a composite of energetic neutrals, metastable ions, uncorrelated or mixed events, and electronic noise (generally minimal). Retarding fields [2] have been used to partially resolve a given peak into its molecular ion, metastable and neutral components. Parallel electrostatic deflector plates can also be used to separate the ions and neutrals into two "beams" which can be monitored individually. The mixed event problem has been investigated and may contribute up to 50% to the background [3].

In an effort to decrease the significant component of the background due to neutrals, the ion flight length was doubled to reduce the acceptance angle of the detector for the divergent neutrals beam. The fraction of the total ion counts per unit time due to neutrals from a bovine insulin on nitrocellose were recorded vs. the diameter of a collimating iris with +3kV across the deflector plates. The results are shown in Fig 1. The fraction due to neutrals is indeed decreased with length; however, there is a ten-fold decrease in the intensity of the $(M + H)^+$ ion. Apparently, the insulin ion has a lifetime limitation and/or the ion beam diameter was larger than the detector active diameter. (A einzel focusing lens was employed to control the ion beam diameter but its effect on the very divergent beam off nitrocellulose was marginal at best).

In PDMS the analyte molecule is detected if the corresponding ions obtain sufficient velocity for detection and assume trajectories which intersect the active area of the detector. Thus, the threshold velocity and detection efficiency [4], the characteristic beam diameter [5], and the detector active area are important parameters in the design of a PDMS system for large molecules. Recent work by Geno and Macfarlane [1,4] has yielded a practical model for predicting the detection probability of a given biomolecular ion based on its mass and velocity. Fig 2 illustrates the effect of velocity on detection efficiency. The velocity that an ion attains is a function of its m/z and the total acceleration potential, which is the sum of the primary acceleration and post-acceleration potentials.

For this system, a detector with large active diameter and high of post-acceleration capability is desirable. Because of the relatively divergent ion beam characteristic of the PDMS system, the active diameter of the ion detector must accomodate the beam for optimal sensitivity. The actual diameter of the anode in a commercially-available dual 40mm microchannel detector with a 50 ohm anode is 20mm. (The advantage of the impedance-matched anode over the flat collector with RC "pickoff" circuit is well-known [6].) To aid in the design of such a detector, the ion optics simulation program "SIMION" [7] was employed to optimize the authors' ideas. Two such "SIMION" designs as well as the conventional detector, in which about half of the secondary electrons strike the anode, are included for comparison. Using three microchannel plates (MCP), a detector capable of-10kV post-acceleration voltage was designed (Fig 4), implemented, and tested. (Note that the electrons emitted from the front MCP are focused onto the

center portion of the chevron, thus providing a full 40mm active diameter.) The data set given previously in Fig 2 was acquired using this detector configuration in which the post-acceleration voltage could be varied while maintaining a constant voltage across the front MCP. In spite of the positive results for this novel detector, there are problems with noise and saturation of the chevron which limit its practicality for routine use.

Fig 5 shows a more practical detector with a full 40mm active diameter and a wide range of possible post-acceleration potentials in either polarity. Here, focusing occurs behind the chevron rather than in front as before. This electron focusing chevron detector (EFCD) configuration is similiar to that of Olthoff and Cotter [9] in that it utilizes a ring to focus the electrons onto the conical anode. The present configuration rather unconventionally uses a voltage on the anode in addition to that on the focusing ring. The signal is "picked off" via an R-C circuit(in vacuum and in close proximity to the anode). With the use of 50 ohm coaxial cable and a BNC-to-BNC vacuum signal feedthrough, the signal shape is preserved. The spectra for insulin using the EFCD at two anode voltages (Fig 6) serve demonstrate the focusing action. These results are preliminary - the details and further test results are forthcoming [10].

In summary, this report has reviewed the problem of background in PDMS and the relatively poor detection efficiency of high mass molecules. With these restrictions in mind, various detector configurations, and other hardware features to enhance the sensitivity of ^{252}Cf-PDMS were presented.

USE OF A MICROCHANNEL ARRAY DETECTOR IN A FOUR-SECTOR TANDEM MASS SPECTROMETER

J. A. Hill, S. A. Martin and K. Biemann
Dept. of Chemistry, Mass. Institute of Technology, Cambridge, MA 02139

Mass spectra generated by collision induced dissociation (CID) of a selected precursor ion are characterized by a relatively low ion current but the "chemical noise" observed in normal FAB spectra is absent. Integration of the signal is the best way to increase the sensitivity and to average out the electronic and ion noise. This is best achieved by placing an array detector in the limited focal plane of the spectrometer and recording the spectrum by integrating the ion current of consecutive segments for the proper length of time repeatedly. The data are then assembled to the full spectrum. The array detector can also be used to record a normal FAB spectrum[1] in a similar manner or in the "enhanced resolution mode"[2].

We have constructed an array detector consisting of a 2" microchannel plate and a 2" Reticon photodiode array consisting of 2048 diodes (Fig. 1). It is placed in the focal region of the JEOL HX110/HX110 tandem mass spectrometer, which has a 3" focal plane at an angle of approximately 20° to the incident ion beam[3]. The 2" array covers 6.6% of any given mass range.

The detector can record signals generated in any of three modes: 1) MS/MS (sample in ion source of MS-1), 2) Molecular ion region at "enhanced resolution" (sample in the ion source of MS-1), and 3) Normal FAB or EI spectra (sample in the ion source of MS-2). Because of the high increase of sensitivity, the array detector is particularly useful in the MS/MS mode. Fig. 2 shows the CID spectrum of the $(M+H)^+$ ion of a peptide, Substance P (M_r = 1346.7), 0.2 nmol in glycerol, at an accelerating voltage of 10 kV, the collision cell at 5 kV and recorded with the array detector.

The potential applied to E_2 and the magnetic field B_2 were stepped (by the JEOL DA5000 data system) in such a way that an imaginary ion beam ("center mass") is consecutively focused at the center of the MCP in increments of 6% of mass, to provide some overlap of the consecutive segments. To assure efficient transmission through E_2 of product ions differing in kinetic energy by 6%, the collision has to be carried out after significant deceleration and before reacceleration. For this reason, the collision cell is floated at 5 kV. The spectrum shown in Fig. 2 was recorded in 48 steps to cover the mass range from m/z 68 - 1326. For each step the ion current was integrated for 200 msec repetitively. The photodiode readout (ten 0.2 sec integrations per step) was acquired by a dedicated data system before transfer to a VAX 750 for processing. The center mass and the dispersion of the spectrometer permits conversion to mass and alignment of the consecutive segments to the complete mass spectrum. Figure 3 shows the good signal-to-noise ratio at sample concentrations down to 500 fmol (Fig. 3C).

Resolution of a normal spectrum is considerably increased when using all 4 sectors in the "enhanced resolution" mode[2]. In this mode the focal plane is even further inclined, at an angle of approximately 14° to the incident ion beam[3]. This is one of the reasons why the array detector is designed for changing position and angle without breaking the vacuum. The achieved resolution is evident in Fig. 4, the molecular ion region of glucagon.

TIME RESOLUTION AND MS/MS ANALYSES OF GROUP A STREPTOCOCCUS PYROLYSIS MASS SPECTRA UNDER ATMOSPHERIC PRESSURE IONIZATION

A. Peter Snyder, U.S. Army Chemical Research, Development and Engineering Center, Aberdeen Proving Ground, MD 21010-5423

Willem Windig, GEO-CENTERS, INC., 10903 Indian Head Highway, Ft. Washington, MD 20744

Analysis of macromolecular biological compounds in solid and solution/liquid suspension is of concern to a number of scientific disciplines. Because of their high molecular weight these substances (biopolymers and microorganisms) must be reduced in size so as to form low yet informative molecular weight products for effective mass spectral analysis. Other objectives desired from the sample preparation, processing and data analysis methods are that they are simple, rapid, convenient and produce information that is characteristic to the biological substance whether it be generic or specific in nature. Ribbon oxidative pyrolysis was the method of choice for sample introduction (1) while the Atmospheric Pressure Chemical Ionization (APCI) conditions in the ion source provided attractive benefits to the process. Ramped heating conditions prevailed at 300 °C/min to a final set temperature of 600°, and an air flow of 150 ml/min was directed over the heating zone.

In the interest of rapid data analysis, a univariate method for component deconvolution was developed, called the Scaled-Power-Total Ion Current (SP-TIC). It is approximately 20-100 times faster than multivariate analysis techniques (2) and is highlighted by a minimum of operator interaction. The theory is pictorially represented in Figure 1, and practical application is then applied to a pyrolysis (Py)-APCI-time resolved, mass spectrum (Figure 2) of a Group A Streptococcus strain. Three main components (Figure 3) were isolated with the SP-TIC technique and each main component was observed to consist of a number of individual components.

This distillation of the mass spectral data provided a clearer visual analysis for component identification. Muramic acid is found only in the cell walls of bacteria and its Py-APCI-mass spectrum is shown in Figure 3. The late eluting component C (Figure 4) consisted of a pattern highly similar in m/z and intensity distribution to that of proteinaceous substances. The first component consisted of, among other features, m/z 90 and 108. Daughter ion analysis (Figure 5) confirmed their identities as arising from muramic acid. A similar analysis of m/z 127 (Figure 6) shows that it arises from the thymine (MH^+) base from deoxyribonucleic acid along with a contribution from the hexose sugar components.

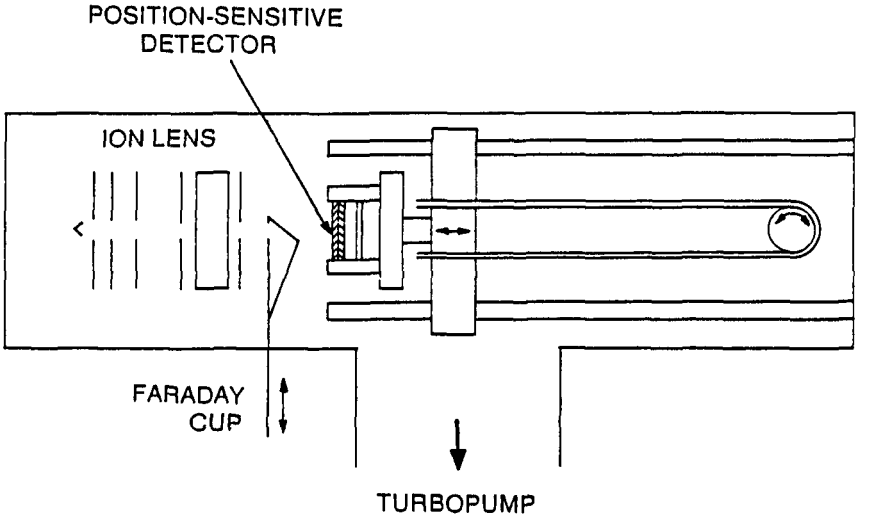
AN ION-OPTICAL BENCH FOR TESTING ION SOURCE LENSES

J. J. Stoffel(s) and D. R. Ells
Pacific Northwest Laboratory
Richland, WA 99352

An ion-optical bench (see figure below) has been designed and constructed to obtain experimental data on the focusing properties of ion lenses in three dimensions. The heart of the apparatus is a position-sensitive detector (PSD) that gives output signals proportional to the x and y positions of each ion impact. The position signals can be displayed on an oscilloscope screen to give a visual picture of the ion beam cross section. The effect of tuning the voltages on the lens plates can be viewed in real time. The position signals can also be analyzed by a two-parameter pulse-height analyzer to give a three-dimensional picture of the ion intensity distribution.

The PSD itself is mounted on a track and is movable during operation from a position following the ion lens to 30 cm away. This enables the rapid collection of accurate data on the intensity distribution and divergence angles of ions leaving the source lens. A movable Faraday cup can be inserted into the beam to measure ion transmission efficiency of the lens.



An example of the measurements that can be made with the ion-optical test bench is given below. The ion lens used is one designed at the National Bureau of Standards [1]. The lens was equipped with a single V-filament surface ionization source loaded with cesium. Ion beam cross sections are shown as they appeared on the oscilloscope screen at different distances from the exit of the lens. From the 'scope photos, we can determine that the beam was diverging in the horizontal plane at an angle of 1.0 degree about the axis. The beam was also brought to a focus in the vertical plane by adjustment of the voltage on vertical focus plates.

This example demonstrates the ease, rapidity and accuracy with which ion beam parameters can be measured. With the ability to show instantaneously the effect of tuning the lens voltages, the ion-optical bench is a powerful tool for electrostatic lens evaluation.

We thank J. D. Fassett for use of the NBS ion lens and voltage divider.

GAS ANALYSIS OF LOW-PRESSURE MERCURY-ARGON DISCHARGE

EDWARD PANG GTE ELECTRICAL PRODUCTS, DANVERS, MA 01923
ARMIN EICH GTE ELECTRICAL PRODUCTS, ERLANGEN, WEST GERMANY

An electric discharge between two electrodes within a glass tube filled with argon (2 ~ 3 torrs) and mercury (3 ~ 5 x 10^{-3} torr) produces UV radiation. It is emitted by excited mercury atoms returning to their ground state. The surplus energy (excited state --> ground state) is released by the atom as UV at 253.7 nm. This radiation strikes special phosphors producing visible radiation. Gaseous impurities can affect the discharge. For example, molecular hydrogen interacts with some meta-stable argon atoms transferring off the excitation energy and then dissociates. Electrons that strike hydrogen molecules lose part of their kinetic energy and are slowed down. As a result, the number and the kinetic energy of the electrons have to be increased to compensate for the loss. Discharges with high and normal operation voltages were monitored using mass spectrometry.

EXPERIMENTAL

The experimental system and the circuit for discharge operation are shown schematically in Figures 1 and 2, respectively. A well-degassed heated stainless steel inlet system was connected to a VG MM14-80 magnetic sector mass spectrometer for analysis. Typical background pressure in the source was about 6 x 10^{-9} torr. The inlet manifold was evacuated to 8 x 10^{-8} torr. Each discharge tube was operated for at least two hours before analysis. High purity argon was used as carrier gas for impurities evolved during operation. m/e = 2, 12, 14, 18, 28, 32, 43, 44 peaks were monitored.

RESULTS

1. Normal discharge tubes showed an operating voltage of 25.0 volts. Discharge tubes with high voltages were operated at 28.0 volts.
2. Mass/Charge = 2, 18, 32, 43, 44 peaks did not change significantly.
3. Typical CO concentration-time profiles are shown in Figure 3.
4. In discharge tubes with normal operating voltage, the average rate of CO evolution was 2.7 x 10^{-9} torr·liter·second^{-1}.
5. In discharge tubes with high operating voltage, the average rate of CO evolution was 67.0 x 10^{-9} torr·liter·second^{-1}.

DISCUSSION

1. This invsetigation strongly suggests that CO evolution is related to increasing operating voltage in low pressure mercury-argon discharge.
2. Excitation of CO molecules to higher vibrational states may low the energy of accelerated electrons in the discharge.
3. The presence of CO may lead to Mercury oxide formation.
4. Possible poisoning of electrodes by CO increases the work function of electron emission.

A SINGLE COLLECTOR MAGNETIC MASS SPECTROMETER FOR RESPIRATORY APPLICATIONS

Rosemarie A. Ungarelli, John L. Lehr, Donald J. Marshall

Boston University, Boston, MA 02215; Brigham and Women's Hospital, Boston, MA 02115; Measurement and Analysis Systems, Inc., Acton, MA 01720

The objective of this project is to adapt a single collector magnetic sector mass spectrometer for respiratory studies. The desired performance characteristics include a time response of less than 100 ms, minimal calibration, a mass range including all normal respiratory gases as well as tracer gases, and a dynamic partial pressure range of 10^5 or greater. Existing respiratory machines include multiple detector magnetic and quadrapole instruments. The single collector magnetic instrument offers advantages of good long term stability, wide dynamic range, continuously selectable mass range, and adjustable resolving power. An interface has been designed to operate a 3 inch, 60 degree Nuclide magnetic instrument with multiple peak stepping among up to five gases (He, N_2, O_2, CO_2, SF_6) by a DEC PDP-11 computer. The system can control the electric and magnetic fields, and can vary electrometer gain in log steps over a range of 10^6. The output of the mass spectrometer is digitized and results are processed on line in real time. The entire operation is well-prompted: the user initiates operation by specifying gases and introducing an appropriate standard mixture containing each of the gases to be analyzed. Thereafter, the instrument selects all parameters, locates the peaks, and determines the required electrometer gains. The system then goes into the automatic analysis mode and cyclically steps through each component of the mixture in 10 ms per gas -- compensating for the response time of the instrument in each gas -- while solving the mixture analysis matrix. For example, the instrument corrects for the contribution of SF_6 to the O_2 peak, as well as for the CO_2 produced by the filament in the presence of O_2 in the analyzer. The automatic gain correction for instrument sensitivity variation is made every cycle, as well. Since the stepping among gases must be as rapid as possible (10 ms), the electric field, rather than the magnetic field, is varied; however, this limits the mass range of the instrument. Hence, in order to read both He and SF_6, SF_6 must be examined as mass 54, the fragment SF_4^{++}, which greatly reduces the sensitivity of the analyzer. Although its output is limited under these conditions, the instrument is still capable of detecting concentrations as low as 0.2% SF_6 with a signal-to-noise ratio of one.

The automatic gain correction adjusts for variations in instrument sensitivity by multiplying the partial pressure of each of the gases by its sensitivity constant, and subtracting the crosstalk effects of the remaining gases in the mixture. The sensitivity constants are derived by summing the partial pressures of the gases and comparing the result to atmospheric pressure. The deviation of the calculated sum from the theoretical sum is denoted by ERROR. A new sensitivity constant is then derived for each gas as:

$$\text{NEW K} = \text{OLD K/ERROR}$$

where OLD K is a pre-determined, measured constant. The automatic gain

correction then adjusts each component of the gas mixture by solving the equation:

$$\text{NEW P} = \text{NEW K}(\text{OLD P} - \text{CROSSTALK})$$

where OLD P represents the partial pressure of the gas prior to the gain correction. The sensitivity constants (NEW K) are updated each complete peak stepping cycle.

The time response of any type of mass spectrometer is a complex function of inlet response, and source, analyzer, and detector response; it is different for every gas. The observed time response of the instrument for each gas is corrected in the time domain using the measured step response of the instrument and classical inverse filtering techniques.* The output data string is derived from the instrument's output using the deconvolution formula:

$$Y(I) = \sum_{j=-m/2}^{m/2} (H(J) \cdot X(I - J))$$

where X(I - J) denotes the mass spectrometer output after correction for the delay, H(J) is the impulse response of the inverse filter of length m, and Y(I) represents the desired deconvolved signal.

The impulse response of the inverse filter is determined by measuring the step response of the instrument and solving the system of equations:

$$Y^T \cdot X = Y^T \cdot Y \cdot H$$

where H is a vector of length m representing the impulse response of the inverse filter, X is a vector of length n representing the step input, and Y is a matrix of dimensions m by n, representing the mass spectrometer step response.

The final data for each of the gases, corrected for response time and instrument sensitivity variations, can be displayed, stored, or output as analog signals.

A Magnetic Field Selector (MFS) for a VG 7070F Double Focussing Mass Spectrometer to enable Multiple Program High Resolution Selected Ion Monitoring (HRSIM).

D. A. Durden
Neuropsychiatric Research Unit, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0

Introduction

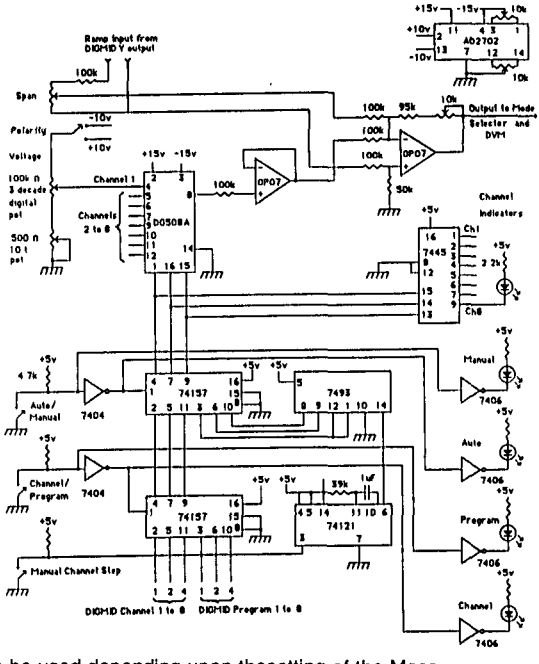
The VG 7070F Mass Spectrometer was designed to be able to perform a wide variety of analyses under both low and high resolution conditions. As with most older double focussing mass spectrometers High Resolution Selected Ion Monitoring (HRSIM) is achieved by changing the Accelerating (V) and Electric Sector field (E) at constant Magnetic Field (B). If a range of ion masses is selected so that a series of compounds can be detected during a GC-MS analysis, the sensitivity of the instrument towards the high masses is reduced drastically due to the reduction of V. If, however, B is changed periodically during the GC run so that the high mass ions are detected at close to the maximum acceleration potential the sensitivity is increased for these ions.

A Magnetic Field Selector unit has been constructed to operate in conjunction with the VG digital multiple ion detector (DIGMID which controls V and E) and the Hall effect field control unit to select up to 8 magnetic fields (B) during the analysis time and enable up to 64 ions to be detected at maximum sensitivity. The operation is similar to a recently reported computer controlled system (1) but is much simpler to construct and allows independent monitoring of the ion masses being detected which can be verified by peak matching.

The system can also be used for Seleced Metastable Peak Monitoring (SMPM) of up to 8 transitions.by controlling B while the DIGMID controls E at constant V.

Instrumentation

The schematic diagram of the MFS is shown in fig 1.The output of a ±10.000V precision voltage source is fed into eight digital pots each of which is in series with an analog ten turn pot. These latter pots permit fine tuning of the mass position during the GC run. The outputs of the digital pots are sampled by an analog multiplexer followed by a low noise amplifier to removes the effect of the "on" resistance of the multiplex gates. The channel voltage is then buffered by a second amplifier which allows a span signal from the DIGMID to be added so that the ion peak can be scanned by B or by E and V. This output is connected to the Mode Selector of the 7070F so that the MFS will control the magnetic field when the settings are LRMID and KV/ESA and the magnet is under Scan control.



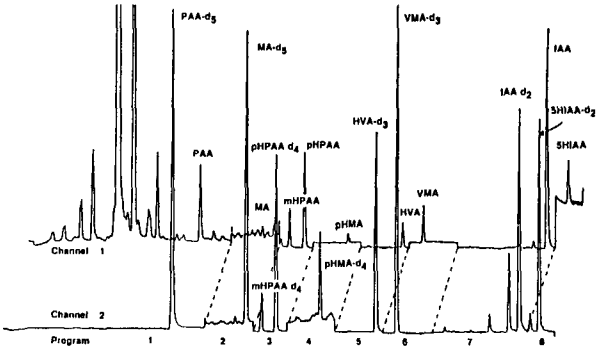
Either current or field control can be used depending upon thesetting of the Mass Indicator Mode switch. The channel of the MFS is controlled by either the Program or Channel number of the DIGMID unit or can be selected manually from the MFS itself.

Program control is used for the HRSIM analyses for which the MFS controls the magnet and the DIGMID controls E and V (at constant E/V ratio).

Channel control is used for (SMPM) for which V is kept constant and the DIGMID controls E alone. The ratio B/E is kept constant by the respective settings of the MFS and DIGMID values. The Mode is set to LRMID and ESA with the magnet under Field control.

Results

The output is very stable and enables operation of the mass spectrometer at resolutions in excess of 10,000. Fig 2 shows the analysis by HRSIM at 5000 resolution of a biological sample, in this case human plasma, for putative neurotransmitter metabolites phenylacetic acid (PAA), mandelic acid (MA), meta and para hydroxyphenylacetic acids (mHPAA and pHPAA), para-hydroxymandelic acid (pHMA), homovanillic acid (HVA), vanilmandelic acid (VMA), indoleacetic acid (IAA) and 5-hydroxyindoleacetic acid (5-HIAA) as either trifluoroethylesters or methyl esters of the acidgroups and pentafluoropropionyl esters of the phenolic and alcoholic groups using deuterated internal standards (3). The ions selected range in mass from 218.0555 to 547.0394 and by grouping them into eight programs with eight reference ions ranging in mass from 213 9903 to 463.9743 (from perfluoro-tri-n-butylamine) it has been possible to keep the mass ratios within 20% of unity.



If the instrument is operated in the original mode using a single mass reference ion a high mass ion such as that of pHMA (m/z 474) looses sensitivity by a factor of about 3 when it is run against a low mass reference ion m/z 214 at an accelerating voltage ratio of 0.45144 (1.81 KV) instead of against a higher mass reference ion such as m/z 464 at a ratio of 0.97881 (3.91 KV). The other limitation of the single reference mass system is the loss of mass spectrometer resolution as the accelerating potential is reduced and the ion beam becomes less precisely focussed.

For SMPM (at constant V) the values of E and B for 6 metastables selected for the compounds mHPAA, pHPAA (same ions), HVA and IAA and for their deuterated isotopomers.may be loaded onto the same DIGMID program. The cycle time of 1 18 sec was considerable greater than the aggregate of the dwell times 0.72 sec due to the magnet settling time and the chromatographic peaks of the eluting compounds were sampled unsatisfactorily If, however, the 8 metastable transitions in pairs (protio and deutero) are put into four programs that change during the GC run, the cycle time is shortened to 0.36 sec for three channels (including a reference mass) and the GC peaks are sampled optimally

THE USE OF CYCLIC NITROBENZAL ACETAL DERIVATIVES IN NEGATIVE ION MASS SPECTROMETRY OF LONG CHAIN 1,2 AND 1,3 DIOLS.

Mallet A.I., Rendell N.B. and Minnikin D.E.*
St Thomas' Hospital, London and
*University of Newcastle on Tyne**, UK.

Sensitive methods for the characterisation and quantitation of diols have been required in our laboratories for two classes of naturally occurring diols. One consists of the family of 1-O-alkyl glycerols produced by degradation of *lyso*-platelet activating factor and the other are the 1,3 diols, phthiocerols, which result when the high molecular weight lipid which is characteristic of the organism *Mycobacterium leprae*, the causative agent of leprosy, is reductively hydrolysed.

This presentation describes preliminary approaches to the production of volatile, stable derivatives which on NICI-MS produce molecular weight information. While a number of methods are available for the derivatisation of each hydroxyl group separately, those giving good NICI signals in the molecular ion region gave molecules with excessively high molecular weights, especially in the case of the phthiocerols. We have examined the production of cyclic benzylidene acetals from these diols and have found these derivatives to be prepared easily and in high yield by the action of a solution of the appropriate aldehyde in toluene together with a trace of p-toluenesulphonic acid as a catalyst. The aldehydes chosen included o-, m- and p-nitrobenzaldehydes and *bis*-trifluoromethylbenzaldehyde. Analyses were carried out on non-polar capillary gc columns interfaced directly to a VG Masslab Ltd Trio-2 quadrupole mass spectrometer operating in NICI mode with methane as the moderating gas.

The meta-nitro derivatives performed consistently worse, in terms of chromatography and mass spectrometric signal, than the ortho- and para-nitro derivatives, but all three gave base peaks of the molecular anion with both families of diols. The bis-trifluoromethyl derivative gave a base peak at m/z 242 ($C_9F_6H_4O$) and a small molecular ion when formed from the alkyl-glycerol. The sensitivities for detection of the derivatives was not better than in the 100 pg range (Figure 1) and this lack of signal would appear to be a result of poor chromatographic performance especially during the 'splitless' mode injection, during which decomposition appears to occur. Figure 2 shows the result of an analysis of the extracted and derivatised products from a sputum sample from a tuberculosis patient. In this disease mycobacteria are also found and these too have phthiocerol containing lipids in their cell envelopes. The trace of the expanded region shows the presence of a n=22 phthiocerol A component (m/z 687).

These derivatives show excellent molecular weight information for the diols examined here and were simple to prepare in good yields. The chromatographic performance was poor and further experimentation is required to optimise this aspect of the method with attention being given to alternative methods of sample injection such as cool, on-column techniques.

QUANTITATIVE DETERMINATION OF FUNGAL STEROLS BY GC-MS-SIM AND ITS APPLICATION TO THE CHEMOTAXONOMY OF DERMATOPHYTES.

A.I. Mallet and S.A. Howell.
St Thomas' Hospital, London U.K.

The dermatophytes are a closely related group of fungi which are responsible for skin and nail infections, including ringworm and athletes' foot. This group consists of three genera, *Trichophyton, Microsporum* and *Epidermophyton* which are currently identified on the basis of morphological criteria. Two other species of fungi which cause infections similar to those produced by dermatophytes, are members of a different taxonomic class and are *Hendersonula toruloidea* and *Scytalidium hyalinum*. Three colonial variants have been described for *H. toruloidea*, on the basis of growth rate and morphological characteristics. We present a study of the sterol composition of these fungi and describe the application of these analyses as a taxonomic tool.

All the fungal cultures were from clinical isolates obtained from within the Institute of Dermatology. Fungi were grown for ten days at 30°C on Sabouraud's dextrose broth. The mycelia were collected and freeze-dried and the sterols were extracted by an alkaline saponification for 2 hours at 60°C. The sterols were derivatised with MTBSTFA in acetonitrile, to produce the tBDMS ethers. Analysis was carried out by SIM of the m/z values expected for the $[M-57]^+$ ions using on-column injection onto capillary columns coupled to the source of a VG Analytical Ltd 305 mass spectrometer. SE-30 stationary phases were employed with temperature gradients, starting at 175° for 2 mins and increasing to 245° at 30°/min and then to 300° at 7°/min. The sterols eluted between 10 and 18 mins. All data was collected by and presented on, a Technivent Data system. Principal component analyses were performed using the SIMCA package (Sepanova AB, Sweden).

It was possible to identify eight sterols on the basis of their mass spectra and by comparison with the GC-MS behaviour of standard sterols. Several other sterol-like substances were observed in the extracts and for the ten ions monitored a total of 80 distinct peaks were observed. While it was possible to identify qualitative differences in the ion chromatograms, for all ten ions and all the genera and species analysed, visual observation was too inexact and a more objective method was sought. This was provided by the use of the SIMCA package, with which principal component analysis and class modelling could be achieved. The height of each peak in the ion chromatograms was corrected for isotopic cross contribution and expressed as a percentage of the total peak heights for each strain. In principal component analysis each measured variable (time resolved, m/z peak height) provides a dimension of comparison with other objects, (in our case fungal strains) and the principal component plot displays two dimensions at a time.

Figure 1 illustrates the ability to distinguish between the three colonial forms of *H. toruloidea* and the *S. hyalinum* isolates. Form 3 strains are clearly separable from the other morphological variants. While two of the *S. hyalinum* isolates appear mixed in panel (i) they can be clearly distinguished on a different plane, panel (ii).

Further analysis was carried out using the class modelling feature of SIMCA. This procedure is illustrated in Figure 2. *H. toruloidea* form 1 is chosen as one class (x-axis) and this is tested for similarity against a second chosen class, in this case *S. hyalinum* expressed as distance between the classes. The diagram records four regions, A contains strains with sterol patterns similar to form 1 isolates and B those similar to *S hyalinum*. Region C would contain strains not identifiable as either and D, those outside the confidence limits. The lines represent 95% confidence limits.

The procedure has proven an effective one for distinguishing fungal strains on the basis of their sterol patterns and is now being applied to studies of the development of resistance to imidazole drugs which are thought to act on sterol synthesis pathways.

HOW PURE IS PURE? THE CERTIFICATION OF SRM 911b CHOLESTEROL

Michael J. Welch, Alex Cohen, and Edward White V
Center for Analytical Chemistry, National Bureau of Standards
Gaithersburg, Maryland 20899

Determination of the purity of an organic compound is frequently not straightforward. The process may involve a variety of analytical techniques, each of which is used to detect and/or quantify impurities in the material. In that sense, it becomes a problem of trace analysis. This paper describes the process involved in certifying the purity of a new batch of cholesterol to be issued as Standard Reference Material (SRM) 911b.

Initial Screening Suppliers of chemicals were contacted to determine if they had high purity cholesterol from a single lot that might be suitable as an SRM. Samples of three candidate materials were obtained and subjected to chemical analysis to identify the purest material.

The materials (X, Y, and Z) were examined by GC, GC/MS, Direct Probe MS, TLC, and UV. When compared to the existing SRM (911a), material Z was clearly inferior; the other two were comparable. Material X appeared to be slightly better and it was examined further. However, when this material was subjected to NMR analysis it was found to contain a significant silicone impurity (probably silicone grease). Thus material X was rejected.

Material Y was then examined further. NMR analysis did not find any silicones. Impurities found by GC/MS appeared to be present at marginally higher levels than in SRM 911a, but the material was judged to be sufficiently pure for the lot to be conditionally accepted as the candidate material. The lot was then vialed (5 grams/bottle) and the vials subjected to further testing.

Testing of the Candidate Material

Direct Probe MS The material was examined by direct probe mass spectrometry as a test for solvents and other volatile impurities. No solvents were detected but evidence was found for the presence of some other steroids in the material.

GC/MS Samples, treated with N,O-bis-trimethylsilylacetamide to convert cholesterol and other steroids to their TMS derivatives, were examined by GC/MS. Low levels of three other steroids were found in the material. The retention times and molecular weights of these impurities were consistent with campesterol (mw 400), sitosterol (mw 414), and 7-dehydrocholesterol (mw 384). Two suspected impurities in cholesterol, cholestanol and lathosterol, were tested for, but were not found. A standard additions experiment using campesterol was performed to estimate the concentration of the impurities that were found. The levels for campesterol, sitosterol, and 7-dehydrocholesterol were estimated to be 0.05%, 0.05%, and 0.03%, respectively.

GC/MS was also used to investigate the vial-vial homogeneity of the candidate material. Samples from seven vials were derivatized and analyzed. The sizes and number of impurity peaks were compared. No significant differences were found. Thus, the material is homogeneous at least with respect to the impurities detected by GC/MS.

ID/MS Samples of the candidate material and SRM 911a were spiked with a solution of cholesterol-$^{13}C_3$ and their isotopic ratios carefully measured by our ID/MS definitive method for cholesterol. No significant differences were found, but differences of <0.1% probably would not be detected by this technique.

Infrared Spectra IR spectrum of the candidate material in Nujol was not significantly different from that of SRM 911a.

Thin-layer Chromatography TLC of both the candidate material and SRM 911a found traces of three impurities and these had the same rf values for both materials.

Differential Scanning Calorimetry DSC analysis of the candidate material found a total impurity of 0.095 ± 0.039 mole % compared with 0.150 ± 0.035 mole % for SRM 911a. This technique measures impurities which are soluble in the melt but insoluble in the crystalline material. This was the only case where the candidate material was found to be purer than SRM 911a.

Melting Point Candidate material melted at 149.0-149.2 °C. compared with SRM 911a which melted at 149.0-149.1 °C.

Insoluble Matter Chloroform solutions of the candidate material were filtered through a preweighed teflon membrane (0.5 um porosity), yielding an average increase in weight of the membrane corresponding to 0.036% of the weight of cholesterol. Filtering solutions through porcelain crucibles (1.5 um porosity) yielded an average of 0.017%. The former is probably high because cholesterol was detected on the membrane after filtering; the latter is probably low because of the large pore size.

Volatiles Weight loss for samples of the candidate material heated at 60° in vacuum were 0.020%, identical to the losses measured for SRM 911a.

Total Ash Content Two 3 gram samples of the candidate material were heated in a muffle furnace, yielding ash weights of 0.0048 and 0.0061%.

Halogens Neutron activation analysis was used to determine the chlorine, bromine, and iodine in the candidate material. The average results for two samples were: 6 ppm, 38 ppm, and <0.1 ppm for chlorine, bromine, and iodine, respectively. For SRM 911a the results were 7 ppm, 12 ppm, and <0.1 ppm. Traces of sodium and manganese were also observed, but zinc, which is used in the purification of cholesterol, was not found.

The form of the halogens affects their contribution to the weight of impurities. If they are predominantly in the form of sodium halides, the total impurity (NaCl + NaBr) would be 59 ppm or 0.006%. In contrast if the form is cholesteryl halides the total would be 280 ppm or 0.028%. These two cases represent the extremes among the reasonable possibilities for the halide forms.

Ultraviolet Spectra Four maxima from 296-350 nm were found in the UV spectrum of a 4% solution of the candidate material in CH_2Cl_2. The peak at 296 nm is probably from the 7-dehydrocholesterol believed to be present at about 0.03%. The other peaks are probably from some impurities with longer conjugated pi systems, possibly including a triene.

Conclusion We evaluated the data to determine reasonable upper and lower limits for the total impurity The lower limit is set by the DSC data and is 0.1%. The upper limit is from the sum of the GC/MS, halide, volatiles, ash, and insolubles data and is 0.3%. The DSC data is probably low because certain types of impurities will not be detected. The upper limit is probably high because some of the impurities probably contribute to more than one analysis. We therefore believe the best estimate of the total impurity is 0.2 ± 0.1 %, identical to the certified level of impurity for SRM 911a.

INTRODUCTION

Platelet Activating Factor (PAF) is a potent mediator of biological activity. PAF has been implicated in the onset of several physiological disorders including inflammation, asthma and shock. Work in our laboratory on the mechanism and treatment of septic shock led to the belief that PAF could play a major role in its development. In order to test this hypothesis an accurate, sensitive and reproducible method was needed to quantitate PAF. Recently several analytical methods have been reported with the apparent sensitivity needed for such a potent compound. However, these methods include the degradation of the parent compound to a molecule that is amenable for derivatization and GC/MS analysis. This process requires that the sample be highly purified in order to obtain artifact free results. Thus the multiple purification, degradation and derivatization steps required for the existing methods make them cumbersome for large scale animal or clinical studies.

OBJECTIVES

Develop a simple, fast and reliable method to quantitate PAF and eventually lyso-PAF from biological matrixes. Develop a method which does not require that the parent compound be purified, degraded and derivatized before analysis. Develop a method with a limit of detection (LOD) of approximately 10 femtomoles per sample.

MATERIALS AND METHODS

PAF was purchased from Sigma Chemical Company as the product isolated from natural sources. Deuterated PAF was synthesized by the reaction of lyso-PAF (Sigma) and d6-acetic anhydride (MSD Isotopes). Although several FAB matrixes were utilized the optimum results were obtained with a 1:1:1 mixture of methanol:glycerol:thioglycerol. Standard curves were prepared by adding a fixed volume of d3-PAF in the matrix to varying concentrations of d0-PAF in the matrix. Final concentrations were 50pg/µl d3-PAF and 5,10,50,100,500 pg/µl of d0-PAF. Clinical samples of puss fluid were extracted utilizing Bley and Drier conditions, chromatographed on TLC plates and the PAF band extracted with a 1:1 mixture of methanol:chloroform. These samples were dried under a stream of nitrogen and resuspended in a minimum volume of the matrix just before the analysis.

INSTRUMENTATION

Experiments were conducted on three different instruments: 1) The Kratos MS-890 was located at the Idaho Nuclear Engineering Laboratory in Idaho Falls, ID. The instrument's accelerating potential was set at 6 keV and Xenon was used as the FAB gas. Data was collected and analyzed utilizing the DS-90 data system. 2) The VG-70SQ was located at the Burroughs Wellcome Research Laboratories in Research Triangle Park, NC. This instrument's accelerating potential was set at 8 keV and Xenon was used as the FAB gas. During the MS/MS experiments the collision energy was set at approximately 25 volts and the collision gas was Argon (when used). Data was collected and analyzed utilizing the VG-250 data system. 3) The VG-70SEQ was located in the Dept. of Med. Chem., Univ. of Wash., Seattle, WA. Operating parameters were the same as those given for the VG-70SQ above.

All the instruments were calibrated using CeI clusters in positive ion FAB mode with the resolution nominally set at 1000. The MS/MS experiments were conducted with and without collision gases (collision induced decompositions, CID and unimolecular decompositions).

Results

Initial attempts to quantitate PAF by FAB/MS utilizing either selected ion monitoring or narrow scan mode found limits of detection in the range of 1-10ng applied to the probe. These limits were only marginally affected by the type of FAB matrix employed. A variety of matrixes were utilized including triethanolamine, glycerol, 'magic bullet', glycerol:thioglycerol and phosphoric acid. A 1:1:1 mixture of methanol:glycerol:thioglycerol was judged superior based on its apparent increased ability to solvate PAF. However, analysis of the full scan FAB spectra of PAF revealed that two ions were predominate in all matrixes. These were the M+H of the parent compound and a 184 fragment ion which was the base peak. The structure of the 184 fragment ion has been assigned as the protonated phosphocholine head group. In addition these full scan FAB spectra demonstrated a great deal of the usual back-ground or 'grass' noise. Thus, to take advantage of this facile fragmentation pathway and to increase the methods sensitivity by eliminating the FAB background, FAB/MS/MS was attempted. Initially, we choose to look at the full scan daughter ions of the M+H parent ion. These experiments indicated that a recognizable spectra could be achieved with as little as 2 pg of PAF loaded onto the FAB probe. Although results could be obtained in MS/MS mode under unimolecular decomposition conditions, the quantity of the 184 ion increased by more than an order of magnitude when a collision gas was introduced into the RF only quadrupole region. Therefore the CID conditions were chosen for most of the succeeding studies.

A deuterated internal standard was synthesized from lyso-PAF and d_6 acetic anhydride. The full scan FAB spectra of this compound displayed the expected plus three M+H ion, but the daughter ion was 185, indicating a shift of a deuterium from the acetate to the phosphocholine group during fragmentation. Therefore by alternately monitoring the 524->184 and the 527->185 decompositions in Multiple Reaction Monitoring (MRM) mode we are able to quantitate PAF at the 5 pg level. The standard curves were linear as long as the concentration of the internal standard did not exceed 10 times that of the unlabeled compound.

Preliminary, analysis of puss fluid extracts from patients with active bacterial infections exhibited levels of 0-5pg/100ul of PAF. With future studies we hope to better characterize and validate the method as well as add lyso-PAF to the list of compounds quantitated.

Conclusions

Based on these results, we can make the following preliminary conclusions: 1) that PAF can be quantitated to the low pg level without extensive purification and degradation; 2) that FAB can be a sensitive analytical technique if the background can be eliminated; and, that the fragmentation of PAF to the 184 daughter ion involves the transfer of a proton from the acetate group.

MASS SPECTROMETRIC DETERMINATION OF PLATELET-ACTIVATING FACTOR FROM HUMAN SUBJECTS

Kiyoshi SATOUCHI, Makoto ODA* and Kunihiko SAITO

Department of Medical Chemistry
Kansai Medical School, Moriguchi, Osaka 570, JAPAN

Platelet-activating factor (PAF) is now recognized as one of the most potent chemical mediators of allergy and inflammation (Fig. 1). In fact, evidences are now accumulating that drugs affecting the PAF action have a potential as a therapeutic agent in the fields of anaphylatic and endotoxin shocks (1).

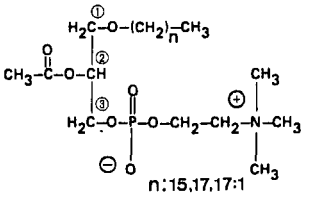

Fig. 1 The chemical structure of PAF

For evaluating PAF role in the disease process, it is essential to detect and quantitate PAF exactly. However, the concentration of PAF in the body is extremely low, and the available volume of blood or body fluid from patient is limited. Furthermore, there is a system in our body to quickly metabolize newly-synthesized PAF into an inactive form (2). For above reason, PAF detection from patients has been hampered.

We have applied a gas chromatography/electron impact selected ion monitoring (GC/EISIM) technique to PAF determination using a stable isotope labelled internal standard and tert-butyldimethylsilyl derivative. Recently, Ramesha and Pickett have also developed a gas chromatography/negative ion chemical ionization selected ion monitoring (GC/NICISIM) technique using pentafluorobenzoyl derivative. These mass spectrometric methods are now useful as a strategy of PAF determination because of their high specificity and sensitivity (3).

We have examined PAF activity of various body fluids, such as pleural effusions, bronchoalveolar lavage fluid, middle ear effusion and so on. However, as stressed above, the volumes of these fluids from patients were limited. Accordingly, PAF was detected on the basis of its ability to cause the immediate aggregation of washed rabbit platelets, and identified on the bases of its behaviors on thin-layer chromatography and against the pretreatment of platelets with the specific PAF antagonists, CV-3988 and L-652, 731 (4). Detection and identification of PAF in brochoalveolar lavage fluid from asthmatic patient is shown (Fig. 2)

Among the body fluids, pyothorax, an infectious lung disease with abscess, was further subjected to PAF assay by GC/EISIM technique

By the monitoring at m/z 117, the ion due to acetic acid, and the comparison of retention times on GC with standards, PAF and acyl-form PAF were detected. By the calculation using internal standards, major species were 16:0 in chain length in both PAF and acyl-form PAF, and the content of 1-hexadecyl-2-acetyl-sn-glycero-3-phosphocholine was 10 times more abundant than that of 1-palmitoyl-2-acetyl-sn-glycero-3-phosphocholine.

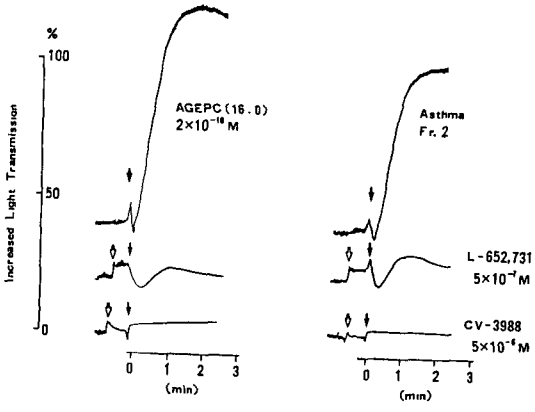

Fig. 2 The identification of PAF in BALF from asthmatic patient

By bioassay, PAF can be detected as little as picogram quantity. Furthermore, specific receptor antagonist to PAF molecule is now available. Accordingly, identification and determination of PAF are easily attainable. However, it is recently known that substantial amount of acyl-form PAF produced concomitantly with PAF. Unfortunately, acyl-form PAF has nearly negligible activity of platelet activation compared with that of PAF. This indicate the limitation of bioassay.

In contrast, SIM technique can achieve the separate quantitation of PAF and acyl-form PAF. In the present experiment of pyothorax, PAF and one-tenth amount of acyl-form PAF were detected. Human neutrophil produce PAF and one-fifth amount of acyl-form PAF when stimulated with calcium ionophore A23187 (5). Pyothorax is an infectious disease, characterized by the infiltration of neutrophils. Taken together, it is suggested that neutrophil is the origin of PAF detected.

Only SIM technique, information above can be gained. GC/SIM coupled with capillary GC will prove to improve the sensitivity. Another approach to improve the sensitivity in the mass region is to apply high resolution MS or tandem MS.

In any event, PAF detected by bioassay shoud be subjected to SIM assay. If not, we can not have any information other than that PAF is there.

MASS SPECTROMETRIC ANALYSIS OF PLATELET ACTIVATING FACTOR (PAF) IN MOUSE URINE.

Benfenati E., Bettazzoli L., Davoli E., Gavinelli M., Macconi D., Noris M.
Istituto Mario Negri,24100 Bergamo and 20157 Milano Italy

INTRODUCTION

PAF is a phospholipid mediator of inflammatory reactions which has been recently suggested to play a role in immune glomerulonephritis. Given its short plasma half-life, PAF measurement in the urine is likely to reflect events taking place in the kidney. Thus, we have developed a GC-MS quantitative method for PAF analysis in mouse urine which will allow to evaluate the role of this autacoid in immune injury.

EXPERIMENTAL

Chemicals

- PAF C 16 : 0	1-O-hexadecyl-2-O-acetyl-sn-glycero–3-phosphocholine
- PAF d_3	1-O-hexadecyl-2-O-acetyl-d_3-sn-glycero-3-phosphocholine
- ALP	1-O-octadecyl-2-O-methyl-glycero-3-phosphocholine

Preparation of deuterated PAF
1.5 mg of lyso-PAF was added with 200 µl of acetic anhydride-d_6 and heated at 80° C for 3 h. The purity of PAF d_3 was checked with TLC, GC-MS and FAB-MS.

Animals
Female Crl:CD-1 (ICR) BR mice had free access to standard diet and water. The animals were housed in metabolic cages that allowed collection of the 24 h urine sample.

Extraction of urine
24 h urine samples were added with internal standard (20 ng of PAF d_3 or 5 ng of ALP) and methanol to a final rate of 3:2 CH_3OH/urine. After gentle mixing for 30', the samples were centrifuged. Chloroform and water were added to the supernatant to obtain a solvent mixture containing chloroform, methanol and water (1:1:0.9 vol/vol). The chloroform layer was removed and evaporated under N_2.

Silicic acid column
The extract was applied to a silicic acid column (0.5 g) and eluted using a sequential solvent system of chloroform, acetone, acetone/methanol (1:1), chloroform/methanol (1:4). The fourth fraction containing PAF was evaporated under nitrogen.

Hydrolysis and derivatization
Purified samples were treated with 0.2 ml of 50% HF at room temperature for 4 h. Hydrolized PAF was extracted twice with 0.5 ml of hexane. After removing the solvent under N2 , 50 µl of PFBCl were added to each sample. The system

was heated at 100° C for 40'. The exceeding reagent was removed and the residue was dissolved in iso-octane for GC-MS analysis.

Mass spectrometry

GC-MS analyses were carried out on a VG 70-250 mass spectrometer coupled to a DANI 6500 gas chromatography . A silica capillary column CPSil 25 m 0.32 mm I.D. was used . Oven temperature was: 140° C isothermal for 1.3 min; then programmed from 140° to 280° C , 18°C min. For chemical ionization ammonia was used as reagent gas. SIR analyses were done on derivatized samples , monitoring the ions at m/z 552 for PAF and ALP, and 555 for PAF-d_3.

RESULTS AND CONCLUSION

SIR traces of PAF in mouse urines are shown in figures 1-2. In both cases PAF produced two separated peaks with a characteristic shape and relative intensity ; this contributed, with masses and retention time, to the identification of the compound .

The same chromatographic pattern appeared for the PAF-d_3 too. Calibration curves using PAF-d_3 (400 pg) was linear from 2 to 800 pg (fig. 3). A similar linearity was found for the curve built with ALP (data not shown) .

PAF excretion in 24 h fresh urine samples, measured by GC-MS using two different internal standards, PAF-d_3 and ALP, was comparable (2.81 ± 1.25 ng and 3.60 ± 0.84 ng respectively) . Similarly no significant difference was found in frozen samples (3.69 ± 2.15 ng).

In conclusion we developed an analytical method useful for quantitation of PAF in urines that represents the first quantification of PAF in urine using GC-MS.. The method appears selective and sensitive, able to quantify very low amounts of PAF. This technique will be used to investigate the biological origin of PAF in urine and its significance in different models of disease.

Quantitative analysis of Lysophosphatidylserine (LPS) by FAB-MS

Benfenati E., Bettazzoli L., Chen S., De Bellis G., Fanelli R. and Pege G.°

Istituto Mario Negri, 24100 Bergamo and 20157 Milano, Italy
°Fidia Research Laboratories, 35051 Abano Terme, Padova, Italy

Since it first appeared, FAB has been used to study phospholipids (PL), a class of biomolecules of fundamental importance. A review on PL analysis with FAB and other ionization techniques recently appeared (1). However quantitative studies of these substances by FAB are scant; other methods routinely used to quantify PL are old and require many steps.
LPS is difficult to be analyzed using usual methods; nevertheless it could be of particular biological importance. Extending our work on PL analysis by FAB (2-4) we present here a method for quantifying LPS by negative FAB in biological samples (rat brain).
We used a VG 70-250 mass spectrometer with its standard FAB source and target, and Xenon accelerated at 8kV as bombarding gas. Quantitative measurements were done scanning from m/z 450 to m/z 600 at scan speed of 4 sec/decade. The samples were dissolved in $CHCl_3$ / MeOH / H_2O (10:1:0.1) and deposited on a surface of diethanolamine (DEA), used as liquid matrix. This solvent/matrix pair gave good sensitivity. It is important not to mix the sample with the matrix. This technique is similar to the "surface precipitation" technique and has provided good results for other PL (4).
Since in FAB spectra of rat brain, the biological material of our interest, we didn't detect ions corresponding to LPS 16:0, we used this as internal standard. The standard LPS was obtained from PS (bovine brain) treated with phospholipase A_2. This class is mainly LPS 18:0, no significant peak corresponding to LPS 16:0 appeared. The standard curve was prepared adding a constant amount of LPS 16:0 (250 ng) to varying amount of LPS standard (10,20,50,100,250,500,1000 ng). Scans (at least 40) were acquired and peak intensity of $(M-H)^-$ ions, m/z 524 (18:0) and 496 (16:0), were recorded by usual scan mode. The average value over 25 scans (from scan 5 to 30) of absolute peaks height were used to design the curve. We obtained stable ion current and constant intensity ratio. The standard curve was linear with a correlation coefficient (squared) of 0.999 from 10 to 1000 ng. This curve was used for the quantification of LPS in rat brain; in particular we extracted cortex (40 mg) according to Bligh and Dyer (5) after addition of 25 µg of LPS 16:0. After purification on TLC analysis has been performed as above described. The quantity of LPS 18:0 in cortex of rat brain is 475 (+/-40) ng / mg of cortex. This value is very close to that obtained using phosphorus assay (597 (+/-79) ng / mg of cortex).
A major difference between the two methods is that in our experience N-FAB MS analysis is at least 50 times more sensitive than phosphorus assay.
In conclusion we provided an effective analytical method for LPS quantification by N-FAB MS. This method appears to be more sensitive than the ones currently available and provide also informations on the fatty acid chains present in the molecule.

CHARACTERIZATION OF EPOXIDES OF UNSATUTRATED FATTY ACIDS BY MASS SPECTROMETRY VIA PICOLINYL ESTERS

M. BALAZY AND A.S. NIES
Division of Clinical Pharmacology, University of Colorado, HSC
Denver, CO 80262

INTRODUCTION

The goal of this poster is to describe a convenient gas chromatographic-mass spectrometric method for qualitative analysis of regioisomeric epoxides of unsaturated fatty acids. These epoxides are products of cytochrome P-450 monooxygenase mediated metabolism and are found in incubates from hepatic or renal microsomal preparations stimulated with NADPH. Linoleate epoxides are found in leukocytes from hyperoxic lung. Epoxyeicosatrienoic acids (EET) also occur in human urine and in phospholipids of rat liver and rabbit kidney. Human platelets convert arachidonoylphosphatidylinositol into 14,15-EET.

Epoxyeicosatrienoic acids are potent mediators of diverse biological activities including for example inhibition of platelet aggregation and cyclooxygenase activity, and inhibition of vasopressin stimulated osmotic water flow. EETs are also involved in the release of somatostatin, leutinizing hormone, insulin and glucagon. Microsomal calcium mobilization as well as ion transport in the rabbit cortical collecting tubule are also believed to be altered by arachidonic acid epoxides. These epoxy acids can be succesfully analysed by GC/MS as methyl or pentafluorobenzyl esters but these derivatives do not easily distinguish between regioisomers.

We report here a rapid and mild procedure for the synthesis of picolinyl (with 3-pyridylcarbinol) esters of fatty acid epoxides. These esters had characteristic mass spectra and allowed differentiation between isomeric epoxides at the nanogram level. The picolinyl esters were previously applied to GC/MS analysis of fatty acids (D.J. Harvey, Biomed. Mass Spectrom. 9, 33, 1984) and presented here method extends the application of this unique derivative in GC/MS to another group of compounds, e.g. epoxides of unsaturated fatty acids.

METHODS

Epoxides were prepared by the reaction of metachloroperbenzoic acid (MCPBA) with linoleic, arachidonic and docosahexaenoic acids as described (Chung and Scott: Tetrahedron Lett. 35, 3023, 1974).

SP-HPLC: column: Altex Ultrasphere Si 250*4.6 mm, 5um; solvent: hexane/isopropanol/acetic acid (500:0.5:0.25) isocratic 15 min then isopropanol increased to 50% in 15 min; flow: 1 mL/min; detection: UV at 200 nm with Waters HPLC system.

Derivatization: To 0.15-1.5 nmol (50-500 ng) of epoxide dissolved in 100 uL of methylene chloride 10 uL of 1,1'-carbonyldiimidazole solution (50 ug/mL) was added and after 1 min 10 uL of 1% 3-pyridylcarbinol (Aldrich) solution was added along with 10 uL of triethylamine. After 10 min at room temperature the solvents were evaporated and the residue dissolved in hexane/ethyl acetate (3:1) and chromatographed on silica. The yield was quantitative based on the recovery of radioactive arachidonate epoxides.

Rat liver microsomes isolation and incubations were performed as described (Oliw, Guengerich, and Oates, J. Biol. Chem. 257, 3771, 1984). The incubate was subjected to TLC and SP-HPLC, and fractions containing epoxides (E1 to E4) were derivatized as described above.

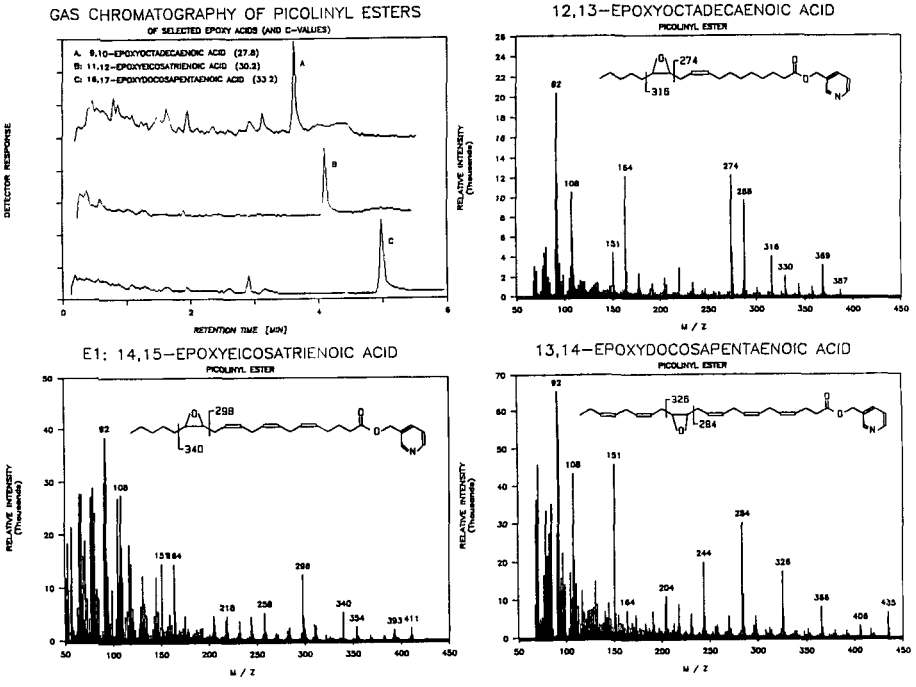
June 5-10, 1988, San Francisco, CA

Gas chromatography-mass spectrometry: 15 m DB-1+ column was temperature programmed from 200 deg C at 15 deg min-1. Injections were made with solvent-less injector. Mass spectra were recorded with VG 7070H spectrometer interfaced to a Teknivent data system. Operating conditions were: electron energy, 70 eV; trap current, 200 uA; accelerating voltage 4 kV, scan 2s per decade-1, exponential.



CONCLUSIONS

1. Mass spectra of picolinyl derivatives of epoxides of linoleic, arachidonic and docosahexaenoic acids showed two characteristic abundant ions produced by formal cleavage of alfa carbon bonds at oxirane ring and were therefore characteristic for each regioisomer studied providing easy and sensitive way of differentiating between them.

2. The spectra not only provided the information about the position of the epoxy group, but also the position of double bonds in the unsaturated chain can be concluded.

3. Other nitrogen containing esters, e.g. N,N-dimethylaminoethyl 3-pyridyl were studied but their spectra were not as characteristic as picolinyl derivatives.

4. Described here method can be appplied to the analysis of epoxides extracted from biological fluids.

STRUCTURAL ELUCIDATION OF CAROTENOID PIGMENTS BY FAB-CAD-MS/MS

Douglas A. Gage, Chris Rock, Jan A D. Zeevaart and J.T. Watson
Michigan State University, East Lansing, Michigan 48824

INTRODUCTION

EIMS has played an important role in the structural elucidation of carotenoid pigments (1, 2, 4, 5). Fragmentation pathways have been determined which provide information on substitution pattern in both the end groups and polyene chain (1, 2, 4, 5). However, because carotenoids are thermally unstable, reproducible EI spectra are difficult to obtain. Factors such as probe temperature, heating rate and position, as well as source temperature and pressure can dramatically affect the spectra obtained (5). Furthermore, EI spectra of carotenoids are often contaminated with ions from pyrolysis products produced during sample volatilization. Metastable analysis techniques (linked scans at constant B/E) have been applied to eliminate some of these problems (3, 4). Structurally significant ions have been observed in the daughter ion spectra of the $M^{+\bullet}$ decomposition, but these ions are rarely seen more than about 230 mass units below the $M^{+\bullet}$ ion. Other diagnostic ions found at lower m/z values are not observed.

Recently, the positive FAB mass spectrum of ß-carotene in 3-nitrobenzyl alcohol (with trichlorobenzene as a cosolvent) was reported (6). A strong $M^{+\bullet}$ ion was observed, instead of an $[M+H]^+$ ion Few fragment ions were present in the spectrum.

We have examined a series of oxygenated carotenoid pigments by positive FAB CAD MS/MS of the $M^{+\bullet}$ ion using linked scans at constant B/E to increase the amount of fragmentation in the spectrum

RESULTS AND DISCUSSION

All carotenoid compounds examined to date produce a dominant $M^{+\bullet}$ ion, rather than $[M+H]^+$, in FABMS when using 3-nitrobenzyl alcohol as the matrix. In glycerol, however, the more typical $[M+H]^+$ ion is dominant. Using the strong $M^{+\bullet}$ ion as the parent ion, the CAD MS/MS spectra of violaxanthin, lutein and neoxanthin contain fragments which are structurally diagnostic. Most of the fragment ions observed in these spectra are also found in the EI spectra of these compounds (1) It is possible to distinguish the two isomeric compounds violaxanthin and neoxanthin by their FAB CAD MS/MS spectra.

The CAD MS/MS technique was also useful in determining the structure of an unusual violaxanthin ester. The shift of several key end group containing fragments in the CAD MS/MS spectrum clearly showed that the new compound is a C_{14} fatty acid ester of violaxanthin (violaxanthin myristate). This was confirmed by hydrolysis and CAD MS/MS and VIS spectroscopy of the carotenoid product.

Several fragment ions are observed in the FAB CAD MS/MS spectra of these compounds which are not present in their EI spectra. For example, in the spectrum of violaxanthin one such prominent ion is seen at m/z 446. This ion shifts to m/z 488 in the spectrum of the monoacetate of violaxanthin, and to m/z 530 in the spectrum of its diacetate. These results suggest the unknown fragment contains both end groups of the molecule. An unknown ion at m/z 526 in the spectrum of violaxanthin myristate cannot be easily related to the ion at m/z 446 in the CAD MS/MS spectrum of violaxanthin At present, the structures of these ions remain unclear.

CONCLUSIONS

Positive FAB CAD MS/MS of the molecular ion of carotenoids is a convenient method to obtain structurally significant fragment ions. The spectra are easy to acquire and are reproducible. This is an important advantage over EIMS All of the diagnostic fragment ions found in the EI spectra of these compounds are also observed inthe FAB CAD MS/MS spectra. However, a few prominent, as yet unidentified, fragment ions are seen in the CAD MS/MS spectra that are not found in the EI spectra of these compounds. Some preliminary evidence suggests that at least one of these fragments contains both end groups of the compound. Additional studies with isotope labelled carotenoids will be required to determine the structure of these unknown ions

EXPERIMENTAL

Carotenoids: Compounds were isolated from fresh roots of *Xanthium strumarium* by extraction with methanol Extracts were partitioned into diethyl ether after dilution with aq 10% NaCl. Carotenoids were purified from the root extracts by semiprep normal phase HPLC using a hexane-ethyl acetate gradient. FAB CAD MS/MS: Carotenoid solution in methanol (1-10 nmol/µl) was mixed with 2 µl of matrix (3-nitrobenzyl alcohol) on the FAB probe tip. The precursor ions ($M^{+\bullet}$) were formed by fast atom bombardment using 6 keV Xe atoms in a JEOL HX 110 double focussing mass spectrometer. The accelerating voltage was 10 kV and the resolving power was 1000. Helium was used as the collision gas in a cell located in the first field free region. The helium pressure was adjusted to reduce the abundance of the precursor ion ($[M]^{+\bullet}$) by 50% A JEOL DA-5000 data system generated a linked scan at constant B/E. The data profiles were acquired at 30 sec/decade. The spectra shown were produced from a single scan.

QUANTITATIVE ANALYSIS OF PLATELET ACTIVATING FACTOR BY TANDEM MASS SPECTROMETRY. Peter E.Haroldsen and Simon J. Gaskell, Center for Experimental Therapeutics, Baylor College of Medicine, Houston, Texas 77030

Platelet activating factor (PAF) is a unique biologically active phospholipid (1-0-alkyl-2-acetyl-sn-3-glycerophosphocholine) synthesized from cellular lipid stores and implicated as an important mediator of inflammatory reactions. The detection and quantitation of PAF is of great importance to gain a better understanding of inflammatory events and for potential pharmacologic intervention. Various physiochemical techniques have been used to analyze PAF (1) and have relied upon scrupulous purification procedures as well as molecular alteration and derivatization. Tandem MS analysis of individual components in complex mixtures can be achieved with retention of a high degree of selectivity and specificity often obviating the need for extensive purification. Here we report the use of a hybrid instrument of BEqQ design (VG-ZAB-SEQ)to detect and quantitate biologically derived PAF by parent ion scanning.

In common with other phosphatidylcholine molecular species, PAF fragments to produce a protonated choline phosphoester (m/z=184) in the source, as a metastable transition or under CAD conditions with FAB ionization. CAD analyses were performed on MH^+ ions using argon as collision gas in the first quadrupole (q, rf only) employing the second quadrupole filter (Q) for daughter ion separation. Daughter ion spectra of authentic standards of hexadecyl (C16:0) PAF and its trideutero analog ($^2H_3$-acetyl) contained one major ion at m/z=184 and 185, respectively. The 1 amu shift observed for $^2H_3$-PAF indicates a rearrangement process involving one of the acetate methyl hydrogens upon formation of the phosphocholine fragment. A high conversion of PAF parent ions to a single daughter ion in q (representing up to 16% of the ion intensity at BE) is observed suggesting that PAF can be detected and quantitated based on selected reaction monitoring of parent ions → daughter ion (parent ion scanning). For quantitation, dual reaction monitoring was performed to detect both PAF and $^2H_3$-PAF internal standard (IS) by alternate switching of the Q mass filter to transmit m/z=184 or 185 during repetitive magnet scans. This technique is sufficiently sensitive to allow detection of <100pg of a C16:0 PAF standard on probe (S/N=10/1).

The application of this methodology to the analysis of biologic samples has been made using Ficoll-HyPaque purified human neutrophils. Cells were incubated with (stimulated) or without (control) 10μm calcium ionophore (37°, 20 min) and lipids extracted (chloroform/methanol/water). Lipid classes were initially separated by open column chromatography (aminopropyl Bond Elut). PAF was purified from other phospholipids by TLC (2). Analysis of a biological sample derived from stimulated neutrophils by parent ion scanning indicates the presence of both C16:0 PAF and IS (Fig. 1). Measurement of ion ratios in conjunction with a standard curve indicated the levels of PAF in stimulated cells to be 75-169 ng per 10^7 cells and nondetectable in controls. Other PAF species, (C18:0, C18:1) were detected representing < 5% of the major C16:0 PAF species. Comparison of the parent ion scan of biologically derived PAF (Fig. 1) with that of the same sample analyzed by a conventional mass scan (Fig. 2) can be made. A significantly increased signal to noise ratio is observed with parent ion scanning. A lack of matrix ions results in a 20 fold increased signal to noise response and greatly improved sensitivity. The results of this study demonstrate tandem mass spectrometry to be well suited to the detection and quantitation of the inflammatory lipid mediator PAF.

A COMPARISON OF PROSTAGLANDIN LEVELS IN HUMAN AND RHESUS MONKEY CEREBROSPINAL FLUID:

James A. Yergey, Norman Salem, Jr., John W. Karanian, Markku Linnoila, Laboratory of Clinical Studies, DICBR, NIAAA, Bethesda, MD 20892, and Melvyn P. Heyes, Laboratory of Neurophysiology, NIMH, Bethesda, MD 20892.

INTRODUCTION:

The ability of central nervous system tissue to produce prostaglandins (PG) *in-vitro* has been known for quite some time, and they appear to be involved in many brain functions. It has been assumed that measurement of PG in cerebrospinal fluid (CSF) are indicative of their brain production, although there have been disparate results for PG concentrations in the CSF of healthy human volunteers. Literature values range from undetectable (e.g. < 10 pg/mL CSF) to as much as 1 ng/mL CSF. We have developed an assay based on the selected-ion-monitoring, negative chemical ionization GC/MS detection of the MO-PFB-TMS derivative of prostaglandins E_2, E_1, $F_{2\alpha}$, $F_{1\alpha}$, and 6-keto-$F_{1\alpha}$. This assay has been used to measure PG concentrations in lumbar CSF of healthy human volunteers and abstinent alcoholic patients, cisternal CSF of Rhesus monkeys, and in continuously sampled lumbar CSF of awake Rhesus monkeys.

METHODS:

Sampling: Human lumbar CSF samples were drawn on ice and the 22-23 mL of a 30 mL tap was transferred to a tube containing tetradeuterated internal standards ($^2H_4$-PGE_2, $^2H_4$-$PGF_{2\alpha}$, and $^2H_4$-6-keto-$PGF_{1\alpha}$). Initially, sampling tubes contained indomethacin to inhibit PG formation, however, this was found to be unnecessary. Rhesus monkey CSF samples were acquired in order to investigate another closely related source of CSF, which had the possibility for larger sample sizes and timed profiles . Rhesus monkey lumbar CSF samples were drawn from an indwelling lumbar catheter. Sampling began after ketamine anesthesia wore off and continued for 3-4 days. Rhesus monkey cisternal CSF was drawn following administration of ketamine. Samples were frozen at -70°C and deuterated internal standards added to weighed samples just prior to extraction

Derivatization and Extraction: Thawed samples were methoximated at room temperature overnight (1% MOX-HCl in KH_2PO_4). Solid phase extraction, using 1 mL Bond-Elut C_{18} cartridges, proceeded as follows: condition with 2 mL of CH_2OH and 2 mL of H_2O, apply sample, rinse with 2 mL of 80:20 H_2O:CH_2OH, dry with vacuum for 10 min, rinse with 2 mL of CH_2Cl_2, elute PG with 1 mL of CH_2OH into silanized glass vials. Samples were further derivatized to the pentafluorobenzyl ester (0.1% PFBB, 10% DIEA in CH_3CN, 60°C for 15 min), trimethylsilyl ether (BSTFA in CH_3CN, 60°C for 15 min) and dried samples dissolved in 10 µL of dodecane.

GC/MS Determination: Separations were performed on a 15 m, 0.25 mm i.d., 0.25 µm film thickness DB-5 column. Samples (2 µL of 10 µL) were injected into the Carlo-Erba 4160 gas chromatograph using the cooled on-column injector, with the column oven at 215°C. The column was immediately heated to 315°C at 50°C/min, and the PG eluted between 3 and 4 min. The column was fed directly into the ion source of a Kratos MS-80 mass spectrometer which was kept at 250°C. The mass spectrometer was operated in selected-ion-monitoring, electron-capture negative ionization mode using CH_4 reagent gas and the $[M\text{-}PFB]^-$ ions of the PG and internal standards were monitored.

Assay Improvements: Indomethacin was found to be unnecessary during sampling, thereby eliminating its interference with the GC/MS determinations. Aqueous oximation avoids the use of pyridine, and allows methoximation by-products to be separated from PG during extraction. Using 100-fold less pentafluorobenzyl bromide during esterification greatly reduces electron capturing contaminants. Dodecane was used as the final solvent, allowing reduction of the GC/MS cycle time to less than 7 min/sample (RT 3-4 min).

RESULTS AND DISCUSSION:

The concentrations of PGE_2, PGE_1, $PGF_{2\alpha}$, $PGF_{1\alpha}$ and 6-keto-$PGF_{1\alpha}$ are below the assay detection limit of 5-pg/mL CSF in cerebrospinal fluid of healthy human volunteers and Rhesus monkeys (Figure 1 and 2, Table 1). Alcoholics sampled following a three week period of abstention also had prostaglandin levels below 5 pg/mL CSF. Literature reports of much higher levels in healthy humans are in error, most likely due to methodological problems. Future studies of prostaglandins in the human central nervous system should include samples from healthy volunteers in order to demonstrate similarly low levels for these PG. The low levels observed are most likely due either to very low production rates in the healthy brain and/or transport phenomena which limit their bulk CSF concentrations.

TABLE 1: Prostaglandin Concentrations in CSF of Humans and Rhesus Monkeys (pg/mL)

QUANTIFICATION OF 12S-HYDROXYEICOSATETRAENOIC ACID RELEASE FROM HUMAN PLATELETS BY NEGATIVE ION MASS SPECTROMETRY

K. Yamashita, J. Capdevila and I. A. Blair
Departments of Pharmacology and Medicine, Vanderbilt University
Nashville, TN 37232

It is well known that the major product of arachidonic acid derived from platelet lipoxygenase is 12S-hydroxyeicosatetraenoic acid (12S-HETE).[1] Stimulation of human platelets with a number of pro-aggregatory stimuli results in release of arachidonic acid and synthesis of 12S-HETE together with products of the cyclooxygenase pathway of metabolism. Published data reporting the quantification of 12S-HETE during platelet aggregation are confusing and contradictory.[2-4] To clarify the consequences of lipoxygenase activation during platelets aggregation, it was considered essential to develop a precise and sensitive method for quantification of 12S-HETE. We have developed a stable isotope dilution assay based on the use of negative ion chemical ionization mass spectrometry (NICIMS) for 12S-HETE. The method has been applied to the analysis of 12S-HETE released during platelet aggregation stimulated by thrombin and collagen in the presence and absence of a cyclooxygenase inhibitor.

Oxygen-18 labelled 12-HETE for use as an internal standard was prepared by the method of Murphy et al.[5] The methyl ester of 12-HETE was saponified with 0.2 N $Li^{18}OH$ in 50 μL tetrahydrofuran/water (1:1). Successive exchange of oxygen-16 in the carboxyl moiety to the corresponding oxygen-18 was performed by repeating the procedure of methylation and subsequent saponification. Carrying out the exchange reaction for six cycles resulted in the formation of ^{18}O labelled 12-HETE with overall yield of 40% ($^{18}O_2$, 88.3%; $^{18}O^{16}O$, 11.4%; $^{16}O_2$, < 0.3%).

Washed human platelets (10^8/mL) were stimulated with thrombin (1 unit/mL) or collagen (0.5 mg/mL) in a Payton aggregometer and aggregation allowed to proceed for 10 min. The platelet suspension was added to ethyl acetate (1 mL) containing the internal standard (10 ng in 50 μL of ethanol). The ethyl acetate layer was separated and the aqueous layer was extracted with a further 1 mL of ethyl acetate. The combined organic extracts were evaporated under nitrogen. The residue was dissolved in methanol (0.5 mL) and then hydrogenated at room temperature for 5 min using PtO_2 (1 mg/mL) or Rh/Al_2O_3 (1 mg/mL) as catalyst. The catalyst was removed by filtration through a small column containing glass wool and the hydrogenated product was esterified with 5% pentafluorobenzyl (PFB)-bromide in acetonitrile (40 μL) containing diisopropylethylamine (10 μL). After evaporation of excess reagent, the PFB ester was extracted with n-hexane (1 mL) and H_2O (1 mL). The aqueous layer was extracted with a further 1 mL of n-hexane. The combined organic layer was evaporated under nitrogen. The product was purified by silica gel TLC (Whatman LK6DK) using n-hexane/ethyl acetate (90:10) as a developing solvent. The purified PFB ester of 12S-HETE was silylated with BSTFA at 60 °C for 30 min. Samples were analyzed on an SPB-5 fused silica capillary (30 m) in the NICI mode using methane as reagent gas.

The PFB ester-trimethylsilyl (TMS) ether derivative of hydrogenated 12S-HETE had excellent gas chromatographic properties, particularly when compared with the non-hydrogenated derivative. The amount of catalyst used in the hydrogenation was critical. Optimal yields were obtained with 1 mg/mL of catalyst (PtO_2 or Rh/Al_2O_3). A fully saturated C-20 acid was always formed as a by-product during hydrogenation with PtO_2, however, the formation of this compound was minimized by the use of Rh/Al_2O_3 as catalyst. Figure 1 shows the NICI mass spectrum of the PFB-TMS ether derivative of hydrogenated 12S-HETE. The mass spectrum was characterized by the ions at m/z 399 and 309, which were formed by the loss of PFB moiety and subsequent elimination of TMSOH from the molecular ion, respectively. The structure of the fragment ion at m/z 178 was thought to be $[C_6F_4CH_2O]^-$. A good linearity was observed between the peak area ratio of m/z 399 (M-PFB of hydrogenated 12S-HETE-PFB ester) to m/z 403 (M-PFB of hydrogenated $^{18}O_2$-12S-HETE-PFB ester) and weight ratio of 12S-HETE to $^{18}O_2$-12-HETE in the range of 0.5 ng to 10 ng/mL. This confirmed that no significant back exchange of labelled ^{18}O took place during the extraction and derivatization processes described above.

The method was applied to the analysis of 12S-HETE released from human platelets in response to thrombin and collagen stimulation. The amounts of 12S-HETE released from platelets increased after stimulation in a time-dependent manner. Concentrations of 12S-HETE in human platelets suspension at 10 min after and thrombin and collagen stimulation were 80.0 ng/10^8 platelets and 29.6 ng/10^8 platelets respectively. In the presence of aspirin these concentrations increased to 131.5 ng/10^8 platelets and 100.9 ng/10^8 platelets respectively. Thus, pre-treatment of platelets with aspirin resulted in remarkable enhancement of 12S-HETE production. This was attributed to the specific blockade of the platelet cyclooxygenase with aspirin and a consequent increase in the amount of substrate available for the lipoxygenase.[6] There was no significant effect on 12S-HETE production by labelling with ^{14}C-arachidonic acid prior to stimulation.

In conclusion, the development of a precise and sensitive analytical method based on the use of ^{18}O-labelled internal standard and NICI mass spectrometry enabled us to determine low concentration of 12S-HETE in human platelet suspension. The present methodology for 12S-HETE promises to provide a wealth of information on the role and function of the platelet lipoxygenase products during platelet activation.

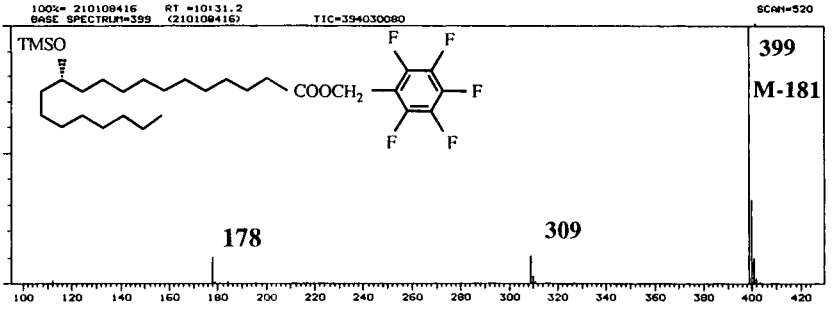

Figure 1: Mass spectrum of the PFB-TMS ether derivative of hydrogenated 12S-HETE released from human platelets in response to thrombin stimulation.

STRUCTURAL CHARACTERIZATION OF THREE ENDOTOXINS FROM *Salmonella minnesota* RESPONSIBLE FOR HUMAN PLATELET ACTIVATION:

V.N. Reinhold, G.R. Her, R.S. Johnson, J. Grabarek, J. Hawiger,
Harvard Schools of Public Health and Medicine, Boston, MA

Introduction

Gram-negative bacteria have many cellular targets, including blood platelets, granulocytes, monocytes, lymphocytes, erythrocytes, and endothelial cells. Some of these effects contribute to the development of intravascular coagulation and septic shock, and it is estimated that approximately 71,000 patients per year in the United States develop gram-negative bacteremia, resulting in 18,000 deaths. The most frequent cause of death is disseminated intravascular coagulation and shock. Therefore, efforts have been focused on *in vitro* evidence of human platelets interact with the endotoxic principle, Lipid-A. Lipid-A is the name given to a chloroform-methanol extract of partially hydrolyzed lipopolysaccharides. The extract is complex and the major components are a series of multiply acylated 2-amino-2-deoxy diglucose homologs which once constituted the membrane anchor for the outer cell wall polysaccharides of gram-negative bacteria. Under conditions of isolation, this fraction occurs as a complex mixture with varying degrees of O-deacyltion and aminoethylation.

Results & Discussion

Using a combination of TLC and FAB-MS, eight individual components have been detected in the Lipid-A fraction obtained from *Salmonella minnesota*. Three of the fractions have been shown to activate human platelets. This activity is manifested by platelet secretion of serotonin and subsequent aggregation: a process which may be analogous to human intravascular coagulation and septic shock upon gram-negative bacteremia. The extracts were analyzed directly by FAB-MS as the monophosphoryl analogs from the complex extract by FAB-MS The most active component (I) provided the mass spectrum shown in Figure 1, suggesting it to be the heptaacyl monophosphoryl Lipid-A (1). FAB-MS of the other two fractions (II, III) proved to be somewhat less active and their structures are presented below. Most interestingly, compound I was not detected in the original extracts when analyzed by FAB, but it was easily detected by FAB-MS following TLC purification. Moreover, addition of small amounts of the original extract completely suppressed desorption of this biologically active component. FAB spectra from complex matricies are frequently biased by the components exhibiting enhanced surface activity and this continues to be a matter of great concern with impure biological isolates. To approach this problem we are currently applying SFC and SFC-MS. Preliminary data indicates that quantification of these materials by an SFC using an FID detector is comparable to independent tests for phosphate. To position points of acylation (2,3) we have combined a series of O-deacylation steps with positive FAB-MS to position each residue. Under positive FAB-MS a glycosidic cleavage fragment provides molecular weight information for each monosaccharide residue and this in combination with C-3 and C-3' de-O-acylation differentiates the varying possibilities of N- and O-acyl groups.

IMPROVEMENTS IN STRUCTURAL DETAIL FOR GLYCOSPHINGOLIPID SAMPLES USING CO_2 & CO_2/CH_3OH MIXTURES AS A DCI REAGENT GAS:

G.R. Her, D.M. Sheeley, V.N. Reinhold.
Harvard School of Public Health, Boston, MA 02115.

Introduction

Glycosphingolipids (GSLs) are amphoteric conjugates of a long chain base, a simple fatty acid, and one or more carbohydrate residues. The base and its fatty acid conjugate frequently impart heterogeneity to the molecular ion region as a consequence of alkane chain modifications in one or both of these residues. The molecular ion distribution can most frequently be related to variations in chain length, unsaturation, hydroxylation or their combinations in either the long chain base or the fatty acid. Negative FAB-MS has been successfully applied to underivatized GSLs, often producing many sequence related fragment ions. However, no fragment ions that can be used to determine the ceramide composition. Although positive FAB has shown little value in the analysis of underivatized GSLs, it has proven very useful for permethylated samples. Despite some reports in the literature (1), positive FAB-MS of permethylated GSLs rarely show intense fragment ions which can be used to determine the ceramide composition (2). Recently, MS/MS has shown that it could be used to determine ceramide composition (3).

As a consequence of independent SFC-MS studies, using CO_2 or CO_2/CH_3OH as mobile phases, we have looked closely at using these gases for DCI analysis of GSLs. When evaluated with these samples, these gases show one major advantage over the commonly used ammonia reagent gas, a unique α-cleavage fragment of the long chain base allows the assignment of contributing molecular heterogeneity. In addition, the ions defining the carbohydrate sequence are often clearer and more abundant.

Figure 1 shows the CO_2/CH_3OH (4:1) DCI mass spectrum of permethylated GM1. The pair of protonated molecular ions (m/z 1854 and 1826), with a 28 dalton interval, indicates that this fraction occurs with approximately half the sample containing an alkane side chain shortened by two methylene units. The ions at m/z 1479 and 1451 can be ascribed to loss of a neuraminyl residue from the molecular ion $(MH-375)^+$. Since this loss does not alter the ceramide moiety, the alkane heterogeneity is still observed. The ion at m/z 1573 does not show the alkane heterogeneity and can be accounted for by considering cleavage α to the nitrogen with elimination of the aliphatic sphingoid residue. The corresponding events, loss of heterogeneity and sphingoid residue elimination, indicate that the alkane chain variation resides with this residue. This fragment also shows the facile loss of a neuraminyl group, at m/z 1198. In the absence of methanol (100% CO_2), these two fragments (m/z 1573 and 1198) are the most abundant ions (Fig. 2).

This technique has been tested on other GSLs such as GD1a, GD1b, ceramide trihexoide, globoside(GL4) and lignoceroyldihydrolactocerebroside, α cleavage fragments were observed for every sample tested. Based on these fragments, fatty acid composition of each compound can be assigned.

Detection of urinary arachidonic acid metabolites (AAMs) by capillary GC/MS involves extensive sample preparation. The methoxime-pentafluorobenzyl ester-trimethyl silyl (MO-PFB-TMS) derivative used with electron-capture negative chemical ionization (EC-NCI) is the most sensitive and specific technique for the trace determination of prostaglandins (PGs). Immunoaffinity (IA) purification using polyclonal antibodies has been shown to provide sufficient sample purification prior to analysis of urinary PGs by electron ionization (EI) GC/MS/MS (1). This method of analysis reduces the need for extensive sample clean-up and utilizes the increased selectivity and reduced chemical noise inherent with MS/MS. However, the time required for derivatization and GC dominates the overall analysis time.

Evaluation of the relative trade-offs between analysis time and selectivity with respect to sample preparation, sample introduction and mass spectrometry in the determination of urinary PGs was accomplished. All GC/MS and GC/MS/MS experiments were performed using a Finnigan MAT TSQ 45, while the direct chemical ionization (DCI) experiments were performed on a Finnigan MAT TSQ 70. Methane EC-NCI of the MO-PFB-TMS derivative of PGE_2 and $^2H_4$-PGE_2 in urine was examined.

In the GC/MS (SIM) studies performed on a 10 m capillary column, the $(M\text{-}PFB)^-$ ion of both PGE_2 (524^-) and $^2H_4$-PGE_2 (528^-) were monitored. The comparison between the single-ion monitoring (SIM) profiles demonstrates that increased selectivity is required in the sample preparation for the GC/SIM determination of PGE_2. The increased selectivity obtained with IA solid phase extraction (Figure 1) is obtained at the expense of increased sample preparation time. Nevertheless, it appears that IA in combination with high resolution GC/MS (e.g. use of a 30 m column) would work quite adequately.

The GC/MS/MS selected-reaction monitoring (SRM) profiles were obtained by monitoring the selected reactions of $524^- \rightarrow 268^-$ for PGE_2 and $528^- \rightarrow 348^-$ for $^2H_4$-PGE_2. Figure 2 illustrates the advantages of using SRM for the determination of PGE_2. The increased selectivity of SRM results in a reduction of the chemical noise. The 845 pg of $^2H_4$-PGE_2 injected on the column is slightly above the detection limit, while PGE_2 is below the limit of detection. A possible explanation for the poor sensitivity of PGE_2 is that other components in the sample, eluting from the column at the same time, may quench the formation of the parent ion. However, despite the increased selectivity of SRM, better chromatographic separation is required to avoid the quenching problem. Figure 3 illustrates the ultimate trade-offs between selectivity, the time spent for sample preparation, sample introduction (GC) and MS/MS. Some of the additional time spent on sample preparation (IA) is recovered by using a short capillary column (e.g. 3 m instead of 10 m).

Analysis times can be further reduced by coupling IA with direct chemical ionization (DCI)/MS/MS. In this method, an abbreviated derivatization step using only the PFB derivative of PGE_2 is employed. If proceeded by IA, it appears that DCI with SRM would be the ultimate method in terms of speed of analysis. The SRM profile for $^2H_4$-PGE_2 ($355^- \rightarrow 335^-$) demonstrates that it may be possible to detect PGs in the low nanogram levels (4 ng on the probe) in urine with DCI/MS/MS (Figure 4). Levels lower than the nanogram range may be extremely difficult to detect as observed

when monitoring the $(M-PFB)^-$ ion $351^- \rightarrow 315^-$ for PGE_2. Monitoring other characteristic reactions for SRM did not seem to solve the problem. Although DCI allows for rapid analysis times, it is possible, with rapid heating of the probe, to vaporize undesirable components of the urine, which can interfere with the analysis. This creates problems with contamination of the ion volume and the source region, and leads to a drastic reduction in sensitivity. Another reason for the poor sensitivity is the possibility of quenching effects, which may occur when many components are vaporized at the same time.

In summary, GC/SIM determination of PGE_2 can be successfully performed when using both SEP-PAK and IA solid phase extractions with a sufficient length of capillary GC column to yield adequate separation. Reduced sample preparation (SEP-PAK only) should be possible, if conventional lengths of capillary GC columns (20-30 m) are used with MS/MS (SRM). A useful trade-off between selectivity and analysis time can be achieved with IA and short capillary GC columns coupled with MS/MS (SRM). DCI/MS/MS is a rapid analysis technique which may reduce lengthy derivatization procedures, but requires further investigation if it is to become a viable technique for the determination of urinary PGs.

COMPARATIVE GC/MS TECHNIQUES FOR THE IDENTIFICATION OF FATTY ACIDS AND ALCOHOLS FROM HUMAN CERUMEN.

D.J. Harvey,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Cerumen, or ear wax, consists of wax esters and cholesterol esters which, on hydrolysis yield complex mixtures of fatty acids, alcohols and cholesterol. The structures of the constituent acids and alcohols have not been well studied although it is known that they resemble those in sebum, the main constituent of skin-surface lipids. This paper compares various GC/MS techniques for structural identification of these compounds and an examination of constituents in a typical cerumen sample.

Lipids were extracted from the cerumen with ethyl acetate and hydrolyzed with ethanolic potassium hydroxide. Direct derivatization for GLC and GC/MS involved preparation of TMS, [$^2H_9$]TMS, methyl ester/TMS, picolinyl/TMS (1,2), nicotinate/TMS (3), picolinyldimethylsilyl/TMS (4) and pyrrolidide (directly from the cerumen extract) derivatives. The unsaturated compounds were also converted into cis-diols with osmium tetroxide and acids were reduced to alcohols with lithium aluminium deuteride. These derivatized compounds were examined by GLC using a 50 m x 0.3 mm OV-1 fused silica capillary column and by GC/MS using a VG 70/70F mass spectrometer (70 eV) fitted with a 25 m x 0.2 mm OV-1 fused silica capillary column terminating inside the ion source.

Fig. 1 shows a chromatogram of the TMS derivatives of the constituent lipids from the hydrolyzed cerumen. Nearly 100 compounds were identified; these consisted of straight-chain, branched-chain, saturated and unsaturated acids and alcohols. Although the TMS and Me/TMS derivatives were the best for gas chromatography, they gave little structural information on the aliphatic chains of the acids and alcohols. This information was best obtained by preparation of other derivatives. Hydroxylation of the double bonds with osmium tetroxide and conversion of the resultant glycols into TMS derivatives was the most satisfactory method for double bond location in the mono-unsaturated acids and alcohols but was very much less satisfactory as the number of double bonds increased. This was mainly the result of the great mass increment of the TMS group giving, after hydroxylation and TMS ether formation, an increase of 178 mass units for each double bond. The main advantage of these derivatives for mixture analysis was that differences in double bond position were indicated by only two very abundant ions at distinctly different masses in the mass spectra of isomeric compounds. This method did not, however give structural information on methyl branch points.

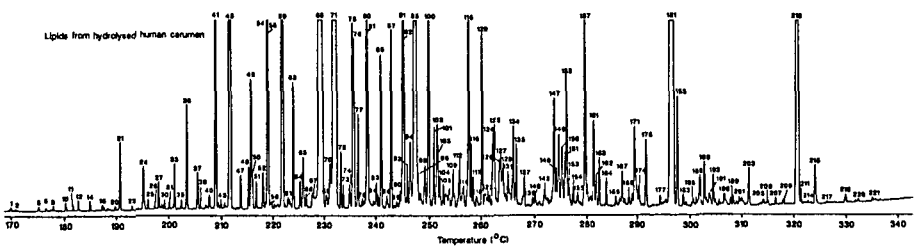

Fig. 1. Gas chromatogram (50 m fused silica capillary column) of the fatty acids and alcohols from human cerumen separated as TMS derivatives.

Both pyrrolidide and picolinyl (Fig. 2) derivatives gave structural information on the full range of acids present. These derivatives initiate a radical-site fragmentation following hydrogen abstraction from any position of the chain resulting in a series of ions spaced by 14 mass units from saturated compounds. Positions of methyl branch-points are indicated by the absence of a peak and unsaturation can be determined both by the mass numbers and by the presence of two ions of higher abundance produced by abstraction of either of the two allylic hydrogen atoms. Of the two derivatives of this type, the picolinyl esters gave spectra with much more abundant ions than the pyrrolidides. However for structural determination of isomers that were not separated by GLC, these derivatives were not as satisfactory for double bond location as the isomers produced ions at common masses and the largest differences in the spectra were those of ion abundance rather than mass.

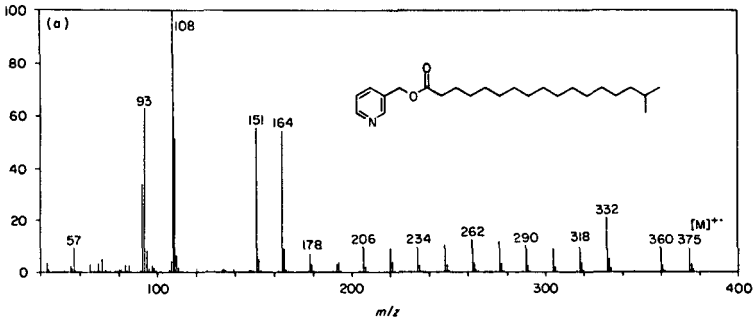

Fig. 2. 25 eV Mass spectra of the picolinyl derivatives of iso-octadecanoic acid.

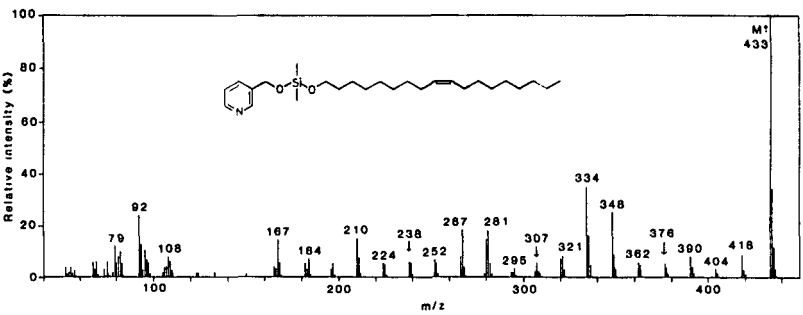

Fig. 3. 25 eV mass spectrum of the PICSI derivative of n-octadecanol.

Nicotinate derivatives were among the most satisfactory for identification of alcohols. These fragmented in the same way as the picolinyl esters and could, thus, be used for both unsaturated and branched-chain compounds. PICSI Derivatives fragmented in a similar way and had the additional advantage of producing abundant molecular ions.

The major carboxylic acids in the cerumen sample were n-16:1,delta-6 (peak 68, Fig. 1), n-16:0 (peak 71), n-18:1,delta-9 (peak 95), n-14:0 (peak 45). n-15:0 (peak 59), ai-15:0 (peak 54), n-14:1,delta-6 (peak 41), 17:1, delta-6 (peak 76), n-17:1,delta-6 (peak 80) and n-18:2,delta-9,12 (peak 90). The major alcohols were n-20:0,delta-10 (peak 115), n-18:0 (peak 87), n-19:0 (peak 103), n-20:0 (peak 120), n-22:1,delta-12 (peak 147), n-24:1,delta-14 (peak 171) and 16:0 (peak 63). Peak 181 was squalene and peak 210 was cholesterol.

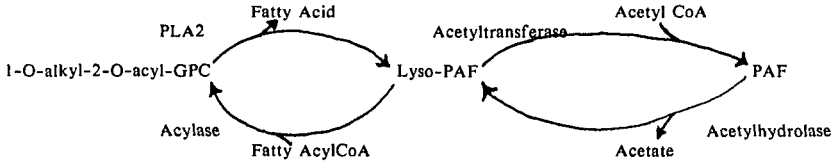
Determination of the Phosphocholine Molecular Species Which are Direct Precursors of Platelet Activating Factor

Keith L. Clay and C. A. Johnson

University of Colorado Health Sciences Center
Department of Pharmacology
4200 E. 9th Avenue
Denver, CO 80262

In response to appropriate stimulation, human and animal neutrophils synthesize platelet activating factor (PAF, 1-O-alkyl-2-O-acetyl-glycero-3-phosphocholine) which is predominantly hexadecyl in the sn-1 alkyl chain (1,2). By contrast, the putative precursor pool of ether-linked phosphocholine in human neutrophils is almost an equal mix of alkyl chains which contain 16 carbon atoms and alkyl chains with 18 carbons atoms (3). This fact implies that there is significant selection in the acetylation of lyso-PAF species to give PAF. The basis for that selectivity was the subject of this investigation.

Specificity in the synthesis of a unique molecular species of PAF in the presence of a rather heterogeneous precursor pool could arise at any point in the synthetic or degradative pathways. The major pathways for the synthesis of PAF and its subsequent catabolism are diagrammed in Fig. 1.



None of the enzymes shown to be involved in this cyclic process have shown specificity based on the alkyl chain length, but there is at least one report that the initial hydrolysis mediated by Phospholipase A2 may have some specificity for a specific acid, arachidonic acid, in the sn-2 position, (4). The possibility, therefore, exists that the basis for specificity in the synthesis of PAF is in the specific molecular species of phosphocholine which serves as substrate for PAF biosynthesis.

To define the presursor alkyl-linked GPC which serves as proximate substrate for PAF biosynthesis, we labelled those ether phospholipids with deuterium by incubation with stable isotopically labelled variants of normal phospholipid precursors. PAF synthesis was then initiated with appropriate stimulus, the PAF and phosphocholine pools were then isolated, the PC was further fractionated by HPLC into its constituent molecular species and the isotopic composition of the alkyl ether chains in PAF and each of the molecular species was determined. Comparison of isotopic composition of the PAF with a putative precursor pool then allowed some estimation of the contribution of that molecular species to the synthesis of PAF.

Deuterated lyso-PAF was synthesized from beef heart phosphochoine by reduction with deuterium gas in the presence of platinum on carbon. Deuterated alkylgycerol was then derived from this lyso-PAF by hydrolysis with concentrated hydrofluoric acid. Tritiated lyso-PAF was added to the deuterated lyso-PAF prior to incubation with the cells to allow easy visualization of the areas of incorporation of label (both deuterium and tritium) into the cellular phospholipids.

Human neutrophils were isolated from blood of healthy volunteers and then re-suspended in Hank's balanced salt solution to which the labelled precursors had been added. The incubation was carried out for various lengths of time and then terminated by the addition of methanol. Cellular lipids were extracted and a PAF and PC fraction were obtained by TLC. The PAF fraction was then derivatized with pentafluorobenzoyl chloride for negative ion chemical ionization GC/MS. The PC fraction was further fractionated by reverse phase HPLC into its constituent molecular species. The identity of each of the fractions was determined by fast atom bombardment mass spectrometry.

These separated fractions were then degraded to alkylglycerols and derivatized with acetone to the *corresponding isopropylidene derivatives. The isotopic composition of the alkyl ether chains in* these molecular species was then determined by positive ion GC/MS.

As illustrated by the data in tables 1 and 2, the basic conclusion which can be derived from this study is that PAF is synthesized from a pool of phosphocholine which is much more highly enriched than any of the identified pools of PC molecular species. The most highly enriched pool of alkyl-acyl-PC is that containing arachidonic acid in the sn-2 position, and this data therefore supports the hypothesis that alkyl-arachidonyl-GPC is the primary pool used as precursor for the synthesis of PAF in the human neutrophil, and probably in other cells.

Table 1. Isotopic Composition of PAF and PC
Molecular Species after Incubation with Deuterated lyso-PAF

Sample	Ratio, D_2/D_0 Hexadecyl	Ratio, D_2/D_0 Octadecyl	Mol. Species**
D_2-Lyso-PAF	2.54(80%)	1.61(20%)	
PC, from TLC	0.06	0.06	
HPLC Fractions*			
46,47	0.17		16/20:4
48,49	0.06		16/18:2
57,58	0.15	0.15	16/20:3 + 18/18:3
64,66	0.04	0.11	16/16:0 + 18/?
78,79		0.14	18/20:4
83,84		0.07	? (18/18:2?)
PAF	0.47	0.09	

Table 2. Isotopic Composition of PAF and PC
Molecular Species after Incubation with Deuterated Alkylglycerol

Sample	Ratio, D_2/D_0 Hexadecyl	Ratio, D_2/D_0 Octadecyl	Mol. Species**
PC, from TLC'	0.07	Not measurable	
HPLC Fractions*			
35,36	0.05		16/20:4
48	0.04		16/16:0
49,50	0.03		16/16:0 + 16/16:1
55,56	0.03	0.5	16/20:2 + 18/20:4
PAF	0.09	Not measurable	

* Slightly different mobile phase conditions were used for these sets of HPLC separations
** Data are shown as alkyl ether chain length/acyl species. i.e. 16/20:4 = hexadecyl-arachidonyl-PC

In the study with lyso-PAF incubation, most of the precursor was acylated with arachidonic acid in the sn-2 position, and the PAF synthesized came from that pool. In the incubations with alkylglycerol, most of the precursor was synthesized to a hexadecyl-palmitoyl-GPC species, and the PAF synthesis was not from that pool. These data are most consistent with the synthesis of PAF being from a sub-pool of hexadecyl-arachidonyl-GPC.

ANALYSIS FOR LEUKOTRIENE B_4 IN HUMAN SERUM BY GC-MS

Helen Hughes, Jerry R. Mitchell and Simon J. Gaskell
Center for Experimental Therapeutics
Baylor College of Medicine
Houston, Texas

Leukotriene B_4 (LTB_4, (5S, 12R)-5,12-dihydroxy-(ZEEZ)-6,8,10,14-eicosatetraenoic acid) is formed from arachidonic acid via the 5-lipoxygenase pathway. It is a potent chemotactic agent for polymorphonuclear leukocytes and is thought to be an important mediator in several pathological processes involving inflammatory and allergic responses. The analysis of LTB_4 in vivo poses significant problems. First the role of ex vivo formation during blood sampling and serum preparation must be assessed before the circulating concentration can be determined. The method must have both high sensitivity and the specificity to distinguish between LTB_4 and several isomeric dihydroxyeicosatetraenoates which have been identified in different cell incubation systems. We have developed a method based on electron capture negative ion mass spectrometry for the analysis of LTB_4 in serum at low pg/ml concentrations.

Blood is collected into the 5-lipoxygenase inhibitor nordihydroguaiaretic acid (NDGA) to suppress ex vivo formation. Serum is isolated, equilibrated with the internal standard [$^2H_4$] LTB_4, and extracted using C-18 cartridges. Following derivatization to the pentafluorobenzyl esters, the extracts are purified by straight-phase HPLC (Figure 1). Gas chromatographic-mass spectrometric analysis was accomplished on the tert-butyldimethylsilyl ether derivatives. A DB-1 capillary column (30 m x 0.32 mm) was used for the analyses and was programmed from 210° to 310° at 5°/min. Ions were monitored at m/z 431 and 435, which correspond to loss of tert-butyldimethylsilanol from the M-PFB anions of endogenous and [$^2H_4$] LTB_4 respectively.

This method takes advantage of the high sensitivity under electron capture negative ion MS conditions rendered on the eicosanoids by virtue of the PFB ester moiety. The limit of detection for LTB_4 standards was well below 5 pg, injected on column. The concentration of LTB_4 in human serum, collected with NDGA, was 11.0 pg/ml (Figure 2). At this concentration the interassay coefficient of variation was 16.7%. The method showed a high degree of accuracy as determined by the analysis of five 25 ml serum samples spikes at concentrations of 5, 10, 25, 50, and 100 pg/ml with unlabeled LTB_4 and carried through the analysis (Figure 3). The serum concentration of LTB_4 measured in this study is less than 10% of that previously reported by Blair and colleagues (1985) where no lipoxygenase inhibitor was used. Ex vivo formation of LTB_4 can therefore be a major obstacle when assessing the circulating concentration.

Blair, I.A., Brash, A.R., Daugherty, J., Fitzgerald, G.A. (1985) in Advances in Prostaglandin, Thromboxane and Leukotriene Research (Hayaishi, O., Yasmamoto, S., eds.), Vol. 15, pp. 61-65, Raven Press, New York.

Various oxygenated metabolites of arachidonic acid are known to be generated by cells following stimulation *in vivo* (1). For example, leukotriene B_4, an important 5-lipoxygenase metabolite of arachidonic acid is known to be synthesized by the human polymorphonuclear leukocyte which is undergoing phagocytosis (2). While there is a great deal of interest concerning the generation of such lipid mediators derived from arachidonic acid, it has been a challenging analytical problem to develop means by which one can accurately and specifically measure these molecules produced in picomolar amounts. We have been interested in the potential for generation of leukotrienes by a transcellular metabolic process which would involve the synthesis of one intermediate, for example leukotriene A_4, within one cell which is then transferred to another cell for subsequent processing into leukotriene B_4 or leukotriene C_4 (3). Some evidence has been obtained to suggest that such a complex route of synthesis for leukotrienes may take place in tissues including whole blood (4). A major objective of the work presented here was to develop means by which one could accurately measure LTB_4 and 20-hydroxy-LTB_4, a subsequent metabolite of LTB_4, using stable isotope dilution and mass spectrometry. An extraction based method has been developed which results in substantial purification by taking advantage of the unique chemistry inherent in the 5-lipoxygenase products and facile formation of neutral δ-lactones.

Human blood was collected from healthy volunteers who had not previously taken nonsteroidal antiinflammatory agents for at least one week prior to donation. It was immediately anticoagulated with 3.8% sodium citrate in polypropylene tubes. Differential cell counts of neutrophils, platelets, monocytes, and red blood cells were carried out for each blood sample taken for study. Incubations were performed at 37°C in 15 ml sterile polypropylene tubes, placed in a shaking bath after a 5 min equilibration period. Zymosan was boiled in saline for 2 hrs, washed, and sonicated twice before being suspended in HBSS at 50 mg/ml. Zymosan was added to whole blood at a final concentration of 2 x 10^3 particles per neutrophil. Incubations were carried out for 30 min. Following the incubation period, stable isotope labeled LTB_4 and 20-OH-LTB_4 were added and cell suspensions were centrifuged. The supernatants were treated with 4 volumes of ethanol to precipitate proteins followed by centrifugation. Supernatant was acidified to pH 3 with formic acid and diluted with 4 volumes of water. The leukotrienes were partially purified by solid phase extraction (5).

Formation of the LTB_4 lactone was carried out by treating the residue with 100 μl of 1% isobutyl chloroformate and 10% diisopropylethylamine in acetonitrile at room temperature for 30 min (Figure 1, Step A). After evaporation to dryness, the sample was suspended in .1 M phosphate buffer (pH 7.5) and extracted with methylene chloride. The organic layer was separated, taken to dryness, then treated with a solution of 50 μl pyridine, 20 μl 1.0 normal LiOH and 200 μl 0.1 M phosphate buffer (Figure 1, Step B). Lactone hydrolysis was carried out for 15 min at room temperature followed by the addition of 1.8 mls of water. This alkaline solution was extracted with methylene chloride to remove neutrals and the aqueous layer acidified with 20 μl of 10 N HCl. After extraction with 2 mls of methylene chloride, the organic layer was removed and taken to dryness (Figure 1, Step C). This residue was then derivatized to the pentafluorobenzyl ester, trimethylsilyl ether derivatives (Figure 1, Step D as previously described) (5).

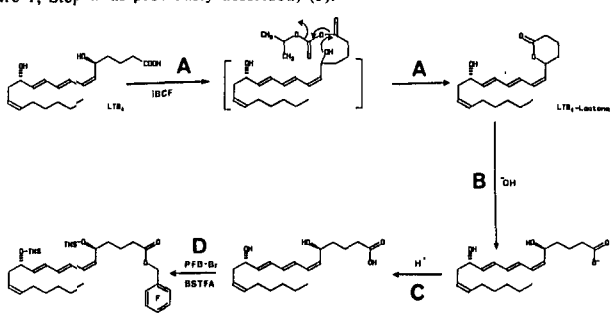

Figure 1. Transformations of LTB_4 during the extractive isolation procedure for LTB_4 and 20-OH-LTB_4.

The leukotrienes in this sample were quantitated by selected ion monitoring, capillary gas chromatography/mass spectrometry as previously described (5). Table 1 shows the recovery of LTB_4 as assessed by radiolabeled LTB_4 added to the biological matrix prior to the various organic extractions steps and formation of the lactone. Overall, the yield was 65% starting from the biological mixture as compared to a typical yield following an HPLC purification protocol which yielded only 30% of the starting LTB_4 (Table 1). Figure 2 shows the selected ion monitoring trace of LTB_4 and deuterium labeled LTB_4 obtained by the extractive technique monitoring ions at m/z 479 and 483. This LTB_4 was generated by zymosan phagocytosis in whole blood.

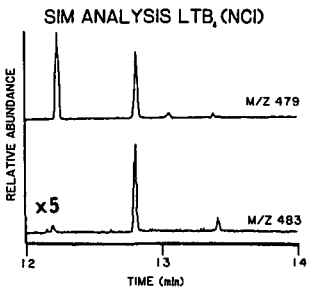

Figure 2. Selected ion monitor recordings for m/z 479 (LTB_4) and m/z 483 (D_4-LTB_4) by negative ion electron capture mass spectrometry. LTB_4 was produced by zymosan challenged whole blood and isolated by the extractive techniques.

Table 1

Recoveries (LTB_4)

Step	HPLC Method		Step	Extractive Method	
1	Sep Pak	80%	A	Sep Pak	80%
2	HPLC	30%	B	Alkaline Wash	75%
			C	Acidic Wash	65%

The facile formation of δ-lactones of LTB_4 and 20-hydroxy-LTB_4 can be used in an extractive technique for the isolation of these molecules. Very high yields can be achieved and substantial purification is realized.

EI,CI LC/MS THROUGH FRIT VAPORIZATION SYSTEM

K.Matsuura, K.Otsuka, T.Kobayashi, E.Kubota, Y.Itagaki,
B.D.Musselman and T.Higuchi
MSG JEOL, 3-2-1 Musashino Akishima Tokyo 196 Japan

Introduction

Development of a multipurpose LC/MS interface which enables ionization of various types of compounds has been expected. The authors reported the FRIT-FAB LC/MS interface as a new LC/MS technique (1). And now, a LC/MS interface with a frit which enables EL and CI has been developed. Using this interface, LC/MS analysis of glycerides and polyaromatic hydrocarbons were performed.

Experimental

This interface has improved the FRIT-FAB LC/MS interface ionization chamber heating to a high temperature of over 400℃. A frit was installed at the ionization chamber of the EI/CI/FAB combination ion source. The effluent from the HPLC column is vaporized on the heated frit and ionized by EI and CI. The mobile phase solvent is used as a reagent gas for CI, and also it is possible to add a reagent gas like ammonia. The equipment used was the JMS-DX303 mass spectrometer with a DA5000 data processing system(JEOL). The effluent from the column was precisely split and introduced at 5μl/min to the frit. The column outlet and ion source were connected by a 60μm I.D x 1m fused silica capillary tube. Ionization current was 300μA. The column was a SFPAK ODS-5S25 1.7mm I.D. x 25cm(JEOL) and the flow rate was 150μl/min.

Results and Discussion

1. Polyaromatic hydrocarbons(PAHs)

LC/MS analysis of PAHs is difficult by LC/MS based on CI because of the property of their lower proton affinity. PAHs are easily ionized by EI. Using EI LC/MS with a frit PAHs containing naphthalene, anthracene, pyrene, chrysene, 3,4-benzopyrene, dibenzoanthracene and coronene were analysed. Separation of these compounds was carried out by a ODS column under a gradient elution from 70% acetonitrile in water solution to 100% acetonitrile. Ionization chamber temperature was kept at 350℃. Fig.1 shows a mass chromatogram of M^+ for each compound. Their compounds were separated and detected at the same sensitivity. The chromatogram showed a stable and symmetrical peak shape and it means that the sample is smoothly vaporized and ionized on the frit. Fig.2 shows the EI mass spectra of 3,4-benzopyrene, dibenzoanthracene and coronene giving an intense molecular peak and a doubly charged peak.

2. Trilaurin

The mobile phase used was acetone. In order to enhance soft ionization of the sample, ammonia gas was added to the ionization chamber. The ionization chamber temperature was kept to 320℃. Figure 3 shows a mass chromatogram of $M+NH_4$ for trilaurin and the impurities. Figure 4 shows the mass spectrum of trilaurin. A m/z 656($M+NH_4$) is the base peak and m/z 439 ($M-C_{11}H_{23}CO_2$) shows the existence of fatty acid moieties.
Since minor components showed a similar mass spectral pattern, the constitutive fatty acids were easily identified. Peak 1 was dilaurin, peak 2 decanoyl didodecanoin, and peak 4 was tetradecanoyl didodecanoin.

A non-aqueous mobile phase such as tetrahydrofuran or acetonitrile is used generally in the case of LC runs of fat oil containing triglycerides. The FRIT-CI LC/MS technique is suitable for such analysis.

Conclusions

Using the frit,a LC/MS interface which enables EI and CI has been developed. The interface has a simple structure and gives stable chromatograms, thus allowing molecular weight determination and structural analysis of volatile compounds.

CAPILLARY ZONE ELECTROPHORESIS/MASS SPECTROMETRY OF SULFONATED AZO DYES

Thomas Covey, Sciex Inc., 55 Glencameron Road, Thornhill, Ontario, Canada, L3T 1P2

Edgar Lee and Jack Henion, Equine Drug Testing and Toxicology, Cornell University, 925 Warren Drive, Ithaca, NY 14850

Zone electrophoresis in open tubular capillaries (capillary zone electrophoresis, CZE) has been shown to be a promising technique for the high resolution separation of charged substances in solution (1). A high voltage (10-50 kv) is applied across a length of open tubular capillary (30 cm) and positively charged ions, neutral molecules, and negatively charged species migrate toward the cathode through the combined effects of electromigration, and electrosmotic flow. Typically, both the anode and cathode are immersed in buffer resevoirs with UV or fluorescence detectors constructed around short lengths of the separation capillary. Smith and co-workers (2) demonstrated that the cathode need not be in a buffer but only at a negative potential relative to the anode.

The ion spray interface for liquid chromatography-mass spectrometry (3) is a device which produces gas-phase ions from charged species in solution by the ion evaporation mechanism (4). This combination is ideally suited for the detection of ionic compounds separated in capillary zone electrophoresis (5). It consists of a modified electrospray interface enhanced with pneumatic nebulization for the production of ions at atmospheric pressure. Ion evaporation is an extremely mild form of ionization producing predominately pseudo-molecular ions and multiply charged species in accordance with the number of charged functional groups on the molecule. Because this system operates at atmospheric pressure, the interfaceing is relatively simple to construct and operate with no accommodations required to counteract a vacuum system pulling on the CZE separation capillary. Smith (2) has previously demonstrated CZE/MS with an electrospray interface on an API source.

A Sciex TAGA 6000E MS/MS equipped with an API source was used to sample ions generated from the API interface. The electrophoresis system consisted of a Spellman 0-60 kv power supply and a 100 um i.d. x 100 cm fused-silica capillary. High voltage was applied to the anode through a graphite vessel containing 60/40 methanol/20 millimolar NH_4OAc. Five to ten second hydrodynamic injections were made (5 cm elevation) resulting in injection volumes of 10-20 nanoliters (2.1 nanoliters/second). Figure 1 shows triplicate 10 second hydrodynamic injection at 4 levels. CZE voltages of 15-40 kv with operating currents of 10-50 micro amps were maintained.

The above-described instrumentation was tested for its capability to separate standard sulfonated azo dyes and a solid-liquid extract of the raw sewage influent to the greater Cincinnati sewage treatment plant. Standard dye mixtures demonstrated resolution capability of 100,000 theoretical plates with SIM detection limits in the high femptomole range of material injected on-column. Figure 2 is a selected ion monitoring electropherogram of a mixture of 6 standard azo dyes at 3 picomoles/component. Figure 3 is the full-scan spectrum (30 picomoles) of acid orange 7 (peak 3). Using parent ion screening techniques and monitoring the daughter ion common to sulfonated aromatic rings (m/z 80, SO_3^-), three dyes were observed in the waste water. Full-scan daughter ion spectra were used for confirmation.

ANALYSIS OF SULFONATED AZO DYES USING SELECTED ION MONITORING AND LIQUID CHROMATOGRAPHY/THERMOSPRAY IONIZATION MASS SPECTROMETRY

MATTHEW A. MCLEAN[a], DONALD A. FLORY[a], MARVIN L. VESTAL[b], ROYAL B. FREAS[a]

[b] VESTEC CORPORATION, 9299 KIRBY DR., HOUSTON, TX 77054

INTRODUCTION: There has been increased concern in recent years over the release of azo dyes and aromatic amines into the environment. This concern arises from the toxic nature of these compounds and their ability to travel large distances in ground and surface water without being degraded. The Environmental Protection Agency has listed a number of azo dyes, particularly sulfonated azo dyes, on the Appendix VIII Hazardous Constituent List. A method to identify and measure these compounds has not yet been developed. Methods involving chromatographic separations and mass spectrometric detection are attractive because species can be tentatively identified by chromatographic retention time and in many cases confirmed using mass spectral data. Several mass spectrometric techniques including FAB, electrospray/API and thermospray are compatible with on-line liquid chromatography/mass spectrometry and have shown promise in analyzing polysulfonated azo dyes.[1-3]

Thermospray has proven useful in analyzing nonsulfonated dyes using tandem mass spectrometry for detection and confirmation.[4] However, sulfonated azo dyes have been more difficult to analyze using this technique, presumably due to their lack of volatility. Some instrumental parameters have been changed to increase the sensitivity of thermospray with regard to sulfonated azo dye analysis. These instrumental changes include: (a) restriction of the thermospray vaporizer exit orifice which is done to increase the initial charge per unit area on the thermospray droplet and (b) addition of a needle-tip repeller to a conventional thermospray ion source to increase ion extraction efficiency. In addition to these modifications, a liquid chromatographic procedure was developed that is highly efficient in separating the sulfonated dyes and is compatible with thermospray mass spectral detection.

EXPERIMENTAL: A Hewlett-Packard Model 5988A mass spectrometer was used and operated in the negative-ion mode. The mass spectrometer was coupled to a Scientific Services Inc. high-performance liquid chromatography (HPLC) gradient system via a Vestec Thermospray™ liquid chromatography/-mass spectrometry (LC/MS) interface. The Vestec ion source was modified by machining away the step restriction in the ion volume thus making a more open region around the sampling cone. A needle-tip repeller was added opposite the sampling cone to enhance ion extraction efficiency from the ion source. The thermospray vaporizer was modified so that the orifice size could be varied using different sizes of fused silica tubing held in place by a graphite/vespel ferrule and a screw-on cap. All chromatograms were obtained using selected ion monitoring (SIM) at a flow rate of 1.2 mL/min with a exit orifice of 100 microns. The HPLC procedure consisted of the following linear gradient elution:

TIME(min)	%A (0.01M NH_4OAc)	%B (35/65 ACN/H_2O)
0	100	0
1	100	0
4	0	100

RESULTS: An LC/MS procedure was developed to separate and detect sulfonated azo dyes after instrumental parameters were optimized for sulfonated azo dye detection. Restriction of the thermospray vaporizer and addition of a repeller in the ion source are necessary to obtain mass spectra of disulfonated azo dyes. A number of important problems were encountered in developing a suitable LC/MS procedure for sulfonated azo dyes. Foremost was developing an LC procedure that would separate sulfonated azo dyes while still being compatible with thermospray detection. Previous results indicated that ammonium acetate concentrations higher than 0.01M were detrimental to sulfonated azo dye detection due to neutralization reactions occurring in the ion source.[3] As a result, a reverse-phase LC procedure was developed using a low concentration of ammonium acetate as an ion-pairing agent.

Full-scan mass spectra of selected disulfonated azo dyes in a mobile phase of 30:28:42 0.01M $NH_4OAc_{(aq)}$/acetonitrile/water are shown in Figs. 1 to 3. Characteristic ions were obtained in all spectra. These diagnostic ions include $[M-2Na]^{2-}$, $[M-2Na+H]^-$, and $[M-Na]^-$ ions. In some mass spectra, other diagnostic ions such as $[2M-3Na]^{3-}$ and $[2M-3Na+H]^{2-}$ were observed.

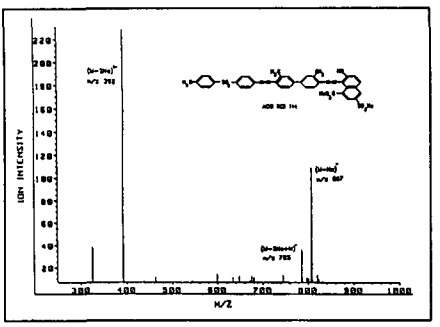

Figure 1. Full scan thermospray mass spectrum of Acid Red 114.

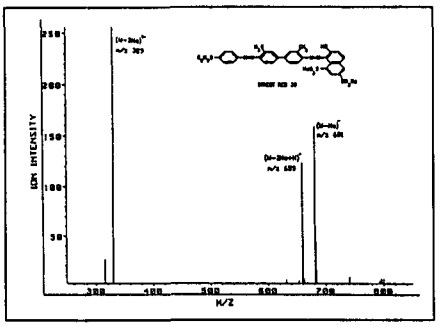

Figure 2. Full scan thermospray mass spectrum of Direct Red 39.

Molecular weight information is therefore available and in many cases can be used to identify a dye or to narrow down the possibilities for an unknown. Further mass spectral fragmentation and matching the retention time of a standard are needed for confirmation. An SIM trace of five dyes is shown in Fig. 4. All dyes were present in concentrations of about 500 ng assuming 50% purity. Only the $[M-2Na+H]^-$ ion was monitored for each dye. Selected ion chromatograms show that other characteristic ions such as $[M-2Na]^{2-}$ and $[M-Na]^-$ ions can also be used to confirm the presence of a dye in a particular sample even though their abundance is generally less than that of the $[M-2Na+H]^-$ ion.

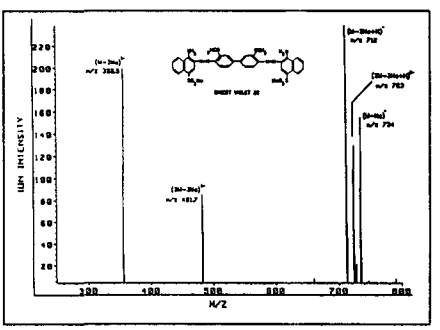

Figure 3. Full scan thermospray mass spectrum of Direct Violet 32.

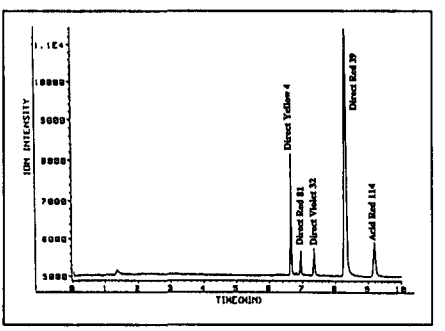

Figure 4. Selected ion chromatogram for a mixture of five disulfonated azo dyes monitoring the $[M-2Na+H]^-$ ion for each dye.

CONCLUSIONS: Modifications to a thermospray ion source and vaporizer are needed to obtain mass spectra for sulfonated azo dyes. These modifications include restricting the exit orifice of the thermospray vaporizer and the addition of a needle repeller in the thermospray ion source. A linear HPLC gradient of 100% 0.01M aqueous ammonium acetate to 100% 35:65 mixture of acetonitrile/water can be used to efficiently separate a mixture of disulfonated azo dyes using SIM detection. Mass spectra obtained under these conditions give pseudomolecular ions which can be used to determine the molecular weight of an unknown dye species.

IDENTIFICATION OF CARBONYL COMPOUNDS IN TOBACCO SMOKE BY LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

Henry L. Chung, Michael F. Borgerding, and Rebakah S. Dunn

R. J. Reynolds Tobacco Company, Bowman Gray Technical Center
Winston-Salem, NC 27102

An improved LC method for the determination of low molecular weight carbonyl compounds in tobacco smoke has been developed. A variety of reagents have been used to derivatize carbonyl compounds for subsequent chromatographic analyses. The reagent chosen for this work was 2-diphenylacetyl-1,3-indandione-1-hydrazone which reacts with carbonyl compounds to form an azine derivative and water. This method was based on work reported by Swarin and Lipari (1) which indicated the following advantages when using the hydrazone reagent: (a) The reagent is carbonyl specific; (b) Derivatives are formed rapidly and quantitatively with a minimum of sample preparation; (c) The derivatives fluoresce enabling detection at ppb levels; and (d) Accurate and precise quantitation is possible with liquid chromatography.

Although the hydrazone reagent appears ideal based on literature reports, additional chracterization was necessary before a useful, valid method could be developed. An on-line liquid chromatographic/mass spectrometric (LC/MS) system with a direct liquid introduction (DLI) LC/MS interface was used to identify the derivatized carbonyl compounds.

Carbonyl compounds in the smoke samples were collected and reacted with the derivatizing reagent under catalytic condition. A reversed-phasé C-18 column with an acetonitrile/water gradient as mobile phase at 1.2 ml/min was used for separation. All compounds of interest were sufficiently resolved. Positive chemical ionization mass spectra were obtained with protonated molecular ions for all the carbonyl-azine derivatives.

Fifteen carbonyl compounds were identified in mainstream tobacco smoke. Of interest is the identification of the existence of two isomers of acrolein-azines which have not been reported in the literature. These two isomers of acrolein-azine in the standard and the tobacco smoke were observed at m/z 393 by using the selected ion monitoring.

DLI- AND OTLC-MS ANALYSIS OF METRIBUZIN AND ITS METABOLITES

B.H. Escoffier, C.E. Parker, J.S.M. deWit, T.C. Mester, and K.B. Tomer

Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709

Metribuzin (MZN) is a 1,2,4-triazine herbicide which has been widely used on foodcrops, including soybeans, tomatoes, and sugarcane. Differences in crop tolerance to this herbicide has led to studies of its metabolism. Three metabolites are presently known: DA, deaminated metribuzin; DK, diketo metribuzin and DADK, deaminated diketo metribuzin.

The objective of this study was to compare Open Tubular Liquid Chromatography (OTLC) and Direct Liquid Introduction (DLI) LC/MS for the analysis of metribuzin and its metabolites in soybean plant extracts, and to evaluate LC/MS as a confirmatory technique when the presence of these metabolites is indicated by other less-selective detectors.

All four of the metabolites could be separated by DLI; three could be separated by OTLC on the available column. The fourth compound was of very low sensitivity, however, which would limit its detectability in either LC/MS mode. On column detection limits in the negative ion mode for MZN, DA, and DK were 10-30 pg in OTLC and 2-5 ng by DLI.

The positive and negative ion spectra obtained by OTLC/MS, which uses a heated interface were essentially identical to those obtained by DLI, where the interface is cooled. Since no additional fragmentation was observed in OTLC/MS, there is no evidence of thermal degradation of these compounds. For on-line injection of standards, OTLC had a sensitivity advantage of ~200. This can be partly explained by the absence of a solvent stream split in OTLC (<20% of the injected sample enters the source in DLI), and partly by the greatly reduced peak width in OTLC, leading to a higher mass flow per scan. Also, in DLI some of the sample may be lost with the solvent as the source pressure is adjusted by moving the probe inside the desolvation chamber.

The original OTLC injection system wasted too much sample (~200 ul was needed in order to inject 1 nl). A "dip" technique, analagous to on-column injection in capillary GC/MS, was developed in which the vacuum in the mass spectrometer is used to suck a known small volume (~1 nl) into the OTLC column. This low injection volume of OTLC (~1 nl) means that LC/MS analysis can be performed on very small sample volumes. This small injection volume, however, severely limits the amount of analyte that can be delivered to the source. Concentrating the sample prior to injection helps somewhat, but may lead to analyte solubility problems, and, since the matrix components are concentrated as well, may lead to plugging of the capillary column. A better LC/MS system may involve the use of packed capillary LC columns, which are presently under development.

Sensitivities of both OTLC and DLI LC/MS were sufficient to allow detection in extracts of soybean plants treated with 0.04 ppm metribuzin in the culture medium. Due to the limited injection volume of OTLC, however, the plant extract had to be concentrated by a factor of almost 100 compared to DLI before the metabolites could be detected. One would expect that the sample preconcentration and the relative sensitivity advantage of OTLC over DLI would compensate for the small injection volume of OTLC and result in similar responses between the two techniques for the plant extract analyses. DLI, however, gave a much better response than did OTLC. The plant matrix apparently has an extremely deleterious effect on the performance of the OTLC/MS system, and some of the analyte may have been lost during the extensive sample concentration process. Matrix effects in conventional HPLC have been observed in previous studies on these metabolites (1,2). Matrix effects are reduced in DLI LC/MS both by the inherent sample loading

characteristics of the larger column and by the injection system developed for on-line sample concentration and cleanup. This injection system combines the principles of "back cutting" (3) with column switching (3,4). An extra LC pump is used so that flow is not interrupted to the DLI probe during sample concentration and cleanup.

The major metabolite detected in both diploid (MZN-sensitive) and tetraploid (MZN-tolerant) soybean shoots was DA. A trace of DK was also detected. This pattern of metabolites was confirmed by radiochemical detection, which also indicated the presence of additional later-eluting metabolites. No consistent differences in the ratio of DA and MZN between the diploid and tetraploid soybeans could be detected by DLI, mainly due to the lack of suitable internal standards for quantitation. The major differences appeared to be in the late-eluting metabolites, detected by radiochemical detection. These metabolites did not show masses characteristic of the previously-identified metabolites. The structure of these metabolites have not been determined and are the subject of continuing investigation.

POSITIVE- AND NEGATIVE- ION CHEMICAL IONIZATION MASS SPECTROMETRY OF ALDICARB AND ITS DERIVATIVES BY PARTICLE BEAM HPLC/MS

Bert C. Lynn, Jr., G.D. Marbury, J.R. Tuschall, Jr., Northrop Services, Inc., Research Triangle Park, NC 27709
R.C. Willoughby, Extrel Corporation, Pittsburgh, PA 15238
E.J. Kantor, U.S. Environmental Protection Agency, EMSL/QAMDD, Las Vegas, NV 89193

The oxime carbamate pesticide, aldicarb and its oxygenated derivatives, aldicarb sulfoxide and aldicarb sulfone present a diffcult problem for the analytical chemist due to their relative instability of these compounds. To overcome these analytical problems, an HPLC/MS method was evaluated using the Thermabeam^R interface. Using flow injections, these aldicarb compounds were found to exhibit classic EI spectra, free from solvent interferences. However, the EI spectra, as with other sample introduction means, were highly fragmented, and there was very little structural information obtained for the three compounds. Therefore, chemical ionization (CI) was explored using a variety of reagent gases. With methane as a reagent gas in positive CI (PCI), the aldicarb compounds produced protonated molecular ions and ions resulting from the loss of the N-methylcarbamic acid group. For example, aldicarb showed $[M+H]^+$ (m/z 191), $C_5H_{10}SN^+$ (m/z 116), and $C_4H_7NO^+$ (m/z 85). Under negative CI (NCI), these compounds were found to produce unusual adduct ions. For example, aldicarb produced an anion at m/z 74 in the form of an N-methylcarbamic acid anion and an ion at m/z 264 (Figure 1) The anion at m/z 264 appears to arise from a "self CI" process in which a N-methylcarbamic acid anion reacts with an aldicarb molecule to form this adduct ion. To confirm that this process was not an artifact of the particle beam HPLC/MS interface and establish the parameters involved in this process, the NCI of aldicarb was investigated using solid probe and desorption CI (DCI) sample introduction.

The adduct formation was found to be concentration dependent appearing at levels greater than 0.1 ug and increasing through 20 ug. The formation of adduct ions was also dependent on the source pressure and type of reagent gas. Isobutane was found to produce the highest relative percentage of adduct to N-methylcarbamic acid anions between 0.25 and 0.50 torr, indicated source pressure. Electron energy had little or no effect on the ratio of m/z 264 to m/z 74, discounting classic CI processes. Based on these data, we hypothesize that the mechanism of this reaction involves aldicarb's ability to produce a flux of reactive n-methylcarbamic acid anions; these reactive anions interact with aldicarb molecules and are stabilized by energy transfer to reagent gas molecules resulting in the formation of the m/z 264 ion observed under NCI conditions.

To develop a selective reagent anion for aldicarb and its derivatives, experiments were conducted to exploit the process of adduct formation. Because the formation of N-methylcarbamic acid anions were observed from oxime carbamates, we investigated compounds that would , upon ionization, produce stable cationic leaving groups and carbamic acid anions. Benzyl carbamate formed a tropylium cation and a carbamic acid anion under CI conditions using methane as a reagent gas. Co-ionization of aldicarb and benzyl carbamate produced ions which could only arise from "cross CI" reactions (Figure 2). The ion at m/z 250 resulted from combination of a carbamic acid anion and an aldicarb molecule.

We are continuing experiments in the area of post column introduction of benzyl carbamate into the HPLC mobile phase to produce a steady state flux of carbamic acid anions for selective reaction with aldicarb and its derivatives.

A COMPARISON BETWEEN POSITIVE AND NEGATIVE ION MODES IN THERMOSPRAY LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY FOR THE DETERMINATION OF CHLOROPHENOLS AND HERBICIDES.

D. Barceló
Environmental Chemistry Dept. CID-CSIC
c/ Jorge Girona Salgado, 18-26. 08034 Barcelona (Spain)

INTRODUCTION

The thermospray (TSP) technique is becoming the most popular method for interfacing a liquid chromatography (LC) column with a mass spectrometer (MS) and typically involves the use of reversed-phase columns and volatile buffers such as ammonium acetate. TSP LC-MS has been employed for analyzing a large variety of pesticides and herbicides such as organophosphorus and pyrethroid insecticides and urea, triazine and chlorinated phenoxy acid herbicides (1-4). As the PI mode is the most popular way of operating TSP LC-MS, it is of interest to devote more attention to NI formation, specially for compounds of stronger acidity than acetic acid in the gas phase (1458 $KJ.mol^{-1}$). The ion-forming reactions observed in NI, TSP LC-MS are of a similar type to those in NICI-MS, with mechanims of proton abstraction $[M-H]^-$, resonance capture, dissociative capture and ion-molecule reactions (2,3).
In order to demonstrate the utility of NI, TSP LC-MS and examine the formation of adducts, 2,4-dichlorophenol, 2,4,5-trichlorophenol, pentachlorophenol, Linuron and Cyanazine were chosen as model compounds. The results are compared with those obtained using PI. Attention will be paid to the use of ammonium formate as ionizing additive in thermospray operation for characterizing the triazine herbicides Simazine, Atrazine and Propazine.

RESULTS AND DISCUSSION

For the first time, the NI, TSP-MS spectra of 2,4-dichlorophenol, 2,4,5-trichlorophenol, pentachlorophenol, Linuron and Cyanazine are reported. The effectiveness of NI versus PI in TSP LC-MS is demonstrated for compounds which are gaseous acids stronger than acetic acid, such as the chlorophenols, which are not even detected in the PI mode. For compounds which give higher signals in the PI mode than in NI mode (about 1 order of magnitude) such as Linuron and Cyanazine, the use of the NI mode offers valuable complementary information for the MS identification of these analytes Concerning the use of ammonium formate in the LC eluent it has been proved that this was an adequate buffer choice for analyzing triazine herbicides with slightly better sensitivities than when ammonium acetate was employed The generation of ammonium and formate or acetate ions as reactant ions for a gas-phase chemical process should be considered with different adduct ions formation in each case.

THE ROLE OF MASS SPECTROMETRY COMBINED WITH REVERSED PHASE HPLC IN THE IDENTIFICATION OF AN UNUSUAL SHELLFISH TOXIN#

R.K. Boyd, L.R. Hogge*, W.D. Jamieson, J.W. McLaren**, M.A. Quilliam, P.G. Sim, P. Thibault*** and J.L.C. Wright

National Research Council of Canada, 1411 Oxford Street, Halifax, Nova Scotia, B3H 3Z1 (* 110 Gymnasium Road, Saskatoon, Saskatchewan, S7N 0W9; ** Montreal Road, Ottawa, Ontario, K1A 0R6; *** 6100 Royalmount Ave., Montreal, Quebec, H4P 2R2), CANADA.

In November, 1987, an outbreak of shellfish poisoning occurred which was traced to cultured blue mussels (Mytilus edulis) from a very localized area of eastern Prince Edward Island. Symptoms induced in affected humans and in test mice used in the AOAC standard bioassay for paralytic shellfish toxins (1) indicated an excitatory neurotoxin but were unlike those induced by known toxins. Initially, several laboratories participated in screening contaminated and control mussels for known anthropogenic xenobiotics (methods such as ICP/MS for metals, GC/MS for organics) without success. By December 13, bioassays showed the toxin(s) not to have been lipophilic and our approach changed to concerted and parallel extraction, fractionation and characterization of contaminated and control mussels by quantitatively comparable bioassays, and by chemical assays. A team of more than 40, chemists as well as biologists and experts from Fisheries and Oceans Canada, cooperated in this work based at our Atlantic Research Laboratory in Halifax. The main chemical methods used were reversed-phase HPLC with UV diode-array detection (DAD), high voltage paper electrophoresis, micro-FTIR spectroscopy of thin dried films, and FAB-MS (VG Analytical ZAB-EQ) using a glycerol/water/HCl matrix.

As the toxicity was progressively concentrated, toxic extracts were marked by a peak in the HPLC/DAD chromatogram which gave a UV spectrum with a 242 nm maximum, while FAB positive mass spectra showed an increasingly characteristic ion at m/z 312 (m/z 310 in negative mode) suggesting a molecular mass of 311. The mass of the m/z 312 species was measured to be within 5 ppm of 312.146. Tandem mass spectrometry on ions of m/z 312 showed two and possibly three successive losses of 46 Da, attributable to HCO_2H, a characteristic (2,3) of protonated amino acids. Tentative identification of the toxin as an amino acid was supported by an intense fragment (CID spectrum) of m/z 312 at m/z 74, probably (2,3) due to $HCO_2CH{:}NH_2^+$. From the accurate mass and the evidence of at least four oxygen atoms, the molecular formula was taken to be $C_{15}H_{21}NO_6$.

Linked searches of chemical and toxicological databases suggested the unknown toxin was probably domoic acid 1, previously described (4,5) as occurring in Chondria armata, a marine alga native to Japan. Though mass spectra of domoic acid had not been reported, the data we had recorded were consistent with its structure, and the formula agreed as did other chemical characteristics such as the UV spectrum (4,5) shown in Fig. 1 (peak E). Later preparative HPLC isolated enough adequately pure toxin for NMR (proton, carbon-13) and FTIR spectra to confirm the toxin structure as 1. That these confirmatory results were obtained on December 16, and confirmed independently by Health and Welfare Canada the following day, shows the dedication, skill and stamina of the many who were involved. This work will be described fully elsewhere (6). Though the aquaculture industry must be interested in this new toxin, it will also be important in neurobiological research as it is the most potent known substrate for the kainate receptors of the central nervous system (7).

Further work on the mass spectrometry of 1 has shown: a positive FAB-MS ion at m/z 314 is due to beam-induced transformation of 1; tandem

NRCC No. 29014

mass spectrometry (Fig. 2) will be useful in discriminating between several of the isomers of 1 found at low levels in extracts of mussel tissue; thermospray-MS (Finnigan/Vestec) or plasmaspray-MS (VG ZAB-HF) of 1 yield few ions; continuous-flow HPLC-FAB-MS determinations of 1 should have a detection limit of 30 ng (full scan, lower in selected-ion mode; compare with 3 ng with full UV spectrum by HPLC-DAD, 0.3 ng for detection at 242 nm); GC/MS determinations should be feasible following conversion of 1 to the tert-butyldimethylsilyl (8) derivative. Relevant analytical procedures have been communicated to several laboratories in Canada, the U.S.A. and Europe who have been provided with an interim instrument calibration solution and reference samples, pending availability of certified reference materials.

RESIDUE ANALYSIS OF FOSAMINE AMMONIUM IN SOIL BY LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

L. M. Shalaby and J. E. Eble
E. I. du Pont de Nemours and Company, Inc.
Wilmington, DE

INTRODUCTION

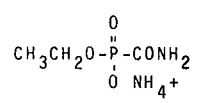
In the area of agricultural products, crops and soils are analyzed for parent and metabolites. These analyses are necessary to understand the manner in which the compound behaves in the environment. These levels are normally low. The highest acceptable limit of quantitation is generally 0.05 parts per million (ppm). Due to the low levels in difficult matrices, we look for high selectivity and high sensitivity in an analytical technique. We found the thermospray LC/MS to offer both.

Krenite® Brush Control Agent is a product which is applied as a foliar spray for control and/or growth suppression of many woody species. A field dissipation study is one of the studies run to monitor the behavior of the compound in soil. In this study, the dissipation of the active ingredient, fosamine ammonium, and the formation and dissipation of the major degradation product must be monitored under actual field conditions down to the 0.05 ppm level.

Both of these compounds are difficult to analyze in a soil matrix. The molecules are highly ionic and are not extracted into non-aqueous media. Also, due to their ionic nature, gas chromatography cannot be used. Numerous attempts at derivitization of fosamine ammonium to improve detection or allow the use of gas chromatography have led to more than one product and/or irreproducible results.

The compounds can be quantified with an ion exchange chromatography method. However, since the molecules have relatively low absorptivity, the compounds cannot be quantified down to the necessary 0.05 ppm limit in soil. We are able to quantify fosamine ammonium using an ion exchange liquid chromatographic method in tandem with thermospray mass spectroscopy.

STRUCTURE



Fosamine Ammonium
(mol. wt. = 170.1)

METHODOLOGY

The samples are received frozen and are maintained frozen unless being prepared or analyzed. The preprocessing is done as quickly as possible to minimize degradation of fosamine ammonium. The samples are prepared by placing the entire contents of a sample into a bag which is pounded with a wooden mallet until the contents are broken into small pieces. The bag is shaken and the entire sample, except for stones and plant matter, is passed through a mesh sieve by rubbing the thawing soil against the mesh.

A representative amount of the wet sample is immediately weighed into a large centrifuge tube. The first portion of extracting solvent is added as described below. At the same time moisture content of the soil is determined so that calculations made be done on a dry-weight basis.

The sample is extracted on a wrist action shaker with a mixture of ammonium carbonate and methanol. After centrifugation, the supernatant is passed through a C18 solid phase extraction (SPE) cartridge into a round-bottom flask. The combined extracts are concentrated on a rotovap and passed through a C18 SPE cartridge connected to a SAX SPE cartridge. Any residual fosamine ammonium remaining on the SAX cartridge is eluted by rinsing the cartridge with 0.2 M ammonium acetate. The combined rinses are evaporated to dryness. The dry tubes have been held in the refrigerator for three weeks with no sign of degradation.

The chromatographic system is an anion exchange system using a 25-cm Zorbax® SAX analytical column with a mobile phase of 0.05 M ammonium acetate plus glacial acetic acid to a pH of about 6.5. The HPLC pumps used were Spectroflow 400 models from ABI Analytical, Kratos Division. The thermospray LC/MS unit is the Vestec 201 form Vestec Corporation.

After the system is equilibrated an injection is made with the effluent from the column being directed to waste. The effluent remains directed to waste until 1 to 2 minutes before the elution of fosamine ammonium. The retention time of fosamine ammonium is about 13 to 15 minutes. When the elapsed time is within about two minutes of the elution of fosamine ammonium, the eluent is directed into the thermospray interface and the tip temperature brought to the predetermined optimal value. The timing is kept as consistent as possible from injection to injection. This procedure minimizes source contamination and eliminates matrix effects. Data is acquired by SIM at m/e of 171.

RESULTS

Investigations on the optimum stem temperature indicate a plateau of less than 7°C before reaching the take-off temperature. Recoveries were run on spiked control soil from two separate sites over a range of 0.05 ppm to 1.0 ppm. The average recovery was 84% +/- 19% with a limit of quantitation of 0.05 ppm. The use of SIM allowed us to obtain selectivity and sensitivity that we were unable to accomplish with any other technique.

A Comparative Evaluation of Liquid Chromatography/Thermospray Mass Spectrometry and Immunochemical Assay for Paraquat and Monoquat

T. L. Jones, L. D. Betowski, and J. M. Van Emon, U.S. Environmental Protection Agency, Las Vegas, NV 89114.

INTRODUCTION

Paraquat is an extensively used bipyridinium herbicide that is water soluble and has a low vapor pressure. Evidence of paraquat's acute oral toxicity to humans has been reported[1]. It has also been recently suggested that Parkinson-type disorders may be linked to paraquat exposure[2].

An enzyme-linked immunosorbent assay (ELISA) was developed for the determination of paraquat in various matrices[3,4]. A study was undertaken to use liquid chromatograph/mass spectrometric (LC/MS) and LC/MS/MS methods to monitor the purity of the compounds, the synthesis of the haptens, and the results from ELISA with another analytical technique. Other compounds that can cross-react within the immunochemical assay were also targeted for LC/MS monitoring.

EXPERIMENTAL

The paraquat dichloride standard was obtained from Sigma Chemical Co. (St. Louis, MO). Monoquat and paraquat hapten were synthesized by Dr. Van Emon[3]. The diquat dibromide was obtained from the U.S. EPA Repository (RTP, NC).

Thermospray LC/MS was performed with a Finnigan MAT 4500 Triple Stage Quadrupole (TSQ) interfaced with a Vestec Corp. thermospray system and a Spectra Physics SP8700-XR solvent delivery system. The HPLC flow rate was set to 0.4 mL/min with the following gradient elution conditions: 0 minutes, 50% methanol, 50% water; 5 minutes, 20% methanol, 40% water, and 40% ammonium acetate; 5 min hold time. A post-column addition of water was used to make up a total flow rate of 1.3 mL/min.

FAB mass spectra was obtained with a VG model ZAB-3F(8kV, Xe FAB reagent gas, He CAD reagent gas).

RESULTS AND DISCUSSION

The solvent environment played an important role in the final analysis of the paraquat structure as determined by LC/MS and LC/MS/MS. The predominant ion was m/z 186 when water was used as the post-column solvent. However, the use of ammonium acetate as a post-column solvent resulted in the disappearance of m/z 186 ion and the emergence of m/z 187 ion. It was proposed that the attachment of a hydride ion forms the m/z 187 ion[5]. The lack of evidence for the m/z 93 dication and the appearance of the m/z 186 ion, in an aqueous environment, would suggest a one-electron reduction of the dication.

It is interesting to note the difference in their CAD spectra between the m/z 186 ion and the m/z 187 ion. Initially the m/z 186 ion and the m/z 187 ion both lose 15 amu to give m/z 171 and m/z 172 respectively. Further CAD experiments on these ions are instructive in the fact that the m/z 171, an even-electron ion, loses methane(CH_4) and the m/z 172, an oddelectron ion, does not show this behavior as the major channel is loss of a methyl radical ($CH_3^{\cdot}$).

CONCLUSIONS

The results demonstrate that the use of water as a post-column solvent enhances the paraquat m/z 186 ion detection. LC/TSP/MS, though not as sensitive as ELISA, provides a selective detection method for cross-validating immunochemical assays, while the specificity of MS/MS provides for greater compound identification.

Future experiments will include analysis of various matrix extracts for immunochemical assay comparisons.

SURFACE ANALYSIS WITH A TIME-OF-FLIGHT MASS SPECTROMETER WITH CHARGE COMPENSATION FOR SECONDARY IONS AND POSTIONIZATION OF NEUTRALS

E.Niehuis, B.Hagenhoff, T.Heller, G.Kampwerth,
D.van Leyen and A.Benninghoven

Physikalisches Institut, Universität Münster
4400 Münster, FRG

Secondary ion mass spectrometry (SIMS) has become a well established surface analytical technique. A variety of e/m-analyzers are applied for mass analysis of the generated secondary ions: magnetic sector fields, quadrupols, and, more recently, ion cyclotron resonance (ICR) and time-of-flight (TOF) instruments.

Time-of-flight features some important properties, which make this technique most attractive for secondary ion mass spectrometry: high transmission, unlimited mass range, and quasisimultaneous detection of all masses.

We built a number of TOF-SIMS instruments which we apply successfully to a wide variety of analytical problems. Main fields are:

- detection, identification and structural analysis of biomolecules
- characterization and surface analysis of polymers
- characterization and surface analysis of electronic materials
- detection of organic as well as inorganic traces

The successful application of TOF-SIMS in these different fields is based on instrumental developments in the following directions:

- high mass resolution,
- charge compensation for insulating materials, and
- postionization of sputtered neutrals for quantitative element analysis

1. High mass resolution

The mass resolution of a time-of-flight instrument is determined by the quality of the primary ion pulse, the energy focusing properties of the drift path, and the time resolution of the detection and registration unit.

In our TOF-SIMS instruments the primary ion pulse is generated by an EI gas ion source combined with a pulsed 90°-deflector, a bunching system and a lense. For 10 keV Ar^+-primary ions we obtain mass separated ($m/\Delta m = 350$) ion pulses below 1 ns with a repetition rate between 5 and 10 kHz. Each pulse contains up to 10.000 ions. The beam diameter on the target surface is typically 100 µm.

Secondary ions are accelerated by a 3 kV extraction voltage and separated in a single stage reflectron with first order energy focusing properties.

Figs 1 and 2 present sections of the positive secondary ion spectrum in the low mass range for a contaminated GaAs surface (Fig. 1) and a polymer surface (Fig. 2). The high mass resolution allows the separation of Fe^+ and CaO^+ as well as the separation of metal ions from the corresponding hydrocarbon ions emitted from the GaAs surface. In the PMMA-spectrum pure hydrocarbon ions are separated from those containing oxygen.

2. Charge compensation

During ion bombardment of insulating materials charging of the bombarded surface occurs. This results in a loss of resolution and transmission. We have developed a pulsed charge compensation device which avoids completely these effects /1/. Charge compensation is realized by low energy (5 eV) electron injection into the target region during the time between two ion pulses. By an appropriate pulsed field modification in the target region all disturbing effects of postaccelerated electrons, as EI of particles in the gas phase, electron bombardment induced ion emission, etc. can be avoided. We have

applied this charge compensation device successfully to many insulating samples as glasses, polymers, oxides, etc.

3. Postionization of sputtered material

The majority of sputtered particles emitted from a solid surface during ion bombardment are neutral. Their postionization can be realized most efficiently by EI or by laser irradiation. We have applied the technique of UV-multiphoton postionization described by Becker and Gillen /2/ by attaching an Excimer laser to our TOF-SIMS. We obtained useful yields for atomic particles in the 10^{-3} range for metals and semiconductors /3/.

ANALYSIS OF DRUGS OF ABUSE BY PARTICLE BEAM LC/MS

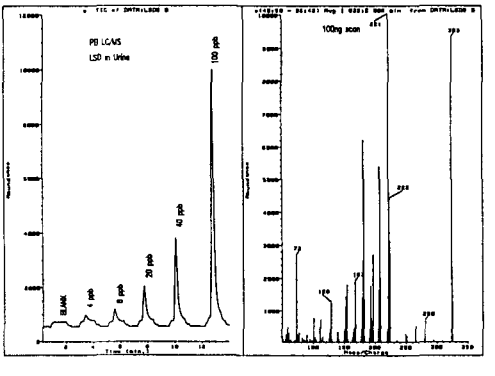
A. Apffel; Hewlett-Packard Company, Palo Alto, California 94304

The introduction of Particle-Beam based LC/MS (PB LC/MS) interfacing techniques opens the opportunity of utilizing high performance liquid chromatography on a wide range of applications in which GC/MS is not applicable, while retaining high information content EI spectra at low detection limits (mid-pg).

The analysis of drugs of abuse (e.g. LSD, Amphetamines, and Fentanyl) by GC/MS requires extensive pre-treatment involving extraction, preconcentration and derivatization. The use of precolumn technology in HPLC automates cleanup procedures of large volumes of physiological fluids, negating the need for labor intensive sample work-up. Furthermore, PB LC/MS generates EI or CI spectra for thermally labile or low volatility compounds, negating the need for derivatization

The following three applications demonstrate these advantages.

1. LSD has been analyzed with derivatization, generating library searchable EI spectra below 10ng Automated preconcentration procedures allow SIM detection below 1 ppb.



2. A mixture of amphetamines has been analyzed in biological fluids generating EI spectra below 100ng. The use of automated on-line precolumn concentration allows large volumes of physiological fluids to be analyzed for these drugs at low levels with positive confirmation.

3. Fentanyl and Sufentanyl have been rapidly cleaned up from plasma samples with off-line solid phase extraction procedures. Analysis of the extracted fraction yields rapid identification of the components in this complex matrix.

LSIMS of Intact Oligosaccharides: Comparison of Sensitivity and Spectral Quality Among Selected Derivatives

L. Poulter, R. Karrer, K. Jiang, B.L. Gillece-Castro and A.L. Burlingame
Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446

In this laboratory we are pursuing a comprehensive strategy to separate and characterize oligosaccharides isolated from low levels of glycoproteins. To increase sensitivity in the LSIMS analysis it is necessary to derivatize oligosaccharides, thereby increasing their surface activity within the liquid matrix. However, before mass spectrometry can be applied, the oligosaccharides need to be purified. An ideal derivative would therefore incorporate a radiolabel or a chromophore to aid detection during chromatography, as well as a hydrophobic group to increase surface activity. To address this issue we have extended our work[1] and that of others[2], by using a series of alkyl esters of p-aminobenzoic acid to derivatize the reducing termini of oligosaccharides.

All esters that were not commercially available were synthesized from p-aminobenzoic acid and the corresponding alcohol[3] and reductively coupled to the reducing termini of oligosaccharides as shown in Figure (1). Reverse phase HPLC (Vydac, C4 or C18) using water and acetonitrile was effective in desalting samples prior to mass spectrometry with monitoring at λ = 304 nm to detect the derivatized oligosaccharides.

Maltoheptaose (M7) was derivatized with all esters from methyl to tetra-decyl and the relative sensitivities of these derivatives were compared. Figure (2) shows the time courses obtained for protonated molecular ions using 0.1 µg of M7-ABXE in 1 µl of glycerol:thioglycerol (1:1). From the graph it is clear that increasing alkyl chain length does have a profound effect on sensitivity in LSIMS. Esters higher than octyl did have greater absolute sensitivity, however the yields obtained in the derivatization were considerably reduced, largely due to problems of solvent incompatibility.

Figure (3) shows the negative-ion spectrum obtained on 0.2 µg of a hexasaccharide derivatized with the octyl ester. Glycosidic bond cleavages are observed with charge retention at the derivatized reducing terminus providing the structural information shown. The chemical noise arising from the matrix was eliminated by resorting to positive-ion MS/MS (carried out on a four sector Kratos Concept with array detection) which provided clear glycosidic bond cleavages with charge retention on both reducing and non-reducing termini[3].

Studies carried out within our group have shown that derivatization with the ethyl ester of p-aminobenzoic acid provides a sensitivity in LSIMS comparable to that achieved by permethylation or peracetylation. While one might not expect this ester derivative to be as surface active as a permethylated or peracetylated sample, the reverse-phase HPLC step used after derivatization provides an extremely clean sample for MS analysis. By using the octyl ester, the amount of sample needed is decreased by approximately a factor of ten. The small increase in mass obtained upon derivatization is an important factor when larger oligosaccharides are of interest, while the lack of under- or over-derivatized products and salt adducts makes mass spectral interpretation much easier, particularly in the case of oligosaccharide mixtures. Reducing terminal fragments predominate in the negative-ion mass spectra of the ester derivatives, as opposed to non-reducing terminal fragments in the case of permethylated or peracetylated samples; however by using MS/MS methods on the ester derivatives both reducing and non-reducing terminal fragments can be obtained.

CHARACTERIZATION OF A PRE-S2 GLYCOPEPTIDE FROM HEPATITIS B SURFACE ANTIGEN BY LIQUID SECONDARY ION MASS SPECTROMETRY

B. L. Gillece-Castro and A. L. Burlingame, Dept. of Pharmaceutical Chemistry and the Liver Center, University of California, San Francisco, CA 94143-0446 and D.L. Peterson, Dept. of Biochemistry, Medical College of Virginia, Richmond, VA 23298

The comparison of protein and carbohydrate structures of vaccines for Hepatitis B is the goal of this work. Hepatitis B surface antigen (HBsAg) used in vaccination is a complex macromolecular structure containing glycoproteins embedded in a lipid bilayer. The protein components are all derived from a single open reading frame in the viral genome, referred to as the S+Pre-S2+Pre-S1 gene. The majority of the proteins contain only S sequences however 10% or less contain both Pre-S2 and S sequences. HBsAg from human plasma and that expressed in Chinese Hamster Ovary (CHO) cells were analyzed to confirm the amino terminal sequence, determine the amino terminal blocking groups, and determine the structures of the asparagine linked oligosaccharides of the Pre-S2 region.

The amino terminal Pre-S2 glycopeptide was isolated from the antigen by tryptic digestion of the intact antigen and HPLC isolation of peptides. The 16 amino acid amino terminal peptide could not be sequenced by Edman chemistry without the removal of the N-terminal Met which was blocked. A strategy of enzymic (PNGase F) deglycosylation of glycopeptides followed by separation of the peptide and oligosaccharide portions by reverse phase HPLC and LSIMS analysis of the products was followed. MH^+ ions for cloned and human peptides were found at *m/z* 2033 or 43 Da greater than predicted. In this manner it was determined that both plasma and CHO derived peptides were acetylated on their amino termini and the glycosylated Asn was converted to Asp.

The oligosaccharides which eluted in the void volume of the previous HPLC were derivatized at their reducing termini with p-amino benzoic acid esters ABEE or ABOE (1,2,3) to introduce a hydrophobic chromophore and site of charge localization. Acidic and neutral fractions of the derivatized oligosaccharides were separable by reverse phase HPLC (Figure 1) and LSIMS data is shown for the neutral fraction of the cloned antigen oligosaccharides. Molecular anions (not shown) at *m/z* 2226 and 2064 were observed from the acidic fraction of the cloned HBsAg as the ethyl ester (ABEE) derivative. These correspond to biantennary complex oligosaccharides with one fucose and one N-acetyl neuraminic acid (sialic acid). The larger oligosaccharide is shown while the other is truncated by the loss of one hexose. The neutral oligosaccharides are shown (Fig 2) as the octyl ester derivatives (ABOE) which gives an improved signal to noise. The major component is the fucosylated biantennary structure (*m/z* 2019) shown. However a higher molecular weight triantennary structure is also present (*m/z* 2384) as is a bifucosylated biantennary oligosaccharide (*m/z* 2165). Evidence for truncated structures is subtle in this spectrum and is represented by the abundance of the ions at m/z 1857, 1653 and 1492. The oligosaccharides from plasma derived HBsAg were similarly treated and the LSIMS data included the molecular anion is m/z 1873 and fragments of this biantennary oligosaccharide are noted. It is significant to note that no fucosylated or triantennary structures are presented by the human antigen, but are present on the CHO cell antigen. The strategy of enzymatic deglycosylation followed by HPLC isolation of peptide and oligosaccharide portions and subsequent LSIMS analysis of peptides and reducing terminal derivatives of oligosaccharides was successful in identifying peptide modifications as well as characterizing the oligosaccharides attached at a paricular site.

LSIMS Analysis of High Mannose and Complex Sialylated Oligosaccharides Isolated from Low Levels of Glycoprotein: Application to α_1 Acid Glycoprotein and the Nicotinic Acetylcholine Receptor

Linda Poulter and A.L. Burlingame
Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446

The full characterization of N-linked oligosaccharides from membrane-bound glycoproteins, such as insulin receptor and epidermal growth factor receptor, is a goal of our research group. Since typically only picomole to nanomole quantities of these proteins are available from most sources, a successful approach requires high recovery in the isolation and purification of oligosaccharides as well as excellent sensitivity in the subsequent mass spectral analyses.

We first developed a protocol using 2 nanomoles of α_1-acid glycoprotein from human plasma which, although not an integral membrane protein, possesses large and highly sialylated oligosaccharides. Having established the appropriate methods, we then turned to the more challenging analysis of 2 nanomoles (500 µg) of the nicotinic acetylcholine receptor (nAChR) from Torpedo californica[1]

In the generalized procedure, glycoproteins were deglycosylated using peptide-N-glycosidase F (PNGase F) in ammonium bicarbonate buffer (100 mM, pH 8.6) in the presence of 0.1% sodium dodecyl sulphate (SDS) and 0.6% Nonidet P-40 (NP-40). Analytical SDS-polyacrilamide gel electrophoresis was used to test for complete deglycosylation. SDS was precipitated by adding guanidine hydrochloride (1.0 M) dropwise, and after cooling and centrifugation, the supernatant was applied to a C-18 Sep pak cartridge. Oligosaccharides were eluted with water, and the protein was removed subsequently with 80% acetonitrile/0.1% TFA. The aqueous phase was lyophilized and the reducing termini of all oligosaccharides were derivatized with p-aminobenzoic acid hexyl ester in the presence of sodium cyanoborohydride, and then chromatographed by reverse phase HPLC. Derivatization introduces a chromophore (λ_{max} = 304 nm) and also a hydrophobic tail to aid sensitivity in the LSIMS analysis[2,3], while RP-HPLC desalts the samples effectively and separates the oligosaccharides largely on the basis of net charge.

Positive-ion LSIMS, using 200 pmol - 500 pmol of oligosaccharide, gave molecular weight information only, while negative ion spectra provided extensive fragmentation with cleavage of glycosidic bonds and charge retention at the derivatized reducing termini of all oligosaccharides. Figure (1a) shows the negative-ion spectrum of the monosialylated fraction from nAChR revealing no less than eight molecular ions [$(M-H)^-$ = 1932, 2094, 2135, 2176, 2338, 2379, 2500 and 2541, nominal masses]. The molecular weights provide monosaccharide compositions (on the basis of deoxyhexose : hexose : hexosamine : sialic acid), while fragment ions confirm proposed structures [e.g. see $(M-H)^-$ = 1932 and 2094 in Figure (1b)]. Table (1) lists data on all of the oligosaccharides found in this analysis. Negative-ion spectra on oligosaccharide mixtures or on further purified components provided branching information.

The lack of mass spectral complexity, such as that brought about by under- or overderivatized oligosaccharides or the presence of salt adducts, is notably absent using our procedure. The application of this method when dealing with heterogenous mixtures of oligosaccharides is therefore particularly useful. The small increase in mass of oligosaccharides upon derivatization is also an important factor when larger structures are to be analyzed.

IDENTIFICATION OF 5'-DEOXYXANTHOSINE IN HUMAN URINE:

Thomas D. McClure and Karl H. Schram, Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, Arizona, 85721 and K. Nakano and T. Yasaka, PL Comprehensive Institute, 1 Kamiyamacho, Tondabayashi, Osaka 584, Japan.

Introduction

The occurrence of 5'-deoxynucleosides or nucleotides as natural components of biological systems is rare. Until recently, the only known member of this class was 5'-deoxyadenosine (5'-dA), which occurs as a result of the metabolism of nicotine adenine dinucleotide. Chheda, et. al. have isolated the second such compound, 5'-deoxyinosine(5'-dI)[1], from the urine of chronic myelogenous leukemia patients. This report describes the isolation and identification of 5'-deoxyxanthosine(5'-dX) the third compound of this class, from human urine.

Isolation and Preparation

5'-dX was isolated and identified from normal human urine by the following methods. The urinary nucleosides were separated from other urinary components using the boronate-gel method of Gehrke, et. al.[2]. A preliminary separation of the nucleoside mixture was then accomplished using HPLC[3]. The HPLC fractions were converted to their trimethylsilyl(TMS) derivatives[4] for GC/MS analysis.

GC conditions include: linear temperature programing from 150 to 300 deg. at 6 deg. per minute using a bonded phase 30m capillary column; splitless injection; and direct inlet into the ion source of the mass spectrometer. Mass spectrometer conditions include: low resolution (R=1000); GC/MS scanning a range of m/z 70 to 1000 at 2 scans per second; high resolution studies (R=7200) on the reference compound were acquired by peak matching from the direct inlet probe. The instrument used was a Finnigan MAT90 with a Varian 3400 GC.

Reference Compound Synthesis

A reference compound of 5'-dX was prepared using a combination of biochemical and chemical methods. Initially it was believed that 5'-dX might be the product of purine metabolism involving first the adenosine deaminase (ADA) conversion of 5'-dA to 5'-dI. 5'-dI is then oxidized by xanthine oxidase (XO) to 5'-dX. Under these experimental conditions, 5'-dI was not converted to 5'-dX, leading to the conclusion that 5'-dI is not a substrate for XO. The next attempt to produce 5'-dX involved the use of purine nucleoside phosphorylase (PNP) to couple xanthine to 5'-deoxyribose-1-phosphate (5'-dR-1-P)[5]. No reaction occurred. PNP did couple guanine to 5'-dR-1-P to form 5'-dG, which was then deaminated chemically to 5'-dX.

Discussion

Major points of interest[6] in the low resolution mass spectra of the TMS derivative of 5'-dX include a) m/z 556 which is a very weak ion, and m/z 541 assigned as the $M^{+\cdot}$ and M-15 ions for 5'-dX; b) m/z 260 (S-H), m/z 217 ($C_3H_3O_2TMS_2$), and m/z 171 (S-90) which indicate the presence of a deoxypentofuranose. The very low intensity of m/z 103 (CH_2OTMS) suggests the 5' position is lacking a hydroxyl group; c) m/z 423(B+128), m/z 369(B+74), m/z353(B+58), m/z 325(B+30), m/z 297(B+2H) and m/z 281(B-14) assigned as containing the base plus portions of the sugar. A comparison of the spectra of the reference and urinary compounds is found in fig.1. Structures of the above ions were further substantiated by preparation of the TMS-$^2H_9$ analog and analysis of the resulting spectrum.

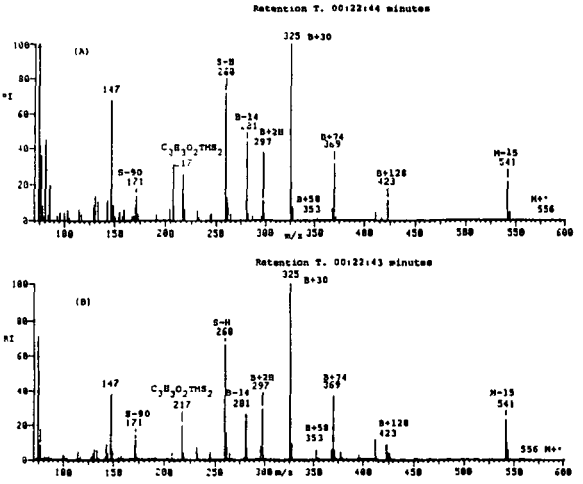

Fig. 1 Low resolution mass spectrum of (a) urinary 5′-dX and (b) biochemically synthesized 5′-dX.

In order to eliminate 2′- and 3′- dX from consideration, the low resolution spectra of these compounds were compared to that of 5′-dX. Important differences in the mass spectra of 2′,3′ and 5′-deoxynucleosides have been noted[7], and this comparison establishes the 5′ position as the site of deoxygenation.

High resolution MS was performed on the reference compound for the ions listed above. Elemental composition for these ions is established and is consistent with the assigned structures.

The LC and GC retention times for the reference compound and the urinary component were in agreement within experimental error, further verifying the identity of the urinary component as 5′-deoxyxanthosine.

MASS SPECTRAL CHARACTERIZATION OF ACRYLONITRILE OXIDE DNA ADDUCTS. ALKYLATION AT N-3 OF CYTOSINE RESULTS IN HYDROLYTIC DEAMINATION TO A URACIL ADDUCT.

Jerome J. Solomon, K. Decker, F. Mukai and A. Segal

Institute of Environmental Medicine, New York University Medical Center, New York, NY 10016

Acrylonitrile epoxide (2-cyanoethylene oxide, ANO) is a mutagenic 3-carbon epoxide. ANO has been suggested to be the ultimate carcinogenic metabolite of the rodent carcinogen acrylonitrile (AN, CH_2=CH-C≡N) in part due to its structural similarity to vinyl chloride. AN is extensively used in industrial applications with a production in 1986 of 2.3 X 10^9 lbs. OSHA has estimated that 278,000 workers are potentially exposed to AN. AN requires metabolic activation to cause mutations with S. typhimurium but has also been found to be a weak direct-acting mutagen in E. coli WP2. We previously examined the ability of AN to form adducts with calf thymus DNA without metabolic activation. Alkylation via Michael addition was very slow at physiological pH and temperature and adducts were reported after a 40 day reaction. Cyanoethyl (CNE, -CH_2CH_2CN) adducts were detected at N-7 guanine and N-3 thymine but carboxyethyl (CE, -CH_2CH_2COOH) adducts were produced at sites adjacent to an exocyclic nitrogen (N-1 adenine and N-3 cytosine). We proposed a mechanism for the rapid hydrolysis of CNE adducts to CE adducts. The CE adducts that result at N-1 of A and N-3 of C are common lesions that we have shown to be produced by several rodent carcinogens including β-propiolactone, AN, acrylamide and acrylic acid.

The purpose of this study was to characterize how ANO modifies DNA. ANO was reacted at pH 7.0-7.5 and 37°C for 3 h with 2'-deoxynucleosides and formed a variety of adducts. Figure 1 gives the structure of the adducts detected and includes the yields determined after 3 h reaction. Attempts to obtain EI and CI spectra for several of these adducts were unsuccessful due to the polarity of the adducts. Derivatization resulted in volatile products whose EI mass spectra are shown in Figure 2. Table I lists the results of accurate mass measurement studies on M and M-CH_3 ions for the trimethylsilyl (TMS) derivatives of ANO-DNA adducts. A proposed pathway for the formation of 1,N^6-etheno-dAdo (ε-dAdo) and N^6-(2-hydroxy-2-carboxyethyl)-dAdo (N^6-HOCE-dAdo) is given in Figure 3. Conversion of 1-(2-hydroxy-2-cyanoethyl)-dAdo (1-HOCNE-dAdo) to 1-HOCE-dAdo occurs as with AN at N-1 of A where the nitrile group was hydrolyzed to a carboxylic acid. The formation of ε-dAdo from ANO and dAdo is similar to the formation of ε-dAdo from the reaction of the structurally related epoxide of vinyl chloride with dAdo. A scheme for the alkylation at N-3 of dCyd which results in a dUrd adduct, 3-HOCE-dUrd, is shown in Figure 4. The initial ANO adduct contains a OH group in the 3-carbon side chain which catalyzes the hydrolytic deamination of 3-HOCE-dCyd to 3-HOCE-dUrd.

ANO was reacted with calf thymus DNA (pH 7.0-7.5, 37°C, 3 h) and yielded N^6-HOCE-dAdo (2 nmol/mg DNA), ε-dAdo (11 nmol/mg DNA), 3-HOCE-dUrd (80 nmol/mg DNA), 7-(2-oxoethyl)-Gua (7-OXE-Gua, 110 nmol/mg DNA) and 3-OXE-dThd (1 nmol/mg DNA). The ANO adduct which results from hydrolytic deamination of an initially formed adduct at N-3 of dCyd is a major lesion in DNA. Experiments with other 3-carbon epoxides including propylene oxide, epichlorohydrin and glycidol indicate that this C to U conversion may be a common phenomenon with aliphatic epoxides containing a primary carbon in the oxirane ring and may play an important role in the biological activity of this class of compounds.

FAB-MS/MS AS A SCREENING METHOD FOR DETECTING TRACE AMOUNTS OF BIOMOLECULES IN HPLC FRACTIONS

Andrea M. Dietrich[1], Christian R. Guenat[2], Kenneth B. Tomer[3], Louise M. Ball[4]
[1] Div. of Envir. Engr. and Envir. Sci., Virginia Polytechnic Institute, Blacksburg, VA 24061-0246; [2] CIBA-GEIGY AG, Basel, Switzerland; 3 Laboratory of Molecular Biophysics, NIEHS, Research Triangle Park, NC 27709; [4] Dept. Environmental Sciences and Engineering, University of North Carolina, Chapel Hill, NC 27599-7400

FAB-MS/MS is a useful technique to generate characteristic fragmentation data from specific molecules in complex mixtures/matrices. In this research FAB-MS/MS was applied to successfully detect and identify the DNA nucleoside adduct **N-(deoxyguanosin-8-yl)-3-aminofluoranthene (MW 482)**. This biomolecule was produced from reacting calf thymus DNA with reduced 3-nitrofluoranthene under acidic conditions, followed by aqueous enzymatic hydrolysis of the DNA to 2'-deoxynucleosides. The digested DNA, which contained both modified and normal nucleosides, was extracted with n-butanol which preferentially concentrates the nucleosides containing the non-polar fluoranthene moiety.

The n-butanol extract, which was taken to dryness and redissolved in methanol, was subjected to +FAB-MS and +FAB-MS/MS. Mass spectrometric experiments were performed on a VG ZAB-4F (BEEB configuration) with an 11-250 datasystem. The xenon FAB gun was operated at 8 kV and 1 mA current with a matrix of dithiothreitol/dithioerythritol (DTs). Full scan mass spectrometric data, acquired at a scan rate of 10 sec/decade, 8000 kV accelerating voltage, and 1000 resolution, indicated the presence of the protonated molecular ion at m/z 483, and a major fragment ion at m/z 367 due to loss of the deoxyribose moiety and migration of a deoxyribose proton to the modified guanine base (see structure in Figure 2). Collisionally activated decomposition (CAD) spectra were obtained by collision of m/z 483 and m/z 367 with helium in the grounded collision cell of the third field free region. Mass analysis of the daughter ions was achieved by a B_2/E_2 linked scan of MS_2. The scan rate was 30 sec/decade. The MS/MS spectrum of m/z 483 lead to a single daughter ion at m/z 367. The MS/MS spectrum of m/z 367 yielded numerous characteristic daughter ions, including ions related to cleavage of the C-N bonds of guanine-aminofluoranthene, and a series of ions due to loss of fragments from the purine ring.

Initial chromatographic separation of the n-butanol extract demonstrated a complex, poorly resolved UV/VIS HPLC chromatogram containing approximately 30 components (Figure 1). Only one of these components was the desired adduct, and only about 100 ug were present. In order to isolate the adduct and recover as much N-(deoxyguanosin-8-yl)-3-aminofluoranthene as possible, HPLC fractions were collected and then screened for the presence of this adduct using FAB-MS/MS analysis of m/z 483 and m/z 367. Initially four HPLC fractions (7-14 minutes each) were collected during a 40 minute HPLC separation program, and the adduct was identified in Fraction 3 (Figures 1 and 2). The impurity at m/z 329 in Figure 2 was not present in the unfractionated sample, and was shown to be both an artifact primarily due to a DTs adduct of dimethyloctadecylsilanol from the C_{18} column (328 + 154 + 1).

Fraction 3 was still a complex sample, so it was further chromatographed from 70% methanol/30% water to 83% methanol/17% water in 20 minutes, and six HPLC fractions were collected. These fractions were again screened by MS/MS for the presence of m/z 483 fragmenting to m/z 367. If m/z 367 was present, then the daughter ion spectrum was obtained to confirm the presence of N-(deoxyguanosin-8-yl)-3-aminofluoranthene in the fraction. A third level of chromatographic separation using a methanol/water gradient from 60% methanol to 75% methanol in 30 minutes was necessary to resolve and isolate purified N-(deoxyguanosin-8-yl)-3-aminofluoranthene. The final purified adduct yielded spectra similar to those obtained for the unpurified adduct in the initial n-butanol extract. The major differences were due to the presence on impurities such as the DTs/dimethyloctadecylsilanol adduct cited above. Although several iterations of HPLC separation, fraction collection, and FAB-MS/MS screening were necessary, the chromatographic peak containing the adduct was identified, and N-(deoxyguanosin-8-yl)-3-aminofluoranthene was successfully isolated and purified.

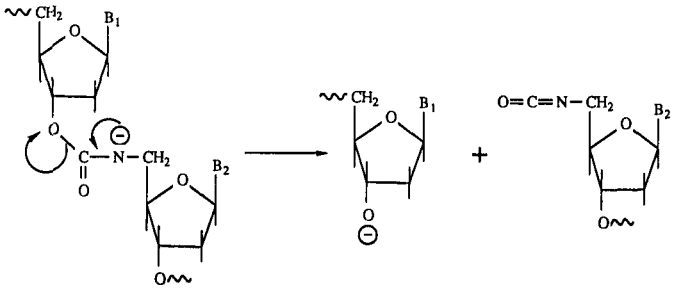
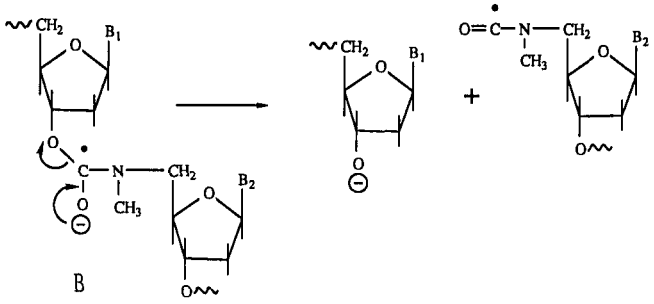
FRAGMENTATION OF OLIGODEOXYNUCLEOTIDES

J.A. Laramée[1], B. Arbogast[1], G. Stirchak[3], D. Weller[2], and M.L. Deinzer[1]
Departments of Agricultural Chemistry[1] and Chemistry[2]
Oregon State University, Corvallis, Oregon 97331 and
Antivirals, Inc.[3], Corvallis, Oregon 97333

Predictable fragment ions from oligonucleotide carbamate analogs (A) can be used to confirm their base sequence (Griffin et al., 1988). Primary cleavage occurs at the carbamate linkage between the carbonyl carbon and ether oxygen at the 3'-ribose position (cleavage A). Fragmentation results in a regular anion series with the negative charge borne by the 3'-oxygen and formation of an isocyanate moiety at 5'-carbon on the next base unit. This mechanism should proceed if ionization occurs from the amide nitrogen to yield $(M-H)^-$ anions (Eq. 1). The presence of a methyl carbamate unit in the backbone of the oligonucleotide carbamate analog (B) yields the same ion series despite the absence of weakly ionizable amide protons. Capture of thermal electrons generated in the matrix (Williams et al., 1987) to generate the radical anion and subsequent dissociation to form the alkoxide ion is proposed (Eq. 2). Calculation of $(M-H)^-$ isotope distribution shows poor fit with experimental measurements, but inclusion of calculated isotopic abundance for $M^{+\cdot}$ in the molecular ion composition, shows much better agreement with experimental isotopic patterns.





The presence of low-lying molecular orbitals seems to enhance formation of $M^{\pm}$ relative to $(M-H)^-$ ion. The experimental results for p-nitrophenyl ester of a morpholino nucleic acid (C) molecular ion cluster, for example, suggests considerable contribution of $M^{\pm}$ ion. The fragment ion with m/z 571.2, on the other hand, shows good agreement between calculated and experimental isotope cluster patterns.

Electron capture in negative ion FABMS or LSIMS may be more general than previously realized. For example, molecular ion centroid clusters are shifted to higher mass for oligodeoxynucleotides and this shift seems mass dependent (Fig. 1). Oligodeoxynucleotides, therefore, may fragment from the $M^{\pm}$ ion yielding the expected 3' and 5' ion series (Grotjahn et al., 1982) (Eq. 3).

MASS SPECTROMETRIC APPROACHES TO THE CONFIRMATION OF MADURAMICIN α IN CHICKEN FAT

S. J. Stout, L. A. Wilson, A. I. Kleiner, A. R. daCunha, and T. J. Francl

American Cyanamid Company, Agricultural Research Division, Princeton, New Jersey 08540

Introduction

Maduramicin, a polyether ionophore antibiotic, is a potent coccidiostat effective at a level as low as 5 ppm. Regulatory agency requirements state a confirmatory assay should yield high chemical specificity concomitant with providing structural information for unambiguous drug residue identification. Because mass spectrometry meets these criteria, it has gained widespread acceptance as the preferred analytical technique for confirmatory methods of analysis. For a confirmatory assay, coupling the thermal instability and low volatility of the ionophores with matrix coextractives essentially precludes the more routine mass spectrometric confirmatory approaches of GC/MS and solid probe/MS. Fast atom bombardment (FAB) was recently used for the quantitation of the polyether ionophore, monensin, in chicken fat, but did not provide sufficient fragmentation data for a confirmatory analysis(1). Additionally, FAB contributes further matrix to that already present from the tissue coextractives. Desorption chemical ionization (DCI) in conjunction with tandem mass spectrometry (MS/MS) has been reported for the confirmation of ivermectin, an antiparasitic compound, in cattle tissue. However, extensive sample cleanup was required prior to mass spectrometric analysis(2).

Objective

To develop a mass spectrometric confirmatory method for maduramicin α in chicken fat at the 0.5 ppm level.

Sample Preparation

The analyte is extracted from chicken fat using CH_3CN. After filtration, the CH_3CN extract is partitioned with hexane and then deposited on an acid alumina column for final cleanup. The analyte is eluted from the alumina with 10% H_2O in CH_3CN, the solvent is evaporated, and the residue redissolved in an aliquot of CH_3OH for analysis.

Results and Discussion

With the success in using DCI in conjunction with MS/MS for the confirmatory analysis of ivermectin(2), DCI appeared to offer a simple and straightforward approach to a confirmatory method for maduramicin α in chicken fat. While standards gave excellent DCI (NH_3) mass spectra, extracts prepared by the cleanup procedure left visible residues filling the loop of the emitter wire and generated ions at every mass during analyte vaporization. Coupling the matrix interferences with a low analyte recovery (only 6%) would probably doom efforts at MS/MS without an exhaustive cleanup. However, developing a prep-LC cleanup prior to DCI would prove difficult owing to the lack of a decent UV chromophore on the analyte.

While DCI did not succeed because of matrix coextractives, the favorable CI(NH_3) mass spectrometric data did suggest thermospray (TSP) LC/MS as a potential approach. Not only could TSP LC/MS serve as an ionization technique similar to CI(NH_3)(3), but it could also provide a much needed chromatographic cleanup prior to mass spectrometric analysis(4). Establishing acceptable thermospray conditions for the analyte was the most demanding challenge. A 10°C change in the vaporizer temperature was the difference between obtaining molecular species and thermally degrading the analyte in an irreproducible fashion. After establishing acceptable thermospray conditions, preliminary TSP LC/MS experiments on control and fortified chicken fat tissues were very encouraging. Ions at nominal masses of m/z 939, 934, 895, 890, and 805 were monitored to ensure compliance with confirmatory criteria(5). The response at m/z 939, used for quantitation and recovery calculations, was linear from 50 to 500 ng injected on-

column (corresponding to 0.25 to 2.5 ppm of analyte in tissue) and all confirmatory ions were present. The molecular species could be readily detected down to 10 ng on-column (0.05 ppm in fat) but the confirmatory ions were no longer present.

After seemingly having a successful route to a confirmatory method, the tip of the thermospray vaporizer had to be cut after plugging, a normal maintenance procedure. Upon restoring thermospray conditions, the fragment ions previously monitored could not be generated. Either only molecular species were generated, or the analyte was thermalized into irreproducible fragment ions. Apparently the fragment ions previously monitored had at least some origins in thermal and/or catalytic processes dependent upon the exact nature of the cut vaporizer tip. Approaches considered for inducing reproducible fragmentation included use of the filament, which did nothing, and use of repeller-induced CAD using a discharge electrode(6,7), which was not available at the time. Further analyses of the fat extracts in the full scan mode indicated that lower mass fragment ions generated for single stage MS analysis would not work owing to intense chromatographic peaks containing lower mass ions and a continuous background of ions below m/z 800 after several extract injections.

Consequently, coupling TSP LC/MS with MS/MS was considered in order to generate reproducible fragment ions from the molecular species obtained from thermospray. By using the program RF mode to pass all ions above m/z 900, implementation of MS/MS was far easier than getting TSP LC/MS to work. Because of the high molecular weight of the analyte and the absence of interferences in that mass region, using program RF circumvented the need to detune the Q_1 resolution to provide adequate response for MS/MS(8). Compared to TSP LC/MS of the analyte, the program RF mode without collision gas in Q_2 attenuated the parent ion responses about 50%. The conditions chosen for the CAD experiment in Q_2 (Ar @ 1 mT; collision energy, -15 V) provided an acceptable compromise between retention of the molecular species, sufficient fragmentation, and overall response.

CAD fragment ions at m/z 895 and 877 from the protonated sodium salt (m/z 939) in addition to CAD fragment ions at m/z 647 and 629 from the protonated ammonium salt (m/z 934) were monitored along with the molecular species. Control extracts were clean at all monitored ions. Analyses of five fortified tissues gave an average recovery of 68.9% (range 61.3 to 79.6%). While recoveries are not as important to a confirmatory method as the structural information provided, these values are within guidelines for regulatory methods(5). Analyses of five biologically incurred tissues confirmed the presence of the analyte in each case and gave an average residue level of 0.33 ppm (std dev = 0.041 ppm) in excellent agreement with a value of 0.40 $\pm$ 0.028 ppm from the LC/fluorescence determinative method.

INFLUENCE OF DIET ON THE OXIDATION OF FATTY ACIDS IN HUMANS USING ISOTOPE RATIO MASS SPECTROMETRY

M.A. French, E. Kielo, S. Pharazyn, A.B.R. Thomson, L. Wang, R. Rajotte and M.T. Clandinin
Nutrition and Metabolism Research Group, 533 Newton Research Building
University of Alberta
Edmonton, Alberta, CANADA T6G 2C2

Animal studies have shown that diets high in polyunsaturated fats increase absorption of medium and long chain fatty acids (1,2). The present study was undertaken to determine the effects of the quantity of fat and degree of polyunsaturation on absorption and whole body oxidation of fatty acids in humans.

Six healthy adult males were placed on a diet to meet maintenance energy requirements for 15 days in four test periods. During each test period, the subjects were provided with a different diet treatment. The diet was formulated (3) to contain 40% fat by energy in the high fat diets and 30% fat in the low fat diets. The polyunsaturated to saturated fat (P/S) ratio fed was either 0.2 or 1.0 at both levels of fat intake. The ratio of 10:0/16:0 was kept constant at 0.14 for all the diets and this was achieved by adding MCT oil to the diets.

Within each diet treatment, three menus were used. The same menu was always consumed one day prior to and on all test days. Meals were prepared in a metabolic kitchen and consumed at fixed times. On the test days duplicates of each subject's meals were prepared, homogenized and freeze-dried. Subsequently total fat and fatty acid content were analyzed by GLC of the fatty acid methyl esters (4,5).

The first 9 days of each test period served as a stabilization period. During days 9, 10 and 13 of each test period, the subjects were confined to the metabolic laboratory and provided hourly breath samples from 0730 to 1630 h for 6 minutes. On day 9 analysis of the $^{13}CO_2$ background enrichment enabled measurement of ^{13}C abundance due to the diet alone. On days 10 and 13 of each test period either [1-^{13}C] palmitic acid or [1-^{13}C] decanoic acid was ingested in capsule form by the subjects with the breakfast meal. The labeled fatty acids were administered at a dose of 15 mg of 99% [1-^{13}C]16:0 per kg of body weight and 3 mg of 99% [1-^{13}C]10:0 per kg of body weight, respectively.

The CO_2 in the expired breath was trapped in 1N NaOH. The CO_2 was regenerated under vacuum with phosphoric acid and the ^{13}C enrichment was measured by a Finnigan MAT 251 Isotope Ratio Mass Spectrometer against a laboratory CO_2 standard.

The average response to [1-^{13}C]10:0 was approximately ten times that of [1-^{13}C]16:0. Figure 1 shows that increasing the P/S ratio from 0.2 to 1 increased the Atom Percent Excess (APE) of ^{13}C in breath CO_2 by an average of 12%, and on the low fat diet increasing the P/S ratio increased the APE by 18% when the substrate fed was C10:0. When [1-^{13}C]16:0 was fed the APE increased by 25% on the low fat diet when the P/S ratio was increased.

The rate constants for the disappearance of ^{13}C from the breath were calculated when the substrate was C10:0. Figure 2 show the ratio of the rate constants for the low P/S diet compared to the high P/S diet at the two fat levels. The rate of disappearance of ^{13}C from the breath is consistently higher on a low P/S high fat diet for all subjects.

The results of this study suggest that the type and amount of fat in the diet affect the absorption and oxidation of fatty acids in normal subjects. This may have implications for nutritional therapy of individuals with chronic malabsorption diseases.

THE ROLE OF SOLVENT CHEMISTRY IN DESORPTION IONIZATION MASS SPECTROMETRY

Kelsey D. Cook
Department of Chemistry, University of Tennessee, Knoxville, TN 37996-1600

Developments in matrix-assisted desorption ionization (DI) have extended not only the range of chemicals to which mass spectrometry can be applied, but also the range of chemistry subject to characterization. The detailed speciation of solution components made possible through DI is often unrivaled by other analytical techniques, providing great potential for both qualitative and even quantitative investigations of reacting and equilibrated systems. However, care must be taken to account for variations in sensitivity and for the invasiveness of the probe in such spectral interpretations. In particular, careful studies by several workers have demonstrated that a bombarding particle beam can induce chemical changes (e.g., reductions and rearrangements) that could be severely misleading in the interpretation of a spectrum of an unknown. Even in the absence of a probe beam (as in the case of electrohydrodynamic (EH) MS), important "matrix effects" can complicate spectral interpretation. Work in our laboratory has sought to assess the impact of these effects in EH MS, for subsequent comparison with corresponding FAB data. This should ultimately allow resolution of bombardment artifacts.

To investigate the role of sample redox chemistry, EH spectra of a series of transition metals and their complexes were compared with corresponding published FAB data (Tables 1-2). Evidence of reduction was generally less extensive in EH than in FAB, confirming the role of bombardment-induced radicals invoked elsewhere to explain aspects of FAB spectra. A key example is Cu^{2+}, whose reduction by glycerol is known to be prevented by Cl^-. While reduction products are nevertheless evident in FAB spectra of $CuCl_2$, they are absent in corresponding EH spectra (Table 1). Reduction products were strongly evident in EH mass spectra only of those transition metals and complexes with $E^o > 0.1$ V, indicating that the EH spectra may accurately reflect the unperturbed redox chemistry of glycerol.

A conclusion that solution chemistry is not substantially perturbed by EH sampling does not constitute a "declaration of independence" from the effects of variations in sampling efficiencies. Two examples of chemical effects on sampling efficiencies were illustrated in a study of a series of quaternary ammonium salts described elsewhere in this Volume. In that study, ion pairing was noted to depend predictably on counterion identity. While extensive pairing reduced sensitivities by neutralizing singly charged ions, it actually enhanced sensitivity by reducing solvation of (otherwise) multiply charged ions. The implication that solvent dielectric constant and electrolyte selection are important parameters of matrix design may also pertain to other DI experiments (an hypothesis still largely untested).

A second chemical implication of matrix selection evident in the study of quaternary ammonium salts arises from the role of mass transport in affecting sampling efficiencies. In order to "cross the solution-vacuum barrier," an analyte ion or molecule must reach the interface. In EH MS, this occurs largely through convection and diffusion, both of which depend on matrix viscosity. While convection should supply all analytes at an equal rate, diffusion coefficients of components of a mixture may differ, introducing sampling bias against those components which diffuse more slowly. This rationale was invoked to account for the persistence of sampling bias against heavier members of the homologous series of quaternary ammonium salts, even in solutions where ion pairing was expected to be negligible. The bias was found to be amplified by the introduction of electrolytes which increased solvent structure (and therefore viscosity). For a given viscosity, the bias (a difference in relative sensitivities) was unaffected by a change to a counterion expected to pair less extensively; the members of the series were evidently all affected by ion pairing to the same extent.

ELECTROSPRAY IONIZATION PHENOMENA AND THE INTERFACE OF CAPILLARY ELECTROPHORESIS AND MASS SPECTROMETRY

Richard D. Smith, Charles J. Barinaga, and Harold R. Udseth
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory (operated by Battelle Memorial Institute)
Richland, WA 99352

The electrospray ionization (ESI) for mass spectrometry was first explored by Dole and coworkers. Recently, Fenn and coworkers have contributed extensively to the understanding of ESI and its potential applications for LC-MS interfacing. The interest in our laboratory has been to use ESI as an interface between capillary electrophoresis and mass spectrometry. The success of this application depends strongly upon our ability to manipulate and exploit the ESI process.

Capillary electrophoresis refers to a set of micro-scale analytical and preparative separations methods which include capillary zone electrophoresis (CZE), gel electrophoresis, isotachophoresis, isoelectric focusing and electrokinetic chromatography (although the latter is more strictly considered a chromatographic method, since it involves analyte partitioning with an electrophoretically migrating micellar phase). Capillary zone electrophoresis is a form of free zone electrophoresis conducted in small diameter capillaries and capable of ultra-high resolution separations. Separations are based on differences in the electrophoretic mobilities of analytes and more than 10^6 theoretical plates can be obtained in less than twenty minutes. Electroosmotic flow of the buffer mediums makes it an elution technique which resembles chromatography, although the use of capillaries filled with gels is also feasible. Thus, CZE provides high-resolution separations and selectivities which can be manipulated by changing the electrophoretic medium (i.e., typically pH and buffer composition, as well as equilibria with electrophoretically migrating micellar phases).

Recently a new electrospray ionization interface for capillary electrophoresis-mass spectrometry (CE-MS) has been developed. The interface uses a sheath flow of liquid to make the electrical contact at the CZE terminus, thus defining both the CZE and electrospray field gradients. This allows the composition of the electrosprayed liquid to be controlled independent of the CZE buffer, providing operation with buffers which could not be used previously (e.g., aqueous and high ionic strength buffers). The interface operation is substantially independent of CZE flow rate, CZE capillaries are easily replaced, and require no additional preparation. Since the electrospray occurs directly from the CZE capillary terminus, additional mixing volumes and metal surfaces are avoided and electrophoretic separation efficiency appears unperturbed. The dead volume associated with the electrospray interface is < 10 nL, corresponding to < 0.1 s for typical flow rates of the sheath electrode liquid.

Ions created by the ESI process are sampled through a 1 mm orifice (nozzle) into a region mechanically pumped at 50 L/s using a single-stage roots blower. The ions entering this region are sampled through a 2 mm diameter skimmer orifice located 0.5 cm behind the nozzle orifice. Ions passing through the skimmer enter a radio frequency focusing quadrupole. This region is pumped by a cryopump, consisting of a standard compressor and cold head with a custom cylindrical second stage baffle (cooled to ~14 K) which encloses the quadrupole and provides an effective pumping speed of >30,000 L/s for N_2. The analyzer quadrupole chamber was pumped at 500 L/s with a turbomolecular pump. A single ion lens with an 0.64-cm aperture separated the ion focusing and analysis quadrupole chambers. The pressures in the focusing and analysis chambers were ~1 x 10^{-6} and 2 x 10^{-7} Torr, respectively. The countercurrent flow of N_2 (at ~70 °C) for desolvation of the electrospray was in the range of 3 to 6 L/min.

In the following we use a simple mixture of four quaternary phosphonium salts to illustrate the characteristics of capillary electrophoresis separations with mass spectrometry and to illustrate the potential analytical value of these new methods. The CZE-MS total and single ion electropherograms for the quaternary phosphonium salts are shown in Figure 1. The separation was conducted in a relatively short 60 cm capillary, using an 11 kV CZE voltage drop. Buffer conductivities were generally chosen to be on the order of 10^3 µmho/cm. The separation in Figure 1 was obtained using a 0.05 M potassium hydrogen phthalate aqueous buffer with 10^{-4} M KCl adjusted to pH 4.8 by titration with NaOH. The sheath electrode liquid was 8.7% water in isopropanol containing 0.1 M ammonium acetate and 2 x 10^{-5} HCl at a pH of 8.9. Although 40,000 to 80,000 theoretical plates are obtained in the separation of the individual components, as shown for the single ion electropherograms, the four component mixture is resolved into only two peaks. It is not surprising that the vinyltriphenyl and ethyltriphenyl phosphonium ions elute simultaneously due to the expected similarities in their electrophoretic mobilities; it was somewhat less expected that the tetrabutyl and tetraphenyl phosphonium ions coelute.

Isotachophoresis in a capillary format is an alternative electrophoretic method which provides an attractive complement to CZE. The instrumentation used for capillary isotachophoresis (CITP) can be nearly identical to that of CZE. In CZE analyte bands separate on the basis of differences in electrophoretic mobilities in an electric field gradient, which is ideally unperturbed by their presence (due to the much lower effective concentrations). In contrast, for isotachophoresis the analyte mobilities define the electric field strength.

Two different electrolyte solutions are chosen as the leading and terminating electrolyte solutions which have sufficiently high and low electrophoretic mobilities, respectively, to bracket the electrophoretic mobilities of the sample components of interest.

A direct CITP-MS combination is an attractive complement to CZE for a number of reasons. First, the sample size which can be introduced is greater by several orders of magnitude than can be tolerated in CZE and is limited primarily by the volume of the capillary and the time allowed to obtain a separation (which is inversely related to voltage). Second, CITP generally results in concentration of analyte bands (depending upon concentration relative to the leading electrolyte), which is in contrast to the inherent dilution obtained with CZE. These two features can provide a substantial improvement in detection limits compared to CZE. A third benefit of CITP is derived from the nature of separations compared to CZE or chromatographic methods. The chromatographic peak capacity needed to separate all the components of a sample greatly exceeds the number of sample components. In other words, to obtain conditions such that no two components coelute most of the detector observation time during a separation is wasted. In contrast, for isotachophoresis one sample band immediately follows another (once a separation is obtained).

The application of CITP-MS to the same phosphonium salt mixture used for the CZE-MS experiments is shown in Figure 2. The separation was conducted using a 2 m x 100 μm i.d. untreated fused silica capillary and the separation conducted at 35 kV. The leading electrolyte was 10^{-3} M ammonium acetate and the trailing electrolyte was 10^{-3} M tetraoctyl ammonium bromide in a 1:1 water-methanol solvent mixture. The separation is well developed with minimum band overlap and sharp edges. The widths of the four bands are nearly equivalent, consistent with the similar sample concentrations and the minor discrimination expected using electromigration for introduction of this mixture.

The most striking feature of the separation shown in Figure 2 is the excellent resolution of the four phosphonium salts, which were not resolved in the short CZE separations, and even in longer separations on a 2 m capillary. The fact that the vinyltriphenyl and ethyltriphenyl phosphonium ions are clearly resolved illustrates the potential of CITP-MS to generate high resolution separations. Another advantage is the greater signal-to-noise ratios. The development of capillary isotachophoresis-MS promises to provide a powerful complement to CZE-MS. Other variations of capillary electrophoresis, including isoelectric focusing, gel electrophoresis and capillary electrokinetic chromatography also appear amenable to mass spectrometric detection using the new interface methods. The rapid developments in injection techniques and the use of buffer media providing enhanced selectivities promise increasing interest in these attractive instrumental methods.

We thank the U.S. Department of Energy, Office of Health and Environmental Research, for support of this research under Contract DE-AC06-76RLO 1830.

MAGIC-LC/MS: A VERSATILE SAMPLE INTRODUCTION PATH FOR MASS SPECTROMETRY

Richard F. Browner, J. Daniel Kirk, W. Eric Harris and Deborah D. Perkins
School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

MAGIC-LC/MS provides a simple, mechanical means of interfacing LC effluents of virtually any composition with a mass spectrometer. Controlled drop size aerosol is formed from the LC effluent, and after dispersion with helium, the solvent evaporates under kinetic conditions controlled by thermal transport to the evaporating aerosol drops. The resulting mixture of essentially solvent-free analyte particles, solvent vapor and helium then passes to a momentum separator, where after supersonic nozzle expansion, the analyte particle beam is preferentially skimmed from the jet in a two-stage process. The highly enriched, largely solvent free analyte particle beam then passes to the mass spectrometer ion source area, where various ionization techniques may lead to the generation of mass spectra.

The process of aerosol generation is not yet totally characterized, but is believed to involve a two-step process, whereby a stream of drops initially approximately twice the diameter of the liquid injection capillary is further shattered by a stream of He to produce a laminar flow stream of drops with diameters roughly the same as the diameter of the liquid capillary. The drop size distribution of this drops stream is still quite narrow, although under certain conditions some multimodality may be introduced. Collection of the desolvated particles, and size measurement using electron microscopy, shows that the diameters of the dry particles entering the mass spectrometer ion source region are precisely as predicted from calculations based simple solvent evaporation theory. Consequently, there appears to be very little agglomeration or other process taking place to increase particle size after initial aerosol formation takes place. The manner in which particle vaporization in the ion source is able to give rise to classical EI and CI spectra is a direct consequence of the rapid vaporization step which occurs when the small particles flash vaporize in the ion heated source.

MECHANISM OF FAB SPECTRA FORMATION TEMPERATURE DEPENDENCE

J. Sunner, Department of Chemistry,
Montana State University, Bozeman, MT 59717.
A. Morales and P. Kebarle, Department of Chemistry,
University of Alberta, Edmonton, Alberta, Canada T6G 2G2

Fast Atom Bombardment (FAB) spectra frequently reveal strong matrix effects. For example, an analyte with a low concentration in the near-surface region of the liquid matrix may dominate the FAB spectrum. A kinetic scheme, based on ion/molecule reactions occurring in high-pressure mass spectrometry, was previously shown to be able to reproduce FAB spectra of varying concentration diethanol-amine (DEA) in glycerol (1). The presence of an intermediate gas-like state is supported by the observation that the protonation of the analyte is determined by gas-phase energetics and by the indications that extensive +/-ion recombination occurs during the desorption event. We have explained the formation of the gas-like state in desorption ionization in terms of fundamental thermodynamic properties of liquids in the Phase Explosion model (2). However, in its first version this model could not explain the very strong dependence of FAB spectra on the temperature of the bulk matrix, T_b, observed by Field et al. (3). We here report investigations into the temperature dependence of FAB spectra of some simple systems. The spectra of glycerol and of DEA in glycerol were successfully modelled by the same kinetic scheme that was previously used (1). In a refined Phase Explosion model, interactions of the gas-like state with the surrounding liquid is considered.

Fast Atom Bombardment (FAB) spectra of glycerol and of solutions of analytes in glycerol were studied as a function of the temperature of the FAB matrix, from -30°C to +40°C. In agreement with Field et al. (3) it was found that the spectra deteriorated towards a series of nondescript peaks as the matrix temperature (T_b) decreased. It was also found that the intensities of analyte ions decreased more rapidly with decreasing T_b than even the glycerol cluster ions.

Figure 1 shows the temperature dependence for major ions in FAB spectra of neat glycerol. It is seen that the dependence on T_b is quite regular. Noteworthy is the very strong decrease for the "noise-ions" (which includes all background peaks) with increasing T_b and the corresponding increase for the molecular ion. With regard to their temperature dependence, the ions on the glycerol spectrum follow the order:

$$\text{"noise-ions"} < F_G^+ < GlH^+ < (Gl)_2H^+ < (Gl)_nH^+;\ n \geq 3 \qquad (1)$$

This is the same order that was previously observed (1) for the attenuation of the different ions as DEA was gradually added to the glycerol matrix. Figure 2 shows the temperature dependence of ions for a 10 mol% solution of DEA in glycerol. The DEA ions are seen to have a very strong temperature dependence.

Results like those shown in Figures 1 and 2 were reproduced by the kinetic model. The modelling required the assumption that t_{max} increased with T_b, where t_{max} is the time after the atom impact when ions emission ceases, Figure 3. The results of the kinetic modelling are shown by the dotted lines in Figures 1-2.

The strong dependence on t_{max} on T_b can be understood qualitatively as a consequence of the radial expansion of the gaseous cavity formed by the fast atom. At low temperature, when the glycerol viscosity is high, a high temperature, high pressure gas that has considerable radiation damage is very rapidly expelled from the cavity. At higher matrix temperature, the lower viscosity allows for an initial radial expansion of the cavity gas. As a result this gas cools very considerably and the pressure decreases. The rate of expulsion decreases and the rate of heat transport to the surrounding liquid becomes competitive. The conditions described by the initial phase explosion model are asymptotically reached.

MASS TRANSPORT IN LIQUID SIMS

Peter J. Todd
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, Tennessee 37831-8121

Secondary ion emission occurs only from the sample surface. From glycerol solutions containing involatile solutes, enhanced emission of solute-characteristic ions occurs because the solutes become adsorbed to the surface from the bulk solution. The flow of solutes to the surface is controlled by diffusion. This mechanism of mass transport was investigated by using the method of finite differences[1] to evaluate Fick's equations and comparing the results to SIMS spectra. The results show that flow of solute to the surface is influenced by a number of factors which can neither be controlled nor evaluated with any confidence. Volatile solutes, such as amines can be adsorbed to a glycerol surface from the gas phase at a rate independent of diffusion. SIMS spectra of such surfaces appear much like Langmuir isotherms, and are highly reproducible. Furthermore, from a knowledge of the amine surface activity and Henry's Law constant, the actual surface concentration can be determined. This feature permits an explicit comparison between SIMS spectra and surface activity.

For diffusion, calculations were made by assuming the sample to consist of two phases. In the bulk phase, diffusion coefficients, D were assumed to be between 10^{-11} and 10^{-9} cm^2/s. A surface phase was assumed to have no thickness and infinite diffusion. That is, the surface phase was assumed to behave as a two dimensional gas. Mass transport between the surface phase and the bulk was determined by assuming the surface phase to have an effective concentration, C_s, related to the actual surface concentration, Γ(moles/cm^2), by the Gibbs Equation, (1)

$$\Gamma = -(C_s/RT)(d\gamma/dC) \quad (1)$$

where R= Gas constant
T = Temperature
$(d\gamma/dC)$ = variation of surface tension with analyte concentration.

The surface concentration can be mathematically generated by diffusion and depleted at different rates as a fraction of surface coverage to mimic sputtering by different primary ion currents. The surface concentration does not reflect the bulk concentration, as might be expected from the Gibbs equation, but rather to a fraction, between 1 and 10% of the bulk concentration. Figure 1 shows plots of concentration vs depth for a sample under 1 $\mu A/cm^2$ primary ion bombardment, where it can be seen that the origin of this effect is the depleted region of the bulk solution near the surface. Furthermore, as the surface is depleted by the primary ion beam, surface concentration is determined by the flux of solute to the surface, a function of dC/dx, which is itself time-dependent.

To ensure that the flow of surfactant was not a function of time, amines were introduced as vapors onto the surface of glycerol under bombardment. Figure 2 shows plots of protonated octylamine ion intensity vs. amine pressure. The shape of this curve is that of a Langmuir isotherm. Such behavior is described by equation (2)

$$P/I = P/I_{max} + 1/(bI_{max}) \quad (2)$$

where P = amine pressure
I = fractional secondary ion current carried by protonated amine
b = ratio of adsorption/desorption rate constants

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

When data such as that plotted in Figure 2 are plotted in the terms of equation (2), straight lines are obtained for each plot. For a series of data taken under different primary ion current density, lines are parallel, with intercepts that differ by a constant proportional to primary ion current density. From the intercept data, erosion of the surface monolayer occurs at a rate of 1 monolayer/7s. for a primary ion current density of 1 $\mu A/cm^2$. Furthermore, the data indicate that if there is an amine molecule within a radius of approximately 250 Angstroms from a primary ion impact point, that amine will be ejected as a protonated secondary amine ion.

APPLICATIONS OF ELECTROPHORESIS COUPLED WITH SECONDARY ION MASS SPECTROMETRY

M.S. Stanley and K.L. Busch
Department of Chemistry, Indiana University, Bloomington, IN 47405

A custom-built secondary ion mass spectrometer (SIMS), originally used in the direct analysis on thin layer chromatograms [1], has now been used in the analysis of compound mixtures separated with paper and slab gel electrophoresis [2].

Paper electrophoresis is a technique that is frequently used in the separation of small charged molecules. For example, in a clinical setting, determination of the chemical composition of a kidney stone has been accomplished through paper electrophoresis [3]. The kidney stone was composed mostly of xanthine and hypoxanthine. The SIMS analysis of xanthine shown in Figure 1, using glycerol acidified with p-toluenesulfonic acid (ptsa), contains a fairly intense ion corresponding to the protonated molecule at m/z 153. Xanthine undergoes little fragmentation under SIMS conditions; the intense ion at m/z 147 appears to be contamination within the instrument (probably a silane-related compound). Hypoxanthine behaves similarly, giving an intense ion corresponding to the protonated molecule and no apparent fragmentation. Xanthine and hypoxanthine can be cleanly separated by paper electrophoresis. The SIMS spectra of the paper electropherogram give spectra of xanthine and hypoxanthine that are qualitatively similar to the spectra acquired from the neat compounds. The SIMS spectrum of xanthine acquired out of a Whatman 3MM paper electropherogram is shown in Figure 1. Glycerol doped with ptsa was used to extract the analyte out of the 3MM paper. The protonated molecule at m/z 153 is still quite intense, and there is a low level of signal corresponding to the glycerol and ptsa matrix as well as the contaminant peak at m/z 147.

For polyacrylamide gel electrophoresis (PAGE), the high water content of the gel (80-90%) precludes the direct analysis of the electropherogram by SIMS. In gel electrophoresis, however, blotting techniques are frequently used to transfer separated mixture components qualitatively and quantitatively from the gel matrix onto a membrane. This renders the components more accessible to reagents. In addition, nitrocellulose, frequently used in the transfer of proteins, is vacuum compatible and can be directly analyzed by mass spectrometry. Small peptides, such as angiotensin I, neoendorphin, and bradykinin, and larger peptides, such as insulin, myoglobin and cytochrome c, as well as the antibiotic bacitracin, are being used to explore the possibilities of mass spectral analysis of gel electropherograms. The secondary ion mass spectrum of bradykinin acquired out of nitrocellulose after transfer from a developed electrophoretic gel is shown in Figure 2. The protonated molecule is clearly visible at m/z 1061 and several of the ions, such as those at m/z 905, m/z 568, and m/z 120, are indicative of structure. The protonated molecule can be monitored to obtain an image of the bradykinin band in the nitrocellulose, Figure 3. The image shows a good signal-to-noise ratio between the actual bradykinin band and the surrounding nitrocellulose. The shape of the image is similar to the shape of the image obtained by staining the band with Coomassie Blue R following mass spectral analysis.

Work is also being started in the analysis of gel electropherograms containing peptides with molecular weights above 3,500 daltons. The current mass range of the chromatography/SIMS instrument is approximately 3,500 daltons, which is too low for the analysis of most peptides separated using gel electrophoresis. In order to analyze higher molecular weight peptides with the chromatography/SIMS instrument, the peptides must be broken down into fragments that are lower in mass but which together define the original peptide structure. The use of reagents such as cyanogen bromide and trypsin, to selectively cleave the peptides after transfer into the membrane and before mass spectral analysis has been considered and is shown schematically in Figure 4.

CAPILLARY ELECTROPHORESIS/FLOW FAB MS

Robert D. Minard, Dean Chin-Fatt, Paul Curry Jr., and Andrew G. Ewing,
Chemistry Dep't., Penn State Univ., University Park, PA 16802 USA.

Capillary electrophoresis (CE) is a new and rapidly advancing separation technique that offers the potential of very efficient separations (> 10^5 theoretical plates with elution times in minutes) with sample mixtures as diverse in nature as simple metal ions and high molecular weight proteins.[1] Resolution improves as the capillary diameter (usually less than 100 μm) and quantities injected (picomoles down to attomoles) decrease. Injection volumes on the order of 10 picoliters to 1 nanoliter and flow rates of less than 100 nanoliters/minute are common. These parameters pose a serious challenge to modern methods of chemical detection. On-column fluorescence detection[2], post column electrochemical detection[3], and electrospray ionization mass spectrometry[4] have shown promise as detection methods with sufficient sensitivity. Of these, mass spectrometry offers the advantages of very nearly universal detection and enhanced molecular characterization. However, detection of higher molecular weight non-volatile compounds requires the use of either spray (thermo-spray, plasma-spray, electro-spray, etc.) or surface (plasma desorption, fast atom bombardment(FAB), liquid SIMS, etc) ionization techniques.

FAB was regarded as a static ionization method until Takeuchi et. al. [5] and Caprioli et. al.[6] demonstrated continuous flow FAB (FFAB). In order to combine capillary electrophoresis and FFAB mass spectrometry, it is necessary to develope an interface which will 1) not degrade the separation efficiency of capillary electrophoresis; 2) allow for completion of the electrophoretic external circuit; and 3) allow different solvent systems to be used in the electrophoresis capillary and the FFAB capillary and 4) supplement the low flow of CE (<100 nL/min).

Based on a previously developed design for coupling post-column detectors with CE , we constructed a flow "make-up" CE-FFAB interface as shown in Fig. 1. Its construction involves the careful alignment of the end of the electrophoresis capillary and the end of the FAB flow capillary with a gap of approximately 20 μm. This open junction is immersed in the FAB matrix solution which was methanol or methanol/acetonitrile with 4 to 20% glycerol. (The glycerol content was varied to control the source pressure and stabilize the ion beam). The electrophoretic circuit was completed as shown with the cathode at the make-up coupling.

Our initial work involved optimizing the transfer in the flow FAB capillary and the CE capillary was not connected. Using the standard KRATOS flow FAB probe tip, we found that sample peak widths (5% above baseline) were greater than one minute using a Rheodyne injector with a 0.5 μL sample loop. Narrower sample peak widths (15 to 30 sec) were obtained when the sample was introduced by dipping the capillary

FIGURE 1:

Capillary Electrophoresis-Flow FAB Interface

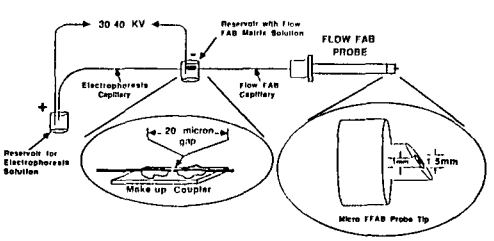

FIGURE 2:

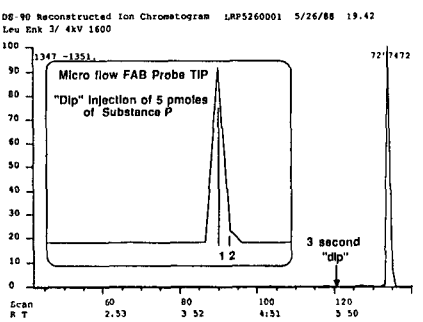

into the sample for one to three seconds but there was still a large amount of tailing. In order to minimize the sample residence time on the flow FAB probe tip, the tip was modified by reducing its size to a 1.5 mm diameter nub on a 1 mm stem. Using this smaller flow FAB probe tip with a 95 cm x 75 μm flow capillary, peak widths of 4 to 6 sec. were obtained when a non-aqueous solvent/matrix was used (4:1 acetonitrile/methanol with 4% glycerol) and samples were introduced using the dipping method. Figure 2 shows the reconstructed ion chromatogram of the molecular ion region (m/z 1347-1352) from a 3 s. "dip" injection injection of about 5 pmole of Substance P. Transit time through the capillary was about 75 s.

Initial results from the use of this CE-FFAB interface are very promising. Figure 3 shows a 3 second, 40 kV electrokinetic injection of a 400 ng/μL solution of leucine enkephalin which is equivalent to 3.6 pmoles of this pentapeptide. The peak width at half height is only 12 seconds. The CE capillary was 60cm by 75μm and the FFAB capillary was 70cm by 50μm. A current of 2.5 uA passed through the 1 mM ammonium formate electrophoresis buffer solution in the CE capillary. The flow FAB make-up matrix consisted of 20% glycerol in 4:1 acetonitrile water. The number of theoretical plates calculated for this separation was 6800 which is a reasonable preliminary result considering the broadening due to the interface, the low buffer concentration, and the fact that the CE capillary was not treated to deactivate its surface. A CE separation is shown in Figure 4. A mixture of approximately 1 ng each of Substance P (MW 1347), leu enkephalin (MW 555) and met enkephalin (MW 573) was injected. Leu and met enkephalin co-elute between scan 150 and 165. Substance P appears earlier (scan 100 to 140) showing that electrophoretic separation has, in fact, occurred.

COMPLETE MS/MS DATA FIELD ACQUISITION ON THE CHROMATOGRAPHIC TIME SCALE BY TIME-RESOLVED ION MOMENTUM SPECTROMETRY (TRIMS) WITH TIME ARRAY DETECTION (TAD)

B.A. Eckenrode, J.T. Watson, J.F. Holland and C.G. Enke
Departments of Chemistry and Biochemistry,
Michigan State University, East Lansing, MI 48824

Mass spectrometry/mass spectrometry, (MS/MS), provides an additional dimension of mass spectral data to aid in mixture analysis or structure elucidation. MS/MS data acquisition consists of detecting daughter ions that arise from dissociation of parent ions produced in the source of a mass spectrometer. The relationships between parent and daughter ions involved in metastable ion decomposition or in collisionally activated dissociation (CAD) can be established by MS/MS analysis. These relationships are often indicative of specific structural characteristics. Acquisition of the **complete** MS/MS map (all daughters of all parents) typically is a relatively lengthy process (requiring up to several minutes) and consequently, much more sample (milligram quantities) is required than for conventional mass spectrometric analysis with electron impact or chemical ionization. Another disadvantage associated with long acquisition time is its incompatibility with sample introduction via a chromatographic inlet.

Time-resolved ion momentum spectrometry (TRIMS) (1,2) in combination with time-array detection (TAD) (3) was developed to remove the limitations described above and to allow for the acquisition of complete MS/MS maps in a single sweep of the magnetic field. A schematic of the instrument is shown in Fig. 1. TRIMS is achieved by determining flight times of ions following momentum analysis. Discrete ion packets are created by post-sector beam deflection and an integrating transient recorder (ITR) records the arrival time transient.

Collecting the full MS/MS data field on the time scale of a chromatographic peak is accomplished by incrementing the magnetic field and summing ion arrival time spectra at each momentum setting (see Fig. 2). To optimize the signal-to-noise ratio, a variable number of transients can be summed at each momentum. Interrogation of the full data field can then be made after the data have been written to disk.

The trade-offs in resolution, sensitivity and acquisition time can be related with the following equations:

(transients/scan)/(transients/sec) = sec/scan (1)

TOF scans/sweep = mass range/mass resolution (2)

mass range/mass resolution x sec/scan = sec/sweep (3)

where scan is defined as the summation of a number of transients, and sweep represents a single magnetic field transit over the desired mass range. Equation (1) is related to the S/N at each momentum setting. Equation (2) is related to the desired mass resolution and is dependent on the nature of the signal and the objectives of the analysis. Equation (3) represents the time for a complete MS/MS map acquisition with TRIMS/TAD and is determined by the temporal characteristics of the sample.

Results for methyl stearate are shown in Fig. 3. This is a GC/MS/MS map acquired in 10 seconds. Unit mass resolution was obtained on both the momentum and time axes.

AN IMPROVED INTERFACE FOR CAPILLARY ZONE ELECTROPHORESIS-MASS SPECTROMETRY

R. D. Smith, J. A. Loo, C. J. Barinaga, and H. R. Udseth
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory, Richland, WA 99352

We have recently developed an improved electrospray ionization interface for capillary electrophoresis mass-spectrometry (CZE-MS). Our initial interface employed a vacuum deposited metal film at the exit of the capillary to make an electrical contact with the eluting buffer and establish the electrospray field gradient (1). This interface had several attractive features including negligible dead volume and avoidance of a nebulizing gas with the attendant problems (2). We were able to demonstrate high efficiency separations in excess of 10^5 theoretical plates with detection limits in the attomole range (3) using this interface for selected compounds.

This interface did, however, impose significant limitations on the range of capillary electrophoretic (CE) separations that could be performed. The flow rates typically used were near the minimum at which a stable electrospray could be generated so that separations with low electroosmotic velocity (i.e. CZE with surface modified capillaries, gel filled capillaries, etc.) could not be performed. Since the buffer solution was directly electrosprayed, constraints were placed on its composition. Aqueous solutions cannot be electrosprayed, nor can high ionic strength solutions. Since many separations are optimally performed in aqueous solutions at high ionic strength, it was necessary to compromise the separations by the addition of organic solvents and reduction of ionic strength to utilize the interface. Unfortunately, the use of lower ionic strength buffers also lowers the maximum sample size which can be utilized without degrading separation efficiency. The vacuum deposition of a metal film CZE electrode was also a tedious process. In addition, the vapor deposited metal film had poor adhesion characteristics and a limited lifetime.

To circumvent these limitations an interface that does not require a metalized tip was designed and developed. In the new approach, the electrical contact at the column exit is made through a flowing liquid sheath. Figure 1 shows a schematic illustration of one version of the liquid sheath electrode interface A 1/16" O. D. teflon tube that contains the fused silica capillary and the sheath liquid runs down the center of a polycarbonate holder. The capillary and the sheath liquid are brought together via a teflon tee outside the probe body (not shown). The central teflon tube is slip fit over a 21 gauge stainless steel (ss) needle which is cut flat and electropolished at its tip. The capillary protrudes slightly from the ss tube (approx. 0.3 mm) so that a positive flow of liquid from the sheath is necessary to make electrical contact. The liquid flow is maintained by a small syringe pump (Sage Instruments, Model 341B, Cambridge, MA). The central teflon tube is wedged in place by six concentric teflon tubes. An auxiliary gas flow can be delivered through these tubes to flow over the tip in the direction of the electrospray.

The principal advantage of this interface is that it allows operation with a much broader range of electrophoresis conditions. The sheath flow can be readily varied in both composition and volume. Thus, the composition of the electrosprayed solution, which is the mixture of the sheath and the capillary eluent, can be readily varied independently of the separation buffer. If the buffer is aqueous, an organic solvent such as methanol or acetonitrile can be added in the desired amount at the capillary terminus. If the ionic strength of the buffer is too high, it can be effectively diluted by the sheath liquid at the terminus. Some additional benefits also accrue in this design. The removal of any metal contact eliminates any possibility of electrochemical processes involving the analyte and reduces the likelihood of a corona discharge. (Such discharges are most readily generated from micro protrusions on metal surfaces.) The sheath liquid can also be used for post-column derivitization, to mix reagent ions into the electrospray plume, and to introduce a calibration compound.

Figure 2 shows an example of an ESI spectra for a previously intractable buffer solution. Fig. 2A is the negative ion spectra (the addition of oxygen as done by others (4) is needed to suppress discharges) and 2B is the positive ion spectra from an aqueous solution of 0.05 M sodium dodecylsulfate (SDS). The solution can not be electrosprayed directly, but the addition of 5 μL/min of isopropanol through the sheath produces a stable well behaved electrospray. Details of the interface design and performance will be published elsewhere (5).

PARTICLE-INDUCED DESORPTION MASS SPECTROMETRY : PRODUCTION, IDENTIFICATION, AND USE OF INCIDENT MEV POLYATOMIC IONS*

D. L. Fishel[a], A. E. Ruthenberg[b], M. Salehpour[c], and J. E. Hunt[c]

[a] Kent State University, Department of Chemistry, Kent, OH 44242
[b] Physics Division, and [c] Chemistry Division, Argonne National Laboratory, 9700 S. Cass Ave., Argonne, IL 60439

The use of accelerators to select incident ion parameters has defined the role of MeV atomic ions in desorption of organic compounds. We have used MeV molecular and polyatomic ions to study desorption. Information about the enhanced energy deposition of polyatomic ions over their constituents atoms[1] has motivated us to investigate the potential of these species as incident particles in desorption ionization mass spectrometry experiments. We have shown that high yields of the secondary molecular ion of interest are observed as a result of incident polyatomic ion impact.[2]

The production and identification of MeV polyatomic ions for use in desorption studies requires an ion source capable of producing such ions coupled to a particle accelerator. The Dynamitron accelerator at Argonne National Laboratory is used to produce MeV polyatomic ions. The useful operating range of the accelerator is from 500keV to approximately 4.5 MeV. An ion source is located at the high-voltage terminal of the accelerator. Polyatomic ions are produced in a modified duoplasmatron ion source. The major alterations to the duoplasmatron ion source are in the electrode structure. A grid covering the electron filament reduces the electron current in the ionization region, thereby preventing the formation of a plasma. In this mode, electrons, which drift into the usual plasma region, are accelerated and impact the gas molecules in the entrance to the extraction region. This modification makes the ion source comparable to a low-current variable-energy electron-impact ion source with a small electron energy spread. As the molecules are ionized they drift through an aperture to an extraction electrode where they are focused and accelerated to an energy determined by the terminal potential of the accelerator. The total output current is typically below 1na. The efficiencies of the ion source and extraction have not been measured, however, for desorption studies reported here the most useful measure of the output is the ion count rate at the target. Depending on the number and type of ions produced in the ion source, the count rate is between 10^2 and 10^4 polyatomic ions/sec. This count rate range is ideal for desorption ionization studies.

The polyatomic ions that have been produced and accelerated are C_2^+, C_3^+, CH^+, CH_3^+, $C_3H_3^+$, $C_4H_9^+$, $C_7H_{15}^+$, CO^+, O_2^+, CO_2^+, CF^+, CF_3^+, $C_3F_5^+$, and $C_4F_7^+$. These ions were produced from allene (C_3H_4), n-decane ($C_{10}H_{22}$), CO_2, and a low-boiling point perflurokerosene mixture (PCR Chemicals, Gainesville, FL, USA). A removable energy detector placed 3 m from the bending magnet was used to identify the polyatomic ions. The collisions with the rest gas in the evacuated beam line (~1 x 10^{-6} torr) fragments a small number of the polyatomic ions, which is useful in identification of the polyatomic ions as follows. Figure 1 shows the energy spectrum of CF_3^+ recorded in a multichannel analyzer. CF_3^+ was produced from perflurokerosene, accelerated to 3.9 MeV with the analyzer tuned to mass 69 and charge state +1. The predominant species observed is CF_3^+. The inset of fig. 1 is an expanded vertical range showing the energy spectrum resulting from the fragmentation of the parent molecule. The mass of the fragments can be deduced from

the fraction of the energy they carry away from the intact polyatomic ion. The analysis of the fragments clearly identifies the accelerated species as CF_3^+. Fig. 2 shows the yield of valine negative molecular ions as a function of the energy of three different incident ion species. For C^+ to CF_3^+, at the same velocity, represents a factor of 40 increase in yield.

The desorption results show that high yields of secondary molecular ions are obtained as a result of polyatomic ion impact. We believe that this polyatomic ion source/accelerator combination should have may applications in the study of the desorption mass spectrometry.

A NEW UHV INSTRUMENT FOR ION/SURFACE COLLISIONS

H-J. Laue, J.W. Amy, B. Winger and R.G. Cooks
Purdue University
Department of Chemistry
West Lafayette, IN 47907, USA

A new ultra high vacuum (UHV) instrument has been designed to allow the study of polyatomic ion/surface collision phenomena as a function of the collision energy, angle of incidence and the nature of the surface. The mass spectrum and translational energies, as well as the angle of scattering of the emerging particles, will be measured. The object is to study collisions over a wide range of collision energies (1 eV to 3000 eV) at surfaces which are well-defined. A significant objective is to study the kinematics and dynamics of surface scattering, both elastic and inelastic, as well as charge changing and reactive collisions. In addition, by using ion beams of higher flux and very low translational energies, chemical modification of the surface will be attempted.

Figure 1 shows the Finnigan MAT 212, the interface chamber and a cross section of the main chamber. The MAT 212 serves as one of two main beam delivery systems for the main chamber. It is capable of delivering a mass analyzed ion beam of up to 3000 eV and, with suitable deceleration, as low as a few eV. The DC-quadrupole doublet, which is located in the interface chamber, is used to focus the ion beam at the target. Depending upon the specific experiment employed, the beam can be focussed, either to a tight spot (most SID experiments), or a high narrow slit (angle resolved experiments). The interface chamber is differentially pumped using a 100 l/s ion pump, therefore allowing for ultra high vacuum conditions to exist in the main chamber. Using the MAT 212 as the main beam delivery system will allow for variations of the collision energy and the mass of the primary ion.

The second main beam delivery system which is incorporated into the design of the instrument is a Riber secondary ion mass spectrometer (SIMS). The SIMS will be used to deliver a low energy, high flux beam to modify the target surface. In one experiment the SIMS-produced beam will be transported into the main chamber. In another experiment the target will be transferred to a satellite preparation chamber for modification. Using the mass analyzing quadrupole, the SIMS will deliver mass selected ions which were previously produced in the desorption ionization process. An overhead view of the entire apparatus, which includes the MAT 212, the main chamber and the Riber SIMS is shown in Figure 2.

The main chamber serves as the scattering and analyzing chamber of the instrument. The sample target, which is mounted on a goniometer, is located in the center of the chamber. The goniometer can be rotated 360°, therefore, the angle of incidence of the primary ion can be varied. As seen in Figure 1, the analyzer system, which consists of an electric sector analyzer (ESA), a quadrupole mass filter and an electron multiplier (not shown), are all mounted on a ring-rail, allowing for rotation of the analyzer system while under UHV. Therefore, the products of an ion/surface collision can be collected and analyzed, independent of the incident angle. To control the selection of the angle and energy of the emerging ions, an externally controllable slit system is located just after the target and after the ESA (Figure 3). The main chamber is pumped by a 270 l/s ion pump supplemented by a 1250 l/s cryopump and is designed to achieve pressures on the order of 10^{-10} torr. An ion pump fitted with a titanium sublimation pump is mounted on the bottom center of the main chamber, allowing for differential pumping of the target region. To maximize the pumping differentially, a tube, which is equipped with an aperture allowing the primary ion beam to enter and a rather long slit on the other side for extracting the secondary ions, encompasses the target. This would enable the target region to attain a pressure in the 10^{-11} torr regime.

Figure 4 is a reproduction of a GIOS [1] calculation which shows the ion beam path from the source of the MAT 212 to D3, the electron multiplier detector located in the main scattering chamber. GIOS and SIMION ion optical programs were used throughout so as to ensure that the instrument was designed with well-defined ion optical characteristics.

QUADRATURE FT/ICR MASS SPECTROMETRY

Francis R. Verdun,§ Steven L. Mullen,# Tom L. Ricca,§ and Alan G. Marshall§

A Fourier Transform Ion Cyclotron Resonance (FT/ICR) signal is usually produced by radiofrequency excitation on one pair of opposed pair of plates and subsequent detection on a second pair of opposed plates[1]. However, use of both pairs of plates for excitation effectively reduces the necessary excitation amplitude by a factor of two and, use of both pairs of plates effectively increases the signal-to-noise ratio by a factor of $\sqrt{2}$. Quadrature detection therefore enhances signal-to-noise ratio by the same factor as time-domain two-fold oversampling of the signal, whether done directly or by the interleaving of two spectra (see ref. 2 and paper #TPB3) but requires neither a doubling of the analog-to-digital conversion (ADC) speed nor acquisition of two successive spectra differing by one-half of an ADC dwell period between excitation and reception events.).

In FT/ICR (or any other FT) spectroscopy, the Nyquist limit requires that the time-domain ICR transient signal be sampled at a frequency, 2SW, in which SW is the highest ICR frequency in the detected spectrum. The discrete Fourier transform of such a signal gives a spectrum which correctly represents signals in the frequency range, 0 to 2SW; however signals with frequencies between SW and 2SW violate the Nyquist limit and are "aliased" or "folded over" to appear at mathematically negative frequencies. Stated another way, the signal detected by a **single** pair of opposed receiver plates is linearly polarized and therefore cannot distinguish between positive and negative frequencies (e.g., right- and left-circularly polarized rotations of ions of the same mass but opposite charge). Thus, it is usual to excite (and/or filter out all but) signals in the range only from 0 to BWI (in direct-mode), or from $\nu_{carrier}$ to $\nu_{carrier}$ - SW (in heterodyne mode).

In contrast, detection of signal components from **two** perpendicular pairs of plates makes it possible to discriminate positive and negative frequencies. Advantages of such "quadrature" detection compared to single-channel detection include: (a) for a given ADC rate and number of time-domain data points, the Nyquist frequency is doubled (i.e., the low-mass limit is halved in either direct or heterodyne mode; (b) for a given number of time-domain data points and mass range, the ADC rate is halved; (c) for a given ADC rate and mass range, signal-to-noise ratio is increased by a factor of $\sqrt{2}$.

Experimental

FT/ICR mass spectra were acquired with a modified Nicolet FTMS-1000 instrument. Ions were produced by electron ionization with a standard event sequence.[2] For experimental simplicity, quadrature detection was performed by use of a single ADC operated in either of two possible modes.

Simultaneous sampling, with alternate ADC delay. In this procedure, the signals from both pairs of plates are sampled and held separately and simultaneously. One of the two signals is digitized immediately, and the other is held until the first digitization is complete. Thus, although the signals from the two channels are digitized alternately, they are sampled simultaneously. This process is equivalent to use of two independent

ADC's, each operated at half the sampling rate of the single-ADC experiment. The experimental enhancement of ~30% in signal-to-noise ratio (see Figure 1) is somewhat below the theoretically possible 42%, because the electronic components were not identical for the two detector channels (e.g., a time-shift between the two channels will reduce the orthogonality between the two signals. Improvements are available and are in progress.

Alternate sampling/ADC In this procedure, the signals from the two channels are simply sampled/held/digitized alternately. As a result, it is necessary to phase-correct the data from the second channel for the time-delay between sampling of the two channels. The signal-to-noise improvement (compared to single-channel detection) is again ~30% (see Figure 2) and should again be improveable to the theoretical 42% limit. For strongly damped time-domain ICR signals, simultaneous sample/hold is preferable to avoid change in signal magnitude between alternate-channel readings. A detailed treatment of quadrature and oversampling will be published elsewhere.

ICR-TOF. TIME OF FLIGHT MEASUREMENT OF PHOTOFRAGMENT ENERGIES IN THE ICR ION TRAP

R. C. Dunbar, Chemistry Department, Case Western Reserve University, Cleveland, OH 44106.

G. H. Weddle, Chemistry Department, Fairfield University, Fairfield, CT 06430.

A new approach is described which combines the ion-trapping capabilities of the ICR instrument with time-of-flight velocity analysis to observe the kinetic energy of photofragmentation product ions. As indicated in Fig. 1, the experimental sequence is as follows: After electron-impact ionization, the parent ions are thermalized and also relaxed to the center of the cell (along the z axis) by about 30 collisions with parent neutral or other collision gas; Then the laser pulse is fired, and simultaneously the trapping potential is dropped to zero, allowing free flight of all ions along the z axis. After time T the trapping voltage is turned back on, retrapping all those ions which have not yet struck the trapping plate, and an ICR detection sequence is used to measure the fraction of ions remaining in the trap. A plot of fraction of ions retained versus T gives a time-of-flight analysis of the one-dimensional velocity distribution along the z axis. Interpretation of the time-of-flight curves in terms of three-dimensional velocity distributions has been outlined in a forthcoming publication [1]

Figures 2 and 3 show recent results for 2-iodotoluene ions, photodissociated with the 308 nm output of a XeCl excimer laser. Fig. 2 shows the time-of-flight curve for the parent ion, which should reflect a thermalized Maxwell-Boltzmann distribution of velocities: Comparison with the expected 350 K thermal curve shows good agreement with this expectation. Fig 3 shows the m/e 91 photofragment results. The fragment ion has substantial excess kinetic energy: The predicted curve for monoenergetic ions with 75 meV of kinetic energy fits the data moderately well, but the data clearly reflect a spread of kinetic energies. An excellent fit to the data is found for the three-dimensional Maxwell-Boltzmann distribution at a kinetic temperature of 750 K, as shown. This indicates an average kinetic energy of about 98 meV, which can be converted to an average kinetic energy release of about 140 meV for the photofragmentation. This is quite similar to the result quoted earlier for the corresponding photodissociation in 4-iodotoluene ion.[1] The magnitude of kinetic energy release is reasonable for statistical dissociation of a molecule this size excited to 1.8 eV above threshold, as is the case if direct dissociation to the tolyl ion product is assumed. There is no indication of a major extent of rearrangement to benzyl or tropylium product, which would be accompanied by very large kinetic energy release.[2,3]

Valid time-of-flight product-ion analysis depends on the fragmentation being fast compared with flight times, which requires in this case that the dissociation be complete within a few microseconds. PEPICO study[3] has indicated that this is true; Additional confirmation comes from a time-resolved ICR photodissociation experiment, as shown in Fig. 4, showing the amount of m/e 91 formed as a function of delay after the laser pulse. The shortest delay time was 8 μsec, at which time the product signal was already a maximum. Allowing a few additional μsec for cyclotron excitation, this indicates that dissociation is entirely complete within much less than 15 μsec. The ICR-TOF technique is succesful in showing the extent of kinetic energy release for fragmentations of parent ions whose internal excitation (governed by the photon energy) is very well known As in the present case, it is readily discerned whether the kinetic energy release is sharply peaked or is spread out in a more nearly Maxwellian distribution. The technique will be readily applied to a variety of photodissociation systems, and also is promising for similar kinetic energy studies of the fragment ions from dissociative multiphoton ionization, which we intend to carry out soon.

The External Ion Source for High Magnetic Field ICR Spectrometry
Experiment and Theory

P. Kofel*, M. Bamberg, I. Pezsa, H. Knoll and K. P. Wanczek,
Inorganic Chemistry, NW 2, University of Bremen, D-28 Bremen 33,
West Germany

External ion sources (1) for ICR can easily be incorporated in instruments with high magnetic field superconducting magnets which have solenoidal fields. The external source has several advantages. Because it can be pumped differentially, ions can be generated at high pressure, the external source is easily accessible. The very elaborated ion sources already available for mass spectrometry can be employed. However, the incorporation of such a source leads to a greatly increased complexity of the instrument, especially of the mechanical structure.

Three important factors have to be considered for an external ion source: ion generation, injection of the ions through the magnetic fringing field, and trapping of the ions.

Two types of external ion sources can be distinguished (2): pulsed and continous sources, while the first allows mass selection according to the different flight times of ions of different masses, the second method is employed for broad band spectroscopy. In axial beam ion sources no disturbance of the site of ion generation by the stray magnetic field is observed. The disturbance of the electron beam by the stray magnetic field can cause severe problems even in magnetically shielded sources.

From the Lagrange-Helmholtz equation criteria for the ion injection can be derived. The focus of the injection lens has to be such that the ions are injected parallel to the magnetic field lines. The properties of electrical lens systems are changed in the magnetic field if the relevant time is not much smaller than the time for one cyclotron gyration.

The axial kinetic energy of the ions does not influence the transfer. For narrow beams of low energy the influence of space charge is high and limits the ion current and the number of ions, which can be transferred. Defocusing of the beam is observed. If the radius of the ion beam is not enlarged and the beam is only focused, a large spread of the axial energies occurs, which can be as great as 1 eV.

Fig. 1 shows the relevant parameters for ions trapping. The spread of the axial energies is $q\Delta V$. Assumig equipartition of the axial translational energies of the ions, the number of ions N which can be trapped is

for $\Delta V \geq V_t$

$$N = \frac{1}{q}\int_{U=0}^{V_t} dQ(U) = \frac{2cI}{q\Delta V}\left(\frac{2mV_t}{q}\right)^{1/2}$$

and for $\Delta V \leq V_t$

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

$$N = \frac{1}{q}\int_{U=0}^{\Delta V} dQ(U) = \frac{2cI}{q}\left(\frac{2m}{q\Delta V}\right)^{1/2}$$

where $dQ(U)$ is the charge of the ions with mass m with energies between U and $(U + \Delta U)$, I is the ion current, and V_t is the trapping potential.

The equations show that the trapping of externally generated ions depends in a crucial manner from the energy spread of the ions. With fixed ΔV the maximum of trapping efficiency is reached if $\Delta V \leq V_t$. For fixed V_t, ΔV has to be as small as possible. For high resolution spectra, trapping potentials of approximately 1 V are employed, therefore $\Delta V \leq 1$ V.

The external source can be used to trap the ions in the residual magnetic field. The trapped ions can then be transferred to the ICR cell (3). *This can lead to a great improvement in sensitivity. For a comparable set of spectrum parameters and the same spectrum recording* time of a GC ICR instrument the relative signal-to-noise ratios of a spectrometer with a single cell, a double cell, an external ion source, and an external trapped ion source have been calculated to be 1:70:15:2500. Also the use of a radiofrequency ion trap as external source should be studied.

NEW FTMS METHOD FOR TRAPPING IONS THAT ARE INJECTED FROM AN EXTERNAL ION SOURCE INTO AN ICR CELL

Carlito B. Lebrilla, I.Jonathan Amster, and Robert T. McIver, Jr.
Dept. of Chemistry, University of California, Irvine, CA 92717

After nearly three years of effort, the new external ion source FTMS instrument at U.C. Irvine is operational. In this paper the features of the spectrometer are described and some of the first mass spectra are presented.

The basic concept of the instrument is the same as the tandem quadrupole-Fourier transform mass spectrometer that was described previously [1-4]. In order to operate at elevated ion source pressures, the instrument has three differentially pumped regions: an external ion source, an ion transport region, and an ion detection region with an ICR cell. The ion source region consists of a 6" stainless steel cube which has mounted on it an ion source (either EI or FAB), a direct insertion probe, a batch sample inlet port for gases, an ionization gauge tube, and a 6" gate valve attached to a Balzers TPU 170 turbomolecular pump. Ions are extracted from the source through a 0.063" diameter hole and accelerated into a RF quadrupole lens assembly which guides them to the ICR cell. The quadrupole lens assembly, which is 46" long, is mounted in a 6" tee along with pumping constrictions, a VAT gate valve, and an Air Products 6" cryopump. A second Air Products 6" cryopump evacuates the ion detection region and the ICR cell. The base pressure in the ICR cell is usually in the 10^{-10} torr range, and a gradient of 40,000:1 can be maintained between the ion source region and the ion detection region. The ICR cell is positioned in the homogeneous region of a 6-T superconducting magnet made by Oxford Instruments, and the FTMS experiments are controlled by an OMEGA data system manufactured by IonSpec Corp.

Much of our effort has been devoted to developing the RF quadrupole lens assembly. It serves two purposes in our experiments. First, it focuses the ions into a tight beam of only a few millimeters diameter and guides them through the fringing fields of the superconducting magnet. When the ion beam is properly focused by the quadrupole lens, very high ion trapping efficiency for injected ions can be achieved. For example, we estimate that from 10% to 20% of the injected ions can be trapped in the cell and that weak ion currents can be accumulated or "integrated" in the cell for 20 seconds. The data in Fig. 1 show that as the injection time period is lengthened, the intensity of the Xe^+ signal increases until the space charge limit is reached. For this particular injection current, the space charge limit is reached after about two seconds. However, a weaker injection current can be accumulated for a much longer time. The second purpose of the quadrupole lens is to select which ions are transported to the cell. Ideally, it should function like a "bandpass filter" so that only ions in a preselected mass range are transmitted to the ICR cell. This is important for the FAB and other experiments we plan to perform because the dynamic range of the ICR cell is limited and the cell can be easily filled to its space charge limit by uninteresting matrix-related ions.

The mass resolution and sensitivity of the new instrument have exceeded our expectations. Figure 2a shows a single narrowband acquisition for m/z 132 formed by EI of xenon gas in the cell. The transient signal extends for more than 6 seconds, and the mass resolution is 2,600,000. Very recently we have begun FAB experiments using a cesium ion beam. Figure 2 (a) shows a single scan, narrowband acquisition for the cluster $(CsI)_9Cs^+$, m/z 2471, at a resolution of 120,000, and Fig. 2c shows a single scan, narrowband acquisition for the cluster $(CsI)_{37}Cs^+$, m/z 9746, at a mass resolution of 53,000. Figure 3 shows a spectrum of Gramacidin S produced by FAB with a glycerol matrix at a resolution of 120,000 for the molecular ions.

Desorption Ionization and Ion Injection into a Quadrupole Ion Trap Mass Spectrometer

John N. Louris, Jennifer S. Brodbelt-Lustig, Raymond E. Kaiser, R. Graham Cooks
Purdue University
West Lafayette, IN 47907

The quadrupole ion trap mass spectrometer has become an increasingly important tool for the qualitative and quantitative analysis of relatively volatile organic compounds. Previously, ions were always generated within the cavity of the ion trap rather than being generated outside of the trap and injected into the trap. In theory, ions injected into the trap must eventually strike a wall because of the excess kinetic energy which allowed them to enter the trap from the outside. This requirement severely restricts the use of modern ionization methods such as FAB, SIMS, and laser desorption because of poor access to the cavity of the trap. However, since a relatively high pressure of helium is used in the trap, the possibility exists of trapping injected ions by removing energy through collisions.

We recently reported the construction of an electron impact ion injection source for the trap. Spectra were readily obtained by ion injection. We now report the use of this source for laser desorption ionization. A fiber optic was positioned in an aperture in the side of the ion volume, situated so that the end was 0.2 - 0.4 cm from a metal target within the ion volume. This target was affixed to a removable probe to permit convenient changing of the sample. The fiber optic entered the vacuum manifold through an O-ring seal, and light from a pulsed Nd:YAG laser (532 nm) was focussed 0.1 - 0.3 cm from the end of the fiber optic. Figure 1 shows the arrangement of optics used to separate the harmonics in the laser light and to focus the beam on the fiber optic. Figure 2 shows the external parts of the injection source, including the fiber optic and the probe (which enters the ion volume through a hole in the back of the ion volume). The laser was triggered by the instrument's single board computer when ions were to be admitted into the trap.

A single pulse of the laser was capable of filling the trap to the "space-charge limit". Injected gold ions were used to study the effectiveness of gases other than helium in promoting the trapping of ions; helium, neon, argon, and xenon all promoted the trapping of Au^+. Neon was as effective as helium at promoting trapping, but argon and xenon yielded signals only 10-20% as intense as helium. In addition, xenon produced broad peaks in the mass spectrum (about three mass units wide) whereas the other three gases produced peaks of unit resolution.

Injected metal ions could also be used as CI reagent ions. For example, when gold ions were injected into the trap in the presence of 5×10^{-7} torr benzene vapor, ions were observed corresponding to Au^+, the charge exchange product $C_6H_6^{+\cdot}$ and the condensation products $[Au\text{-}C_6H_6]^+$, $[Au(C_6H_6)_2]^+$ and $[H_2O\text{-}Au\text{-}C_6H_6]^+$. Figure 5 shows the ionization of cyclohexene by injected copper ions. Ions corresponding to the bis-cyclohexene adduct (227/229), the mono adduct (145/147), the mono adduct with water (163/165), and the mono adduct less 28 are observed. This system was studied further by collisionally activated dissociation. The ions of m/z 163 were first isolated using a combination of DC and RF voltage; after excitation, ions of m/z 145 were produced, corresponding to loss of water. After isolation and excitation, ions of m/z 117 and m/z 81, were produced. The ions of m/z 81 probably result from the removal of all substituents on the copper ion, followed by reaction with adventitious water. The use of metal ions for the chemical ionization of organic compounds has been extensively studied using FT-ICR spectrometry (1). The ability to inject metal ions into the quadrupole ion trap provides a practical, alternate method of investigating this chemistry.

Laser desorption and ion injection of organic compounds has also been achieved. Figure 3 shows the spectrum of a quaternary ammonium salt. Amino acids and small peptides gave spectra when mixed with a potassium salt. However, the positioning of the probe proved critical in obtaining strong signals, and the sample was often desorbed before the position could be optimized. A more rigid mechanical arrangement may make the acquisition of such spectra more facile.

The use of a DC component for the isolation of ions (as was done for Figure 6) is explained in Figure 4: the ions of interest are given a q to place them beneath the "upper cusp" of the stability diagram, and DC is applied to bring the ions almost to the cusp itself. Figures 7 and 8 are spectra of xenon (not ion-injection) to help characterize the method. For Figure 8, m/z 132 was given a q beneath the cusp, and the DC component was increased linearly. The ions of other m/z values are excluded from the trap, and m/z 132 is isolated without loss in intensity. In Figure 7, both the RF and the DC are varied (angled axis) such that the DC/RF ratio is constant. This set of spectra is actually a mass analysis using the cusp of the stability diagram, and shows unit resolution in the isolation step.

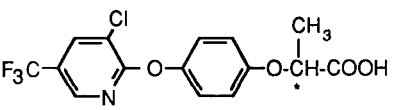
STEREOCHEMICAL INVERSION OF HALOXYFOP IN THE FISCHER 344 RAT. Michael J. Bartels and Fred A. Smith, Health & Environmental Sciences, Dow Chemical Co., Midland, MI 48674

The compound haloxyfop [2-(4-((3-chloro-5-(trifluoromethyl)-2-pyridinyl)oxy)phenoxy)propionic acid] is currently being evaluated for use as a herbicide. This compound is structurally similar to a group of 2-arylpropionates



HALOXYFOP

which have been shown previously to undergo stereochemical inversion in a variety of mammalian species. The toxicicity/ oncogenicity studies performed in our laboratory, to support registration of haloxyfop as a herbicide, have been performed with the racemic test material. To support registration of the herbicidally active (R)-enantiomer of haloxyfop, further experiments were carried out to determine if racemic haloxyfop undergoes stereochemical inversion to the (R)-enantiomer in the rat, similar to the related 2-aryl-propionates.

Following administration of racemic test material (11 mg/kg, po) to male and female Fischer 344 rats, urine and feces were collected daily for 10 days. Selected, pooled urine samples were fortified with D_4-haloxyfop (center ring label), acidified, extracted (EtOAc), the haloxyfop enantiomers converted to diastereomeric derivatives ((S)-phenylethylamine) and analyzed by SIM GC/MS. Selected urine samples were also analyzed by HPLC. Selected, pooled fecal samples were fortified with D_4-haloxyfop, base-hydrolyzed (60°C - 30 min), acidified, and extracted with EtOAc. The EtOAc extracts were purified by reverse phase HPLC prior to derivatization and GC/MS analysis.

In the female rat the urinary haloxyfop was found to be nearly all (R)-enantiomer (>98%) and comprised 69.6% of the administered dose. Similar results were obtained for the test material present in all female rat fecal samples analyzed, in which 7.7% of the administered dose was recovered as haloxyfop. In the male rat, 52.2% of the dose was recovered in the day 1-10 urine and feces as haloxyfop. The stereochemistry of the parent compound present in these samples was similar to the results seen in the female rat (>98% (R)). These results show that (S)-haloxyfop undergoes rapid and nearly complete inversion to the (R)-enantiomer in the male and female Fischer 344 rat.

LY186641 METABOLISM IN HUMANS: DETERMINATION OF HUMAN PLASMA AND URINARY METABOLITE STRUCTURES BY THERMOSPRAY LC/MS AND FAST ATOM BOMBARDMENT MS

Patricia H. Dhahir, Alan Breau, Marta Hamilton,
Richard D. Barton and Winston G. Satterlee
Lilly Research Laboratories, Eli Lilly and Company
Indianapolis, IN 46285

INTRODUCTION:

LY186641, a diarylsulfonylurea derivative (Figure 1), is currently undergoing evaluation for antineoplastic activity against solid tumors. This compound is the first oncolytic application from the diarylsulfonylurea chemical class. During plasma level determinations two putative metabolite peaks were obtained on the HPLC-UV assay for parent. The retention times of the two putative metabolites were identical with two analogs in the LY186641 series. The identification of the two compound related peaks was determined using thermospray LC/MS, fast atom bombardment (FAB) mass spectrometry and chemical derivatization procedures.

MATERIALS AND METHODS:

Isolation and separation of metabolites

Acidified plasma and urine samples were extracted from an Analytichem C-2 cartridge using methanolic HCl. The extracts were reconstituted in mobile phase (25% acetonitrile/75% 0.1 M ammonium acetate) and injected onto a 25 cm x 4.6 mm Supleco LC-18-DB column. A Kratos 400 solvent delivery system pumped mobile phase at 1.0 ml/min through the column into a Waters 441 absorbance detector set at 254 nm. Each metabolite peak fraction was collected, pooled and concentrated under nitrogen.

Identification of metabolites

The concentrates were extracted into 90% hexane/10% ethyl acetate and reinjected onto the HPLC system (vide supra) to compare retention time with the synthetic analogs. Thermospray LC/MS spectra of the concentrates were obtained by analyzing the two concentrates on a Finnigan 3200 mass spectrometer through a Vestec thermospray interface.

The mass spectrometer was scanned from 150-500 amu every 2 seconds. The negative ions were detected at an electronmultiplier setting of 1450 V. The Vestec thermospray interface was operated in the discharge "on" mode with a tip temperature of 150 C, a vapor temperature of 240 C and a source block temperature of 290 C. No molecular ion was observed in thermospray LC/MS analysis, thus the samples were reanalyzed using FAB mass spectrometry. The FAB analyses were performed on a Nermag R30-10 triple stage quadrupole mass spectrometer operated in the single scan mode. The samples were dissolved in "magic bullet" matric on a stainless steel target. The target was bombarded with neutral Xenon gas (7 x 10-5 torr) accelerated to 7 kv using a Wallis M Scan FAB gun. The mass range of 300-800 amu was scanned every 10 seconds. The thermospray and FAB analyses indicated a keto and a hydroxy metabolite were present. The keto group was further confirmed by sodium borohydride reduction to the hydroxy which was monitored using FAB.

RESULTS AND DISCUSSION:

The thermospray LC/MS analyses of LY186641 does not produce a molecular ion but a major fragment at m/z/=180 representing the loss of the HN-(C=O)-NH-ARYL-CL group is observed. Fortuitously the major site of metabolic transformation occurs on the indan ring (Figure 2) which corresponds to the m/z=180 (Figure 3) fragment. The thermospray data indicates that the putative metabolites produce ions at m/z=194 (Figure 4) and m/z=196 (Figure 5) which are consistent with a keto (Figure 6) and hydroxy (Figure 7) indan ring structure. The retention times of synthetic standards of the keto and hydroxy metabolites are identical to the metabolites isolated from biological fluids. Since only one synthetic keto derivative is available, the location of the keto function on the indan ring is accomplished by reducing the keto metabolite with sodium borohydride. The hydroxy derivatrive that is formed can be compared using HPLC retention time data to the known synthetic hydroxy isomers.

Since only the indan ring is monitored using thermospray LC/MS, FAB is used to provide structural information about the total moiety. FAB produces a molecular ion and natriated adducts. The FAB analysis of parent produces a molecular ion at m/z=351 (Figure 8). The keto metabolite produces a molecular ion at m/z=365 (Figure 9) an increase of 14 daltons from the parent drug. The hydroxy metabolite has a molecular ion at m/z=367 (Figure 10) which represents a 16 mass increase over parent. The FAB spectra of the sodium borohydride treated keto metabolite produces a very small hydroxy parent at m/z=367 as well as a series of sodium adducts at m/z+389 and m/z-411 (Figure 11). The FAB spectra are consistent with the parent drug (Figure 1), hydroxy metabolite (Figure 12) and keto metabolite (Figure 13) structural assignments as well as the formation of the hydroxy metabolite following sodium borohydride reduction. The mass range of the FAB acquisitions is sufficient to detect any major conjugates. No major conjugates are observed.

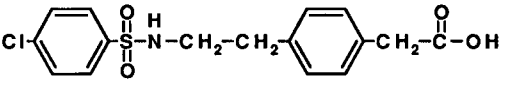
Characterization of Rat Biliary Metabolites of Daltroban (BM 13.505/SK&F 96148 By Fast Atom Bombardment and Thermospray Liquid Chromatography/Mass Spectrometry.

D. Dulik, G. Kuo, R. Gagnon, M. Davis, and J. Kao, Dept. of Drug Metabolism, SmithKline and French Research Labs, Swedeland, PA 19479

Daltroban (BM 13.505/SK&F 96148, I) is an orally active non-prostanoid thromboxane receptor antagonist currently under development in conjunction with Boehringer Mannheim GmbH for a number of cardiovascular and renal indications. This compound has been shown to be a potent anti-aggregating and antithrombotic agent in vitro and in animal models.



I

The objective of this study was to determine the metabolic profile of I in male and female rat bile and to structurally characterize the metabolites. Early studies by BM indicated that I undergoes extensive first pass metabolism to produce polar conjugates. Male and female Sprague-Dawley rats were bile duct cannulated and exteriorized for collection of samples. ^{14}C-I (171 uCi/mg; 100 mg/kg total dose) was administered as the sodium salt either orally or iv. Bile samples were collected into 10% aqueous glacial acetic acid and frozen immediately at the following time points: 0.5, 1, 2, 4, 6, 8, and 24 hrs. Bile samples were analyzed directly by thermospray LC/MS and LC/MS/MS on a Finnigan TSQ-45. Metabolites were also purified by gradient reversed phase HPLC and characterized by FAB mass spectrometry and proton NMR

Five major drug-related components were found in male rat bile, designated as M1-M5. These components accounted for 14, 20, 49, 14, and 1 percent of the excreted dose in the 2-4 hr collection period. In female bile, no M1 was found; M2 to M5 corresponded to 4, 77, 11, and 6 percent, respectively, for the same collection interval. Time dependent changes in the metabolite profile were evident. In males, the relative percent of M3 decreased from 70% in the 1-2 hr sample to 21% in the 8-24 hr sample. Conversely, the percent of M1 increased from 5 to 34% and M2 increased from 7 to 34% over the same time intervals.

The thermospray LC/MS spectrum of M1 gave a protonated molecular ion at m/z 477, 479 and an ammonium ion at m/z 494, 496. Negative ion FAB analysis produced an $(M-H)^-$ ion at m/z 475, 477. Proton NMR analysis of M1 combined with the mass spectral data was consistent with a taurine conjugate of hydroxylated I. LC/MS/MS analysis of M1 gave diagnostic fragment ions at m/z 126 for the taurine moiety and

m/z 308 for decarboxylated parent, as well as ions corresponding to dehydration products. The thermospray LC/MS spectrum of M2 gave a protonated molecular ion at m/z 461, 463 and ammonium adduct at m/z 478, 480. Negative ion FAB analysis gave an $(M-H)^-$ ion at m/z 459, 461. Proton NMR analysis of M2 was consistent with a taurine conjugate of I. LC/MS/MS analysis of M2 gave a base peak fragment ion at m/z 126 corresponding to loss of the taurine moiety. The thermospray LC/MS spectrum of M3 gave an ammonium adduct ion at m/z 547, 549. Negative ion FAB analysis produced an $(M-H)^-$ ion at m/z 528, 530. Proton NMR showed a strong anomeric proton signal at d 5.5, indicative of a 1-O-acyl glucuronide. LC/MS/MS analysis was also consistent with this proposed structure, with fragments at m/z 371, 373 from loss of glucuronic acid and m/z 194 for glucuronic acid itself. Both thermospray LC/MS and positive ion FAB analysis of M4 gave a protonated molecular ion at m/z 497. Little fragmentation in LC/MS/MS analysis was observed. The proton NMR spectrum combined with mass spectral analysis of M4 was consistent with the carnitine conjugate of I. Several other carnitine conjugates of acidic xenobiotics in animal species and humans have been previously reported. M5 was shown to be parent (I) by coelution in HPLC, thermospray LC/MS and LC/MS/MS, and FAB mass spectra.

The pH stability of M3, the 1-O-acyl glucuronide conjugate, was studied under physiological conditions. Authentic M3 was synthesized using immobilized microsomal UDP-glucuronyltransferases from rabbit liver. The product was purified by HPLC and characterized by mass spectrometry. M3 was stored in aqueous phosphate buffer (0.1 M, pH 7.4) at 37°C overnight. Aliquots were removed at various time points and the incubation mixture was monitored by HPLC. The half-life of M3 was less than 1 hr under these conditions. Stability of M3 was greatly enhanced by decreasing the pH of the incubation mixture to 3.0 and/or decreasing the temperature to -18°C.

Dept. of Drug Metabolism, Smith Kline & French Laboratories, Swedeland, PA
and *Syntex Research, Palo Alto, CA

SK&F 86466 (6-Chloro-2,3,4,5-tetrahydro-3-methyl-1H-3-benzazepine) is an α_2-adrenoreceptor antagonist which has been shown to be an effective agent for lowering blood pressure in a variety of animal models[1,2]. Female beagle dogs received a 10 mg/kg oral dose of ^{14}C-SK&F 86466. Approximately 75% of the dose was excreted in the urine within 24 hours. Urine was acid stabilized on collection, then subjected to HPLC on a semi-preparative C_{18} column using linear gradients of 0.1% acetic acid (v/v) in water and methanol or 0.1M ammonium acetate and methanol. Fractions of column eluent containing radiolabel were pooled and repurified by isocratic HPLC prior to analysis by mass spectrometry and NMR.

A total of 8 major metabolites were observed, designated as 1-8 on the basis of their relative polarity. Metabolites were analyzed by FABMS, HPLC/MS, HPLC/MS/MS, DEP/EI MS, GCMS, ^{1}H-NMR, and ^{13}C-NMR. FAB mass spectra were obtained on a VG7070-EHF mass spectrometer using glycerol or thioglycerol as the matrix. Accurate mass determinations were made by on-line peak matching using the VG 11-250 data system. HPLC/MS and MS/MS analyses were conducted on a Finnigan TSQ-45 mass spectrometer equipped with a Finnigan Thermospray source and controller. GCMS and DEP/EI mass spectra were recorded on a Finnigan 4535 mass spectrometer. ^{1}H-NMR and ^{13}C-NMR spectra were obtained on a Bruker HX-360 spectrometer.

Metabolites 2 and 3, which account for a total of 22% of the drug-related material present in the urine, correspond, respectively, to the previously identified N-oxide metabolite (SK&F 102102) and the N-desmethyl metabolite (SK&F 101055)[3].

Following repurification by HPLC using the ammonium acetate/methanol mobile phase system, Metabolite 4 was found to be Metabolites 4A-4D, which account for 1%, 2%, 3%, and 10%, respectively, of the total radiolabel in the urine. Analysis of Metabolite 4D by FABMS gave $(M-H)^-$ at m/z 260 in negative ion mode. HPLC/MS gave $(M+NH_4)^+$ at m/z 279. HPLC/MS/MS analysis of m/z 279 yielded m/z 182, which corresponds to a protonated N-desmethyl moiety. The accurate mass of $(M-H)^-$ is 260.0157, which gives an elemental composition match of $C_{10}H_{11}NClSO_3$. The molecular weight information is consistent with an N-sulfonate metabolite of SK&F 101055. Additional evidence for this assignment was obtained by ^{1}H-NMR spectroscopy which showed the three aromatic protons and the eight azepine ring protons to be present. Acid hydrolysis of metabolite 4D resulted in the formation of the N-desmethyl metabolite, SK&F 101055, which was identified by GCMS.

Metabolite 7 accounts for 16% of the drug-related material found in the urine. Analysis by FABMS gave m/z 400 ($(M-H)^-$) in negative ion mode and m/z 402 ($(M+H)^+$) and 424 ($(M+Na)^+$) in positive ion mode. Analysis by HPLC/MS gave m/z 402 ($(M+H)^+$) and m/z 419 ($(M+NH_4)^+$). HPLC/MS/MS analysis of the ion m/z 402 showed fragment ions at m/z 226 (loss of a glucuronic acid moiety) and 182 (protonated SK&F 101055). The accurate mass of $(M-H)^-$ was found to be 400.0789, consistent with the composition $C_{17}H_{19}NClO_8Cl$. A ^{1}H-NMR spectrum of Metabolite 7 revealed three aromatic protons, eight azepine ring protons, and five non-exchangeable glucuronyl protons to be present. When analyzed by ^{13}C-NMR spectroscopy, the carbon resonances of the benzazepine and glucuronide moieties were present with an additional signal corresponding to the carbamate carbonyl. A structure consistent with these data is that of an acyl glucuronide of an intermediate carbamic acid, formed by the addition of CO_2 to the N-desmethyl metabolite.

Metabolite 8 accounts for 14% of the drug-related material in the urine. FABMS in negative ion mode gave $(M-H)^-$ at m/z 372. High resolution FABMS determined the accurate mass of $(M-H)^-$ to be 372.0847, which is consistent with the composition $C_{16}H_{19}NO_7Cl$ and corresponds to the elements of the N-desmethyl metabolite, glucuronic acid, and an additional oxygen. HPLC/MS/MS analysis of $(M+H)^+$ yielded the fragmentation sequence of 374->198->180 which is consistent with an O-glucuronide, but the position of substitution on the benzazepine ring cannot be determined from this data. ^{1}H-NMR analysis of this metabolite showed the three aromatic protons to be present but broadened signals of the azepine ring protons did not allow for accurate integration of their number and subsequent determination of the site of substitution. Following complete exchange in D_2O, Metabolite 8 was analyzed by negative ion FABMS using $^2H_8$-glycerol as the matrix. $(M-D)^-$ was observed at m/z 375 which demonstrated that the structure contains four exchangeble hydrogens. This eliminates all structural possibilities except an N-O-glucuronide, formed from an intermediate hydroxylamine of SK&F 101055.

Metabolite 1 was analyzed by negative ion FABMS with thioglycerol used as the matrix. $(M-H)^-$ was observed at m/z 276. This indicates a shift of 96 amu from the molecular weight of SK&F 101055, which implies the addition of a sulfate group to the N-desmethyl metabolite. High resolution FABMS analysis of m/z 276 determined the accurate mass of $(M-H)^-$ to be 276.0103. The molecular formula, $C_{16}H_{11}O_4NSCl$, is consistent with $(M-H)^-$ of a sulfate ester of SK&F 101055. The DEP/EI mass spectrum of the acid hydrolysis product of Metabolite 1 gave (M^+) of m/z 197, which is consistent with a hydroxylated N-desmethyl metabolite. ^{1}H-NMR analysis of Metabolite 1 showed two doublets in the aromatic region, corresponding to H7 and H8. A singlet, corresponding to H9, present in ^{1}H-NMR spectra of SK&F 101055, is absent in the spectrum of Metabolite 1, indicating C9 as the site of hydroxylation and subsequent sulfation of SK&F 101055.

The limited quantities of other metabolites made full characterization impossible, but molecular weight information was acquired for both Metabolites 4C and 6. FABMS analysis of Metabolite 4C in positive ion mode gave molecular ion species containing a chlorine isotope pattern at m/z 416,418. Fragment ions were observed at m/z 240 (loss of glucuronic acid moiety) and m/z 196 (loss of glucuronic acid moiety and CO_2). HPLC/MS gave a weak signal at m/z 433 and an intense signal at m/z 196 (protonated SK&F 86466). These data are consistent with a quaternary amine carbamate glucuronide of SK&F 86466.

When analyzed by FABMS, Metabolite 6 showed $(M+H)^+$ at m/z 550 and $(M+Na)^+$ at m/z 572 in positive ion mode and $(M-H)^-$ at m/z 548 and $(M+Na-H)^-$ at m/z 570 in negative ion mode. This data is consistent with a diglucuronide of the desmethyl metabolite. ^{1}H-NMR analysis of this metabolite failed to give useful structure elucidation information.

Following oral administration in the dog, SK&F 86466 undergoes N-oxidation to yield the N-oxide and C-oxidation to yield the N-desmethyl metabolite. The N-desmethyl is metabolized further by phenylhydroxylation followed by sulfation, N-sulfation, carbamylation followed by glucuronidation, and oxidation to a hydroxylamine followed by glucuronidation.

STRUCTURE DETERMINATION OF A54145A. A PEPTOLIPID CONTAINING NON-MAMMALIAN AMINO ACIDS

R. E. Chance, D. S. Fukuda, J. M. Gilliam, A. H. Hunt,
J. S. Mynderse, and J. L. Occolowitz*
Lilly Research Laboratories, Eli Lilly & Co., Indianapolis, IN 46285

The antibiotic A54145A (I) and several related compounds were produced by fermentation. Amino acid analysis showed that approximately 70% of the MW of A54145A, 1643d, was due to known amino acids. I contains one tryptophan residue, and a peak at m/z 341, $C_{21}H_{29}N_2O_2$, in its FABMS suggested that this was due to an N-decanoylated tryptophan moiety. Figs. 1a. and 1b. compare the CID spectra of m/z 341 and m/z 355, an undecanoyltryptophan moiety which occurs in the FABMS of A21978C_1 (II), a known antibiotic. Their similarity confirmed the presence of acyltryptophan in I. Both I and II contain threonine which further suggested that I might bear some structural similarity to II in which a lactone ring is formed by reaction of the C-terminal carboxylic acid with the threonine hydroxyl. This assumption was supported by formation of ring-opened A54145A (III), MW=1661d, by treatment of I with base. Enzymatic deacylation of I resulted in deacyl-A54145A(IV). Subsequently III and IV were used for FABMS, and Edman/FABMS sequencing, respectively.

FABMS of III indicated the partial sequence,
C_9H_{19}CONH-Trp-Glu------Gly-Asn-Glu-Ile-OH.
Fig.2. shows the FABMS evidence for the partial C-terminal sequence.

Edman sequencing of IV indicated the sequence,
H-Trp-Glu-X_1-Thr-Sar-Ala-Asp-Lys-X_2-Gly-Asn-Glu-Ile-OH
where X_1 and X_2 were unknown amino acids. The mass of X_1 was found by subtracting the mass of the residues obtained from the 2nd and 3rd Edman cycles. (Figs. 3a. and 3b.), and its composition determined by subtracting the accurate masses of the b_2 and b_3 sequence ions present in the FABMS. The composition of X_2 was found by subtracting the accurate mass of all of the known moieties from that of III. Thus, X_1 was found to be derived from an amino acid $C_4H_8N_2O_4$ and X_2 from $C_5H_9NO_5$. NMR analysis of IV established that these two amino acids were hydroxyasparagine and methoxyaspartic acid, respectively, and showed that the C-terminal isoleucine was bonded to the threonine hydroxyl in I.

The CID spectrum of the MH^+ from III, Fig. 4., supported its sequence. Sequence ions for the Lys-Asp(OCH_3) cleavage, not present in the CID spectrum, were found in the positive and negative FABMS of III.

The structure of A54145A is shown in Fig. 5.

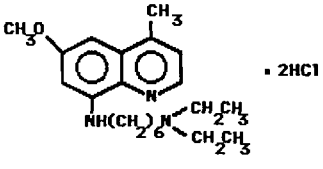
THERMOSPRAY LC/MS ANALYSIS OF METABOLITES OF THE CANDIDATE 8-AMINOQUINOLINE ANTILEISHMANIAL DRUG WR 6026 GENERATED IN THE ISOLATED PERFUSED RAT LIVER MODEL (IPRL)

RW Ashmore, LA Shipley, MD Coleman, TG Brewer, and AD Theoharides;
Department of Pharmacology, Walter Reed Army Institute of Research,
Washington, DC 20307-5100

Introduction

Leishmaniases are a widespread group of tropical diseases characterized by protozoal infections of the viscera, skin, and mucous membranes (1). 8-(6-Diethylaminohexylamino)-6-methoxy-4-methyl quinoline dihydrochloride (WR 6026) is a rapidly metabolized candidate antileishmanial drug which is currently in phase I clinical pharmacology studies.

Studies on the disposition of WR 6026 in vivo in the hamster (2) have shown that 48% of the dosed radioactivity was eliminated in the feces with 21% remaining in the liver. It is likely, therefore, that the drug undergoes hepatic uptake and biliary elimination in vivo. Therefore, the Isolated Perfused Rat Liver model (IPRL) would be a useful model to study the metabolism of WR 6026.



WR 6026.2HCl

Methodology

Rats were anesthetized with sodium pentobarbital and their livers isolated using standard techniques (3). The IPRL preparations were perfused in a circulating system (15 ml/min) at 37 °C as previously described (4). Bile was collected at 30 minute intervals after bolus injection of WR 6026 containing 25 uCi of [14C] labelled drug.

Reverse phase gradient HPLC analyses were performed using a Waters liquid chromatography system equipped with Raytest-Ramona-LS radiodetector. Gradient runs of acetonitrile:0.1 M ammonium acetate (pH 4.5) mixtures from 20:80 v/v to 50:50 v/v, concave curve, 30 minute ramp, at 1.5 ml/min were used. Elution was monitored by UV @ 254 nm and/or radiochemical detection. Radiochemical detection demonstrated the presence of a minimum of 12 more polar metabolites of WR 6026 in bile collected from this perfusion model.

A representative aliquot of total bile production for each half hourly sample was combined for a pooled sample. A subsequent aliquot was removed from this pooled sample for hydrolysis treatment (pH 5.0, 37 °C, 16hr) with b-glucuronidase preparation from bovine liver (1 unit/ml bile) or aryl sulfatase preparation obtained from Helix pomatia (1 unit/ml bile). Bile was injected directly on column for LC/MS analysis with equivalent volumes for hydrolyzed samples. Injection of standard compounds verified retention order and retention times found for some metabolites in the bile samples.

Thermospray LC/MS analyses were performed with identical chromatographic conditions to those described above. The chromatography equipment was interfaced to a NerMag R10-10C quadrupole mass spectrometer with Vestec Thermospray probe and gradient controller. The Finnigan Super INCOS data system was used for data acquisition and manipulation. The thermospray source was operated at 200 °C with probe run with T1 = 105 °C and T2 = 190 °C. No filament, repeller or discharge current was applied.

Results

Biliary excretion of [14C] accounted for 18.20±5.03% of the dose eliminated during the four hour experimental period. Only 2.80±0.68% was identified as WR 6026 and 0.63±0.11% as the desethyl metabolite. The remaining radioactivity was accounted for as highly polar metabolites of WR 6026. Treatment of the bile with hydrolyzing enzymes (B-glucuronidase and aryl sulfatase) facilitated the identification of three glucuronidated and two sulfated metabolites by LC/MS.

LC/MS spectra of all phase I unconjugated metabolites showed a protonated molecular ion as base peak, whereas sulfated and glucuronidated metabolites showed little or no molecular ions in the spectra, however the protonated deconjugated metabolite was base peak in all cases, i.e. $[M-SO3]+$ or $[M-C6H12O7]+$.

The structure of two of the glucuronidated metabolites were assigned as the 6-desmethyl glucuronide and the 6-desmethyl desethyl glucuronide metabolites of WR 6026. The third glucuronidated metabolite, an N-glucuronide of the side chain cleaved 8-amino metabolite could not be assigned exactly as to the position of the glucuronide moiety. The sulfated metabolites were identified as the 6-desmethyl sulfate and the 6-desmethyl desethyl sulfate metabolites.

Unconjugated metabolites identified were the 8-amino (side chain cleaved), desethyl, 6-desmethyl, 6-desmethyl desethyl metabolites. Two unidentified metabolites appeared after hydrolysis, and another metabolite was assigned a dihydroxylated structure, however the exact positions of the hydroxylations are as yet unknown. The HPLC intensity and chromatographic mobility of this metabolite was unaffected by treatment with either enzyme.

Summary

The data show that LC/MS analysis in conjunction with appropriate gradient HPLC conditions and enzyme hydrolysis procedures is a very powerful technique in drug metabolism studies.

GC/MS CONFIRMATION OF SULFAMETHAZINE AND SULFISOXAZOLE IN MILK.

Agnes Van Langenhove (a) and Elizier Zomer (b); (a) Enseco - Erco Laboratory, 205 Alewife Brook Parkway, Massachusetts, 02138 and (b) Penicillin Assays Inc., 36 Franklin Street, Malden, Massachusetts, 02148.

Sulfamethazine and sulfisoxazole are sulfonamides used in combination with antibiotics as feed supplements to promote growth and retard bacterial infection in cattle. Contamination of milk samples with such sulfonamide residues is now being widely reported across the United States.

We are currently refining the Gas Chromatography/Mass Spectrometry (GC/MS) methodology for the confirmation of sulfonamide residues in milk samples that test positive in a newly developed radio receptor assay for sulfonamides and other antibiotics (1). In this competitive receptor assay, specific binding sites for drug classes are immobilized on microorganisms. For sulfonamide residues, concentrations of 5 ppb can be detected. GC/MS confirmation will only be needed for milk samples that test positive above the action levels set by the Food and Drug Administration. These tolerance limits will range from 10-100 ppb.

Our procedure for confirming the presence of a specific sulfonamide residue currently involves an initial High Performance Liquid Chromatography (HPLC) analysis of the lyophilized milk sample. The sulfonamide is characterized on the basis of its retention time, and quantitative determination is done by linear regression of area calculations of HPLC peaks at 275 nm. Tritium-labeled analogs have been used to validate this methodology. Final confirmation is done by GC/MS/Electron Ionization (EI) in the multiple ion detection mode. For these analyses, the HPLC fractions are collected. After evaporation of the solvent, the residue is methylated with diazomethane and analyzed by GC/MS.

Initial method validation was done for sulfamethazine at low nanogram GC/MS detection levels. Ions at m/z 92, 227, and 228 were monitored. The ions at mz 227/228 are indicative of sulfamethazine and not just of the sulfonamide portion. The methodology was applied to a milk sample that had been found to contain low ng levels of sulfamethazine. The absence of the confirmatory ions in a control blank used in conjunction with the retention time of N^1-methylsulfamethazine in the standard provided conclusive confirmation of sulfamethazine residues in the milk sample.

The methodology was then extended to five other sulfonamides: sulfanilamide, sulfathiazole, sulfapyridine, sulfisoxazole, and sulfadimethoxine. The methylated derivatives of these compounds were well resolved by GC/MS. Representative ions were selected for each individual compound and a combined standard was analyzed by GC/MS/EI in the Multiple Ion Detection (MID) mode. The following ions were selected (m/z values): sulfanilamide (92, 156, 172), sulfisoxazole (281, 156, 92), sulfapyridine (198, 199, 92), sulfathiazole (204, 205, 92), sulfadimethoxine (259, 260, 92). The ions chosen for sulfisoxazole provide less specific information about the compound than the ions selected for the other sulfonamides. The ions at m/z 92 (aniline) and mz 156 are indicative of the sulfonamide class only and are not specific for sulfisoxazole. An attempt to confirm sulfisoxazole at low ng levels in a milk sample by including monitoring of m/z 217 was only partially successful because the abundance of m/z 217 in the mass spectrum of N^1-methylsulfisoxazole is too low.

The GC/MS/EI evaluation studies done so far therefore indicate that selection of confirmatory ions is straightforward if the ions at $(M-SO_2)^+$ and $(M-HSO_2)^+$ can be selected (or for sulfanilamide, the abundant M^+). These ions are of low abundance in the mass spectrum of sulfisoxazole and the mass spectrometric confirmation of sulfisoxazole at low ng levels would therefore be better accomplished by positive chemical ionization mass spectrometry. We are currently awaiting actions levels to be set by the FDA for selection of the final methodology.

EXAMINATION OF THE MASS SPECTRA OF AMINOGLYCOSIDE ANTIBIOTICS BY THERMOSPRAY MASS SPECTROMETRY AND FAB MASS SPECTROMETRY

T.A. Getek, W.A. Korfmacher, and J.P. Freeman
National Center for Toxicological Research
Jefferson, AR 72079

ABSTRACT: Aminoglycoside antibiotics represent an important class of broad spectrum antibiotics used in injectables and topical solutions. Thermospray mass spectrometry (TSMS) and fast atom bombardment (FAB) mass spectrometry (MS) are two forms of ionization that are effective for the mass spectral analysis of aminoglcosides and sugars. In the course of investigating the utility of TSMS and FAB MS for the these compounds, it was noted that the aminoglycoside sulfates exhibited unusual behavior in TSMS and FAB MS.

EXPERIMENTAL: The thermospray (TS) mass spectrometer was a DELSI Ribermag R10-10C with a Vestec TS controller capable of discharge assistance at 1 kV. The aminoglycosides and sugars were examined by direct injection from a 20 *u*L loop using 0.1 M ammonium acetate as the liquid carrier at a flow rate of 1.0 mL/min. The FAB MS analyses of the aminoglycosides and sugars were performed on a Finnigan TSQ-70. A thioglycerol matrix and a sample load of 1.5 *u*L was utilized. Concentration of samples was ca. 2 mg/mL in water.

RESULTS AND DISCUSSION: In TSMS, aminoglycoside sulfates fragmented readily yielding only a small percent abundance of $[M+H]^+$ and large peak intensity for the individual sugar fragments formed from the cleavage of the glycosidic bonds (see TABLE I). In the course of maximizing peak intensity with discharge assistance, it was observed that the m/z for the aminoglycoside fragments at high tip temperature increased by one mass unit. One speculation for this one mass unit increase may be proton attachment to a neutral fragment. This neutral fragment may have been formed via a different ionization pathway for the parent molecule due to the discharge being on and higher tip temperature. This anomaly was not observed with the discharge off.

The FAB MS analyses of aminoglycoside sulfates in thioglycerol (TG) showed typical $[M+H]^+$ as well as nH_2SO_4 clusters (see TABLE II). The number (*n*) of clusters observed varied with the aminoglycoside. Confirmation of the effects of sulfate on the FAB mass spectra of aminoglycosides was demonstrated by using tobramycin, a non-sulfate, and adding H_2SO_4 to the matrix. Without H_2SO_4, only the $[M+H]^+$ ion was detected. With H_2SO_4, clusters containing H_2SO_4 were observed in FAB MS.

Several sugars were examined by TSMS and FAB MS including the trisaccharides raffinose and melezitose. In TSMS, behavior of the trisaccharides was simlar to the the aminoglycoside sulfates in that extensive fragmentation occurred with minor ion intensity for $[M+H]^+$. The ions indicative of $[M+NH_4]^+$ and $[M+Na]^+$ were also detected in TSMS. Comparable observations were reported by Hsu and coworkers [1]. The FAB MS analyses gave the expected $[M+H]^+$ ion and a cluster with TG, that is, $[M{\cdot}TG+H]^+$. An undefined ion was also observed at $[M+215]^+$.

In summary, the unique mass spectra of aminoglycoside sulfate antibiotics obtained by TSMS and FAB MS may be a means by which additional structural information may be asecrtained. For TSMS, the observation of fragments due to glycosidic cleavages indicated the overall molecular moiety. The FAB MS analysis suggested that the number of H_2SO_4 clusters observed for aminoglycoside sulfates may be dependent upon the aminoglycoside molecule. At this time, no definitive correlation can be made but is a point for future investigation.

CAPILLARY GAS CHROMATOGRAPHY-REACTION INTERFACE/MASS SPECTROMETRY. A HIGHLY SELECTIVE METHOD FOR THE DETECTION OF ^{13}C, ^{15}N, and ^{2}H LABELED DRUGS AND THEIR METABOLITES.

Donald H. Chace and Fred P. Abramson; Department of Pharmacology, The George Washington University Medical Center, Washington, D.C., 20037.

Markey and Abramson (1) developed a microwave-powered reaction interface that converts complex organic molecules in the presence of a reactant gas into small stable molecules which are detected by mass spectrometry (RIMS). These molecules reflect the elemental composition of the original analyte. The combination of a reaction interface and a mass spectrometer produces an element- or nuclide- selective detector for samples which are flowing from a capillary gas chromatograph (GC-RIMS).

In the presence of SO_2, $^{12}CO_2$ at m/z 44 and $^{13}CO_2$ at m/z 45 were produced from carbon atoms contained in the original analyte while ^{14}NO at m/z 30 and ^{15}NO at m/z 31 were produced from nitrogen atoms. These products were detected using a medium resolution Dupont 491 mass spectrometer equipped with a Trek Model 667 power supply. The data were acquired using a Teknivent data system. Using H_2 as the reactant gas rather than SO_2, HD at m/z 3.022 was produced from deuterium atoms which were present in the analyte. This product was detected using a higher resolution Dupont 492 mass spectrometer which was also equipped with the Trek power supply and Teknivent data system. HD was detected at a resolution of 2000.

Following the administration of 50 mg of either 2,4,5-(^{13}C)-, 1,3-(^{15}N)2-(^{13}C)-, or 10(D)-phenytoin (PT) to a male beagle dog, each urine sample was analyzed for its ^{13}C, ^{15}N, or deuterium content by GC-RIMS. The urine was hydrolyzed using enzyme isolated from Helix Pomatia, purified with XAD-2 resin, and derivatized first by extractive ethylation using tetrabutyl ammonium hydroxide and 1:3 ethyl iodide:methylene chloride. This was followed by acylation using trifluroacetylimidazole. The internal standard (I.S.) was either 1,3-(^{15}N)2-(^{13}C)-phenobarbital or 5(D)-primidone which was added to the urine at a concentration between 250 - 500 ng/mL.

M/Z 44, measuring $^{12}CO_2$, is a nonselective detection channel of ^{12}C. The chromatogram for a processed urine sample from a dog administered 2,4,5-(^{13}C)-PT is shown in Figure 1. More than 100 peaks were detected. ^{13}C was detected at M/Z 45 . Because the natural abundance of $^{13}CO_2$ and $^{12}C^{17}O^{16}O$ at M/Z 45 is 0.01182%, the M/Z 45 chromatogram was also nonselective as shown in Figure 2. By subtracting the natural abundance contribution of CO_2 at m/z 45, a net enrichment chromatogram at M/Z 45 is produced. The following equation was used for this computation.

Net M/Z 45 = Gross M/Z 45 - [0.01182% * M/Z 44]

The results are shown in Figure 3. Only ^{13}C-enriched I.S., PT and PT metabolites were detected. The detection limits were in the low nanogram per mL range which represented less than 1% of the metabolites present in the selective chromatogram. Approximately 10 metabolites were detectable. To demonstrate that all the peaks were metabolites of PT, a urine sample which was collected 24 hours prior to drug administration was also processed. The I.S. was added to this urine. The results are shown in Figure 4. No peaks other than the internal standard were detected. (M/Z 44 "Out of Range" indicates that the signal height for this peak at m/z 44 saturated the data system so that the net M/Z 45 equation is not accurate).

In a repeat analysis with the reaction interface turned off, the EI mass spectra of peaks shown by RIMS to be enriched permitted the identification of phenytoin and at least four of the approximately 10 detected metabolites. These have been identified as meta- and para-hydroxyphenytoin, the catechol, and the O-methyl catechol forms of phenytoin.

Similar metabolic profiles for ^{15}N and D-enriched PT were found. The detection of ^{15}N and deuterium by RIMS was as selective and sensitive as for ^{13}C. All three methods were linear and reproducible.

Praziquantel (PZQ) is used to treat the parasitic disease schistomiasis. Because schistosomiasis affects the liver, the question being addressed was whether the metabolism of PZQ is altered during this disease. In order to answer this, an assay for PZQ and its metabolites had to be developed. We found that tandem mass spectrometry (MS/MS) was particularly useful in evaluating the structures of PZQ metabolites and changes in their concentration in the urine of the control and infected mice which were the test animals.

EXPERIMENTAL. Groups of control and schistosome-infected CD-1 mice were given 200 mg/kg i.p. injections of PZQ and 24 h urine specimens were collected. Twenty-five ml portions were lyophilized, redissolved in 1 ml of acetate buffer, and enzymatically deconjugated. This mixture was next purified on an Amberlite XAD-4 column which was rinsed with 4 ml of water and eluted with 15 ml of a 1:1 mixture of acetone and methanol. This was dried and reconstituted in 2 ml of the acetone:methanol mixture. The mass spectrometry experiments used a Finnigan Model 3500 triple quadrupole. Two μl of the urine extract was introduced via the direct introduction probe which was heated ballistically from 30 to 450 °C. Positive chemical ionization with methane was used. The collision gas was argon and the collision energy was 20.8 eV.

QUALITATIVE ANALYSIS. The CAD spectrum of the quasimolecular ion of PZQ showed major fragments which represented structurally useful information. One fragment, m/Z 203, represented three of its four rings (the ABC ring fragment), and another, m/Z 83, represented the fourth, a cyclohexyl ring (ring D). We assumed that hydroxylations to any of the four rings would be appropriately recognized by shifts in the masses of these two complementary portions of the molecule. No authentic sample of any metabolite was available so that certain assumptions were made in order to tentatively interpret the spectra. If a hydroxylation occurred on an aromatic ring, it would not dehydrate, while if hydroxylation occurred on an aliphatic carbon it would always dehydrate. Thus, three masses might appear for the ABC ring fragment: m/Z 219 if the OH was in a stable position, m/Z 201 if the OH was unstable and dehydrated, and m/Z 203 if the OH was on the D ring which leaves the ABC group intact. A similar interpretation for dihydroxylated ABC fragments can be developed. By setting the first quadrupole to pass molecular ions of PZQ (m/Z 313), monohydroxyPZQ (m/Z 329), dihydroxyPZQ (m/Z 345), etc., and examining the ABC ring components of the daughter spectra, we were able to tentatively identify 3 monohydroxy- (M1-M3) and 6 dihydroxyPZQ metabolites (D1-D6) from these urine extracts.

QUANTITATIVE. Although the qualitative interpretation scheme was only tentative, the spectra could be quantified in order to examine differences between control and infected mice. To do this, urine samples from 9 groups of control and infected mice were analyzed for intact PZQ, the 3 monohydroxyPZQ metabolites and the 6 dihydroxyPZQ metabolites. PZQ was also analyzed by gas chromatography using nitrogen-selective detection where its area was compared to the total area of the chromatogram. For unchanged PZQ, three different MS/MS quantitation schemes were used: method A used the total ion current from m/Z 313 and its daughter ions compared to the sum of the parent and daughter ions of PZQ metabolites, method B compared only the parent ion intensities, and method C compared only the daughter ion intensities. The results are expressed as the percent of total signal representing PZQ along with the SEM (N = 9). In all cases, there was a significant increase in unmetabolized PZQ in the infected animals.

METHOD	CONTROL MICE	INFECTED MICE
GC	3.9 ± 0.6%	7.8 ± 1.8%
A	1.7 ± 0.2%	2.6 ± 0.2%
B	8.3 ± 0.7%	10.5 ± 0.7%
C	1.0 ± 0.1%	1.7 ± 0.2%

Although the three MS/MS methods gave different values, their precision was comparable to the GC method.

The quantitation of the metabolic pattern of PZQ was accomplished by normalizing each level of hydroxylation to 100% These percentages ± SEM (N = 9) from control mice are reported below.

METABOLITE	RELATIVE AMOUNT	METABOLITE	RELATIVE AMOUNT
M1	1.7 ± 0.1%	D1	8.8 ± 0.7%
M2	16 ± 0.7%	D2	11.3 ± 0.6%
M3	82 ± 0.8%	D3	2.8 ± 0.1%
		D4	6.4 ± 0.2%
		D5	58 ± 1.0%
		D6	13 ± 0.7%

Again, although the accuracy of these data is uncertain, the precision is good implying that MS/MS could be used successfully for quantitative analyses of this type if authentic materials were available as standards.

CONCLUSIONS. The reproducibility of MS/MS for quantitative analysis of metabolic patterns from "real" biological specimens appears good by using structure-defining fragmentations. In this way, an increase in the excretion of PZQ, and alterations in metabolites D2, D3, and D6 were observed in infected animals (data not shown). Thus schistosomiasis affects the metabolism of praziquantel.

FRAGMENTATION AND TANDEM MASS SPECTROMETRY OF PENICILLINS

SOMCHAI SUWANRUMPHA AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TEXAS 77204-5641

We have studied ampicillin and its fragment ions using several mass spectrometric techniques. Isobutane chemical ionization (CI) and thermospray ionization (TI) mass spectra of ampicillin (MW 349) exhibit abundant ions at *m/z* 160 and *m/z* 191, and low abundances of the protonated molecule at *m/z* 350 (Figs. 1 & 2). The ions at *m/z* 160 and *m/z* 191 correspond to cleavage of the β-lactam ring. Siegel et al. have reported a similar thermospray mass spectrum.[1] The fragmentation of ampicillin has been discussed.[1] A fast-atom bombardment (FAB) mass spectrum of ampicillin from a glycerol matrix (Fig. 3) shows an abundant protonated molecule at *m/z* 350 and an abundant ion at *m/z* 160. The ion at *m/z* 192 was observed to be more abundant than the ion *m/z* 191. The FAB mass spectrum is similar to that reported in the literature.[2] Collision-induced dissociation (CID) spectra were acquired using a tandem, hybrid (EBQQ) mass spectrometer. Protonated ampicillin (*m/z* 350) fragmented to yield an ion at *m/z* 192, but an ion at *m/z* 191 was not observed (Fig. 4).

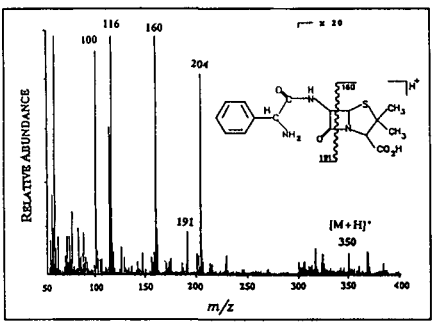

Figure 1. Isobutane CI mass spectrum of ampicillin (MW 349).

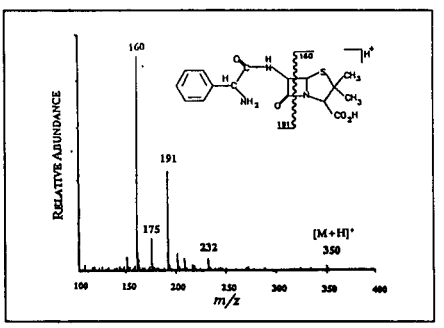

Figure 2. Thermospray ionization mass spectrum of ampicillin (MW 349).

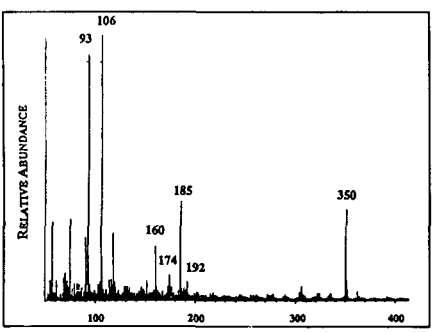

Figure 3. FAB mass spectrum of ampicillin (MW 349).

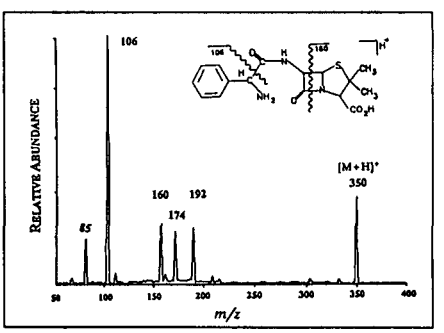

Figure 4. Collision-induced dissociation of protonated ampicillin (*m/z* 350).

The mechanism for forming *m/z* 191 versus *m/z* 192 is elucidated by inspecting the CID spectra of ampicillin, amoxicillin (a substituted analog of ampicillin), ampicillin piperazine-2,5-dione (an ampicillin metabolite), and amoxicillin piperazine-2,5-dione. The CID spectra of *m/z* 192 from ampicillin and of *m/z* 191 from ampicillin piperazine-2,5-dione are comparable except the corresponding fragment ions lie one mass unit apart (Figs 5 & 6). This suggests that the structure of *m/z* 192 from ampicillin is similar to the structure of *m/z* 191 from ampicillin piperazine-2,5-dione. The unit mass difference corresponds to the substitution of an -O- for an -NH- group. A postulated mechanism for forming the ion at *m/z* 192 is

shown in Fig. 7. The mechanism involves losing NH_3 at the amino side chain, an oxygen rearrangement, and a 2+2 cycloreversion to cleave the β-lactam ring. This results in a fragment analogous to the *m/z* 191 fragment from ampicillin piperazine-2,5-dione. The proposed loss of NH_3 in the first step is supported by the CID spectrum of *m/z* 349 from amoxicillin, which corresponds to the loss of NH_3 from protonated amoxicillin (MW 365). The CID spectrum shows the formation of a fragment ion at *m/z* 208 (Fig. 8). The ion at *m/z* 208 from amoxicillin is analogous to ion at *m/z* 192 from ampicillin.

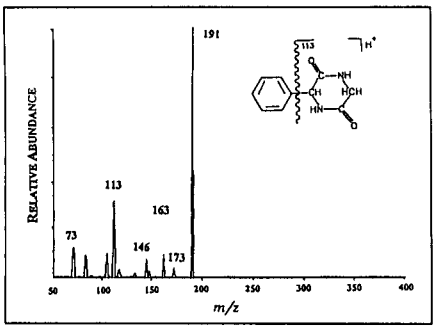

Figure 5. Collision-induced dissociation of *m/z* 192 from ampicillin.

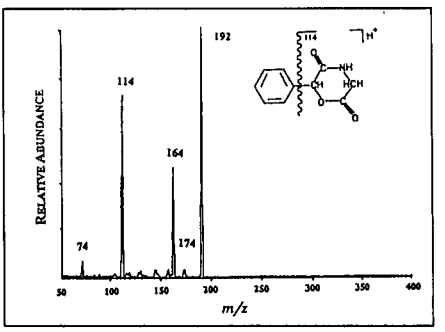

Figure 6. Collision-induced dissociation of *m/z* 191 from ampicillin piperazine-2,5-dione.

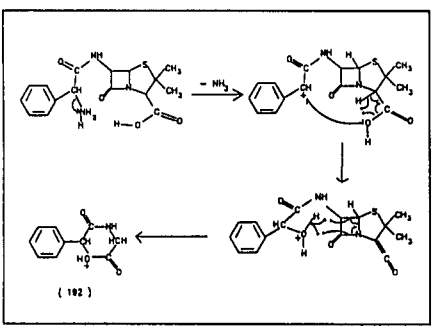

Figure 7. Postulated mechanism to form *m/z* 192 from ampicillin.

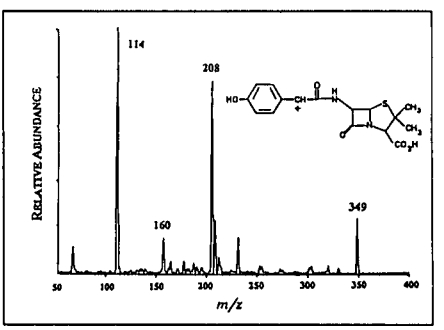

Figure 8. Collision-induced dissociation of *m/z* 349 from amoxicillin.

The formation of *m/z* 191 in the thermospray and CI mass spectra is postulated to arise from a gas-phase protonation of the neutral product (at 190 u) of the β-lactam ring cleavage. The FAB mass spectrum of ampicillin shows substantially less abundant *m/z* 191. This is because gas-phase ion/molecule reactions are less likely occur in the FAB ion source than they are in the CI and TI ion sources due to lower ion source pressures. The importance and usefulness of identifying fragmentations can be used in the determination of penicillins and their metabolites from biological fluids.

DETERMINATION OF DIETHYLSTILBESTROL AND DIENESTROL IN CHICKEN BY GC AND SELECTED ION MONITORING

Yang Yinghua and Liu Li
Jilin Import and Export Commodity Inspection Bureau,
81 Stalin Street, Changchun, China.

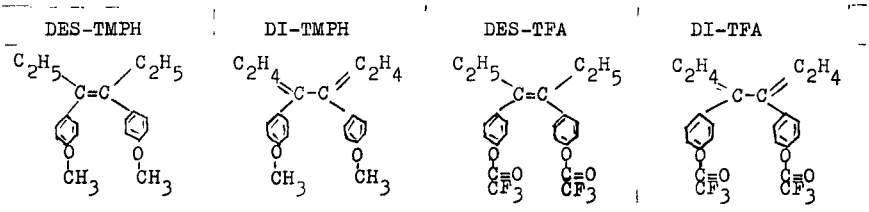
Diethylstilbestrol(DES) and dienestrol(DI) are synthetic estrogen,and used as growth promoters in meat-producing animals and fowl. Because of the carcinogenic potential of DES and DI, any residue of it in food is not allowed, and it is necessary to determine DES and DI in chicken for export. DES and DI have been determined by GC and HPLC, but only few reports using MS for the determination. The method described here for the determination of DES and DI is based on the combination of GC and selected ion monitoring technique. This method provides high sensitivity and high specificity.

The recoveries of DES and DI added into chicken samples in different concentration were examined and the detection limits determined. The results obtained from two kinds of derivatives of DES and DI were compared and dicussed

All experiments were carried out on a JMS-D_{300} Mass Spectrometer.
GC: glass column, 2M×2.5mm packed with 3% OV-17, carrier gas, He.
MS: electron impact source; resolution 500; ion source temperature, 220°C;ionization current,300μA; ionization voltage, 70V.

1, Sample treatment: Homogenize 5g chicken sample in 250ml glass stoppered flask, add 3-5ml 10% Na_2CO_3, shake for 2min. add 20ml toluene and shake vigorously for another 5min. 1) TMPH derivative: transfer 2ml clear upper layer toluene into a conical centrifuge tube, add 30μl TMPH shake vigorously by hand for 1min. centrifuge for 2min, and TMPH phase is ready to be determined. 2) TFA derivative: transfer 2ml clear upper layer toluene into a conical centrifuge tube, evaporate it in a gentle N_2 stream at room temperature till it is day. Then add 30μl 1:1 (ethyl acetate:TFA) and TFA phase is ready for determination.

2, Mass spectrum: Mass spectra of DES and DI(two kinds of derivatives) were determined with standard solutions. EI mass spectrum of the derivatives of DES and DI and their structure, major ions, relative intensities are shown in table 1:



compound	MW.	major ions and relative intensity
DES-TMPH	296	296(1oo),281(18),267(37),159(57),121(84),135(27),91(26).
DI -TMPH	294	294(1oo),279(66),265(31),263(27),241(26),128(3o),115(35).
DES-TFA	46o	46o(1oo),431(43),317(24),241(96),217(23),2o3(71),115(38).
DI -TFA	458	458(1oo),345(64),241(28),217(31),215(31),2o3(27),115(52).

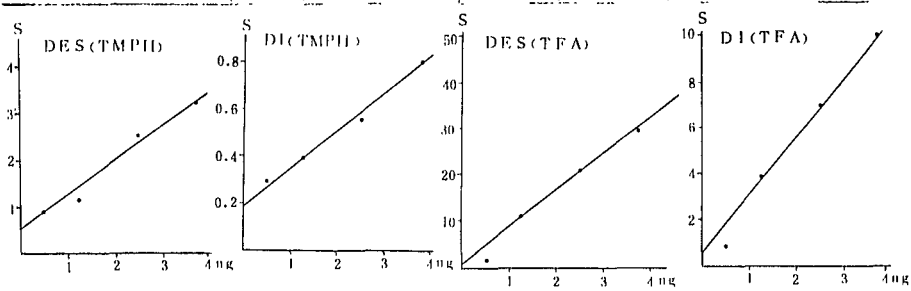
3, According to EI Mass spectra, the base peaks M/Z296,M/Z294,M/Z46o, M/Z458 were chosen as monitoring selected ion respectively. Then recoveries of different spiked chicken samples were determined.Recoveries of the derivatives added into the chicken samples are shown in table 2:

added(ng)	recovery %		added(ng)	recovery %	
	DES-TMPH	DI-TMPH		DES-TFA	DI-TFA
15	85.3	74.9	3o	68.8	9o.4
5	83.2	74.3	15	68.3	88.6

For TMPH derivative the recovery of DES is higher than that of DI; while for TFA derivative the recovery of DES is lower than that of DI.

4, The standard curves obtained are shown in table 3 and figure1-4:

added(ng)	DES-TMPH	DI-TMPH	DES-TFA	DI-TFA
3.75	3.13	o.82	29.74	1o.12
2.5o	2.56	o.56	21.14	6.98
1.25	1.14	o.39	1o.97	3.96
o.5o	o.85	o.29	1.52	o.92



It is shown the standard curve had a good linear relationship from o.5ng-3.75ng of DES-TMPH,DI-TMPH,DES-TFA and DI-TFA. The method has been used to analyse practical samples. Determination of DES and DI residues in actual five chicken samples were all shown a negative result.

Under the experimental conditions above mentioned the detection limit of the method for either species is shown to be o.5ng. It is suitable for determination of trace DES and DI in chicken samples. We have successfully determined trace methyl-alcohol and higher alcohols in beverage by this method.

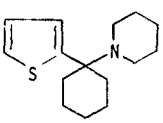
The Identification of Products Cosynthesized In the Preparation of Thienylcyclohexylpiperidine (TCP).

Louis A. Jones, M.K. Lee, Department of Chemistry, and
C.A. Haney, GC/MS Facility
North Carolina State University, Raleigh, NC 27695-8204

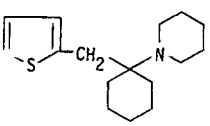
The thienyl analogue of the Schedule I abused drug Phencyclidine (PCP) is prepared by the addition of 2-thienylmagnesium bromide in ether to 1-piperidylcyclohexyl carbonitrile.[1] Using the reversed-phase ion pair chromatographic system developed for PCP[2], at least 10 other cosynthetic compounds in addition to the major product 1-(2-thienyl-cyclohexyl)-piperidine (TCP) were indicated. In the case of PCP, three of the thirteen PCP cosynthetics have been chromatographically isolated, identified (^{1}H NMR and mass spectrum), and synthesized. They are 1-[1-(phenylethyl)cyclohexyl]piperidine, 1-[1-(1,1'-biphenyl-4-yl)cyclohexyl]piperidine, and 1,1'-(1,4-phenylenedicyclohexylidene)bis[piperidine].[3]

The objective of the research reported herein is to determine if analogous cosynthetics are formed in the TCP preparation. Both TCP[4] and PCP[5] are difficult to analyze by GC/MS because of the numerous thermal decomposition products which occur with injection port temperatures over 180°C. As we had done in our PCP GC/MS investigations,[5] the conditions necessary to reduce this decomposition utilizing capillary column GC/MS were studied. Where cosynthetics from the crude TCP mixture were suggested by GC/MS results, they were synthesized and identified by comparison of GC retention times and mass fragmentation patterns.

Mass chromatograms were obtained with an injection port temperature of 175°C and separation was achieved with a 15m DB-5 column by temperature programming from 50°C (2 minute hold) to 250°C at 5°C/minute with a helium flow of ca. 1 mL/min. Identified in the crude TCP mixture were 1-piperidylcyclohexane, 1-piperidylcyclohexene, 1-piperidyl-1-cyclohexylcarbonitrile (PCC), TCP, 1-(2-thienylmethyl)cyclohexylpiperidine (methyl-TCP),



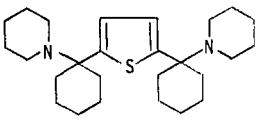
TCP



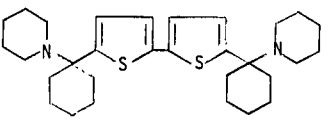
Methyl-TCP

and 1,1'-(2,5-thienylenedecyclohexylidene)bis[piperidine] (bis-TCP). The latter two compounds were confirmed by independent synthesis and GC/MS comparison.

Bis-TCP was found to be thermally stable under direct probe conditions but decomposed under all GC/MS conditions with both processes resulting in characteristic fragmentation patterns suitable for positive identification. Mass spectral evidence suggested that synthetic bis-TCP also contained the compound di-TCP which was not found in the crude TCP mixture. No analogous compound has been found in the PCP preparation.



bis-TCP



di-TCP

Methyl-TCP decomposes with injection port temperatures in excess of 200°C while 1-piperidylcyclohexene thermally derives from unreacted PCC. This latter decomposition occurs only partially at injection port temperatures of 175°C but increases with increasing injection temperatures.

Interestingly, the 1-piperidylcyclohexane is not observed in the analysis of synthetic bis-TCP, or methyl-TCP or PCC. It is concluded that it is therefore a cosynthetic product of the TCP synthesis but not a PCP cosynthetic. Its synthetic origin is as yet unknown.

DIRECT ANALYSIS OF CONTAMINATED PHARMACEUTICAL PREPARATIONS BY LC/MS/MS

IDENTIFICATION OF SUCCINYL CHOLINE IN CONTAMINATED DEXAMETHASONE

Thomas Covey, Sciex Inc., 55 Glencameron Road, Thornhill, Ontario, Canada L3T 1P2

George Maylin, Richard Eckerlin, Edgar Lee, Per Olof Edlund, and Jack Henion, Equine Drug Testing and Toxicology, New York State College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Contaminated pharmaceuticals are encountered in spite of extensive quality control programs at drug manufacturing and packaging facilities. Accidental and malicious contamination of human medicaments have been discovered at the National level over the past few years.

We herein describe a situation where a grossly contaminated vial of dexamethasone, causing the death of three veterinary patients, was rigorously analyzed by many standard methods to no avail. We further describe the methodologies that arrived at the proper diagnosis of the problem. The analytical technique employed was LC/MS and LC/MS/MS using a Sciex TAGA 6000E MS/MS instrument equipped with the standard atmospheric pressure ion source (API) and an ion spray LC/MS interface.

SAMPLE HISTORY

A bottle of generic dexamethasone was used in a clinically acceptable manner by a veterinary practitioner. However, after the loss of three canine patients the formulation became suspect. Within 20 minutes of administration, total physiological collapse and death resulted.

The submitted suspect vial was subjected to extensive chemical analyses including TLC, cyanide testing, inorganic testing with x-ray fluorescence and ICP emission spectroscopy, HPLC with diode array detection, radioimmunoassay for narcotics, endotoxin analysis, and GC/MS. No differences between the toxic suspect vial and a standard vial of injectable dexamethasone could be observed.

METHODS

The injectable material was 50% by weight polypropylene glycol which was used as a carrier. Because no chemical information was available about the toxin no attempt was made to pre-fractionate the sample before HPLC analysis. The viscous sample was injected directly into the LC/MS/MS system.

A 2.1 mm x 10 cm Spherisorb-NH_2 column was used with a 20 minute gradient from 100% methanol to 100% water, simulating normal-phase conditions. A previous analysis utilizing a C_{18} column with a 100% water to 100% methanol reversed-phase gradient system resolved no suspect peaks. The mass spectrometer used was a Sciex TAGA 6000E triple quadrupole mass spectrometer equipped with a standard atmospheric pressure ion source and an ion spray LC/MS interface. The flow rate was 200 uL/min split to introduce 50 uL/minute into the source.

RESULTS

A peak was observed in the chromatogram having only m/z 145 in the mass spectrum. Profiling m/z 145 revealed it to be a doubly charged ion (isotope peaks 0.5 amu spaced) identifying the molecular ion of the suspect compound to be 290 (Figure 1). MS/MS of m/z 290 further verified the doubly charged nature of the compound showing singly charged daughter ions at m/z greater than that of the parent ion at m/z 145 (Figure 2).

Adjustments to the pH of the chromatographic eluant (pH 2-8) produced no shift in the mass spectrum toward the singly charged species (m/z 290). The observation that the functional groups responsible for the positive charges on the molecule could not be titrated suggested that the suspect material was a diquaternary amine having a permanent charge in solution regardless of pH. This hypothesis was derived from knowledge of the mechanism of ion evaporation, which is the means by which the ion spray interface produces gas phase ions (1). Ionic species in solution are directly desorbed to the gas phase as a result of high localized electric fields surrounding the nebulized droplets. Adjustments to the eluent pH will result in changes to the charged state of molecules in solution, and this will be observed in the spectra. Quaternary amines are permanently charged and thus do not respond to pH adjustment. Succinyl choline was the only diquaternary amine compound of molecular weight 290 listed in several molecular weight indices of organic compounds. Analysis of standard succinyl choline gave the same daughter ion spectra and retention time as the suspect compound. Administration of succinyl choline to test animals gave physiological reactions identical to the

contaminated dexamethasone vial.

CONCLUSIONS

Succinyl choline was identified to be the toxic substance in a veterinary formulation of dexamethasone. After employing several analytical methodologies to no avail, ion spray LC/MS/MS finally cracked the case. Investigations are underway to determine the source of the contamination, possibilities being contamination during pharmaceutical preparation, cross contamination by the professionals using the vial, or by sabotage.

STUDIES OF ANABOLIC STEROIDS BY THERMABEAM LC/MS

Matt J. Dilts, Edward W. Sheehan and Ross C. Willoughby
Extrel Corporation, Pittsburgh, PA 15238

INTRODUCTION

Steroids as a class of structurally complex molecules pose a special challenge to the analytical chemist. The mass spectral characterization of free steroids has been dominated by gas chromatography/mass spectroscopy (GC/MS) with both electron (EI) and chemical impact (CI) ionization. Less volatile steroids and steroid conjugates are thermally labile molecules which have been characterized by using other techniques: derivatization to more volatile compounds, DCI, FAB, FD, SIMS and thermospray LC/MS(1,2).

This prompted us to investigate the possibility of using ThermaBeam LC/MS in the analysis of anabolic steroids. Our objectives of this study were to demonstrate (i) the generation of library searchable EI spectra with minimal pyrolysis fragments, (ii) CI spectra, (iii) obviating the derivatization step necessary with GC/MS, (iv) linearity and uniform response over a wide concentration range under SIM (5-50ppm) and full scan conditions (10-50ppm), (v) and the applicability of this technique for clinical and forensic studies by analyzing an injectable form of testosterone propionate.

EXPERIMENTAL

All work described was performed on an EXTREL 400-1 differentially pumped mass spectrometer equipped with EI/CI switchable source interfaced with the liquid chromatography system by means of the ThermaBeam LC/MS interface. The chemical ionization reagent gas was methane. Data was acquired under full scan conditions from 80 to 450 AMU at 100 AMU/sec; or by monitoring the molecular ion of the individual components for the SIM experiments.

The chromatographic system consisted of a Waters Model 600 solvent delivery system equipped with a Model 490 UV detector. The column used was a 2 mm i.d. x 250 mm C-18 reverse phase (Solvent Miser, Alltech) with a precolumn packed with the same material. A gradient elution program using acetonitrile and water as the solvent system was used (Table I) with a flow rate of 0.25ml/min.

Testosterone (TEST), 17-methyltestosterone (METH-TEST), testosterone propionate (TEST-PRO) and testosterone cypionate (TEST-CYP) were chosen as prototypical compounds. Five to fifty ppm solutions were prepared in acetonitrile and analyzed. An injectable form of testosterone propionate (100mg/ml, in sesame oil) was chosen as a real life sample. A working solution of 15ppm was prepared and analyzed the same as the above standards.

RESULTS AND DISCUSSION

The total ion current chromatograph and UV tracing (254nm) of 50ppm each of the above steroids are shown in Figure 1. The peaks eluted in the following order: TEST, METH-TEST, TEST-PRO, and TEST-CYP.

Figure 2A shows the uniform and linear response over the range, 10-50ppm that was obtained. Upon analyzing TEST-PRO in sesame oil, we obtained a reading of 13.8ppm (92%) present in the 15ppm working solution. A comparison plot of sample and TEST-PRO standard is shown in Figure 2B. The EI spectrum shows the presence of the molecular ion (m/z 344) plus the loss of the propionic acid group (M-56, m/z 288) as would be expected.

June 5-10, 1988, San Francisco, CA

CONCLUSION

Using the ThermaBeam LC/MS interface, we did not experience decomposition during the chromatographic separation or the complicated spectra of fragment ions of less volatile steroids upon vaporization. And, in addition, we avoided the need to derivatize nonvolatile steroids to enhance their volatility.

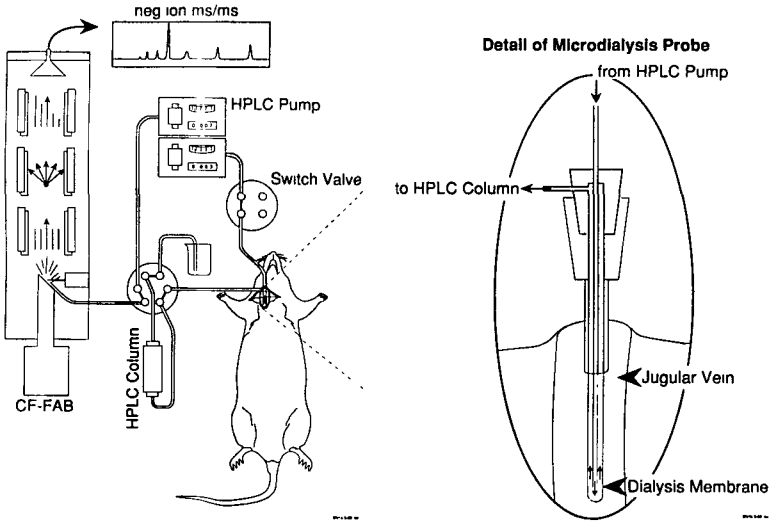
ON-LINE ANALYSIS OF DRUGS IN LIVE ANIMALS USING CF-FAB AND MICRODIALYSIS

Shen-Nan Lin and Richard M. Caprioli
The University of Texas Medical School
Houston, Texas 77030

An experimental procedure was developed to achieve pharmacokinetic analysis of drugs from single live animals. The schematic diagram of the experimental set-up is shown in Figure 1. The procedure utilizes two new techniques; continuous-flow FABMS (1) and microdialysis (2).



The drug used in this study, penicillin G, was injected intramuscularly. In order to potentiate the drug in the system, the rat was first given an intramuscular injection of probenecid. A microdialysis apparatus (BSA Inc) was inserted through a needle cannula into the jugular vein in the neck of the animal. The drug circulating in the blood dialyzed into the microdialysis probe and was carried to a small HPLC column for concentration. At a proper time interval, the drug was eluted from the column and analyzed on-line by MS/MS via a continuous-flow fast atom bombardment interface fitted to a Finnigan MAT TSQ70. In a typical experiment, the dialysate was allowed to flow through the RP-300 micro HPLC column (2x2 mm) for 5 min, then the column was subjected to a one-step wash with 50% acetonitrile, 5% glycerol, 0.7% TFA in water at a rate of 7 μL/min, and this effluent passed directly into the mass spectrometer. A complete loading and injection cycle took 9 minutes. For penicillin G the $(M-H)^-$ parent negative ion at m/z 333 was analyzed by collision activated decomposition and the daughter ion spectrum obtained by continuously scanning from m/z 100 to 350 in 2 sec.

Figure 2 compares mass spectra obtained 1h and 3.5h after penicillin G administration. The relative intensities between the m/z 192, the major ion fragment of penicillin G, and 149, that of the background at this parent mass, are markedly different. This is the result of the higher concentration of penicillin G in the 1h sample, relative to the 3.5h sample and consequent suppression of background ions to a greater extent. When the relative ratio of ion intensities of 192 and 149 was used to follow the time course of penicillin G in the blood, we found the concentration of the drug peaked at 1.7h. This is in agreement with other work (3) which has

shown that intramuscular administration of penicillin G to a human treated with probenecid was approximately 2h.

A SOLID PHASE EXTRACTION METHOD FOR GC/MS ANALYSIS OF COCAINE AND ITS MAJOR METABOLITES IN URINE

R. ESPINOSA-LENIZ, THE AMERICAN UNIVERSITY, WASHINGTON, D.C. 20016, L.R. HILPERT, M.J. WELCH AND E. WHITE V, NATIONAL BUREAU OF STANDARDS, GAITHERSBURG, MD 20899.

The routine testing for drugs of abuse in urine has increased enormously in the last few years. This activity has highlighted the need for certified reference standards for drugs of abuse and their metabolites in urine. The use of Standard Reference Materials (SRMs) improves both the accuracy and reliability of test results and will help insure the compatability of results among laboratories. The National Bureau of Standards (NBS), in cooperation with the College of American Pathologists (CAP), has initiated a program designed to issue SRMs for drugs of abuse in freeze-dried urine. An SRM for THC (marijuana) has already been issued and certification of an SRM for urinary cocaine metabolites is in process.

The present work deals with the certification of an SRM for cocaine and one of its major metabolites, benzoylecgonine, in freeze-dried urine. The development of this SRM has involved developing analytical procedures for the compounds of interest, preparing pools of urine with the compounds present at the desired concentrations, and certifying the concentrations in the SRM by two independent analytical methods: A GC/MS method using the trideuterated analogs (CD3 on the nitrogen) of the analytes as internal standard, and an HPLC method.

We have modified a solid phase extraction method described by Svenson1 for HPLC analysis of benzoylecgonine in urine to make the method suitable for GC/MS. The sample preparation is as follows: 1) spike a 5 mL urine sample with the internal standards; 2) mix the spiked urine with an equal amount of 0.5 M ammonium phosphate buffer at pH 9.3; 3) precondition a Sep-pac C18 solid phase extraction cartridge by rinsing with 3 mL of methanol followed with 5 mL of water; 4) load the cartridge with the buffered urine; 5) wash the cartridge with 10 mL of a 0.01 M NaOH solution in 20% acetonitrile/ water; 6) wash with 15 mL of a 0.01 M NaH_2PO_4 solution in 20% acetonitrile/ water at pH 2.1; 7) elute the analytes with 3 mL acetonitrile; 8) take the eluent to dryness under a gentle flow of N_2; and 9) dissolve the residue in 0.1 mL of bis(trimethylsilyl)acetamide by heating 30 min. at 60 °C.

Gas chromatography is performed on a 30m DB-5 capillary column held at 120 °C for 10 min., then heated at a rate of 30 °C/min to 300 °C which are maintained until the end of the run (25 min. total). The mass spectrometer is a quadropole instrument operated in the electron impact mode(at 70 eV with an ion source temperature of 200 °C).

The mass spectra of cocaine and the TMS derivatives of benzoylecgonine and methylecgonine show intense peaks at m/z 82 (m/z 85 for the internal standards); this means that by single ion monitoring at m/z 82 and 85, it is possible to analyze for all three compounds. The response is not linear and therefore the internal standard is spiked at a level as close as possible to the actual level of the analyte. (For the measurements used for the certification, bracketing at two different concentration levels will be used to improve accuracy).

Mass chromatograms of methylecgonine and its TMS derivative show two (and on occasions three) peaks with almost identical mass spectra, suggesting epimerization occurs under our GC conditions. Since the extent of the epimerization varies from experiment to experiment, methylecgonine will not be certified (although it will be present) in the SRM.

In the manufacturing of the SRM a pool of urine was divided into four equal volumes, one was kept as blank, and the other three were spiked at approximately at 100, 300 and 500 ng/mL each of cocaine, benzoylecgonine and methylecgonine, then freeze-dried in 10 mL aliquots.

A preliminary analysis of four aliquots for each level of cocaine and benzoylecgonine gave the following results:

Target level (ng/mL)	Actual Cocaine (ng/mL)	s.d.	Actual Benzoylecgonine (ng/mL)	s.d.
100	76	9.9%	108	7.1%
300	252	13.0%	292	7.2%
500	473	4.7%	576	2.9%

The precision of these preliminary measurements was unsatisfactory. Since the actual levels of the analytes were different from the target levels, the spiking levels of the internal standard were not as close as intended to the actual level of the analyte. These preliminary results will permit spiking the urine with the correct amount of internal standard. We plan to refine the method further to achieve satisfactory precision for the certification.

STUDIES ON THE STRUCTURE OF DIAMOND PHENOL POLYETHYLENEGLYCOL—LONG LASTING CONTRACEPTIVE BY MASS SPECTRA

YANG KAI -Qun ZHENG HU
Analysis and Testing Center, Chengdu Branch of Chinese Academy of Sciences, Chengdu, CHINA

Diamond phenol(DP) is a very good new contraceptive. But it hasn't long lasting contraception effect. In order to get long lasting contraceptive, we had synthensized diamond phenol polyethyleneglycol (DPPEG) by reaction of DP and polyethyleneglycol (PEG) . DP is a target as low-molecular part connecting PEG. The reasons are as following : 1. A small dosage of DP has been used in the clinic and its weight changes larger. Therefore DP will take obvious proportion of weight in forming new compound when it joins up with polymer. The new compound connected with polymer need not overweight much than the monomer of DP if used in clinic. 2. DPPEG is possible to change its drug metabolism kinetic behavior of DP jointed PEG. The selectivity of the complex with polymer may be increased. 3. DP is insoluble in water. If it attaches to PEG, the product becomes soluble in water.

We have researched the relation between molecular structure and mass spectra peak of the title compound. We separated the synthesis mixture into a series singl chain title compound with thin-layer chromatograph. Then we test average spectra of every component and the synthesis mixture. The quantitative results of every component in the synthesis mixture are computed by matrix method. Therefore we get the molecular weight distribution chart and component quantity of differential chain title compounds.

$DP(PEG)_n$	RELATIVE PEAK HIGH OF AVERAGE SPECTRA (%) (DCI METHOD)	DRUG EFFECT OF EVERY MEMBER
$DP(PEG)_1$	5	-
$DP(PEG)_2$	8	-
$DP(PEG)_3$	12	-
$DP(PEG)_4$	20	*
$DP(PEG)_5$	33	*
$DP(PEG)_6$	42	**
$DP(PEG)_7$	54	**
$DP(PEG)_8$	68	***
$DP(PEG)_9$	71	***
$DP(PEG)_{10}$	69	***
$DP(PEG)_{11}$	58	**
$DP(PEG)_{12}$	40	*
$DP(PEG)_{13}$	28	*
$DP(PEG)_{14}$	24	*
$DP(PEG)_{15}$	10	-

- (representation no effect);
* (representation low effect);
*** (representation high effect);

The method is built by MS which can quickly and reliably test molecular weight distribution chart of long lasting contraceptive. In order to review and control produce of a good DPPEG, we give a good criterid to long lasting contraceptive.

QUANTIFICATION OF PHYSOSTIGMINE IN PLASMA BY CAPILLARY COLUMN CHROMATOGRAPHY USING CHEMICAL IONIZATION MASS SPECTROMETRY. E.M. Jakubowski, J.R. Smith, US Army Medical Institute of Chemical Defense, Aberdeen Proving Ground, Edgewood, MD 21010-5425; and S.M. Musser, P.S. Callery, Univ of Maryland, Baltimore, MD, 21201.

A novel assay has been proposed to quantify physostigmine, a gem diamine, in human plasma by gas chromatography-mass spectrometry (GC-MS) using isobutane or ammonia chemical ionization. Previous methods ignored the possibility of using direct injection into the GC which would rely on thermal dissociation of the physostigmine salt(1-3). In this study, human plasma (1 mL) was spiked with physostigmine salicylate (0.3 to 12 nanograms free base). To the spiked samples, neostigmine bromide (500 ng/mL) and d_3-(carbamate) physostigmine salicylate (5 ng) were added. Plasma samples were then filtered through CN-solid phase cartridges that were conditioned first with 2x1 mL of methanol and then 2x1 mL of 0.2M phosphate buffer (pH 7.0). The plasma loaded cartridges were washed with 2x1 mL of water and then eluted with 0.4 mL of methanol. Evaporation of the methanol produced a final sample volume of 10 to 20 microliters. One to two microliters were injected into a Finnigan 4500 GC-MS under the following conditions: 250°C injector, 30m DB-1 column, 86°C initial oven temp., 260°C final oven temp., 40°C/min program temp. rate, 1mL/min helium carrier flow rate, and 0.25-1.00 Torr isobutane or ammonia reagent gas pressure. Selected ion monitoring was used to quantify the physostigmine by collecting ion current data on the m/z 276 ion of physostigmine (MH^+) and the m/z 279 ion of the internal standard. In addition, the m/z 219 ion (M-carbamate+H^+) was monitored to ensure correct peak identification. In order to prolong the lifetime of the injector port glass insert a small amount of silanized glass wool was placed into the insert. Figure 1 shows a physostigmine calibration curve generated without the use of an internal standard. Concentrations of methanol solutions ranged from 0.25 to 2 ng of the salicylate salt. Linear regression of this data produced a line with a correlation coefficient of 0.999. Results of the simple methanol matrix confirm the analytical usefulness of thermal dissociation of this amine salt in the injector. Linear calibration curves (r=0.995) were produced by the internal standard method for human plasma spiked in the range of 0.3 to 12ng physostigmine free base (FIG 2). Isobutane was used for the plasma work instead of ammonia. Ammonia provided a factor of 1.5 greater sensitivity, however MS conditions were difficult to control. Methane as a reagent gas caused too much breakdown of the carbamate as compared to isobutane or ammonia. Since the internal standard was located on the carbamate only the ions related to the intact drug could be used for quantification. One of the most important elements of this assay was to control the injector port temperature. Table 1 illustrates the change in signal intensity as the temperature is varied. Besides maximizing the analyte peak area the area of the breakdown product, eseroline, should be considered. Eseroline represents the loss of the carbamate group from physostigmine which can occur in the hot injector. Figure 3 shows a TIC of an injection of physostigmine were the injector temperature was 300°C. The first peak represents eseroline as confirmed by its EI spectrum and the second peak is physostigmine. Figure 3 also shows the spectrum of physostigmine. Above 260°C the efficiency of the thermal dissociation does not increase but degradation to eseroline does increase. Other amine salts demonstrate similar injector port characteristics with respect to thermal dissociation(4). Therefore, the optimum injector temperature was between 260 to 270°C.

MASS FRAGMENTATION OF ISOQUINOLONES AN UTILITY TO CHARACTERIZE THALICTRUM ALKALOIDS

Ahmed M. Galal, Youssef Aly, Paul L. Schiff, Jr., Lan K. Wong and Emil W. Fu
Dept. of Pharmaceutical Sciences, University of Pittsburgh, School of Pharmacy, Pittsburgh, PA 15261; Sandoz Research Institute, East Hanover, NJ 07936

The mass spectral fragmentation patterns of two synthetic samples of isoquinolones, namely, 1-oxo-2-methyl-5-methoxy-6,7-methylenedioxy-1,2,3,4-tetrahydroisoquinoline (1) and 1-oxo-2-methyl-5,6-methylenedioxy-7-methoxy-1,2,3,4-tetrahydroisoquinoline (2) were elucidated in order to characterize fragment ions which can provide unambiguous assignments of the positions of the methylenedioxy and the methoxy groups. This information is of great utility to clarify the location of the methylenedioxy and the methoxy substituents at the 5, 6 and 7 positions of many Thalictrum alkaloids by oxidizing the alkaloids, such as thalmelatidine (3), to the aforementioned isoquinolones.

The isoquinolone (1) was synthesized according to the scheme shown. The formylation of 1-methoxy-2,3-methylenedioxybenzene by DMF in the third step of the the reaction sequence yielded two isomeric aldehydes, namely, 2-methoxy-3,4-methylenedioxybenzaldehyde indicated in the scheme, and 2,3-methylenedioxy-4-methoxybenzaldehyde (not shown). The two isomeric aldehydes were separated by flash column chromatography. The latter one was used to prepare the isoquinolone (2) by an analogous synthetic sequence. Mass spectra were obtained on a Finnigan-MAT 4600 mass spectrometer with a Superincos data system. The instrument was operated in the electron ionization mode with an electron energy of 70 eV and a source temperature of 110 C.

Both isoquinolones (1) and (2) show prominent M^+ and very intense fragment ions at m/z 192 and 164 in their EI mass spectra. Most spectral features are similar except compound (1) exhibits a significant ion 4 at m/z 134 (about 25%) while the corresponding ions 5 for compound (2) is relatively weak (less than 5%). The higher intensity of 4 is attributed to the greater stability of this ion. Thus by noting the intensity of this ion, it is possible to characterize the isoquinolone products from the oxidation ($KMnO_4$ in acetone) of many Thalictrum alkaloids and definitively assign the methoxy and methylenedioxy substituents at the 5, 6, and 7 position.

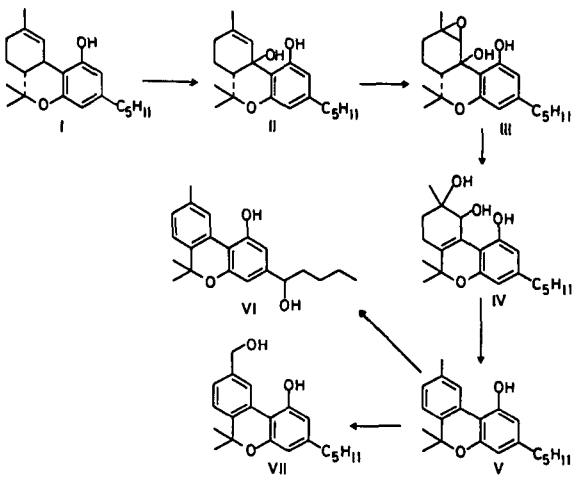
IDENTIFICATION OF DECOMPOSITION PRODUCTS OF DELTA-9-TETRAHYDROCANNABINOL BY GC/MS.

D.J. Harvey and N.K. Brown,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Delta-9-tetrahydrocannabinol (delta-9-THC, I), the major psychoactive constituent of marihuana, decomposes over a period of several months to cannabinol (CBN, V). Studies, predominantly by Turner et al. using mass spectrometry (1), have resulted in the proposed decomposition pathway shown below.



Although the dihydroxy-delta-10a-THCs (cannabitriols) of type IV have been well characterized, the intermediate 10a-hydroxy-THC (II) and its 9,10-epoxide (III) have not been reported. We have investigated several aged samples of cannabis, both dry and ethanolic extracts, and decomposition products resulting from biochemical experiments and have observed several other decomposition products including compounds II and III.

The aged samples were an ethanolic extract dating from about 1840 and three dry samples of plant tops dating from the turn of the century. TMS derivatives were prepared from all three samples. Liver and lung microsomes were obtained from mice, rats and guinea pigs and incubated with delta-9-THC and its [10a-^{2}H]- and [1',1',2',2'-$^2H_4$]-analogues. Products were extracted with ethyl acetate, concentrated by chromatography on Sephadex LH-20 and examined as TMS and [$^2H_9$]TMS derivatives. GC/MS on all of the samples was performed using VG 12B (2m x 2 mm SE-30 packed column) and 70/70F (25 m x 0.2 mm OV-1 fused silica capillary column) mass spectrometers and a VG 11/250 data system.

Details of the analysis of the ethanolic sample have been reported (2). The gas chromatogram (TMS derivative) is shown in Fig. 1. Major constituents were CBN and the cannabitriols of type IV. The dried samples showed a different profile (Fig. 2). CBN was again the major component but the cannabitriols were not observed. However additional oxidation of CBN had occurred to give 1- (VI) and 11-hydroxy-CBN (VII). These compounds have not been observed as decomposition products before although they are known as metabolites. Decomposition products from the microsomal incubations (Fig. 3) contained several novel compounds in addition to CBN and cannabitriol. 10a-Hydroxy-delta-9-THC was identified as a decomposition product by its formation in both normal and boiled microsomal mixtures. Incubations with [1',1',2',2'-$^2H_9$]delta-9-THC and the observation of a 4 mass unit shift in the mass of the molecular ion verified the formation of the compound from THC. Its structure was confirmed by the loss of the deuterium from the 10a-position of [10a-^{2}H]-delta-9-THC. The spectrum of its $^2H_9$TMS derivative indicated formation of the base peak at m/z 459 ([M - CH_3]$^+$ by loss of a gem methyl group following charge localization at the 10a-substituent.

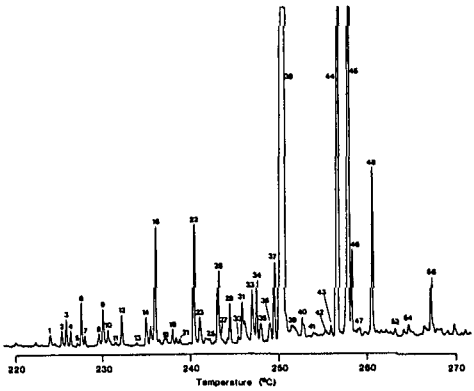


Fig. 1. Gas chromatogram of cannabinoids from a sample of cannabis tincture dating from about 1840. Peak 38 is CBN, peaks 44 and 45 are cannabitriols

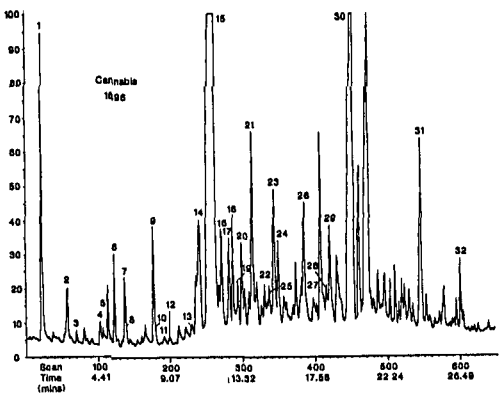

Fig. 2. Gas chromatogram of cannabinoids from a sample of cannabis from 1896. Peak 21 is CBN, peaks 21 and 29 are the 1'- and 11-hydroxy derivatives.

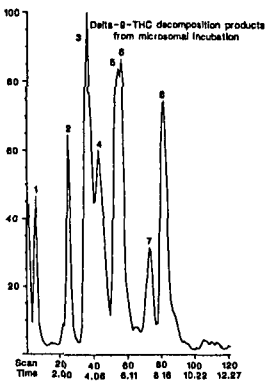

Fig. 3. Ion chromatogram of THC decomposition products from a microsomal incubation. Peak 3 is CBN, peaks 4 and 5 are hydroxyepoxides, peak 8 is 10a-OH-THC.

Several compounds having masses of 490 (TMS derivatives) were present. These compounds all had two TMS groups indicating that hydroxylation of the THC had occurred. The mass increment of mass units indicated the presence of an additional oxygen atom. No reaction with TMS reagents was observed under forcing conditions showing that this was not another hydroxy group and reaction with lithium aluminium deuteride confirmed the presence of an epoxide. This reaction produced cannabitriol demonstrating the presence of a 9,10-epoxide.

These observations confirm the reaction scheme proposed by Turner et al. for CBN formation from delta-9-THC and demonstrate that samples exposed to the air are capable of further hydroxylation CBNs.

Quantification of Pyridostigmine in Plasma by Packed Capillary HPLC/FAB-MS/MS: Preliminary Results

Mark R. Bauer and Mark F. Yancey

Battelle Columbus Division, Columbus, Ohio 43201

Pyridostigmine is a cholinesterase inhibitor used in the treatment of myasthenia gravis, a neuromuscular function disorder. Pretreatment with pyridostigmine, in combination with atropine and an oxime, is also being investigated as an antidote for organophosphorus poisonings. The magnitude of individual differences in absorbtion and disposition of pyridostigmine has not been well defined because of a lack of sensitive analytical methodology for routine quantification in biological fluids.

Pyridostigmine, a quaternary amine, decomposes under normal GC conditions, but is amenable to FAB ionization. Therefore, our proposed approach to quantifying pyridostigmine in plasma at the sub ng/mL level, is to use our recently developed HPLC/FAB interface. Earlier experiments in our laboratory indicated that MS/MS would be necessary because an unidentified species present in the plasma interfered with low level pyridostigmine determinations.

An analog of pyridostigmine, deuterated at the quaternary ammonium methyl group, was prepared for use as an internal standard. Figure 1 shows the low energy CAD daughter ion spectra of pyridostigmine and d_3-pyridostigmine. Both spectra contain daughter ions at m/z 72, indicating that both species could be detected by utilizing parent scans of m/z 72. Figure 2 shows such a parent ion spectrum of a mixture of the two compounds collected using a conventional FAB probe. Using this method we were able to quantitate standards at the 1 pg level. If needed, lower detection limits could be achieved by using reaction monitoring methods.

Figure 3 shows a reconstructed ion chromatogram of the protonated molecular ion of pyridostigmine generated using our HPLC/FAB probe. Chromatography was performed on an HPLC column (1 m x 0.25 mm I.D. packed with 3 μm C-18) contained within a custom continuous flow FAB probe built in-house.(1) The column effluent was transferred to the probe tip via a 2 cm length of 50 μm fused silica capillary tubing. The short interface results in a minimum of peak broadening.

For analysis, plasma samples were first spiked with the d_3-pyridostigmine internal standard and then carried through a simple liquid extraction. The extract was then injected directly onto the HPLC column for quantification by FAB. Figure 4 shows the reconstructed ion chromatogram of a 1/2 μL injection of an extract of plasma which had been spiked with approximately 10 ng of pyridostigmine.

In conclusion, we have found that using d_3-pyridostigmine as an internal standard and m/z 72 parent scans constitutes a viable means of quantifying low levels of pyridostigmine. We have demonstrated that our HPLC/FAB interface works and that plasma extracts containing pyridostigmine can be analyzed by this method. Future work includes testing the method using HPLC/FAB and MS/MS scans, generating standard curves and establishing detection limits, and finalizing extraction conditions.

Mass Spectral Analysis and Fragmentation of Second Generation ACE-Inhibitors Containing Phosphinic and Phosphorous Acids

Mark S. Bolgar*, G.C. DiDonato, R. Gedamke, T.J. McCormick,
S.E. Unger and B.M. Warrack

INTRODUCTION

Since the introduction of the first angiotensin converting enzyme (ACE) inhibitor for treating hypertension,[1] numerous other drugs of this class have been synthesized[2]. Second generation ACE-inhibitors containing a phosphinic or phosphorous acid moiety are currently under development for NDA filing.

These modified peptides are amenable to characterization using desorption ionization methods such as FD, thermospray and FAB. Facile degradation under thermospray conditons yield ions which are not ascribed to gas-phase unimolecular dissociation but arise as degradants. These species parallel degradation processes seen in long-term stability studies of fosinopril and may be useful for predicting the stability and degradation pathways of certain ACE inhibitors[3].

Accurate mass measurements and MS/MS analysis have been used to define the fragmentation of this class of compounds. Apart from loss of the phosphinic or phoshorous acid and loss of proline derivatives or the sidechain alkane and ester, these compounds exhibit a previously unreported rearrangement. This is the migration of an oxygen atom from the beta-carbonyl to the phosphorus atom, resulting in the phosphorous acid anion.

IONIZATION TECHNIQUES

1) Fast atom bombardment: Due to surface activity of the phosphorus acid group intense molecular or pseudomolecular ions are obtained.
2) Microbore LC/FAB: Molecular ions and fragments obtained. Ion source temperature must be kept below 80°C to avoid thermal decompositon.
3) Field Desorption: Abundant $(M)^+$ ions
4) Electron Ionization/Chemical Ionization: This class of compounds is not amenable to EI/CI due to extreme thermal lability.
5) Thermospray: Weak molecular ions and formation of thermal degradants limits usefulness as an analytical method. Degradation parallels that seen in long term stability studies

FOSINOPRIL

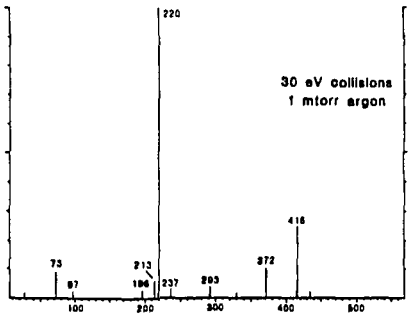
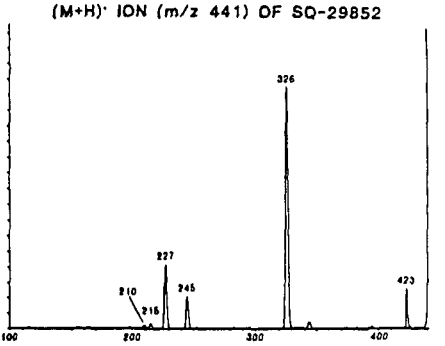
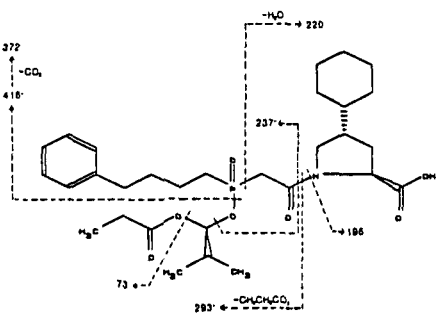
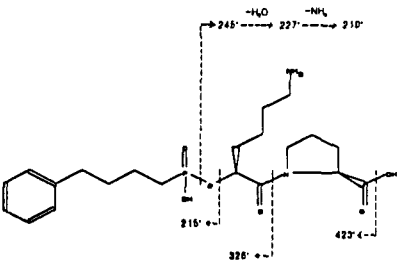
DAUGHTER ION MASS SPECTRUM OF (M-H)⁻ ION (m/z 562) FROM FOSINOPRIL



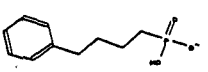
DAUGHTER ION MASS SPECTRUM FROM (M+H)⁺ ION (m/z 441) OF SQ-29852







The structure of the 213⁻ ion is assigned as the rearrangement product resulting from the migration of the oxygen atom from the beta-carbonyl to the phosphorus atom.



This ion is also present in the negative FAB mass spectrum of fosinopril. The exact mass is m/z 213.0686, which supports the emperical formula $C_{10}H_{14}O_3P$ (calcd. 213.0681). The MS/MS spectrum of the 213⁻ ion and that from authentic material both yield the PO_3 ion as their only daughter.

CONCLUSION

Second-generation ACE-inhibitors containing phosphinic or phosphorous acid moieties are readily characterized using soft ionization techniques such as fast atom bombardment, microbore LC/MS, and field desorption. However, due to the thermal lability of these compounds, techniques such as EI/CI or thermospray produce little or no molecular ions and result in thermal degradants. FAB generated parent ions do yield diagnostic daughter ion spectra upon CID, providing useful structural information. A rearrangement to produce 4-phenyl-n-butyl phosphorous acid is confirmed via MS/MS and accurate mass measurements.

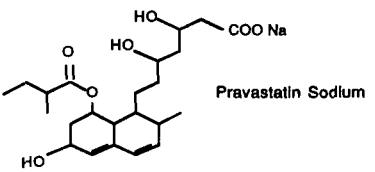
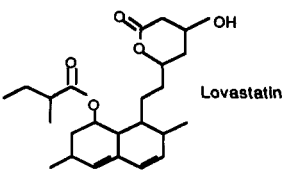
QUANTITATION BY GC/NICI-MS OF TWO ANTI-HYPERCHOLESTEROLEMIC DRUGS IN PLASMA AFTER SOLID PHASE EXTRACTION

D. Wang-Iverson, E. Ivashkiv, P. T. Funke, M. E. Arnold, M. Jemal and A. I. Cohen
The Squibb Institute for Medical Research
New Brunswick, New Jersey 08903.

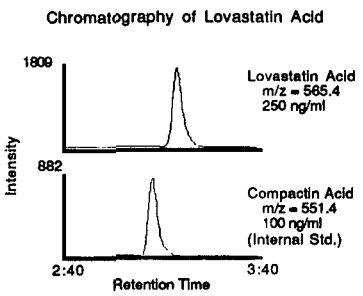
Pravastatin sodium (P) and lovastatin (L) have been shown to reduce plasma cholesterol in humans. In order to support clinical trials, we developed methods to extract and quantify these compounds.

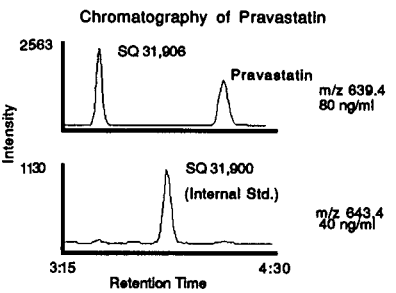




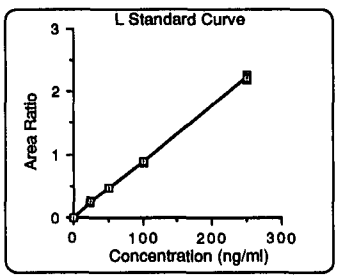
While L is administered as a lactone, it is converted *in vivo* to the free acid which is its active form. Therefore, the methods were devised to take advantage of the now routine technique of esterifying the carboxyl group with pentafluorylbenzyl bromide (PFB). The acid form of compactin was used as an internal standard for the L assays while the tetrahydro form of P was used for the P assays

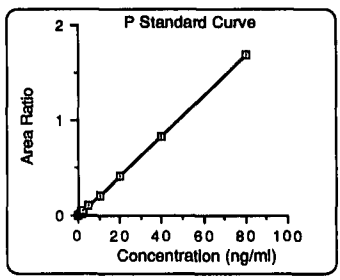
1.0 ml plasma samples, first spiked with the appropriate internal standards and diluted with phosphate buffer were passed through solid phase extraction columns (C_2 for L and C_{18} for P) The columns were rinsed with 5 ml of buffer, 5 ml of heptane and then the compounds were eluted with 3 ml of methanol for the P extraction or 1.5 ml of acetonitrile for the L extraction. The extracts were first derivatized with pentafluoro-benzyl bromide and then BSTFA. After derivatization, they were diluted with 300 ul of tetradecane and analyzed with an automated quadrupole GC/MS system using ammonia chemical ionization and negative ion detection. Single ions representing the $(M-181)^-$ species for each component were monitored. Typical chromatograms are shown below:





Standard curves for the two compounds were linear over the range of 0-250 ng/ml for L and 0-80 ng/ml for P:





The detection limit for each was approximately 0.5 ng/ml, which represents an injection of 2 pg on column. The table below shows the results of studies performed to determine the accuracy and reproducibility of the assay. Blank plasma samples containing various amounts of the compounds were extracted and analyzed as described above.

Accuracy and Precision of Assay

	Lovastatin			Pravastatin			
Amount Added (ng/ml)	25	50	100	2.5	10	40	80
Amount Determined	26.7	47.9	99.3	2.7	10.5	40.4	80.0
Standard Deviation	2.5	2.6	2.8	0.3	0.3	1.4	2.6
Coefficient of Variation	9.4	5.4	2.8	9.5	2.5	3.5	3.2
No. of Determinations	94	95	96	64	72	72	72

As can be seen, the accuracy and reproducibility of the method are quite good with the amount determined within 10% of theoretical and CVs less than 10%.

We are currently performing this assay on a VG Trio-2 GC/MS/DS which is equipped with a Hewlett-Packard 5890 gas chromatograph and a 7673A autosampler. With this equipment it is possible to analyze upwards of 100 samples per day, usually via unattended overnight runs.

Mass Spectral Studies of Cholesterol-Lowering Agents

Bethanne M. Warrack*, M.S. Bolgar, G.C. DiDonato, and S.E. Unger
The Squibb Institute for Medical Research, Princeton, NJ 08543-4000

INTRODUCTION

High levels of cholesterol in the blood contribute to the development of *atherosclerosis, a major cause of death in the U.S.* and other countries. Compounds such as mevastatin, pravastatin, lovastatin, and simvastatin have been shown to inhibit cholesterol biosynthesis at its rate-limiting enzyme 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase. These cholesterol-lowering agents undergo numerous chemical transformations: lactone ring-opening, double bond/hydroxyl migration, hydroxyl epimerization, oxidation, and hydrolytic loss of ester sidechains.

Structural studies of hypocholesterolemic agents and related analogues have been carried out using a variety of techniques, including fast heating *EI and CI, FAB, MS/MS, and TSP LC/MS*, to define characteristic fragmentation for this class of compounds. The use of derivatives, labeled compounds and accurate mass measurement has *assisted in their* characterization.

EXPERIMENTAL

1. Fast heating EI (70 eV) was recorded with a Finnigan TSQ–4600 mass spectrometer equipped with a Finnigan direct exposure probe.
2. Fast heating CI mass and MS/MS spectra were recorded using the instrumentation described above. Reagent gases were NH_3 or a CH_4/N_2O mixture. Collisions were 30 eV with argon.
3. Thermospray spectra were obtained by fitting a Vestec thermospray interface onto the TSQ-4600. The ion source was held at 250°–275°C with the vaporizer adjusted to 160°–240°C. Flow rates of 1.0–1.5 ml/min were used. Mobile phases contained 0.1M NH_4OAc *and* CH_3CN.
4. FAB and MIKES spectra were recorded with a VG-ZAB-HF mass spectrometer using dithiothreitol-dithioerythritol as solvents. Air was used for 8 kV collisions. High resolution was accomplished using poly(*ethylene glycols*) *as internal standard* for peak matching (1:8000).

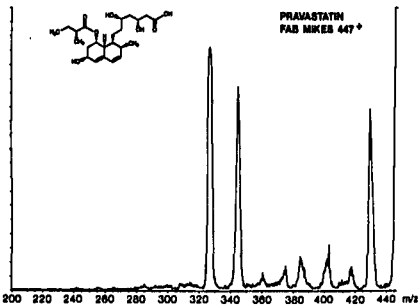
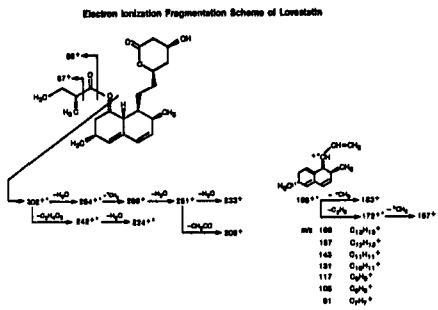
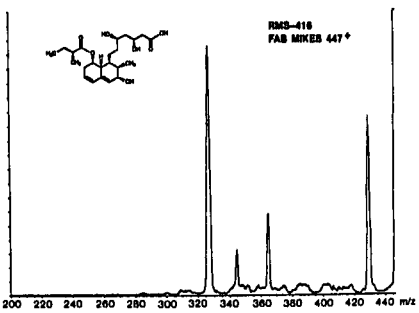
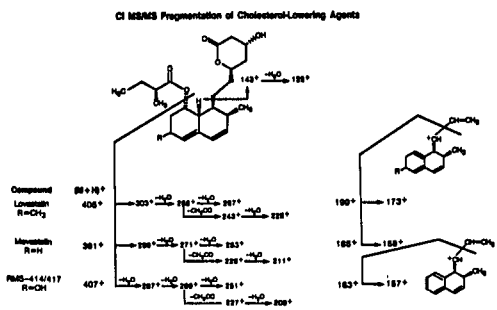
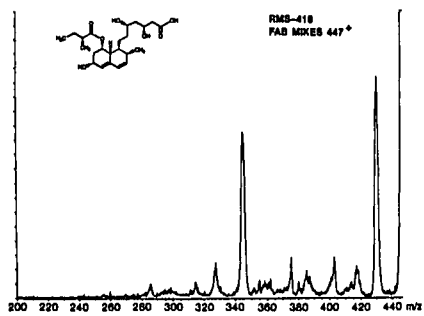
Differentiation of stereoisomers and regioisomers by positive FAB MIKES. Note the difference in 345+: 327+ ratio. These isomers cannot be distinguished using negative ions.











CONCLUSION

Differentiation between the pro-drug lactone and the active acid is possible from their behavior under fast heating CI conditions. Transformations of hypocholesterolemic agents which involve the lactone ring or the ester sidechain are easily determined from their mass and MS/MS spectra. More subtle changes on the fused rings are difficult to characterize and require the use of high energy collision conditions, charge-changing dissociations, and breakdown curves generated from MS/MS data. Positive or negative MIKES is used to differentiate between stereoisomers and regioisomers. Mixtures of such agents are rapidly profiled by monitoring loss of the C_5 and C_6 acids from the ester sidechain in the neutral loss mode.

FAB-MS OF NOVEL FLUOROGENIC IONOPHORES

D. M. Hindenlang, M. E. Lucas, D. Masilamani, R. D. Sedgwick

Corporate Technology, Allied-Signal Inc., Morristown, NJ 07960

Introduction

FAB-MS has been employed for structural characterization in the development of some novel fluorogenic ionophores for ultimate applications to fiber optic-based clinical analysis of alkali metals in biological fluids. Ionophores are generally cyclic organic structures bearing heteroatoms that ligate ions, and depending on the cavity size may be highly specific for solution binding of a particular ion. The present work involves FAB-MS to guide the development of fluorogenic ionophores which are indicators for alkali ions, with measurable changes in their fluorescence upon binding. Exploratory synthesis has led to an optimal series of coumaro cryptands, highly specific and sensitive for K^+, Na^+, and Li^+. These products are highly selective, sensitive, stable, compatible with aqueous media at neutral pH, and suitable for existing clinical instrumentation or fiber optic-based sensors. The preferential solution binding of these ionophores is reflected in their FAB spectra, which show competitive cationization by the same preferred alkali species. These results indicate FAB ionization by desorption of preformed ionic complexes from solution.

Synthetic Design Guided by FAB-MS

The exploratory development of novel fluorogenic ionophores followed variations of selective ion-recognizing moieties conjugated to diverse aromatic chromophores. The success of these synthetic routes was monitored by FAB-MS analysis of diverse ionophores, intermediates, and side products. Various chromophoric groups were explored incorporating catechol derivatives, dihydroxy-naphthalene units, and a coumarin (1,2-benzopyrone) based moiety. Aryl oxygens from these groups were built into ion-recognizing crown ether and cryptand macrocycles.

The MS instrumentation for this examination of fluorogenic ionophores was a VG Analytical ZAB-HF reverse geometry double focusing mass spectrometer with FAB ion source using 7 keV xenon atom bombardment. Spectra were recorded on the VG 11-250 instrument control and data collection system, with magnetic scanning using field control and an ion energy of 8 keV. Positive ion spectra were more intense and generally of greater analytical value. Negative ion spectra generally provided little information regarding the ionophore, being dominated by halide counter ions remaining from the synthesis.

Positive ion spectra are generally dominated by very intense pseudomolecular ion patterns, MH^+ and alkali cation adducts. The details of the molecular patterns depend on the nature and extent of alkali contamination during the synthesis. The less alkali, the greater is the observed MH^+ intensity, but even minor alkali contamination produces relatively intense cation adducts. Fragmentation information is most useful for open chain intermediates and final products with appended side groups. However, the predominance of molecular weight information facilitates the assignment of even minor side products.

Competitive Binding of Coumaro Cryptands with Alkali Cations

Incorporation of 6,7-dihydroxy-4-methyl coumarin into cryptands provides optimal selectivity and sensitivity for fluorogenic ionophores. Three coumaro cryptands were synthesized and studied: [2.2.2], [2.2.1], and [2.1.1] . With excitation at 330 nm the fluorescence observed at 410 nm is enhanced dramatically by selective alkali binding. This enhancement is quantitative at clinical concentrations, even in the presence of non-target ions. Cationized FAB-MS pseudomolecular ions similarly show selectivity and sensitivity of binding for this series of coumaro cryptands. Competitive alkali binding experiments were conducted in glycerol matrix containing equimolar LiCl, NaCl, and KCl.

The control FAB-MS experiment contained no ionophore, simply glycerol and equimolar concentrations of Li^+, Na^+ and K^+. We observe no specificity of the cations for the glycerol matrix. The spectrum shows nearly equivalent ion intensities for m/z 99^+ (GLi^+); 115^+ (GNa^+); and 131^+ (GK^+) along with considerable m/z 93^+ (GH^+). In experiments with ionophores, this pattern was not reproduced nor were the observed ratios of m/z 7^+ (Li^+), 23^+ (Na^+), and 39^+ (K^+) maintained. The distortions were generally in favor of the alkali ion preferentially bound by the particular ionophore. These results indicate variations in the surface concentration of the alkali cations enhanced by the ion binding and surface activity of the ionophores.

FAB-MS of the coumaro [2.2.2] cryptand (MW506) shows a predominant m/z 545^+ (MK^+) with minor 529^+ (MNa^+) along with weak glycerol matrix adduct ions. No reliable MH^+ or MLi^+ species are observed. These results correlate with solution fluorescence data which show that this system is highly selective and sensitive for K^+. FAB-MS of the coumaro [2.2.1] cryptand (MW462) shows a predominant m/z 485^+ (MNa^+) with minor possible MLi^+ (m/z 469^+) and MK^+ (m/z 501^+) along with glycerol matrix adducts. Fluorescence spectra demonstrate a dramatic enhancement selective for Na^+ as expected. FAB-MS of the coumaro [2.1.1] cryptand (MW418) shows a predominant m/z 425^+ (MLi^+) with weak 419^+ (MH^+), 441^+ (MNa^+), and 457^+ (possible MK^+), along with glycerol matrix adducts. Fluorescence spectra demonstrated a dramatic enhancement with the addition of Li^+.

All three of the above coumaro cryptands were similarly dissolved together in glycerol matrix with equimolar Li^+, Na^+, and K^+ for a competitive binding FAB-MS experiment. The observed three dominant pseudomolecular species (see Figure) are in accord with the solution binding specificity, viz. m/z 425^+ [2.1.1]Li^+; m/z 485^+ [2.2.1]Na^+; and m/z 545^+ [2.2.2]K^+.

Conclusions

FAB-MS of these coumaro cryptands illustrates a clear correlation of cationized pseudomolecular ions with solution binding specificity and fluorogenic sensitivity. The conclusion that the FAB-MS is representative of selective solution binding of alkali cations to these fluorogenic ionophores is particularly emphasized in the final competitive experiment. These data indicate FAB ionization by desorption of specific performed ionophore alkali cation complexes from solution. These results are generally inconsistent with a CI plasma, random cationization model for FAB ionization. A CI model would predict more equivalent intensities for adducts of these equimolar cations, since all alkali pseudomolecular ions appear stable. Alternatively a CI model might favor a modified distribution based on cation gas phase energetics.

HRGC-MS MEASUREMENT OF PLASMA NICOTINE LEVELS AFTER SMOKING OR CHEWING NICOTINE GUM.

Enrico Davoli, Giulio Mariani, Emilio Benfenati and Roberto Fanelli; Pharmacological Research Institute "Mario Negri", Milano, Italy, 20157.

INTRODUCTION:
Recently, a new product for the Italian market, nicotine chewing gum (Nicorette) has been released as a therapeutic agent for tobacco addiction.
It is well known that plasma nicotine level is an important factor in physical dependence on cigarette smoking. Smokers can partially regulate their nicotine intake when switching to brand of cigarette with different strength. This indicates the importance of measuring plasma concentrations of the alkaloid during the treatment with a smoking withdrawal aid.
The leading cigarette brand in Italy is MS, a high-tar brand, which represents 32 % of the market. This results in a quite homogeneus population of smokers.
With this in mind it was decided to test in a controlled trial the nicotine plasma levels obtained after smoking MS cigarette or after chewing Nicorette 2 or 4 mg.

EXPERIMENTAL
Human studies
Eight smoker volunteers partecipated to a three day trial, chewing 2 or 4 mg Nicorette tablets or smoking MS cigarettes hourly.
The first day they were asked to smoke a cigarette per hour, the second to chew a 2 mg Nicorette tablet, the third a 4mg tablet. Three 2 ml blood samples were collected after four hours from the beginning of the experiment, 30 min after each treatment. Subjects were asked to chew the tablets for thirty minutes.

Plasma nicotine assay and synthesis of deuterated nicotine
Deuterated nicotine was used as internal standard.
5,5-D2-Nicotine was obtained by reduction of cotinine with LiAlD4 (1).

Instrumental analysis
Experimental conditions for selected ion recording (SIR) were as follows:
Instrument: VG TS-250
Coloumn: CP WAX CB (11m 0.22 ID) Chrompack
Ion recording: m/z 162 (nicotine) and m/z 164 (nicotine-D2).

Extraction from biological samples
Plasma samples were extracted basically as reported (2).

Recovery studies
Recovery studies were performed adding a fixed amount of nicotine-D2 and increasing amounts of nicotine to non smoker plasma samples. Fig.1 shows the calibration curve obtained when spiked plasma samples were prepared and analysed as described above.
The intercept on Y axis corresponds to the sum of signals from background plasma nicotine levels and from contribution of M-2 ions of deuterated nicotine (10 %).

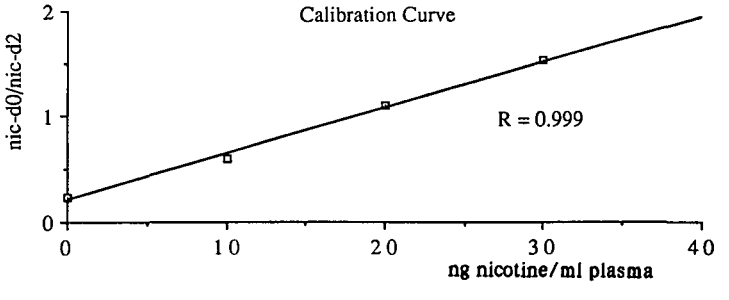

Fig 1: Calibration curve

RESULTS

Results (fig.2) show that the plasma nicotine obtained after cigarette smoking (19.21+1.16 ng/ml) lies between the levels obtained after chewing 2 mg (14.31+0.91 ng/ml) and 4 mg (23.69+1.65 ng/ml) Nicorette.

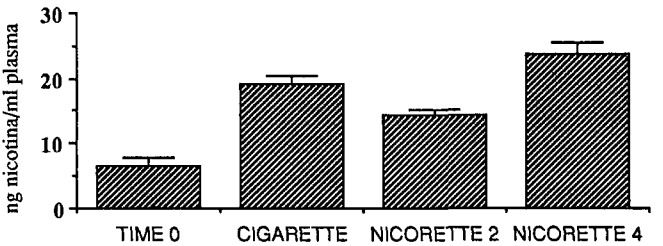

Fig 2: Nicotine plasma levels before the experiment (Time 0) and after smoking or chewing Nicorette (2 or 4 mg).

CONCLUSIONS

These results reflect quite closely data previously obtained by British and American studies (3,4). Our data indicate that nicotine plasma levels obtained after chewing Nicorette gum are comparable with levels obtained smoking the most popular cigarette brand in Italy.

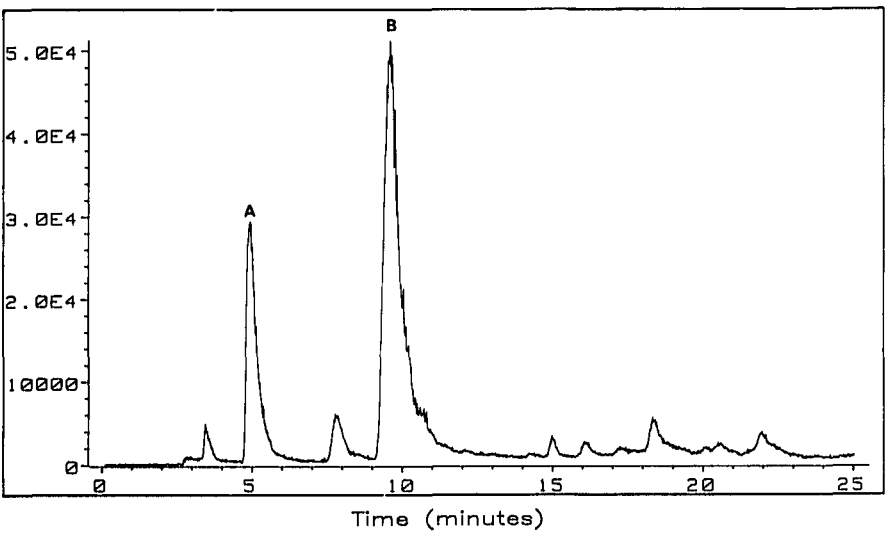
PRELIMINARY STUDIES ON THIOTEPA-DNA ADDUCTS USING THERMOSPRAY LC/MS: Steven M. Musser, Patrick S. Callery and Su-Shu Pan, Department of Medicinal Chemistry and Pharmacognosy, Univ. of Maryland, Baltimore, MD. 21201 and Univ. of Maryland Cancer Center, Baltimore, MD. 21201

Thiotepa [tris(1-aziridinyl)phosphine sulfide] is a clinically useful anticancer drug whose proposed mechanism of action is alkylation of DNA bases. Although thiotepa has been used clinically for over 30 years very little is known about its interaction with DNA. Since thermospray LC/MS is an excellent technique for the analysis of nucleosides we proposed that it would also be useful for the identification of unknown modified nucleosides.

Calf thymus DNA and thiotepa were incubated at 37 °C at various pH's ranging from 4.6 to 7.4. The DNA was isolated and digested enzymatically. The enzymatic digest and supernatant remaining after removal of the DNA from the reaction mixture were chromatographed on an HPLC reverse phase C-18 column with the effluent being fed directly into the thermospray ion source of a Hewlett-Packard Mass Selective Detector or a Finnigan 4500 mass spectrometer. The molecular ion of deoxyguanosine was used to optimize thermospray conditions, since the ratio of the molecular ion to the ion corresponding to the purine base without the suger is good measure of the extent of thermal hydrolysis occurring in the ionization process.

The position and bases at which DNA was modified by thiotepa were established using HPLC/thermospray mass spectrometry. The structures of the two adducts have been assigned as 7-(2-aminoethyl)guanine and 7-(2-aminoethyl)adenine. The assignments are based on the observation that N-7 modified purine nucleosides rapidly undergo depurination under neutral or acidic conditions (Hemminki, K., Chem.-Biol. Inter., 48:249-260). Since the adducts were found in the supernatant of the thiotepa-DNA reaction mixture and not in the hydrolyzed DNA fraction and the mass spectra indicate that the deoxyribose is not present on the adducts we conclude that the the N-7 position of guanine and adenine are the sites of alkylation by thiotepa. The ratio of N-7 alkylated guanine to N-7 alkylated adenine is approximately 3:1, making 7-(2-aminoethyl)guanine the principal adduct formed when thiotepa alkylates DNA. Although it is possible for thiotepa to alkylate DNA as the intact molecule the absence of adducts containing a phosphoramide bond indicates that thiotepa may be fuctioning as a prodrug for aziridine.



Thermospray total ion chromatogram of the supernatant from the thiotepa/DNA reaction mixture. A. 7-(2-aminoethyl)adenine B. 7-(2-aminoethyl)guanine

SIMULTANEOUS QUANTITATION OF CARBAMAZEPINE, CARBAMAZEPINE-10,11-EPOXIDE, AND CARBAMAZEPINE-10,11-DIOL IN PLASMA BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

D. Alkalay, S. Carlsen, J. Miotto, and D. Gaudry

Development Department, Pharmaceuticals Division,
CIBA-GEIGY Corporation, Ardsley, N.Y. 10502

Carbamazepine (I) is widely used for treating epilepsy and trigeminal neuralgia. The drug is known to undergo extensive biotransformation and to yield many metabolic products. Prominent among these are carbamazepine-10,11-epoxide (II), known to have anticonvulsant activity in animal models, and carbamazepine-10,11-diol (III).

A number of published methods allow the quantitation of I, or I and II. A need existed, however, for a simple procedure permitting the simultaneous determination of all three compounds in biological fluids. The development of such a procedure became the objective of this work.

The method we developed relies on 10-methoxycarbamazepine (IV) as internal standard. It utilizes N-methyl-N-trimethyl-silyltrifluoroacetamide (MSTFA) as derivatizing agent. One-ml plasma samples, containing appropriate amounts of I, II, and III, were spiked with internal standard and extracted with $CHCl_3$. Following treatment with MSTFA, aliquots were injected for GC/MS analysis.

We utilized a Nermag R10-10C mass spectrometer interfaced with a Varian Vista 6000 gas chromatograph. The GC/MS was linked to a PDP 11/73 computer and was equipped with a split/-splitless capillary injector and an Alltech FSOT RSL-150 capillary column (30 m x 0.32 mm). The system was operated under CI conditions with He as carrier and NH_3 as reagent gas. The temperatures were 100 to 250°C for GC programming, 250°C for the injector, and 290°C for the GC/MS interface.

Compounds I, II, III, and IV give the trimethylsilyl (TMS) derivatives V, VI, VIII, and IX, respectively. The epoxide, in addition, undergoes a rearrangement to give 9-acridinecarboxyaldehyde (VII).

Selected ion monitoring was conducted on the M+1 ions of V, VI, VII, VIII, and IX, with respective m/z values of 309, 208, 325, 487, and 339. For determinations of the epoxide, we can use the rearrangement product VI as well as the derivative VII.

All three compounds showed a good linear relationship between the peak area ratio of analyte to internal standard and the concentration of the analyte. The range was tested from 40 ng/ml up to 10 ug/ml.

The method is specific, linear, accurate, and precise. It provides a convenient opportunity to monitor levels of the drug and the two metabolites resulting from single and multiple therapeutic doses. It can be especially useful in pharmacokinetic studies employing cold isotope-labelled carbamazepine.

QUANTITATION OF THE SELECTIVE DOPAMINE AGONIST CGS 15873A IN PLASMA BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

S. Carlsen, D. Alkalay, D. Gaudry, and J. Miotto

Development Department, Pharmaceuticals Division,
CIBA-GEIGY Corporation, Ardsley, N.Y. 10502

CGS 15873A (I) is a new dopamine autoreceptor agonist currently being evaluated in man. Because of its potency, it is administered at low doses. As a result, the levels attained in plasma are rather low.

In order to investigate the pharmacokinetic behavior of the drug in man, it was necessary to determine the levels it attained in plasma after the administration of a single dose. That need was met by the procedure we describe, which allows the necessary low level drug determinations.

One-ml plasma samples, containing appropriate amounts of I, were spiked with one ng of the analogue CGS 15855A (II), used as an internal standard. They were extracted with a mixture of heptane and ether (7:3) and the extract was evaporated to dryness. The residue was derivatized with a toluene solution saturated with pentafluoropropionic anhydride (PFPA) to yield III and IV. Prior to injection, the excess reagent was destroyed with an aqueous solution of KH_2PO_4.

We utilized a Nermag R10-10C mass spectrometer interfaced with a Varian Vista 6000 gas chromatograph and linked to a PDP 11/73 computer. The system had a split/splitless capillary injector and an Alltech FSOT RSL-150 capillary column (30 m x 0.32 mm). The system was operated under CI conditions with He as carrier and NH_3 as reagent gas. The temperatures were 100 to 300°C for the GC programming, 255°C for the injector, and 290°C for the GC/MS interface.

Selected ion monitoring was conducted at m/z 394, a value common for the M+1 ions of III and IV.

The method is very sensitive and allows dependable analyses down to plasma concentrations as low as 2 pg/ml. We tested the critical range range from 2 to 200 pg/ml. Our results, expressed as % of added drug concentrations, averaged 101.6 + 9.2 (n = 27).

In conclusion, this method is specific, linear, accurate, and precise. It allows dependable low level analyses, which makes it particularly suitable for single dose human pharmacokinetic studies.

Determination of Arecoline in Plasma By Selected Ion Monitoring GC/MS

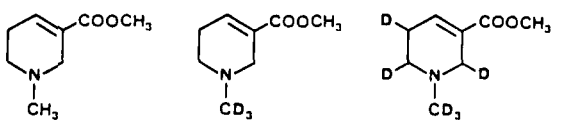
M. J. Hayes, L. Khemani, M. Bax, and D. Alkalay;

Development Department, Pharmaceuticals Division, CIBA-GEIGY Corp.,
Ardsley NY 10502

Arecoline is a natural product of the betel nut. It is known to have parasympathomimetic and cholinergic properties. It is also effective in treating cholinergic brain disfunction.

Previously published analytical methods for arecoline have not had sufficient sensitivity or specificity for use in the determination of arecoline in plasma. Determination of arecoline at levels of clinical interest (1 ng/ml) is made difficult due to its low molecular weight (155) and the many interferences that result from plasma.

The present work describes methodology for the determination of both arecoline (I) and d3-arecoline (II) in human plasma. The quantitation of both unlabeled and labeled arecoline needed for use in conducting comparative bioavailability studies with alternative dosage forms. D6-arecoline was used as the internal standard. The d6-arecoline has 0.03% residual d0 and 0.59% d3 and therefore does not contribute significantly to the blank for either compound.



I II III

The removal of drug from plasma was accomplished by a two-step liquid/liquid extraction procedure. The plasma was acidified, then washed with ethyl acetate. Extraction was then done at pH 9 using 5% triethyl amine in ethyl acetate. The wash sequence was critical to achieving the 1 ng/ml quantitation limit.

The mass spectrometer used was a Nermag model R10-10C with a Varian 6000 GC. A 30 m methyl silicone bonded phase capillary column was used for GC. Injections were made in the splitless mode with an injector temperature of 220oC. The temperature program was 60oC for 1 min, then 40oC/min to 220oC, hold for 4 min.

Mass spectrometry was under ammonia CI conditions at a source pressure of 0.2 torr (ammonia flow, 6 ml/min/atm). The [M+H]+ ions were monitored at m/z 156, 159, and 162 for compounds I, II, and III respectively.

Quantitation was done with peak area ratios of drug to internal standard followed by weighted linear least square regression (weighting = 1/x2). Calibration curves were reproducible with regression coefficients of 0.996 or greater. The mean of the absolute deviations of individual standards from the regression line ranged from 4 to 12%. Quality control samples gave a mean recovery of 101.4% with a std. dev. of 7.6% (n = 17).

The application of the method is illustrated with results from a study in dogs. Arecoline was administered to four dogs via the left femoral vein in ascending doses of 0.3, 1.0, 3.0, and 10 ug/kg/min for 30 minutes each. The results of the analysis are plotted in Figure 1. Plasma levels can be seen to rise linearly with increasing dose.

The method described is sensitive, precise, accurate, and selective and has been applied to pharmakokinetic studies in both humans and animals.

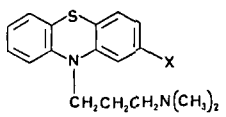
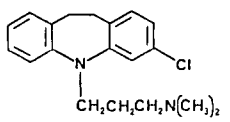
Dechlorination Reactions in FAB Mass Spectrometry of Phenothiazine Related Drugs

R.W. Edom, P.W. Brooks and G. McKay
College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0

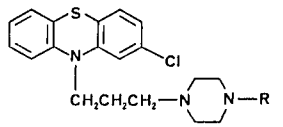
Chlorinated phenothiazine and tricyclic antidepressant drugs appear to undergo extensive dehalogenation reactions in FAB mass spectrometry, resulting in the appearance of characteristic dechlorinated ions in the spectra. This has presented problems in the identification of new metabolites of these drugs using FAB. The presence of artifactual dehalogenated ions can confuse the structure eludication of unknown metabolites. Therefore a study to examine the nature and extent of dechlorination reactions for these two groups of drugs was undertaken using the representative compounds presented below.



X = H PROMAZINE
X = Cl CHLORPROMAZINE

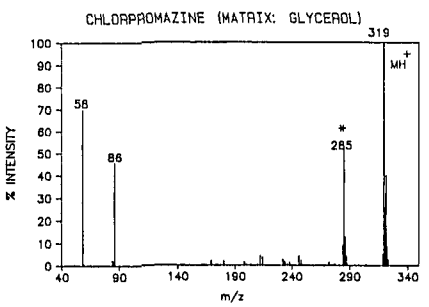


CLOMIPRAMINE



R = CH_3 PROCHLORPERAZINE
R = CH_2CH_2OH PERPHENAZINE

Dechlorination is suspected to result from a reaction in the sample matrix replacing the chlorine atom with a hydrogen, and giving rise to an apparent fragment ion. Presented for example are the positive ion FAB spectra of chlorpromazine and clomipramine. The dechlorinated species in each spectrum is marked with an asterisk. It appears at a mass shift of 34 amu from the MH^+, with no distinictive chlorine isotope. Table 1 summarizes the relative intensity and percent exchange of the dechlorinated species in each compound used for this study. As indicated in the table, dechlorination results in abundant artifactual ions in the FAB mass spectra of these compounds.



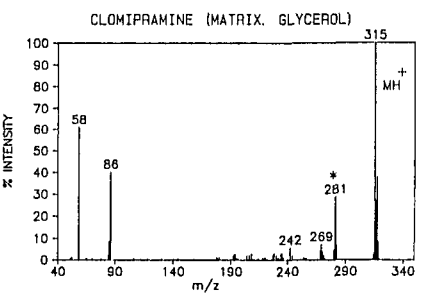


Table 1: Extent of FAB Induced Dechlorination

	Mol. Weight	m/z (% Rel. Intensity) $M_{Cl}H^+$	$M_H H^+$	% Exchange
Chlorpromazine	318	319 (100)	285 (45.7)	26.3
Clomipramine	314	315 (100)	281 (28.7)	17.5
Perphenazine	403	404 (100)	370 (41.9)	23.9
Prochlorperazine	373	374 (100)	340 (31.9)	19.4

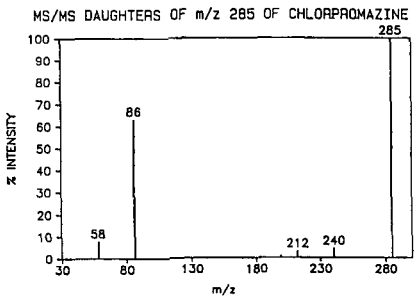
Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

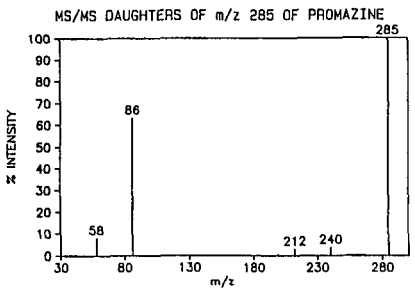
In Table 1 the % Exchange was calculated from the relative intensities of the ions using the equation:

$$\% \text{ Exchange} = M_H H^+ / (M_H H^+ + M_{Cl} H^+)$$

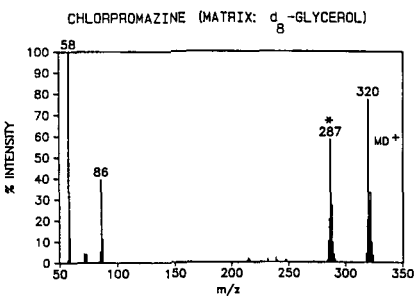
In the equation, $M_{Cl}H^+$ represents the sum of the intensities of the ^{35}Cl and ^{37}Cl isotopes. Where appropriate the intensity of the ^{37}Cl isotope was corrected for the contribution of ^{18}O and ^{34}S from the ^{35}Cl isotopic species.

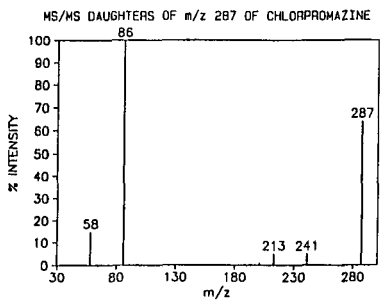
To confirm the structure of the dechlorinated ion (m/z 285) in chlorpromazine, FAB-MS/MS was conducted on a VG 70SQ mass spectrometer. Promazine (the dechloro-analog of chlorpromazine) was used as an authentic reference. The CAD daughter ion spectrum of m/z 285 from chlorpromazine was identical to the daughter ion spectrum of the MH^+ of promazine, proving the incorporation of hydrogen for chlorine in the process of dechlorination. The spectra are presented below.





A FAB spectrum of chlorpromazine using d_8-glycerol as the sample matrix is shown below. Here the dechlorinated ion is observed at m/z 287, a shift of 33 amu from the MD^+. This indicates replacement of the chlorine with deuterium. To confirm this observation, a FAB-MS/MS spectrum was determined on m/z 287. Daughter ions were observed at m/z 213 and 241, which proves the incorporation of deuterium for chlorine when compared to the corresponding daughter ions of m/z 285 of chlorpromazine and promazine determined in glycerol.





The results of this research have proven that chlorinated phenothiazine and tricyclic antidepressant drugs undergo extensive dechlorination reactions in positive ion FAB mass spectrometry. These reactions produce intense ions in the spectra which account for a range of 17.5% to 26.3% chlorine exchange and appear in the spectra from 28.7% to 45.7% relative abundance. Since metabolic dechlorination is a possiblity, investigators must be alert for the appearance of artifactual dechlorinated ions when attempting to elucidate the structure of unknown metabolites of halogen containing drugs such as those presented in this study.

The authors gratefully acknowledge the financial support of the Medical Research Council of Canada (P.G. 34 and a MRC studentship for R. Edom).

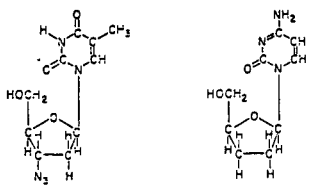
Quantitation of Dideoxycytidine in Human Plasma by GC/MS. Felix R. Rubio, Theodore Crews, W.A. Garland and Elaine K. Fukuda*, Hoffmann-La Roche Inc., Nutley, NJ 07110.

The 2',3'-dideoxynucleosides are a class of chemicals with potent activity against the human immunodeficiency virus responsible for the AIDS (acquired immunodeficiency syndrome) disease [1,2]. One member of this chemical class, AZT (azidothymidine), has been approved for clinical use [1], and another member, DDC (dideoxycytidine), is undergoing clinical trials [1].



The quantitation by HPLC of these chemicals in the plasma of patients undergoing treatment with the dideoxynucleosides is complicated by interferences due to the intensive concomitant chemotherapy required to treat the effects of the disease. For very potent nucleosides such as DDC, the administered dose also gives plasma concentrations too low to be measured by traditional HPLC [3,4] or LC/MS [3].

This presentation reports a GC/NCIMS assay for DDC in the plasma of AIDS patients undergoing treatment.

The method involves several steps: 1) precipitation of plasma proteins with acetone, 2) ether wash, 3) ethyl acetate:methanol (9:1) extraction reaction with t-butyl dimethyl chlorosilane to silylate the 5'-hydroxyl group, 5) pentafluorobenzoylation of the amino group with pentafluorobenzoyl chloride, 6) methylation of the ring nitrogen adjacent to the amino group with diazomethane. The resulting derivative is quantitated using stable isotope dilution, selective ion monitoring and methane negative chemical ionization mass spectrometry.

Plasma concentrations of DDC were measured over a range of 2 to 200 ng/ml using 1 ml of plasma for extraction.

Plasma concentration-time profile of DDC in the plasma of an AIDS patient given a single oral 5 mg dose of the drug. The continuous line represents the fit of the data (solid circles) to the equation for a one compartment single oral dose [5].

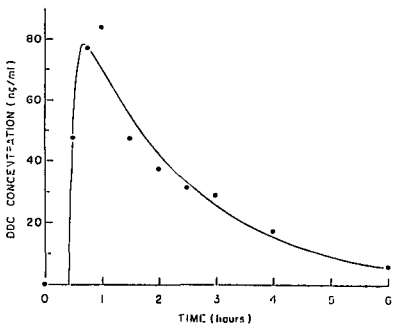


Figure 1

To date, the assay has been used to measure concentrations of DDC in the plasma from AIDS or AIDS related complex patients given 0.5 or 5 mg of either oral or IV doses of DDC. If lower doses are to be used, the sensitivity of the assay will have to be improved.

APPLICATION OF DICYANDIAMIDE AS A MATRIX ADDITIVE IN FAST ATOM BOMBARDMENT MASS SPECTROMETRY

G. W. Caldwell, A. B. Reitz and J. A. Masucci, Janssen Research Foundation at McNeil Pharmaceutical, Spring House, PA 19477

INTRODUCTION: FAB mass spectra are influenced by various aspects of matrix solution chemistry(1). Chemical reagents are often added to the FAB matrix to confirm the molecular ion and/or improve the sensitivity by enhancing the proton attachment ([M+H]+) or the proton abstraction ([M-H]-) emission(2). The pH of the FAB matrix can be modified with common organic acids or bases with the objective of more fully ionizing the analyte in the solution and thereby increasing its FAB sensitivity(3). Surfactants can be used to enhance the response of an analyte relative to a matrix by enriching the surface composition with analyte(4). In conjunction with the development of the use of chemical additives, a distinct set of derivatization reactions have emerged which endow the analyte with ionic character and/or surface activity(5,6).
This poster describes the properties of dicyandiamide (DCDA) as a chemical additive to the FAB matrices thioglycerol and glycerol for the analysis of organic compounds. We show that DCDA can be used to generate adduct ions for a variety of organic compounds to confirm the protonated molecular ion. It is demonstrated that amines work well with this chemical additive (Table 2).

$$RR'R''NH^+ + N{\equiv}C\text{-}NH\text{-}C(=NH)NH_2 \longrightarrow [RR'R''NH_2..N{\equiv}C\text{-}NHC(=NH)NH_2] \quad (1)$$

Reaction of DCDA with primary and secondary amines produces biguanides (Figures 1-3) (7).

$$RR''NH{\cdot}HCl + N{\equiv}C\text{-}NH\text{-}C(=NH)NH_2 \longrightarrow RR'N\text{-}C(=NH)NHC(=NH)NH_2 \quad (2)$$

The FAB spectra and the high sensitivity of biguanides (nanogram range) are described for the first time (Table 3). The dual role of DCDA makes it an interesting and unique chemical additive.

DISCUSSION: Table 2 demonstrates that DCDA can be used as a chemical additive for a variety of amines to confirm the molecular ion in FAB spectra. Approximately 25 g of amine and 50 g of DCDA were loaded onto the FAB probe tip and analyzed. The protonated amine ion ([M+H]+) and the adduct ion ([M+H+84]+) were observed. The [M+H]+ ion was the base peak in all FAB spectra except compound 11, here, the protonated molecule of DCDA (85 m/z) was the base peak. Relative to the [M+H]+ ion intensity the [M+H+84]+ ion intensity was observed in the range 3-32%. The ratio of the ion intensities [M+H+84]+: [M+H]+ throughout the entire emission period (ca 3 m) changed only slightly (1-2%) with time.
Figure 1 shows the derivatization of compound 15 (267 m/z) with time to its corresponding biguanide (351 m/z). The FAB spectra denotes the reaction initially (time 0) and at 2 h and 7 h. The major matrix background ions for the thioglycerol/DCDA/DMSO mixture were [109 + (108)x]+, [85 + (84)x]+, [79 + (78)x]+, [109 + (84)x]+, and [85 + (78)x]+ where x equals 0-2.
Eight amine hydrochloride salts (1-3, 6, 7, 10, 13 and 15) were derivatized along with three tertiary amine hydrochloride salts (4, 8, 16) used as controls (Table 2). As expected, the ratio of ion intensities [M+H+84]+: [M+H]+ remained constant for tertiary amines and increased for primary and secondary amines. It is clear that primary and secondary amines react via (2) to form biguanides while tertiary amines do not. Compounds 7 and 8 demonstrate that derivatization can distinguish secondary and tertiary amine isomers.
Derivatized amines (biguanides) were readily detected at 200 ng in the full range FAB spectrum (Figure 3). By contrast, underivatized amines 1, 6, 7, 10, 13 and 15 (Table 2) provided no data whatsoever at 200 ng while 3 was detected. Some of the low FAB sensitivity for the underivatized amines may be due to evaporative loss from the FAB probe-tip. The greater enhancement of 3 as compared to the other derivatized (or underivatized) amines appears to be related to the hydrophobic character endowed by the n-hexyl carbon chain(6).
The most abundant ions in the FAB spectra are listed in Table 3 for five commercially available biguanides (17-21). There is little or no fragmentation in these molecules and the base peak is the [M+H]+ ion. The ion abundance is concentrated in the base peak, thereby enhancing its sensitivity. Many biguanides are themselves important medicinal compounds. From the above results, the FAB analyses of biguanides in plasma at the low nanogram range may be possible directly.

LIQUID SIMS OF METALLOPORPHYRINS WITH A STRONG AFFINITY TO TUMOR TISSUE

M. Suzuki, N. Takeda, K. Masuda, K.-I. Harada and A. Tatematsu (Faculty of Pharmacy, Meijo University, Tempaku, Nagoya 468, Japan), I. Sakata (Toyo-Hakka Co. Ltd., Okayama 719-03, Japan) and I. Nakajima (The 1st Department of Surgery, Asahikawa Medical College, Asahikawa 078, Japan)

Introduction

It is well known that porphyrin is apt to extensively accumulate in tumor tissue and yield fluorescence. Investigation of the use of porphyrins and metalloporphyrins for tumor diagnosis and treatment began about half of a century ago[1]. We have also developing a ^{111}In-labeled gallium-containing porphyrin (1), which is semi-synthesized from dimethylester of protoporphyrin, as a new tumor imaging agent[2]. In general structural characterization of porphyrins and related compounds have been performed by UV and NMR spectroscopy, and X-ray analysis. However it is relatively difficult to obtain structural information in the case of **1** which is very complicated because this type compounds become often insoluble and form polymer. In the present study we applied liquid SIMS to structural characterization including determination of molecular weight of metalloporphyrins and further studied the potentiality of the method for the purpose mentioned above.

Material and Methods

About 30 of metalloporphyrins studied were synthetically prepared from dimethylester of protoporphyrin. The detailed synthesis will be reported elsewhere.

SIMS and linked scanning (B/E mode) were performed using a double focusing Hitachi M-80B mass spectrometer fitted with a M-0101 data system. Operating conditions were: primary ion, Xe^+; accelerating voltage, 8 kV (primary) and 3 kV (secondary). Samples were dissolved in a solution of chloroform and methanol (1:4). Each sample solution (1-5 ul) was loaded on a silver target. About 3 ul of matrix material was added to the sample on the target. Glycerol, magic bullet, m-nitrobenzyl alcohol (NOBA) and o-nitrophenyl octylether (NPOE) were used as matrices.

Results and Discussion

ATN-2 (2) is a key intermediate for **1**, in which gallium (III) is coordinated to the porphyrin system through gallium-nitrogen bonds and it has also a hydroxyl group and water as axial ligands. Since **1** and **2** are relatively complex metalloporphyrins, mass spectrometric behavior of such type compound was extensively studied using a simpler model, AT-1-3 (3) which is an important synthetic starting material for **1** and **2**.

When **3** was measured with the four matrices, molecular ion species such as protonated molecule $(M+H)^+$ and cationized molecule $(M+Na \text{ or } K)^+$ were not detected. Instead characteristic ions (**a** and **b**) which were formed by a loss of the axial ligands (H_2O and/or OH) appeared together with their matrix-attached ion (**e**) in molecular ion region. These are corresponding to ions shown in Fig. 1. Additionally their associated ions with Na^+ and K^+ were occasionally found. Other fragmentations such as elimination of carbon monoxide and formic acid mainly occurred in the propionic acid side chains under SIMS conditions.

On the other hand SIMS spectra of an alternative model compound, AT-1-3(OAc) (4), in

which a hydroxyl group and water as axial ligands in **3** are displaced by acetoxyl group and acetic acid, respectively, were measured under same conditions. In this case the $(M+H)^+$ ion clearly appeared at m/z 749 together with **b** type ion. The linked scanning (B/E mode) from the $(M+H)^+$ show that **a** (m/z 689) and **b** (m/z 629) ions are directly derived from the parent ion. These results support that **4** is a six-coordinated metalloporphyrin.

Although the similar results were obtained using the four matrices, a characteristic behavior was observed in the cases of glycerol and magic bullet. That is, these matrices reduced the substrate to give partially reduced product which did not show normally calculated pattern for gallium-containing compound (^{69}Ga:^{71}Ga=6:4), while normal spectra were surely obtained using NOBA and NPOE. However, because NPOE has a drawback that it dissolve poorly this type compound, NOBA proved to be most suitable for our study.

Finally measurements of **1** and **2** were carried out based on the results mentioned above. As expectedly no molecular ion species appeared, but **b**, $(b+Na)^+$ and $(b+K)^+$ ions were observed as the highest ion species. These correctly give molecular weight information apart from axial ligands.

The results accumulated in this study clearly indicate that liquid SIMS with NOBA is promising for structural characterization of metalloporphyrins and would contribute to various studies in this field. Now we are studying metalloporphyrins containing other metals.

UTILITY OF LC-MS FOR THE ANALYSIS OF CHLORAMPHENICOL AND SEVERAL OF ITS ANALOGUES

W. A. Korfmacher, T. A. Getek, E. B. Hansen, Jr., C. E. Cerniglia, S. Abou-Khalil[1] and A. A. Yunis[1]

INTRODUCTION

Chloramphenicol (CAP) is a broad spectrum antibiotic. The clinical use of CAP has decreased because CAP is known to be hemotoxic and to cause aplastic anemia in humans (1,2). Therefore, CAP is used in humans only when other less toxic antibiotics have no effect, for example, for treatment of ampicillin resistant H influenza strains. HPLC analysis of CAP in biological fluids is typically performed using ultraviolet detection (3). More recently, electrochemical detection of this compound has been reported (4).

Thermospray (TS) is a recently developed mass spectrometric (MS) ionization technique that is ideal for direct LC-MS analysis of samples (5,6). Thus, it was decided to investigate the utility of TSMS and direct LC-MS for the analysis of CAP and several of its analogues which are potential metabolites of CAP. The TS mass spectrum of CAP has been reported (7), but no information on the LC-MS analysis of this compound or its analogues has been published.

In this report, we describe the LC-TSMS analysis of CAP and 3 of its analogues which are potential metabolites of CAP. The TS mass spectrum of CAP glucuronide is also reported.

EXPERIMENTAL

Chemicals

CAP was purchased from Parke-Davis (Morris Plains, NJ). The dehydrochloramphenicol (DHCAP), the aminodehydrochloramphenicol (ADHCAP), and the *nitrophenylaminopropanediol (NPAPOL) were provided by Zambon Labs (Milan, Italy).* Chloramphenicol glucuronide (CAP-GLU) was purchased from Sigma Chemical Co. (St. Louis, MO).

Thermospray Mass Spectrometry (TSMS)

Thermospray mass spectrometry was performed using a Delsi (Houston, TX) R1010C quadrupole mass spectrometer system equipped with a Vestec (Houston, TX) thermospray source. Twenty microliter volumes of the sample were directly injected into the TSMS system in order to obtain TS mass spectra of the individual samples. Except where indicated, all experiments were performed in the "filament off" and "discharge off" thermospray ionization mode.

Liquid Chromatography-Mass Spectrometry (LC-MS)

LC-MS analyses were performed using the TSMS system described above with a Supelco (Bellefonte, PA) 5 micron diphenyl bonded phase HPLC column (25 cm x 4.6 mm) added in line between the Rheodyne (Cotati, CA) 7125 LC injector and the TS inlet. The mobile phase consisted of 0.05 M ammonium acetate (adjusted to pH 4)/methanol/isopropanol (80/10/10, v/v/v) and was set to 1 ml/min. The source block was set to 286°C, the control temperature was set to 118°C, and the tip temperature was 232°C.

RESULTS AND DISCUSSION

LC-TSMS analysis of a mixture containing CAP, DHCAP, NPAPOL, and ADHCAP was performed using the conditions described above. Baseline separation of the 4 compounds was achieved with an HPLC analysis time of less than 25 min. Figure 1 shows the TS mass spectrum obtained for CAP. Under TSMS conditions, CAP produced $[M+H]^+$ ions at m/z 323 and fragment ions, including a peak at m/z 305 which may be the $[M+H - H_2O]^+$ ion. Similar TSMS results were obtained from the analysis of DHCAP, ADHCAP and NPAPOL.

Using the "discharge on" mode, similar spectra were obtained for these 4 compounds. The main difference was an increase in signal. Using the "discharge on" mode and limited range mass scanning conditions, a detection limit of 10 ng was obtained for CAP when analyzed by direct (flow injection) TSMS.

The results obtained by TSMS analyses of CAP-GLU were found to be particularly dependent upon the TS conditions. In general, a significant peak at m/z 499, corresponding to the $[M+H]^+$ ion, was obtained along with a peak at m/z 516, attributable to the $[M+NH_4]^+$ ion. In addition, fragment ions at m/z 481, m/z 340, m/z 323 and m/z 305 were observed, corresponding to the $[M+H - H_2O]^+$, $[M+NH_4 - 176]^+$, $[M+H - 176]^+$ and $[M+H - H_2O - 176]^+$ ions, respectively. The loss of 176 corresponds to the elimination of dehydroglucuronic acid and is characteristic of glucuronic acid conjugates analyzed by TSMS and FABMS (8,9).

CONCLUSIONS

TSMS has been shown to be a useful method for the analysis of CAP and several of its analogues including CAP-GLU. LC-MS analysis of CAP and 3 of its analogues has also been demonstrated. This methodology should be applicable for the analysis of CAP and its metabolites obtained from *biological* studies.

THERMOSPRAY (TSP) FRAGMENTATIONS OF AMIDINOUREAS AND LC/MS METHOD FOR QUANTIFICATION OF LIDAMIDINE AND ITS N-DESMETHYL METABOLITE

S.-Y. Tang, Rorer Central Research,
800 Business Center Drive, Horsham, PA 19044

Lidamidine, [1-(2,6-dimethylphenyl)-3-methyl amidinourea] hydrochloride (RG W-1142A), has been shown to have potent antimotility, antidiarrheal, and intestinal antisecretory activity in mice, rats, and dogs. It has been tested in man and has demonstrated efficacy as an antidiarrheal drug. Analysis of this drug and its metabolites in biological fluids cannot be obtained by GC/MS techniques because of its thermal lability. GC/MS through chemical derivatization also experienced great difficulty due to low recovery and the formation of secondary reaction products.

TSP is a soft ionization technique which produces predominantly pseudo molecular ions. In most applications fragmentations are minimal, however, for very delicate compounds, fragmentations do occur. Amidinoureas fall into the latter category of compounds which fragment even under pure thermospray ionization. To apply LC/MS as a qualitative and quantitative technique for the analysis of lidamidine and its metabolites, we have studied the thermospray fragmentations of some amidinoureas, lidamidine (RG W-1142A), N-desmethyl lidamidine (RG W-1049), and RG W-1094. Figure 1 shows their structures.

Using 0.1 M ammonium acetate as the buffered solution, amidinoureas gave $M \bullet NH_4^+$ ions at either pH 7 or pH 4, adjusted by either CH_3COOH or CF_3COOH. When an organic modifier (CH_3OH or CH_3CN) was used in the buffer, $M \bullet H^+$ ions started to form. With CH_3OH/0.1 M NH_4OAc (50/50, V/V) adjusted to pH 4.0 with CH_3COOH, lidamidine gives both $M \bullet H^+$ and $M \bullet NH_4^+$ ions. When the pH was adjusted to 4.0 with CF_3COOH, lidamidine forms predominantly the $M \bullet H^+$ ion (Figure 2). The bond cleavages of amidinoureas under thermospray ionization mainly occurred at C-N bond, with hydrogen transfer, and with the formed molecules containing a terminal $-NH_2$ group. Assignments of the TSP ions of the amidinoureas studied are listed in Table 1.

Since RG W-1142, -1049 (Figure 3), and -1094 give predominantly $M \bullet H^+$ ions when a mobile phase of 50/50 (v/v) CH_3OH/0.1 M NH_4OAc (pH adjusted to 4.0 by CF_3OOH) was used, a TSP LC/MS assay for lidamidine (RG W-1142) and its N-desmethylated metabolite (RG W-1049) in rat plasma was developed. The assay involves a solid phase extraction of plasma samples from a C-18 bond-elut column. RG W-1142, -1049, and 1094 (added as internal standard) were eluted from the column with 10% ethylacetate in methanol. Using a Supelco 15 cm x 4.6 mm, 5 μ, LC-8-DB column and the above mentioned mobile phase, the quantities of RG W-1142, -1049, -1094 were determined by selected-ion-monitoring (SIM) of their protonated molecular ions from the TSP mass spectra while they were eluted from the HPLC column.

Linear standard curves were obtained by spiking blank plasma (1 ml) with 100-600 ng of RG W-1142A, 10-100 ng of RG W-1049A, and 300 ng of the internal standard (RG W-1094A). Very good linear (r = 0.99) calibration curves were obtained for RG W-1142A (Figure 4) from 100 to 600 ng/ml and RG W-1049A (Figure 5) from 40 to 100 ng/ml. The results indicate that TSP LC/MS is a suitable quantitation technique for lidamidine in rat plasma.

THE USE OF THERMOSPRAY LC/MS/MS FOR THE CLASS IDENTIFICATION AND STRUCTURAL VERIFICATION OF PHYTOESTROGENS IN SOY PROTEIN PREPARATIONS:

Robert J. Barbuch and John E. Coutant; Merrell Dow Research Institute, Cincinnati, OH 45215; K.D.R. Setchell and Mary Beth Welch; Children's Hospital Medical Center, Cincinnati, OH 45229

The ubiquitous occurrence in plants of compounds possessing estrogenic activity has led to extensive studies of their effects in animals following their ingestion. Deleterious effects upon reproduction have been reported for several animal species including sheep, California quail, rats and exotic cats and attention has recently focussed on the potential role of dietary estrogens in man.

Two main classes of phytoestrogens occur in plants, the isoflavones and coumestans and both groups are heterocyclic phenols having close structural similarity to the naturally occurring mammalian estrogenic steroids.

Suitable methods are therefore required for the detection of this class of compounds and a technique utilizing liquid chromatography with ultraviolet, electrochemical detection and thermospray ionization-mass spectrometry was recently developed (1). The latter procedure, however, yields mass spectra characterized by intense protonated molecular ions with no structural information. We therefore report on the use of a thermospray ionization LC/MS/MS technique for these compounds that affords greatly increased specificity and allows the screening for compounds bearing commonality in structure (see Figure 1). The method has been applied to the detection of phytoestrogens in a variety of diets and biological fluids.

The LC/MS/MS was run with a Vestec LC/MS interface on a Finnigan MAT TSQ-46. The separations were run on a Hypersil ODS (C_{18}) column with a mobile phase of 60/40 methanol/0.1 M ammonium acetate at 1.3 mL/min. Argon was used as the collision gas at an indicated cell pressure of 2 millitorr and a collision energy of -30eV.

The phytoestrogens have intense protonated molecular ions and their daughter ion spectra contain ions unique to the different structural characteristics of each phytoestrogen subclass and can be used both to confirm identification and propose structures for unknowns. In addition to unique ions, phytoestrogens also show a common neutral loss of 56 (due to consecutive losses of CO) that can be used as a class identifier to detect phytoestrogens.

A neutral loss of 18 amu is the subclass identifier for Daidzein, Genistein, and similar compounds. Formononetin, Biochanin A, and similar compounds show neutral losses of 15 and 32 amu. The subclass identifier for Coumestrol is a neutral loss of 44 amu.

In the Old Nebraska Feline Diet, Daidzein and Genistein were detected as well as an unknown phytoestrogen of the Biochanin A subclass. This unknown has been tentatively identified as 6,7-dihydroxy-4'-methoxyisoflavone using its daughter ion spectrum.

These results demonstrate the utility of thermospray LC/MS/MS for the class identification and structural assignments of phytoestrogens in diet preparations.

Thermospray LC/MS and GC/MS analysis of oxygenated metabolites of polyunsaturataed fatty acids

Hee-Yong Kim and Norman Salem Jr.
Laboratory of Clinical Studies, DICBR, NIAAA, ADAMHA, Bldg. 10, Room, 3C-218, 9000 Rockville Pike, Bethesda, MD 20892

Polyunsaturated fatty acids can be oxygenated by lipoxygenase to form hydroperoxy and, subsequently, hydroxy derivatives. It is often suggested that these compounds may possess significant biological activity. Analysis of such compounds produced in biological systems is sometimes quite difficult, since complex mixtures may be formed via several possible enzymatic and non-enzymatic pathways.

Reversed phase liquid chromatography in conjunction with on-line thermospray mass spectrometric and UV detection provides a simple and efficient method for qualitative analyses of eicosanoids or related compounds, since complex mixtures can be separated and analyzed simultaneously. In addition to the molecular weight, the number and type of functional groups can often be deduced from the simple fragmentation pattern found in the thermospray spectra of these oxygenated metabolites (1,2). However, GC/MS analysis after derivatization is usually necessary to confirm the position of oxygenation.

Thermospray LC/MS analysis of the hydroperoxy forms of these polyunsaturates indicates that information concerning the position of this functional group can be readily obtained from the spectra. Using ammonium acetate and methanol as carrier solvent, thermospray ionization resulted in cleavage of the C-C bond adjacent to the hydroperoxy group. Examples are depicted for 15- and 5-hydroperoxyeicosatetraenoic acids (HPETE) in figure 1. The peaks at m/z 336, 320, 319, 318, 303 and 301 represent the $MNH_4^+-H_2O$, $MNH_4^+-H_2O_2$, MH^+-H_2O, $MNH_4^+-2H_2O$, $MH^+-H_2O_2$ and MH^+-2H_2O, respectively. Besides these simple fragments which preserve the intact carbon backbone, additional fragments (F) were observed from the cleavage of $C_{15}-C_{16}$ and C_4-C_5 for 15- and 5-HPETE, respectively. These fragments also produced the cluster of ion peaks including $FNH_4^+-H_2O$, FH^+-H_2O, $FNH_4^+-H_2O$ and FH^+-2H_2O, although the relative intensities of each peak differ between isomers. In order to determine if this fragmentation generally occurs, hydroperoxy derivatives of docosahexaenoic acid (22:6w3) prepared by autooxidation were examined. These derivatives were separated by reversed phase chromatography using an Axxichrom ODS column (5u, 4.6mm x 25cm) and a linear gradient of 0.1M ammonium acetate : methanol ranging from 40:60 to 10:90 in 60 minutes with a flow rate of 0.8 ml/min. Each separated isomer was detected by UV, then analyzed by the thermospray mass spectrometer in a continuous manner. Spectral analysis of the ion chromatogram thus obtained (figure 2) showed that each isomer fragments essentially in the same fashion observed for HPETE's. They all exhibited the same peak clusters of MNH_4^+, MH^+, $MNH_4^+H_2O$, $MNH_4^+-H_2O_2$, MH^+-H_2O, $MNH_4^+-2H_2O$, $MH^=-H_2O_2$ and MH^+-2H_2O at m/z 378, 361, 360, 344, 343, 342, 327 and 325, respectively. However, the fragment ion peaks, $FNH_4^+-H_2O$, FH^+-H_2O, $FNH_4^+-2H_2O$ and FH^+-2H_2O were specific to the corresponding isomers. All of the ten possible isomers could be represented by FH^+-H_2O in this chromatogram except the 8-hydroperoxy derivative which was displayed using $FNH_4^+-H_2O$. From these observations, it is apparent that structure determination based on the fragmentation of the C-C bond adjacent to the hydroperoxy group is generally applicable to isomers of various chain lengths and numbers of double bonds. This procedure can eliminate the need for GC/MS analysis which requires lengthy purification and derivatization steps. This approach is particularly useful for analyzing lipoxygenase reaction mixtures where reductase activity is low or absent, such as in some *in vitro* incubations with pure enzyme preparations.

As an application, 22:6w3 was incubated with soybean lipoxygenase-1 *in vitro*. The spectrum of the primary product showed the peaks at m/z 378, 361, 360, 344, 343, 342, 327 and 325 which were expected for any hydroperoxy 22:6w3. From the fragment ion peaks at m/z 292, 275, 274 and 257 which correspond to $FNH_4^+-H_2O$, FH^+-H_2O, $FNH_4^+-2H_2O$ and FH^+-2H_2O, respectively, the structure was readily deduced to be 17-hydroperoxy 22:6w3.

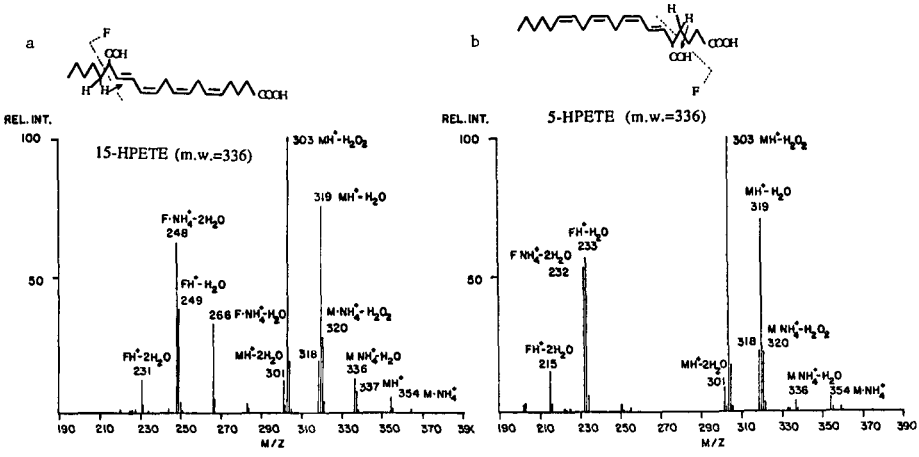

Figure 1. Thermospray mass spectra of 15- (a), and 5-HPETE (b) obtained by injecting lug each through a reversed phase column, as described for the autooxidized 22:6w3 in the text.

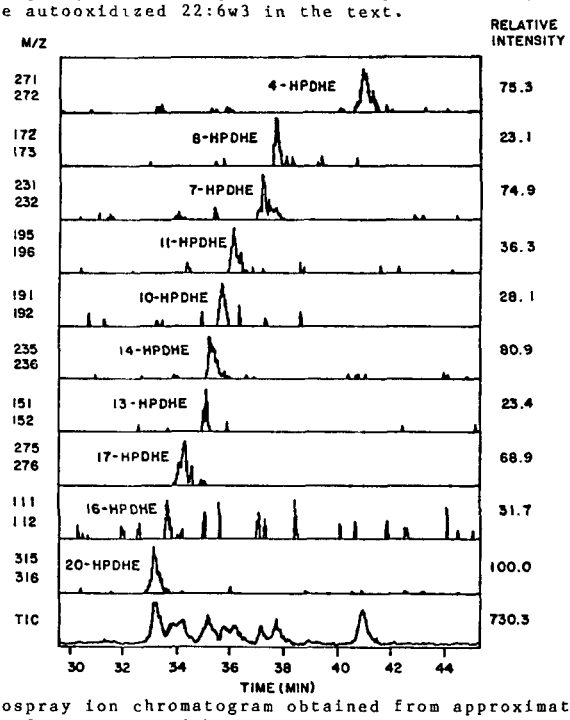

Figure 2. Thermospray ion chromatogram obtained from approximately 10ug total of autooxidized hydroperoxy 22:6w3.

INVESTIGATION OF FLAVONE-8-ACETIC ACID METABOLITES BY THERMOSPRAY AND GAS CHROMATOGRAPHY MASS SPECTROMETRY

Jan R. Crowley, Robin J. Hood, Department of Chemistry and Guy Chabot, Division of Oncology, Wayne State University, Detroit ,Michigan 48202

Flavone-8-acetic acid (FAA;NSC-347512) is a new anticancer drug with broad solid tumor activity. In preclinical studies it was found to be active against a variety of transplantable solid tumors of mice. Among the tumors studied were some pancreatic ductal adenocarcinomas, colon adenocarcinoma mammary adenocarcinoma and ovarian tumors. It was found to be curative for colon adenocarcinoma #38. Studying the metabolism of a drug can often provide a clearer understanding of how the drug functions. Initial metabolism studies of FAA have been done with the urine of mice injected with the drug using both TSP/MS and GC/MS keeping two questions in mind. Can good TSP spectra be obtained with the drug and if so are there any advantages over GC/MS? And can one use GC/MS and/or TSP/MS to obtain information about the metabolism of the drug.

A Finnigan 4000 GC/MS system equipped with a Vestec Thermospray ionizer was used in the study. Optimum operating parameters for TSP/MS included a reverse phase isocratic solvent system H_2O:CH_3CN:HOAC (65:35:1), a 1.5 ml/min flow rate and a vaporizer temperature of 240-260 degrees. GC conditions included a 15M methyl silicone capillary column with splitless injection. Temperature programming was from 100-280 deg at 20 deg/min. The initial temperature was held at 100 deg for one min. The samples were all heated for 30 min. at 60 deg. with BSA to form a TMS derivative before GC/MS analysis.

Thermospray of FAA and hydroxylated FAA standards gave good spectra. The base peak is M+1 with little other fragmentation observed. An example of this is shown in FIG 1. GC data shown in FIG 2 provided more stuctural information and the M+ was always present. The sensitivity of GC/MS was about 30x greater than TSP/MS.

Ethyl acetate extracts of urine from BGD2F1 mice which had been injected with FAA (180 mg/kg,i.v.) were analyzed. Thermospray data provided supporting evidence, in addition to the H.P.L.C. retention times, that unmetabolized FAA and the glucuronide conjugate of FAA accounted for most of the injected FAA. dose, FIG 3. and FIG 4. Thermospray of the conjugate provided some structural information in addition to the molecular weight data.

Negative ion thermospray gave no additional structural information from that observed with positive ions. However, the molecular ion for the glucuronide was sometimes not observed with positive ions but was always seen with negative ions. If the NH4OAC was not in the solvent the ratio of M+1/fragment ions was improved although the overall sensitivity was down. The glucuronide was not volatile enough for GC analysis. While the FAA conjugate is not important for the function of the drug, if the FAA is metabolized to the antitumor agent this agent could very probably also be conjugated and therefore not found by GC/MS. Therefore TSP/MS will primarily be used for detection in future studies.

Southampton, UK

M.R. Clench*, R. Owen, V.C. Parr, O. Weir and D. Wood
VG Tritech Ltd, Crewe Road, Wythenshawe, Manchester, UK.

Introduction

Measurement of urinary organic acids can be useful in the diagnosis of a number of inherited metabolic disorders which may be present in infancy. Their usual method of analysis is by capillary gas chromagraphy with or without mass spectrometry after extraction and derivatisation. Recently HPLC using cation exchange columns and ultraviolet (UV) detection at 210nm has been proposed as a rapid alternative technique. To overcome the lack of specificity of ultraviolet detection we have investigated the potential value of combined plasmaspray HPLC-MS for profiling organic acids (1). A problem however was that the detection limits with the initial source design did not allow normal levels of acids to be seen.

We report here experiments with an ion source modified for improved sensitivity, and some preliminary MS/MS experiments.

Experimental

HPLC: Aminex HPX-87W cation exchange column (300 x 7.8mm)
25mmol/litre formic acid at 0.8ml/min 50°C ± 0.1

Mass Spectrometry: VG Tritech TS-250 mass spectrometer with plasmaspray interface
Accelerating Voltage: - 4000V
Resolution: 500 (10% valley)
Source Temperature: 250°C Vapour Temperature: 140°C
Plasma discharge voltage: 500V
CID : 4keV Energy

Results and Discussion

Analytical Results

Under the experimental conditions organic acids exhibit intense (M-H)- ions with little fragmentation. The minimum detection limit of the system in the single ion recording mode (SIR) was 10ng for hipperic acid (Fig 1). This contrasts to a detection limit of 400ng reported with the previous interface and source design (2). The new sensitivity levels allow normal levels of organic acids to be observed.

Daughter ion spectra of the acids (Fig 4 & 5) show characteristic loss of a CO_2 group (M-1-44)-. Multiple reaction monitoring of the transistion 178 -> 134 in hippuric acid gave a detection limit of 50ng. In further work it is hoped to demonstrate the diagnosis by loop only injection of organic aciduras by loop only injection making use of the increased specificity of MRM to eliminate the chromatographic step.

Clinical Results

Figures 2 and 3 show selected ion recording traces for m/z 117 and 115 for two patients diagnosed as suffering from methyl malonicaciduria and fumaric aciduria. The evelated levels of the two acids can be clearly seen.

Application of Thermospray Liquid Chromatography-Mass Spectrometry to the Analysis of Bile Acids

C. H. Vestal, and K. D. R. Setchell, Vestec Corporation, Houston, TX 77054, and Clinical M.S. Labs., Children's Hospital Res. Found., Cincinnati, OH 45229

Chromatographic techniques are widely used in clinical and clinical-research laboratories for the analysis of bile acids. Most frequently bile acids are analyzed by GC or GC-MS as derivatives of the unconjugated bile acids following isolation and hydrolysis of the conjugate moiety. Direct derivatization of the glycine conjugates without hydrolysis has been applied to serum analysis. Taurine conjugates have not been successfully analyzed by GC without prior hydrolysis. However, major strides have been made in the use of HPLC for bile acid analysis yet the main problems with the technique continue to be the relative lack of specificity and chromatographic resolution. Despite the use of pre- and post-column reactions and more selective detectors, interferences from the biological matrix and difficulties with peak identification remain the main problems to overcome. With the advent of thermospray LC-MS the HPLC eluent may be continuously monitored and mass spectrometer employed as a highly specific and sensitive detector.

A series of glycine and taurine conjugated bile acids were studied using a Vestec Model 201N Dedicated Thermospray LC-MS system. LC separation employed a Beckman Ultrasphere-ODS column (4.6mm x 25cm, 5 micron particle size) with deionized water/methanol (containing 0.1M ammonium acetate), pH = 5.7 (25/75 V/V) as the mobile phase. All of the compounds analyzed elute within 25 minutes at a flow rate of 1.0 mL/min. Figure 1 shows the total ion chromatogram of 8 conjugated bile acids 5 μg each of the standards was injected onto an ODS column while scanning m/z 400-550 in 5.5 seconds and using filament-on ionization. Glycochenodeoxycholic acid (GCDCA) and taurodeoxycholic acid (TDCA) coelute at 11 minutes. Apparently there is partial separation of these two compounds, even though they are not resolved in the TIC. Greater sensitivity is achieved in negative ion detection mode compared with positive ion which tends to give NH_4^+ adducts. The thermospray negative ion spectrum consisted of the base peak at $(M-H)^-$ with some fragmentation corresponding to consecutive losses of water. Typical examples are shown in Figure 2. The most important parameter for the analysis of conjugated bile acids is the thermospray vapor temperature. Increasing either the source temperature or the vaporizer temperature causes an increase in fragmentation, and at vapor temperatures above about 280°C the fragment ion is the base peak. The optimal thermospray conditions are the following: T_1(control temp.) = 126°C, T_2(vaporizer temp.) = 201°C, T_3(source block temp.) = 318°C, T_4(tip heater temp.) = 315°C, T_5(vapor temp.) = 265°C, and T_6(lens heater temp.) = 120°C.

Results for the standards obtained using the thermospray filament-on ionization and negative ion detection are summarized in Table I. The detection limits are in the range of 4 to 10 nanograms (10 to 25 picomoles) using selected ion monitoring (only monitoring the deprotonated molecular ions).

The bile acids and their conjugates from serum were extracted using commercially available reverse-phase octadecylsilane bonded silica cartriges (1). The bile acid concentrations of bile or duodenal aspirate (mmole/L) are much higher than those of serum (μmole/L). Extracts of human bile (patients B1 and B2), pig bile, and serum (patients S1 and S2) were analyzed using thermospray LC-MS. Figure 3 shows the TIC of (a) human bile (patient B1) and (b) pig bile compared with that of the standards under the full scan conditions. Results on the serum extracts using selected ion monitoring are shown in Figure 4 and summarized in Table II. Applications to the analysis of bile acids in biological samples presented in this paper serve to highlight the potential of thermospray LC-MS interface for enhancing the specificity of the HPLC technique.

THERMOSPRAY LC/MS STUDIES WITH INOSITOL PHOSPHATES

Fong-Fu Hsu, H. Duane Goldman and William R. Sherman

**Washington University School of Medicine, Department of Psychiatry,
St. Louis, MO, 63110.**

D-myo-Inositol-1,4,5-trisphosphate (IP_3)is an intracellular "second messenger" that is produced from phosphatidylinositol-4,5-bisphosphate following receptor stimulation. The production of this trisphosphate is one of the early steps in a series of metabolic events that lead to the functional result called for by the stimulation. Thus the appearance of the trisphosphate is evidence for the participation of specific receptor-linked events, information that is often difficult to obtain by other means. Recent advances in this area have revealed the presence of a large number of metabolites of IP_3 including mono-through pentakis-inositols as well as isomers of many. Even hexakis-inositol phosphate (phytic acid), previously thought to be only a plant product, has been found as a metabolite in mammalian cells.

The analysis of IP_3 most often used is radiometric, following experiments in which the establishment of labeling equilibrium is usually an uncertainty. Information about minor components is often lost because of the necessity for incremental collection of eluates. Because of the increasing involatility and adsorption losses of inositol phosphates, as the number of PO_4 moieties increase, gas-phase methods have thus far been unusable for biologically-relevant amounts of material (low picomolar amounts per analysis) except in the case of the inositol monophosphates which can be analyzed readily by GC/MS (1). Thus there is a need for a sensitive mass-based and general analytical method that has not yet been met.

When we examined the (+)ive ion thermospray LC/MS of inositol mono- to hexakis-phosphates, using ammonium formate as the eluting buffer, in no case did we find surviving phosphorylated inositols; only the total hydrolysis product is seen as the ion m/z 198, i.e., $[NH_4 \cdot Inositol]^+$. This was the case even with inositol hexaphosphate where all phosphates were removed and no trace of the parent species was seen. Hoping to find that we were only seeing trace amounts of hydrolysis products because the phosphates did not form (+)ive ions we looked to the (-)ive ion spectra and found there only ($[Inositol \cdot HCOOH\text{-}H]^-$) with smaller amounts of $[Inositol\text{-}H]^-$, again, all of the phosphates were removed in every case examined. As a result information regarding the phosphate content of each species is lost and is revealed only by elution order necessitating the establishment of that elution order by other means.

Since it appeared that the loss of phosphate was by hydrolysis as the sample passed through the heated thermospray tip (at a temperature that was determined by the thermospray process) we decided to maximize the hydrolysis by using a heated length of stainless steel or nickel capillary tubing as a reactor prior to thermospray analysis. A cooling section following the reactor was necessary in order to retain thermospray tip temperature regulation by the control thermocouple. By this means the sensitivity was increased over ten-fold (Figure 1), the minimum amount detectable with loop injection being about 50 pmole (s/n 4:1), decreasing, due to adsorptive losses, as the number of phosphate moieties increase.

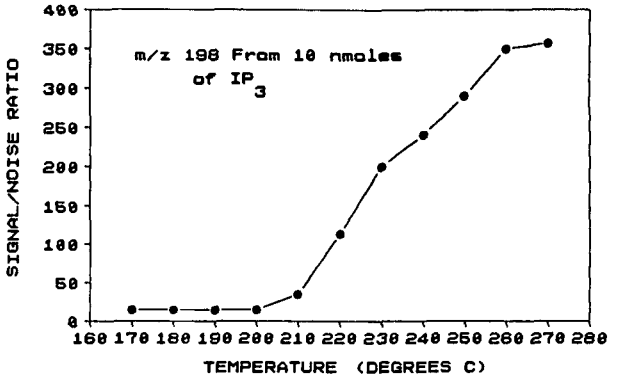

Figure 1

Thermospray ionization is strongly affected by the eluting buffer, and the inositol phosphate separations are brought about by ionic strength gradients. An improvement in the method, which eliminates the effects of the gradient on the thermospray ionization process, is to run a counter-gradient which is mixed with the column effluent to normalize the salt content, thus simplifying the establishment of optimum thermospray ionization conditions. This can be achieved either by using a separate set of gradient-forming HPLC pumps or by using two low-pressure gradient makers each supplying an HPLC pump.

We have also explored the effects of acetylation of inositol phosphates on separations by gradient-elution ion exchange chromatography and the effects of that derivatization on thermospray ionization. The (+)ive ion spectra obtained showed that both thermospray-induced phosphate hydrolysis and acetate hydrolysis took place. Use of the thermal reactor increased the analytical sensitivity of the acetates as it did with the underivatized inositol phosphates. Molecular ions were of low intensity and, surprisingly, the first losses from either MH^+ or $[M{\cdot}NH_4]^+$ is phosphate, not acetate. This is followed by acetate loss (- 42 U, it is not known whether by fragmentation or hydrolysis). No ions corresponding to hydrolytic loss of acetate from either of the parent ions are observed. Because there are high-mass ions that do not lose acetate, information is retained about the degree of phosphorylation of the species eluting from the chromatographic process. Thus an inositol trisphosphate and a tetrakisphosphate will show high mass ions of the triacetate-triol and the diacetate-tetraol respectively. While the total ion current is distributed between a number of ions, the sensitivity, using ion monitoring and a structurally-specific ion, is similar to that obtained with underivatized inositol phosphates. In (-)ive ions the highest mass ion seen, in the case of the acetylated trisphosphate, is the diol-monophosphate, but it is of weaker intensity than the completely dephosphorylated species. This work was supported by NIH grants NS 05159, AM 20579 and RR 00954 as well as a grant from Perstorp Pharma, Perstorp, Sweden.

DEVELOPMENT OF A QUANTITATIVE LCMS ASSAY FOR THE DETERMINATION OF GR 43175 BASE IN PLASMA.

J. Oxford and M.S. Lant.

Department of Biochemical Pharmacology,
Glaxo Group Research Limited, Ware, Hertfordshire, U.K.

INTRODUCTION

GR 43175C is a '5HT$_1$-like' receptor agonist effective in the treatment of migraine (1). During early development of the drug an analytical method was required for the analysis of human plasma samples. The assay requirements were that it should be developed rapidly, have an accuracy and precision of approximately 10% or better and a limit of quantification of 5ng/ml. Thermospray LCMS (TSP LCMS) was selected because it offered the advantages of specificity i.e. minimal sample 'clean-up' would be required and robustness, in that it can be connected on-line to an Advanced Automated Sample Processor (AASP) (2).

METHODS

Compounds: GR 43175C, GR 40370B and [$^2H_3$]GR 43175 base (Figure 1) were supplied by the Chemistry Division, Glaxo Group Research Limited, Ware, Hertfordshire, U.K.

Isolation: 1ml portions of centrifuged plasma samples or standards containing GR 43175 base and either 24ng GR 40370B or 50ng [$^2H_3$]GR 43175 base were applied to conditioned C_2 AASP cartridges. The cartridges were eluted on a Vac-Elut box then washed with 1.8ml water and 1.8ml water : methanol (7 : 3) prior to loading onto the AASP module (Varian) which was connected via a column to the TSP interface (Vestec).

Instrumentation: A 3µm Spherisorb ODS2 column (5cm x 4.6mm i.d.) protected by a Waters C_{18} guard column was eluted with methanol : 0.1M ammonium acetate (60 :40) at a flow rate of 1ml/min. The HPLC pump was an HP 1090. The mass spectrometer (HP 5987A) was operated at a source temperature of 250°C in the positive ion (filament off) mode. The protonated molecular ions m/z 296, 299 and 310 derived from GR 43175 base, [$^2H_3$]GR 43175 base and GR 40370 base respectively were monitored. Data were acquired and processed using the standard HP 1000 software.

RESULTS AND DISCUSSION

The combination of the AASP with TSP LCMS gave the advantage of analysing 100% of a 1ml plasma extract. Although the isolation method was precise (93.9% ± 1.3%, n = 4) an internal standard was needed to compensate for TSP variability. The assay precision using a homologue, GR 40370 base which was partially resolved from GR 43175 base, was too variable, however [$^2H_3$]GR 43175 base gave superior results. Figure 2 shows typical SIR chromatograms obtained from the analysis of plasma standards.

The working range of the assay was 2 - 50ng/ml. The assay was limited to 2ng/ml because a component from the AASP cartridge eluting slowly from the analytical column had an adverse effect on the accuracy and precision of the measurement of lower concentrations. Over the range 5 - 50ng/ml the intra-assay variability was <5%, at 2ng/ml it was 11% (n = 6). Similar results were achieved for the inter-assay variability. In contrast, with GR 40370 base as internal standard, the intra-assay variability was higher (up to 26% at 22ng/ml). The assay has been used for the analysis of human plasma samples following administration of GR 43175C.

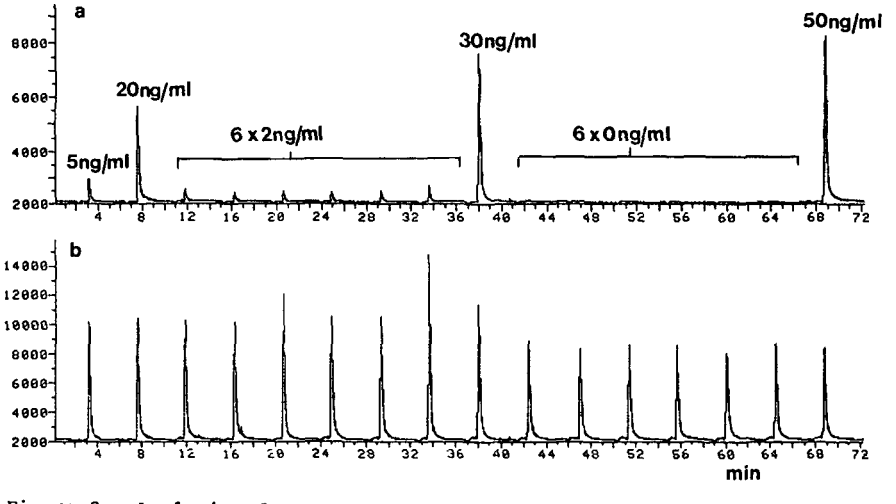

Figure 2. Analysis of 16 prepared AASP cartridges (a) m/z 296-GR 43175 base, (b) m/z 299-50ng, internal standard, [$^2H_3$]GR 43175 base/ml plasma.

CONCLUSIONS

A reliable, accurate and precise LCMS assay was developed for the analysis of GR 43175 base in plasma, meeting specified criteria. Since selective and specific AASP-TSP LCMS assays can be developed relatively quickly, this technique is used in our laboratory to provide an important preliminary assay for drug absorption studies prior to longer term development of a cheaper assay for routine analyses.

pH-related changes in relative ion intensities of fragments of LY170680;

*Breau, A., P. and Goodwin, R. M., Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN 46285.

OBJECTIVE: The principal objective of this study has been to evaluate the thermospray LC/MS technique for the detection of LY170680, a leukotriene antagonist in plasma. Since the acid group and tetrazole moiety of the molecule can be ionized in solution it was postulated that pre-formed ions could be generated more easily at low pH, thus enhancing the thermospray ionization efficiency and increasing the sensitivity of the assay. In fact, altering mobile phase pH did not dramatically increase the total ionization of LY170680, but pH dependent relative fragment intensity differences were observed. Previous thermospray studies have noted that source temperature, tip temperature and mobile phase composition influence LC/MS thermospray fragmentation patterns. In this study, ion source temperature, tip temperature and mobile phase composition were held constant and the mobile phase pH altered.

MATERIALS AND METHODS: Investigations of the pH effect were performed using a direct loop mode in order to perform the comparative analyses without having to re-equilibrate the column. This allowed rapid analysis, minimizing any changes in instrument parameters that could influence the fragmentation patterns. Loop injections of 2 ug were made in 20 ul . Mobile phase (60% methanol/ 40% water) was pumped through the Vestec Thermospray interface at 1 ml/minute into a Finnigan 4500 mass spectrometer. The chromatography was monitored in-line with an absorbance detector set at 237nm. The interface was operated in the "discharge on" mode with a tip temperature of 208 C and a source block temperature of 300 C. The mass range was 200-500 amu at 2 seconds/scan. The electron multiplier setting was 1350 v in negative ion detection. The pH of the aqueous component of the mobile phase was varied using acetic acid(pH 4.0) or ammonium hydroxide (pH 8.0 and 10.0).

RESULTS: Mass spectrometric analysis of LY170680 using thermospay "discharge on" ionization did not reveal a prominent molecular ion, but two prominent fragments occured at m/z=366 and m/z=350 in negative ion detection. Using a mobile phase at pH 4.0 the major fragment observed was at m/z=366 with a minor fragment at m/z=350. With a pH 8.0 mobile phase a much more intense ion at m/z=350 was observed. At pH 10.0 the major fragment was at m/z=350.

DISCUSSION: Both the acid and tetrazole moieties of LY170680 (Figure 1) have pka's of approximately 4.5. The negative ion fragment at m/z=366 is due to the loss of S-(CH2)2-COOH (figure 2). A plausible mechanism for the formation of this fragment is through attack of the S by the oxygen through a 5-membered ring mechanism (figure 3). The fragment at m/z=350 occurs through the loss of an additional OH group from the fragment at m/z=366 (figure 4) with proton transfer. Since the acid moiety is protonated at pH 4.0 the ionic state of the acid group may affect the 5-membered cyclic rearrangement mechanism and force an alternative mode of fragmentation leading to the formation of the m/z=350 ion.

CONCLUSIONS: LY170680 is structurally similar to such biologically important molecules as leukotrienes and prostaglandins. In the future, it is likely that thermospray LC/MS will be used for the detection of these types of compounds from biological fluids. Thus in some cases it will be necessary to monitor the pH of plasma extracts in order to assure accuracy in quantitation using LC/MS thermospray ionization especially in conjunction with single ion monitoring detection.(The authors thank Mr. John Occolowitz, Dr. William J. Wheeler and Prof. Klaus Biemann for their helpful discussions.)

DEVELOPING ANALYTICAL METHODS FOR DETERMINATION AND CONFIRMATION OF β-LACTAM ANTIBIOTICS IN MILK AND TISSUE USING HPLC/UV AND HPLC/MS.

Robert D. Voyksner and James Raymer, Analytical and Chemical Sciences, Research Triangle Park, NC 27709; Krystyna Tyczkowska, School of Veterinary Medicine, North Carolina State University, 4700 Hillsborough Street, Raleigh, NC 27666.

Maintaining a record for human food safety requires constant efforts in developing and improving analytical methods for animal drug residues in milk or tissue. β-Lactam antibiotics are one class of drugs commonly used in animals destined for human consumption. β-Lactams antibiotics are very polar, non-volatile, and thermally unstable compounds which have few chromophores, preventing sensitive detection. Current research focuses on developing new analytical strategies for the extraction, determination, and confirmation of five β-lactam antibiotics (ampicillin, amoxicillin, hetacillin, cloxacillin, and penicillin G) in tissue and milk by HPLC/UV and thermospray HPLC/MS.

The extraction of the β-lactam antibiotics from a matrix such as milk was performed in one step using a micro separation system. A 0.5 mL milk sample and 0.5 mL of a protein-binding releasing solvent (i.e., acetonitrile:methanol:water 20:40:40) were sonicated then centrifuged through a 10,000 molecular weight cut-off filter. The filtrate can be concentrated or directly analyzed by HPLC/UV or HPLC/MS. The extraction method results in sample recoveries from 68% to 82% for the five β-lactam antibiotics.

HPLC/UV methods were developed for the determination of the five β-lactam antibiotics in milk matrices. The HPLC conditions employed a Brownlee Phenyl-Spheri-5 2.1 mm x 22 cm column using an isocratic mobile phase containing acetonitrile, ion pair reagents S-8 and S-12 and water, (percentages of each solvent were dependent on the particular β-lactam antibiotics analyzed) at a flow of 0.2-0.4 mL/min. The retention time for the target β-lactam antibiotics ranged from 6-13 min. The various β-lactam antibiotics were detected by UV absorbance at 215-225 nm. The HPLC/UV method was very sensitive (detection limit 10-50 ppb) and capable of quantitating each β-lactam antibiotic in milk.

Thermospray HPLC/MS was very specific and sensitive for the detection and confirmation of the β-lactam antibiotics in food matrices. The thermospray spectra of the β-lactam antibiotics exhibited $[M+H]^+$, $[M+NH_4]^+$ and $[M+Na]^+$ ions along with several fragment ions (Table I). The fragment ions detected were postulated to be thermal degradation products. One represented a loss of 26 from the molecular ion due to ring opening followed by hydration and loss of CO_2. The others were from ring opening and cleavage resulting in a common ion for all β-lactam antibiotics at m/z 160 and a specific ion related to the R group of each β-lactam antibiotics. The analysis of hetacillin was also complicated by its conversion to ampicillin in solution (in less than 4 hours).

Thermospray HPLC/MS proved useful for confirming the HPLC/UV assay as well as for quantitation of β-lactam antibiotics in milk. For example, the detection of penicillin G by monitoring the $[M+H]^+$ ion (m/z 335) and $[M+H+H_2O-CO_2]^+$ ion (m/z 309) enabled detection of 10 ng of the β-lactam antibiotic and could be used to generate a linear calibration curve (correlation coefficient 0.9982) from 10-1000 ng. The detection of penicillin G in dosed bovine milk samples showed minimal interference from the milk matrix. The HPLC/MS chromatograms showed a peak at the proper retention time as well as the simultaneous maximization of the ions at m/z 309 and m/z 335 confirming the presence of penicillin G in milk. The comparison of the measured quantity for penicillin G in milk by HPLC/UV and HPLC/MS (Table II) indicates agreement between the two different methods. The mean difference in measured values between HPLC/MS and HPLC/UV was 32%, with the highest errors observed at the lower concentrations. HPLC/UV and HPLC/MS was also useful in showing the difference in the excretion rates of penicillin G in bovine milk. Clearly, penicillin G residue was found in milk 48 hours after bovine dosing at the ppm or high ppb level.

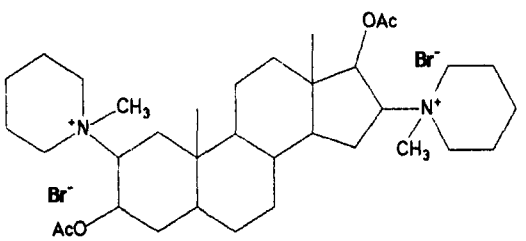
MASS SPECTROMETRIC STUDIES OF NEUROMUSCULAR BLOCKING AGENTS USING CI AND FAB/MS

Timothy R. Baker and Paul Vouros
Northeastern University and Barnett Institute, Boston, MA 02115

J. A. J. Martyn
Harvard Medical School and Massachusetts General Hospital, Boston, MA 02114

Since the introduction in 1942 of curare as an anesthetic, there has been great interest in the chemistry, pharmacology, and clinical uses of a class of compounds known as neuromuscular blocking agents. Among them is Pancuronium, which is a member of a series of bis-quaternary ammonium steroids. Previously reported assays for Pancuronium involved the use of fluorescence, TLC, and direct probe mass spectrometry. There are drawbacks in each one of these methods in terms of specificity and sensitivity.

PANCURONIUM BROMIDE



The purpose of this work is the development of mass spectrometric procedures for the analysis of these bromide salts, based on HPLC coupled to

MS. Of particular interest is the differentiation of the drug Pancuronium from a suspected metabolite, the mono-quaternary analog Vecuronium. As these two compounds are thought to be hydrolysed *in vivo*, analysis of the deacetylated analogs was also a focus of this work. Spectra of the compounds were acquired via the moving belt LC/MS interface in the CI and FAB/MS mode.

In the CI analysis the analytes undergo thermal demethylation upon flash vaporization from the moving belt surface. Spectral patterns can be interpreted on the basis of fragmentation derived from protonated demethylation products. Pancuronium and Vecuronium have identical thermal demethylation products resulting in indistinguishable CI spectra. The sensitivity of this technique has been demonstrated by the detection of three nanograms of Pancuronium with single ion monitoring.

Spectra can be obtained by Fast Atom Bombardment of xenon gas applied directly to the moving belt surface. In all cases fragmentation is initiated by loss of bromide followed by a series of eliminations of piperidine, water, and acetyl groups, in various combinations. An obvious advantage of the FAB technique for analysis of these compounds is the ability to differentiate Pancuronium from Vecuronium. The matrix free environment provided by the moving belt has advantages over the more traditional FAB experiment, in terms of spectral purity.

A normal phase HPLC separation on silica has been developed for Pancuronium and Vecuronium. The adsorption of these charged compounds onto any available metal site necessitated the use of non-metallic tubing and a glass column for this LC/CI-MS assay. The spray device, previously reported by us, for deposition of eluent on the moving belt was modified to incorporate a fused silica insert.The possibility for capillary LC coupled to flowing FAB-MS has also been demonstrated.

The work described here illustrates the applicability of the moving belt introduction system for the mass spectrometric analysis of Pancuronium, Vecuronium, and their deacetylated analogs. Identification of these drugs and their suspected metabolites is possible with CI or FAB/MS.

THERMOSPRAY MS OF MUSTARD GAS AND SELECTED METABOLITES.

E.M. Jakubowski and S. Munavalli
U.S. Army Medical Research Institute of Chemical Defense,
Aberdeen Proving Ground, MD 21010-5425.

Analysis of bis(2-chloroethyl) sulfide, commonly known as mustard gas, has always been difficult due to the reactive nature of the molecule. The ability to analyze for the presence of both mustard gas (actually a liquid, boiling pt 217°C) and its metabolites or degradation products can be of considerable help in their detection and identification as well as in understanding the mechanism of their biological activity. Gas chromatography has been the method of choice for quantification of mustard while mass spectrometry being used for confirmation.[1] The object of this paper was to illustrate the unique capabilities of thermospray LC-MS in the analysis of the warfare agent mustard and its metabolites. Six oxidation and hydrolysis metabolites of mustard have been studied. The mustard was provided by the U.S. Army Medical Research Institute of Chemical Defense in methanol with a concentration of 0.005M. Mustard sulfone, mustard sulfoxide, half mustard, thiodiglycol sulfone, and thiodiglycol sulfoxide were synthesized using known methods from either mustard or thiodiglycol, and their identity and purity were confirmed by GC/MS and NMR. Thiodiglycol was procured from Aldrich Chemical Company, Inc. All analytes were first dissolved in anhydrous methanol and directly injected into the thermospray source using the discharge mode. Characteristic positive and negative ion mass spectra were recorded for all of the compounds listed above except for the negative ion spectrum of mustard due to a low concentration of available mustard solutions. Analytes other than mustard were analyzed at a concentration of 0.01M in methanol. Methanol was glass distilled from EM Science and filtered through a 0.45 micrometer membrane (Millipore, Inc) before being used for TSP LC/MS.

All studies were accomplished on a Finnigan 4500 MS modified with a Vestec interface. A Waters model 510 LC pump was used with a pulse dampener, model LP21 LoPulse, and a Rheodyne injector model 7125. The conditions were as follows: LC flow rate=1.2mL/min, mobile phase=100% methanol, injection volume=20 microliters, TSP control temp.=100°C, TSP tip temp.=150°C, TSP source temp.=300°C.

Direct injection TSP LC/MS of mustard and its metabolites yielded mass spectra dominated by nucleophilic substitution reactions. Representative spectra are shown in Figures 1-4. Ions representative of both condensed phase reaction intermediates and products were observed in the TSP degradation of all analytes. Of particular interest is the appearance of ions that would demonstrate the presence of the postulated three membered cyclic sulfonium ion intermediate or its equivalent. In the condensed phase at ambient temperatures, loss of chloride from mustard has been reported to occur readily to yield a highly reactive positively charged intermediate. Thiodiglycol is stable at room temperature but can under TSP conditions form the thiiranium intermediate or its equivalent (Fig.4 , m/z=105). All of the analytes produced spectra showing the substitution of a methoxy group for either the terminal hydroxy or chloro groups. Mass spectra of the chloro- and hydroxy-congeners differed qualitatively in the methanol matrix. One major difference was the tendency of the hydroxy- compounds to form dimers, trimers, and other polymers. For example, thiodiglycol exhibited an ion at m/z=245 which represents the product of two molecules of the substrate. This ion had a relative abundance of 45%. Polymers were also very characteristic of the negative ion spectra of the thiodiglycol congeners. Another important difference between chloro- and hydroxy-congeners is the appearance of the distinctive chlorine isotopic abundance patterns. For example, mustard has ions at m/z=123 and 125. In general, TSP MS analysis of mustard and its metabolites yielded structural information able to confirm the presence of mustard derivatives.

APPLICATION OF QUANTITATIVE THERMOSPRAY LC/MS TO PULSE DOSE PHARMACOKINETIC STUDIES OF CARBAMAZEPINE IN HUMANS:

M. J. Moor, R. H. Levy, M. S. Rashed* and W. N. Howald*;

Departments of Pharmaceutics and *Medicinal Chemistry, University of Washington, Seattle, WA 98195

Introduction

Thermally labile carbamazepine-10,11-epoxide (CBZ-E), Figure 1, is one of the principal metabolites of the anticonvulsant carbamazepine (CBZ). The majority of CBZ-E formed is ultimately converted to carbamazepine-10,11-transdihydrodiol (CBZ-D) by the enzyme system epoxide hydrolase (EH). Since CBZ-E/CBZ ratios are reportedly higher in children than in adults[1,2], this implies that there may be age-related changes in EH activity. To investigate this possible relationship between age and EH activity in humans, tracer quantities of isotopically-labelled 1-^{15}N, 2-^{13}C-CBZ-E were orally administered to children on CBZ monotherapy.

The analytical objective of the work presented here was to develop and evaluate a thermospray (TSP) liquid chromatographic/mass spectrometric (LC/MS) method enabling the quantitative determination of the thermally labile CBZ-E and the parent compound in blood utilizing stable isotope-labelled internal standards.

Experimental

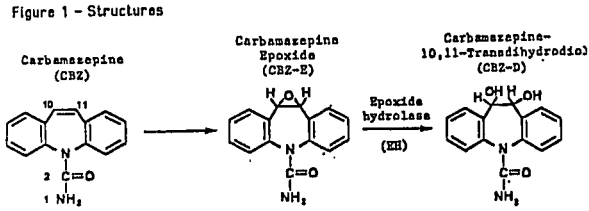
Carbamazepine was obtained from CIBA Pharmaceutical Co. (Summit, N.J.). Authenticated [$^2H_4$]-CBZ, [$^2H_4$]-CBZ-E and [^{13}C, ^{15}N]-CBZ-E were prepared in-house, the procedure to be published elsewhere. [$^2H_4$]-CBZ and [$^2H_4$]-CBZ-E were employed as internal standards. All solvents used were analytical grade obtained from commercial sources.

Sample Preparation - An aliquot of blood (250µl) was transferred to a screw-capped glass tube and distilled water added to yield a final volume of 500µl. The two internal standards were then added with thorough mixing. After the addition of 5ml of dichloromethane and vortexing, the sample was shaken for 20 min. in a horizontal shaker and centrifuged at 2000 rpm for 5 min. The organic layer was first transferred to a disposable tube and finally to a glass storage tube using a pasteur-pipet. The solvent evaporated under nitrogen , the tube was capped and stored at -20°C prior to LC/MS analysis. Calibration and control samples were prepared in conjunction with each set of patient samples. Calibration samples were prepared by the admixture of appropriate amounts of analytes and the two internal standards to blank human blood, while the two controls, Table 1, were prepared from stocks of spiked human blood utilized throughout the entire study.

Instrumental - The samples were analyzed by thermospray LC/MS/SIM using a LKB 2150 pump and LKB 2152 controller HPLC solvent delivery system (LKB, Bromma, Sweden) interfaced to a Vestec Model 201 Thermospray MS (Vestec Corp., Houston, TX). Sample injection was via a Valco C6W injector (Valco Instruments Houston, TX) fitted with a 100µl sample loop. Separations were performed using a Spherisorb C8 octyl, 25cm x 4.6mm i.d., 5µm analytical column (Phase Separation Inc., Norwalk, CN) and a Brownlee RP-18, 1.5cm x 3.2mm i.d., 7µm guard column (Brownlee Labs, Santa Clara, CA). The mobile phase was acetonitrile: 0.1M ammonium acetate (40:60), at a flow rate of 1.0 ml min^{-1}. Retention times for CBZ-E and CBZ were 5 and 7.5min, respectively. Control and probe tip temperatures were 120°C & 180°C, respectively, and adjusted to maintain a source vapor temperature of 250°C. Selected ion analysis was performed using an HP 59979C ChemStation computer system to monitor and record ion intensities at m/z 253.1, 255.1 and 257.1 corresponding to the [MH]+ of the CBZ-E analytes and deuterated internal standard with a dwell time of 350ms/ion, and m/z 237.1 and 241.1 corresponding to the [MH]+ of CBZ and its deuterated analog with a dwell time of 750ms/ion.

All samples were reconstituted in 100µl of mobile phase prior to analysis. Aliquots of 25µl were taken for TSP LC/MS/SIM analysis.

Figure 1 - Structures



Results and Discussion

As shown in Figure 2, the peak area ratios of 253/257, 255/257 and 237/241 were used to quantify CBZ-E, [^{13}C, ^{15}N]-CBZ-E and CBZ over the concentration ranges of 0.250 - 5μg ml^{-1}, 0.050 - 1μg ml^{-1} and 0.50 - 10μg ml^{-1}, respectively. The areas observed for m/z 255 were corrected for the isotopic contribution of CBZ-E. The method demonstrated excellent linearity with correlation coefficients >0.999 for all analytes.

As shown in Table 1, the method exhibited good precision, with intra- and inter-day coefficients of variation of 5.74 and 6.24, respectively, for [^{13}C, ^{15}N]-CBZ-E at the 100ng ml^{-1} level.

The limit of detection for CBZ-E was found to be 16ng ml^{-1} (S/N = 10:1) or 1ng injected.

Conclusion

The stability, sensitivity and specificity of TSP MS detection combined with the separation and simple sample workup associated HPLC analysis make the method most useful in continued pulse dose pharmacokinetic studies of carbamazepine metabolism.

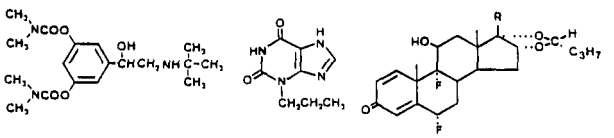
THERMOSPRAY LC/MS - A VERSATILE TECHNIQUE FOR DETERMINATION OF DRUGS IN PLASMA

Claes Lindberg and Jan Paulson

Bioanalysis, AB Draco (Astra), P.O.Box 34, S-22100 Lund, Sweden

During the last few years thermospray (TSP) LC/MS has been extensively used for the identification of polar and thermally labile compounds of biomedical interest. The technique has been less widely used for quantitative analysis, possibly because careful optimization of TSP conditions is necessary to obtain high sensitivity and reproducibility (1). There is, however, a great potential for the TSP mass spectrometer as a selective and universal LC detector. We have previously applied TSP LC/MS to the determination of terbutaline enantiomers after separation on a chiral column (2) In the present work we have studied a wider range of compounds and implemented automated procedures, which are desirable for routine quantitative analysis.

Fig. 1
Compounds measured by TSP LC/MS



Bambuterol Enprofylline D5116

Methods based on TSP LC/MS were developed for three anti-asthmatic drugs (Fig. 1) Bambuterol and D5116 were isolated from the plasma matrix (2 mL) by solid phase extraction (BondElut C18) Enprofylline could be measured directly in plasma (0.1 mL) after protein precipitation. Deuterium labeled analogues were used as internal standards in all cases. The instrumentation and the LC conditions are shown in Figs. 2 and 3, respectively.

Fig. 2
Instrumentation

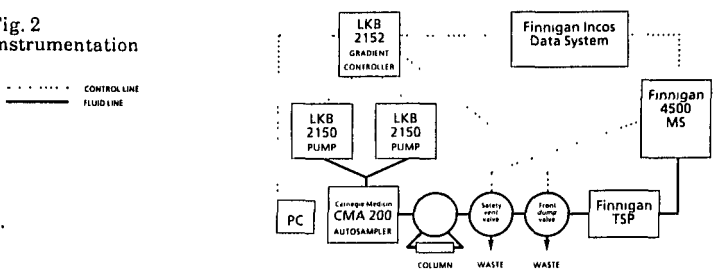


Fig. 3
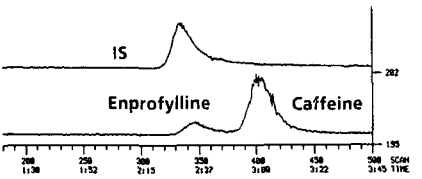
LC conditions

Column: 33x4 6 mm C18, 3um
Mobile phase: 0 1 M ammonium acetate, pH 5, containing X % methanol

	ENPROFYLLINE	D5116	BAMBUTEROL
Methanol	14%	65%	6.3% for 3 min, linear program to 40% during 12 min
Flow rate	1 60 mL/min	1 50 mL/min	1 40 mL/min

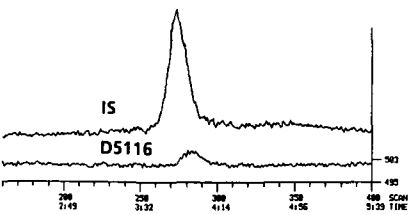
Enprofylline was measured in the range 0.88-22 mg/L (Fig. 4). TSP LC/MS was used as a reference method to check some unexpectedly high plasma concentration measured by LC/UV. No significant difference between the methods was found To check if an artifact was caused by the sample work-up, some samples were reanalyzed by direct injection of 5 uL of plasma (diluted with buffer). The results were the same.

Fig. 4
Determination of **enprofylline** in plasma (standard 0.88 mg/L).



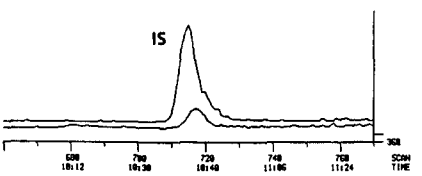
After careful optimization of the TSP conditions D5116 could be measured in plasma down to 0.2 nmol/L (Fig 5) TSP LC/MS increased sample throughput three times compared with a method based on LC with chemiluminescence detection, used for similar corticosteroids. Method development was accomplished in less than a month.

Fig. 5
Determination of **D5116** in plasma (standard 0.2 nmol/L).



A method based on TSP LC/MS was developed for the simultaneous determination of bambuterol and its metabolite, terbutaline, in dog plasma (Fig 6). The precision of the method was 4.0% (CV) at a bambuterol plasma concentration of 4 nmol/L. The results show that gradient elution is compatible with quantitative TSP LC/MS.

Fig. 6
Determination of **bambuterol** in plasma (standard 2 nmol/L).



Conclusions

TSP LC/MS can normally be used for measuring drugs in plasma at the nmol/L level, and in favourable cases at the pmol/L level. Minimal sample pretreatment is required and short retention times can be allowed. The mild sample handling and high selectivity makes TSP LC/MS a suitable reference for the validation of other methods. It can also be utilized for quick development of an urgently needed assay. Sample injection and data acquisition can be automated, allowing unattended operation overnight.

MAGIC-LC/MS ANALYSIS OF ALKALOIDS

W. Eric Harris and Richard F. Browner
School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

The ability of MAGIC-LC/MS to generate searchable EI spectra for a wide range of compounds is by now well established. This is a result of the interface's highly efficient solvent removal capability. As a consequence, both normal phase and reversed phase LC separations may be carried out with few restrictions on the separation conditions. Gradient elution separations, including those with aqueous buffers, may also be readily used with relatively minor signal loss. As a consequence of these properties, the MAGIC-LC/MS interface is uniquely suited to provide structural information on various classes of compounds of biochemical interest.

This paper will discuss the performance of MAGIC-LC/MS for the separation and identification of a series of alkaloids of the pyrrolizidine group. Pyrrolizidine alkaloids are found in approximately three percent of plant life, and are known to be fatal to humans and animals if ingested. Their prime importance in current biochemical research is as anticancer agents. For instance, indicine-N-oxide has proved effective against advanced gastrointestinal cancer, melanomas and leukemia. The need for reliable mass spectral identification of these compounds is most important to further synthetic and clinical research in this area, but alkaloids of this type are not amenable to GC/MS analysis because of their high thermal lability.

Experimental issues of interest included species detection limits, chromatographic performance and mass spectral fragmentation patterns observed. The alkaloids studied had been either isolated from plant materials or prepared synthetically. Figure 1 shows the single ion monitoring response at m/z 155 for indicine-N-oxide, with 100 ng and 10 ng injections. Signal-to-noise ratios were quite satisfactory, and showed the possibility to obtain low detection limits for this representative compound. Separations were carried out with gradient elution conditions, using an aqueous buffer of 0.05 M NH_4OAc at proportions ranging from 0 - 70 %. Over this range, there was approximately a 3x signal loss. However, the mass spectra obtained under all conditions were quite reproducible, and compared well with the anticipated loss of fragments predicted from the literature (Figures 2 and 3).

From these studies, the feasibility of using MAGIC-LC/MS to provide valuable structural information, not otherwise readily obtainable, has been demonstrated on both natural plant pyrrolizidine alkaloids and on some semi-synthetic analogues.

THERMOSPRAY LC/MS OF PYROLLIZIDINE ALKALOIDS AND METABOLITES

C.E. Parker, S. Verma, and K.B. Tomer

Laboratory of Molecular Biophysics, N.I.E.H.S., P.O. Box 12233, Research Triangle Park, NC 27709

R.L. Reed, B. Kedierski, and D.R. Buhler

Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331

Pyrrolizidine alkaloids (PAs), found in a large number of plant species, are important because of their carcinogenic and hepatotoxic properties. They have been responsible for the poisoning of livestock through the direct consumption of PA-containing plants, and may enter the human food chain through the consumption of grain contaminated with PA-containing seeds, or through the drinking of "herbal teas" or milk from exposed animals (1).

The objective of this study was to evaluate thermospray LC/MS for the analysis of pyrrolizidine alkaloids, their metabolites and conjugates. The mass spectrometer used was a VG 12-250 quadrupole mass spectrometer and data system. The thermospray interface was a Vestec model 701 source and controller. Operating conditions for the alkaloid standards in the positive ion mode were: discharge off, block 275°, vaporizer 268°, control (T1) 151°, tip (T2) 295o, tip heater 429°, lens 35°, and repeller 28V. Operating conditions in the negative ion mode were: discharge on, block 275°, vaporizer 271°, control (T1) 146°, tip(T2) 295°, tip heater 429°, lens 35°, and repeller -11V.

Under these conditions, thermospray MS gives very simple spectra for the pyrrolizidine alkaloids studied, containing mainly $(M+1)^+$ ions in the positive ion mode, and $(M-1)^-$ ions in the negative ion mode. Sensitivities are lower for the PA metabolites studied, and the spectra show mainly $(M+1-H_2O)^+$ ions in the positive ion mode.

Thermospray mass spectra obtained from a synthetic cysteine conjugate are consistent with the replacement of one of the DHR hydroxyl groups with a cysteine moiety. No evidence was found of a proposed conjugate with cysteines replacing both DHR hydroxyl groups.

No ions corresponding in mass to either of these cysteine conjugates were found in an incubation of rat hepatic cell microsomes with senecionine and cysteine. Instead, TSP analysis of the reaction mixture shows ions corresponding in mass to a conjugate formed by the addition of cysteine across the DHR double bond.

ANALYSIS OF ACYLCARNITINE BY HPLC AND LC/MS

Toshihiro Shinka, Tokuo Mizuno* and Isamu Matsumoto
Department of Biochemistry, Institute of Human Genetics, Kanazawa Medical University, Uchinada, Ishikawa 920-02, *JEOL, Akishima, Tokyo 196, Japan

L-Carnitine is an essential mediator for the ß-oxidation of fat. Hereditary disorders of fats and amino acids metabolism are often associated with abnormally high ratios of acylated carnitines to free carnitine in the urine and blood. The analysis of acylcarnitine profiles in these parients is very useful for the understanding of the clinical conditions and metabolic abnormalities, and for deciding treatment. We have developed a simple derivatization and determination method of acylcarnitines by HPLC and LC/MS using a disposable/double moving belt interface[1].

The standard acylcarnitine-HCl salts were a generous gift of Dr. D.S.Millington (Duke University). 9-Anthryldiazomethane (ADAM) was purchased from Funacoshi Co. Ltd. (Tokyo, Japan).

Standard acylcarnitines were dissolved in water at concentrations of 1-10µmole/ml. Acylcarnitine solution (100µl) was added to 1 ml urine. The mixture was vortexed and applied to a 0.9 x 4 cm glass column of Bio Rad AG-1X8 (200-400 mesh, Cl- form) anion exchange resin. Excluded species were eluted from the column with 6 ml deionized water. The effluent was collected in a glass test tube and the content was lyophilized. ADAM reagent was dissolved in ethylacetate at a concentrations of 0.2 %. To the dry residue from the isolation procedure was added 200 µl of 0.2 % ADAM solution and allowed to stand for more than 5 hours at 40°C. Sample aliquots(5 µl) were injected diectly into chromatograph.

The liquid chromatograph consisted of Waters Model M 45 pump, UK 6 syringe loading sample injection valve, Soma S-310A UV detector, and Waters 730 data module. Chromatographic separation was carried out on a 3.9 mm x 30 cm column containing µBondapak C_{18} (Waters) or 4.6 mm x 25 cm column containing Chemcosorb SCX cation exchange resin (Chemco, Osaka, Japan). For the reversed phase column, the mobile phase was 0.05 M triethylamine-HCl and acetonitrile (5 : 95, v/v) and the eluent was pumped at 1.5 ml/min. For the cation exchange column, the mobile phase was 0.05 M triethylamine-HCl and acetonitrile (85 : 15, v/v) and the eluent was pumped at 0.8 ml/min. UV spectrum was obtained using Shimadzu SPD-M1A diod-array detector. Absorbance of the effluent stream was monitored at 254 nm.

FABMS at low resolution was performed using a JMS-DX303 mass spectrometer (JEOL) and JMA-DA5000 data acquisition system (JEOL). LC/MS consisted of FAMILIC-300S HPLC (JASCO), JMS-DX303 and JMA-DA5000. µs-Finepak SIL C_{18} (1.5 mm x 25 cm) was used for the separation of acylcarnitines. In LC/MS, the eluent was pumped at 100 µl/min.

Fig. 1 shows the HPLC chromatogram and UV spectrum of propionylcarnitine anthrylmethyl ester. There are two major peaks (P1 and P2) on the chromatogram. The UV spectrum shows that peak 2 was propionylcarnitine. The derivative has the max at 254 nm and the other small peaks at 350, 370 and 385 nm.

The samples were also analyzed by LC/MS equipped with a disposable/double moving belt interface. The block diagram of this interface is shown in Fig. 2. In the conventional

LC/MS, it is hard to use the inorganic salt solvent, and the endless belt type interface has a memory trouble. With the new interface, the sample is covered with the other belt.

Thus, the memory trouble at ion source is completely avoided, and an inorganic solvent system can be used.

Fig. 3 shows the HPLC chromatogram and FAB mass spectrum for octanoylcarnitine anthrylmethyl ester. The difference of the retention time between UV detection and mass chromatogram is coursed by the interface lag time. Octanoylcarnitine anthrylmethyl ester has molecular ion at m/z 478, and a fragment ion at m/z 288 is due to [M-190] (free octanoylcarnitine).

The ion at m/z 191 is assigned to 9-methyleneanthracene.

Eighty percent derivatization of acylcarnitine was accomplished within 1 hour, and the derivatives were stable at room temperature for several weeks.

The sensitivity of HPLC-UV detection method was similar to that of the direct FABMS detection method. The calibration curve for octanoylcarnitine was linear over a sample concentration range of 10 - 150 nmole/ml. More efficient separation of acylcarnitines was achieved by cation exchange resin HPLC. It is possible to detect the acetyl-, propionyl-, butyryl-, isovaleryl-, and hexanoylcarnitine using an isocratic solvent. Using the gradient solvent method, it is possible to separate acylcarnitine more efficiently and obtained longer acylcarnitines.

STUDY ON THE DECOMPOSITION OF QUATERNARY AMMONIUM SALTS BY THERMOSPRAY LC/MS.

Domenick Vicchio and Alfred L. Yergey, National Institute of Child Health and Human Development, NIH, Bethesda, MD 20892.

INTRODUCTION:

The biologically active quaternary ammonium compounds, carnitine, choline and their acylated derivatives have been analyzed with both good sensitivity and reproducibility by thermospray LC/MS (1,2). Although the parent ion is usually a prominent peak in the mass spectra of these compounds, there appears to be, especially for the carnitines, a great deal of thermal degradation to tertiary amines and what are believed to be alkenes. Since the mass spectra of these compounds vary considerably with vaporizer and block temperatures, the nature of the degradation was investigated to better understand and predict the thermospray behavior. The mass spectra of substituted and labeled carnitine chlorides, dodecylpyridinium chloride, tetrabutylammonium hydroxide, and benzyldimethyldodecylammonium chloride were recorded at various vaporizer temperatures, and for select compounds at various pH values. The results indicate that there is temperature dependent degradation that varies depending on the structure of the quaternary compound. A pH dependence was also observed. Structures are proposed for the characteristic fragments observed in the mass spectrum of the carnitines.

EXPERIMENTAL:

Twenty nmoles of various carnitines were introduced into the source either directly, i.e. without a column, or through a 15 cm x 4.6 mm ID Ultrasphere ODS column. The mobile phase varied depending on the compound being analyzed; carnitine and acetylcarnitine were eluted from the column with 1.0 ml/min of 1% methanol in 0.1 M ammonium acetate (pH 6.7). Propionylcarnitine was eluted with 5% methanol in the same buffer.

The effect of pH on the mass spectrum of the quaternary compounds was investigated by changing the pH of the effluent with the post column addition of 0.5 ml/min of a basic (NH_4OH) or acidic (CH_3COOH) solution.

Dodecylpyridinium, benzyldimethyldodecyl and tetrabutylammonium salts were eluted from a 15 cm x 2.1 mm ID ODS column with 0.25 ml/min of 90% methanol, and 1 mM pyridine in 0.1 M ammonium acetate. The relative amount of methanol reaching the source was reduced with post column addition 1.0 ml/min of 0.1 M ammonium acetate.

The effluent from the LC column was introduced into a Vestec Thermospray source coupled to a Hewlett-Packard Mass Selective Detector. The block temperature was maintained at 350 ± 20 °C, while the vapor temperature was varied from 250-360 °C. The mass spectrometer was operated in either SIM or scanning mode. In the SIM mode each mass was monitored for 500 msec for direct injections, and 1000 msec for on column injections. When scanning the range was varied from 100-350 amu depending on the mass of the analyte.

RESULTS:

The data figures 1 and 2 indicate that quaternary ammonium salts undergo thermal degradations when subjected to thermospray mass spectrometry, and that this fragmentation is not the same for all the compounds investigated. For example, at high vapor temperatures, the carnitines degrade completely. Whereas, dodecylpyridinium and tetrabutylammonium salts reach a temperature maximum for fragmentation, and beyond this temperature the parent ion predominates. Further, based on the presence of both a tertiary amine and alkenes in the mass spectra of carnitines, it was concluded that the mechanism of fragmentation is analogous to the Hoffman degradation. Although tertiary amines were also observed in the mass spectra of both tetrabutylammonium hydroxide and dodecylpyridinium chloride, no alkenes was observed for the tetrabutyl salt, while the alkene from the pyridinium salt gave a weak signal, this is likely due to the poor sensitivity of the unsubstituted alkenes by thermospray. Finally based on the order of elimination from benzyldimethyldodecylammmoium chloride it was concluded that the order of elimination from ammonium salts is benzyl>methyl>longer chain alkyls.

THERMOSPRAY LC/MS OF α-CARBOXYAMIDO AMINO ACIDS AND PEPTIDES

Anthony M. Treston, Alfred L. Yergey, Frank Cuttitta and James L. Mulshine.
SMAMS, LTPB, NICHD, and NCI-Navy MOB, COP, DCT, NCI, NIH, Bethesda, MD 20814.

The most common amino acid modification present in hormonally active peptides is amidation of the α-carboxyl terminus of the peptide. To identify novel or unrecognized peptide hormones involved with lung cancer biology, we are using detection of posttranslational chemical modifications of amino acids (such as amidation) signifying biological activity. Enzymatic cleavage of α-carboxyamidated peptides using the peptidyl amino acid amide hydrolase (PAAAH) activity of selected carboxypeptidases releases α-carboxyamido amino acids which can be separated from non-α-amidated amino acids and identified using thermospray LC/MS.

HPLC of pure amino acids and amino acid amides was carried out on reversed phase (C_{18}) columns with 0.1% trifluoroacetic acid/ammonia, pH 7.0, with a step gradient from water to 20% methanol in water. Alternatively, a cation exchange column was used with a three-stage step gradient from pH 3.5, 10 mM formic acid/ammonia; to pH 7.0, 0.2 M ammonium formate; to pH 7.5, 0.5 M ammonium formate. Post-column addition of ammonium acetate or ammonium formate to a final concentration of at least 0.1M provides the necessary solvent ions for direct (filament-off) thermospray ionization. The mass spectrometer used was a Hewlett-Packard MSD equipped with a Vestec Thermospray source operating in positive ion mode. Moderate vaporization (230°C) and block temperatures (380°C) give the most reproducible mass spectral characteristics. For equimolar mixtures of amino acids and amino acid amides, SIM provides ready quantification (S/N 25-100:1) of 200 pmol on column.

Analysis of serial samples of enzymatic digests was carried out using the C18 column method described above. Rates of release of amino acids and α-carboxyamido amino acids provide sequence information on peptides. Further information can be obtained from mass spectral identification of the series of truncated peptides produced by the enzyme/s. For example, using CCK 30-33 amide (F-G-L-M amide) as a model, digestion with malt carboxypeptidase II or carboxypeptidase Y sequentially liberates the amino acids M amide, L, and G and F. The truncated peptides F-G-L and F-G could also be identified.

A number of model peptides were hydrolyzed using both Malt Carboxypeptidase II and Carboxypeptidase Y, and the released amino acids and amino acid derivatives were resolved using the cation exchange column method described above. Peptides studied include F-G-L-M amide, W-M-D-F amide, Y-F-M-R-F amide, Y-24-R amide (terminating in .....Q-I-R amide), Y-G-G-F-L amide, acetylD-Y-M-G amide, Y-dA-F-G-Y-P-S amide, and Y-P-V-P amide. The spectrum of activity of the enzymes was shown to be dependant on assay pH, peptide sequence, and identity of the C-terminal α-carboxyamido amino acid.

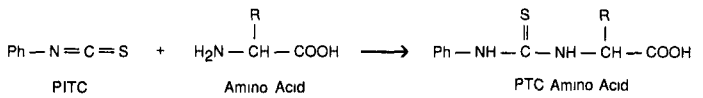
IDENTIFICATION OF PHENYLTHIOCARBAMYL AMINO ACIDS BY THERMOSPRAY LC/MS FOR AMINO ACID COMPOSITION ANALYSIS OF PROTEINS AND PEPTIDES.

Bikash C. Pramanik, Carolyn R. Moomaw and Clive A. Slaughter; Howard Hughes Medical Institute, Dallas, Texas 75235. Claudia Evans; VA Medical Center and University of Texas Southwestern Medical Center, Dallas, Texas 75216. Steven A. Cohen; Waters Chromatography Division of Millipore, Milford, Massachusetts 01757

Amino acid composition analysis of peptides and proteins is commonly accomplished by reverse-phase high performance liquid chromatography (HPLC) of the phenylthiocarbamyl derivatives of amino acids. These derivatives are formed by reaction of the free amino acid residues which phenylisothiocyanate:



PTC amino acids are readily detected by UV absorption and are normally identified solely by comparing chromatographic retention times with those of synthetic external standards.

The aim of the present study was to establish a method of employing thermospray liquid chromatography/mass spectrometry (LC/MS) for confirming identifications made in this way and acquiring information useful for identifiying non-standard components of amino acid mixtures.

Chromatographic conditions which are compatible with thermospray LC/MS were identified for use in separating PTC amino acids derived from protein and peptide hydrolysates. Fig. 1 shows a typical analysis of a standard PTC amino acid mixture containing 1 nmole per component.

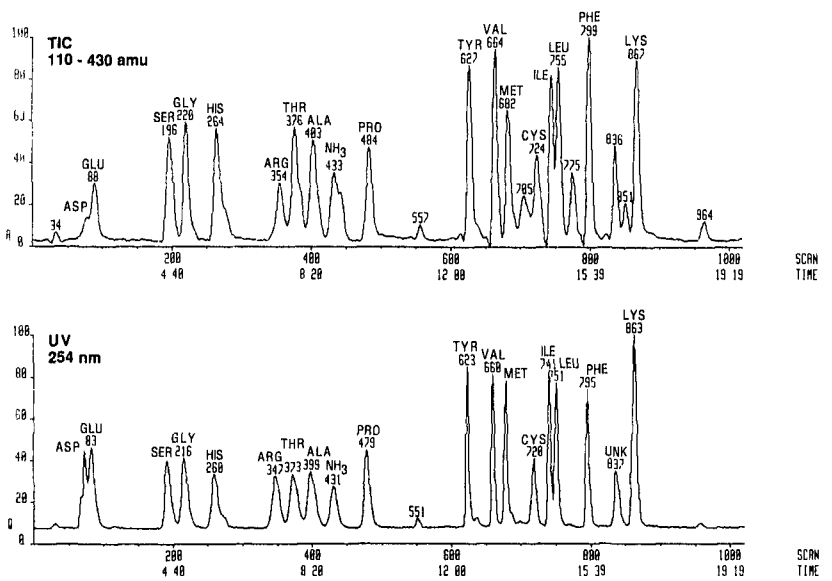


Figure 1

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

The protonated molecular ions for all standard and modified PTC amino acids so far tested, except PTC-cys, have been observed in on-column mass spectra. However, fragmentation and pyrolytic cleavages affecting the PTC skeleton, as well as special fragmentation pathways affecting the more reactive amino acid side chains have also been identified. Examples are shown in Fig. 2.

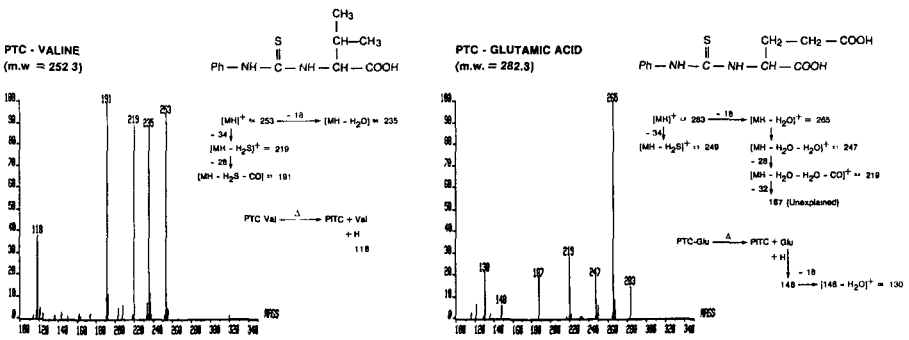

Figure 2

Each amino acid could be identified on the basis of the protonated molecular ion or a characteristic fragment ion with signal-to-noise ratios of 80:1 or better at the 250 pmole level.

The method was used to assist with the identification of two UV absorbing by-products of the coupling reaction: phenylthiourea, which represents the addition of PITC to ammonia, and dimethylphenylthiourea which represents the addition of PITC to ethylamine, a possible breakdown product of the triethylamine coupling buffer.

The procedure was tested on several proteins, including examples containing amino acids which have been covalently modified in vitro (eg. pyridylethylated cysteine) and in vivo (eg. hydroxyproline and hydroxylysine in collagen).

The method was applied to a study in which citrate synthase isolated from porcine heart was compared to the protein expressed by a recombinant porcine gene in E. coli. The data, acquired using a modified gradient method, showed that the recombinant protein lacked a covalently modified residue, trimethylysine, which is characteristically present in the catalytic site of the enzyme expressed in mammalian tissues. Since the recombinant protein was nonetheless catalytically active, the study indicated that this modification is not required for the expression of enzymatic activity.

REACTION MONITORING USING MICROBORE AND FRONTAL LIQUID CHROMATOGRAPHY WITH CF-FAB

William T. Moore, Beverly DaGue, Millie Martin, and Richard M. Caprioli

Department of Biochemistry and Molecular Biology and the
Analytical Chemistry Center
The University of Texas Medical School at Houston
Houston, Texas 77225

The application of LC/MS techniques is currently of great interest for the analysis of enzymic digests of proteins, particularly those produced by recombinant DNA methods and for the characterization of products from automated synthesis (1). We have previously shown that aqueous samples can be directly analyzed by FAB-MS using the continuous-flow (CF) probe (2). Since glycerol (5%) is miscible with a solution of 60% acetonitrile and 0.1% TFA in water and is an effective sample matrix for the analysis of peptides by CF-FABMS (3), we have in this study used the CF-FAB probe to directly introduce the effluent of a microbore LC column into the source of a mass spectrometer. Representative data in the form of LC/FAB-MS peptide maps obtained from the tryptic digestion of two proteins, apolipoprotein A-I (Fig. 1A) and recombinant human growth hormone (Fig.2A) are presented for evaluation and indicate the augmented analytical resolving power offered by coupled microbore LC/FAB-MS. Molecular ions were observed for all the numbered fragments indicated at the different scan positions of the reconstructed ion chromatograms in the figures. In Figure 1A the numbers of the peaks indicate that 26 out of 27 possible tryptic peptides were detected. Also in Figure 1, a "frontal chromatography" generated specific ion chromatogram profile (Fig. 1C) is compared to a longer (30-min gradient 5-100% B) conventional gradient elution specific ion chromatogram profile (Fig. 1B). Frontal chromatography is the elution of peptides in a solvent front created by performing a steep gradient elution (2.4-min gradient, 5-40%B). This comparison is made to demonstrate that a mass spectrometer detector with its mass resolution capability makes the chemical resolution of peptides on a column a less critical factor in the analysis of protease digests thereby permitting shorter LC run times for analytical purposes. The individual mass chromatograms effectively distinguish between several peptides eluting at the same retention time as indicated by the shapes of the selected ion chromatograms in Fig. 1C.

Microbore HPLC was performed using an Applied Biosystems Inc. Model 130A Separation System and a 1 X 50 mm Aquapore RP-300 (7-um) C8 bonded reverse phase microbore column. Pre- and post-column solvent flow splitters (Waters stainless steel compression screw tees fitted with 0.006-in. Teflon tubing crimped manually by screw clamps for flow rate control) were used to control gradient development times and effluent flow rates. An optimal flow rate for CF-FAB sample introduction into the source of the mass spectrometer is 5 μL/min. Mobile phases consisted of acetonitrile/ /glycerol/water/TFA in the following proportions: Solvent A - 0/5/95/0.1 (v/v); Solvent B - 60/5/35/0.1.

FAB mass spectrometry was performed with a Finnigan MAT 90 equipped with an Ion Tech b11NF saddle field ion gun using Xe to create energetic atoms. The continuous-flow probe used was the Finnigan-MAT Bioprobe. The spectrometer was generally operated at a resolving power of 1500 and an accelerating voltage of 4.8 KV. The magnet was scanned at approximately 10 sec/decade. Data were collected with multichannel analyzer programs available on the data systems. CsI was used to calibrate the instrument.

Another example of the clear advantage of coupling microbore HPLC with FAB-MS via a continuous-flow probe interface is evident from the mass spectral data presented in Figure 2C and 2D derived from scan positions along the RIC representing the LC/FAB-MS tryptic peptide map of a 1% deliberately contaminated recombinant human growth hormone. In this example we were able to detect a modified recombinant human growth hormone fragment (a monosulfoxide derivative) derived from the 1% "contaminant"

eluting at a position indicative of its more hydrophilic character (compare peptide structure inserts in the mass spectra Figure 2 B & C). The tryptic digest of native rhGH + 1% monosulfoxide derivative mixture was provided by Dr. Gerald Becker of Lilly Research Laboratories and was created by a trypsin treatment of a mixture of 10 mg of native rhGH and 100 ug of monosulfoxide derivative for the purpose of this study. Since 240 pmoles of native recombinant human growth hormone had been delivered to the source for FAB analysis, the spectrum for the monosulfoxide derivative is that derived from 2.4 pmole. The signal intensities indicated on the right hand ordinates support this contention.

We conclude that LC/FAB-MS coupling through the CF-FAB probe is a powerful, high resolution, and sensitive tool that can be exploited by the protein chemist to assess protein/peptide structure and the purity of protein preparations.

ANALYSES OF HIGH MOLECULAR WEIGHT POLAR COMPOUNDS BY THERMOSPRAY

R.H. Bateman, S. Hibbert, D.S. Jones & S.T. Krolik.

VG Analytical Ltd., Floats Road, Wythenshawe, Manchester. M23 9LE.

With the possibility to analyse high molecular weight polar molecules[1] by thermospray, there exists a lack of calibrant materials suitable for mass measurement of signals obtained at masses in excess of 3000 daltons.

Indeed, the whole question of calibration to quite moderate mass has been the subject of vigorous debate[2,3]. Currently, calibration of mass spectrometers is routinely possible using polyethylene glycols to mass 1500. For calibration to mass 3000, a suitable mixture of polypropylene glycols is appropriate.

However, obtaining signals of sufficient intensity and simplicity for calibration is far from trivial. Typically the calibration process will involve the following:

1) Choosing a mobile phase suitable for obtaining calibrant signals. Frequently, this is quite different from the mobile phase used for the main investigation.
2) Optimisation of the calibrant signal often involves careful consideration of such parameters as:
   a. source temperature[3]
   b. calibrant concentration[3]
   c. mobile phase
   d. probe tip temperature
3) Preparation of calibrant mixtures at appropriate concentration levels to give ions of balanced intensity over the entire calibration range.

A typical problem for calibration algorithms is that the software choose the most intense mass within a specified mass window. At high mass, the molecular ion (as defined by the ^{12}C isotope) is often not the most abundant as shown by spectra of polypropylene glycol at mass 2000 and 3000 obtained by plasmaspray (Figs. 1 and 2).

A solution to these various problems is to use fast atom bombardment for calibration. The obvious advantage of using caesium iodide as calibrant, is that both component atoms are monoisotopic, effectively avoiding the problem of isotope clusters.

To incorporate the feature of the ease of FAB calibration with the usefulness of thermospray and plasmaspray, we have designed a combined source enabling the user to perform all these functions without removal of the source.

This is achieved by focusing a FAB beam onto a removable target located above the thermospray ion block. This is shown diagramatically as Fig. 3. To illustrate the usefulness at both high and low mass, we show:

1) the molecular ion of bovine insulin (M.W. 5734) mass-measured against caesium iodide (Fig. 4).
2) a mixture of polyethylene glycols (M.W. 200-1000) mass-measured against caesium iodide from m/z 100-1000 with associated mass measurement errors (Fig. 5).

ON-LINE CAPILLARY ZONE ELECTROPHORESIS/ION SPRAY TANDEM MASS SPECTROMETRY DETERMINATION OF SMALL PEPTIDES

Edgar D. Lee, Jack Henion and Wolfgang Muck, Equine Drug Testing and Toxicology New York State College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Thomas Covey, Sciex, 55 Glencameron Road, Thornhill, Ontario, Canada L3T 1P2

Capillary zone electrophoresis (CZE) has been used primarily to separate species which have a permanent charge in solution such as amino acids, peptides, and salts (1). Typically, CZE is performed in a small diameter capillary of 100 um i.d or less. The capillary is filled with buffer and each end is placed in a separate reservoir containing buffer. A high potential field is then applied across the capillary to accomplish the electrophoretic separation. Samples are introduced at the anode end of the capillary and on-line ultraviolet or fluorescence detection is accomplished a few centimeters before the cathode. Olivares and co-workers (3) have demonstrated with mass spectrometric detection that the cathode need not be in a buffer but requires only an electrical connection at a negative potential relative to the anode.

The Ion Spray interface for combined liquid chromatography/mass spectrometry (LC/MS) produces a mild form of ionization at atmospheric pressure and ambient temperature, and is particularly well-suited for the determination of species which exist as ions in solution (2). Ion spray appears to be ideally suited for interfacing CZE with a mass spectrometer equipped with an API ion source.

A Sciex TAGA 6000E mass spectrometer equipped with an API source was used to sample ions generated from the ion spray LC/MS interface. The electrophoresis system consisted of a Spellman 0-60 kV power supply and a 100 um i.d. x 100 cm fused-silica capillary. High voltage was applied to the anode end of the capillary via a carbon vessel containing a acetonitrile/NH_4OAC buffer. Injections were made by the hydrostatic technique.

The peptide dynorphins 1-6,1-7,1-8,1-9 and leucine enkephalin were separated with a CZE voltage of 27 kV and 50/50 acetonitrile/30 mM ammonium acetate/acidic acid buffer at pH 4.8 (Figure 1). The last eluting peak, leucine enkephalin, exhibited an excess of 200,000 theretical plates, demonstrating the high separation efficiency obtainable by CZE.

Ion spray mass spectra of the peptides studied contained primarily the $[M+H]^+$ and $[M+2H]^{2+}$ ions. The degree of protonation corresponded to the number of terminal basic functionalities. For example, the mass spectrum of leucine enkephalin contained only the $[M+H]^+$ molecular ion and the mass spectra of dynorphin 1-6,1-7,1-8 and 1-9 contained both the $[M+H]^+$ and $[M+H]^{2+}$ ions with the diprotonated species being the base peak. The ratio of the $[M+2H]^{2+}$ ion to the $[M+H]^+$ ion increased with increasing acidity of the eluent. CZE/MS/MS of the $[M+H]^+$ or $[M+2H]^{2+}$ ion contained daughter ions which were consistent with the sequence of the peptide (Figure 2). The limit of detection for this system is in the low fmole range for the compounds investigated.

QUANTITATION OF ENDOGENOUS SUBSTANCE P BY COMBINED MICROCOLUMN-LC/DYNAMIC FAB-MS

C.A. Lisek, J. Bailey, L.D. Aimone, L. Benson, T.L. Yaksh and I. Jardine

Depts. of Pharmacology and Neurologic Surgery
Mayo Clinic, Rochester, MN 55905

Substance P (Figure 1), a putative pain transmitter found in the spinal cord, is one of an increasing number of peptides which function as intracellular messengers, i.e. neurotransmitters, in the nervous system. Neurotransmitters are usually quantitated by radioimmunoassay (RIA), an immunological method which affords high sensitivity (fmol range) of analysis but lacks complete specificity. We have developed a strategy (Figure 2) for the quantitative analysis of substance P which combines immunological methods with the sensitivity and specificity of microcolumn LC/dynamic FAB selected ion monitoring (SIM) mass spectrometry. This strategy is detailed below.

Cat spinal cords were boiled in 0.1 N HCl, homogenized, concentrated in vacuo, then dissolved in phosphate-buffered saline (PBS) solution (0.5 M KH_2PO_4, 0.9% NaCl, pH 6.5). An aliquot of the PBS solution of the extract was assayed for substance P (SP) activity by RIA using I^{125}-SP (yield: 252 pmol). To the rest of the extract was added a 10-fold molar excess (2520 pmol) of deuterated (d_8-Phe^8) substance P as an internal standard. One half (26 ml) of this solution was then applied in 2 mL aliquots to an immunoaffinity column containing rabbit polyclonal antibodies (IgG fraction) immobilized on cyanogen bromide-activated Sepharose 4B. Substance P was eluted with 20% aqueous formic acid. The formic acid fractions from all 2 mL aliquots were pooled and lyophilized, and a small aliquot was assayed by RIA for SP activity (yield: 40.7 pmol). The remaining half (26 mL) of the PBS solution of the extract was lyophilized.

Both the immunoaffinity purified and non-immunoaffinity purified samples were desalted on a C4 wide pore (40 μm) disposable filtration column, then quantitated by microcolumn LC/dynamic FAB SIM MS. An aliquot (0.1 or 0.5 μL) of sample was injected onto a C18 packed fused silica microcolumn (0.32 mm ID) fitted to a VG 30-253 quadrupole mass spectrometer dynamic FAB-MS inlet. The mobile phase was 0.1% TFA and 5% glycerol in 75:25 MeOH:H_2O and the flow rate was 5 μL/min. After ionization by FAB-MS, the protonated molecular ions of d_0- and d_8-substance P were selectively monitored.

In Figure 3 is a comparison of the results obtained upon analysis of immunoaffinity purified and non-immunoaffinity purified endogenous substance P. Deuterated internal standard (5 pmol) was injected before and after each endogenous sample. These results strongly suggest that immunoaffinity chromatography is a necessary purification step prior to MS analysis. A comparison of the results from the analysis of the immunoaffinity purified endogenous sample with those results from standard solutions of (d_0 + d_8)-SP is depicted in Figure 4. From the d_0/d_8 ratios obtained from the standard solutions, a response curve (Figure 5) was generated. The d_0/d_8 ratio for the endogenous sample was 0.2585. Since the amount of d_8-SP in the standard solutions was 400 pmol, and the endogenous sample contained 1260 pmol d_8-SP, the corrected d_0/d_8 ratio for the endogenous sample was 0.2585 x 400/1260 or 0.0821. This ratio corresponds to 39.0 pmol of d_0-substance P, which is in agreement with that value (40.7 pmol) determined by RIA.

In conclusion, (1) endogenous substance P was quantitated by combined microcolumn LC/dynamic FAB SIM MS; (2) the dynamic FAB SIM MS results for substance P were in agreement with those determined by RIA; and (3) the combination of immunoaffinity chromatography with both RIA and microcolumn LC/dynamic FAB SIM MS detection provides an optimal analytical methodology for endogenous neuropeptides.

MIXTURE ANALYSIS BY COMBINED CAPILLARY COLUMN LIQUID CHROMATOGRAPHY - DYNAMIC FAB MASS SPECTROMETRY

R.H. Bateman & D.S. Jones.

VG Analytical Ltd., Floats Road, Wythenshawe, Manchester. M23 9LE.

Fast atom bombardment is now a well established ionisation technique, extremely useful for producing both molecular weight and structural information from a wide variety of compounds. This is especially true in the field of biochemistry where many species of interest are of high molecular weight and thermally labile in nature. The versatility of the technique, however, has been severely limited by the inability to combine the ionisation technique with any method of on-line separation.

However, with the recent development of packed capillary column liquid chromatography, previous incompatibility with liquid chromatography can be largely overcome. In particular, the low solvent flow rates (3-10µl/min) are well-suited to the limited pumping capacity of mass spectrometers. The additional benefit of high chromatographic resolution (up to 100,000 theoretical plates per metre) offers the potential for separation of complex mixtures prior to ionisation.

For this study, a mixture of four enkephalins have been separated by liquid chromatography.

Materials

Samples of leu enkephalin, met enkephalin, leu enkephalinamide and d-ala d-leu enkephalin were obtained from the Sigma Chemical Co.

Mass Spectrometer

Analyses were performed using a VG 70-250S mass spectrometer operated at 8000V accelerating voltage.

Liquid Chromatography

The column used for separation was a home-made packed fused silica column 0.32mm x 10cm packed with ODS2 3 micron particles.

A gradient separation was achieved using:

Solvent A	Solvent B
20% acetonitrile	45% acetonitrile
75% water	50% water
5% glycerol	5% glycerol
0.1% TFA	0.1% TFA

100% solvent A to 100% solvent B in 15 minutes, 100 nanolitres of the mixture of enkephalins was injected onto the column. The injected amount corresponds to 100ng per component.
Flow through the column was 5 microlitres per minute.

Results

Single ion chromatograms are shown as Fig. 1. Figs. 2-5 show corresponding mass spectra for each of the four components. Fig. 6 demonstrates both the capillary column resolution and chromatographic profile of the eluting peak.

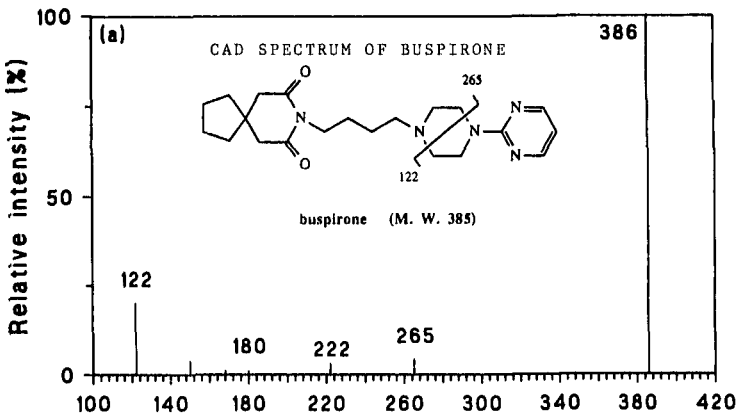
THERMOSPRAY LC-MS/MS STUDIES ON THE ANTIANXIETY DRUG BUSPIRONE AND ITS METABOLITES

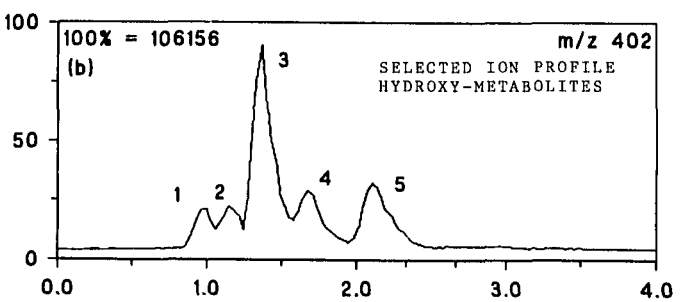
Daniel A. Garteiz, TEXms Inc., Houston, TX.,
Ian A. Blair, Dept. Pharmacology, Vanderbilt Univ., Nashville, TN and R.F. Mayol, H.K. Jajoo, Bristol-Myers Co., Wallingfort, CT.

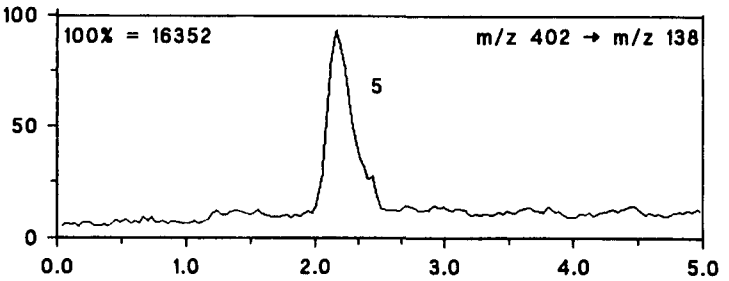
Buspirone, a potent anti-anxiety drug, has been recently introduced into clinical practice. Due to the polar nature of its metabolites, extensive preparation is required prior to GC/MS analysis. In order to facilitate metabolite identification from different patient populations, an LC/MS/MS study was initiated using a Nermag R3010 triple quadrupole mass spectrometer. Buspirone has excellent thermospray characteristics. Its TSP mass spectrum yields a very intense protonated parent at m/z 386. Using collisional induced dissociation (CAD) with Argon as collision gas, it was possible to fragment the parent ion to yield structural revealing daughter ions.



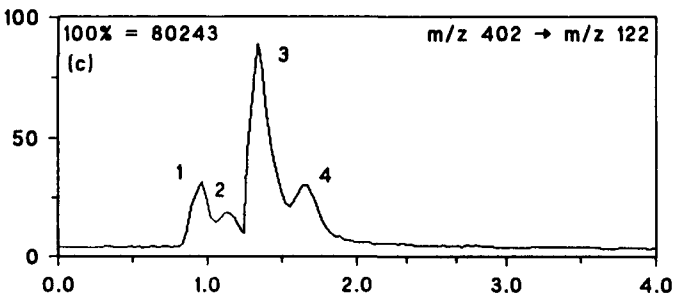
The daughter ion at m/z 122 is thought to arise from cleavage across the piperazine ring. This daughter, as well as the one at m/z 265 are useful for identifying sites of hydroxylation.

Buspirone undergoes a complex series of biotransformations to give a series of hydroxylated products. These products generate protonated molecular ions 16 daltons higher tha buspirone (See figure below.)

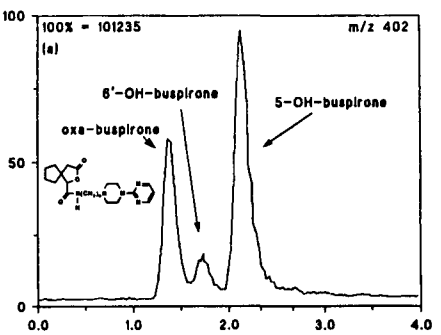




Out of the five hydroxylated metabolites detected, only one was found to contain the transition m/z 402 to m/z 138. This fact immediately identified the metabolite as having undergone pyrimidinyl hydroxylation (See above).



Four other metabolites were found to yield the m/z 402 to m/z 122 transition. Three of these metabolites were tentatively identified as 3-hydroxy, 6'-hydroxy and oxa-buspirone. Their identity was later confirmed by comparison of their CAD spectra and their retention times to the auththentic compounds.



In summary, the combination of hepatocyte incubations followed by TSP-LC/MS/MS analysis provides a powerful tool for the characterization of buspirone metabolites. In addition, TSP-LC/MS/MS greatly reduces the analysis time, which will allow the study of larger patient populations.

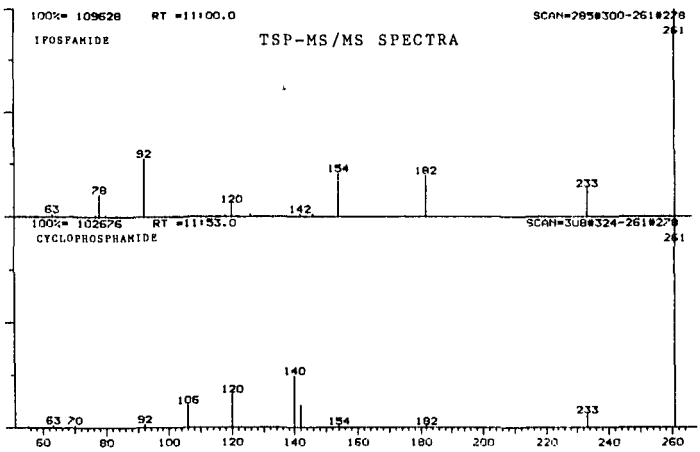
RAPID ANALYSIS OF IFOSFAMIDE IN HUMAN PLASMA BY THERMOSPRAY LC/MS/MS

Daniel A. Garteiz, TEXms Inc., Houston, TX
and Robert A. Newman, Dept. Medical Oncology
Univ. Texas M.D. Anderson Cancer Center

Ifosfamide is an alkylating oxazaphosphorine used in a wide variety of tumors including soft cell lung cancer, soft tissue carcinoma and ovarian cancer. Recently, our laboratories have developed an HPLC assay using cyclophosphamide as an internal standard. Although the HPLC assay reduces sample preparation significantly, the chromatographic separation of ifosfamide from the internal standard requires c.a. 16 minutes. For this reason, the laboratory can only process 3-4 samples per hour.



We now wish to report on a rapid analysis method for ifosfamide based on thermospray followed by tandem mass spectrometric analysis. The TSP-MS/MS spectrum of cyclophosphamide displays a daughter ion at m/z 140 which arises from the dichloro substituent on the phosphoramido nitrogen. This daughter is not present in the spectrum of ifosfamide. Ifosfamide displays a daughter at m/z 154 which is absent in the cyclophosphamide spectrum. These daughters were used to quantitate ifosfamide in human plasma.

EXPERIMENTAL: A Nermag R3010 Triple Quadrupole System was used for this work. The TSP-LC/MS/MS conditions were as follows: Collision Gas: Argon Collision Energy: -16ev; Collision Pressure: 50 MilliTorr; LC Flow: 1.5 ml/min.; Mobile Phase: 27/73 Acetonitrile/$NH_4^+Ac^-$ Buffer; RP column

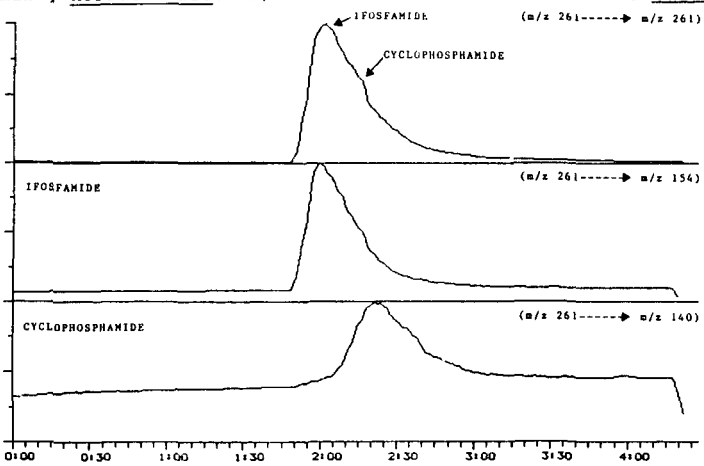

FIGURE 1: SRM TRACE AT 30 MINUTES POST-DOSE

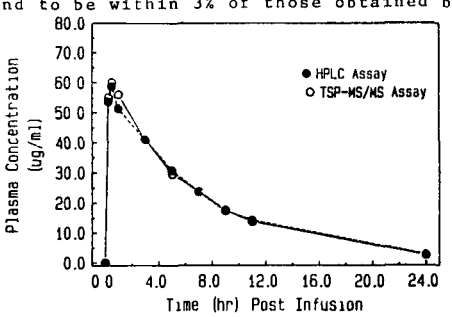
SAMPLE PREPARATION: An aliquot of human plasma is spiked withcyclophosphamide, made basic and extracted with chloroform. After evaporation, the residue is dissolved in mobile phase (200ul) and 20ul are analyzed.

RESULTS: The use of a fast column and the fact that chromatographic resolution was not needed, allowed for analyses every four minutes. Ifosfamide levels were measured in a patient given an IV infusion of the drug. Levels were easily detected 24 hours post dose. The TSP-LC/MS/MS measurements were found to be within 3% of those obtained by HPLC/UV.



CONCLUSIONS: This work clearly reveals that TSP-LC/MS/MS analyses can be used to carry out quantitative measurements as are required in bioavailability/pharmacokinetic studies. Furthermore, in our study, the speed of analysis resulted in a 500% increase in sample throughput.

DETERMINATION OF DIANABOL AND ITS METABOLITES BY COUPLED-COLUMN LC/TANDEM MASS SPECTROMETRY, Per Olof Edlund and Jack Henion, Equine Drug Testing and Toxicology, New York State College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Monitoring steroid use requires an understanding of steroid metabolism in the species in question and development of sensitive methods for screening of the steroid or its metabolites in urine. In the present work Dianabol and its metabolites were extracted from equine urine by liquid-liquid extraction and separated from remaining urine components by coupled-column chromatography on two reversed phase columns with different selectivity. The sample was first separated on a phenyl-silica column. The fraction containing the steroid of interest was collected onto a short ODS-column for enrichment (peak compression) and then eluted with reversed flow direction onto an octyl-silica column for the final separation.

Two complimentary LC/MS interfaces were used for on-line LC/MS and MS/MS to confirm the identity of Dianabol and to identify metabolites in equine urine. An atmospheric pressure ion source (API) equipped with a heated pneumatic nebulizer and a corona discharge needle was used for neutral steroids. The corona discharge initiated the ionization of solvent ions which were used for chemical ionization at atmospheric pressure. The ions formed were focussed and declustered through a dry nitrogen curtain and then through a 100 um orifice into the vacuum region for mass analysis.

The ion spray interface which combines some of the characteristics of electrospray and ion evaporation was used for confirmation of Dianabol-sulfate. Both ionization techniques gave little or no fragmentation and collision induced dissociation (CID) was used to obtain fragmentation for structural confirmation. Dianabol was excreted to the urine as an unstable conjugate of sulfuric acid. Nucleophilic attack by water in urine gave 17-epi-Dianabol. Elimination of the sulfate group gave a tertiary carbonium ion at the 17-position that rearranged and eliminated water to form 18-nor-17,17-dimethyl-1,4,13(14)androstatrien-3-one. Mono- and di-hydroxylated metabolites were also identified. LC/LC/MS of Dianabol and 17-epi-Dianabol gave simple positive ion mass spectra showing the $[M+H]^+$ at m/z 301 and a fragment for loss of water. Their MS/MS mass spectra were identical with several characteristic daughter ions presumably corresponding to: loss of water to give m/z 283, a fragment involving the C and D-ring at m/z 149, A-ring and part of B-ring at m/z 173 and A-ring at m/z 135 and 121. The fragment involving the C and D-ring was verified by MS/MS spectrum of 17-deuteromethyl-Dianabol which gave a labeled fragment at m/z 152. Ion spray coupled-column LC/MS of Dianabol-sulfate gave the molecular ion $[M-H]^-$ at m/z 378. CID of this ion gave the parent ion and a fragment corresponding to HSO_4^- at m/z 97. 17-epi-Dianabol was detected in urine by UV up to 6 days after a 250 mg i.m. dose to a horse. The half life of the elimination phase was 78 h.

June 5-10, 1988, San Francisco, CA

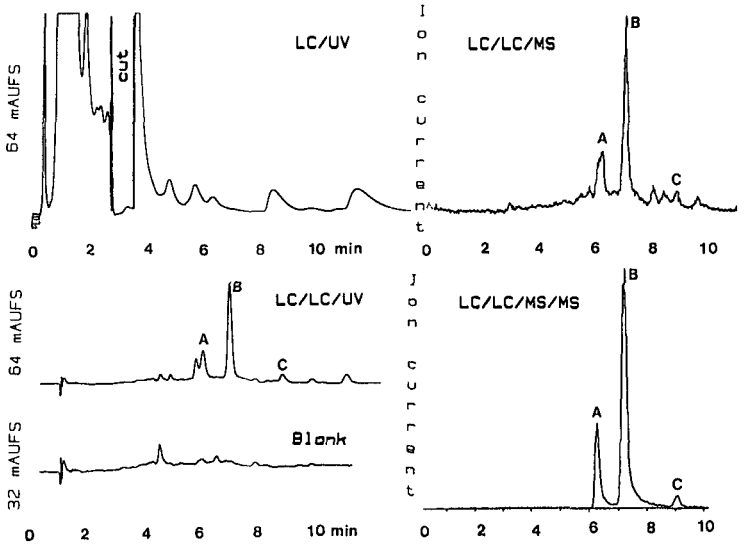

Figure 1. Comparison of LC/UV and LC/MS chromatograms obtained from an extract of a 8 h urine sample containing 46 ng/mL of Dianabol (peak B). The other peaks were identified as 13-hydroxy-17,17-dimethyl-1,4-androstadien-3-one (A) and 17-epi-Dianabol (C) incompletely resolved from Dianabol on the first column. The cut from the phenyl-column (LC/UV) was collected by column switching and separated on the octyl-column with UV detection (LC/LC/UV), detection by mass spectrometry (LC/LC/MS) and tandem mass spectrometry (LC/LC/MS/MS).

Thermospray LC/MS of the LL-F28249 Macrocyclic Lactones

*Kenion, G.B., Carter, G.T. and Borders, D.B.
American Cyanamid, Pearl River, NY

The macrocyclic lactones **1-4** (LL-F28249 alpa, beta, gamma, and lamda) are highly potent antiparasitic agents effective against many endo- and ectoparisites of mammals[1]. The mass spectra of **1-4** were obtained in the positive and negative ion modes. Since chromatographic considerations precluded the use of ammonium acetate buffer, our study relied upon the discharge electrode and filament modes of ionization.

All spectra were obtained using a Finnigan TSP-46 dedicated thermospray LC/MS system. A 75% MEOH/ 25% H_2O solvent system at 1.2 mL/min was used throughout the study. The optimum vaporizer temperature was 95°C, while the optimum jet temperature was 220°C.

Positive ion spectra generated using filament ionization are characterized by an M+1 ion with a relative abundance of 10-20%. The most abundant fragment ions (including the base peak) correspond to losses of methanol or water. Compounds 1 and 2, with a hydroxy rather than a methoxy substituent at C-5, have a characteristic ion corresponding to a loss of 110 amu from the parent M+1 ion.

Positive ion spectra obtained via discharge electrode ionization exhibited enhanced fragmentation, although essentially the same ions were produced. An M+23 sodium adduct, formed in aproximately equal abundance to the M+1 ion, is unique to the discharge electrode ionization mode. Full spectra (scanning 400-650 amu) are obtainable via loop injection from as little as 265 ng of sample.

Negative ion spectra obtained using the filament ionization mode are dominated by M- peaks produced by electron capture. Gartiez[2] reported a similar M- ion at m/z 874 for a related compound, 22,23 dihydroavermectin B_{1a}, using a solvent system of 80/20 acetonitrile/water with a Vestec Thermospray LC/MS interface. Introduction of acetonitrile and/or ammonium acetate buffer to our solvent system shifted the base peak from the M- ion resulting from electron capture to an M-1 ion characteristic of a deprotonated alchohol. Fragmentation is limited to loss of methanol or water and fairly abundant ions due to loss of 110 amu for the compounds with a hydroxy substituent at C-5. Full spectra (scanning 400-650 amu) are obtainable via loop injection from as little as 212 ng of sample.

Negative ion spectra generated using discharge electrode ionization are

similar to those obtained with filament ionization, although filament ionization produces less background noise and higher sensitivity for LL F28249 alpha,beta,gamma and lambda.

Thermospray LC/MS of LL-F42248 alpha

*Kenion, G.B., Carter, G.T. and Borders, D.B.
American Cyanamid, Pearl River, NY

The tetrachlorinated, nitropyrrole antibiotic LL-F42248 alpha is the first tricyclic member of the pyrrolomycin family to be reported[1]. Thermospray LC/MS spectra have been obtained in both positive and negative ion modes using buffer only, discharge electrode, and filament ionization. Corresponding spectra have also been obtained for labelled LL-F42248 alphas. Compound **1a** contains >95% ^{15}N enrichment at both nitrogen atoms. Compound **1b** is similarly >95% ^{15}N enriched and also contains 60% ^{18}O enrichment in the two oxygens of the nitro group. Comparison of these spectra allows determination of the fragmentation patterns.

All spectra were obtained from a Finnigan TSP-46 dedicated Thermospray LC/MS. A solvent system of 60% methanol, 40% 0.1 M ammonium acetate at 1.2 mL/min was used throughout the study. The optimum vaporizer temperature was 95°C, while the optimum jet temperature was 230°C. The ^{15}N and ^{18}O labelled LL-F42248 alpha was derived from fermentations of Streptomyces fumanus supplemented with ^{15}N and ^{18}O enriched precursors.

The positive ion fragmentation pattern is outlined in Scheme 1. The number of nitrogens assigned to each struture was based on a corresponding peak two mass units higher for the ^{15}N labelled analogue, while the assignment of nitro group oxygens is based on comparison with the ^{15}N,^{18}O labelled analogue. The discharge electrode and filament enhanced fragmentation. The fragments at m/z 339 and m/z 325 are unique to these ionization modes. It appears that the nitro group is reduced via the oxime to the amine, whereas in the buffer only ionization mode the nitro group is probably lost through protonation and subsequent SN2 dislpacement by the carbonyl oxygen. The filament provides the most efficient means for ionization in the positive mode for LL-F42248 alpha, with a full spectrum (scanning 250-450 amu) obtainable from 1ug of sample.

The negative ion spectra, as outlined in Scheme 2, are dominated by the facile loss of CO corresponding to the base peak fragment at m/z 354 for filament and discharge electrode ionization and m/z 353 for buffer only ionization. The negative ion, filament ionization mode provides optimal sensitivity for LC/MS analysis of LL-F42248 alpha, with a full spectrum obtainable from 42 ng of sample.

MASS SPECTRAL INVESTIGATIONS OF BORON NEUTRON CAPTURE THERAPY (BNCT) AGENTS

By

D. L. Miller and L. J. Peterson-Wright
Idaho National Engineering Laboratory
EG&G Idaho, Inc.
P.O. Box 1625
Idaho Falls, ID 83415-2208

Boron neutron capture therapy (BNCT) is a promising technique for the treatment of selected types of brain tumor and potentially for other tumor types. In this therapy, a ^{10}B-enriched species is administered to the bloodstream and selectively deposited in the tumor. The selective deposition in the tumor is due to either the breakdown of the blood-brain barrier or to the chemical nature of the boron-containing compounds. Once a sufficient concentration of boron is attained in the tumor (approximately 25 ppm), the tumor is irradiated with a controlled energy neutron beam (preferably epithermal, 1 eV to 10 keV), at which time neutrons are captured by the incorporated boron atoms. The capture results in the reaction, $^{10}B(n,)^{7}Li$, which produces a localized nuclear reaction capable of destroying the tumor cell containing the boron.

A variety of boron containing compounds have been evaluated for use in BNCT. One of the most promising of the compounds is the disodium salt of mercaptoundecahydrododecaborate ($Na_2B_{12}H_{11}SH$), commonly referred to as BSH. This particular compound has been used in Japan in treatment of more than 90 patients over the last 20 years with good results. Even though good success with this compound has been achieved in Japan, its use has come into question in the United States due to an incomplete characterization of the chemical constituents present in the administered drug. BSH is known to be an unstable compound when exposed to air and moisture. The BSH compound is also known to dimerize and the dimer is known to undergo further oxidation to produce a thiosulfinate species. Both of these secondary products have been demonstrated to have considerably higher toxicity than the parent compound. This high degree of toxicity requires that stringent quality control examination be performed on every lot of BSH prior to use to ensure safety. The analytical procedures utilized to examine the species of interest have consisted primarily of chromatographic procedures (TLC, HPLC, IC, and isotachophoresis) and occassionally nuclear magnetic resonance (NMR). These procedures have proven to be inadequate by themselves due to incomplete chromatographic resolution, lack of sensitivity, and inability to identify unknown peaks arising from manufacture or packaging. Given the nature of the species of interest, it was decided to examine the use of mass spectrometry incorporating fast atom bombardment ionization to determine if the potential existed for the development of a HPLC FAB/MS analytical procedure utilizing the new continuous-flow FAB inlet.

All experiments were conducted on a KRATOS MS890 equipped with an 8 kV MS50-type FAB source. The MS890 was equippped with an Ion Tech (11NF) saddle field ion gun and xenon was used as the FAB gas. Initial experiments using BSH were conducted in both positive and negative ion modes using a variety of FAB matrices. Positive ion experiments were discontinued

when no peaks indicative of the compound of interest were observed. The positive ion spectra were dominated by peaks arising from sodium reacting with the various matrices used.

Experiments conducted in the negative ion mode proved to be much more productive. A variety of matrices were tested with BSH. These matrices included glycerol, thioglycerol, 3-nitrobenzyl alcohol, triethanolamine, and PEG-600. No peaks indicative of the BSH compound were observed when glycerol was used as the matrix, even though the BSH was readily soluble. For the remainder of the matrices tested, good solubility of the BSH was also observed as well as peaks using BSH containing the natural isotopic abundance of boron (approximately 20% ^{10}B and 80% ^{11}B). When examined using thioglycerol as the matrix, a cluster of peaks indicative of boron was observed with the most intense peak occurring at M/Z 197. This cluster arises from the loss of a sodium from the parent compound. The distribution of peaks obtained from the FAB/MS experiment was compared to the expected theoretical distribution for the elemental composition $NaB_{12}H_{11}SH$ and found to closely match. Additional clusters of peaks were observed indicative of $B_{12}H_{11}$ and $B_{12}H_{11}SH$. However, the spectra were complicated and of low intensity due to the distribution of ion current arising from the large numbers of boron atoms and its multi-isotopic nature. To overcome this problem, BSH enriched to 95% ^{10}B (Callery Chemical, Pittsburgh, PA) was used in the remainder of the experiments. Upon reanalysis, using thioglycerol as the matrix, the cluster around M/Z 197 was observed to have collapsed to a single peak at M/Z 187. Similar results were observed for the lower molecular weight fragments. By utilizing the ^{10}B-enriched material, the ion current was concentrated into fewer peaks permitting a more detailed examination of the spectra to be performed. It was observed that, although the majority of the signal from the BSH was arising from the peak at M/Z 187, a minor amount of reaction was occurring between the BSH and the thioglycerol producing clusters of higher molecular weight. Similar results were obtained with 3-nitrobenzyl alcohol and triethanolamine. However, when PEG-600 was used as the matrix, no reaction of the BSH with the matrix was observed. Additional matrices are being examined to find other nonreacting matrices.

Aqueous solutions of the BSH compound, as well as other boron species of interest, were combined with the FAB matrices mentioned above to determine if the presence of water would prevent the detection of the compounds of interest. These experiments were conducted to determine if currently existing HPLC techniques which use paired-ion chromatography with 1:1 water methanol as eluant could be adapted for use in a continuous-flow FAB application. It was determined that the presence of the water did not have an adverse effect of the analysis, thus allowing the use of continuous-flow FAB inlet. Additional work is currently underway to examine the dimer and thiosulfinate form of the dimer which show limited solubility in the matrices examined to date and to convert the existing HPLC technique to a microbore column for use with continuous-flow FAB.

SIMULTANEOUS IDENTIFICATION AND QUANTITATION OF MORPHINE AND CODEINE IN URINE BY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Wen-neui Lin, Jau-Wen Chu
and Craig C. Foreback

Division of Chemistry, Dept. of Pathology
Henry Ford Hospital, Detroit, MI 48202

A Gas Chromatography/Mass Spectrometry (GC/MS) method has been developed for the simultaneous identification and quantitation of morphine (M) and codeine (C) in urine. Urine (5.0 ml), spiked with internal standards (5 μL of 100 ng/mL morphine-D^3 and codeine-D^3 each) was autoclaved with 0.5 mL of concentrated HCl at 121°C for 20 minutes. After cooling the tube, 0.8 mL of 10 N NaOH and 100 μL of glacial acetic acid were added to each tube. The pH of the sample was adjusted to 4.4-4.6. The CLEAN-SCREEN® DAU column (130 mg, Worldwide Monitoring, Horsham, PA 19044), attached with a stopper, was placed in the Adsorbex system and washed twice with methanol and twice with distilled water. An 8 mL fritted reservoir was attached to the top of the column. Sample was added to the reservoir and pulled through the column at a flow rate of 1.0 mL/min. The column was washed twice with 1.0 mL of distilled water, once with 1.0 mL of 0.1 M acetate buffer (pH 4.0) and twice with 1.0 mL of methanol. The opiates were eluted twice with 1.0 mL of elution solvent (methylene chloride: isopropanol 8:2 with 2% NH_4OH). The eluents were evaporated to dryness under nitrogen and derivatized with 50 μL of N.O-bis(trimethylsilyl)-trifluoroacetamide (BSTFA) at 70°C for 20 minutes. Identification and quantitation of drugs were accomplished by using HP 5970A Mass Selective Detector (MSD), coupled with HP 5890 Gas Chromatograph (HP Ultra-2 capillary column 12m x 0.2mm x 0.33 um) and the HP 59970 ChemStation analytical workstation. All data were acquired by using Hewlett-Packard's GC with the following parameters: injection port temperature, 260°C; transfer line temperature, 290°C; temperature equilibration time, 0.5 min; purge time, 0.8 min; oven initial temperature, 80°C; initial time, 1.0 min; program rate, 20°C/min; final temperature, 280°C; and final time, 2 min. Helium was used as carrier gas at flow rate of 30 mL/min with head pressure of 2.5 psi. Splitless mode was used. For quantitation, the MSD was operated in the Selective Ion Monitoring (SIM) mode. Morphine, morphine-D^3, codeine and codeine-D^3 were monitored at 429, 287, 196 amu; 432, 290, 199 amu; 371, 234, 178 amu and 374, 237, 181 amu respectively. Calibration curves, when plotted as peak area ratios of analyte to internal standard versus the concentrations of analyte, are linear from 5 to 1200 ng/mL for both morphine and codeine. Detection limits are 5 ng/mL for both compounds. Absolute recoveries range from 85% to 95% for both morphine and codeine. Day-to-day variations (N=8) are 4.5% for codeine and 5.3% for morphine. Within-day variations (N=10) are 1.4% for codeine and 1.9% for morphine. The method of sample preparation we have developed using CLEAN-SCREEN® DAU column has resulted in high recoveries with excellent reproducibility for the analysis of morphine and codeine in urine. We conclude that this procedure is simple, rapid, specific and cost-effective and is suitable for the routine confirmation of opiates in clinical laboratories.

ANALYSIS OF PIPECOLIC ACID IN PEROXISOMAL DISEASES BY GCMS WITH SELECTED ION MONITORING

Yong Y. Lin

N.Y.S. Institute for Basic Research in Developmental Disabilities
Staten Island, New York 10314

OBJECTIVE

Excessive excretion of pipecolic acid(PA) has been used as a biochemical marker for the neurogenetic disorder of peroxisomal diseases, such as Zellweger syndrome(ZS) and neonatal adrenoleukodystrophy(NALD).

However, the analysis of pipecolic acid(PA) by conventional amino acid analysis has been hampered by the lackings of both sensitivity and specificity. The GCMS method with selected ion monitoring is developed for the analysis of PA in plasma and urine. The analytical method is highly sensitive and specific, and accurately determines the levels of PA in different types of peroxisomal diseases.

PEROXISOMAL DISORDERS

1. Zellweger Cerebrohepatorenal Syndrome (ZS):
   * hepatomegaly, renal cortical cyst, hypotonia, do not thrive, usually die in 6 months
   * absence of morphologically detectable peroxisomes in liver and kidney
   * accumulation of very long chain fatty acids ($>C_{24}$)
   * elevation of pipecolic acid

2. Neonatal Adrenoleukodystrophy:
   * progressive destruction of cerebral white matter and adrenal cortex
   * absence or enzyme defects in peroxisomes
   * accumuration of very long chain fatty acids ($>C_{24}$)
   * elevation of pipecolic acid

GCMS ANALYSIS OF PIPECOLIC ACID

1. Sample Preparation:

Plasma or Urine (0.1-0.5ml)

↓ add 50 nmol DL-pipecolic acid-d_{11} as I.S.
adjust to PH 2

AG50W-X8 (H^+)

↓ wash with H_2O, 1N HCOOH
elute with 1N NH_4OH

AG1-X8 (OH^-)

↓ wash with H_2O
elute with 1N HCOOH

Dried Sample

↓ add 100ul HCl/butanol
heat 90 C for 30 min

Butyl Esters

↓ add 100ul 25% trifluoroacetic anhydride in EtOAc
heat 90 C for 30 min

Trifluroacetyl Butyl Ester

2. GCMS
   * DB-17(fused silica column), 0.55u x 15 ft
   80 - 280 C at 15 C/min
   * NH_3CI
   * SIM
      pipecolic acid: m/z 180, 208, 282, 299
      pipecolic acid-d_{11} m/z 189, 217, 291, 308

RESULTS

Patients	Age(yr)	PA in Urine (nmol/mg creat.)	PA in Plasma (nmol/ml)	Diagnosis
1	23 days	539.1	4.7	ZS
2	1/12	111.7	8.6	ZS
3	2/12	541.7	4.7	ZS
4	1/12	1,412.6	*	ZS
5	2/12	13.0	*	Pseudo ZS
6	3/12	*	4.7	Pseudo ZS
7	2/12	11.3	108.7	NALD

CONCLUSION

GCMS with selected ion monitoring technique offers a highly sensitive and specific analysis of PA contents in plasma and urine. The analysis of PA contents in urine and plasma from patients of peroxisomal diseases shows ZS patients are characterized by a large elevation in urinary PA, >100 nmol/mg creatinine, with little elevation in plasma PA levels. On the other hand, NALD patients show a moderate urinary PA level, <50 nmol/mg creatinine, but their plasma PA are largely elevated, >100nmol/ml; thus, differentiation between ZS and NALD may be simply made by the PA analysis. Several variants of ZS and NALD and other non-peroxisomal neurogenetic diseases show no elevation in PA levels. The results further confirm the disorders of lysine metabolism in peroxisomes.

ADVANCES IN MS/MS ANALYSIS WITH THE ION TRAP MASS SPECTROMETER

M. Weber-Grabau, P.E. Kelley, S.C. Bradshaw, D.J. Hoekman
Finnigan MAT, San Jose, California 95134

In a conventional beam mass spectrometer, the steps of ionization, parent ion selection, collison-induced dissociation (CID), and daughter mass analysis are separated in space; in particular, multiple analyzers are required for an MS/MS experiment. In the quadrupole ion trap, the analysis steps are separated in time and all occur inside the ion trap electrode assembly. Since both parent and daughter ions are trapped simultaneously, daughter ion yields are 30-100%. With recently developed electronics and software, it is possible to take full advantage of the inherent multichannel/multianalyzer capability of the ion trap mass spectrometer (ITMS) and conduct novel experiments not possible before.

After creation by EI or CI, parent ions of a single m/z value are isolated by the application of both RF and DC voltages to the ring electrode, i.e., temporary operation of the ion trap near the apex of the stability diagram (1). This single-mass isolation step also eliminates space charge due to other analyte ions or background ions, allowing longer ionization times and resulting in an increase in sensitivity by several orders of magnitude. The selected parent ion is dissociated and the daughter spectrum is acquired in the mass-selective instability mode.

MS^n is easily achieved by adding more mass isolation/dissociation steps to the computer-controlled scan program. An EI/MS/MS/MS scan function is shown in Fig. 1. Fig. 2 gives an example for the application of this scan function; the parent ion chosen is m/z 503 from perfluorotributylamine (FC-43). m/z 503 is the carbon-13 isotope peak of the fragment ion with the elemental composition $C_9F_{20}N$; its abundance, relative to the base peak at m/z 69 in the original EI spectrum, is 0.8% (Fig. 2a). With an efficiency of about 60%, m/z 503 is dissociated into daughter ions at m/z 219, 220, 264, and 265 (Fig. 2b). The ratio of the two intense daughter ions at m/z 264 and 265 (4:5) reflects that the number of carbon atoms in the parent and daughter ions are 9 and 5, respectively. Then, the daughter ion at m/z 265 is isolated (Fig. 2c) and dissociated, and the full granddaughter spectrum is recorded (Fig. 2d). The efficiency of this step is 30%. This experiment also illustrates the sensitivity and internal dynamic range of the instrument; the granddaughter ion at m/z 69 is at a relative abundance level of only 1/10,000 of the intensity of the same mass ion in the original EI spectrum. Fig. 3 shows picogram sensitivity in the isobutane CI/MS/MS analysis of DIMP, a chemical warfare simulant. The daughter ion at m/z 163 is due to an interference; single-stage MS analysis or selected ion monitoring would not allow differentiation between sample and background at m/z 181.

The full-scan sensitivity of the ITMS is increased by more than one order of magnitude with the introduction of axial modulation. For low sample detection limits and high signal-to-noise ratios, it is desirable to build up a large ion population prior to mass analysis. While the maximum ion storage capacity of the ion trap is around 10^6 to 10^7 ions, only 10^4 to 10^5 ions can be stored for mass analysis with unit mass resolution in an RF-only scan. With this limitation, sample ion intensities may be weak compared to ion signals from the chemical background. A similar situation exists when an analyte ion of interest is present only at a very low abundance level. Overloading the trap to increase the number of sample ions leads to resolution loss due to space charge interactions (Fig. 4a). Ions of higher mass, still stored in the trap when a mass is near instability, reduce the effective trapping field; thus, the ion ejection is delayed, and mass peaks show tailing. This effect can be overcome by the application of an axial modulation voltage between the endcaps of the ion trap as Fig. 4b shows.

The modulation is applied at a fixed frequency and amplitude during the mass analysis RF ramp. The frequency is close to 1/2 of the fundamental RF frequency. Unlike the quadrupole field, which is zero in the center of the trap, the field generated by the modulation frequency is nearly homogeneous in the axial direction. Ions that are just about to be ejected from the trap (near q=0.91 and beta=1) are in resonance with this field, and their ejection is facilitated, leading to the improved mass resolution. High-sensitivity EI/GC/MS results with axial modulation are described in (2), but improved resolution at higher sample ion intensities is also observed in CI and MS/MS analyses.

NEGATIVE ION CHEMICAL IONIZATION AND MS/MS OF NEGATIVE IONS IN AN ION TRAP MASS SPECTROMETER

Scott A. McLuckey, Keiji G. Asano, and Gary L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN

At the 1987 ASMS meeting in Denver we described experiments in which MS and MS/MS analyses were performed on negative ions formed from polyatomic molecules in an Ion Trap Mass Spectrometer.[1] We found that negative ions could be readily formed and that MS/MS efficiencies varied widely depending upon the anion. Since then, we have continued with experiments involving the use of the ITMS for the study of polyatomic anions. These experiments have involved both the formation of anions within the trap, as described in Denver, and the formation of anions in a high pressure ion source followed by injection into the ion trap for analysis. Results from both experiments are described here.

We have found that, in general, it is highly desirable to avoid the build up of positive ions in the trap while forming anions in order to avoid neutralization. This can be done in several ways by using either a DC voltage on the ring electrode, a tickle voltage on the end caps, or a combination of both. In any case, however, we find that the signals obtained for the negative reagent ions are roughly 10^3 lower than those for the positive ions derived from the same reagent gas. This may well be due to the fact that electrons are not stored in the trap under conditions for ion storage. The number density of thermal electrons in the trap is therefore always relatively low resulting in poor conditions for electron capture.

We have studied in greater detail the reagent ions derived from water, i.e. $O^{-\cdot}$ and OH^-. The hydroxide anion is formed form the reaction of the oxide anion with water. We have measured the rate for this reaction to be 2×10^{-10} cm^3/molecule-s under the normal ion trap operating conditions. The hydroxide anion can be selected as the only reagent ion either by mass selecting OH^- using the proper combination of rf and DC voltages, tickling out $O^{-\cdot}$, or simply by allowing all of the $O^{-\cdot}$ to react with water to give OH^-. The ion/molecule reaction chemistry of OH^- can then be studied in a straightforward manner. For example, Figure 1 summarizes the results of the reaction

$$OH^- + CH_3CH_2COOH \longrightarrow H_2O + CH_3CH_2COO^-$$

studied as a function of time. The rate constant derived from these experiments is $k = 3 \times 10^{-9}$ cm^3/molecule-s. Ionization by $O^{-\cdot}$ is less readily studied using water as the reagent gas, on the other hand, due to its reactivity with the parent molecule. Short ionization and reaction times must be used to avoid the conversion of $O^{-\cdot}$ to OH^- which limits the reactions that can be studied to those with rate constants much greater than 2×10^{-10} cm^3/molecule-s and requires sample pressures on the order of the pressure of water. Other reagent gases are therefore likely to be more appropriate for ionization by $O^{-\cdot}$.

For analytical purposes, it is perhaps preferable to form negative ions in an external ion source with high thermal electron concentrations and to inject the anions into the ion trap for analysis. We have recently succeeded in injecting anions into an ITMS from an atmospheric sampling glow discharge ion source and have observed much larger signals than are obtained from forming anions within the trap itself. Although it is possible to avoid injecting positive ions into the trap while anions are injected, care must nevertheless be taken to avoid build-up of positive ions resulting from electron impact ionization by the electrons that are injected with the anions. Most of the positive ions are m/z 32 or less so that recombination is largely avoided by setting the rf voltage on the ring electrode to reject

these low mass ions. Figure 2 shows the mass spectrum and MS/MS spectrum of 2,4,6-trinitrotoluene (TNT) present at a concentration of a few ppb in the air sample drawn into the atmospheric sampling glow discharge ion source. An MS/MS spectrum of sufficient S/N for identification can be obtained for TNT in 0.35 s. These preliminary results are promising for the combination of a high pressure external ion source with the ITMS.

We have obtained MS/MS spectra from a variety of organic acids and nitro compounds during the injection experiments. As a rule, the $(M-H^+)^-$ derived from alkylcarboxylic acids show very poor fragmentation efficiencies (< 1%) in the MS/MS spectra whereas the $M^{-\cdot}$ anions of organic nitro compounds tend to give efficiencies > 10%. These studies have reinforced earlier findings that the competition between electron detachment and fragmentation with charge retention is highly compound dependent.

COMPARISON OF CHARGE EXCHANGE AND ELECTRON IONIZATION IN QUADRUPOLE ION TRAP AND TRIPLE QUADRUPOLE MASS SPECTROMETERS

D.W. Berberich, M.E. Hail, R.A. Yost, University of Florida, Department of Chemistry, Gainesville, FL 32611.

Interest in the quadrupole ion trap has recently undergone a resurgence, due in part to the commercialization of the ion trap detector and the ion trap mass spectrometer (Finnigan MAT ITMS). In traditional quadrupole mass spectrometers, electron ionization (EI) is performed in a low pressure (~ 10^{-6} torr) continuous ionization source located before the mass analyzer. In the ITMS, EI occurs in the same region as mass analysis, in the presence of ~ 10^{-3} torr of helium buffer gas, and with ions stored for several milliseconds. A significant question concerning ionization in the ITMS is what type of ionization, EI or charge exchange (CE), predominates under standard EI operating conditions.

Charge exchange on traditional mass spectrometers is usually performed in ionization sources using reactant gas pressures of 0.3 - 1.5 torr (1,2). The limitation of this approach is that the spectra may be the result of CE of the desired reactant ion and sample molecule, as well as both CE with undesired reactant ions in the source and EI. Alternatively, CE spectra may be obtained with a triple quadrupole (QQQ) instrument (Finnigan MAT TSQ-70) by allowing CE reactions to occur in the collision cell (Q2). A schematic representation of the Q2 CE scan is shown in Figure 1. The reactant gas is introduced into the ion source and ionized with 70 eV electrons. Q1 is used to mass select the desired CE reactant ion and pass it into Q2. Samples are introduced into Q2 via a direct leak from a fine metering valve. The sample molecules and the reactant ions react in Q2 to produce the charge exchange product ions that are mass analyzed by Q3. This approach eliminates spectral interferences produced by EI and CE with undesired reactant ions. Figure 2A shows a normal (Q1) mass spectrum of n-butyl-benzene obtained on QQQ instrument with He reactant gas present in the ion source. The spectrum shows ions produced by various CE processes, as well as by EI. In contrast, Figure 2B shows a CE spectrum of n-butylbenzene obtained with the Q2 CE scan in the collison cell of the QQQ instrument. Note the very low intensity of the molecular ion (m/z 134) and the increased intensity of the fragment ions m/z 39 and m/z 65 in Figure 2B resulting from the energetic He CE.

In the ITMS, CE occurs in the same region as mass analysis, and is achieved by trapping ions for milliseconds at a much lower pressure ($<10^{-3}$ torr). The ITMS is normally operated in a RF-only mode. Operation of the ITMS with both RF and DC voltages (i.e selective mass storage) allows for the storage of a single m/z. Thus, unambiguous CE reactions can be obtained by mass selecting a single reactant ion, and allowing the CE reaction to occur over a specified period of time. The resulting CE spectrum is obtained by ramping the RF voltage and causing the ions to be ejected from the quadrupole ion trap.

Helium, nitrogen, argon, and carbon dioxide were examined as reactant gases, since it was anticipated that these gases would produce markedly different CE spectra. This is due to the fact that the amount of internal energy deposited into a molecule ionized by CE is dependent upon the difference between the recombination energy of the reactant ion and the ionization potential of the molecule (Table 1). The N_2, Ar, and CO_2 CE mass spectra of phenylacetonitrile and n-butylbenzene obtained on the respective instruments are very similar. Figure 3 shows a comparison of N_2 CE on the ITMS (RF-DC mode of operation) and N_2 Q2 CE on a QQQ for n-butylbenzene. The ratio of m/z 91 to m/z 92 ions differ by only 2% on the respective instruments, which is well within the limits of experimental error.

The experiments with helium as a reactant gas indicate that He CE does not contribute significantly to the EI spectra obtained in the ITMS. This may be due to the fact that although helium ions are formed in the ITMS,

they are not stored long enough to allow CE to occur. The experiments on the QQQ indicate that "true" CE can not be effectively performed in the ionization source, while selective CE can be performed using the Q2 CE scan. By means of the Q2 CE scan, it is possible to select a variety of reactant ions from the same reactant gas. For example, argon produces three different reactant ions Ar^{+} , Ar^{+2} , and Ar_2^{+}, which can be used as reactant ions in the Q2 CE scan. This is useful since one may be able to obtain both structural and molecular weight information by simply selecting different reactant ions which have different recombination energies. Similar capabilities exist in the ITMS, although potential interferences may arise from other reactant ions being produced with long reaction times.

MS^n EXPERIMENTS WITH AN ION TRAP MASS SPECTROMETER:

Gary L. Glish, Gary J. Van Berkel, Keiji G. Asano, Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831

MS/MS has become a fairly routine analytical technique. Addition of another stage of mass spectrometry or MS/MS/MS (MS^n, n=3) can provide added specificity in an experiment. For beam type instruments in which the ions pass sequential analyzers, each additional stage of MS/MS requires an additional analyzer. However, with trapping type mass spectrometers, the ions are manipulated in time using a sequence of rf (and sometimes DC) voltages. Thus, multiple stages of mass spectrometry can be performed with one analyzer. The experiments discussed in this paper were done with a Finnigan MAT Ion Trap Mass Spectrometer (ITMS), which is a three dimensional quadrupole.

A very simple but potentially very useful MS^n experiment that can be done with the ITMS is selected reagent ion chemical ionization (SRICI). In this experiment the MS/MS capability of the ITMS is used to select one specific reagent ion from the suite of ions usually formed. This ion is then allowed to react with the analyte. A mass spectrum obtained in this way is an MS^n experiment where n=2. Doing MS/MS on an analyte ion makes n=3 and futher stages of MS/MS can also be performed. The SRICI experiment can not be performed on beam instruments unless the analyte has a high vapor pressure under the operating conditions of the reaction region. An example of the effect of the SRICI experiment is shown in Figure 1 where three mass spectra are shown for the compound promethazine, one obtained with all the methane reagent ions present, one in which m/z 17 was selected as the reagent ion, and one in which m/z 29 was selected. As can be seen, the spectra are quite different, especially when using m/z 17 as the reagent ion. The SRICI experiment allows the differentiation of ionization and fragmentation mechanisms. When using ammonia as a reagent gas, only the proton donating species m/z 18 is present so it might be assumed that the SRICI experiment is unnecessary. However, the base peak in the mass spectrum without reagent ion selection is m/z 72, which is completely absent in the spectrum in which m/z 18 was selected as the reagent ion. The ion at m/z 72 is assumed to arrise from residual EI of a thermal decomposition product of the promethazine, which must be in much greater abundance than the promethazine. It should be noted that the mass spectra without reagent ion selection are the same as those observed with conventional CI sources on beam instruments.

One of the characteristics of the ITMS that makes it possible to do MS^n experiments is its high MS/MS efficiency. A series of experiments with 2,5 dimethylpyrrole showed overall ion trapping efficiencies of greater than 50% for MS^n experiments with n=5. Conversion efficiencies of the parent ion to the great,great granddaughter ion of several percent have been obtained with the ITMS.

Another feature of the MS^n experiment is that not all the stages have to be CID. Ion/molecule reactions can be performed at any time during the course of an experiment. Figure 2 shows an example of this in which the structure of the $(M+H-17)^+$ daughter ion from 2,5-dimethylpyrrole was determined by reacting it with methane and then doing two more stages of MS/MS (CID), making the total experiment MS^5. These spectra along with confirming spectra from standards (benzene and toluene) indicate that this $(M+H-17)^+$ ion has the same structure as protonated benzene.

MS^n experiments have been performed with octaethylporphyrin where n is as large as 8. In these experiments the alkyl substituents are sequentially cleaved off of the porphyrin ring. Other MS^n experiments with porphyinogens have demonstrated the utility of the experiment for obtaining pyrrole sequences. This type of experiment should be a powerful tool for structure analysis of these and and many other types of compounds.

ION TRAP MS/MS ASSAYS OF BIOLOGICAL EXTRACTS USING rf/DC

Robert J. Strife and John R. Simms
The Procter and Gamble Co.
Miami Valley Laboratories
P.O. Box 398707
Cincinnati, OH 45239-8707

INTRODUCTION -- The Ion Trap Mass Spectrometer (ITMS) offers the potential for very selective and sensitive GC/MS/MS assays. This is because: 1) it is an ion storage device and 2) using MS/MS scan functions (tandem in time) very high CAD efficiencies are observed, even 100% in some cases.

One objective of MS/MS is to simplify sample preparation prior to analysis. This is especially helpful in studies dealing with fundamental pharmacology or drug disposition. In this study we wanted to examine quantitative GC/isotope-dilution-MS/MS of a known biological system, using the ITMS, before moving on to problem solving of unknowns. The model chosen was tryptamine in rat brain tissue, reported by two separate groups at levels from 100-500 pg/g using GC/MS(SIR) of the bis-pentafluoropropionamide derivative[1,2].

The full scan mass spectrum of the derivative at the 25 pg level is shown in Figure 1 with the reconstructed mass chromatogram (m/z 289) in the inset. It matched the spectrum at the 2.5 ng level fairly well and demonstrates the full scan sensitivity of the ITMS in the rf-only mode. The most obvious choice of a parent ion for sensitive MS/MS is m/z 289. Its structure, based on classical rules of fragmentation, is shown in Figure 1.

rf/DC Scan For MS/MS on the ITMS -- Use of an rf/DC scan function, recently described for prostaglandin analysis[3], allows storage of ions of only one m/z value in the trap. All other ions created by the initial electron pulse go into unstable trajectories and leave the trap. The selected ion, m/z 289 in this case, is then subjected to CAD by the normally used methods. Using rf/DC has important consequences for biological sample analysis (vide infra).

Daughter Ion Spectra -- The GC/MS/MS analysis of a 50 pg standard, using the rf/DC scan function, is shown in Figure 2 with the total daughter ion current trace inset. Two derivative-specific cleavages are seen (m/z 170, loss of C_2F_5, and m/z 142, loss of C_2F_5CO). Based on our previous work, monitoring these reactions may hold marginal benefit for improving the selectivity observed in GC/MS. Finally loss of C_2F_5CO + HCN, from the indole backbone, is observed and would be predicted to give more enhanced selectivity than the other reactions. The loss of HCN vs C_2H_3 (both 27 u) is supported by studying the spectrum of 3-(1,1,2,2-[^{2}H]$_4$-ethylamino)-indole, e.g. deuterated tryptamine. All daughter ions of m/z 292 (corresponding to m/z 289) are shifted by 3 u.

GC/Isotope Dilution MS/MS -- To perform isotope-dilution-MS/MS experiments, rf/DC MS/MS scan functions for the native and deuterated compound are loaded into the firmware and performed alternately. This is accomplished with a FORTH language programming editor. This process is only about half as fast as a normal single-function MS/MS experiment. Two scans are averaged per second for the labelled and unlabelled compound each, giving a data point (averaged spectrum) per second for the d_0- and d_4 chromatograms. Initial results were encouraging. For 100 pg - 2.5 ng tryptamine and about 10 ng of deuterated material on column (5% of the derivatized sample), the equation $y = .00668x - .003$ ($r=.9986$) was found for the reaction ($289^+ \rightarrow 115^+$)/($292^+ \rightarrow 118^+$) vs. ng d_0-tryptamine (Figure 3).

Crude Biological Extract Analysis -- Because sample preparation schemes are shortened for MS/MS analyses, the extracts are of a more-crude nature than

might be prepared for a typical GC/MS assay. Since the trap has a finite storage capacity for ions, it is necessary to eliminate matrix-related ions as efficiently as possible. This is the critical advantage of the rf/DC scan function.

Figure 4a shows an attempted analysis of a crude brain extract spiked with 500 pg derivatized d_4-tryptamine. Using an rf-only MS/MS scan function, the analysis is a failure. Other experiments indicate this is due to an excessive ion population in this mode, since only a high-pass mass filtering is achieved after ionization (e.g. all ions above m/z 289 are stored prior to MS/MS). Using an rf/DC scan function, and analyzing the same sample, the peak is clearly detected (Fig. 4B) and the daughter-ion spectrum is correct. This is a direct result of the selective-mass-storage condition achieved through the use of rf and DC voltages. The initial space-charge is eliminated and spatial focussing may be occurring also[4]. Further work is aimed at understanding these and other factors necessitating rf/DC scan functions for crude extract analysis, and optimizing the extraction scheme for tryptamine.

SIMULTANEOUS MS-II MEASUREMENTS USING HADAMARD TRANSFORM FOURIER TRANSFORM MASS SPECTROMETRY

S. Y. Loh, E. R. Williams, F. W. McLafferty and R. B. Cody[1]
Chemistry Department, Cornell University, Ithaca, NY 14853-1301
(1) Nicolet Analytical Instruments, 5225-1 Verona Road, Madison, WI 53711

The ideal instrument for MS/MS would have multichannel detection capabilities for both MS-I and MS-II, to be able to dissociate many precursor ions and to collect their daughter spectra simultaneously. Fourier transform mass spectrometry (FTMS) measures all ions of a spectrum simultaneously; in addition, any number of precursor ions can be selected and dissociated simultaneously. We recently proposed [1] a Hadamard method for combining these two features of FTMS for simultaneous recording of multiple MS-II spectra. Using Hadamard masks, different combinations of half of n precursors are selected for dissociation. From the resulting n spectra, individual daughter spectra are obtained by solving n simultaneous equations.

This method has been applied to a synthetic mixture of 11 compounds using a Nicolet FTMS-2000. A SWIFT waveform [2] is used for high resolution selection of the precursor ions formed by 14 eV electrons (figure 1). Different combinations of 6 of these are subsequently excited and allowed to undergo collisionally activated dissociation. After the Hadamard transform, daughter ion spectra for each of the precursors are obtained (figure 2a,b) A signal-to-noise enhancement of 2.4 is achieved over spectra measured individually under identical conditions (figure 3). Spectra collected using both high and low energy collisions makes possible complementary high and low energy fragmentation, respectively. The Hadamard method of multiplexing yields the greatest advantage with large numbers of precursor ions. Thus, daughter ion spectra of 100 precursors can be collected in 1/25 the time.

For MS/MS/MS, Hadamard masks can be applied to n MS-I and i MS-II ions to produce i MS-III spectra. Again, the individual MS-III spectra can be extracted from the different combination of Hadamard masks and will result in a $(n \cdot i)^{0.5}/4$ enhancement in signal-to-noise. The Hadamard method is compatible with alternate methods of ion dissociation, including photodissociation and EIEIO, and can also be used for studying numerous ion-molecule reactions simultaneously. For the latter purpose, the Hadamard method has advantages over the 2D ICR technique of Bodenhausen and Gaumann [3], including a greater S/N advantage and higher MS-I selectivity.

FOURIER TRANSFORM TANDEM MASS SPECTROMETRY FOR THE QUALITATIVE ANALYSIS OF COMPLEX MIXTURES

Marcus B. Wise and Michelle V. Buchanan
Organic Spectroscopy Group, Analytical Chemistry Division
Oak Ridge National Laboratory, Oak Ridge TN 37831-6120

Tandem mass spectrometry (MS/MS) is a technique of growing importance in the field of analytical chemistry. In particular, the ability to qualitatively analyze complex mixtures without prior chromatographic separation of the constituents often results in faster sample turn-around than a corresponding GC/MS analysis. Further, by having a wide range of parent ion excitation energies available such as is the case with Fourier transform mass spectrometry (FTMS), the fragmentation of an ion is more easily controlled than is the case with electron impact ionization. This in itself can be an important tool for structure determination.

Although FTMS is capable of being operated as a high performance tandem mass spectrometer often with very efficient parent-daughter ion conversion, application of this technique to complicated direct probe or batch inlet samples is very labor intensive. As a result, we have developed software for the Nicolet FTMS-2000 that significantly increases the analytical utility of the MS/MS mode of operation for complex mixture analysis. This software consists of a Fortran program and several command files which operate together as a "batch" data acquisition and processing scheme for automated parent ion MS/MS scans. Since a complete daughter ion spectrum is obtained for each parent ion, a real-time peak extraction routine is used to monitor specific neutral losses and constant daughter ions. Program options allow the storage of the complete daughter ion and extracted ion spectra and at the end of a parent ion scan, hard copies of spectra are output on the plotter.

For a typical direct probe sample, low energy electron impact or chemical ionization is used to minimize fragmentation of constituents in the mixture. Prior to the start of an experiment, several parameters must be entered by the user including the parent ion scan limits, the parent ion excitation energy, the relative threshold below which a parent ion will be ignored, the neutral loss masses to be monitored (up to 5), the constant daughter ions to be monitored (up to 5), and the filenames for data storage. The program then collects a complete mass spectrum of the sample (no MS/MS) in order to determine the maximum peak intensity for the parent ion relative threshold calculations. Once this is accomplished, the parent ions are sequentially dissociated starting at the low mass of the scan limits. Prior to the dissociation step, all ions within 12 amu of the low mass side of the parent ion are ejected from the cell using the double resonance pulses. The parent ion excitation time is then calculated for the specific parent ion mass in order to produce the requested kinetic energy level. Following application of the excitation pulse and a 50 msec collision period, the daughter ion mass spectrum is collected and the specific ions (neutral losses and constant daughters) are extracted. Corresponding mass and intensity information is then directed to the printer and the spectra are stored if desired. This process is then automatically repeated until all parent ions above the relative threshold (an within the scan range) have been dissociated. An option also exists for background subtraction in which a spectrum with no dissociation is collected immediately prior to each MS/MS spectrum and subtracted from the extracted ion results. This is particularly useful for reducing false contributions to the daughter ion spectrum which may result from the incomplete ejection of the low mass ions prior to dissociation.

As an example of the utility of this software, a fuel oil (API Home Heating Oil #975) was run using batch inlet sample introduction. Low energy electron impact ionization was used and 8K data points were collected to produce the spectrum shown in Figure 1. Since this sample contains numerous alkyl-substituted benzenes, one of the neutral losses

"The submitted manuscript has been authored by a contractor of the U S Government under contract No DE-AC05-84OR21400 Accordingly the U S Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so for U S Government purposes."

that was monitored was the loss of 15 (CH_3). A parent ion excitation energy of 175 eV was used and parent ions above a 2% relative threshold were dissociated between 75 and 250 amu. For each daughter ion spectrum, a total of 25 spectra were averaged (8K points, 1 MHz bandwidth) and the background subtraction routine was employed. The corresponding neutral loss spectrum shown in Figure 2 clearly indicates which parent ions undergo loss of CH_3. Combined with MS/MS information, the alkyl aromatics are readily identified and consistent with GC analysis of the same sample. The complete run-time for this spectrum was approximately 30 minutes compared with approximately 2 hours for a corresponding capillary GC run. Other applications of this MS/MS software will be for the qualitative analysis of tobacco smoke tars and biological samples.

The ability to evaluate the biological damage produced in the tissues and cells of organisms exposed to chemical carcinogens may facilitate understanding of the role that these agents have in the occurrence of selected cancers. A promising method for assessing such damage is the determination of the covalent interaction of chemical carcinogens with DNA. The methodology currently used to identify and quantitate DNA adducts in organisms exposed to carcinogenic agents consists of chromatographic separation of the components in DNA hydrolyzates followed by fluorescence, ^{14}C radioactivity, or ^{32}P-postlabeling detection. These detection methods, however, yield little structural information and characterization of DNA adducts must be accomplished using some other technique.

In this research, normal and modified nucleosides and nucleotides have been characterized using IR laser desorption Fourier transform ion cyclotron resonance mass spectrometry. The LD-FT-ICR-MS system used coupled a pulsed, TEA CO_2 laser, operating at 10.6 um, with a Nicolet FTMS-1000 spectrometer. Compounds studied were adenosine, guanosine, cytidine, uridine, thymidine, deoxyguanosine, deoxycytidine, 3,N^4-ethenocytidine, adenosine triphosphate, and 1,N^6-ethenoadenosine triphosphate.

All of the nucleosides studies produced positive ion mass spectra dominated by alkali cation attachment (Na^+, K^+) molecular ions (Figures 1 and 2) Similarly, prominent in the negative ion spectra of the nucleosides was the $(M - H)^-$ ion. Use of broadband, medium resolution conditions yielded mass errors of less than 30 mAMU for most of these pseudomolecular ions.

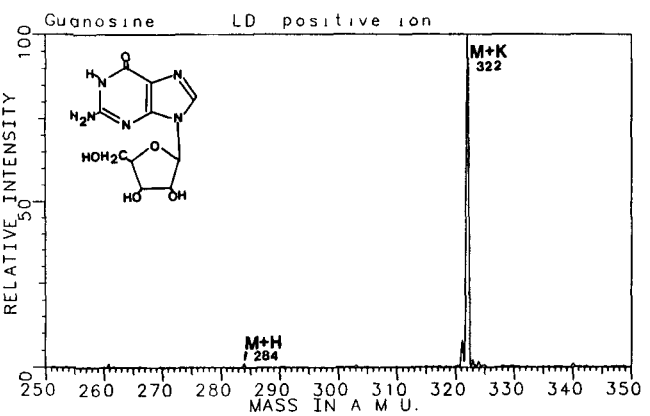

Figure 1.

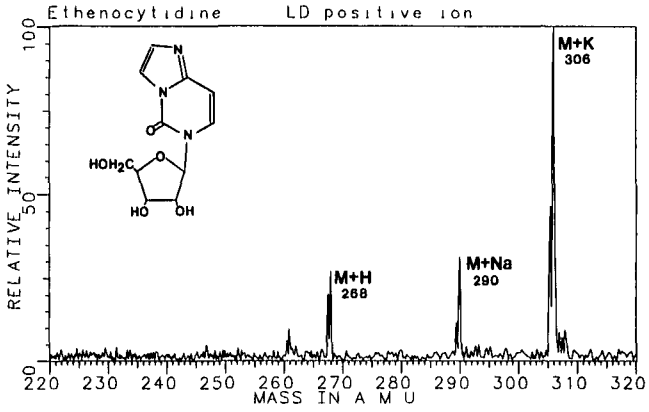

Figure 2.

In contrast, ionization of the nucleotides using the IR laser produced extensive fragmentation; molecular ions were absent in both the positive and negative ion mass spectra. The base peak in the negative ion spectra was the phosphate fragment, PO_3^-. At a lower abundance are the fragment ions corresponding to the nucleobase portion of the molecules. Using negative ion LD-FT-ICR-MS the detection limit of 1,N^6-ethenoadenosine triphosphate was estimated below 100 ng.

The positive ion spectra of the nucleotides were of lower quality than the negative ion spectra. Peaks corresponding to the nucleic base fragment ions, $(B + H)^+$ and $(B + \text{cation})^+$ were present in these spectra. The relative abundance of these ions was quite low, however, and reproducibility of the spectra was poor.

These results demonstrate the ability of LD-FT-ICR-MS to identify modified and unmodified nucleosides and nucleotides present in low levels. This technique combined with other separation methods provides an excellent tool for the study of an important class of compounds.

LASER IONIZATION FOURIER TRANSFORM MASS SPECTROMETRY FOR THE DIFFERENTIATION OF METHYL GUANOSINE ISOMERS*

R.L. Hettich
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Methylation of deoxyribonucleic acid (DNA) is known to be one form of DNA modification induced by simple alkylating agents. In order to probe the nature of DNA alkylation, it is necessary to identify the structures of the modified species at the isomeric level. This report illustrates the application of laser ionization Fourier transform mass spectrometry (FTMS) for the ionization and structural characterization of five methyl guanosine isomers. Specific emphasis was placed on the identification and differentiation of guanosines containing methyl substitutions on the nucleic base (guanine).

Laser ionization of guanosines containing methyl substitutions in the 1-, N^2-, 3'-O-, O^6-, and 7- positions generated negative ions corresponding to loss of hydrogen to form $(M-H)^-$, and elimination of the sugar ring to generate the negatively charged nucleic base. This fragmentation is shown in Figure 1 for 1-methyl guanosine. All isomers with methyl substitution on the nucleic base fragmented to give negative ions at m/z 164 whereas the 3'-O-methyl guanosine (methyl substitution on the sugar ring) yielded a negative ion at m/z 150, corresponding to the normal guanine nucleic base.

Collisional dissociation was used to differentiate the isomers with methyl substitution on the nucleic bases. Isolation and collisional dissociation of the negative ions at m/z 164 for each isomer gave unique daughter ions. The collisional dissociation spectrum of m/z 164 from 1-methyl guanosine is shown in Figure 2. Loss of CH_3NH_2 from m/z 164 was indicative of methyl substitution in the 1 or N^2 positions, whereas HNCO loss was observed for ions with methyl substitution in the 7 or N^2 positions. Loss of CH_3 from m/z 164 was characteristic for methyl substitution in either the 7 or O^6 positions while CH_3OH elimination was specific to methyl substitution in the O^6 position. Combining these results gave the information necessary to differentiate each of the isomers. These daughter ions could be transferred to the analyzer cell of the FTMS-2000 for accurate mass measurement. By using heterodyne detection, high resolution measurements could be obtained for the daughter ions (a resolution of 298,000 [FWHM] for the m/z 133 negative ion from 1-methyl guanosine is shown in Figure 3).

In order to probe the fragmentation pathways, the daughter ions of m/z 164 were isolated and collisionally dissociated. Figure 4 shows the collisional dissociation spectrum of m/z 133, which has been isolated from Figure 2. This ion at m/z 133 fragments to give daughter ions at m/z 66 $(C_2N_3)^-$ and m/z 26 $(CN)^-$. The ions at m/z 35 and 37 are due to Cl^- which was not completely eliminated during the isolation pulse. Figure 4 verifies that the ions of m/z 106 and m/z 42 observed in Figure 2 are not generated by fragmentation of the m/z 133 ion.

The combination of laser ionization and collisional dissociation with FTMS provides a useful method for the structural characterization of nucleosides and can be used in some cases for isomeric differentiation. High resolution and accurate mass measurements combined with sequential collisional dissociation experiments provided the information necessary to examine the fragmentation mechanisms of ions from these nucleosides.

21018 Osborne St, Unit 4
Canoga Park, California 91304

We report here a system for laser microprobe Fourier transform mass spectrometry. The system is based on a commercial spectrometer (Nicolet FTMS-2000) and a frequency-doubled or quadrupled Nd:YAG laser (Quantel Int'l). The system consists of three distinct subsystems: optical, electronic interface, and specimen motion. Each is described separately.

A schematic of the optical system is shown in Figure 1. Light emitted from the laser travels through a attenuator (s) which allows continuous ajustment of beam intensity, a telescope system (R) which allows online focussing, into the vacuum system, through a 75 mm objective lens (K), reflects off a UV-protected mirror (L), and is focussed on the specimen surface (E). Light for illumination of the specimen is generated by a high intensity lamp, passes through a fiber optic (A), into vacuum through a viewport, into a high vacuum compatable fiber optic (D), is reflected off a parabolic mirror (F) which gently focusses it onto the specimen. Viewing light is reflected by the same mirror (L) using for the laser, is collected by the 75 mm objective lens (K), passes out of vacuum, is intercepted by a mirror (Q) on a slidong stage placed in the light path, and is directed to a TV Camera or instant photographic camera.

An exploded schematic of the specimen motion stage is shown in Figure 2. A vacuum linear-motion feedthrough mounted on a flange (A) is connected to a plunger (C) mounted on rods holding cell. The plunger is connected to a cable-in-a-tube system (E,F), connected to a second plunger (H) insulated at its tip by a ceramic piece (I). A specially designed spring-loaded, dovetailed, sliding specimen stage fits on the standard solids probe tip. The ceramic piece contacts the pad section of the stage. When the low mass, magnetic cable is placed in the magnetic field, the second plunger is drawn in and slides the stage down. Retraction of the feedthrough allows the stage to return to its normal position. Coupling of this motion with the rotary motion of the probe allows access to an area of about 1 cm^2.

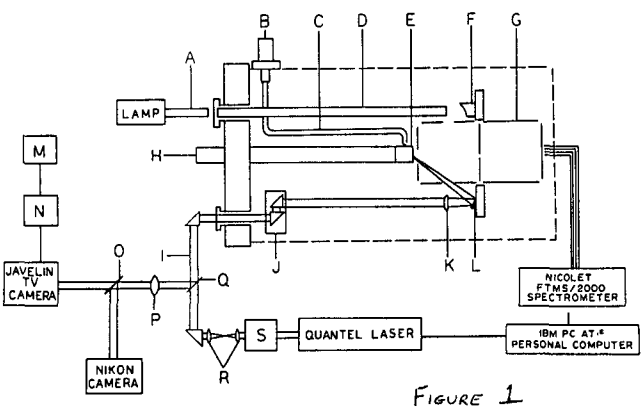

FIGURE 1

A block diagram of the electronic interface is shown if Figure 3. An IBM PC-AT equipped with a Labmaster interface board serves as negotiator between the Nicolet 1280 instrument control computer and the laser electronics. The Labmaster counters are programmed to put out three pulses used to trigger the laser. In "background" mode, only the "charge capacitors" and "fire capacitor" pulses are outputted. This mode allows the YAG rods to attain steady-state temperature without lasing. When a laser pulse is required, the 1280 puts out a pulse which causes the third "Q-switch" pulse to fire, and a laser pulse is obtained. This systems allows optimal laser operation while providing for the use of single or multiple laser pulses for experiment sequences.

The ability of the system to perform local analyses was tested using a 1000 mesh Cu electron microscopy grid silver painted onto a substrate. This specimen presents a surface of copper with interspersed square holes 12 µm on a side. The laser was first directed onto a Cu line. The two Cu isotopes, m/e 63 and 65, are the only ions observed in this spectrum. Next, the beam is directed to ablate material from within in the grid holes. The Ag isotopes, 107 and 109, are observed as the largest peaks in the spectrum. Cu is also present at a level <10%. We conclude from this that the spot size is of the order of 10 µm diameter.

As an additional test of spot size, craters were ablated in a smooth silicon wafer. Minimum crater diameters were shown by electron and reflected light microscopy to be on the order of 3 µm.

APPLICATIONS OF LASER MICROPROBE USING FOURIER TRANSFORM MASS SPECTROMETRY

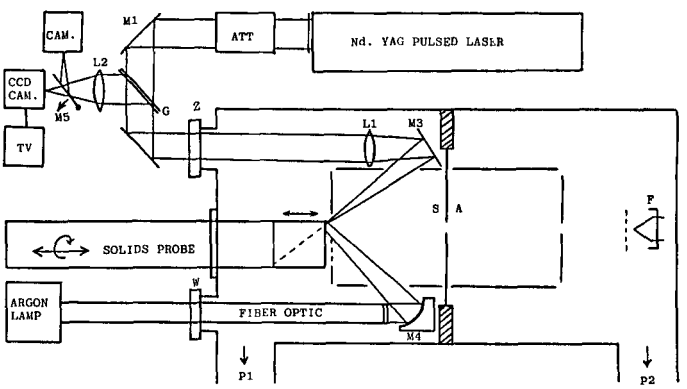
Sahba Ghaderi; IBM, General Products Division, San Jose, CA 95193

Laser microprobe mass spectrometry is a proven technique in the area of surface analysis. Several different types of mass spectrometers equipped with laser microprobe are commercially available. The Fourier transform mass spectrometer (FTMS), however, with its pulsed operation, high mass, and high resolution capability is the best suited technique for pulsed laser applications. The limitations, until recently, has been the lack of proper laser delivery system and the means for viewing the the image of the sample with a reasonable magnification.

A Nicolt FTMS-2000 instrument has been modified for the first time in our laboratory to perform laser microprobe experiments. The goal in this implementation to our instrument has been to perform mass analysis of large and small organic and inorganic molecules on different surfaces. It was also important to us to achieve that goal without major hardware changes and without any sacrifice of instrument performance.

In our design a new laser interface has been substituted for the original one, the cell assembly has been rotated by 180 degrees and modified for a larger laser port flange. A focusing lens and flat mirror are also substituted for the parabolic mirror.

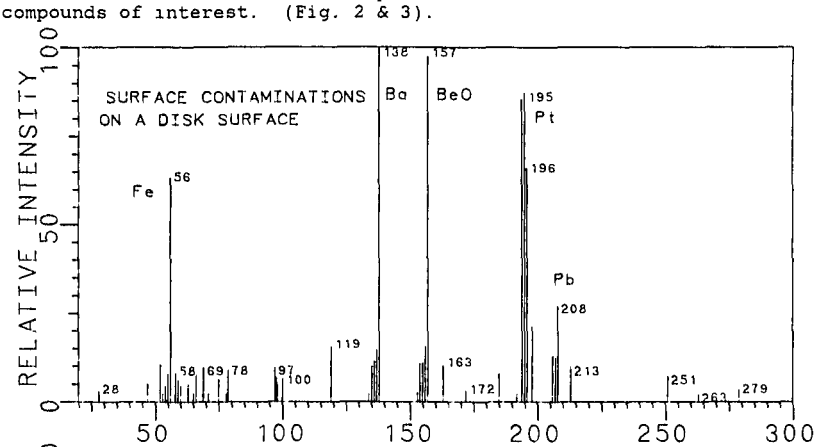
In this set up a focused beam of CO2 laser is used for ablation and ionization of samples. Viewing of the magnified image of the sample is accomplished with a video camera through the same optical path as for the laser. A fiber optic bundle and an external light source provide sample illumination. Laser spot size is 30-50u and magnification is in the order of 60 (Fig. 1).

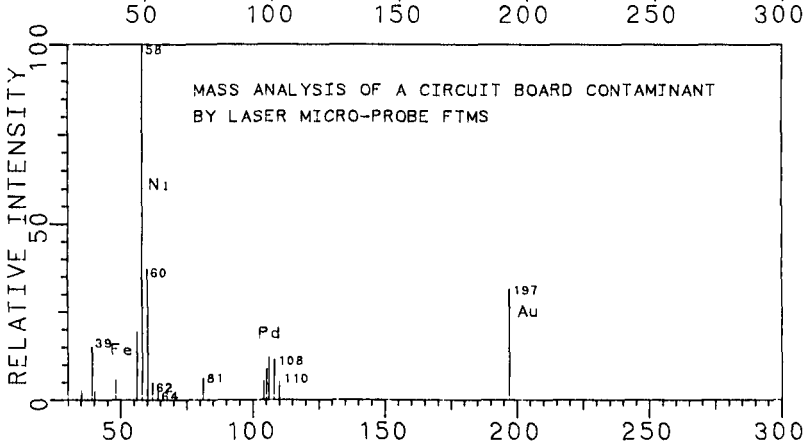


LASER MICROPROBE FTMS AT IBM SAN JOSE

The majority of samples examined by our instrument are related to magnetic storage disk technology. The complex surface of these thin film, multi-layer, ultra high capacity disks provide a very challenging task for the analytical methods used to identify microscopic contaminations.

Other applications of such system include identification of organic and inorganic contaminant on various electronic components, mass analysis of polymers and ceramics, characterization of perfluoriated polyether lubricants on surfaces, as well as general use of the laser in desorption and ionization of different compounds of interest. (Fig. 2 & 3).





Further improvements in our instrument's capability are underway. They include the use of a Nd/YAG laser and modifications in our laser delivery and optical imaging system. These changes are for reducing the laser spot size to below 10u and to improve signal reproducibility. Design and interfacing of an external ion source is also underway in order to improve sample handling and analysis of larger specimens.

THE EFFECT OF ION VELOCITY AND PHASE ANGLE γ ON THE COHERENT ION PACKET

C.D. Hanson, E.L. Kerley, M.E. Castro, and D.H. Russell
Department of Chemistry, Texas A & M University
College Station, Texas 77843.

The analytical capabilities and intrinsic versatility of FT-ICR was recognised early.[1] Although there has been great success in the area of ion-molecule studies, many problems in high mass analysis remain unanswered. The problems incurred in FT-ICR are commonly attributed to the loss of a coherent ion packet. Therefore, in order to achieve the theoretical potential of FT-ICR, the dynamics of a coherent ion packet must be understood. The effect of translational energy on the creation of a coherent ion packet is difficult to study in simple cubic ICR cells. The complicated issue of ion motion and ion kinetic energy can be modeled in a two-section cell. By giving ions translational energy prior to the partitioning event, the effect of translational energy on the creation of a coherent ion packet can be systematically studied.

A coherent ion packet is an ensemble of ions which can be approximated by a single ion. To meet these requirements the ion packet must be both spatially and phase defined. Because ions are initially formed in the ICR cell over several milliseconds (*i.e.*, many cyclotron periods) and with initially random motions, there is a random distribution of phases. The mechanism for the production of a coherent ion packet is ion acceleration by a resonant oscillating electric field. An ion which is initially out-of-phase with respect to the rf excitation must change the period of its synchronous orbit (ω_{eff}) to become phase coherent (see figure 1). The required frequency shift can only occur in ion motion which is dominated by an electric field.

Ions whose frequencies are governed by the Lorentz force of a dominant magnetic field ($\omega_{eff}=\omega_c$) are restricted from undergoing a frequency shift and are therefore locked out-of-phase. Owing to the velocity dependence of the Lorentz force ($F=qv_{xy}B$), the effect of the magnetic field increases with translational energy. Thus, an ion formed with significant translational energies will be held out of phase with respect to the excitation field.

It has been demonstrated that an ion which is translationally excited to a larger cyclotron radius by a resonant oscillating electric field can be de-excited by inverting the phase of the applied rf field with respect to the phase of the cyclotron orbit.[2,3] In this manner the translational energy of selected ions can be systematically regulated by an excitation/de-excitation technique.[4] Ions which are originally excited to radii which exceed the dimensions of the conductance limit orifice can be de-excited to radii acceptable for partitioning. Contained in figure 2 is a schematic of the procedure for investigating the effect of translational energy and relative phase angle in a two-section cell. Following ion production in the source region (A), all ions are excited to larger cyclotron radii by an rf excitation sweep (B). Selected ions are de-excited to the original radii by applying a second rf sweep which is 180° out of phase with respect to the cyclotron motion of the selected ions (C). The phase of the second pulse is selected by a variable delay between the first and second excite pulses. If the delay between the pulses corresponds to an odd integral of $\pi r/2$ (where r is the period of the cyclotron orbit) the second excite pulse will be phase inverted. The radius of the de-excited ion can be analyzed by utilizing the orifice of the conductance limit. Only ions de-excited to energies corresponding to the dimensions of the orifice of the conductance limit will be partitioned into the analyzer region of the two-section cell (D).

An ion which is held out-of-phase with respect to the applied oscillating electric field will be de-excited and lose translational energy. As the ion loses translational energy, the effect of the magnetic field will decrease with respect to the applied electric field. At a point at which the force applied by the electric field is greater than the force applied by the magnetic field, phase shifting can occur by frequency advance. An ion which is initially out-of-phase will become phase coherent with the dominant electric field. As the ion gains energy by the rf field, force of the magnetic field increases and the frequency is determined by the m/z ratio.

Contained in figure 3 is the schematic used to probe the energy of phase advancement. Ions are formed with thermal energies by electron impact and accelerated to larger radii by rf excitation (S1). After a delay of $r/2$ ($\gamma=180°$), a second rf excitation is applied. Because the second excitation is out-of-phase with respect to the ion motion, the ions are de-excited and lose translational energy. If the second rf excitation is allowed to de-excite the ions to a point at

which the electric field becomes dominant, the ions will become phase coherent and gain energy. Contained in figure 4 is a plot of signal intensity in the analyzer region of the two-section ion cell vs. the length of the second rf excitation (S2). Only ions which have been de-excited to smaller radii are allowed to partition due to the conductance limit. The centroid of the peak corresponds to the energy at which the ion phase advances. Ions that become phase coherent with the applied field are accelerated to larger radii and not partitioned.

External ion sources produce ions having random phases and significant translational energies. Because of the strong Lorentz force caused by the translationally hot ions, de-excitation followed by phase advancement results in a broad energy distribution. Owing to the extreme significance of the definition of the ion packet on ion detection, initial translational energy of ions trapped in an ICR cell is of profound importance.

PRIMARY STRUCTURE OF PAIM I, AN α-AMYLASE INHIBITOR FROM *Streptomyces corchorushii*, DETERMINED BY THE COMBINATION OF EDMAN DEGRADATION AND FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Kazuo Hirayama
Central Research Laboratories, Ajinomoto Co., Inc.,
1-1 Suzuki-cho, Kawasaki-ku, Kawasaki, 210 Japan

Paim I and II, protein α-amylase inhibitors, inhibit animal α-amylases from pig, dog, cow, horse, *etc.*, but have no activity against human salivary and pancreatic α-amylases. Paim means pig pancreatic α-amylase inhibitor from microbes. The primary structure of Paim I has been determined by Edman degradation and FABMS 1),2). The primary structures of Paim II have been determined by high-performance tandem mass spectrometry.

Positive-ion FAB mass spectra were recorded with a JEOL JMS-HX110 double-focusing mass spectrometer fitted with a 23-kG high-field magnet and operating at accelerating voltages 10 kV. Tandem mass spectra were recorded with a JEOL JMS-HX110/HX110 tandem mass spectrometer.

Figure 1 shows the primary structures and positions of disulphide bridges of Paim I and Paim II determined by this investigation. Figure 2 shows the positive-ion FAB mass spectrum of RCM-Paim I (reduced and carboxymethylated Paim I) and those of subpeptides generated by *Staphylococcus aureus* V8 protease digestion. RCM-Paim I gave a protonated average molecular ion of m/z 7657.0. The caluculated monoisotopic molecular weight of RCM-Paim I from S1, S2, and S3 agreed well with the estimated monoisotopic molecular weight of RCM-Paim I by FABMS(7652.0). Peptides S1, S2, and S3 were chosen for sequencing by an automated Edman degradation.

Automated Edman degradation of RCM-Paim I revealed the sequence up to the 28th cycle ending with valine(28). The amino acid sequence in this region is

```
 1                                   10
Ala-Ser-Glu-Pro-Ala-Pro-Ala-CmCys-Val-Val-Met-Tyr-Glu-Ser-
                                20                      28
Trp-Arg-Tyr-Thr-Thr-Ala-Ala-Asn-Asn-CmCys-Ala-Asp-Thr-Val-
```

N-terminal amino acids of S1, S2 and S3 were determined as glycine, alanine and serine, respectively by dansyl method. Peptide S2 corresponds to Ala(1)-Glu(13) in this sequence on the basis of its molecular weight, N-terminal amino acid and *S. aureus* V8 protease specificity.

The Edman degradation of peptide S3 revealed the sequence up to the 25th cycle:

```
 14                    20
Ser-Trp-Arg-Tyr-Thr-Thr-Ala-Ala-Asn-Asn-CmCys-Ala-Asp-
                30                          38
Thr-Val-Ser-Val-Ser-Val-Ala-Tyr-Gln-Asp-Gly-Ala-
```

After further digestion by *S. aureus* V8 protease, the COOH-terminal peptide S3-2 from S3 was purified by HPLC. Automated Edman degradation of this peptide revealed the sequence up to the 18th cycle, ending at Gly(54). The sequence of the peptide is

```
 37        40                                    50          55
Gly-Ala-Thr-Gly-Pro-CmCys-Ala-Thr-Leu-Pro-Pro-Gly-Ala-Val-X-Y-Val-Gly-Z
```

Three amino acids, X, Y and Z could not be determined by the Edman degradation method. After treatment with carboxypeptidase Y, peptide S3-2 gave mass peaks at m/z 1627.8, 1471.7, 1370.5, 1269.5, 1170.4, 1099.6, and 1042.6 on the FAB mass spectra. The results indicated that the C-terminal sequence of S3-2 is -Gly-Ala-Val-Thr-Thr-(Val,Gly)-Glu.

Automated Edman degradation of the fragment S1 established the sequence of all 18 amino acids shown below.

```
 56          60                                  70
Gly-Tyr-Leu-Gly-Glu-His-Gly-His-Pro-Asp-His-Leu-Ala-Leu-CmCys-Pro-Ser-Ser
```

The positions of disulphide bonds in Paim I were determined as follows.
The *S. aureus* V8 protease digests of Paim I gave a protonated molecular ion at m/z 2523.2 on the FAB mass spectrum. This ion can be assigned to disulphide bridged peptide Gly(37)-Glu(55)+His(66)-Ser(73). This suggests that Cys(42) must be linked with Cys(70).

Fractionated peptide (f) gave a protonated molecular ion at m/z 2836.2 on the FAB mass spectrum. This ion can be assigned to the disulphide bridged peptide Ala(1)-Glu(13)+Ser(14)-Asp(26).

In conclusion, Paim I has two disulphide bonds, Cys(8)-Cys(24) and Cys(42)-Cys(70).

Figure 3 shows protonated molecular ions of RCM-Paim II. Paim II gave a single-band on the SDS gel electrophoresis, but two peaks were observed in this spectrum. One was m/z 7772.2, the other was 7860.6. This means Paim II consists of two proteins, Paim IIa and Paim IIb. The mass difference between the protonated molecular ion of RCM-Paim I and RCM-Paim IIa corresponds to the molecular weight of an aspartic acid residue. The mass difference of these two peaks corresponds to the molecular weight of a serine residue. Therefore, Paim IIa is larger than Paim I by an aspartic acid residue, and Paim IIb is larger than Paim I by aspatric acid and serine residues. If this homology results from N-terminual varietiy of proteins, it is expected that the peptides having molecular weight 1625.7 and 1538.6 will be produced by S. aureusV8 protease digestion. If this homology results from C-terminal variety of proteins, it is expected that the peptides having molecular weight 1629.7 and 1542.6 will be produced by S. aureus V8 protease digestion. The two N-terminal peptides gave peaks at m/z 1626.8 and m/z 1539.7 on the FAB mass spectrum of S. aureus V8 protease digests of RCM-Paim II. Figure 4 shows the tandem mass spectrum from m/z 1626.8. The primary structures of N-terminal peptides of Paim II were determined by b and x series ions as shown below.

Paim IIb	Ser-Asp-Ala-Ser-Glu-Pro-Ala-Pro-Ala-Cys-Val-Val-Met-Tyr-Glu
Paim IIa	(Asp,Ala)-Ser-Glu-Pro-Ala-Pro-Ala-Cys-Val-Val-Met-Tyr-Glu

STRUCTURE ELUCIDATION OF MERREMOSIDES BY LIQUID SECONDARY ION MASS SPECTROMETRY

Yuzo Nakagawa, Yuji Ikenishi, Minoru Uchida*, and Isao Kitagawa**
Shionogi Research Laboratories, Fukushima-ku, Osaka 553, Japan
*Hitachi Naka Works, Katsuta 312, Japan
**Osaka University, Yamada-oka, Suita 565, Japan

INTRODUCTION

Structures of nine merremosides isolated from the Indonesian folk medicine "Bidara upas", which is known as a drug for diabetes and respiratory system disease, were elucidated mainly by mass spectrometric investigations using positive and negative ion liquid secondary ion mass spectrometry (liq.SIMS) and liq.SIMS-metastable ion (MI) spectrum to be resin glycosides.

EXPERIMENTAL

A Hitachi M-90 mass spectrometer, of which ion optics had an additional second electric field to Hitachi M-4000 mass spectrometer was used for measurement of liq. SIMS and liq. SIMS-MI spectrum by using B/E-linked scanning.

RESULTS AND DISCUSSION

1. Structure of merremoside-d (M-d)

The structure elucidation of **M-d** was described as an example of a series of resin glycosides.

1.1 Structure information on M-d (before investigation by mass spectrometry)

a) Methanolysis of **M-d** gave methyl jalapinolate (methyl 11R-hydroxypalmitate), and methyl rhamnoside. This result indicated that the structure of **M-d** was including jalapinolic acid and rhamnose moieties.

b) Alkaline hydrolysis gave a glycosidic acid which is called merremoside-i (M-i) as well as isobutyric acid.

c) ^{1}H-NMR indicated that three kinds of acyl groups were bonding at 3, 3 and 4 position of rhamnose, respectively.

Consequently, **M-d** was assumed to be glycoside composed of a number of rhamnose partially acylated. Then, in order to determine the structure, number and sequences of rhamnoses, and number and substituted position of acyl moieties were required to be elucidated.

1.2 Me M-i derived from M-d

Me **M-i** which was derived from **M-d** by treating with NaOMe/MeOH gave a prominent ion peak at m/z 893 in its positive ion SIMS (PISIMS). This ion could be sodium adduct ion of summation of four rhamnoses and a methyl jalapinolate group. In the SIMS of Me **M-i**, peaks at m/z 585, 439, 293 and 147 were corresponding to the fragment ions composed of four, three two and one rhamnoses, respectively, which are also observed in the MI spectra. The spectral pattern of Me **M-i** suggested that the four rhamnose sequence was in a straight chain, indeed methanolysis of permethylated **M-i** afforded methyl 2,3,4-tri-O-methyl-L-rhamnopyranoside and methyl 2,3-di-O-methyl-rhamnopyranoside in 1:3 ratio. Thus the structure of Me **M-i** should be jalapinolic acid substituted at 11 with 1,4 linked four rhamnoses as shown in Fig. 1. The aglycone group was remained as methyl ester after NaOMe treating of **M-d** suggested **M-d** had a lactone ring.

1.3 Desacyl M-d

PISIMS and negative ion SIMS (NISIMS) of desacyl **M-d** which was given by mild hydrolysis of **M-d** indicated the molecular weight was 838. Since this number was 32 less than the molecular weight of Me **M-i**, desacyl **M-d** still had a lactone ring. The PISIMS of desacyl **M-d** gave ion peaks $[a + H]^+$, $[b + H]^+$, **i** and **ii** which were corresponding to fragment ions as shown in the Fig. 2, but the ions **iii** and **iv**, which appeared in the spectrum of Me **M-i**, were not found. Then, we could assume lactone ring should be linked with the 2nd rhamnose moiety. Although the NISIMS of desacyl **M-d** did not provide any fragment ion which consist of only sugar moieties, successive loss (146, 146, 128 and 146) from end rhamnose showed the sequence (Fig. 2). This behavior indicated the lactone bond at the 2nd rhamnose cleaved and abstracted one hydrogen from the rhamnose to give a carboxylic acid, and a cleavage occurred at a bond between the 1st and 2nd rhamnose. Consequently, it is assumed that the carboxyl group of jalapinolic acid is formed lactone ring with 3-OH of the 2nd rhamnose.

1.4 Liq. SIMS of M-d

Concerning number and substituted position of isobutyryl group, positive and negative ion SIMS of **M-d** were examined. Since the molecular weight was 978

which was 140 larger than desacyl M-d, two isobutyryl groups were substituted. Fragment ions $[a + H]^+$ and $[b + H]^+$ indicated that each isobutyryl group was substituted in the 3rd and 4th rhamnose, respectively, and MI spectra were also compatible with above informations(Fig. 3). NISIMS and NISIMS-MI spectra confirmed the structural information.

Consequently, it was assumed that isobutyryl groups were substituted at 3-OH of the 3rd rhamnose and 4-OH of the 4th rhamnose, respectively.

2. Structure of merremoside-b (M-b) and merremoside-g (M-g)

Studying PISIMS and NISIMS of M-b and M-g with comparing those of M-d clarified the structures of them. M-b is the isomer of M-d and the isobutyryl group is substituted at 2-OH instead of 3-OH of the 3rd rhamnose. M-g is a glucoside of M-b, the glucose moiety is linked with 3-OH at the 3rd rhamnose

CONCLUSION

Investigation of liq. PISIMS and NISIMS and MI spectrum of nine resin glycosides (merremosides-b, -d, -g, and others) isolated from Bidara upas revealed each structure.

SEX AND AGE DEPENDENT SULFOCONJUGATION AND IDENTIFICATION OF N-SULFONATE WITH NEGATIVE SECONDARY ION MASS SPECTROMETRY

Kazuhide Iwasaki, Mamoru Fujioka* and Hideyo Noguchi

Sulfoconjugation is one of the important metabolic pathways of drugs, and other endogenous and exogenous compounds for human and animals. Compounds which contain phenolic and alcoholic hydroxyl group, and arylamine are metabolized to O-sulfate ester and N-sulfonate, respectively. Recently, we reported nobel N-sulfonate of alicyclic amine and alcoholic O-sulfate ester of tiaramide, an anti-inflammatory agent (1). Moreover, a number of compounds containing alicyclic amine, alkylamine and arylamine are also metabolized to respective N-sulfonate of the amines (2).

Sulfoconjugates are highly polar in biological fluid, and structural information of intact sulfoconjugates is hardly obtained by mass spectrometry with conventional ionization devices. Recent development of soft ionization technique in mass spectrometry makes it possible to analyze directly such highly polar compounds. Throughout the study for identification of N- and O-sulfoconjugates, we found many advantages of negative secondary ion mass spectrometry for getting direct information of their intact structures. We analyzed nine sulfoconjugates by secondary ion mass spectrometry (SIMS). By SIMS in negative mode, molecular ion peak $(M-H)^-$ of all sulfoconjugates was observed as shown in Table. The molecular ion peak was more prominent in the spectra of amine N-sulfonates with low molecular weight. By SIMS in positive mode, molecular ion peak $(M+H)^+$ of the sulfoconjugates was seldom observed. Adduct ion peak with potassium was observed in the spectra of some sulfoconjugates. These results strongly suggest that SIMS in negative mode offers direct information of the intact structure of highly polar sulfoconjugates.

Enzymic characteristics of sulfoconjugations were studied. Sulfoconjugations of amines and alcoholic and phenolic compounds were observed in liver 105,000 g supernatants. The activities depended on biologically active sulfate, 3'-phosphoadenosine 5'-phosphosulfate.

Sulfoconjugating activities of amines and alcoholic compound were very low in neonates of rats and increased gradually until the ages of 3-week-old. There were no sex-dependent differences of the activities before puberty of rats. The activities of female rats exhibited constant high levels throughout the ages from 3-week-old to 2-year-old. The activities of male rats decreased after puberty, and the activities of 7-week-old males were about one third of the levels of 7-weel-old females. The low activities were also observed in 1-year-old males, but the activities of 2-year-old males increased to about half of the levels of 2-year-old females.

On the other hand, sulfoconjugating activities of phenolic compound in male and female neonates of rats were half of the levels of 7-week-old females. The activities of 7-week-old rats were nearly 2-fold higher in males than females. The activities of 2-year-old rats were the intermediate levels between the activities of 7-week-old males and females and there were no sex-dependent differences in the activities of 2-year-old rats.

Species differences of sulfoconjugations were studied. Hepatic 105,000 g supernatants of mice, rats, guinea pigs, rabbits, dogs and monkeys exhibited sulfoconjugating activities of amines and hydroxyl compounds. In general, the supernatants of all species studied, exhibited higher sulfoconjugating activities for phenolic compunds than other substrates. On the other hand, the sulfoconjugation of alkylamine was very low or inert by the supernatants of all species examined. There were great variations in the levels of sulfoconjugating activities for other amines and alcoholic compound by the supernatants.

Thus, the results about age- and sex-dependent changes of sulfoconjugations in rats and about species differences of sulfoconjugations indicate that the substrate for sulfoconjugation could be divided into at least two groups; an amine and alcohol type and a phenol type.

AMINO ACID MIXTURE ANALYSIS BY LASER DESORPTION FOURIER TRANSFORM MASS SPECTROMETRY. M.P. Chiarelli[1], E. Davoli[2], and M.L. Gross[1]. 1. Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588. 2. Mario Negri Pharmalogical Research Institute, Via Eritrea 62, Milano, Italy.

This investigation is intended to be a pilot project for the analysis of larger peptides and particularly their mixtures. A mixture of 15 amino acids was determined at power density of 2 x 10^6 W/cm^2 and a wavelength of 1064 nm with only 3 ng of each applied to the probe. A FAB/MS comparison was made to assess the generality and detection limits of LD/FTMS. Several matrices and cationizing agents were tried and the best results were obtained in a glycerol matrix, giving 11 components at 350 ng each. Sample-specific ions observed in LD/FTMS were of the $(M - H + 2Na)^+$ type, whereas FAB in glycerol yielded $(M + H)^+$ ions.

It can be seen in the LD/FTMS spectrum that ion abundances seem to increase with mass; which is poopsite of what might be expected due to the fact that equal weights were deposited on the copper probe. Simple binary mixtures of the amino acids in excess NaCl were laser desorbed in order to understand the mechanism of discrimination.

The first mixtures investigated were those of Glycine and the alkyl amino acids at 2 x 10^6 W/cm^2. All alkyl amino acids have similar pka's and hydrophobic R groups, only their masses are different. The laser desorption of these mixtures show that the Gly/AA abundance ratios decrease with the increasing mass of the alkyl amino acid. (Table I).

In the next sequence we decided to evaluate binary mixtures of amino acids with similar masses and widely different pka's (Table II). Mixtures of systiene, valine, and threonine were evaluated under the same experimental conditions described above. The tendency to form $(M - H + 2Na)^+$ ions should be controled in part by the pka's of the amino acid in question and therefore cystiene should be the largest component of either binary mixture. This is not the case, and trend seen is just the opposite. Threonine has the largest pka's and is always the major component when assessed agianst cystiene or valine. The ratios in Table IIB suggest that the mechanism of amino acid desorption is controled by intrinsic properties of the amino acids.

The next property investigated was that of sublimation enthalphy. Sabbah and coworkers have studied the temperature dependence of glycine, alanine, and proline sublimation. The maximum temperature of our copper probe can be estimated to be ca. 800 k (3). Sublimation enthalphies at this temperature were estimated from the data cited above and are given in Table IIIA. The enthalphies extrapolated suggest that proline should dominate the spectra of the binary mixtures and indeed it does. The Ala/Pro ratio is closer to 1 than what is suggested by the Gly/Pro ratio but in this study we are assuming a parralel between the thermodynamic properties of the amino acids and the kinetics of desorption and parralel might not followed strictly. Attempt sublimation enthalphy determination of cystiene failed due to its thermal decomposition (4), and this may very well explain its reduced abundance but the kinetics of the desorption process must be the reason why any $(M - H + 2Na)^+$ is seen from the LD of cystiene at all.

Sublimation enthalphies determined by Knudsen Cell Calorimetry at 455 k indicate that the larger amino acids have larger enthalphies than glycine at this temperature (5). This means that the Gly/AA ratios should get larger as the laser power density is reduced and indeed they do as is indicated by the plot given.

ON-LINE ENZYMATIC HYDROLYSIS - THERMOSPRAY HPLC/MS DETERMINATION OF ENDORPHINS.

R. D. Voyksner and T. Pack, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709. H. Swaisgood and D. Chen, Department of Food Science, North Carolina State University, Box 7624, Raleigh, NC 27695.

Progress in neuropeptide research will rely on the existence of specific, sensitive, and accurate methods for identification and quantitation of peptides in various biological matrices. The fact that neuropeptides are active in the picomolar (pM) to femtomolar (fM) range, coupled with the existence of many different individual peptides, places an enormous burden on the analytical methodology. Mass Spectrometry (MS) techniques such as fast atom bombardment (FAB) and thermospray have been used for the detection of peptides in biological matrices. However, both FAB and thermospray are limited in the number of confirming ions (i.e. amino acid sequence ions) for peptides above mw 2000 and lack the sensitivity for low pM analysis. These limitations can be partially overcome by the combination of enzymatic hydrolysis with HPLC/MS.

The two main parameters for enzymatic hydrolysis of peptides are selectivity and activity. Selectivity controls what amino acid bond(s) are hydrolyzed. Selectivity is determined by the particular immobilized enzyme chosen, as shown in Table 1. For example, the analysis of ß-endorphin, a 31 amino acid neuropeptide, by thermospray or FAB/MS results in only the $[M+H]^+$ and multiple charged ions. However, the use of enzymatic hydrolysis with thermospray MS detection enables the detection of specific enzymatic hydrolysis fragments ions related to the amino acid sequence of the peptide. The observed hydrolysis sites for trypsin, chymotrypsin, V8 protease, and thermolysine of ß-endorphin are shown in Figure 1. The extent of hydrolysis (activity) is the other important factor which influences the spectra. Activity of an immobilized enzyme column can be controlled by varying the concentration of the enzyme, recycling the effluent, or altering temperature, pH, and solvent. In most cases immobilized enzyme columns (10cm x 2.1 mm) containing 0.15-0.20g of packing, exhibited activity of 100-200 units/g of packing and were capable of hydrolyzing the endorphins analyzed (Figure 1) Typically, the enzyme activity was greatest at 35-45°C, pH 7.5-8.5, and at low organic HPLC mobile phase concentrations. However, suitable activity (with 30-40% loss in activity) could be achieved at up to 50% organic in the HPLC system.

The combination of thermospray HPLC/MS and immobilized enzyme hydrolysis can be very useful in peptide identification and sequencing. There are a number of ways of combining the enzyme hydrolysis and HPLC with MS detection for peptide analysis. The use of an immobilized enzyme column prior to HPLC/MS will enable the separation of each hydrolysis fragment, permitting acquisition of "clean" mass spectra. The detection of the hydrolysis products aids in specific detection or confirmation of the presence of an endorphin.

The reversal of the column order (i.e., HPLC followed by trypsin hydrolysis) can prove useful in gaining specificity for the detection of individual peptides in a complex matrix. Thermospray mass spectra containing structural information from the tryptic hydrolysis can be acquired from each peptide in a mixture. The increase in organic solvent, necessary for the HPLC separation of the endorphins, lowered the activity of the trypsin column permitting the detection of molecular ions as well as the tryptic fragment ions.

The combination of two or more immobilized enzyme columns with HPLC/MS can prove useful in peptide identification and amino acid sequencing. For example, the tryptic hydrolysis of γ-endorphin results in two peptides. These fragment peptides, separated by HPLC, can undergo further hydrolysis with another immobilized enzyme column (e.g. carboxypeptidase A,B, and Y) for further specificity and to gain amino acid sequence information. Carboxypeptidase hydrolysis enables determination of the amino acid sequence (up to 5 amino acids) on the C-terminus side of each tryptic fragment. The combination of tryptic hydrolysis with aminopeptidase M would enable the determination of the amino acid sequence from the N-terminus of each fragment. Together the trypsin and carboxy and amino peptidases could be used for a complete amino acid sequence for γ-endorphin.

The second advantage of combined immobilized hydrolysis HPLC/MS is sensitivity. The hydrolysis of a peptide with enzymes such as trypsin or chymotrypsin, can drastically lower the molecular weight of the peptide. The lower molecular weight peptide is subject to higher ionization, transmission or detection efficiency over the non-hydrolyzed peptide. For example, the detection of the tryptic hydrolysis fragment T_3 (mw 558) of ß-endorphin resulted in a gain of 30 in sensitivity over the detection of the $[M+2H]^{+2}$ ion of ß-endorphin (mw 3463).

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Clearly the combination of the increased sensitivity and additional structural information obtained through the use of on-line enzymatic hydrolysis-HPLC/MS can prove vital in the identification and detection of neuropeptides.

DETERMINATION OF PREFERRED GLYCOSYLATION SITES IN A LYSOZYME - GLUCOSE MODEL SYSTEM USING FAB PEPTIDE MAPPING TECHNIQUES;

Hartman, T. G.[1], Rosen, R.T.[1], Ho, C-T.[2], Wu, V.[2], Govindarajan, S.[2] and Rosen, J. D.[2]; Center for Advanced Food Technology[1] and Food Science Dept.[2], Cook College, Rutgers University, New Brunswick, N.J.

The site specificity of glycosylation in a lysozyme-glucose model system was determined using FAB-MS, MS-MS and reverse phase HPLC peptide mapping techniques. The effects of time, temperature and water activity on the glycosylation reaction were measured. Lysozyme (M.W. 14,305) was chosen as a model protein for this investigation since its primary, secondary and tertiary structure has been well characterized (1,2). Native lysozyme and lysozyme glycosylated by reactions with glucose for various times, temperatures and water activities were subjected to tryptic and chymotryptic hydrolysis. The resulting digests were then analyzed by a combination of the previously mentioned techniques to provide peptide maps which are correlated back to the original intact protein. Specific glycosylation sites were determined by observing 162 mass unit differences in peptides from native and reacted lysozyme. These correspond to the presence of glucose derived Schiff bases or Amadori adducts which are formed on the free amino groups of lysines, arginines and the N-terminal of the protein. Preliminary data on the complete tryptic and partial chymotryptic peptide maps of native and glycosylated lysozyme has been presented previously (3). We have now defined the complete chymotryptic peptide map of lysozyme. At several sites chymotrypsin was found to cleave lysozyme at asparagine residues when next to acidic or basic amino acid residues. Since literature reports of such cleavage are rare the identity of the resulting peptide was confirmed by MS-MS. At low moisture content and at two temperatures (25 & 50°C) no glycosylation products were observed in mixtures of lysozyme and glucose. However, when incubated for 3 days in a 65% relative humidity environment glycosylation products began to appear. At 25°C the N and C terminal amino acid region was found to react. At the higher temperature of 50°C the reaction progressed to include 6 sites clustered in the same terminal region of the protein (the N and C terminal regions of lysozyme are linked by a disulfide bridge). We postulate that the observed site specificity of lysozyme glycosylation is directed by the microenvironment created as water is sorbed onto preferred regions of the protein. Figure 1 shows the structure of lysozyme and the observed glycosylation sites. The asterisks (*) indicate potential sites for glucose attack which have not been observed.

MS/MS METHODS FOR PEPTIDE SEQUENCING: SUCCESS AND FAILURE.

Lester C. E. Taylor
Wellcome Research Laboratories, RTP, NC. 27709
Linda Poulter
School of Pharmacy, UCSF, San Francisco, CA. 94143

As pointed out by Biemann and others, collision induced decomposition MS/MS often aids in the sequencing of a peptide because the resulting spectrum contains a more complete series of sequence ion types. In addition there is an increase in the number and intensity of fragment ions and the elimination of chemical background.

The analysis of synthetic peptides is usually straightforward because the synthetic route is known and one is looking for problems which may have arisen during the sequential coupling of residues. More challenging however, is the analysis of endogenous peptide material isolated from biological origin where nothing may be known about a particular peptide other than the molecular weight. We have carried out a series of experiments aimed at identifying peptides isolated from bovine adrenal medulla tissue. FABMS analysis of an HPLC fraction from total tissue extract (where standard Leu Enk elutes) shows molecular ion species at 556, 684, 781 and 895 Da, however it would be impossible to conclude that the signal at m/z 556 was due to the MH^+ of Leu Enk. The MS/MS spectrum of the 556 peak gives an intense spectrum which is identical to that observed for standard compound (using ~2 n mol). An estimate for the amount of Leu Enk present in this sample is 50-100 p mol. The presence of Met Enk (MH^+ 574) in another fraction was directly established in the same way. The CID MS/MS spectrum of the m/z 684 peak shows a number of relatively intense daughter ion signals. Interpretation of the spectrum allows the following tentative sequence to be assigned (assuming the molecule is a peptide): V P K/Q L/I D L/I , however there are several daughter ions which are not immediately assignable to this structure and it is possible to assign the peaks to alternative sequences.The degeneracy between K and Q, and L and I cannot be resolved from this spectrum.

Approximately 500 pmol of sample allowed two further experiments to be carried out i) amino acid analysis and ii) manual Edman followed by FABMS. The Edman cycle confirmed the amino terminal V and the presence of one K residue (+135 mass shift from the PTC derivative - valine = MH^+ at 720 Da) which resolves the K/Q assignment. The amino acid analysis confirmed the molar ratios of the amino acids and the presence of L (no isoleucine) and so the sequence is VPKLDL (novel).

The 895 Da peptide gave an MS/MS spectrum from which it was difficult to assign much sequence, however one manual Edman cycle established an amino terminal N and one K residue. It was noticed that an extended form of the 684 Da peptide i.e. the sequence NPVPKLDL is consistent with the 895 Da molecular weight. The amino acid analysis supports the correct molar ratios. Returning to the MS/MS data it now becomes easier to rationalise and explain some of the peaks in the daughter ion spectrum of both the 684 and 895 Da peptides. The peaks at m/z 226,339 and 454 are a series of acylium ions generated from the common ammonium ion PKLDL (585 Da) to give:

P K 226 Da ; P K L 339 Da ; P K L D 454 Da

Unfortunately the occurrence of these ions in the spectrum of an unknown peptide complicates sequence assignment.

Empirically there is a highly variable degree of daughter ion information generated in MS/MS experiments using a hybrid instrument (EBQQ geometry) and we have conducted experiments with several standard peptides and a series of derivatised glucose oligomers.

1. The TRH related peptides <EHPG and <EHPGK give intense fragment ions in their low energy CID spectra. As expected several of the ions arising from the N terminus of the molecule are common to both spectra, e.g. the A and B ions at 221 and 249 Da respectively, as well as the imidazole ion at m/z 110. The <EHPGKR peptide gives a significantly weaker MS/MS

spectrum with little fragmentation.

2. A series of experiments were carried out using Bradykinin (RPPGFSPFR) and des Arg^9 Bradykinin (RPPGFSPF),i.e. one peptide with a basic Arginine on both the N and C terminii and the other with an N terminal Arginine. The low energy CID MS/MS spectrum of the MH^+ using the hybrid instrument was disappointing, with Bradykinin giving only a 904 Da ammonium fragment ion, (also present in the unimolecular spectrum), and some low mass fragments, but nc significant sequence information. The daughter ion spectrum of des Arg^9 Bradykinin also shows a lack of high mass fragmentation over a range of collision energies and gas pressures. One cyle of manual Edman degradation was performed on each of these peptides giving two peptides with an N terminal proline residue. The Bradykinin derived peptide PPGFSPFR exhibits a poor MS/MS spectrum, showing only the ammonium fragment ion at 747 Da and the low mass fragment ions at 155 etc. In contrast however the MS/MS spectrum of the peptide PPGFSPF generated from one Edman cycle on des Arg^9 Bradykinin, gives a high degree of N terminal fragmentation (A and B ions). The presence of a terminal R residue significantly suppresses the intensity and degree of fragmentation observed in the MS/MS spectrum of both the Bradykinin and TRH related peptides.

3. MS/MS experiments were carried out on a series of G_n - ABEE derivatized glucose oligomers. We have studied the CID spectra of compounds with G=3 to 10 to gain some idea of how the MS/MS spectrum changes as a function of mass, by minimising the degree of structural complexity (c.f. peptides). In positive ion mode these compounds give an MH^+ signal but little fragmentation, whereas the negative ion FABMS spectrum shows a series of fragment ions corresponding to cleavage at the glycosidic linkages and charge retention on the derviatized terminus. The positive ion MS/MS spectra of the MH^+ gives a series of product ions also formed by cleavage at the glycosidic linkages as observed in the negative ion MS spectrum, although in this case mass fragment ions were predominant. The unimolecular (i.e. no collision gas) spectra of these sugars show no fragmentation. All the polymers (G3 to G7) gave the same form of MS/MS spectra, although there is a decrease in signal intensity as the molecular weight increases. The experimental upper mass limit was found to be ~1300 Da for the G7 polymer, despite an instrumental limit of ~2000 Da for the second stage MS quadrupole, Fig 1. These sugars give a more consistent series of fragment ions than are observed for peptides of comparable molecular weight, presumably because of the uniformity of structure and the relatively weak hemi-acetal linkage between the glucose units.

The low energy CID MS/MS spectrum of an unknown peptide may contain a variable degree of fragmentation (c.f. the normal FABMS) , albeit A, B" and/or Y" ions, but there may be fragments arising from rearrangement processes. The energies available in the low energy CID experiment give significantly different results from those observed in high energy MS/MS studies where a much greater degree of useful fragmentation is consistently generated at higher mass than in the hybrid instrument.

Characterization of *E. coli* Expressed Human Interleukin-3 by High Performance Tandem Mass Spectrometry, Hubert A. Scoble, Marcia L. Bologna and W. Barry Foster, Genetics Institute, 87 CambridgePark Drive, Cambridge, MA 02140-2387

Interleukin 3 (IL-3) is a multilineage colony stimulating factor capable of supporting *in vitro* the proliferation of human bone marrow hematopoietic progenitors to form granulocytes, erythrocytes, macrophages and megakaryocytes. Due to scarcity of the natural protein, efforts have focussed on the development of bacterial and mammalian expression systems and purification protocols which allow for the isolation of larger quantities of human IL-3. With larger quantities of the protein available, detailed *in vitro* and *in vivo* biochemical studies can begin in order to assess the biological and pharmacologic properties of this important lymphokine. We have extensively characterized *E. coli* expressed human IL-3 using two- and four-sector mass spectrometry. Mass spectrometry offers unique advantages, and in other respects, complements conventional methods of protein structural characterization. One major advantage of mass spectrometric approaches is the ability to rapidly identify posttranslational modifications or posttranslational processing events. This is especially important in the case of a recombinant protein where it is necessary to demonstrate that a natural posttranslational event has occurred, or of equal importance, demonstrate that posttranslational processing has not occurred. Those natural events which one is likely to encounter include: (1) N- and C-terminal processing to the mature protein; (2) N- and O-glycosylation of non-bacterially expressed proteins; (3) phosphorylation; (4) sulphation; (5) acylation; or (6) other natural covalent modification of the protein. Potentially undesirable posttranslational events include: (1) N- and C-terminal processing due to the action of endo- or exoproteases during expression or purification; (2) deamidation; (3) oxidation; (4) inappropriate processing or attachment of N- and O-linked carbohydrate; or (5) undesired covalent modification of the protein. In general, modifications of any amino acid in the protein manifest themselves through a change in mass of the modified amino acid, and thus are detectable mass spectrometrically.

The generalized mass spectrometric strategy which we have employed in the characterization of IL-3 involves specific proteolytic digestion of both native and reduced and alkylated protein, usually with trypsin. Following reversed-phase separation of the digest, the collected fractions are analyzed by FAB/MS. In total, tryptic peptides which have been detected mass spectrometrically account for 98% of the recombinant protein. The small tryptic tripeptide not detected mass spectrometrically is probably not retained under the conditions of the chromatographic separation. The N-terminus of the expressed protein is heterogeneous with 80% of molecules retaining the initiating methionine (Met^1-Ala^2-Pro^3-...) and 20% having the mature sequence (Ala^2-Pro^3-...). Total amino acid compositional analysis yields the expected number of amino acid residues as predicted from the cDNA sequence with the above noted exception of methionine. Conventional carboxy terminal analysis using carboxypeptidase P shows kinetic release of the expected C-terminal amino acids. Mass spectrometrically, however, minor C-terminal species have been detected in which from one to three C-terminal amino acids have been removed, probably due the action of an exoprotease during fermentation or purification. Proteolytic cleavage of recombinant proteins, especially when the N-terminus remains intact, is a difficult problem to assess. The success or failure of conventional carboxy terminal sequencing often depends on the extent of proteolysis. In addition, since most primary protein structural studies involve proteolytic degradation prior to sequencing, it is difficult to ascertain whether cleavage at an unexpected site is due to a nonspecific cut by the enzyme, or is due to proteolysis during expression or fermentation. To answer these questions, tryptic digestion experiments were repeated in $H_2{}^{18}O$ in a procedure similar to that reported by Rose *et al.*. Peptides previously thought to have resulted from nonspecific cleavage during tryptic digestion, had mass shifts indicating incorporation the ^{18}O label. Since, incorporation of the label would not be expected if the peptides were at the carboxy terminus of the protein, the peptides resulted from nonspecific cleavge during digestion. The minor C-terminal peptides previously detected mass spectrometrically had not incorporated the ^{18}O indicating that this cleavge occurred prior to tryptic

digestion. In total, these shortened forms of the C-terminus probably represent less than 1% of the full length C-terminal tryptic peptide. Several peptides incoporated twice as much of the label as expected. Figure 1 shows the MS/MS spectrum of the peptide His-Ile-Pro-His-Ile-Lys which results from tryptic digestion with and without $H_2{}^{18}O$. N-terminal a and b series ions in each spectrum occur at the same mass. The y series ions in panel A ($H_2{}^{18}O$ digestion) occur 4 amu higher than those in panel B.

REFERENCE

K. Rose *et al.*, Biochem. J. (1988) 250, 253-259.

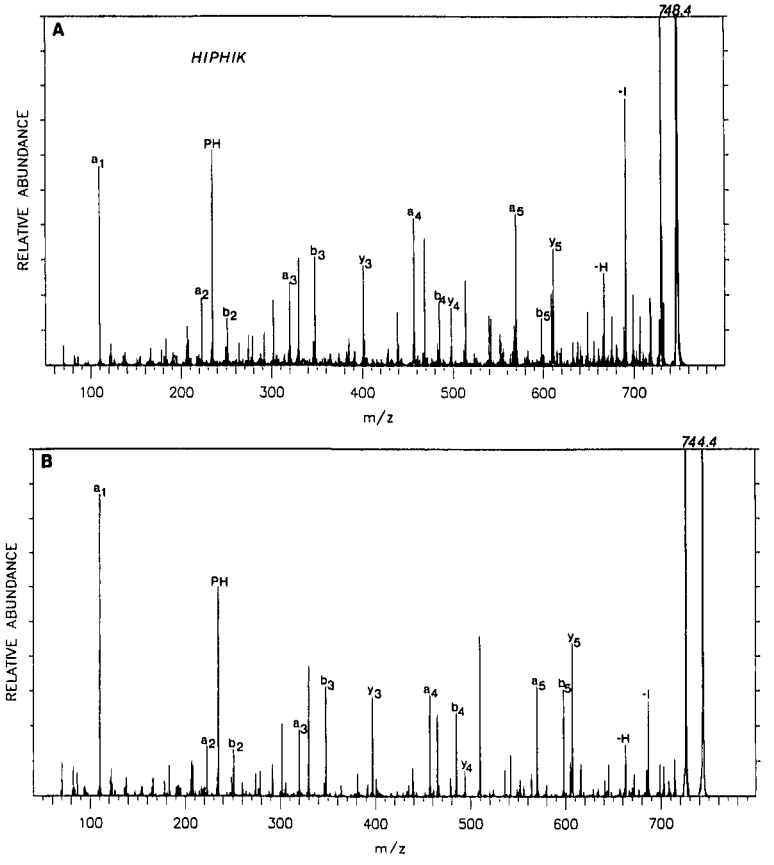

Figure 1. MS/MS spectrum of a tryptic peptide from *E. coli* expressed IL-3. The peptide in panel A, $(M+H)^+$=748.4, results from tryptic digestion in $H_2{}^{18}O$. The peptide in panel B, $(M+H)^+$=744.4, results from normal tryptic digestion. Each spectrum (about 1 nanomole) was recorded by transmission of the ^{12}C ion of the $(M+H)^+$ to MS-2. Precursor ion attenuation was 50% with He at ground potential.

STRUCTURAL CHARACTERIZATION OF THE IMMUNOACTIVE ENZYMATIC DEGRADATION PRODUCTS OF THE C3 COMPLEMENT PROTEIN BY FAST ATOM BOMBARDMENT AND PLASMA DESORPTION MASS SPECTROMETRY

K. Schneider[1], I. Manz[1], R. Gerardi[2], D. Bitter-Suermann[2] and M. Przybylski[1]

[1]Fakultat fur Chemie der Universitat Konstanz, Postfach 5560, D-7750 Konstanz;
[2]Institut fur Mikrobiologie der Medizin. Hochschule, D-3000 Hannover, FRG.

The third component of serum complement, C3, a 180 000 d glycoprotein plays an important role in the modulation of cellular immune functions such as macro phage activation, antibody formation and lymphocyte proliferation. A fragment preparation of C3 containing primarily the anaphylatoxin polypeptide C3a, formed by specific proteolysis, has been shown to exert potent suppression of mixed lymphocyte proliferation. The mechanism(s) and pathways for this activation have been as yet undefined, but have been assigned to enzymatic degradation products of C3 and/or C3a; of particular interest has been recently a low molecular weight (ca. 4000 d) polypeptide with high activity, C3x.

In a study aimed at defining the immune activation cascade and relating the genesis of biologically active fragments on a molecular level to the intact C3 protein structure, endoprotease digestion combined with fast atom bombardment (FAB) and plasma desorption (PD) mass spectrometry (peptide mapping) methods have been applied to isolated C3 fragments. C3, purified from guinea pig serum was cleaved with the cobra venum factor-dependant C3 convertase yielding the N-terminal polypeptide C3a, and C3a and other low molecular weight fragments isolated by sephadex G-100 chromatography and subsequent FPLC. The molecular weight of intact C3a was determined by PDMS (Figure 1; 9278 d). Detailed structural data and correlation of the guinea pig C3a sequence, by using the known mouse C3a sequence as a guiding structure, was obtained from peptide mapping methods with both FABMS and PDMS. Thus, FABMS analysis after trypsin digestion led to the direct identification of the N- and C-terminal peptides among the series of approx. 10 low molecular weight fragments (Figure 2; T1, SVQLMER; T2, EQLNGLAR). The structures of the terminal and of other parts of the C3a sequence were ascertained by the mass shifts of tryptic fragments after carboxypeptidase B digestion, trypsin digestion after reduction and S-carboxymethylation, and peptide mapping analysis after staph. aureus V8 protease digestion. Approximately 50 % of the guinea pig sequence was found homologous to the mouse C3a (Figure 3). The comparison of the molecular weight of the guinea pig with that of the mouse polypeptide (9214 d) indicates an identical number of amino acids (78) to $\pm$ 1 residue.

The application of peptide mapping methods to the highly active fragment C3x, initially believed to be a cleavage product of C3a, did not show any correlation to the C3a structure. Further studies are therefore directed to relate the genesis of this peptide to the large (170 000 d) protein fragment of C3, C3b. C3b and two further degradation products, C3c (150 000 d) and C3d have been characterized, by using a combination of peptide mapping methods. These results form the basis for the identification, and differentiation of immune activation reactions from the intact protein structure to specific polypeptides.

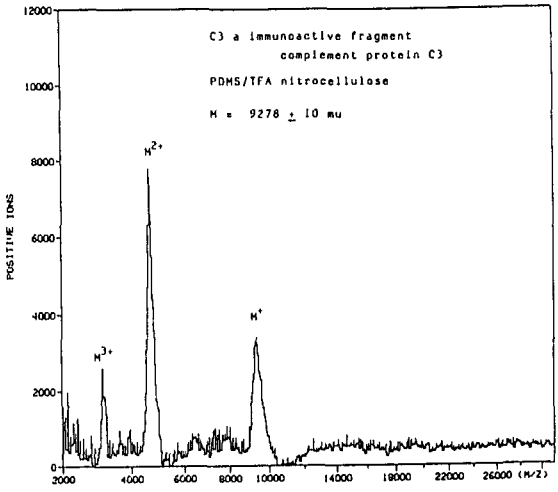

Figure 1
^{252}Cf-PD mass spectrum of polypeptide fragment C3a from guinea pig C3 complement protein. A sample of ca. 300 pmol in 0.2 % trifluoroacetic acid was applied to a nitrocellulose foil; molecular weight determination yielded 9.278 d as an average value.

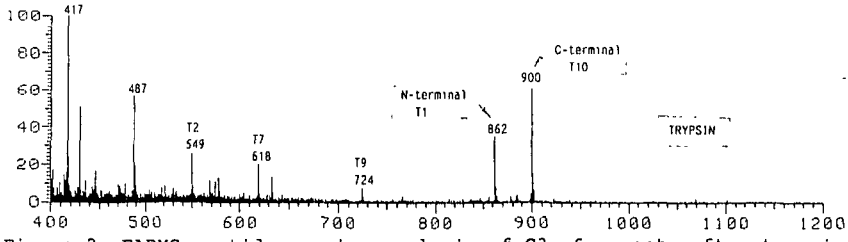

Figure 2. FABMS peptide mapping analysis of C3a fragments after trypsin digestion (ca. 2 nmol; 16 hrs.; 40 mmol NH_4HCO_3). T1 and T10 refer to the N- and C-terminal peptide fragments (S-V-Q-L-M-E-R, T1; E-Q-L-N-G-L-A-R, T10).

A COMPREHENSIVE SUMMARY OF THE FRAGMENTION OF PEPTIDE IONS UNDER CID CONDITIONS AND THEIR IMPLICATION FOR PEPTIDE SEQUENCING

R. S. Johnson, S. A. Martin, J. E. Vath and K. Biemann
Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge MA 02139

In the course of extensive use of tandem mass spectra for the determination of the amino acid sequence of peptides and proteins of previously unknown structure (among them four different thioredoxins, proteins 100-110 amino acids in length), we were often faced with complex CID mass spectra containing many peaks which did not belong to the familiar a_n, b_n, c_n, x_n, y_n and z_n series (Scheme I). However, in order to be certain that the interpretation is correct all significant peaks in the spectra have to be accounted for.

This led to the discovery of three additional ion types, denoted d_n, v_n and w_n (Scheme II). Because of the mechanism of the formation of these ions, their appearance depends on the structure of the amino acid at the point of backbone cleavage. Two of them (d_n and w_n) permit differentiation of leucine and isoleucine, a long standing problem in mass spectrometry.

In the course of these studies we have measured the CID spectra of peptide derivatives which contain a fixed positive charge in the form of a quaternary ammonium ion. These turned out to be particularly rich in a_n and d_n ions when the charge was localized at the N-terminus while localization at the C-terminus favored v_n, w_n, and y_n ions. We found that there exists a gradual transition in the fragmentation of peptides from those containing no basic group where protonation indeed occurs at the nitrogen of the peptide bond leading to b_n and y_n ions, through peptides with weaker and stronger basic sites which bear the proton more and more exclusively and finally to derivatives with a fixed charge (Scheme III). Our observations also indicate that many of these fragmentations occur remote from the charge.

Figure 1 demonstrates the overriding effect of a fixed positive charge at the N-terminus, which leads exclusively to N-terminal ions, over the strongly basic arginine at the C-terminus. Thus, well planned derivatization, particularly of the N-terminus, can be used to resolve ambiguities in the spectrum of an underivatized peptide.

CHARACTERIZATION OF IMPURITIES IN SYNTHETIC PEPTIDES BY FAB MASS SPECTROMETRY

W. Rodney Mathews
Biopolymer Chemistry

Peter E. Haroldsen and Simon J. Gaskell
Center for Experimental Therapeutics
Baylor College of Medicine, Houston, TX, 77030.

Renin is an enzyme that catalyses the production of Angiotensin I from Angiotensinogen which subsequently produces an increase in blood pressure. This pathway is being explored for the development of new therapeutic agents for hypertension. The synthetic peptide shown in figure 1, U74760, is a specific substrate for Renin and is used in an assay for renin actitity. Renin inhibitory peptides have also been synthesized. While characterizing these peptides, we observed that although amino acid analysis and Edman sequencing results were normal, FAB MS revealed the presence of significant impurities The characterization of the impurities in U74760 is described

FAB MS was carried out on a VG 70SE mass spectrometer. The FAB spectrum of U74760 indicated the presence of several impurities. In addition to the observed MH+ at 1224 (100%), ions at 1236 (P+12, 44%),1238 (P+14; 43%), 1248 (P+24, 19%), 1250 (P+26; 15%) and 1344 (P+120, 15%) were observed. The impurities in the U74760 sample were further characterized by subjecting the sample to 6 cycles of manual Edman degradation followed by FAB MS after each cycle (1) The parent ion at 1224 was observed to shift to 1262, 1125, 1028, 881, 744 and 631 after successive cycles corresponding to the addition of 1 PITC group to the E-amino group of K10 followed by loss of P1,H2,P3,F4,H5,and L6 respectively. After each cycle an additional peak was observed in the FAB spectrum that was 14 mass units larger than the base peak. This corresponded to the loss of the same amino acids from P+14, suggesting that the modification in P+14 was located in the C-terminal portion. The P+12 peptide however did not decrease in mass but shifted from 1236 to 1371 corresponding to the addition of 1 PITC group and no amino acid loss. This suggested that the P+12 peptide was blocked at the N-terminal

Additional information was obtained using tandem mass spectrometry carried out on a VG ZAB SEQ instrument of BEqQ geometry (2). The MS/MS spectrum of U74760 (m/z 1224) is shown in figure 2A. Fragment ions are assigned using the nomenclature of Roepstorff and Fohlman (3). The spectrum shows a nearly complete series of B ions providing sequence information from the N-terminal end. A single C-terminal ion (Y8, m/z 990) is seen. The daughter ion spectrum of the contaiminant P+12 (m/z 1236) is shown in figure 2B. The nomenclature used is the same as in figure 2A *i.e.*, based on the expected fragment ions for U74760. N-terminal ions also dominate this spectrum. The B series is seen to be shifted +12 mass units relative to what was observed with U74760 (2A). A smaller ion series corresponding to the expected B series is also observed The Y8 ion is seen as a doublet at 990 and 1002 (shifted 12 mass units). The assignment of these fragment ions was confirmed by repeating the tandem MS experiment after chemical derivatization of the sample. For example after formation of the methyl ester of the C-terminal -COOH, the C-terminal ions were observed to shift 14 mass units while the N-terminal ions did not change.

These FAB MS results suggest the following interpretation: 1 The P+120 contaiminant is the expected peptide with one benzyloxymethyl (BOM) His protecting group remaining. The P+14 peak is due to a mixture of peptides containing methyl-His. The majority of the methyl His is at position 9 based on the FAB/Edman data. The P+12 impurity is also a mixture consisting primarily of a N-terminal P1- H2 methylene bridge. A second component is probably a methylene bridge between H9 and K10. The P+24 and P+26 are due to combinations of the P+12 and P+14 modifications These byproducts likely result from the reaction of formaldehyde generated during the removal of the BOM protecting group with the peptide. Based on these predictions the synthesis of U74760 was carried out using a different H protecting group and pure U74760 was obtained

FAST ATOM BOMBARDMENT MASS SPECTROMETRY OF RECOMBINANT HUMAN α-2 INTERFERON

T. L. Nagabhushan, James E. Labdon, Birendra Pramanik, Anthony Tsarbopoulos, Pradip Das, Paul Reichert, Thomas C. Hassell, Peter L. Bartner and Paul P. Trotta.
Schering-Plough Corp., Bloomfield, NJ 07003 USA

Interferons (IFNs) are proteins which exhibit a variety of biological effects including antiviral, antiproliferative and antitumor activity. Three classes have been identified: α (from leukocytes), β (fibroblast) and γ (from lymphocytes). The α-IFNs represent at least 13 distinct proteins which display immunomodulatory and antitumor effects. Recombinant α-2 IFN (MW=19,269) has been cloned and expressed in E. coli.[1] It has recently been approved as a treatment for hairy cell leukemia.

We have used fast atom bombardment (FAB) mass spectrometry to confirm the sequence and assign the disulfide bonds of α-2 IFN. The purified protein was digested with trypsin in the presence of 0.5% (w/v) ammonium bicarbonate for 24 hours at 37° and the digest was concentrated and analyzed by FABMS without further purification. The mass spectral data of the digest allowed us to confirm the molecular ions of all of the predicted peptides within the mass range scanned (Table 1). The ions corresponding to the cysteine-containing peptides T1, T5, T10 and T17 were very weak (Figs. 1, 2). The intensities of these ions increased dramatically after reduction of the digest with dithiothreitol (25-fold molar excess over protein, 100° for 2 minutes). Assignment of cysteine-containing peptides was also confirmed by FABMS of a tryptic digest of α-2 IFN in which the cystine residues of the native protein were S-alkylated with 4-vinylpyridine in the presence of tri-N-butyl-phosphine[2]. The resulting pyridylethyl cysteine (PEC) tryptic peptides were observed as strong ions with masses 106 units higher than the unmodified peptides (PEC-T1,PEC-T5 and PEC -T17 , Table 1).

Disulfide pairing was established by the observation of ions at m/z 4616 and 2118 in the high-mass region of the unreduced digest (Fig. 2+). These ions correspond to disulfide bonds between peptides T1 and T10 and between T5 and T17 respectively. These ions disappeared upon DTT reduction or PEC derivatization. The FABMS mapping results allowed us to assign disulfide bonds between Cys-1 and Cys-98 and between Cys-29 and Cys-138 in α-2 IFN.

In another experiment, α-2 IFN was cleaved with cyanogen bromide . The 4 fragments were isolated by HPLC and studied by FAB/MS. Mass spectral data provided sequence information for some of the purified fragments.

INACTIVATION OF DOPAMINE β-HYDROXYLASE BY *P*-CRESOL: CHARACTERIZATION OF COVALENTLY MODIFIED ACTIVE SITE PEPTIDES BY MS AND TANDEM MS, S.A. Carr, W. E. DeWolf,Jr., M. Mentzer, G. D. Roberts, P.J. Goodhart, and Lawrence I. Kruse, Smith Kline and French Laboratories, King of Prussia, PA 19406

Dopamine β-hydroxylase (DBH) is a tetrameric glycoprotein complex (ca. 280 kDa) which catalyzes the conversion of dopamine to norepinephrine and thus plays a key role in the biosynthesis of neurotransmitters. *P*-cresol has recently been shown to be an excellent inactivator of DBH, despite the absence of a latent electrophile (1). In order to understand the molecular basis of enzyme inactivation by this new class of inhibitor it was necessary to determine the structure of the inactivated enzyme-suicide substrate complex.

Using a combination of conventional chemical and biochemical strategies in conjunction with MS and tandem MS we have identified the attachment site of the suicide substrate inhibitor *p*-cresol in the sequence of DBH, partially defined the chemical nature of the adduct formed and have determined the sequence of the putative active-site tryptic peptide (2) DBH labeled with tritiated *p*-cresol was digested with trypsin, and a few nanomoles of two labeled peptides, designated hereafter as the early and late eluting peptides, were isolated by RP-HPLC. These peptides were subsequently studied by automated Edman degradation and a variety of biochemical MS techniques. Sequence information obtained by automated Edman degradation on the early and late eluting peptides yielded two virtually identical 24 amino acid long sequences with the exception of residue 13 where a Lys was identified at this position in the former peptide and nothing was detected in the latter peptide. FABMS of 150 pmol of both the early and late eluting peptides yielded chemical average molecular weights of 3131.2. These data clearly indicated that the peptides were substantially larger than suggested by Edman. Furthermore, the difference in mass could not be accounted for by simple addition of one to three residues of *p*-cresol to the obtained sequence suggesting that either the modification involved extensive alteration of the *p*-cresol upon addition or that the amino acid sequence was wrong or terminating prematurely.

In an effort to verify the Edman derived sequence and establish the location within that sequence of the modified residue, ca. 450 pmol of both the late and early eluting tryptic peptides were digested briefly (3h, 37°C, E:S = 1:25) with chymotrypsin and the resulting digests analyzed directly by FABMS. The choice of enzyme was dictated by the Edman sequence data that indicated two prime chymotryptic sites at residues 14 (Trp) and 16 (Tyr). Both the early and late peptides yielded identical spectra exhibiting four peptide signals with $(M+H)^+_{ave}$ of 1131 3, 1455.6, 1695 8, and 2019.8, respectively. None of these peptides could be accounted for simply based on the Edman data. Each of these peptides was analyzed by tandem MS directly from the mixture without isolation or purification. The tandem mass spectrum of the 1695 peptide (Fig. 1) is dominated by amino-terminal sequence ions that define the sequence (Ala,Pro,Asp)-Val-Leu-Ile-Pro-Gly-Gln-Gln-Thr-Thr-Tyc-Trp where Tyc is apparently a modified amino acid residue with an in-chain mass equivalent to the sum of the incremental masses of a Tyr plus cresol (each having lost a H to form a covalent bond), i.e., 163+108−2 = 269; the mass of Tyc is defined by the mass difference from sequence ions C_{13} to C_{12} and B_{13} to B_{12} (Fig. 1). The tandem mass spectrum of this peptide could not be used to independently establish the sequence of the first three residues because amino-terminal sequence ions for the first two residues were not observed. Of course this was not a problem since the Edman data is most reliable at the amino-terminus of a peptide or protein. In a similar fashion we have sequenced the two COOH-terminal peptides in the chymotryptic digest with $(M+H)^+$ of 1131 and 1454. A summary of the sequence information provided in the various chemical and MS experiments on DBH is shown in Figure 2

The linkage of cresol to Tyr was examined by N^2H_3-DCI MS of the PTH-amino acids (ca. 0.5 nmol of each cycle which had not been injected onto the HPLC) from the Edman degradations of the early and late eluting tryptic peptides To achieve subnanomole sensitivity it was necessary to clean up each PTH-amino acid from the large amounts of diphenylurea and diphenylthiourea produced as byproducts of the Edman chemistry by RP-HPLC on C18 in a $H_2O/CH_3CN/TFA$ system prior to analysis by MS. The "core" of a PTH amino acid exhibits two exchangeable protons in the N^2H_3-DCI mass spectra: a rapidly exchanging secondary amine proton and a slowly exchanging methine proton on the α-carbon. Exchangeable protons in the side-chain of the amino acid residue are added to the number of core exchangeables. In the discussion that follows the "H" of the $(M+H)^+$ will be ignored although this clearly increases the apparent number of exchangeable protons by 1 The corresponding DCI mass spectra of cycle 13 from the Edman degradation analyses of the early and late eluting peptides indicated the following numbers of exchangeable protons: 3 rapid, 1 slow vs. 2 rapid, 1 slow, respectively. From this we conclude that the *p*-cresol is C-C linked in the early eluting peptide (i.e., the R group has two free OH groups) while the cresol is C-O linked to Tyr in the late eluting peptide (one free OH in R group). These data are consistent with the elution order from RP-HPLC, as the more hydrophilic derivative should elute earlier

These results provide direct evidence that inactivation of DBH by *p*-cresol is the result of covalent attachment of cresol to the active site Tyr residue presumably by insertion of a benzylic radical or phenolic radical. Tandem MS also provided the sequence of the four amino acids at the C-terminus of the peptide that were not accessible by Edman degradation. All of the studies described here were performed with a total of only 2-3 nanomoles of peptide which highlights the sensitivity of the FABMS and tandem MS methodology employed. Establishing the sequence of this modified peptide and the nature of the linkage by other spectroscopic techniques with such small amounts of material would have been extremely difficult.

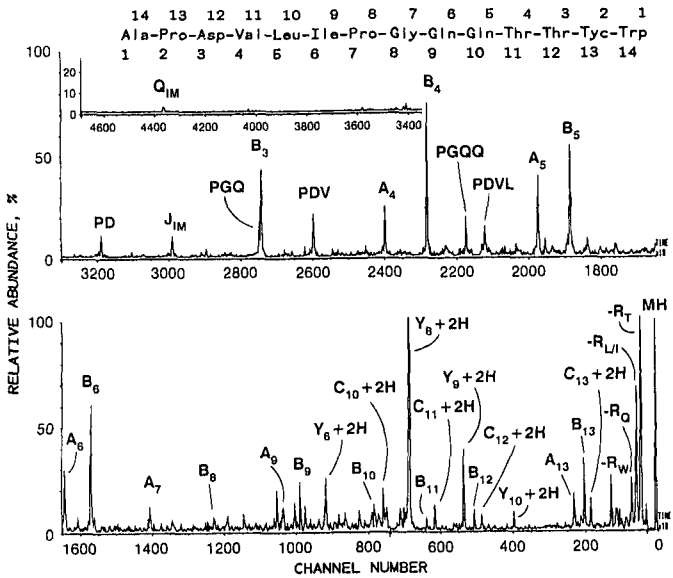

Figure 1. Tandem mass spectrum of the chymotryptic peptide of $(M+H)^+_{ave}$ = 1695.9. FABMS in MS-1 of the VG ZAB SE-4F tandem mass spectrometer was used to identify this parent ion in a mixture of peptides (see text) and to select it for collision with He at 10 keV (atten. = 75%) and mass analysis of the resulting product ions in MS-2. Numbering above the printed single letter code sequence refers to C-terminal ions (V to Z) while that below the printed sequence refers to N-terminal ions (A to C). Low mass fragments with a subscript IM are immonium ions with the general structure $H_2N{=}CHR$, where R is the amino acid side-chain. J = single letter representation of tyrosine with p-cresol covalently attached. PGQ, PDV, PGQQ and PDVL are internal fragments.

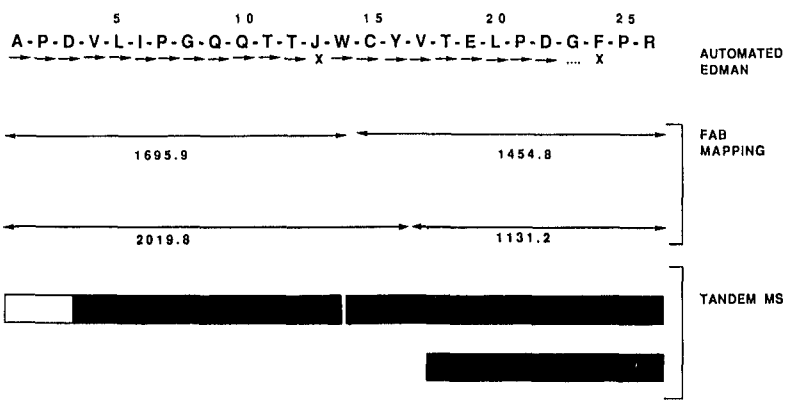

Figure 2. Summary of the sequence information obtained. Single-headed arrows represent cycles of automated Edman degradation, X signifies a residue not identified by Edman and ... corresponds to a weak Edman assignment. Double headed arrows indicate the sequence origins of the signals observed in chymotryptic digests of labeled peptides by FABMS. Rectangles refer to peptides analyzed by tandem MS; blackened regions signify sequences established by tandem MS.

Introduction

Two complementary techniques have been developed to facilitate the analysis of higher mass samples on magnetic sector mass spectrometers by enhancing sensitivity: a cesium ion (LSIMS) source to increase ionization efficiency and an electro-optical array detector for simultaneous ion detection over a 4% mass window.

Cesium Ion Source

A cesium ion gun has been incorporated into an LSIMS source to allow cesium ions of high bombarding energy to be used as the primary beam.

The cesium ions, after evaporation from an indirectly heated anode, are accelerated to a few hundred volts, focussed and finally accelerated out of the gun. This ion beam is directed onto the probe tip by a series of deflector plates, and is protected from stray source fields by an aperture plate situated in front of the probe tip.

The impact energy of the cesium ion beam when it reaches the target is variable up to 35keV with respect to ground potential. Using a high energy cesium ion beam provides increeased sensitivity. For example, an increase of a factor of 10 in sensitivity can be expected for a sample of 10,000 daltons.

Electro-optical Array Detector

Parallel detection of a significant portion of the mass range provides an increase in sensitivity as a greater fraction of the ion current leaving the source is being detected at any given time compared to conventional, single ion detection, and an electro-optical array detector has been developed for this purpose[1]. The array data presented here have been obtained from either a two sector EB instrument (MS50RF or Concept II H), or with the array as the final detector on a four sector EBEB instrument (Concept II HH). Data were acquired by a DS90 data system, and the following types of acquisition are possible:-

1) Survey scanning on a two sector (EB) mass spectrometer.

   Data are collected from the 1024 array channels covering a 4% mass window centered on a specific mass, or over a specified mass range. For the latter case, the number of 4% mass windows required to cover this range is calculated, and data are acquired by stepping the DAC controlled magnet to the central point of each of the mass windows sequentially. Once the specified mass range has been covered, the mass windows are "butted" together to produce a complete spectrum. To achieve a high degree of accuracy for this process, the mass spectrometer focal plane dispersion coefficient for the array detector is calculated and stored by the data system.

   The dispersion of the array is given by the equation:-

   $$\frac{\Delta M}{Mc} = an - bn^2 + \text{higher order terms}$$

   where Mc is the mass in the centre of the array, n is the channel number relative to the centre, and a and b are related to the angle of the array with respect to the focal plane, and to the constants for dispersion along the focal plane.

   This calculation enables mass/channel pairs to be used as a calibration file to mass assign acquired spectra.

The spectrum of bovine trypsin (mw 23,290) in figure 1 illustrates an array acquisition. The data system was used to acquire data from 25 consecutive 4% mass windows by stepping the magnet through a cycle of 25 mass positions covering a mass range from 26,000 to 10,000 daltons. A 5 second exposure was taken at each position. One full cycle corresponds to one exposure at each of the 25 magnet positions, and five cycles were accumulated to produce the spectrum illustrated.

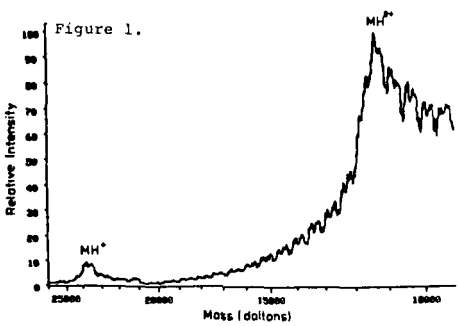
2) Peak Matching on a two sector (EB) mass spectrometer.

Mass Measurements to an accuracy of 20 ppm are obtained by a peak matching procedure where the sample ion of interest is located in an array mass window, centroided and mass converted by the mass/channel pairs stored as a result of the array dispersion calculations.

3) Fragment Ion Scanning on a four sector (EBEB) mass spectrometer.

To achieve a fragment ion scan, the sample is ionized in the first ion source, and the first magnet is set by DAC control to select the precursor ion. The second electrostatic analyser and magnet are stepped simultaneously through a specified mass range to produce a cycle of mass windows which are "butted" together, as for a survey scan.

The fragment ion spectrum from the protonated molecular ion (m/z 1348) of 100 pmole of Substance P using array detection is shown in figure 2.



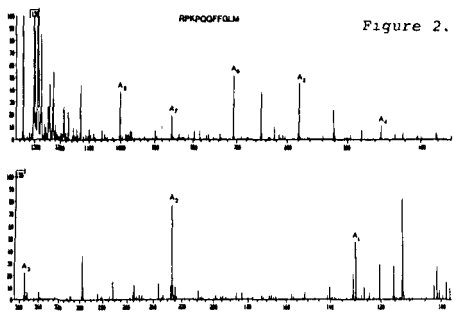


Figure 1 Bovine trypsin (mw 23,290) spectrum acquired from 26,000 to 10,000 daltons over 25 consecutive array detector mass windows.

Figure 2. Substance P (100 pmole) fragment ion scan from m/z 1348 using an EBEB mass spectrometer with array detection.

Conclusion

Ionization and detection efficiencies have been enhanced by the development of a cesium ion source and an electro-optical array detector. A range of software controlled array acquisitions are available for both two and four sector instrumentation.

LIQUID SIMS OF SYNTHETIC PEPTIDES

P.T.M.Kenny, W.-H.Xu, K.Tachibana and H.Naoki

Suntory Institute for Bioorganic Research,
Shimamoto-cho, Mishima-gun, Osaka 618, Japan.

Liquid SIMS has been extensively used for molecular weight determination of thermolabile and non volatile compounds. Peptides have been subjected to numerous investigations and sequence analysis can be accomplished using liquid SIMS. Recently a bioactive peptide named pardaxin P-1 consisting of 33 amino acids was isolated from the defense secretion of a pacific sole[1]. As this peptide displays shark repellent activity we are currently synthesizing it for biological studies. Thus solid phase synthesis of four fragments and subsequent coupling should furnish the entire peptide. Liquid SIMS was the method chosen for analysis of the solid phase synthetic fragments. Thus crude reaction mixtures could be analysed directly to determine the presence of the required peptides. Also liquid SIMS analysis could I. confirm the synthesis II. determine the presence of the protecting groups and III. determine the status of the carboxyl termini. There are a few reports on liquid SIMS of protected peptides[2-4]. Protonated molecular ion species together with fragments due to loss of the protecting groups were observed. Consequently there is less sequence information than in the case of deprotected peptides. In the present study this was not important as we are primarily interested in obtaining molecular weight information. As some of the peptides we wished to measure had molecular weights in the 1000 to 2000 mass range the initial problem was selection of a suitable matrix. The normal glycerol matrix was found to be totally unsuitable for analysis of the protected peptides presumably due to solubility problems. Consequently several other matrices were evaluated. Thioglycerol, diethanolamine, 'magic bullet' and 2-hydroxyethyldisulphide were employed in analysis of the protected peptides. Initially the following protected peptide was chosen as a model compound. Boc-S(Bzl)ALS(Bzl)S(Bzl)G-OH. All of the above matrices furnished molecular ion species aswell as the classic fragments due to loss of the protecting groups. However the most suitable matrix was 2-hydroxyethyldisulphide[5]. This matrix was up to ten times more sensitive than the other matrices used. On the other hand using glycerol as the matrix the deprotected peptides were analysed. Fragment ions corresponding to cleavage along the backbone of the peptide can

be used to confirm the sequence of the peptide. Therefore with a suitable matrix liquid SIMS was used to characterize synthetic peptides in the 1000 to 2000 mass range.

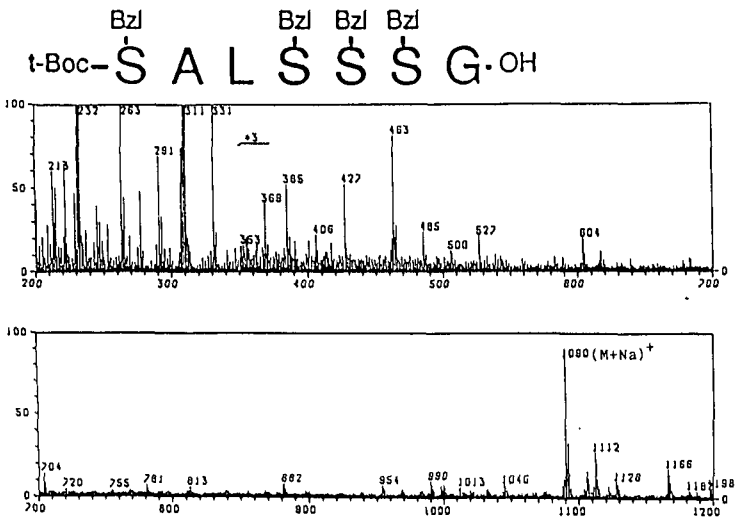

Fig.1. Liquid SIMS of the model compound. Matrix: 2-Hydroxyethyldisulphide.

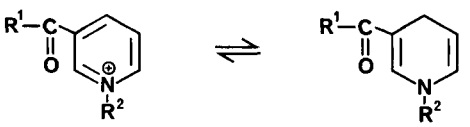
FAST ATOM BOMBARDMENT, THERMOSPRAY AND DESORPTION CHEMICAL IONIZATION MASS SPECTROMETRY OF DIHYDROPYRIDINE ⇌ PYRIDINIUM SALT-TYPE REDOX SYSTEMS

Laszlo Prokai, B.-H. Hsu and N. Bodor; Center for Drug Design and Delivery, University of Florida, College of Pharmacy, JHMHC Box J-497, Gainesville, FL 32601.

Quaternary pyridinium salts and the corresponding (1,4-)dihydropyridine analogs are involved in redox equilibria (Scheme I) in numerous cases where the chemical/biochemical application, or even the mass spectrometric analysis of these compounds are concerned [1]. Improved transport through biological membranes and/or site-specific delivery were reported for a variety of drugs using a dihydropyridine ⇌ pyridinium salt type redox chemical delivery system [2].



Scheme I

A dihydropyridine carrier is attached to the drug via a suitable functional group (usually ester or amide), and undergoes enzymatic oxidation and hydrolysis in vivo providing sustained release and/or site specific release of the drug. The aim of the present study was to examine the capabilities of some common desorption ionization methods in the characterization of these compounds. Because of the limited knowledge on the processes taking place during the production of gaseous ions from condensed-phase samples using different ionization/desorption techniques, and the possible chemical changes of reactive compounds under the conditions applied, investigation of model compounds are not only justified but necessary. These studies appears to be prerequisite for reliable interpretation of data obtained from biological media in order to identify/determine the compounds concerned.

A KRATOS MS80RFA mass spectrometer with a DS90 data system was used throughout the study. Fast-heating desorption chemical ionization (DCI) mass spectra were recorded using a resistively heated platinum-iridium coil and isobutane or ammonia reagent gas. Thermospray ionization (TSP) mass spectra were obtained by vaporizing the sample in aqueous ammonium acetate/organic solvent (acetonitrile) mixture. The organic phase was adjusted according to the solubility of the compounds. Fast atom bombardment (FAB) mass spectrometry was performed using a source operated with xenon at 6 keV beam energy. The samples were dissolved in a suitable liquid matrix

Our observations are as follows:

Fast-heating DCI results in the intact cation of the pyridinium salts with low to just detectable intensity. Thermal dealkylation was found to be favored over the desorption of intact ions from the condensed phase. Although the 1,4-dihydropyridine analogs exhibit low volatility, they mostly produce sufficient vapor pressure under DCI conditions to allow gas-phase ionication. The typical DCI mass spectrum shows a number of structure-related fragment ions.

TSP ionization is characterized by the lack of the intact pyridinium cation from the spectra. The principal route of decomposition is, however, not purely thermal. The hydrolytically most sensitive bonds (i.e., ester or amide bonds at the quaternary substituent) tend to cleave preferentially during TSP ionization. The reaction most probably takes place within the liquid jet droplets indicating the stress exerted by the elevated temperature or the pH and the ion concentration of the liquid medium to the analyte during thermospray formation. Intact cations from solvent-depleted particles may provide dequaternarized (neutral) products by thermal degradation - identical with those observed in DCI. Furthermore, they can be reduced to the dihydropyridine analogs by thermal electrons present in the jet plasma. The neutral dihydropyridine compounds themselves give spectra similar to those obtained with DCI, but "softer" ionization is achieved with TSP wich results in the preferential formation of quasi-molecular ions and limited fragmentation.
FAB is the only technique studied wich is able to provide intact cations of high intensity from these pyridinium salts. The only major fragment ion is originated from the quaternary substituent. The only major fragment ion is originated from the quaternary subsituent. In addition to the expected MH quasi-molecular ions, species of even higher intensity corresponding to the quaternary ion are detected in the FAB spectra of dihydropyridine analogs. The presence of an intense fragment ion characteristic of the quaternary substituent also reveals a matrix-induced oxidation process. The driving force of the reaction may be attributed to the more favorable desorption ability of the ionic species obtained from the process, in comparison with the competitive acid-base reaction (protonation) products. The process appears to occur at the liquid matrix/gas phase interface region via mechanisms involving either hydride abstraction or two-electron oxidation and deprotonation.

To avoid the appearance of "artifacts" in the mass spectra, FAB is the suggested method for the analysis of these types of pyridinium salts, and DCI and TSP are the preferable ionization methods for the corresponding dihydropyridine analogs.

This work was supported by NIH Grant GM26167 (to N. Bodor).

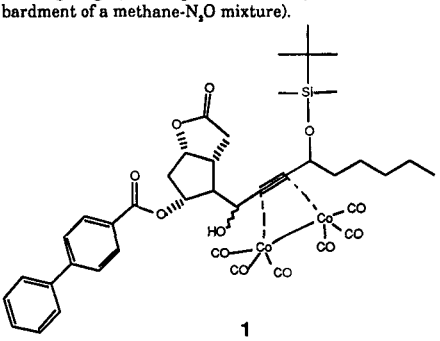
COMPARISON OF LSIMS (FAB) AND DCI MASS SPECTRA OF COBALT CARBONYL COMPLEXES OF PROSTAGLANDIN ANALOGS BY LINKED SCAN TECHNIQUES

K.Chan, A.Spilkin, H.Carpio, J.Mendez, K.Straub
Syntex Research
Palo Alto, California 94304

Numerous studies have revealed similarities between the LSIMS (or FAB) and chemical ionization mass spectra of low molecular weight, moderately polar compounds (1,2). However, compared to CI, LSIMS is more often used to characterize compounds of high molecular weight. Even with the use of rapid heating techniques (eg., 'desorption' CI or DCI), the CI mass spectra of compounds with molecular weights greater than 1500 d. cannot be easily obtained. A direct comparison of the two ionization techniques with respect to the analysis of high molecular weight compounds is therefore not possible. Nevertheless, compounds in the molecular weight range of 800-1200 d. are usually accessible by both DCI and LSIMS, allowing a direct comparison of the two ionization processes to be made. We have observed numerous instances where the mass spectra obtained by LSIMS and DCI differ significantly, particularly in their fragmentation. For example, organometallic compounds such as the neutral prostaglandin cobalt π-complex shown for structure 1 can be analyzed by either DCI or LSIMS, but yield strikingly different spectra. These observations prompted us to explore the possible reasons for these differences.

Mass spectra were recorded on a Finnigan-MAT 8230 double focussing mass spectrometer, operating at Vacc= 3kV. LSIMS spectra were obtained with a Cs+ primary beam of nominal energy 3-5 keV. A liquid matrix consisting of either nitrophenyl octyl ether (NPOE) or triethanolamine (TEA) was used. DCI spectra were obtained using a rapidly heated rhenium wire. Positive ion DCI spectra were obtained using either ammonia or methane as the reagent gas, and negative ion DCI spectra were obtained using hydroxide ion (OH^-, obtained by electron bombardment of a methane-N_2O mixture).



1

Figure 1 shows the negative ion LSIMS spectrum of 1, desorbed from a NPOE matrix. The [M-H] molecular ion species is observed at m/z 875. However, the spectrum is dominated by successive losses of CO or HCO from the parent molecule (m/z 848, 820, 791, etc.). Similar ligand displacement reactions have been attributed to condensed phase chemistry (3). To determine if the detected fragment ions are gas phase unimolecular decomposition products or reaction products in the condensed phase, linked scan MS/MS techniques were employed to characterize the metastable decomposition in the first FFR of the instrument. Figure 2 shows the daughter ion spectrum (B/E scan) of the molecular ion species. The lose of one, two, and three CO ligands is observed. Another decomposition product is the ion of m/z 497. This ion may be rationalized as the loss of *t*-butyldimethylsilanol, water, $Co(CO)_3$, $C_3H_3O_2$, and one additional CO from the parent molecule. The base peak (m/z 469) in the full scan spectrum is therefore a loss of CO from the ion of m/z 497. Other linked scan experiments demonstrate that most of the fragment ions observed in Figure 1 can be formed via gas phase unimolecular processes. These results indicate that the energy imparted to the analyte molecules during LSIMS ionization is large enough to break a number of covalent bonds in the molecule.

In comparison, significantly less fragmentation is observed in the DCI mass spectrum of 1. The negative ion DCI spectrum of 1 obtained with OH^- is shown in figure 3. Only a trace amount of $[M-H]^-$ is detected; the predominant species being the $[M-CO]^-$ ion (m/z 848). Subsequent loss of CO from this ion is small. Other ions detected in the OH- DCI spectrum of 1 may be attributed to the loss of the dicobalt hexacarbonyl group (m/z 590) and an additional loss of the *t*-butyldimethylsiloxy group accompanied by a hydrogen transfer(m/z 460). Linked scan experiments could not confirm the origin of these ions, suggesting that they are not formed via gas phase unimolecular decomposition. Therefore, both of these ions may arise as thermal degradation products formed during the desorption process.

Since the energy imparted to the analyte in the CI process is determined by the difference in proton affinity between the analyte and reagent ions, one may enhance the molecular ion species by selecting an appropriate reagent gas. Figure 4 shows the positive ion DCI mass spectrum of 1 using NH_3 as the reagent gas. The intact molecular ion species $[M+NH_4]^+$ is detected at m/z 894. No loss of CO from the quasimolecular ion is observed. Similar to the OH^- DCI spectrum, other ions detected may be thermal degradation products (*eg.*, m/z 608 as $[590+NH_4]^+$; m/z 478 as $[460+NH_4]^+$) Daughter ion spectra obtained on m/z 894 are characterized by fragments derived from the loss of *t*-butyldimethylsilanol with NH_3 or OH (m/z 745) and a subsequent loss of CO (m/z 717).

In conclusion, both LSIMS and DCI are useful techniques for the characterization of cobaltcarbonyl complexes of prostaglandins analogs such as 1. However, one has to be careful about matrix effects in LSIMS and thermal decomposition in DCI. Our results suggest that, if one can volatilize a compound without degradation into a CI plasma, the energy imparted to the analyte in the CI process can be less than that of the LSIMS process. These results suggest that it may also be possible to control the amount of energy (and therefore the amount of fragmentation) imparted to an analyte during LSIMS ionization by varying the gas phase proton affinity of the liquid matrix.

BEHAVIOR OF FATTY ACID MIXTURES IN VARIOUS FAB MATRICES

K. Caldwell and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588.

FAB has established itself as a useful means for obtaining molecular ions of nonvolatile and/or thermally sensitive compounds The technique has enjoyed the most success with qualitative analysis. Quantitative analysis requires an internal standard which may not always be commercially available or easily made.

If quantitative or at least semiquantitative mixture analysis is to be done by FAB, the problems need to be outlined and understanding of the behavior of simple analyte mixtures in typical FAB matrices is needed.

Some problems associated with quantitative mixture analysis by FAB are: (1) Normal surface activity discrimination resulting in underrepresentation of less surface active species[1]. This is evident in spectra of equimolar mixtures of saturated fatty acids of different chain length and occurs at lower total fatty acid concentrations in the matrix (Fig. 1B and 1C). (2) Formation of micelles leading to underrepresentation of fatty acids with a lower critical micelle concentration in the matrix - typically the longer chain length fatty acids[2]. This is an example of reverse surface activity discrimination and occurs at higher total fatty acid concentrations in the matrix (Fig. 1B and 1C). (3) A change in the relative ratios of a mixture composed of both hydrophilic and hydrophobic fatty acids with time in the atom beam. The early scans are dominated by ions from the most hydrophobic fatty acids and the hydrophilic fatty acids are underrepresented until the hydrophobic fatty acids are sputtered away.

These problems are a manifestation of matrix analyte interactions. Fatty acids greater than about C12 behave much like hydrocarbons. They tend to cluster and even form micelles in polar solvents so that the hydrocarbon tails are closer, thus reducing their energy by the attractive Van der Waals forces. This is evident in the spectrum of the three saturated fatty acids in glycerol/KOH. The KOH was added to the matrix because the fatty acids were not very soluble in glycerol alone. The high ionic strength of a .5M KOH solution also lowers the critical micelle concentration[3].

A means of reducing discrimination effects is to turn to a matrix that shows little differential surface activity effects and minimizes micelle formation. The matrix should have the property of solubilizing the mixture components and so it should resemble the analyte themselves. Dodecanol has been used in this study and Fig. 2 shows an equimolar mixture of 3 saturated fatty acids in the new matrix. Notice that the bulk relative ratios are represented and compare Fig. 1A with 1B and 1C.

The graphs in Fig. 1 were generated by taking the $[M + H]^+$ intensity, in the case of 1A, and the $[M - H]^-$ intensity in the case of 1B, 1C and divided by the actual relative abundances C10:C16:C18 = 1.10:1.00:1.04. If the uncompensated intensities are plotted versus the concentration of each fatty acid in the new matrix, a linear relationship is observed (Fig. 3). The possibility of quantitative analysis by FAB without the use of an internal standard is being explored.

EXPERIMENTAL - The C10, C16, and C18 fatty acids were weighed and dissolved in CCl4. The actual relative molar ratios were: C10:C16:C18 = 1.10:1.00: 1.04. A 33% solution of the matrices in ethanol was mixed with an appropriate amount of the fatty acid stock solution and the volatile solvents allowed to evaporate. The total fatty acid concentrations used in Fig. 1 is assuming 100% evaporation of the volatile solvents. Since dodecanol melts above room temperature, all the solutions just before analysis were brought to 35 °C. Several microliters of these solutions were applied to the probe tip and spectra obtained using an Ion-Tech FAB Gun and a Kratos MS50 TA.

Matrix Effects and Ion Formation in Fast Atom Bombardment Mass Spectrometry of Cyclic Dithia-Diaza Compounds

B.H. Hsu, Department of Medicinal Chemistry, J-485 JHMHC,
University of Florida, Gainesville, Fl 32610

INTRODUCTION

Cyclic dithia-diaza compounds including monocyclo and bicyclo have been designed as the delivery system for technetinium in brain scanning. Fast atom bombardment (FAB) has been proved to be the only ionization vehicle by the mass spectrometric methods to characterize these substances thus far.

The technique of FAB is limited by the contribution of matrix background and the requirement of a soluble sample in the matrix solution. Furthermore, solute /solvent interactions can play a significant role in desorption ionization mass spectrometry (1.2). This work has been in an effort to provide analytical support to the determination of these cyclic dithia-diaza compounds and to explore the ion formation in connection with matrix and mechanistic aspects of particle-induced desorption. Linked scans (B field/E field, is constant) which produce daughter spectra of selected parent ions was used to study fragmentation mechanism.

EXPERIMENTAL

The FAB/MS data were obtained using a Kratos MS80RFA spectrometer utilizing an Ion Tech Saddefield gun which generate a primary beam of xenon atoms at 7KV and 1.5 mA. FAB/MS/MS data were collected with linked scans (B/E). Collision gas (Ar) was introduced into first field-free region at the indication of source pressure at 2×10^{-3} torr.

DISCUSSION

The structure of cyclic dithia-diaza analogues are shown in Fig. 1. A representative FAB spectrum of an analogue (Compound 2) is given in Figure 2. The spectrum contains hydrated molecular ion along with a few fragment ions and one fragment reminiscent of the $(M-H)^+$. The ratio of the relative intensity of $(M-H)^+$ ions can be varied by the amount of added glycerol matrix from 2:1 without any matrix to 1:2 with 100 fold of glycerol. FAB spectra of compound 3 and 4 show no evidence of $(M-H)^+$ and the loss of sulfur. The instability of the charge delocalization on the imidazole moiety for these two compounds might be responsible for that observation.

Table I summarizes the FAB matrix effects for cyclic dithia-diaza compounds. Glycerol adducts of protonated molecular ions were not found if glycerol was used as the only matrix. However, a series of adducts were detected, which include $[M + H + H_2O]^+$, $[M + H + G]^+$, and $[M + H + G + H_2O]^+$ (where M represents intact molecule and G represents glycerol molecule), if p-toluene sulfonic acid (p-TSA) was added to the glycerol and bombarded by the Xe neutral beam. No adducts were present in the FAB spectra of compounds 3 and 4 even p-TSA was added. This accounts for the fact that the formation of adduct ions are involved in the chemical structures with bicyclic or monocyclic analogues with C=N bond.

Solvation of organic cations in desorption ionization experiment involving formation of strong new bonds have been exclusively studied (1,3). Table II lists the fragmentation behavior of adduct ions of compound 1 and 5. The ions selected for examination are all formally glycerol and/or water adducts of protonated molecular ions generated under conventional FAB conditions. Losses of glycerol or water are commonly found in the MS/MS spectra of $[M + H + H_2O]^+$ and $[M + H + G + H_2O]^+$ ions. Nevertheless, loss of water following the loss of glycerol was not detected for the adduct ion of $[M + H + G + H_2O]^+$. In contrast, glycerated form of $[M + H + G]^+$ ion show markedly different behavior, which displays no loss of glycerol; instead it loose 113 daltons. These observations can be recognized as the strong interactions involving covalently bond formation between analytes and solvation solvents.

QUANTITATIVE FAB: IS WHAT YOU SEE WHAT YOU'VE GOT ?

S. L. Hunt and P. A. Lyon
3M, St. Paul, MN. 55144.

Fast atom bombardment mass spectrometry has given us a simple and rapid method for the direct analysis of ionic mixtures. Characterization of ionic mixtures often requires both qualitative and quantitative data. The performance of surfactants, for example, depends upon both the type and concentration of each component. Our work focuses upon the largest class of surfactants, the anionics. Conflicting data exists about the reliability of FAB for quantitation. This study explores the factors influencing the relative abundance of anions generated by FAB and evaluates the quantitative capabilities of the technique for analyses where isotopically labeled internal standards are not readily available or easily synthesized.

The compounds and mixtures included in this study were evaluated by full scan FAB mass spectrometry on a Kratos MS50 RFTA. We examined parameters like desorption time, molecular structure and weight, the matrix, polarity of the experiment, and the counterion. Our results suggest that time averaged FAB data reflect the true composition of sulfonate mixtures (Table I). Time averaging was required because the ion relative abundances change with desorption time (fig. I). Molecular weight and/or structure, possibly as they relate to surface activity, play an important role in desorption preference.

The ability of FAB to perform semiquantitative analyses was tested on synthetic mixtures and an industrial sulfonate sample. Based on FAB results, the industrial sample contained C_1 through C_8 perfluoroalkane sulfonates. The same sample was derivatized with diazomethane and analyzed by GC using microwave plasma detection. Fluorinated impurities interfered with quantitation using the microwave fluorine channel. However, the results obtained from the sulfur channel were in excellent with the FAB data (Table II).

The industrial perflurosulfonate sample was analyzed using three different FAB matrices (glycerol, dithioerythreitol/dithiothreitol and triethanolamine). We measured the abundance of FAB-generated positive and negative ions. These experiments suggest that quantitation of perfluoroalkanesulfonates is relatively insensitive to acquisition polarity or type of matrix.

Most of these surfactants are produced as salts. Therefore it seemed necessary to investigate the effect of various counter ions. Decanoic acid was converted into the following salts: Li, Na, K, Mg, Ca and Ba. The relative abundance of significant ions are summarized in Table 3. It appears that the salts are more amenable to FAB than the free carboxylic acids, lithium salts provide the least information and divalent cations produce usable but complex spectra.

We have found that in many FAB analyses "what you see is what you've got". However, since exceptions exist it is hazardous to generalize about the applicability of FAB for semiquantitation of components without internal standards.

THE BEHAVIOR OF MIXTURES OF PHOSPHOLIPIDS IN THE FAB MATRIX

D N. Heller, R.J. Cotter, C M Murphy, Johns Hopkins University, Baltimore, MD 21205
O M. Uy, Johns Hopkins Applied Physics Laboratory, Laurel, MD 20707
C. Fenselau, University of Maryland Baltimore County, Catonsville, MD 21228

Lipid analyses of bacteria cells over the past 25 years have revealed that phospholipid and glycolipid distributions occur in patterns that are related to taxonomic grouping[1]. We have used negative ion FAB mass spectrometry to generate "lipid profiles"--mass spectra of complex lipid mixtures--to differentiate or identify bacteria[2,3].

Experiments conducted in our laboratory have shown that lipid signals obtained from lysed cells yield reproducible mass/intensity patterns[2], and also combine linearly when various ratios of cells from two different bacteria are mixed in the FAB matrix[3]. Linear regression analysis, the technique used to demonstrate the latter point, depends on the assumption that individual mixture components--the polar lipids themselves--behave independently of one another during the analysis. In other words, the system requires linear addition of signals but not necessarily quantitative response during FAB desorption

While evidence to date suggests that polar lipids are desorbed and ionized independently under the conditions of our previous experiments, the behavior of phospholipids mixtures has not yet been studied through direct analysis of measured mixtures. Our goal is to define conditions under which linear behavior of phospholipids in mixtures is observed in negative ion FAB-MS.

Previous studies have shown that competition for surface sites has a great influence on FAB spectra: relative surface activity accounts for the suppression of matrix ions by analyte, the preferred desorption of one peptide or tetraalkylammonium ion in a mixture, as well as the efficient desorption of highly surface-active analytes[4]. Formation of a surface monolayer of analyte, determined by surface tension measurements, has been correlated with the onset of altered desorption characteristics[5,6,7,8].

Phosphatidylethanolamine (PE) and phosphatidylglycerol (PG) are two of the most common phospholipids occuring in bacteria; these compounds differ only in their polar head group. Dipalmitoyl PE (ave. MW = 691.5) and dipalmitoyl PG (ave. MW = 722.5) were combined at various concentrations and ratios in $CHCl_3$/MeOH 1:2 before being mixed with diethanolamine (DEA) and placed on the FAB probe. Spectra were acquired with the Kratos MS-50RF operated in negative ion mode and scanned at 30 s/dec from m/z 1500-350 (23 s/scan). The Ion-Tek FAB gun used Xe gas and was operated at 7.5 kV and 40uA discharge current. Found desorption ratios were calculated from the intensity of the [M-H]- monoisotopic mass peak in each scan.

During the first two minutes of particle bombardment the found PE:PG ratio remains relatively constant; consequently all measurements are based on average ratios obtained from the first two minutes of each run.

At or below a combined concentration of about 10^{-4} M (Figure 1) the relative response of PE and PG is close to the ratio of their concentrations in the matrix, but at total concentrations above this range the PE:PG desorption ratio steadily decreases.

At [PE]+[PG] ~ 10^{-4} M, linear desorption response is observed for PE and PG over the range 10:1 to 1:10 (Figure 2). Non-linearity at more extreme ratios can be attributed to the relatively large contribution of chemical noise to the smaller of the two lipid signals (signal-to-noise about 5), and could be improved by chemical baseline subtraction. The relative error in found PE:PG ratios increases as concentration decreases (Figure 1) due to the variation in absolute signal intensity.

Linear and nearly quantitative desorption ratios are obtained from dipalmitoyl PE and PG at total probe concentrations ~ 10^{-4} M. Non-quantitative desorption ratios are obtained at total concentrations > 10^{-4} M. Interpretation of this data in light of previous studies with surface-active analytes suggests that complete surface coverage of DEA is achieved at about 10^{-4} M, while at higher concentrations

PG excludes PE from the surface layers.

Linear behavior for a mixture of two common phospholipids has been demonstrated at a total concentration of the same order of magnitude as polar lipids from 30 ug lysed bacterial cells in 2 ul matrix[2,3]. The results of these experiments suggest that the required linear desorption behavior of phospholipid mixtures can be obtained if sample concentration is low enough that surface saturation by polar lipids does not take place.

3-NITROBENZYL ALCOHOL - A VERSATILE MATRIX COMPOUND FOR FAB/MS

B.J. Sweetman and I.A. Blair, Department of Pharmacology
Vanderbilt University, Nashville, Tennessee 37232

Fast atom bombardment (FAB) mass spectrometry was introduced originally by Barber et al. (1,2) in 1981 as a means for the mass spectral analysis of previously intractable polar and/or thermally-labile compounds. To obtain FAB spectra, a compound is usually dissolved in a viscous liquid-matrix and bombarded with fast atoms. The resultant ions arising from the sputtering process are mass-analyzed by the use of the focussing devices of the particular mass spectrometer. Glycerol was the initial matrix suggested for FAB-MS (1,2) and has seen extensive use. A large number of alternative matrix compounds have been suggested to accomplish analyses of specific compounds or specific compound types (3). One of these matrix compounds which has been mentioned occasionally in the literature is 3-nitrobenzyl alcohol (3-NBA). The use of 3-NBA was suggested originally by Meili and Seibl (4) for the analysis of porphyrins and cyclic peptides. Adams and Gross (5) have described recently its use for the structural determination of cationized fatty acids. Miller et al. (6) demonstrated recently that abundant intact doubly-charged cations of certain ruthenium-bidentate ligand complexes could be detected when using 3-NBA as matrix but not with other matrices. They postulated that 3-NBA served as an oxidative quencher for the excited state of the ruthenium complex.

With the availability of a large number of different types of matrix compounds for FAB-MS, the task of the analyst in choosing the optimum matrix compound for a particular analysis is often quite arbitrary and time-consuming. During the past two years we have had the need to characterize a diverse variety of compounds using FAB-MS. Our growing experience has been that 3-NBA comes closer to being a universal FAB matrix compound than any other matrix we have used. This appears to be related to the apparently unique physico-chemical properties of 3-NBA. We have employed 3-NBA to obtain intense, high quality positive and negative ion spectra of a diverse variety of compound types giving, in most instances, results superior to those obtained using glycerol or thiol based matrices. Spectra obtained show little or no interference from matrix or alkali metal cations. Compound types generating excellent results with 3-NBA include peracetylated oligosaccharides, quaternary amine salts, spin labelled nitroxide free radicals, nucleosides, peptides, aryl sulfonates, phosphatidic acids, cephalosporin antibiotics, glutathione and cysteine conjugates of prostaglandins, phosphonium salts, apolar organosulfur and organoselenium compounds. The use of 3-NBA yields particularly useful structural information about phosphonium and quaternary ammonium salts. Alkyl phosphonium bromides are used in the important Wittig reaction in synthetic organic chemistry. Their positive ion spectra show the intact phosphonium cation as base peak and fragment ions corresponding to fission of each C-C bond in the molecule. Primary and secondary phosphonium salts can be differentiated. Negative ion spectra all show $RPBr.Br^-$ attachment ions. The bis-quaternary ammonium salts are representative of compounds such as succinyl choline di-chloride (SC) which are used widely in medicine. The positive ion spectrum of SC shows a peak due to SC.Na-Cl together with a number of structurally significant ions containing a single quaternary ammonium group. Little or no structural information could be obtained from the corresponding spectrum in glycerol.

The spectrum obtained for SC using 3-NBA as a matrix provides a definitive fingerprint for SC. Despite the presence of NaCl, the spectrum is totally free from peaks due to matrix, cationized matrix or cationized SC (Figure). Loss of one chloride from SC gives the doublet at m/z 325/7 and the further loss of the elements of CH_3Cl yields the base peak at m/z 275. Alternatively, loss of the elements of trimethylamine gives m/z 266/8. The spectrum obtained for the same quantity of SC using glycerol (G) as matrix is in striking contrast to the spectrum in 3-NBA. The spectrum is complicated greatly by peaks due to G and G_2 and sodium attachment ions of G and G_2-H. Peaks are also present at m/z 173 and 265, attributed to [GNa.NaCl] and [G_2Na-H.NaCl], respectively. The spectrum obtained using G, by contrast to the spectrum in 3-NBA shows intense peaks at m/z 104 and 204, possibly arising by saponification of SC in G. Abundance of the mono-quaternary ammonium ion at m/z 275 is dramatically reduced. A doublet at m/z 383/5 is attributed to [M-Cl.NaCl] and is not present in the 3-NBA spectrum. 3-NBA failed as a matrix compound for underivatized sugars and the vancomycins because of low solubility of these compounds in 3-NBA. Negative ion spectra obtained using 3-NBA in the presence of halide ions can be complicated by the reaction of matrix with halide ions.

Spectra obtained using 3-NBA are usually prolonged and intense - apparently associated with the unique physical properties of this matrix - low volatility, medium viscosity liquid at room temperature, high dielectric constant and very high dipole moment. 3-NBA has surprisingly good solvent properties for a diverse variety of compound classes and can be used for obtaining either positive or negative ion spectra. 3-NBA is chemically quite inert and we have encountered no instances of reactivity between 3-NBA and solutes during the acquisition of FAB spectra, unlike the use of thiol matrices where reaction of matrix and solute is relatively common. Spectra obtained using 3-NBA almost invariably show molecular ion information (M^+, MH^+, MH_2^+, etc. depending on compound type) and abundant fragment ion information. Spectra of polar molecules such as quaternary ammonium salts, phosphonium salts and phospholipids obtained using 3-NBA are much more resistant to interferences and suppression from alkali metal cations, than are the corresponding spectra obtained using glycerol or thiol matrices. This effect apparently does not extrapolate to acidic peptides, in our limited experiences of these compounds.

On the basis of the results presented here and our experiences with a large variety of compound types, 3-NBA rather than glycerol or thiol matrices should be used as the first-choice matrix compound for the structural analysis of compounds by FAB-MS, where no existing precedent for their analysis exists.

Observation of Surfactant Clusters by Liquid SIMS

E.L. Dorwin, P.W. Bethel and P. Fitch
University of California, San Francisco

The sputtering and ionization of hydrophobic salts at the liquid-vacuum interface is related to the surface activity of the salt. Ion intensities are maximized when surfactant solutions are presented to the bombarding particles at or above the critical micelle concentration. This desorption may involve Marangoni effects or a sputtering of micellar clusters which may decompose before reaching the collector of the mass spectrometer.

Three compounds which are known to form micelles or sub-micellar aggregates in aqueous solutions were studied [1,2]:

$(C_8H_{17})_3N^+CH_2CH_2OH$ mesylate salt

$C_{16}H_{33}N^+(CH_3)_2CH_2CH_2OH$ bromide, chloride salt

In order to characterize the state of aggregation of these hydrophobic salts both before and after ionization, the samples were sputtered from an LSIMS source by bombardment with a cesium ion beam. Clusters were observed at nominal masses corresponding to the aggregate forms (+), (++-), and (+++--) for the mesylate salt sputtered from a tetraglyme matrix. The bromide salt of the cholinate functionalized micelle when sputtered from a glycerol/water matrix (92:8) produced peaks at nominal masses corresponding to (+) and (++-) ions.

Critical micelle concentrations were determined for the cholinate functionalized micelle in the solvent system glycerol/water (92:8). The critical micelle concentration of the bromide salt of the cholinate functionalized micelle was 1.3×10^{-3} M determined by the Wilhelmy Plate method using a Cahn electrobalance. The cmc of the chloride salt of the cholinate functionalized micelle was 3.5×10^{-3} M determined by differential absorption spectrophotometry using phenol as an optical probe of micelle structure [3].

Since the sample of the cholinate functionalized micelle was applied to the probe tip and introduced into the source of the Kratos MS-50 at a concentration of .026 M in glycerol, surface tension measurements indicate that micellar clusters were present in the solution. Whether the aggregates observed at the detector of the mass spectrometer arose from a desorption of pre-formed ion aggregates or a gas phase 'micellization' of surfactant monomers cannot be determined from these preliminary experiments.

Micelle formation in both water and glycerol has been attributed to a combination of hydrophobic and dispersive attractions. The high vacuum of the mass spectrometer would seem to preclude a solvophobic force for cluster formation. The driving force allowing a gas phase micelle to exist may arise from a surface tension difference between the hydrocarbon tails of the surfactants and the vacuum which is even greater than the interfacial tension between hydrocarbons and the glycerol/water matix.

Aside from their theoretical interest for both solution and gas phase aggregate chemistry, functionalized micelles and phase transfer catalysts may have future applications as derivatization reagents in enhancing the surface activity of biopolymers for quantitative Fast Atom Bombardment mass spectrometry.

ENHANCEMENT OF PEPTIDE IONIZATION IN FAST ATOM BOMBARDMENT MASS SPECTROMETRY USING A NITROCELLULOSE MATRIX

Richard B. van Breemen and John C. Le
Department of Chemistry, North Carolina State University
Raleigh, NC 27695-8304

Nitrocellulose has been shown to improve molecular ion yields when used as a solid matrix for plasma desorption (1) and secondary ion mass spectrometry using a time-of-flight analyzer (2). A solid instead of a liquid matrix was used in these studies for greater compatibility with a time-of-flight mass spectrometer. In the present investigation, nitrocellulose was evaluated as a fast atom bombardment (FAB) matrix either by itself or with the addition of the liquid, thioglycerol. Nitrocellulose was used in the analysis of peptides and proteins weighing 3,000 to 8,000 mass units with a double-focussing mass spectrometer.

A JEOL HX110 double-focussing mass spectrometer, equipped with a high field magnet, FAB gun, and DA5000 data system was operated at an accelerating voltage of 10 KeV for all measurements. Xenon gas at 3 KV was used for FAB. Each spectrum represents the sum of five scans which were accumulated by signal-averaging. For optimum results, nitrocellulose (3.5 µg) was applied to the stainless steel probe tip in an acetone solution to form a 0.6 $\mu g/mm^2$ layer. Thioglycerol (1 µg), if used, was then added to the probe tip followed by the sample, which was dissolved in dimethylsulfoxide or water.

Without the addition of thioglycerol, a solid matrix of nitrocellulose could not sustain sample ionization, probably because of damage to the sample surface by the high flux fast atom beam or depletion of sample at the point of impact. However, nitrocellulose plus thioglycerol appeared to enhance the intensity of the signal for peptide samples. An optimum amount of nitrocellulose on the surface of the probe tip was determined to be between 3 and 6 µg. Too much nitrocellulose produced a strong signal (as measured by ion counts at the detector) but also considerable chemical noise so that the signal-to-noise ratio was low (Figure 1).

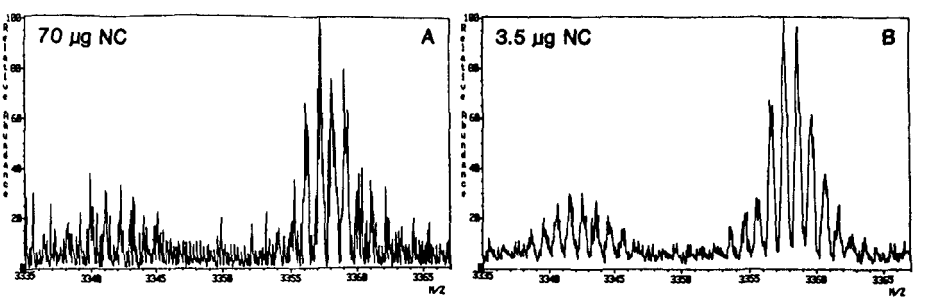

Figure 1. Effect of quantity of nitrocellulose (NC) added to the probe tip along with 1.0 µg thioglycerol. Positive ion FAB mass spectra at a resolving power of 5,000 showing the molecular ion region of human growth hormone releasing factor peptide (amino acids 1-19, 5 µg).

The addition of a layer of nitrocellulose (0.6 µg/mm^2) to the FAB probe tip followed by thioglycerol resulted in a two-fold increase in sensitivity for FAB mass spectrometric analyses of peptides and proteins compared to the use of thioglycerol by itself (Figures 2 and 3). Furthermore, the nitrocellulose/ thioglycerol matrix prolonged sample ionization by reducing the loss of signal associated with redissolving the sample in additional aliquots of thioglycerol after the evaporation of the previous thioglycerol matrix. Nitrocellulose probably reduced the adsorption of peptide and protein molecules to the stainless steel probe tip thereby preventing the effective loss of sample from the liquid matrix solution.

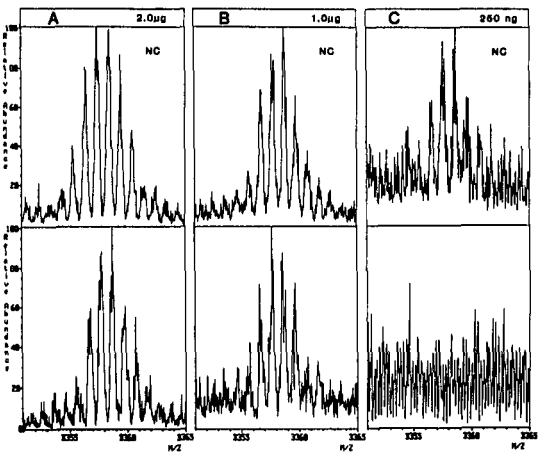

Figure 2. Comparison of sensitivity (detection limit) with or without nitrocellulose (NC) as a function of sample size. The molecular ion region of human growth hormone releasing factor peptide (MW 3357) is shown, obtained by positive ion FAB mass spectrometry at 5,000 resolution.

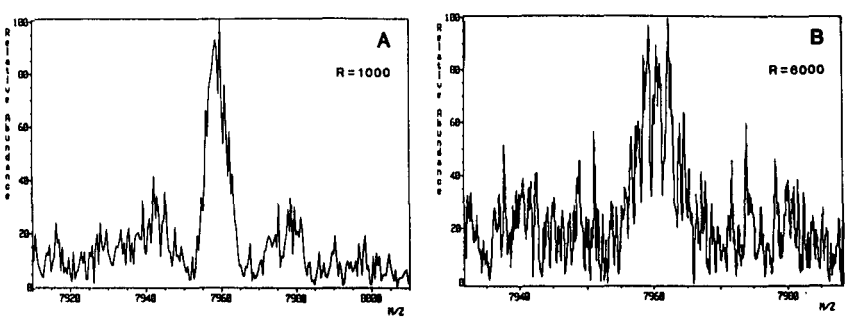

Figure 3. Positive ion FAB mass spectra of α-amylase inhibitor (MW 7958; 100 µg) at 1,000 and 6,000 resolution using nitrocellulose. Without nitrocellulose, twice as much sample was required for similar results.

Characterization of Tetrakis(benzamidinato)dirhodium(II) by Field Desorption and Fast Atom Bombardment Mass Spectrometry.

John C. Le and Richard B. van Breemen
Department of Chemistry, North Carolina State University
Raleigh, North Carolina 27695-8204

In recent years the structure and chemical reactivity of dirhodium(II) complexes have been investigated extensively, but mass spectrometry has only been used to confirm the molecular weights of these compounds. We recently reported the synthesis of a new dirhodium(II) complex, in which the dirhodium center was coordinated to eight nitrogen atoms (1). Here, we report the first extensive mass spectrometric investigation of this novel dimeric rhodium(II,II) compound and its oxygen adducts using field desorption (FD) and fast atom bombardment (FAB).

The tetrakis(benzamidinato)dirhodium(II) complex was the major product obtained from the reaction of $Rh_2(O_2CCH_3)_4$ with excess N,N -diphenylbenzamidine as previously reported (1). In agreement with literature predictions (2), X-ray crystallography showed that this complex, $Rh_2(N_2R_2CR)_4$ (where R = phenyl), possessed no axial coordination. In an attempt to form axially coordinated oxygen adducts, 50 mg of crystalline $Rh_2(N_2R_2CR)_4$ was exposed to sunlight for 2 months in the presence of atmospheric oxygen. The sample was then dissolved in CH_2Cl_2 (3 g/L), and 1.0 µL aliquots were analyzed by FD, FAB, DCI, or EI mass spectrometry.

All mass spectra were obtained using a JEOL HX110 double-focussing mass spectrometer equipped with a high field magnet and DA5000 data system. The FAB matrix was 3-nitrobenzyl alcohol. The resolving power was 3000 for FAB and DCI and 1000 for FD and EI. A silicon emitter was used for FD measurements.

The molecular weight of the tetrakis(benzamidinato)dirhodium complex was confirmed by FD mass spectrometry, which produced molecular ions at m/z 1290.8 and m/z 430.2 corresponding to the singly charged and triply charged molecular ion radicals. No fragmentation was observed.

FAB formed molecular ion radicals, but also fragment ions corresponding to the sequential loss of the bidentate ligands ($[Rh_2(N_2R_2CR)_n]^{+\cdot}$, n = 1-3) (Figure 1). These types of fragment ions have not been observed in previously reported mass spectra of related dirhodium complexes. It is noteworthy that the intensities of these fragment ions increased or decreased depending upon the energy of the xenon fast atoms. The oxygen adducts, $Rh_2(N_2R_2CR)_4 \cdot O^{+\cdot}$ and $Rh_2(N_2R_2CR)_4 \cdot O_2^{+\cdot}$, were also measured by FAB. Coordination of oxygen to only one axial binding site of the complex occurred during exposure to the sunlight. Fragmentation of these complexes in FAB is summarized in Table 1. Electron impact (EI) and desorption chemical ionization (DCI) mass spectra were also obtained. Molecular ion radicals, $M^{+\cdot}$, as well as the doubly charged molecular ions were observed without fragmentation using these ionization methods.

All four ionization methods, FD, FAB, DCI, and EI produced molecular ions, but FD formed them exclusively. FAB provided the most extensive fragmentation and structural information for this new rhodium complex and its oxygenated adducts. These studies should be applicable to many other organometallic compounds such as Pd or Pt complexes.

FORMATION OF MOLECULAR IONS OF MONOSUBSTITUTED GROUP VI PENTACARBONYLS BY NEGATIVE ION FAB MASS SPECTROMETRY

R. B. van Breemen, L. B. Martin, and A. F. Schreiner
Department of Chemistry, North Carolina State University
Raleigh, N. C. 27695-8204

The first negative ion Fast Atom Bombardment mass spectra of a series of monosubstituted group VIB transition metal pentacarbonyls of the general formula Met(CO)5L (where Met= Cr, Mo, or W, and L = $P(C_6H_5)_3$, $As(C_6H_5)_3$, $Sb(C_6H_5)_3$) were obtained. The positive ion FAB mass spectra, which previously have been reported (1), contained molecular ion radicals as well as fragment ions due to the elimination of neutral ligands. Previous studies have shown that electron impact and electron capture negative ion chemical ionization produced negative ion fragments but no molecular ions (2). In the present investigation, the first molecular negative ions of these compounds formed by any ionization method have been obtained. Molecular ions consisting of $[M-H]^-$, $M^{\bullet -}$, $[M+H]^-$, and $[M+CH_3]^-$ were detected using FAB in an aprotic matrix of 18-crown-6 ether in tetraglyme (3). Fragmentation consisted primarily of elimination of neutral ligands such as $[MH-CO]^-$ and $[MH-2CO]^-$ with evidence shown of loss of cationic species such as protons and phenyl groups from the triphenylphosphine, arsine, or stibine. B/E and constant neutral loss linked scanning with collisional activation and high resolution measurements were carried out on a JEOL HX110 double-focussing mass spectrometer. These techniques were used to confirm fragmentation pathways and determine the site of hydride attachment on the transition metal complex.

The observation of a variety of molecular ions complicates the characterization of the ionization mechanisms involved in FAB of neutral complexes. While some compounds such as $Cr(CO)_5Sb(C_6H_5)_3$ exhibited electron capture as an ionization pathway contributing to the molecular ion, most other compounds formed molecular ions primarily through either hydride addition or proton elimination. Modeling experiments using theoretical isotope patterns show that the molecular ion isotope pattern of $W(CO)_5P(C_6H_5)_3$ is a combination of ions from both the hydride addition and the loss of a proton (Figure 1). High resolution measurements of $Cr(CO)_5P(C_6H_5)_3$ after loss of triphenylphosphine ($[Cr(CO)_5]^-$), separated the ions $[^{53}Cr(CO)_5]^-$ from $[^{52}Cr(CO)_5+H]^-$, with R = 30,000. The presence of both these ions is further evidence of the ionization pathways. Electron capture ionization was more prominent for fragment ions that had already undergone neutral loss.

Figure 1 Tungsten Pentacarbonyl Triphenylphosphine

Negative Ion Fast Atom Bombardment

(3). Minard, R.D.; Geoffroy, G.L. paper presented at *the 30th Annual Conference on Mass Spectrometry and Allied Topics*, Honolulu, June 6-11, 1982.

The daughter ion spectrum (Figure 2) of the $[W(CO)_5P(C_6H_5)_3+H]^-$ ion shows ions that have lost a carbonyl neutral but retain the hydride. The constant neutral loss spectrum of $[W(CO)_5P(C_6H_5)_3+H]^-$ (Figure 3) shows ions which have eliminated neutral triphenylphosphine. Each of these ions shows contains a hydride adduct. Because ions that have lost either the triphenylphosphine ligand or all five carbonyls still contain the hydride adduct, this suggests that initial hydride and methide attachment occurs on the metal center. Hydride or methide addition to a six-coordinate complex will most likely result in a seven-coordinate capped octahedral structure, according to LFSE and AO overlap approximations. These experiments highlight the complex nature of FAB ionization, which includes a variety of gas phase ionization mechanisms. The information gathered here will be useful for the further characterization of these compounds as catalytic agents and synthetic intermediates.

VARIATIONS IN ANALYTE/MATRIX ION ABUNDANCES IN HIGH-PRESSURE/ FAST-ATOM BOMBARDMENT MASS SPECTROMETRY

John H. Callahan and Mark M. Ross
Code 6112, Chemistry Division
Naval Research Laboratory
Washington, DC 20375-5000

High-pressure/fast-atom bombardment mass spectrometry (also known as chemical ionization/fast-atom bombardment, CI/FAB [1]) is a technique in which ions and neutrals are sputtered into a relatively high pressure (0.05 to 1.0 Torr) of a buffer/reagent gas. Four types of processes have been shown to occur: collisional stabilization, post-desorption ionization (e.g. proton transfer), charge exchange, and adduct formation [2]. In the studies described here, we have investigated the effect of buffer/reagent gases on relative abundances of analyte and matrix ions.

Two types of ion sources and instruments were used in these studies. A modified chemical ionization source with a 0.050-in hole drilled to admit the fast-atom beam was used with a VG ZAB-2F double-focusing reverse-geometry mass spectrometer. Additionally, a modified chemical ionization ion volume with a 0.025-in hole drilled to admit the fast-atom beam was used with a Finnigan TSQ-70 triple quadrupole mass spectrometer. Source pressures were controlled over a range of 0.05 to 1.0 Torr.

Collisional stabilization was found to affect analyte parent ion/fragment ion abundances in high-pressure/FAB. When methadone was sputtered from glycerol, the ratio for the parent ion (protonated methadone, m/z 310) to the major fragment (loss of dimethylamine, m/z 265) increased as the buffer gas pressure was increased. This apparently results from a decrease in the internal energy of the sputtered ions, which was confirmed by the observation of a five-fold decrease in the $[M+H-45]^+/[M+H]^+$ ratio in mass-analyzed ion kinetic energy spectra (MIKES) of methadone sputtered in 0.1 Torr SF_6. These collisional stabilization effects can be reversed by the application of a sample repeller voltage, probably as a result of increases in the energy of collisions with the buffer gas, essentially producing in-source collision-induced dissociation (CID).

Introduction of a buffer/reagent gas also has significant effects on analyte/matrix ion abundances. For example, figure 1 shows the effect of 0.1 Torr of SF_6 on the mass spectrum of 11 mol% m-nitrobenzylalcohol (mNOBA) sputtered from triethanolamine (TEA). In the absence of a gas, the ratio of $[M+H]^+$ from TEA to that from mNOBA is approximately 1000:1. In the presence of SF_6, the ratio is reduced to 10:1 ($M^{+\cdot}$ is also enhanced). Moreover, significant abundances of $[mNOBA + SF_6]^+$ and $[mNOBA + SF_3]^+$ are observed. When all analyte-containing ions are taken into account, there is a 600-fold enhancement of mNOBA species relative to TEA species.

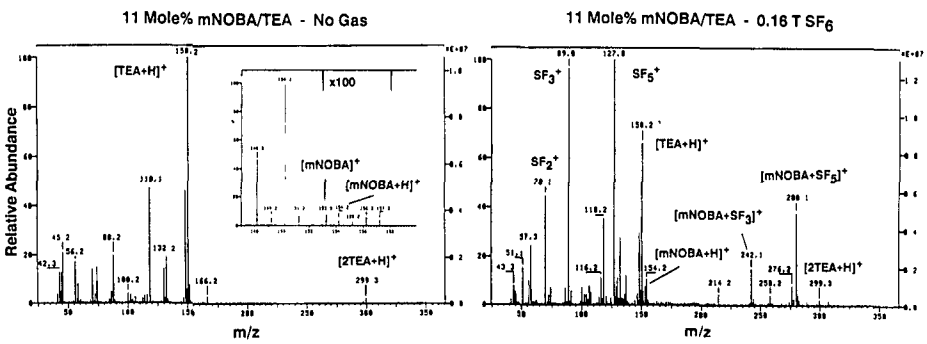

Figure 1. High-pressure/FAB spectra of 11 mol% mNOBA in TEA in the absence and presence of SF_6.

Similar effects have been observed for glycerol (GLY) sputtered from TEA (significant increases in $[GLY + H]^+$ and $[GLY_2 + H]^+$ are observed) and to a lesser extent mNOBA sputtered from glycerol.

Several aspects of the variations of analyte/matrix ion abundances when gases

are present may have implications for models of sputtering processes in FAB. For example, the enhancements in signal intensities due to adduct formation and protonation may result from the significant numbers of neutrals that are sputtered into the gas phase. The results suggest that the neutral/ion ratio in the sputtering process may be on the order of 100:1 - 1000:1. This is similar in magnitude to estimates forwarded by Rollgen and co-workers [3].

A less understood aspect of the sputtering process in high-pressure/FAB is the observation of the enhancement, by non-protonating gases, of protonated species for analytes having gas phase basicities lower than the matrix (e.g. mNOBA in TEA). There are at least two possible explanations for this effect. The first is that $[M+H]^+$ ions that would normally undergo rapid unimolecular decomposition (due to the internal energy obtained from bombardment or from the protonation process) are cooled by collisional stabilization. Alternatively, the buffer gas may affect the kinetics of proton transfer in the selvedge region. For example, if relative analyte/matrix ion abundances are controlled by gas-phase acid-base equilibria (e.g. Kebarle's model [4]) in the selvedge region, then the ion abundances should reflect relative gas-phase basicities. In these experiments, non-protonating buffer gases shift analyte/matrix ion abundance ratios for protonated molecules away from ratios expected based on equilibrium chemistry. This suggests the possibility of kinetic control of ion abundances. In such a model, the initial sputtering event could result in significant numbers of analyte and matrix ions being protonated by fragments and beam damage products. Subsequent collisions between analyte and matrix ions would then begin to establish normally observed equilibria. The presence of a buffer gas could reduce ion and neutral internal and kinetic energies and therefore reduce rate constants for proton transfer. This would in turn prevent establishment of equilibria before the ions were extracted from the source.

In addition to possible implications for models of sputtering mechanisms, high-pressure/FAB may have some important analytical applications. Adduct formation with sputtered neutrals may prove important in structural studies. In one example, low energy CID studies of $[mNOBA + H]^+$ and $[mNOBA + SF_5]^+$ (figure 2) show different fragmentation pathways.

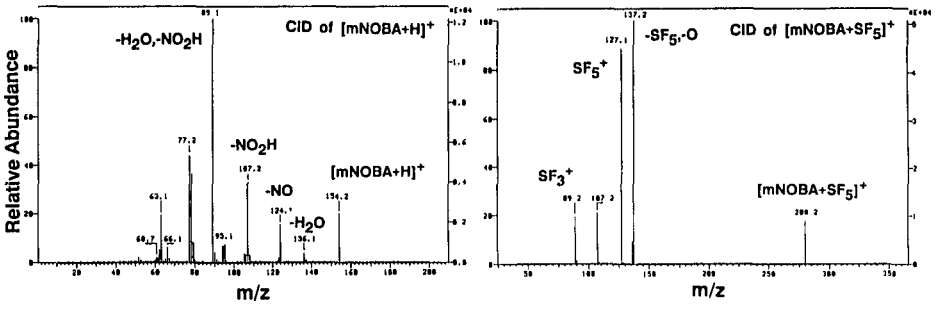

Figure 2. Low-energy CID spectra (10 eV, 1.0 mTorr Ar) of $[M+H]^+$ and $[M+SF_5]^+$ for 11 mol% mNOBA in TEA in the presence of 0.13 Torr SF_6.

The results suggested that while protonation may occur on both the nitro and alcohol groups, adduct formation appears to occur only at the nitro group. High-pressure/FAB may also prove important in improving the sensitivity for sputtered analytes such as peptides, as suggested by the effects noted above. We are currently attempting to gain a better understanding of the structural and thermochemical factors that control such variations in analyte and matrix abundances.

THE INFLUENCE OF SURFACE EXCESS CONCENTRATION IN FAB - MS OF PEPTIDES

G. M Allmaier

Institute for Analytical Chemistry, University of Vienna,
Waehringer Str. 38, A-1090 Vienna, Austria

Over the past several years, FAB-MS has revolutionized the analysis of molecules of biological interest that are highly polar and involatile. For the analysis of peptides and tryptic peptide mixtures at first sight this method turned out to be very straightforward. But soon it became clear that matrix effects as well as suppression phenomena were of considerable importance [1,2,3,4] to obtain optimal results, because the solute is dissolved in a liquid sample support material e.g. glycerol. Therefore the physico-chemical interactions between the liquid matrix, the gas-phase and the peptide must be understood [5,6]. Especially in case of quantification of a single component and in multicomponent analysis, e.g. an unseparated enzymatic digest of a protein, are adsorption as well as competitive adsorption at the glycerol/vacuum interface important factor influencing the mass spectrometric response. The related physico-chemical parameters surface tension, surface excess concentration and critical micelle concentration of peptides in the glycerol matrix are of particular interest [7]

The surface tension of four peptides with a molecular weight range of 200 - 1400 dalton was measured at various concentrations (10^{-4}-10^{-1} moles/L) in glycerol. The model peptides showed sufficient varying hydrophobicity indices (derived from the data of J.M.R. Parker et al. [8], including increments for the free α-amino group at the N-terminus and the free α-carboxyl group at the C-terminus) within the hydrophobic range (see Figure 1.). Then the appropriate Gibbs adsorption equation [9] was used to calculate the surface excess concentration. The different surface activities of the peptides have resulted in surface excess concentrations different from the bulk peptide concentrations (as an example see Figure 2.). The differences between both concentration values were characteristic for each measured peptide, reflecting their different hydrophobicity and solubility in glycerol. The distribution of the sputtered ions has therefore reflected the nature of the glycerol matrix surface that means the three-dimensional order and its chemical composition. The mass spectrometric response of the protonated molecular ion followed the changes in surface peptide concentration. As can be seen in Figure 2., there is a straightforward correlation between the sputtering of protonated molecular ions of hydrophobic as well as hydrophilic peptides and surface excess concentration as a function of bulk peptide concentration. From these results it can be expected that the surface excess concentration of each peptide will be different in glycerol solutions of identical bulk concentration and as a consequence any differences in protonated molecular ion yields will reflect differences in surface activity of the peptides. Minor changes in the primary structure of peptides can induce large changes in surface activity and this also explains the fact besides solubility differences that some peptides exhibit extremely good mass spectrometric response, whereas other very similar peptides are hardly detected at all by FAB-MS.

This finding is in good agreement in terms of the principles of surface chemistry. The treatment is applicable, however, to single peptide/glycerol systems, because of the limitations of the Gibbs adsoprtion equation.

AN INVESTIGATION OF TETRABUTYLAMMONIUM SALTS UNDER +/- FABMS

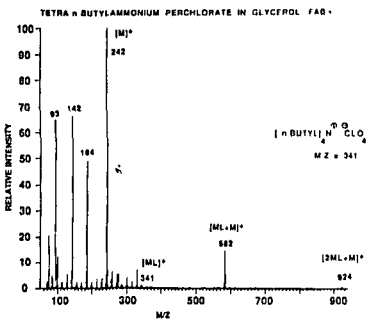
Maya B. Kempff and Robin J. Hood
Central Instrumentation Facility
Chemistry Department
Wayne State University
Detroit, MI 48202

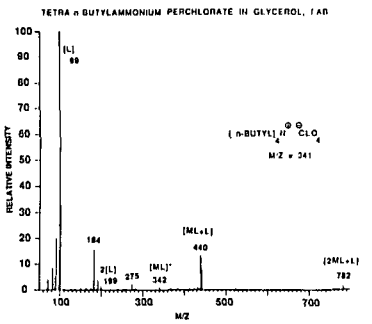
Alkylammonium salts are an important class of surfactants in commercial applications. More recently, they have been found[1] to be useful as liquid phases in gas chromatograph because of their low melting points and chemical stability. Various sulfonates are used as ion pairing agents in ion chromatography. In chemical synthesis, novel anions are often isolated and purified as their tetra-n-butyl ammonium salts. The mass spectral identification of this group of compounds is both interesting and challenging. This study looks at a large number of tetra-n-butyl ammonium salts to determine the best methods of analysis and to establish general rules for the interpretation of their mass spectra.

Despite their low melting points, tetra-n-butyl ammonium salts do not yield molecular ion or fragmentation information under electron impact or chemical ionization because of their lack of volatility. It has been shown[2] that fast atom bombardment mass spectrometry in both the positive ion mode and the negative ion mode are useful for obtaining information on the composition of these compounds. It has also been shown[3] that these compounds can be run successfully without a matrix. In order to better understand the conditions and results for analyzing these compounds, twenty-eight tetra-n-butyl ammonium salts were analyzed under positive and negative FAB MS with and without a glycerol matrix.

The positive ion FAB spectrum of these compounds is dominated by the tetra-n-butyl cation (242) and its fragments due to the loss of butane at mass 184 and the loss of C_3H_6 from this ion to give a peak at 142. Samples deposited directly on the probe from aqueous solution and run after evaporation of the water gave low ion intensities and only cation information. Samples run from a glycerol matrix generally showed some cluster ion of the form $[(ML)_n+M]^+$. These cluster ions were most intense in those compounds with very stable anions. For most of the compounds studied the clusters with n=1 represented one to ten percent of the base peak. This often was not sufficient for positive identification of the compound.

The Negative ion FAB spectrum of these compounds were also obtained under similar conditions. In this case, samples run without a matrix usually gave only weak base peak for the anion. The spectra obtained from glycerol was richer, with the anion as the base peak, strong cluster ion of the form $[(ML)_n+L]^-$ and usually an $[L_2+H]^-$ ion peak. Little fragment information of the anion was observed. CAD spectra using tandem mass spectrometry is necessary[4] to obtain structural information on the anion. The following mass spectra are representative of the data one obtains.





The combination of the positive and negative FAB mass spectra of the alkylammonium salts from a glycerol matrix provide a good method of identification of these compounds.

Molecular Ion Enhancement of Natural Products Using Salts in FAB Matrices

Pradip R. Das, Birendra N. Pramanik and Peter L. Bartner
Research Division, Schering-Plough Corp., Bloomfield, NJ 07003

The use of Fast Atom Bombardment mass spectrometry technique for the characterization of polar, non-volatile molecules has been well established. The use of matrices is an important aspect of FAB mass spectrometry [1,2] and their selection [3] can influence the intensities of the molecular and fragment ions. We have demonstrated significant enhancement of the molecular ions of various natural products with the use of KCl, NaCl or NH_4Cl in the liquid matrix. These include Everninomicin-D (an oligosaccharide antibiotic), Kijanimicin (a macrotetronolid sugar antibiotic), lactoses, phospholipids, macrocyclic and polyether antibiotics. The use of ammonium chloride in mass spectrometry to enhance ionization was originally demonstrated in these laboratories[4,5]. This report describes the use of salts in FAB MS studies.

All studies were carried out on a VG-ZAB-SE double focussing, reverse geometry instrument with a VG 11-250 data system. Xe gas at a source pressure of $2x10^{-6}$ mbar was used to produce fast atoms. Samples were dissolved in DMSO (2-5 μg/μl) to which the salt was added such that sample to salt ratio was approximately 1:4. A thin layer of glycerol/thioglycerol matrix (50:50) was applied on the copper probe tip to which the sample solution was added and thoroughly mixed. The probe was then inserted into the ion source operating at 8 kV.

Our experiences in FAB mass spectrometry have shown that some natural products produce poor mass spectral data. This could be due to the chemical nature of the compound or presence of impurities or both. We have analysed these compounds without and with salt (KCl, NaCl, NH_4Cl) addition and found a remarkable improvement in ionization with salt addition.
The addition of these salts to the FAB matrix containing the sample produced $[M+K]^+$, $[M+Na]^+$ or $[M+NH_4]^+$ ions as the base peak for compounds which otherwise displayed little or no molecular ions in their mass spectra.
Phosphatidylethanol, molecular weight 702 a.m.u., produced <1% relatively abundant molecular ion, $[M+H]^+$, under FAB condition using glycerol/thioglycerol matrix; however, with KCl addition, $[M+K]^+$ was the base peak in the mass spectrum with all characteristic fragment ions present (Figure 1).
Everninomicin-D, an oligosaccharide antibiotic, is non-volatile and difficult to ionize by MS methods[6]. Figure 2 displays the FAB mass spectra without and with NaCl addition to the matrix. $[M+Na]^+$ at m/z 1558 was the base peak whereas $[M+H]^+$ from the non-treated matrix is <20% relatively abundant.
In the analysis of Nigericin, a polyether antibiotic, the usefulness of adding various salts (KCl, NaCl and NH_4Cl) to FAB matrices in determining the molecular weight is illustrated (Figure 3). Initially, a complex spectra, difficult to interpret, was generated. Addition of salts produced very intense ions (all base peaks) which corresponded to the specific cationization of the molecule.

Our results amply demonstrate that for a variety of complex natural products, which are very difficult to ionize by the ususal glycerol/thioglycerol matrix, addition of salts enhance ionization significantly. The formation of the cationized species depends on the nature of the sample, the salt and their relative concentrations and fragmentation of an alkali metal adduct ion is sometimes different from that of a protonated ion. Based on a limited study, there was a tendency of the potassium/sodium adduct ion of some molecules to produce less fragmentation than the corresponding ammoniated ion.

GLUTATHIONE AND NITROCELLULOSE: SOME OBSERVATIONS ON THE DEPENDENCE OF PEAK WIDTHS AND INTENSITIES IN PDMS SPECTRA UPON pH AND pI

L. Silly, R.J Cotter, Johns Hopkins University, Baltimore, MD 21205
C Fenselau, University of Maryland Baltimore County, Catonsville, MD 21228

Plasma desorption mass spectrometry has been used successfully to determine the molecular weights of peptides and small proteins. The recent introduction of two matrices, glutathione (1) and nitrocellulose (2), provide the advantages of improved molecular ion yield, decreased widths of peaks from which isotopically-averaged mass measurements are made and increased relative intensities of peaks from multiply charged ions.

In the present study, we have compared plasma desorption mass spectra of two proteins: bovine milk α-lactalbumin and chicken egg white lysozyme; proteins of similar tertiary structures, approximately the same molecular weights (14,176 and 14,308 amu respectively) but very different isoelectric points (pI=5 and pI=11 respectively). Two experiments are described

- In the first experiment, we have examined the pH dependence of peak width in relation to their isoelectric points. Peptide samples are dissolved in water or in aqueous solutions of glacial acetic acid and ammonium hydroxide at different concentration to achieve a range of pH 1 to 11, then deposited on nitrocellulose foils.
- In the second experiment, the two peptides are "titrated" with glutathione and electrosprayed on the sample foil.

In both cases, the peak widths of singly-, doubly-, triply-charged molecular ions form the major probe for monitoring the formation of ions with low internal and kinetic energy.

In general, for the nitrocellulose matrice, desorption appears to be more facile when solutions of peptides are prepared at pH's close to the isoelectric point. This is translated into spectra with narrow peaks and high intensities (Fig. 1,2). In fact, protein interactions with nitrocellulose are reported to involve mainly hydrophobic interactions (3,4) which are located inside the native proteins (5). This explains why the interactions between nitrocellulose and proteins will be weakest near the isoelectric point where the protein is in a native state. However at acidic pH, broader peak widths observed are due to the unfolded proteins. For these two proteins, the isoelectric point can be correlated with biological activity and stable conformation (6,7,8).

A similar observation has been made when peptides are prepared in a solution containing glutathione. The peak widths are plotted as a function of added glutathione (Fig. 3,4) and reach a minimum at a molar ratio of [30:1] for the lysozyme and of [20:1] for the lactalbumin The reduced form of glutathione has been reported to promote the refolding of peptide (9) and this suggests a relation between protein folding and binding to the sample foil.

In conclusion:

- There is a thereshold of glutathione necessary to get a good spectrum.
- The narrow peak widths are located close to the isoelectric point of proteins.
- Spectra obtained seem sensitive to the conformational structure.
- Molecular ion measurements by PDMS may become an important tool for following conformational changes in peptides.

COMPARISON OF FAB AND Cf-252-PD MASS SPECTROMETRY FOR THE ANALYSIS OF POLAR PESTICIDE METABOLITES

G.M.Allmaier*, E.R.Schmid and P.Roepstorff+

Institute for Analytical Chemistry, University of Vienna, Waehringer Str. 38, A-1090 Vienna, Austria
+Institute for Molecular Biology, University of Odense, Campusvej 55, DK-5230 Odense, Denmark

Highly polar, water-soluble compounds are major metabolites of pesticides in various ecological systems. They are present only in low concentrations either as free acids, glycosides or mainly as alkali salts. After isolation of these polar metabolites from biological matrices (apple peels, Beta vulgaris leaves or soil) and various purification steps as solid phase extraction, TLC, reversed phase HPLC they were characterized by mass spectrometry. Until recently FD or CI mass spectrometry has been used mainly for the analysis of these metabolites, but both techniques showed severe limitations. FAB [1,2] and Cf-252-PD [3] mass spectrometry have been evaluated for the characterization of five polar metabolites of organophosphorus pesticides (Figure 1).

FAB mass spectra in the positive and negative ion mode were obtained with glycerol, triethanolamine and m-nitrobenzyl alcohol as matrix. Quasi molecular ions - $[MH]^+$, $[M-H]^-$ as well as $[MNa]^+$ and $[M-Na]^-$ - were found as dominating ions (see as an example Figure 2). In the negative ion mode the metabolites, which were preformed ions, could be detected in the ng-range. On the other hand the detection limits in the positive mode were in the µg-range. The problem of sample purification prior to MS analysis was critical especially in FAB-MS, because of suppression phenomena in the FAB matrices induced by biological matrix components. The best result for isolated metabolites in terms of S/N-ratio were obtained with m-nitrobenzyl alcohol as FAB matrix.

Positive and negative ion PD mass spectra were recorded from different sample backings. The metabolites were deposited by electrospraying on top of aluminium backing as well as by spin drying on nitrocellulose (NC) backing (with and without rinsing). The positive PD mass spectra were dominated by the cationized molecular ions on both backing materials in contrast to FAB-MS. Cluster ions as $[2MNa]^+$ or $[3MNa]^+$ can be seen with significant intensity (Figure 3). After sample adsorption on NC and subsequent rinsing all sample related ions disappeared except in case of the glycoside (III). The negative PD mass spectra exhibited as dominating ions $[M-Na]^-$. For III the PD technique failed to give an useful negative spectrum. The overall detection limit in the positive as well as negative ion mode was in the µg-range. In contrast to FAB-MS were the negative ion mode was significant more sensitive.

PD- as well as FAB-MS showed no characteristic structural fragments. In summary, both ionization techniques have great potential for the fast identification of highly polar metabolites, especially FAB-MS in the negative ion mode because of the good sensitivity.

ENHANCED PERFORMANCE OF A VOLCANO-FI SOURCE IN PULSED MODE

Steve Young and Michael J. Coggiola
SRI International, Menlo Park, CA 94025

A new mode of operation is described for the volcano-style field ionization source developed at SRI. Normally, gas molecules are ionized continuously in the intense electric field produced between the 25 μm diameter volcano throat and the concentric 100 μm diameter counter electrode. When used with a quadrupole mass spectrometer, the source is typically operated in a cw mode with the volcano biased at +15 volts and the counter electrode and ion extraction elements maintained at -1.2 to -1.5 kV. In the present experiments, the source was operated in a pulsed mode by reducing the bias on the counter electrode to -800 volts (below the threshold for efficient FI), and then pulsing it to -1.8 kV. The pulse width could be varied between 1 and 10 μs with the repetition rate variable between 100 Hz and 2 kHz. Mass analysis was performed either by scanning the quadrupole in the normal fashion, or by operating the mass filter in the RF-only mode, and using TOF methods in conjunction with a microchannel plate detector.

In addition to mass analysis of the ions produced by the volcano-FI source in pulsed mode, a number of other characteristics were determined. The relative ionization efficiency in pulsed mode as compared with the cw mode was assessed by alternately measuring the ion signal (using pulse counting) with a dc potential and the pulsed voltage, and correcting the latter for the duty cycle of the driving voltage. Both measurements were made with the quadrupole tuned to pass only a single ion species, typically the molecular ion of the gas sample. The temporal evolution of the field ionization signal was measured by accumulating ion counts as a function of time following the pulse using a multichannel analyzer. The MCA was gated on at the end of the counter electrode pulse, and acquired counts in 10 μs time intervals for the full 2 ms duration of the voltage pulse.

Although the absolute signal levels produced in the pulsed mode were less than the cw mode, when the signal levels were corrected for the duty factor of the counter electrode pulsing, the effective ion currents were found to increase in most cases by as much as an order of magnitude. Moreover, as the time between pulses was decreased (higher repetition rate for fixed pulse width of 10 μs), this signal enhancement also decreased, falling smoothly toward the dc level. Interestingly, the pulsed mode of operation also produced significant ion currents of many species not normally observed in the cw mode. For example, a number of water-containing molecular ions were readily observed including, H_3O^+, $H_2O{\cdot}H_3O^+$, and $(H_2O)_2^+$. The former two ions showed the same ionization enhancement observed for the organic compounds, while the latter ion was unique in that the effective signal level dropped as the time between pulses was increased. Under typical cw conditions, none of these molecular ions is observable, except at the highest counter electrode voltages.

Typical results of the signal enhancement measured in the pulsed mode are shown in Figure 1 for benzene, n-propylbenzene, and pyridine. For these three compounds, the degree of ionization enhancement varies between 2 and 25 as the time between 10 μs wide pulses increases from 0 to 10 ms. Other organic compounds investigated showed qualitatively similar behavior. Based on the apparent enhancement of ionization efficiency in the pulsed mode, it is reasonable to assume that as the time between pulses is increased, additional neutral sample molecules become adsorbed onto the active ionization sites of the volcano source. During the "on" period of the counter electrode pulse, these neutrals are desorbed either directly as ions, or as neutrals that are rapidly ionized in the strong local fields. In addition, because the rate of change of the local electric field with time is very fast (> 10^{12} V/cm/sec), it may be possible to ionize

species that would otherwise not undergo efficient FI. It is also possible that because of the long residence time of the neutrals on the active emitter sites, surface mediated reactions may occur, leading to species such as $H_2O{\cdot}H_3O^+$, and $(H_2O)_2^+$.

This simple picture of the pulsed volcano FI source would predict that the ion signal as a function of time should show an initial rapid rise as the local electric field is established in the vicinity of the field ionization sites, and the supply of adsorbed neutrals is the greatest. As the sample supply becomes depleted due to field ionization/desorption, the signal level would be expected to decay . Using the MCA as described above, the parent ion signal of pyridine (m/z 79) was measured as a function of time for a 2 ms wide ionization pulse at 10 Hz repetition rate. The arrival time spectrum is shown in Figure 2. As expected, the measured ion signal was sharply peaked at the beginning of the pulse, decaying rapidly toward the nominal dc level. This type of behavior was observed for a number of other compounds as well.

In addition to the operational characteristics described above, the relative signal enhancement factor was also found to vary with the pulse width in an unexpected manner. If the time between pulses was fixed at 2 ms, and the pulse duration was varied, the ion signal exhibited the anticipated enhancement for pulse widths greater than 4 μs. For pulse widths of less than 4 μs, the signal enhancement dropped rapidly, so that for pulse durations of 3 μs or less, the effective signal level actually fell below the cw level. This characteristic minimum width of 4 μs was found to be independent of the dc bias level applied to the volcano prior to pulsing, and does not appear to be related to the rate at which the local electric field is established. At present, the origin of this behavior is not known.

Using acetone, mass spectra were recorded in both the cw and pulsed mode for comparison with the previously reported pulsed FI results of Rollgen and Beckey [Surface Science, 23 69 (1970)]. The normal cw spectra produced using the volcano source consisted primarily of the M^+ and $(M+1)^+$ ions in a ratio of 10:1, similar to the results of Rollgen and Beckey. In the pulsed mode, this ratio was found to be approximately 1:1. The previous work also showed this ratio to change in the favor of the $(M+1)^+$ ion in accordance with the proposed mechanism of field induced proton transfer from a physically adsorbed layer of acetone molecules.

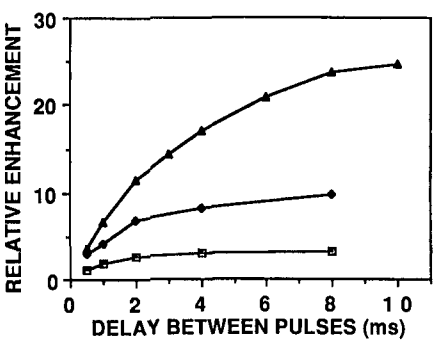

Figure 1. Variation of the ionization efficiency for benzene (—◆—), n-propyl benzene(—▲—), and pyridine (—■—) as a function of the time between 10 μs pulses.

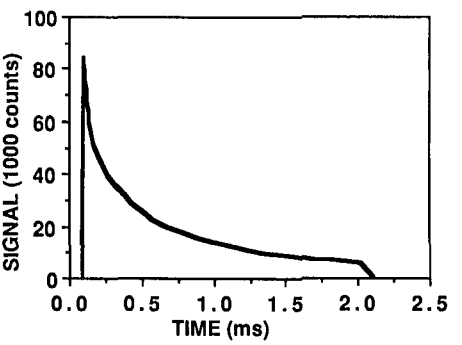

Figure 2. Temporal behavior of the parent ion (m/z 79) from pyridine ionization in the pulsed volcano-FI mode. The pulse duration was 2 ms, and the time between pulses 100 ms.

AN EHD SOURCE FOR THE MASS SPECTRAL ANALYSIS OF PEPTIDES

Terry D. Lee and Kassu Legesse
Beckman Research Institute of the City of Hope
Duarte, CA 91010

John F. Mahoney and Julius Perel
Phrasor Scientific, Inc.
Duarte, CA 91010

Electrohydrodynamic (EHD) emission is a technique in which gas phase ions are generated from a solution by a strong electrical field. As a gentle ionization process that rarely causes fragmentation, it holds great promise for the molecular weight determination of large biomolecules. The ultimate goal of the project is to develop an ion source capable of producing molecular ions for proteins and other macromolecules which are difficult or impossible to analyze by particle desorption methods. Efforts thus far have been concentrated on understanding the mechanism of ion formation, particularly from volatile solvent solutions.

Previous source designs have suffered from a number of problems including unstable emission, sample amount requirements which greatly exceeded reasonable levels for precious compounds, and cumbersome operation which hindered research efforts. A new source (Fig. 1) has been constructed that largely overcomes these limitations. Sample solutions are transported directly from sample vessels at atmospheric pressure to the end of the emitter needle using a 155 μm fused silica tube with an internal diameter of 50 μm. With a length of 30-40 cm, flow is sufficiently restricted that even with 100% methanol, pressure within the ion source housing of a JEOL HX100HF mass spectrometer is $<5\times10^{-5}$ Torr. Total volume of the feed tube is <1μℓ. The use of a continuous glass surface has largely eliminated bubbles that often form when fluid under vacuum encounters junctions and metal surfaces.

Stable emission from the source has been demonstrated for a number of ammonium acetate solutions with different methanol:water ratios. As water content approaches 75%, emission instability is observed that is likely due to ice formation caused by evaporative cooling. At the other extreme, methanol concentrations approaching 90% result in unstable emission, perhaps due to precipitation of the ammonium acetate.

The EHD emitter needle is constructed from a 1.6 mm stainless steel tube with a 175 μm hole through which the fused silica tube is inserted. Two modes of emission have been observed, depending on the location of emission sites relative to the end of the fused silica capillary. With the capillary flush with the end of the stainless steel nozzle (Fig. 2a), emission is from sites on the stainless steel nozzle somewhat remote from the capillary opening. The spectrum of a 1 M ammonium acetate solution (Fig. 3a) is dominated by acetic acid clusters, the more volatile methanol and water having largely evaporated. With the fused silica protruding ~50 μm beyond the nozzle (Fig. 2b), emission is directly from the rim of the capillary and the spectrum is dominated by water clusters (Fig. 3b).

Metastable spectra for small peptides can be obtained from 0-50% energy loss provided sufficient sample is used (>10 mg/ml). Only protonated and doubly protonated species have been observed with no fragmentation. At these sample levels, operation of the ion source is compromised by sample deposits on the tip. At lower sample levels (<1 mg/ml) source operation is stable for hours but molecular ions are often lost in the spectral background. Sample molecular ions are most prominent under conditions approaching "full energy" spectra.

RECENT DEVELOPMENTS IN ELECTROCHEMICALLY ASSISTED FAST ATOM BOMBARDMENT

John E. Bartmess, Department of Chemistry, University of Tennessee, Knoxville TN 37996-1600, and Larry Phillips, Office of Biologics Research and Review, Food and Drug Administration, Bethesda MD 20892.

Electrolysis directly in a thin glycerol drop inside the MS source creates ions, from species which are not ionic to start with, and are normally poorly responsive to FAB MS. We have placed a cage of wires over the top of the "cell", to reduce source detuning effects due to varying the internal disk electrode by up to ±12 V; the outer ring electrode and cage float at the source voltage. The ions sampled are mostly due to processes at the ring electrode, nearest the surface of the matrix.

Since FAB is a surface phenomenon, and ionic surfactants are among the most sensitive compounds to conventional FAB, we have examined <u>non-ionic surfactants</u> for their response to EFAB. Vitamin K1 is chosen as a typical case, due to its long phytyl tail and easily reduced quinone head. As models for the reducible head group, 1,4-benzoquinone (BQ) and 2-methyl-1,4-naphthoquinone (MeNQ) yield negative ion FAB mass spectra whereas 9,10-anthraquinone (AQ) and vitamin K_1 do not. The negative FAB mass spectra of BQ and MeNQ show abundant M^- but with substantial "chemical noise" throughout each spectrum. Reduction processes, giving $(M+H)^-$ corresponding to p-hydroxyphenoxides, also occur. No $(M+2H)^-$ ions are observed; these are not expected to be bound anions. Ions due to simple fragmentations are not observed in either case.

Under EFAB conditions in glycerol, reducing at the ring electrode, BQ and MeNQ still show abundant M^- ions, but with less $(M+H)^-$ and significantly less "chemical noise" in the mass spectrum. In fact, M^- increases considerably, while $(M+H)^-$ and chemical noise remain nearly constant. Ions due to simple fragmentations are not observed in either case. 9,10-Anthraquinone remains resistant to analysis under EFAB conditions.

Vitamin K_1 in glycerol gives only ions due to the matrix in normal negative FAB. Under reducing EFAB conditions, the matrix ions are almost completely suppressed; the predominant ions are m/z 450 (M^-) and m/z 185, from cleavage of the phytyl tail at the benzylic site. Oxidizing EFAB conditions gives more low weight (m/z <100) ions. At V_e = -7.2 V, the intensity of the $[2G-H]^-$ ion at m/z 183 is comparable to that of the m/z 185 fragment. For V_e <-7.2 V, m/z 185 increases in intensity, but not m/z 183.

There is a mass spectral response time to changes in the EFAB voltage. For BQ, both rise and fall of M^- intensity, on application and removal of the reducing potential, has a half-life of ca. 20 sec. The process appears to be reversible over many cycles. For Vitamin K_1, however, the response time is on the order of minutes, presumably due to its reduced diffusion rate. With K_1 in glycerol on a conventional FAB probe, a 9 V battery was connected to two wires, then the wires were placed in either side of the FAB droplet on the probe for a few seconds. Insertion of the FAB probe into the instrument immediately, followed by signal acquisition, resulted in a spectrum typical of the EFAB ones, decaying to a glycerol-like spectrum over several minutes.

We have noticed gradual changes in the electrochemical current drawn by the EFAB probe as pure glycerol ages in the vacuum system. We observe an increase in the conductivity of the glycerol at V_e=-2 V as the probe is warmed in an oven. After FAB bombardment, a similar increase with temperature is observed but at about half the conductivity pre-bombardment. This difference appears to be due to surface aging; if the glycerol drop is stirred after bombardment, and then warmed again, data very close to the pre-bombardment values are obtained. The time response of the current when the probe is bombarded indicates about 1 minute of apparent <u>cooling</u> occurs before the current levels off. After this, a small long-term rise occurs over 10-15 minutes. The change amounts to less than 1°C increase in glycerol temperature.

OPTIMIZING THE IR-LASER DESORPTION OF NEUTRAL MOLECULES.

R. C. Beavis, J. Lindner, J. Grotemeyer and E. W. Schlag

Institut für Physikalische und Theoretische Chemie, TU München
Lichtenbergstr. 4, D-8046 Garching, Germany.

In order to use Infra-Red (IR) laser desorption of intact neutral molecules (LEIM) coupled with multiphoton ionization (MUPI) as an analytical technique, it is necessary to develop a standard, reliable method of preparing thermolabile organic samples for desorption. Simply applying a powdered sample to a probe will produce a spectrum, but only from relatively large amounts of sample. The goal of the research described here was to understand the parameters that affect IR desorption and with this knowledge, develop an "optimized" sample preparation technique.

The approach taken to examine these parameters was to modify the physical properties of the sample by the addition of a "matrix" substance. For the IR laser used (10.6 μm, CO_2 multimode, 25 μs pulse width and about 10^4 W/cm^2), most organic compounds are relatively transparent. Therefore, the first experiments were done to determine the effect of adding an IR absorbing material to the sample. The absorbers used were inorganic salts (e.g. $Na_{3-x}H_xPO_3$, x=0-2) and some organic materials (e.g. ribose). The results demonstrated that adding IR absorbing materials decreases the yield of neutral molecules and completely extinguishes the yield at high concentration. This effect is probably caused by the high temperatures produced at the surface of an absorber.

The opposite was found for IR transparent materials. Inorganic transparent matrices (e.g. KBr, NH_4NO_3) were found to increase the total yield of neutral molecules by up to 100x. Also the stability of the signal was increased, i.e. the IR laser could shoot on one spot of the sample (about 10 μm thick) for many more shots before the yield per shot decreased. For a dipeptide, the increase in the number of shots possible on one spot was approximately 50x. The increase in yield and sample stability can be explained by the increased mechanical stability of the sample when bound to the surface by a transparent matrix. Rapid heating of powdered samples leads to rapid expansion and expulsion of large diameter (about 1 μm) particles of intact sample. This loss of sample by purely mechanical removal is minimized by binding the sample to the probe with a matrix that is unaffected by the IR laser.

The results using IR transparent inorganic matrices led to using organic IR transparent materials, specifically polyethylene, which has a transmission window in the 940 cm^{-1} region. Polyethylene powder can be pressed into thin, strong sheets by applying a moderate pressure (100 MPa). Mixing the sample of interest with the polyethylene powder and pressing the mixture produced uniform small sheets that were stable under IR desorption conditions. The addition of small amounts of metal powder (1 μm diameter Au or Ag) to these sheets increased the yield and reliability of these sheets. Very thermolabile organo-metallic compounds that produced no intact molecules by IR desorption from powders produced strong signals from these polyethylene sheets. Also, a sheet pressed from polyethylene and metal powder could be used as a desorption substrate, i.e. a small amount of sample could be applied to the sheet from solution. This technique made it possible to decrease the amount of sample necessary to produce a good mass spectrum to 1 ug of total sample applied to the probe.

The improvement in total yield and reliability of samples prepared using powder empregnated polyethylene sheets can be explained using a "mechanical" model of the desorption mechanism. Current ideas on fast particle and UV desorption of ions from surfaces point towards the strong mechanical disruption of a surface, by either a shock wave [1] or a phase explosion [2]. Such an idea can also be applied to low power IR desorption of neutrals and particularly to the case of polyethylene/metal powder sheets with a very thin sample overlayer. Without the metal powder, the yield of neutrals from the surface is very low. When the metal powder is added, the individual metal particles heat very rapidly in the IR laser focus because of currents induced by the laser electric field. The particles become incandecent and cause rapid local expan-

sion of both the polyethylene host matrix and nearby soluted gas in the sheet. This expansion leads to a miniature explosion that expells the hot metal particle from the sheet. These glowing particles can be seen as a plume leaving the sheet during IR irradiation. The explosion disrupts the surface and expells part of the surface layer into the gas phase. Therefore, the IR energy is being absorbed a site remote from the sample molecules of interest. During the desorption process for such a composite material, the molecules only recieve translational energy from the shock of the explosion and not directly from the laser. Producing desorption in such an indirect manner means that changes in the physical properties of the sample molecules are of decreased importance because the desorption mechanism is largely independant of the sample molecule involved. This method of producing gas phase molecules is particularly applicable to the use of MUPI, because the matrix has been chosen so as not to appear in the mass spectrum, i.e. the MUPI process is such that polyethylene produces no interference peaks.

Resonance Enhanced Multiphoton Ionization of Nucleosides and Oligonucleotides

David M. Lubman and Liang Li
Department of Chemistry
The University of Michigan
Ann Arbor, MI 48109-1055

The study of nucleosides has presented a great challenge to mass spectrometry due to the polarity and thermal lability of these molecules. In this work we use a pulsed laser desorption/volatilization technique as a means of vaporizing neutral nucleosides (1,2). The resulting plume is then entrained in a pulsed supersonic jet expansion of Ar or CO_2 and swept into a TOFMS for detection by resonance enhanced multiphoton ionization (REMPI). This method allows the separation of the vaporization from the desorption step so that REMPI of neutrals can be performed. The REMPI method has several distinct advantages including: (a) an efficient means of softly ionizing molecules to produce $M^{+\cdot}$; (b) a means of producing controllable fragmentation based upon either laser intensity or frequency; and (c) a wavelength selective means of ionization in combination with the supersonic jet technique (2).

The experimental apparatus consists of a standard supersonic beam/time-of-flight mass spectrometer (1). The desorption is produced using a pulsed CO_2 laser (7×10^6 W/cm^2) which impinges upon a Macor™ probe surface. Typically ~ 10-100 ug of the nucleoside is placed on the surface or may be dissolved in a glycerol matrix which provides a more even pulse-to-pulse desorption stability. The desorbed material is entrained in a jet of CO_2 as shown in Figure 1 and carried into a linear TOFMS. Laser induced REMPI is then produced using the 4th harmonic of a Nd:YAG laser (266 nm) and the ions detected in the mass spectrometer.

The laser desorption/laser REMPI method was used to study adenosine, guanosine and cytosine as well as their various modified nucleosides as shown in Table I for the adenosine analogs. These results were obtained at λ = 266 nm and a $P = 8 \times 10^6$ W/cm^2. The salient feature of the mass spectra observed under these conditions is an intense molecular ion peak without the presence of cationization. In addition, there is generally one principal fragment observed due to bond cleavage at the sugar moiety. This fragment denoted BH^+ corresponds to an ion formed from the base portion of the nucleoside with transfer of one hydrogen atom from the sugar moiety. This process is also observed in EI mass spectra of these compounds. The molecular ion peak, along with the characteristic BH^+ peak, can be used to distinguish between ribose and deoxyribose sugars in the nucleoside.

In addition, two characteristic fragments due to cleavage of the sugar moiety are observed which are denoted as S_1 and S_2 respectively as shown in Figure 2. These fragment ions are particularly useful for structural analysis and easily allow the ability to pinpoint whether there is modification on the 2'-oxygen of a nucleoside. As Table 1 indicates, the mass spectrum of 2'-deoxyadenosine shows a strong molecular ion peak m/z 251 and a fragment BH^+, m/z 135. The mass difference between $M^{+\cdot}$ and BH^+ suggests that it is a deoxyribose. Two fragments, m/z 162 and m/z 164, corresponding to S_1 and S_2 notation, respectively, can be used to locate the deoxy position, i.e. the 2'-position in this case. Or for example, in 3'-o-methyladenosine, S_1 and S_2 fragments indicate that there is no methyl substitution on the 2'-oxygen. Consequently, the methyl group must be in either the 3'-oxygen or 5'-oxygen. The formation of S_1 and S_2 in REMPI appears to be similar to EI in which an intramolecular rearrangement of the H from the sugar to the base occurs during fragmentation. These S_1 and S_2 fragments are easy to detect using REMPI as opposed to FAB where their presence may be obscured due to matrix background. In these experiments the glycerol matrix is transparent to the UV laser light and is not observed in the TOFMS.

Analysis of Organic Solids by Combined Stimulated Desorption and Single-Photon Ionization

J. B. Pallix, U. Schühle and C. H. Becker
Chemical Physics Laboratory
SRI International
Menlo Park, California 94025

Secondary ion mass spectroscopy (SIMS) has long been recognized as a highly sensitive surface analytical tool. SIMS spectra from the surfaces of bulk polymers generally contain useful ion peaks but strong structurally important peaks such as the monomer are frequently lacking. Observation of monomer peaks of significant intensity is extremely useful for easy and unambiguous interpretation of mass spectra especially in investigations of unknown materials. Also for SIMS, both positive and negative spectra are sometimes required for successful analyses, and the desorption is limited to sputtering. An obvious solution to these problems is to detect secondary neutrals because neutral species comprise more than 90% of the material removed from a surface by ion beam sputtering, electron beam desorption or laser desorption. This way the various desorption processes can be studied or chosen from.

A technique recently developed at SRI called surface analysis by laser ionization (SALI), has successfully provided both high sensitivity and reliable quantitation in analyses of a wide variety of inorganic materials [1]. With this method neutral species removed from surfaces by the various desorption methods are typically ionized by an intense untuned uv laser and the photoions are then analyzed by reflecting time-of-flight mass spectrometry. A high power excimer laser is typically used which permits nonselective ionization of all two-photon ionizable neutral species within the laser focal volume, greatly reducing matrix effects.

The use of a high power untuned uv laser is essential to obtain the desired sensitivity and quantitation attainable for inorganic samples. However, when using nonresonant multiphoton ionization (MPI) for studies of surfaces of organic materials (which required high sensitivity) excessive fragmentation can occur resulting in mass spectra containing only small fragments giving no useful information. An experimentally simple alternative to MPI is to use vacuum uv wavelengths for single-photon ionization with photon energies not far above the molecular ionization potential. A number of bulk organic polymers and biochemicals have been studied by this method resulting in fragment mass spectra which are highly characteristic of the parent molecular structure [2-3].

The spectra to be presented are obtained using coherent 118 nm (10.5 eV) radiation for ionization of desorbed neutrals. The VUV photons were generated by tripling the third harmonic from a 10 Hz Nd:YAG laser (355 nm) in a Xe tripling cell. The frequency conversion process is enhanced by phase matching with a Xe/Ar gas mixture.

Some fragmentation may still be observed with the single photon ionization method although this is significantly less than when using MPI. This is due largely to the ion bombardment process rather than the ionization step. Less fragmentation has been observed when using electron stimulated desorption (ESD). SALI spectra of a sample containing a blend of poly(isopropene) (PI rubber), and poly(phenylcarbonate) (PPC) obtained by single-photon ionization following ion beam sputtering and ESD are shown in Figures 2a and b, respectively. A large reduction in fragmentation is seen by comparison of the ion beam

sputtering and ESD spectra which shows that the latter results in greater signal in the higher mass region. Note, for example, the dramatic change in intensity of the CH_3 peak at 15 amu. This lower fragmentation desorption process when combined with single-photon post-ionization is clearly valuable for studies of organic materials. Using the relatively soft VUV photoionization provides insight into the nature of bond-breaking for different desorption processes.

The peak at largest mass in the ion beam sputtering mass spectrum of the polymer blend sample (Figure 1a) is that of the PPC monomer at 254 amu. While this and other high mass peaks are weak relative to the low mass fragments they are still quite useful for determining molecular structure. A more extensive analysis was easier using ESD (Figure 1b). The peaks at high mass in the spectrum correspond to the PPC monomer (±2 hydrogen atoms) at 252 and 256 amu and the PPC monomer + CO + 2 hydrogen atoms at 284 amu. Two progressions are observed (labeled with solid circles) which correspond to the addition of $(CH_n + (CH_2)_m)$ fragments to CO_2 and CO_3. The series of peaks labeled with arrows beginning at m/z = 77 correspond to fragments containing phenyl. The progression represented by ▼ is that originating from the PI polymer (protonated monomer observed at 69 amu) showing the loss or addition of CH_2.

INITIAL KINETIC ENERGY OF LARGE MOLECULES DESORBED BY Cf-252 FISSION FRAGMENTS

D. L. Jacobs and R. D. Macfarlane, Department of Chemistry
Texas A&M University, College Station, Texas 77843

A time-of-flight mass spectrum contains information relating to the initial kinetic energy that an ion receives in the desorption process. Every ion peak is shifted to slightly lower TOF due to this initial energy. If the TOF spectrum is obtained at a very low acceleration voltage, the resulting TOF distribution for each ion peak is dominated by the initial kinetic energy, which can then be calculated for each peak in the spectrum. For this TOF distribution to be usable, it must be well resolved from peaks in the spectrum due to other ions of similar mass and the detection efficiency must be great enough to produce a peak for the ion of interest. These two requirements limit the practical application to small mass ions, i.e. < 500 amu, even though the use of Cf-252 fission fragments is primarily used for the desorption of very large molecules.

However, it is possible to indirectly calculate the initial kinetic energy of ions with a mass > 500 amu. The normal method used to calibrate a TOF spectrum is to take two or more peaks in the spectrum with accurately known masses and use them to generate a calibration curve of TOF vs. $m^{1/2}$ using the method of least squares. This does have the flaw of assuming that all of the ions have the same kinetic energy. An attempt was made to improve the calibration curve for a peptide sample by correcting for the initial kinetic energy. The initial energy for a series of calibration ions (Fig. 1) from the same target as the peptide is measured directly at low acceleration voltages (+800 V). The same target is then run at an acceleration voltage (+17 kV) that is sufficiently high enough to give a strong peak and good TOF value for the molecule of interest (Fig. 2). The initial KE values for the calibration ions are then used to calculate the TOF shift expected due to the initial energy for these ions at high voltage. The TOF values corresponding to E=0 are then used to generate a new calibration curve for any ion in the spectrum with E=0 as shown in table 1. This new calibration curve is then used to a TOF for the molecule of interest at E=0. The difference between this calculated TOF and the experimental TOF should be due solely to the initial kinetic energy of the molecule. This change in TOF can be used to calculate a KE value for the molecule as shown in table 2.

Two peptides, bradykinin (1060.23 amu) and bovine insulin (5733.61 amu), have been examined. These two peptides have been adsorbed onto nitrocellulose. The effect of the conductivity of the substrate has been examined by sputter coating the targets with Au. The results are summarized in table 3.

All of the calculations for the initial kinetic energy were made using absolute tiem-of-flight. A schematic of the the mass spectrometer used is shown in Fig. 3 and the fixed mass spectrometer parameters are shown in table 4. The TOF equation that describes the flight path is shown below.

$$TOF = K\sqrt{\frac{m}{|q|}}\,\frac{a_1\left(\sqrt{|E_0| + sign(q)(U_0 - U_1)} - \sqrt{|E_0|}\right)}{sign(q)(U_0 - U_1)} + K\sqrt{\frac{m}{|q|}}\,\frac{d}{2\sqrt{|E_0| + sign(q)(U_0 - U_1)}} + K\sqrt{\frac{m}{|q|}}\,\frac{a_3\left(\sqrt{|E_0| + sign(q)(U_0 - U_4)} - \sqrt{|E_0| + sign(q)(U_0 - U_3)}\right)}{sign(q)(U_3 - U_4)}$$

The schematic shows that the stop detector is on a movable mount that allows the length of the field free region to be varied. By measuring the TOF of various calibration ions at two different lengths of the field free region, it is possible to reduce the TOF equation to a form that allows calculation of the effective acceleration voltage at the target face, no matter what the magnitude is. This is shown below.

$$U_0 = \left(\frac{1}{2}K\sqrt{\frac{m}{|q|}}\,\frac{\Delta x}{\Delta t}\right)^2$$

Parent Mass Information From Sequences of Peaks of Multiply Charged Ions

Matthias Mann, Chin Kai Meng and John B. Fenn

Department of Chemical Engineering
Yale University, New Haven, CT 06520-2159

As reported in our companion paper Electrospray (ES) ionization can produce intact ions from large biomolecules in solution and deliver them to a mass analyzer in vacuo. Moreover, these ions are characterized by a high degree of multiple charging so their spectra can be obtained with a quadrupole analyzer whose nominal upper limit for m/z is 1500. Such spectra comprise a series of peaks each of which differs from its neighbor by a single unit charge (see fig. 1). We report here on two different algorithms that we have developed and incorporated into our data acquisition program in order to recover as much information as possible from these spectra.

Algorithm I. For any value of parent mass M the measured peak location (m/z values) A_i and the corresponding number of charges n_i must satisfy: $A_i / A_k = n_k / n_i$. If A_i and A_k are adjacent (i.e. $n_k = n_i + 1$) we immediately obtain for the number of charges: $n_i = A_k / (A_i - A_k)$. From this expression we can assign preliminary values of n_i to each peak and then plot A_k / A_i versus n_i . Any systematic deviation from the correct value given by the first relation indicates a "bad" peak due to background noise or another species or to an incorrectly assigned value of n_i . Figure 2 shows such a plot for the spectrum of myoglobin (fig. 1). With this procedure we can quickly and unambiguously determine the number of charges corresponding to each peak and whether a given peak belongs in the series. The individual peak locations can then be used to determine the parent mass M by means of: $M=(1/n)\,(\Sigma_i A_i * n_i)$. It follows that this procedure reduces the uncertainty in M by a factor $\sqrt{n}$. For example, in the hypothetical case of M= 30kD, n=9 and individual peak errors of 0.1D at m/z=1000, the error would be 10D or 0.03%. It should be pointed out, however, that, because of the limited resolution of the quadrupole we used,we can not yet be certain that we are observing purely protonated peaks.

Algorithm II. We make use of the fact that the function

$$F(M^*) = \sum_i f\left(\frac{M^*}{i}\right) \quad i \in N$$

where f is the measured spectrum, has a maximum at $M^* = M$. At that point all the contributions from measured peaks in the sequence are summed up to produce a quasi molecular mass peak. At ideal resolution, the "deconvoluted" spectrum would have small "side peaks" close to M and oscillate with a period of M/2. With finite resolution these side peaks become enhanced and a non-zero background induces a slope into F because the measured spectrum is sampled more often at higher M^* . As long as the shapes of the peaks in the series are similar (i.e. the same shape and same full width at half maximum (FWHM)), the transformed "molecular peak" can be shown to retain this shape.

Figure 3 and 4 show the transformed myoglobin spectrum (fig.1). The FWHM of 1.6% is about what would be expected on the basis of the FWHM of the measured multiplet peaks (1.7%). The value of the algorithm is particularly apparent in figure 6 where it easily resolves two components (myoglogin and cytochrome C) of a mixture which are not easily separated in the original spectrum (fig.5).

SPUTTERING YIELDS FROM GLYCEROL BOMBARDED WITH IONS FROM A FOCUSED LIQUID METAL ION COLUMN

L.F. Jiang, E. Barofsky, and D.F. Barofsky
Department of Agricultural Chemistry
Oregon State University, Corvallis, Oregon 97331

We have previously reported on measuring total yields of secondary particles from liquid, organic substrates by a direct gravimetric method in which the irradiation dose was maintained constant [1] and by a differential gravimetric approach in which the irradiation dose was varied [2]. Our estimates of total particle yields from pure glycerol, bombarded by 3-5 keV indium ions, were determined by the direct gravimetric technique to be in the range of 1,000-3,000 [1]; these yields are two to three orders of magnitude higher than those generally observed from metals in the same energy range. At least one other laboratory has since reported results, which were obtained by an in situ optical method, that are comparable to ours [3-5].

Determinations of total yields based on gravimetric measurements are subject to gross, systematic errors due to evaporation losses, exchanges of volatile materials (e.g. H_2O and MeOH) with the atmosphere, ill-defined or misjudged equilibrium states used as standard states for taking readings, and inaccuracies in calibration. Although a variable-dose or differential method for determining total particle yields reduces the uncertainties due to systematic errors, random sample losses still result from bumping when the sample is exposed to vacuum. Gravimetric techniques are also very time consuming and labor intensive. Indirect in situ methods, such as that of Wong et al. [3-5], incur inaccuracies in estimating and using average evaporation losses and in calibration.

In this study we have taken advantage of the microscopic imaging capability of a finely focusing liquid metal ion column to make direct in situ measurements of mass-losses due to evaporation and sputtering and thereby improve the accuracy of total yield measurements from glycerol. The experimental arrangement consists of a commercial (FEI Corporation), focusing liquid metal ion (LMI) column attached to the FAB-port of a single focusing magnetic sector instrument (Hitachi RMU-6E). Positive ion beams of Ga, In, Sn, Au, and Bi were delivered into 10-25 μm diameter spots on glycerol targets (~40 nL balls) at current densities ranging from 0.1-1.0 mA cm^{-2} and at energies ranging from 10-28 keV. Using an octupole/stigmator (incorporated into the LMI column) to raster the beam over the target, a small electron multiplier located in the vicinity of the sample, and a Tektronix Model 606A display monitor, the apparatus was made to function as a scanning ion microscope and micrographs of the sample probe and its surroundings were recorded at 1-500X. The method used to perform total particle yield measurements is illustrated in Fig. 1.

The total secondary particle yield in a given sputtering experiment is simply the ratio of the number of sputtered molecules (sputtering loss) to the number of primary particles that strike the sample (dose). Doses were determined from measurements of the primary beam current, the bombardment time, and the system's geometry. Sputtering losses were determined from measurement of ball diameters directly off scanning ion micrographs recorded at regular intervals during the course of a sputtering run. The micrographs were accurately calibrated at a given magnification from images of a wire mesh placed exactly in the same position as the sample balls. The second ball permits control for evaporation and other extraneous factors that can affect the yield calculations. This procedure is operationally simpler and more accurate ($\lesssim$ 25%) than previous methods for sample loss determination.

We have determined total particle yields for glycerol as a function of mass (Fig. 2) and energy (Fig. 3). Fig. 4 shows this data combined into a single plot of total particle yield versus momentum. The linear character of the data may be accidental due to the limited energy range; nonetheless, the advantage of using primary ions of the highest combined mass and energy

possible (within the range studied) is obviously increased sputtering yields. Single ion monitoring of secondary ions (glycerol and selected oligopeptides) indicates that ion yields follow, though not linearly, the same trend as do the neutral yields.

ALKALINE EARTH SALTS AS CATIONIZATION AGENTS IN LASER DESORPTION FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

Donald E. Bracken and Thomas J. Nizolek

New Jersey State Department of Health, Trenton, New Jersey 08625

The exposure of humans to toxic chemicals in the environment and the workplace may cause the formation of metabolites and adducts of DNA, RNA, and Proteins which can lead to undesirable health effects and genetic mutations. A laser desorption mass spectrometric (LDMS) technique, that is being applied to the analysis of these thermally labile and polar xenobiotics, uses metal ions generated from metal foils or directly from salts. These metal ions, which attach to the analyte to form cations, include elements from Groups 1 [1] and 3 [2] and some transition metals [3]. Studies of the Group 2 elements (alkaline earth metals) for their potential as "cationization" agents appear not to have been made.

Presented here are some of the preliminary results of an investigation of the salts of Mg, Ca, Sr, and Ba for their potential as cationization agents in LDMS. Using a Tachisto Model 216 pulsed CO_2 laser (10.6 um) interfaced to a Nicolet FTMS-2000 Fourier transform mass spectrometer, mass spectra were obtained for the individual hydrated chloride salts and several organic compounds. The laser desorption mass spectrum of barium chloride, Figure 1, is qualitatively representative of the chlorides of calcium and strontium also. In addition to the interesting singly-charged metal ions, the formation of the hydroxo- and chloro- metal ions appears to be characteristic of the elements. Magnesium, however, gave no evidence for the formation of AOH^+ or ACl^+ (where A is an alkaline earth element) but did "form" the mono- and diaquo- singly-charged metal ions. These observations are summarized in Table 1. The ability of magnesium to retain at least a partial hydration sphere may be due to its high charge density.

Data that illustrate cationization of an organic compound by an alkaline earth ion are presented in in Figure 2. The major peak at m/z 302 is the pseudomolecular ion resulting from the attachment of a barium ion to a molecule of 7-methylguanine, a component of a DNA adduct. Apparently, the loss of a hydrogen (proton?) accompanies the metal ion attachment. A striking aspect of the spectrum is the pseudomolecular ion cluster with additional peaks at m/z 301,300,and 299. These clusters can aid in the location and identification of the peudomolecuar ion.

Glucose, although not shown here, similarly not only produces a cluster of attachment ions with barium at m/z 317 but also undergoes a hydrogen loss. Insufficient data for a variety of compounds presently precludes any generalization on the hydrogen loss.

At this point it is clear that the alkaline earth chlorides can act as cationization agents in LDMS. Also, the particular suitability of barium chloride arises because it can provide the following features:

(1) a large mass separation of the pseudomolecular ion from fragment and barium background species
(2) pseudomolecular ion clusters
(3) internal calibrants
(4) the least deliquescence of the alkaline earth chlorides.

WHAT HEATING RATES AND FINAL TEMPERATURES ARE REQUIRED FOR DESORPTION OF THERMALLY LABILE MOLECULES? INSIGHTS FROM THE DESORPTION/IONIZATION TECHNIQUE, K^+IDS (K^+ IONIZATION OF DESORBED SPECIES); Karen J. Light, Daniel B. Kassel, John Allison, Department of Chemistry, Michigan State University, East Lansing, MI 48824

The K^+ Ionization of Desorbed Species (K^+IDS) is a desorption/ionization technique that has been presented for the analysis of thermally labile compounds.[1,2] A thermionic emitter (K^+ aluminosilicate composition) is built onto the end of a modified direct insertion probe. This emitter is then positioned inside the ion source of a mass spectrometer such that, when the emitter is resistively heated, a large flux of K^+ ions is formed in the ion source. To produce a K^+IDS mass spectrum, a thermally labile compound is placed on top of this emitter. A rapid increase in temperature causes the analyte to desorb into the gas phase. When K^+ ions and neutral species are present in the gas phase concurrently, K^+ adducts form which produce the K^+IDS mass spectrum.

With the original probe design, described previously[1], sample was placed directly onto the emitter, which led to a poor temporal overlap of sample desorption and K^+ emission. There exists a time lag for K^+ ion production. During this lag time, the analyte was experiencing sufficient heating that most of it desorbed before K^+ emission commenced, and thus was undetected. A new probe design was developed to improve this overlap[3]. This design added a second sample support filament, spatially separated from the emitter, that was only radiatively heated. This produced a slower heating of the surface on which the sample was placed and thus delayed sample desorption to provide a better overlap with K^+ emission. This new probe design did not change the resultant K^+IDS mass spectra significantly and therefore was implemented.

Recently, temperature studies have been performed to determine the conditions, i.e. heating rates and final surface temperatures, necessary for desorption of thermally labile compounds, and subsequent production of K^+IDS mass spectra. A typical plot of how the temperature of the emitter and sample wire surface changes as a function of time once current is applied to the emitter is shown in Figure 1. Combining this temperature/time data with mass spectral data, the temperature of the metal wire surface at the time of sample desorption can be determined. The thermally labile compounds we are currently interested in have molecular weights below 1000 amu. Three such compounds were chosen for this study: tristearin, sucrose and hexaglycine. For these "fragile" compounds the temperatures required for desorption were between 150-170°C. This can be seen in Figure 2 for tristearin, where the onset of sample desorption (scan 16) corresponds to a sample wire temperature of 165°C. The rate of heating of the support filament surface was much lower than originally anticipated when compared to most other D/I techniques that truly utilize rapid heating (e.g., laser desorption). Typical heating rates of the second filament wire were on the order of 15°C/s.

EFFECTS OF ION PAIRING ON DESORPTION IONIZATION SAMPLING EFFICIENCIES

Johnny D. Reynolds and Kelsey D. Cook, Department of Chemistry, University of Tennessee, Knoxville, TN 37996-1600.

To the extent that preformed ions play an important role in matrix assisted desorption mass spectrometry, ion pairing in solution could be expected to reduce sampling efficiencies for singly charged ions via neutralization. For multiply charged ions, charge reduction (not neutralization) may actually increase the sampling efficiencies by decreasing solvation interactions, thereby decreasing the potential barrier for the removal of the ion from its matrix. In electrohydrodynamic mass spectrometry (EHMS), this effect could be offset to some extent by a corresponding reduction in interactions with the applied extracting field due to the net charge reduction.

As a test for assessing the balance between these effects, a diquat, $[(CH_3)_3\text{-}N\text{-}(CH_2)_5\text{-}N\text{-}(CH_3)_3]^{2+}$ $2I^-$, was used to measure the dependence of ion paring (P) and sampling efficiency (S) on counterion identity for a series of counterions (Table 1). P and S are defined in Equations 1 and 2:

$$(1) \quad P = I_{AX}1+ \; / \; I_A2+$$

$$(2) \quad S = \frac{(I_A \; / \; C_A)}{(I_R \; / \; C_R)}$$

where I = intensity and C = concentration for A (analyte), R (reference), or AX (ion pair). P and S follow the same trend, suggesting that reductions in S due to ion pairing are more than offset by the effects of reduced solvation.

Table 1

Counter Ion	P	S
acetate	0.13	39.8
nitrite	0.75	49.6
perchlorate	0.87	75.6
chloride	4.28	84.3
nitrate	5.44	116.8

These results are pertinent for resolution of a question remaining from an earlier study of sampling efficiency in a homologous series of quats, $[H(CH_2)_n]_4\text{-}N^+$ for n = 1-5. In that study, S increased up to Q4 (n = 4) because of expected decreases in ion-solvent interactions with increasing quat size. However, the intensity of Q5 was anomalously low. The suppression of Q5 was attributed to mass transport effects, but could also be expected if the intensity of Q5 was reduced due to ion pairing. In light of the data in Table 1, the choice of the chloride counterion in the earlier study may have been a poor one since chloride pairs extensively. We have now repeated that study with the acetate counterion, anticipating that any ion pairing induced suppression would be reduced. Instead, even more severe suppression occurred; now both Q4 and Q5 were suppressed (Table 2).

Table 2: S for Quat Series.

	Chloride	Acetate	Nitrite
Q1	0.36	0.45	0.34
Q2	0.84	0.98	0.84
Q3	0.99	1.21	0.96
Q4	1.00	1.00	1.00
Q5	0.67	0.70	0.72

Measurement of the solution viscosities (Table 3) provided an explanation for the results obtained with acetate counterion. As was the case with Li^+ in the earlier study, the acetate ion induces increased solvent structure, thereby increasing the solution viscosity and increasing the mass transport bias that arises from the relatively slow diffusion of the bulkier quats. When the experiment was repeated using the (low-pairing) nitrite ion, results similar to those for chloride ion were obtained (Table 2). Although ion pairing effects can be substantial, in this case each quat seems to be affected in the same manner.

Table 3

Counterion	Viscosity (Glycerol = 1)
Acetate	1.25
Nitrite	1.10
Perchlorate	1.01
Chloride	1.12
Nitrate	1.05

AUTONEUTRALIZED SF_6^- FOR FAST NEUTRAL BEAM FT/ICR MASS SPECTROMETRY

Ronald E. Shomo, II,# James E. Delmore,@ Anthony D. Appelhans,@, David A. Dahl,@, and Alan G. Marshall#

SF_6^- can be formed in high abundance by attachment of low-energy electrons in the presence of crossed **E** and **B** fields. Acceleration of SF_6^- through a potential of 2.5–28 kV produces a tightly focused ion beam (~0.5 mm circular cross-section). During their ~1 m transit toward a target, about 1/3 of the SF_6^- ions autoneutralize (~10 μs average lifetime[1]) back to neutral SF_6 and an electron:

$$SF_6^- \rightarrow SF_6^- + e^-$$

Because the electron mass is so small, the SF_6 fast neutral beam (FNB) remains tightly focused, and any undissociated SF_6^- and electrons can be removed by passage between charged deflector plates positioned in front of the target.[2]

We have constructed an SF_6 fast neutral beam external ionization source and interfaced it to a Nicolet FTMS-1000 Fourier transform ion cyclotron resonance mass spectrometer, as shown schematically in Figure 1. The beam current is ~5×10^{-12} A, with a circular cross-section of ~0.5 mm diameter. A homebuilt orthorhombic trapped-ion cell was constructed from 400 mesh, with 2" transverse plate separation and 3" separation between the two (end) trapping plates. An electron filament was attached to the cell to confirm its satisfactory conventional FT/ICR performance, and the filament was then removed to permit passage of the fast neutral beam.

FT/ICR - NEUTRAL BEAM SCHEMATIC

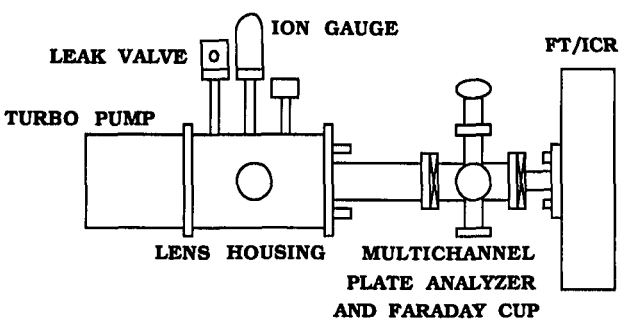

Figure 1. Schematic diagram of fast neutral beam ion source and interface to the ion trap of a Nicolet FTMS-1000 FT/ICR mass spectrometer.

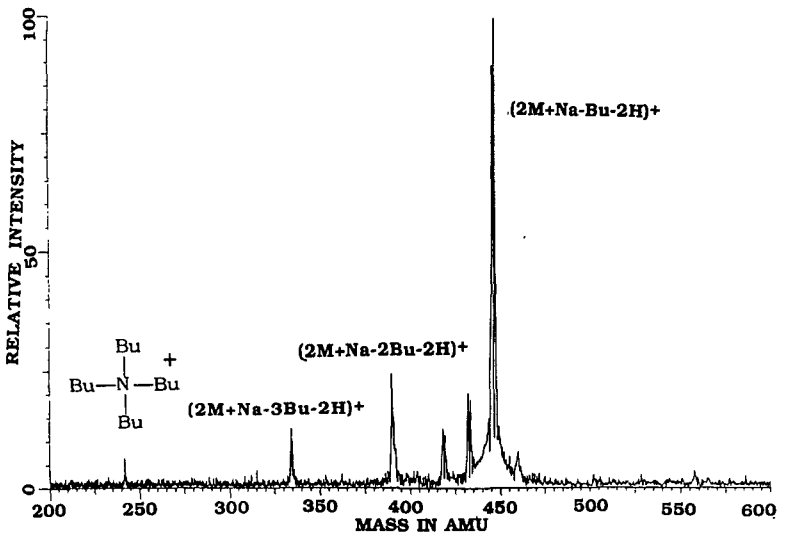

Figure 2. Single-scan FT/ICR spectrum produced by SF_6 fast neutral beam bombardment of evaporated tetrabutylammonium bromide. The molecular ion is at m/z 242, and cluster ions are evident at higher m/z.In contrast to normal pulsed-source operation, in which the signals from many separate pulsed-source experiments are added together, the neutral beam source (10 keV accelerating voltage) was left on continuously for 600 s, and then turned off so that the accumulated ion population could be excited and detected once by FT/ICR. Thus, signal-averaging is effectively continuous rather than discrete.

We are currently engaged in two kinds of systematic comparisons: (a) between FT/ICR and quadrupole mass analyzers for the FNB source; and (b) between FNB and fast atom bombardment as a means for ionizing involatile species. Compared to FAB, the FNB source offers the obvious advantage (in the ICR case) that the neutral beam can be focused and aimed from 2 m away. Moreover, since no liquid matrix is needed for the FNB experiment, FNB should offer an advantage similar to laser desorption for analysis of mixtures of chemically dissimilar species.

CHEMICAL IONIZATION MASS SPECTROMETRY WITH USE OF LITHIUM ION ATTACHMENT TO MOLECULE

Toshihiro Fujii, Miyoshi Ogura and Hitoshi Jimba

National Institute for Environmental Studies
Tsukuba, Ibaraki 305, JAPAN

Recently a large number of literature have appeared concerning the gas phase chemistry of alkali ions with organic molecules which has been often observed in low energy ionization process. Alkali ions such as Na^+ form adduct ions (also refered to as cationized molecular ions) of the type $(M+Na)^+$.

In general, cationized molecules are more stable than radical molecular ions or protonated molecules. The fragmentation of the polar molecules resulting from a cationization by alkali ions, has a higher activation energy than splitting off functional groups after a protonation. Cationization is therefore an interesting tool for the determination of molecular weights. The important question is the feasibility of using the advantages of cationization for the CIMS as a new ionization method.

The purpose of this study is to construct an optimized Li^+ ion source (LIS), to report response and performance characteristics of acetone and to demonstrate the LIS as a new sensitive ionization source for CIMS. The present system employs the thermionic alkali ion emitter in flow of nitrogen buffer gas and high pressure mass spectrometry with ion counting.

EXPERIMENTAL The developed CIMS is shown in Fig. 1, which is the modification of the apparatus originally prepared by Shimazdu corporation for an atmospheric pressure ionization/ mass spectrometry combination study in our laboratory. The components are lithium ion source sampling interface, vacuum system, electrostatic ion lens system, quadrupole mass spectrometer (QMS), and ion detection system.

Lithium Ion Source (LIS). Shown in Fig.2 is a schematic diagram of the LIS and ion optics. The LIS consists of a lithium ion emitter, reaction chamber, and repeller. Lithium ions are emitted from the lithium ion emitter which is a small mineral bead fused to 0.1 mm diameter Pt filament wire. The bead is prepared with a thoroughly grounded mixture of Li_2O: Al_2O_3 : Si_2O in a 1 : 1 : 1 molar ratio for Li^+ alkali ions.

Sampling Interface. The sample gas from the aperture of cone impinges on the skimmer in the tip of which a 1 mm diameter orifice was drilled.

Vacuum System. The system is evacuated differentially by three pumps. The reaction chamber into which the sample gas was introduced through the carrier gas flow line is maintained at 1 to 760 torr.

Electrostatic Lens. The lens system consisted of an extractor (E), deflector (D) and 4 sets of coaxial, sequential cylinders, each biased at a particular dc valtage.

Mass Analyzer. The QMS was used without the electron impact ionizer. The rods were biased below grounded by connecting separate dc supplies into the dc rod driven circuit. The channel electron multiplier detector was operated both in the pulse mode and in analog mode.

Operational Procedures. The characterization study of the present source was carried out with reference compounds through standard gas generator. By employing a permeation tube, acetone was diluted in pure nitrogen gas to produce standard gas. The acetone was used to characterize the LIS response and performance. The formulated gas sample analysis was done as the example of the analytical applications. The analysis was accomplished by introducing the gas sample directly to the LIS.

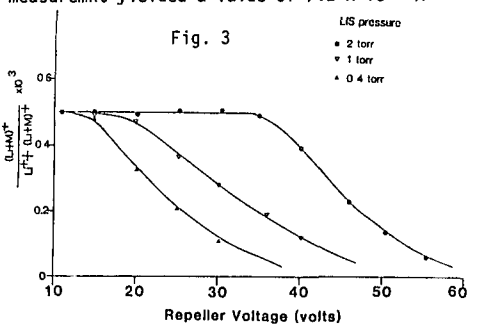
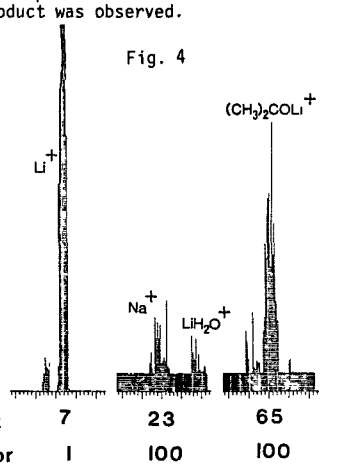
RESULTS AND DISCUSSION

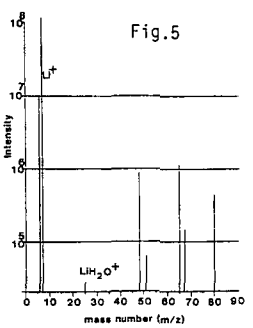
1. Lithium ion intensity We have tested the lithium alkali ion emitter for different temperatures. A simple diode arrangement was used to measure the total lithium emission current; the maximum emission current of Li^+ ions is more than 6 x 10^{-7} A. The Li^+ ion current through the skimmer was determined by using an ion collector electrode which was positioned at the extractor in the vacuum. The measuremnt yielded a value of 7.2 x 10^{-9} A (4.5 x 10^{10} ions/sec).

2. Reactions in source
Ionization in the present source is initiated by formation of alkali ions on the emitter. Under the appropriate operating conditions, chemical and thermal equilibrium occurs before the ions are sampled and positive ion products results mainly from the attachment reactions. A successful method for obtaining lithium ion cationization mass spctra must provide a means for binding lithium ion to the sample molecules.
The intensity of attachment products was greatly influenced by the voltage applied to the repeller, which provides the reactant ion with the kinetic energy. The relationship of $I(M+Li)^+/[I(Li)^+ + I(M+Li)^+]$ to the repeller voltage was examined under the various ion source pressures, using acetone. As can be seen from Fig.3, the portion of Li^+ ion attachment decreases with increasing repeller voltage and finally no product was observed.



3. Sensitivity Considerations
Fig.4 shows three mass spectra around m/e 7, 23 and 65 respectively in which the primary ion Li^+, Na^+, and the Li^+ adduct ion $(CH_3)_2COLi^+$ are monitored. The sampling conditions are as follows; acetone sample is introduced at the rate of 2.6 x 10^{-10} g/sec from the permeation tube at 25°C. The measurement of the adduct ion yielded a value of 2.9 x 10^{-10} A which is output of the ion multiplier with the gain at 2 x 10^3; this current corresponds to 1.5 x 10^{-13} A.Thus, the sensitivity is 5.8 x 10^{-4} A/g/sec.
The minimum detectable amount (m.d.a.) can be estimated. The background rate of our ion counting system is typically 10 counts/sec with all component operating. As a practical and conservative lower limit of quantitative detectability, a signal to background ratio of 10 may be required. Then for a continuous sample, we required 100 counts/sec. Taking the sensitivity for acetone which was determined to be 5.8 x 10^{-4} A/g/sec experimentally, we estimated that m.d.a. is around 2.8 x 10^{-14} g/sec.





4. Analysis of gas sample
Fig.5 shows the Li^+ CI mass spectrum of a formulated mixture of six compounds in N_2 gas in the single scan mode. The scan time was 10 sec. Presumably the peaks at m/z 48, 51, 65, 67, 80, 85 are due to CH_3CN, CH_3CHO, $(CH_3)_2CO$, C_3H_7OH, $(C_2H_5)_2NH$, C_6H_6. Only the quasimolecular species, Li^+ complexes, are present, demonstrating that Li^+ ion chemical ionization mass spectrometry will find numerous applications in the analysis of mixtures. The alkali ion CI appears to have advantages over the conventional CI of CH_4. Since more than one reactive species are generated in the $CI(CH_4)$ source, it does not always provide the single ion species. Furthermore small pressure change can make the mass spectral interpretation difficult because of pressure effects in many ways.

TUNING AND CALIBRATION IN THERMOSPRAY MASS SPECTROMETRY:

Joseph F. Greer and Louis L. Martin
Drug Discovery Dept., Pharmaceuticals Div., CIBA-GEIGY Corp.,
556 Morris Ave., Summit, NJ 07901

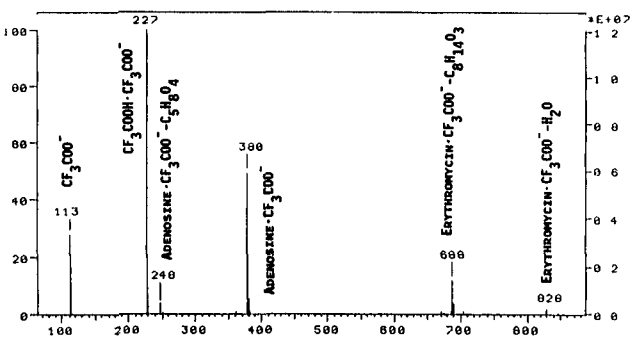
Most manufacturers of thermospray interfaces recommend the use of either PEG 1000 or a mixture of adenosine and erythromycin for tuning the low mass range. We have found that PEG 1000 is unsatisfactory for thermospray tuning since it decomposes at high thermospray source temperatures, resulting in contamination of the source, and it condenses at cooler temperatures, resulting in contamination of other areas of the mass spectrometer. Adenosine and erythromycin produce strong positive ions between m/z 136 and 734, but are not suitable for negative ion tuning. In this paper, compound mixtures which are suitable for tuning and calibration in both positive and negative ion thermospray mass spectrometry are described.

Samples were analyzed on a Finnigan MAT TSQ-70 triple quadrupole mass spectrometer equipped with a Finnigan MAT thermospray interface. A Waters model 510 pump was used with a Scientific Systems model LP-21 pulse dampener. The mobile phase consisted of 60% acetonitrile in water.

In the first experiment, adenosine, erythromycin and trifluoroacetic acid (TFA) were added to the mobile phase at a concentration of 0.1 mg/ml. The following conditions were used: vaporizer temperature, 125°C; aerosol temperature, 240°C; repeller, -50 V (negative ion), +50 V (positive ion); flow rate, 1.1 ml/min. In the positive ion mode (data not shown), abundant ions appeared at m/z 136 (adenine), 268 (adenosine) and 558,756 and 716 (fragments of erythromycin). In the negative ion mode (fig. 1), abundant ions appeared at m/z 113 (TFA), and 227, 248, 380, 688 and 828 (adducts of TFA with itself, adenine, adenosine and two fragments of erythromycin, respectively).

In the second experiment, GC/MS markers 1329 and 1772 (Regis Chemical Co., Morton Grove, Ill.) were added to the mobile phase at a concentration of 0.1 mg/ml together with 0.1% trifluoroacetic acid (TFA). The thermospray spectra were obtained under the under the following conditions: vaporizer temperature, 90°C; aerosol temperature, 300°C; repeller, -125 V (negative ion), +125 V (positive ion); and a flow rate of 1.9 ml/min. In the positive ion mode (fig 2),

Figure 1. Negative ion mass spectrum of trifluoroacetic acid, adenosine and erythromycin.



abundant ions appeared at m/z 1330 ($M+H^+$) and 1773 ($M+H^+$). In the negative ion mode, abundant ions appeared at 1442 and 1885 (TFA adducts of markers 1329 and 1772, respectively). By turning the filament on (fig. 3), ions at m/z 1146 and 1589 were seen. These ions correspond to a loss of $C_3F_7CH_2$ from markers 1329 and 1772 respectively.

Figure 2. Positive ion mass spectrum of Regis markers 1329 and 1772.

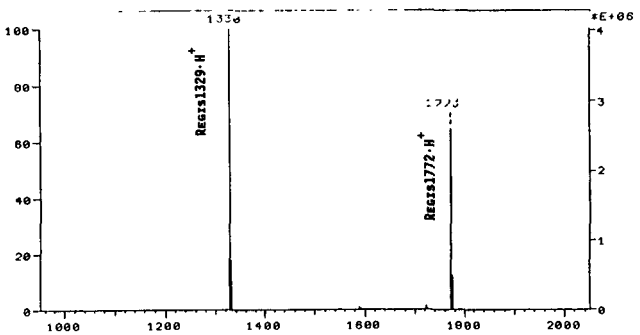


Figure 3. Filament-on negative ion mass spectrum of Regis marker 1329 and 1772 in the presence of TFA.

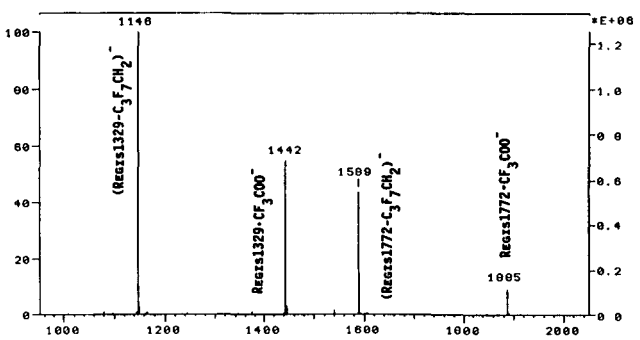

In conclusion, adenosine, erythromycin and mass markers 1329 and 1772 from Regis provide suitable ions in the presence of TFA for tuning in both positive and negative ion thermospray modes. The density of ions is sufficient for low resolution mass spectrometry but may not be adequate for high resolution work. Furthermore, the compounds used in this study produce significantly less contamination of the mass spectrometer than either polyethylene or polypropylene glycol.

OPTIMIZATION OF THERMOSPRAY VAPORIZER AND ION SOURCE.

C. H. Vestal, J. G. Wilkes, G. J. Fergusson, and M. L. Vestal, Vestec Corporation, Houston, TX 77054

The objectives of this work are to obtain experimental data on the effect of key ion source and vaporizer operating parameters on thermospray ionization efficiency; to achieve a better understanding of the processes occurring in the thermospray ion source; and to provide the information needed to routinely optimize thermospray for difficult nonvolatile samples.

Thermospray is now widely recognized as a practical LC-MS interface, but some problems persist particularly for applications to difficult ionic samples such as peptides and polysulfonated azo dyes. This paper presents initial results from an ongoing study of the important parameters affecting efficiency of the overall ionization and detection process. A key component for these studies is a new thermospray vaporizer with an easily replaceable, yet durable, exit nozzle. This allows the diameter of the nozzle to be varied in a precise, known manner. Other parameters varied include power imput to the vaporizer, distance between vaporizer nozzle and ion exit aperture, and repeller potential.

A Vestec Model 201A Dedicated Thermospray LC-MS System was used for these studies. The standard ion source equipped with a repeller was employed without modification. In place of the standard capillary vaporizer, a new vaporizer with replaceable sapphire nozzles was used. A cross sectional diagram of the tip portion of this new vaporizer is shown in Figure 1. The present work employed vaporizer nozzle diameters of 50, 75, and 100 microns, but additional sizes are available as indicated on the figure.

Test solutions used in this work typically consisted of 10 ppm of sample in 0.1 M aqueous ammonium acetate and these were introduced continuously at a flow rate of 1 mL/min to the thermospray vaporizer. Adenosine and arginine were used as test samples in this initial work. Intensities of the major sample ions (e.g. m/z 136 and 268 from adenosine) and a major solvent ion (e.g. m/z 36) were determined as functions of nozzle diameter, vaporizer control temperature, nozzle to sampling aperture distance, and repeller voltage at fixed ion source temperature (ca. 240 C) and tip heater temperature (ca. 280 C).

Additional work will be required before all of the objectives can be accomplished; nevertheless a model which appears to at least partially account for the observations has been constructed. It appears that ions may be produced by direct ion evaporation from charged droplets in two distinct regions of the ion source; initially as the superheated droplets exit the vaporizer, and further downstream due to heat transfer from the ion source. Buffer ions may be converted to sample ions anywhere within the ion source where collisions between the ions and neutral sample should occur. The ion sampling efficiency depends strongly on the position of ion formation. Ions formed near the vaporizer may be sampled less efficiently because of diffusion loss to the walls, and ions formed further downstream may be swept on past the sampling orifice by the high speed vapor flow. The repeller potential may affect both the ion sampling distribution and the ion formation rate.

The primary effect of applying a high positive potential to the repeller is to decelerate and deflect away from the repeller positive ions and droplets while accelerating negatively charged ions, electrons (if any) and droplets to the repeller. Under some conditions the repeller can cause additional fragmentation of sample ions, but this appears to require the presence of free electrons which was not the case here. Under the conditions used in these studies it appears that the major effects due to the repeller can be described as follows. As the repeller is biased more positively the collection efficiency for positive ions formed near the sampling orifice is increased, while ions formed further upstream are collected less

efficiently. Furthermore, if charged droplets or particles reach the vicinity of the repeller, reducing their velocity increases the probability that ions will be produced in the region of high collection efficiency. Also, increasing (or decreasing) the velocity of the charged droplets relative to the surrounding vapor can cause additional vaporization and ionization due to frictional heating.

In summary the new vaporizer with replaceable nozzle allows meaningful studies of nozzle diameter and other important parameters on thermospray performance. The model outlined above accounts qualitatively for the results obtained, but much work remains before a definitive picture may emerge. From studies of a limited number of samples the 75 micron nozzle generally gives the best results and highest sensitivities with mostly aqueous mobile phases at ca. 1 mL/min. The smaller diameter nozzles should, in principle, give better results at lower flow rates, but this has not yet been established experimentally.

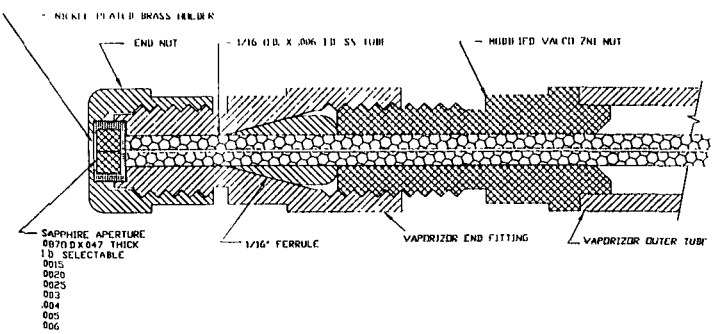

FIGURE 1. Cross sectional view of the new thermospray vaporizer with replaceable sapphire nozzle.

The Dependence of Ion Formation on Thermospray Plume Characteristics

Mike S. Lee and Richard A. Yost; Department of Chemistry, University of Florida, Gainesville, FL 32611.

Previous studies performed in our laboratory using a specially designed vacuum chamber which permitted sampling of the thermospray plume under vacuum conditions have shown that droplet-rich and vapor-rich regions exist within a thermospray plume and that several instrumental parameters may affect these regions. We now describe the results of our studies of tip temperature, source temperature, flow rate, source pressure, and probe position, obtained on a Vestec thermospray liquid chromatograph/mass spectrometry (LC/MS) interface, which show the dependence of fragment ion and pseudo-molecular ion formation on thermospray plume characteristics. These studies were performed with a pure 0.1 M ammonium acetate buffer and with a 100 ppm (4×10^{-4} M) ribavirin standard prepared in 0.1 M ammonium acetate.

In these studies, the desired solution was filled into an ISCO LC-5000 syringe pump and continuously pumped into a Finnigan triple stage quadrupole (TSQ45) mass spectrometer. The scanning parameters were the same for each experiment (15 to 500 amu in 0.40 seconds). When the desired instrumental parameter was adjusted, a full scan mass spectrum was initiated and allowed to run for 20 seconds to several minutes. At the end of the acquisition, the parameter under investigation was adjusted again and another full scan mass spectrum acquisition was initiated. Since no injections were made, the resulting ion intensity trace contained no peaks. Ion intensity traces were characterized by constant, relatively non-fluctuating ion currents observed above baseline. Areas were obtained by quantitating over a specified scan range, usually five scans (2 seconds) wide which corresponds to 77 µg of ammonium acetate and 1 µg of ribavirin exiting the probe for a flow rate of 1.5 mL/min. Repetitive measurements were obtained by quantitating a series of five scan "peaks" within a single acquisition.

Results of the tip temperature, source temperature, and probe position studies indicate that the formation fragment ions are favored by larger droplets at regions (droplet-rich) close (<1 cm) to the probe tip, while pseudo-molecular ion formation is favored by smaller droplets at regions (vapor-rich) further away (>1 cm) from the probe tip. Figure 1a shows the effects of tip temperature on the ion intensities of pure ammonium acetate. Ion intensities of both the positive and negative ions of ammonium acetate maximize at 208 C. The effects of tip temperature on the ion intensities of ammonium acetate with 100 ppm ribavirin present are shown in Figure 1b. Ion intensities of both the positive and negative ions of ammonium acetate maximize at 194 C and decrease rapidly with increasing tip temperatures. The effects of tip temperature on the positive ion intensities of ribavirin are shown in Figure 2a. The ion intensities of the positive fragment ions at m/z 113 and 130 are optimum at higher tip temperatures. The ion intensity of the $(M+NH_4)^+$ adduct is maximum at 204 C while the $(M+H)^+$ and $(2M+H)^+$ ions are maximum at 208 C. The negative ions of ribavirin showed similar behavior as the positive ions (Figure 2b). Here, the ion intensity of the pseudo-molecular ions $(M-H)^-$, $(M+CH_3COO)^-$, $(M+111)^-$, and $(2M-H)^-$ ions are optimum at 208 C while the negative fragment ions at m/z 111 and 171 are optimum at 200 C. Source temperature studies showed similar behavior of fragment and pseudo-molecular ion formation with temperature; however, excessive temperatures (>300 C) were shown to increase the ion intensities of the fragment ions of ribavirin which may be due to thermal decomposition of the pseudo-molecular ions. The results of the flow rate experiments were rather difficult to interpret since this parameter affected many of the other parameters and the magnitude of the contributions of these other parameters may change with flow rate. However, it is evident that the ion intensities do increase with increasing flow rates (up to 2.0 mL/min). The studies dealing with source pressure indicate that there exist optimum source pressures for both fragment ion and pseudo-molecular ion formation. The ion intensities of the respective positive and negative fragment ions of ribavirin at m/z 113 and 111 increased with increasing source pressures. The corresponding ammonia and acetate adducts of these fragment ions, m/z 130 and 171, showed two maxima at 3.5 and 6 Torr. The presence of two maxima may suggest the occurrence of two competing processes in the ionization mechanism, for example, direct ion evaporation of the adduct of the fragment versus chemical ionization (CI) of the fragment with the corresponding reagent ion (NH_4^+ or CH_3COO^-). The positive and negative pseudo-molecular ions of ribavirin were optimum at intermediate source pressures (4-6 Torr) except for the $(M-H)^-$ ion which was optimum at 8 Torr. The

results of the probe position studies showed that distances less than 1.1 cm (from the probe tip to ion sampling cone) favor the production of fragment ions while distances greater than 1.1 cm favor the production of most of the pseudo-molecular ions at a flow rate of 1.5 mL/min.

These results indicate that vaporization conditions which produce larger and, perhaps, more slowly evaporating droplets at or near the ion sampling cone favor the production of fragment ions, while vaporization conditions which produce smaller and rapidly evaporating droplets favor the production of pseudo-molecular ions. However, many of these large droplets are able to come in contact with the heated source walls and evaporate sample molecules. These sample molecules can become pyrolyzed and produce a molecule (molecular weight 112 corresponding to the triazole ring structure) where it can undergo CI with ammonium acetate reagent ions. This possibility would account for the maximum ion intensity of fragment ions at low tip temperatures. Likewise, the vapor-rich plumes do not contain an abundance of large droplets but rather an abundance of smaller droplets (≤1 μm) and vapor. This condition may be more favorable for the direct ion evaporation of pseudo-molecular ions of ribavirin and/or the evaporation of a neutral ribavirin molecule which can become ionized by CI with the ammonium acetate reagent ions. This possibility would account for the increase in ion intensity of the pseudo-molecular ions with higher tip and source temperatures.

EFFECTS OF REPELLER GEOMETRIES ON THERMOSPRAY MASS SPECTRA

SAUL W. FINK AND ROYAL B. FREAS
DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, HOUSTON, TEXAS 77204-5641

INTRODUCTION: Thermospray ionization is a versatile interface for liquid chromatography/mass spectrometry (LC/MS). Thermospray mass spectra are produced with abundant molecular ions and little or no fragmentation. Therefore, molecular weight information of a sample is obtained, but limited structural information is available. The addition of a repeller in the thermospray ion source has increased the usefulness of this technique. We have studied the placement and geometry of the repeller in the ion source and the effects on the mass spectra. Two basic geometries for the repeller were used: a blunt tip and a needle tip.

EXPERIMENTAL: A quadrupole mass spectrometer (HP Model 5988A) fitted with a Vestec Thermospray™ interface (Model 721A) and a gradient HPLC system (SSI Model 230) was used for these studies. The blunt tip was designed by Vestec Corp. The face of the repeller was placed 4 mm from the ion exit aperture. The mobile phase was 0.1 M ammonium acetate dissolved in HPLC water. The samples were introduced into the mass spectrometer by direct flow. Discharge ionization provided a supplemental source of ions as the repeller potentials were applied. The needle tip consisted of a 1-1/2" 0-80 threaded rod machined to a fine point. The tip of the repeller was placed 2 mm from the ion exit aperture. The polyethylene glycol (PEG) sample was prepared by mixing PEG of average molecular weights 300 u, 600 u, 1000 u, and 1450 u. A vaporizer probe tip was constructed using fused silica capillary tubing (100 μm ID).

RESULTS: The blunt-tip repeller has previously been used to study samples. Fragmentation occurs when a filament or discharge electrode produces ions when large potentials are applied to the repeller.[1-3] Reactions that explain this induced fragmentation are collision-induced dissociation (CID), electron-ionization-induced dissociation (EIID), and electron-induced dissociation (EID). Anthracene and acridine are examples of molecules that undergo fragmentation when repeller potentials are applied.

A needle-tip repeller was employed in our laboratory to study the effect it has on ions from PEG (m/z 300 to m/z 1900). Robbins and Crow had previously found that a needle type of repeller electrode improves high mass sensitivity, but that it has no effect in the low-mass region (m/z < 1000).[4] In contrast to previous work,[4] we observed a significant increase in low mass ion current (m/z 300-1000) as well as for high mass ions (m/z 1000-1900). The effects of applying potentials to the needle repeller are displayed in Figs. 1 & 2. The low mass ions increased more rapidly for lower potentials than did the high mass ions, suggesting that the effect was due to increased ion diffusion, enhancing ion extraction from the ion source.

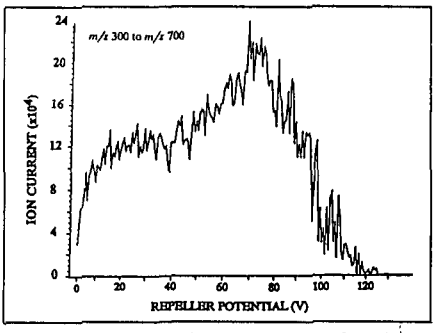

Figure 1. Repeller potential versus ion current for m/z 300-700 of PEG

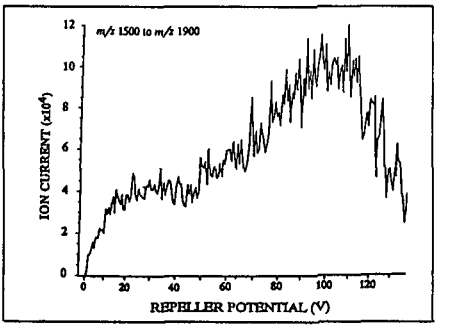

Figure 2. Repeller potential versus ion current for m/z 1500-1900 of PEG

The needle-tip repeller is useful for the study of peptides and proteins. Thermospray LC/MS can be a powerful tool for peptide sequencing. Peptide samples studied with the needle-tip repeller include 20 picomoles of angiotensin I and 10 picomoles of bradykinin (Fig. 3 and 4). The samples were introduced by direct injection using a Rheodyne injection system (Model 7125) fitted with a 20 μL loop.

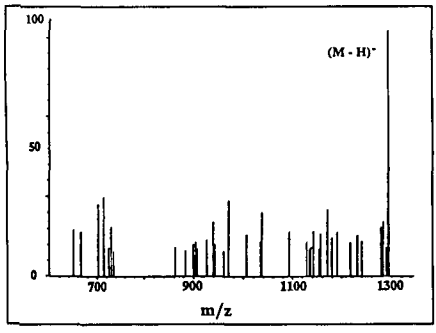

Figure 3. Full-scan mass spectrum of 20 picomoles of angiotensin I (MW 1296).

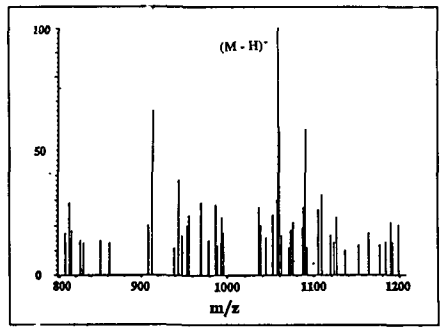

Figure 4. Full-scan mass spectrum of 10 picomoles of bradykinin (MW 1060).

Figure 5 is a chromatogram of hemoglobin W alpha chain. The alpha and beta chains of hemoglobin variants were studied with the previous ion source and have been reproduced using the ion source with the needle-tip repeller.[5] Eight nanomoles of sample were digested in a trypsin column followed by a reverse-phase HPLC column which was connected to the mass spectrometer.

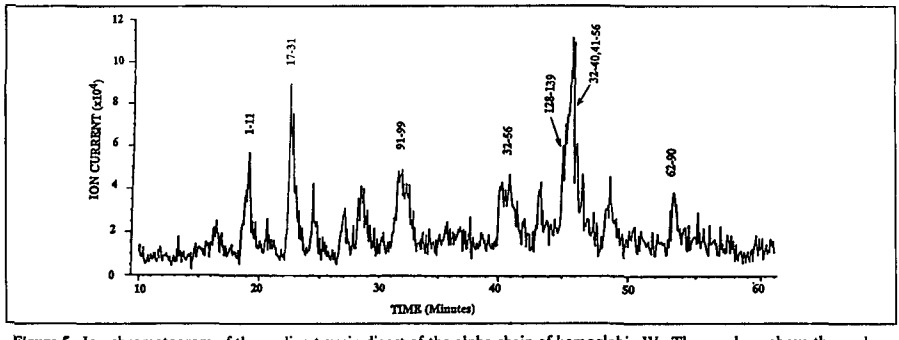

Figure 5. Ion chromatogram of the on-line trypsin digest of the alpha chain of hemoglobin W. The numbers above the peaks correspond to the amino acid sequences in the peptide.

CONCLUSIONS: A blunt-tip repeller electrode has been used to induce fragmentation when repeller potentials are applied in the presence of a supplemental source of ionization. A needle-tip repeller electrode has been used to increase ion currents of low mass ($m/z < 500$) and high mass ($m/z > 1000$). The increase in ion currents is due to increased ion evaporation from the smaller droplets produced by the new vaporizer probe tip and from the influence of an electrostatic field. The increase is also due to the increase in diffusion rates of molecules as the repeller potentials increase.

ENHANCED DETECTION OF SULFONATED AZO DYES USING THERMOSPRAY MS

MATTHEW A. MCLEAN[1], DONALD A. FLORY[1], MARVIN L. VESTAL[2], ROYAL B. FREAS[1]
[1] DEPARTMENT OF CHEMISTRY, UNIVERSITY OF HOUSTON, TEXAS 77204-5641
[2] VESTEC CORPORATION, 9299 KIRBY DR., HOUSTON, TEXAS 77054

INTRODUCTION: A better understanding of critical parameters that affect ion evaporation from thermospray droplets has lead us to modify our thermospray ion source and vaporizer to increase sensitivity for sulfonated azo dye detection. Instrument modifications include decreasing the exit aperture of the thermospray vaporizer and the addition of a needle-tip repeller in the thermospray ion source. Restriction of the vaporizer tip decreases the average droplet size of the spray entering the ion source. The field strength on the droplets increases and the field-assisted ion-evaporation process is enhanced. An increase in field strength created by smaller droplet size results in an increase in dye evaporation and consequently an increase in signal. However, only decreasing the thermospray vaporizer tip does not allow for the desired sensitivity to be obtained due to poor ion extraction efficiency from the ion source. For this reason, a repeller opposite the ion exit aperture was added to increase the ion sampling yield.

EXPERIMENTAL: All experiments were performed using a Hewlett Packard Model 5988A mass spectrometer operated in the negative-ion mode. The mass spectrometer was coupled to a Scientific Services Inc. gradient high performance liquid chromatography system via a Vestec thermospray liquid chromatography/mass spectrometry (LC/MS) interface. The Vestec ion source was modified by machining away the step restriction in the ion volume, thus making a more open region around the sampling cone. A needle-tip repeller was added opposite the sampling cone to enhance ion extraction efficiency from the ion source (see Fig. 1). The thermospray vaporizer was modified so the orifice size could be varied by using different sizes of fused silica tubing held in place by a graphite/vespel ferrule and a screw-on cap (see Fig 2). Results for flow rate versus ion abundance and optimum repeller voltage versus ion abundance were obtained by pumping an aqueous solution of 10-5 M Direct Red 81 directly into the mass spectrometer at various flow rates while stepping the repeller voltage through a region of maximum ion current. This was done for the 100 micron and 50 micron tip sizes.

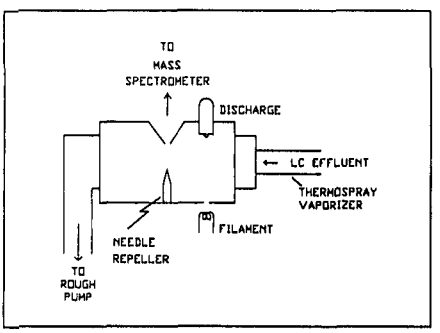

Figure 1. A schematic of the modified thermospray ion source.

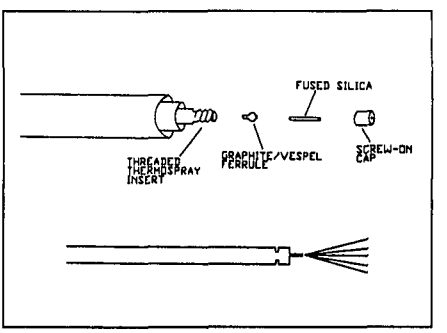

Figure 2. A schematic of the modified thermospray vaporizer probe.

RESULTS: The smaller the thermospray vaporizer tip can be made, the better the sensitivity one can obtain. Reduction of the vaporizer tip decreases the size of the thermospray droplets, which increases the charge per unit area on the surface of the droplets entering the ion source. As a result, field-assisted ion-evaporation is enhanced. Compounds that undergo ionization via chemical ionization (i.e. evaporated as neutrals followed by ionization in the gas phase) should not be affected to a great extent by decreasing the exit orifice of the vaporizer probe and indeed we have found this to be the case. Compounds such as sulfonated azo dyes and peptides, which are ionized in solution and evaporate via field-assisted ion-evaporation, show enhanced sensitivity when the vaporizer tip is restricted.

Figure 3 shows a graph of ion intensity for Direct Red 81 versus repeller voltage for a thermospray probe exit orifice of 100 microns and flow rates of 0.4, 0.6, 0.8 and 1.0 mL/min. Figure 4 shows data for the 100

micron tip at higher flow rates. A summary of the optimum repeller voltage as a function of flow rate for the 100 micron tip is given in Fig. 5.

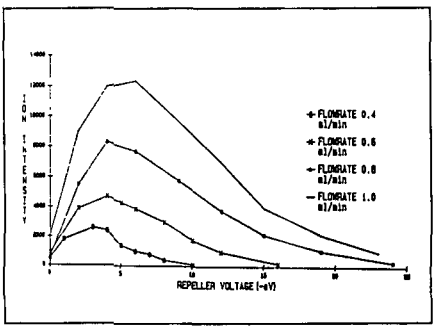

Figure 3. Ion intensity versus repeller voltage at flow rates of 0.4, 0.6, 0.8, and 1.0 mL/min.

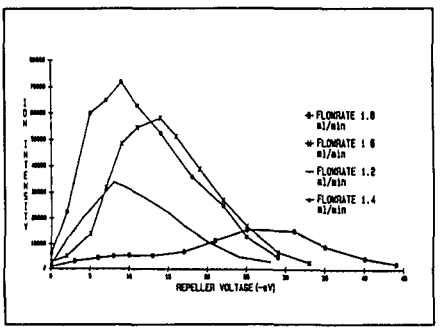

Figure 4. Ion intensity versus repeller voltage at flow rates of 1.2, 1.4, 1.6, and 1.8 mL/min.

Ion source pressure and repeller voltage affect ion extraction efficiency from the thermospray ion source. Both the proper flow rate and repeller voltage are extremely important in optimizing the response for a given vaporizer tip size. The optimum flow rate for a 100 micron tip size was found to be 1.4 mL/min. At this flow rate, a high pressure is achieved in the ion source which allows for high sampling yields while minimizing ion/neutral collisions. At higher flow rates, the greater frequency of collisions within the ion source causes a decrease in ion current due to neutralization reactions between solvent molecules and the dye anion. Similar results were obtained for other tip sizes investigated.

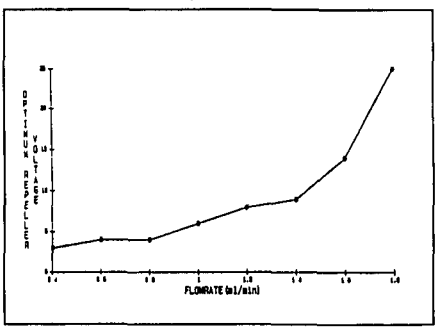

Figure 5. Optimum repeller voltage versus flow rate for a 100 micron vaporizer tip size.

The optimum repeller voltage is also dependent on flow rate. At higher flow rates, higher pressures in the ion source result. The repeller voltage required to influence ion trajectories is then increased. This trend is reflected in Fig. 5.

CONCLUSIONS: Two critical parameters responsible for enhancing thermospray LC/MS sensitivity for sulfonated azo dyes include vaporizer exit orifice size and repeller voltage. Restriction of the thermospray probe exit orifice is needed to enhance field-assisted ion-evaporation and therefore increase the population of dye ions in the gas phase. The ion extraction efficiency of the dyes from the ion source is increased by applying a voltage to a needle-tip repeller located opposite the ion sampling cone. Without these instrument modifications, reproducible thermospray mass spectra of sulfonated azo dyes could not be obtained. For each thermospray probe tip size, an optimum flow rate exists where the total ion current is maximized. For a unique combination of flow rate and tip size, a corresponding optimum repeller voltage also exists.

Methods to Produce Less Active Probe Surfaces to Minimize the Adsorption and Catalysis of Thermospray Probes.

Philip C. Smith[1] and Alfred L. Yergey, Section on Metabolic Analysis and Mass Spectrometry, National Institute for Child Health and Human Development, NIH, Bethesda, MD 20892.

The analysis of very labile compounds by thermospray LC/MS is not routine and often requires much different probe and source conditions than would be employed for stable polar compounds. With compounds such as peptides, fragmentation products are often dominant in the mass spectra, especially when using the near complete vaporization conditions which produce optimal total ion current. The spectra obtained across a chromatographic peak generally vary for these labile compounds with the molecular ion being more prominant at the beginning of the peak evolution. Tailing of ion chromatograms is common, especially when operating near complete vaporization. We have investigated methods to minimize this undesirable apparent adsorption and catalysis. A more inert surface for the Vetec style probe was developed by modifying the stainless steel (SS) vaporizer capillary. The two approaches attempted are the use of gold plating of the SS capillary and insertion of a fused silica lining within the SS capillary.

Methods

Gold plating. Plating of gold to SS was done using electroless processes as have been applied previously for transfer lines for GC/MS. After some experimentation, the final procedure employed sequential electroless plating with copper, nickel then gold after a complex sequence of activation steps with acids and proprietary products (2). Solutions were pumped through the 0.005 inch ID capillary SS tubing at flow rates of 0.5-1.0 ml/min using HPLC pumps. Preliminary experiments using 0.020 inch ID tubing established that the plating process did occur in the interior bore of the tubing. When plating the narrower ID vaporization probe, plating of the exterior surface was used as an indication of successful plating of the interior bore.

Fused silica lined probes. Commercially available glass lined SS tubing cannot be obtained with ID's compatible with the presently employed thermospray process ($\leq$ 150 μm). Therefore, fused silica capillary cladded with polyimide was employed. The fused silica, 100 μm ID, 200 μm OD, was threaded though the capillary of a modified Vestec thermospray probe where the SS capillary had been removed and replaced with one which had an ID of about 250 μm (0.010"). The fused silica was extended past the inlet end of the vaporizer capillary and held in place with vespel ferulles. The fused silica was allowed to extend a few mm beyond the SS capillary at the source end of the vaporization probe during these investigations.

The probes prepared by the above methods were tested using a Biospect quadrupole mass spectrometer retrofitted with a Vestec thermospray source and controller. Source block and vaporizer tip heater temperatures are controlled independently in this configuration. Test solutes included arginine, tripeptides, and enkephalins. Eluent was 0.1 M ammonium acetate at 1 ml/min. Standard testing of the probes for flow cut off and vaporizer control vs. tip temperature was conducted without vacuum with a flow of 1 ml/min 0.1 M ammonium acetate. Parameters of interest when comparing probes were: i. presense of molecular ion relative to fragmentation ions, ii. tailing of the ions produced from sample introduced by direct injection, and iii. reproducibility of spectra across a sample peak.

Results

Plating of gold to the SS capillary necessitated prior application of copper and then nickel plate. When complete, gold plated vaporization probes had similar heating profile and pressure drop as did unplated probes. The flow cut off, normally used as an indirect measure of the capillary ID, decreased from 1.6-1.7 ml/min to about 0.9-1.1 ml/min when gold plating was done. This is likely due to changes is the surface wetting properties of the gold, since the pressure drop of the probe did not change appreciably upon gold plating. The performance of gold plated probes was not improved relative to SS when measured qualitatively for tailing of fragment ions or presence of molecular ion.

The fused silica lined probes behaved much differently than the metal probes. A plot of control vs. tip temperature shown in Figure 1 exhibited no run away vaporization even when the full current available from a Vestec thermospray controller was used. This was not unexpected, as the polyimide cladded fused silica probably limits heat transfer to the eluent. Also noted was that during operation at high probe temperatures the response of fused silica lined probes changed, presumably due to "burn off" of the polyimide and this was confirmed when

the probe was disassembled. Life time of the fused silica lined probe was limited to several days before plugging occurred. The polyimide burnoff may be the source of probe plugging. Because of the poorer heat transfer of the fused silica lined probes, the rate of response and equilibration to changes in applied current to the probe were much slower than for metal probes. However, when inserted into the tip heater within the mass spectrometer, an apparent "run away" temperature was observed when current applied to the probe capillary was increased.

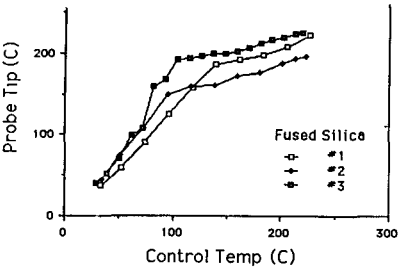

Figure 1. Plot of the vaporization temperature profile conducted without vacuum for 3 fused silica lined vaporizer probes. Flow was 1 ml/min 0.1M ammonium acetate. Highest temperature reflects full applied current of a Vestec thermospray controller.

Compared to the SS probes, the fused silica lined probes gave better thermospray mass spectral performance. Using moderate source block and tip heater temperatures of 300 °C, optimal ion intensities for solvent ions of ammonium acetate were comparable to that obtained with a SS probe. Significant molecular ion was observed for arginine and all the peptides tested and tailing of the total ion current and the fragment ions was significantly reduced (Figure 2). Unlike the SS probe, optimal response for molecular ion and total ion current were correlated and maximal just below the apparent "run away" temperature. Reproducibility of mass spectra across a total ion chromatogram were still not completely satisfactory, but were improved due the reduction in tailing and apparent adsorption of the probe.

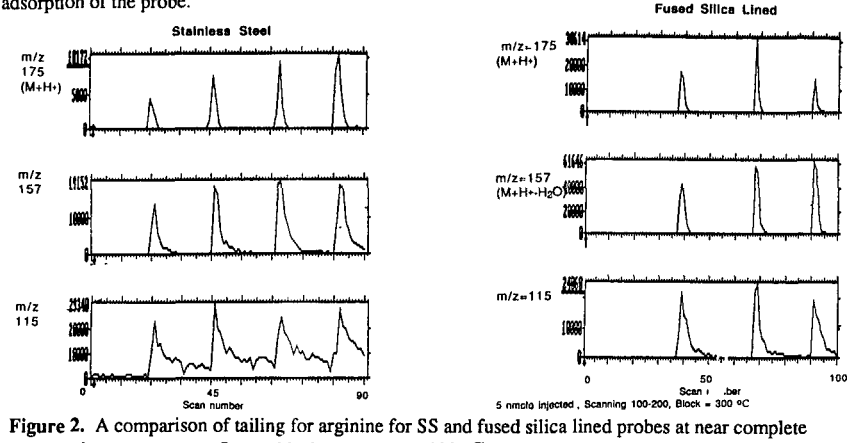

Figure 2. A comparison of tailing for arginine for SS and fused silica lined probes at near complete vaporization temperature. Source block temperature, 300 °C.

Conclusions

The results indicate that the surface of SS probes may be responsible for some of the adsorption and apparent catalysis seen with thermospray LC/MS of labile compounds. Improvements were obtained for the small peptides examined with the polyimide fused silica lined SS probes, but the instability of the polyimide cladding needs to overcome. Presently, we are investigating the use of aluminum cladded fused silica which should have greater temperature stability as well as improved heat transfer properties. The use of fused silica may also have potential application for use with lower flow rates as it is available with ID's as small as 5 μm with precisely controlled tolerances.

ALTERNATIVE IONIZATION PATHS FOR MAGIC-LC/MS

J. Daniel Kirk and Richard F. Browner
School of Chemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

The advent of MAGIC-LC/MS has created the opportunity to generate reference quality electron impact (EI) and chemical ionization (CI) mass spectra for a wide range of compounds present in liquid chromatographic eluents. The generation of such mass spectra is possible because of the highly efficient manner in which the interface removes solvent from the analyte before it reaches the mass spectrometer. Analyte leaves the interface as a stream of small, desolvated particles which then flash vaporize in the heated ion source area, and may be subsequently ionized using EI or CI processes. These modes of operation are, however, limited to compounds which generate an adequate vapor pressure of analyte at the temperature of the ion source to result in a detectable population of ions.

This paper addresses additional options available for the ionization of samples introduced with the MAGIC-LC/MS interface. The two new modes of ionization discussed are: (1) fast atom bombardment (FAB) ionization and (2) small particle enhanced vaporization (SPEV) ionization. The theoretical and experimental bases for both experiments are described in some detail. The FAB approach involves a crossed-beam experiment, in which the desolvated particle beam leaving the interface is intercepted by a stream of fast atoms from a conventional FAB source. The interaction is capable of producing FAB spectra, which are applicable to molecules with inadequate vapor pressures to generate EI or CI spectra under normal operating conditions. A second FAB experiment involves the deposition of the MAGIC particle beam onto a probe tip, which may then be ionized by a FAB source in a more conventional manner.

The SPEV approach involves the production of particles significantly smaller than those normally produced by the MAGIC interface. The smaller diameter particles should result in an enhanced vapor pressure of analyte species, due to the high curvature of the particle surface. This should result in a significantly higher population of vapor phase species than would be predicted for vaporization from bulk material, such as that generated from a probe.

Thus far we have been unable to observe the SPEV effect with the current particle sizes that we are producing. Laser diffraction studies of aerosol droplet formation has shown us that the production of droplets small enough to produce particles with enhanced vaporization may not be possible with an ordinary pneumatic nebulizer. It may be necessary to find some other means of producing extremely small aerosol droplets.

FAB will certainly give us the means to produce spectra of extremely non-volatile compounds and compounds with high molecular weights. Deposition of the particle beam from MAGIC onto a probe tip has been done. FAB spectra are then obtained in the usual manner with or without a matrix. Further research is necessary to produce FAB spectra from the crossed-beam mode shown in figure 1.

ON-LINE HPLC WITH A CONTINUOUS FLOW FAB INTERFACE

M.A. McDowall, V. Gould, *C. Slaughter, *B. Pramanik and **T Dourdeville.
VG MassLab Ltd., 3 Tudor Road, Altrincham, WA14 5RZ. *Howard Hughes Medical Institute, Dallas, Texas 75235, USA. **Waters Division of Millipore, Milford, Mass 01757, USA.

Continuous flow (or dynamic) FAB mass spectrometry permits the continuous sampling of a liquid stream into a Fast Atom Bombardment (FAB) ionization source (Figure 1). In such a system a solvent containing a small proportion of glycerol (2-10%) is continuously introduced into a mass spectrometer through a length of fused silica capillary.

In this study we have sought to explore the potential of Dynamic-FAB for on-line LC-MS analysis. Dynamic-FAB systems typically accept liquid flow rates of only a few microlitres per minute. Thus there are two options available for combining HPLC and Dynamic-FAB. Capillary HPLC columns (<0.5mm id.) can be used without the need to "split" the column eluent prior to mass spectral analysis. Alternatively conventional (4.6mm id.) or microbore (2.0 - 0.5mm id.) columns can be used at their optimum flow rates providing that the eluent is "split". Both chromatographic approaches have their merits. Splitless capillary LC-MS systems yield optimum on-column sensitivity. However the loading capacity of capillary HPLC columns is significantly less than their larger counterparts.

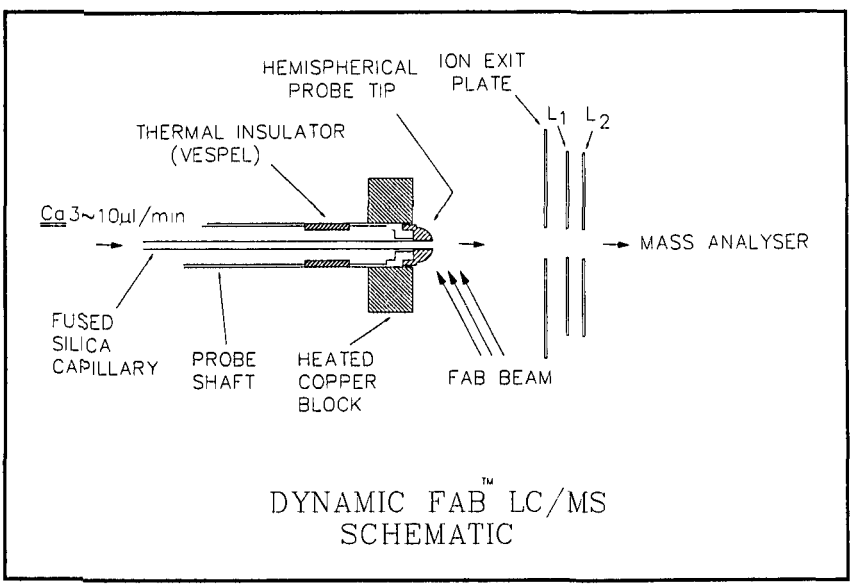

Figure.1. Schematic diagram of the Dynamic-FAB LC/MS ion source used in this study.

In many biomedical applications, sample quantity is severely limited. It is thus desirable to: A) Maximize that portion of the sample which contributes directly to overall signal response. B) Maximize the rate at which individual analytes are delivered to the FAB target to enhance signal-to-noise ratio. C) Minimize the volume in which the analytes are eluted to keep the concentration high at the FAB target. Where on-line flow rates of 10ul/min or less are required, these conditions are best achieved by microbore HPLC.

In transposing a separation method from the conventional to the microbore scale, an HPLC column is chosen with an I.D. appropriate for:
A) Achieving a solvent flow rate compatible with dynamic-FAB.
B) Maintaining the linear solvent velocity constant to minimize alterations in peak retention times.

For example, to sustain a linear velocity of 6.0 cm/min requires in conventional scale HPLC; a flow rate of 1ml/min through a column of 4.6mm I.D. In microbore scale HPLC; a flow rate of 10ul/min through a column of 460mm I.D. would be required.

Experimental

Mass spectra were obtained with a TRIO-3 triple quadrupole mass spectrometer equipped with a Dynamic-FAB LC/MS probe (all from VG MassLab, Altrincham, UK). Conventional (4.6mm I.D.) bore LC-MS was performed using apparatus previously described[1]. Microbore LC-MS was performed using an prototype HPLC system consisting of a pair of syringe pumps (Waters Chromatography, Milford MA. USA) which supply fluid of a programmed composition via a Rheodyne model 7520 microbore injection valve. A microbore reversed-phase column (0.5mm I.D. x 250; C-18) packed in a PTFE capillary was inserted directly into the outlet port of the injection valve. The eluent was conveyed from the column outlet to the FAB target via a fused silica capillary.

Results

Whilst studying small peptides (Met-Arg-Phe-Ala, bradykinin, leu-enkephalin and gramicidin-s) we have found that on-column detection limits (for full scan mass spectra) are improved by circa 100 fold when analyses are transposed to the microbore scale. Of the various stationary phases tested, the large-pore C8 packings such as Brownlee Aquapora RP300 have been found to be the most generally suitable for peptide separations.

ACCURATE MASS MEASUREMENT IN CONTINUOUS FLOW FAST ATOM BOMBARDMENT QUADRUPOLE MASS SPECTROMETRY

M.A. McDowall and J. Roboz*. VG MassLab Ltd., Tudor Road, Altrincham, WA14 5RZ, UK. *Department of Neoplastic Diseases, Mount Sinai School of Medicine, New York, NY10029, USA.

This paper presents a new application, the determination of accurate masses by quadrupole mass spectrometry using continuous flow FAB as the method of sample introduction.

Introduction

Continuous flow fast atom bombardment (dynamic-FAB) mass spectrometry permits a significant extension of the ability of FAB to provide mass spectral data from a wide range of involatile and/or polar labile compounds. Because FAB often produces highly abundant pseudomolecular ions, knowledge of the accurate masses of these ions is of considerable help in identification and molecular structure studies. Hitherto accurate mass determination has been performed by magnetic sector mass spectrometry. The ability to obtain accurate mass data (at unit mass resolution) from single quadrupole mass spectrometers extends the utility of such systems and complements structural information obtained from triple quadrupole instruments.

Experimental

The technique is based on computer-controlled internal mass calibration utilizing known non-interfering masses of a calibration standard, selected to bracket, as closely as possible, the peak of interest from the analyte. Mass spectra were obtained with a TRIO-3 triple quadrupole mass spectrometer equipped with a dynamic-FAB LC/MS probe that incorporated a valve loop (100nl) injector (all from VG MassLab, Altrincham, UK). Samples were analysed by injecting directly into a carrier solvent (methanol/water/glycerol/TFA, 45:45:10:0.1 v/v) via the valve loop injector. Inside the ion source the probe tip was maintained at a temperature of 40-45°C and bombarded with a beam of fast (gun voltage 9keV) Xenon atoms. A 1:1:1 molar mixture of cesium, rubidium and sodium iodides was used as a calibration standard for mass measurement.

Results

In preliminary studies we have analysed vinca alkaloids (vinblastin and vincristin)[1] and small peptides (Met-Arg-Phe-Ala and gramicidin-s). The exact mass of protonated vincristin is 825.4075u. In six repeated determinations the mean value was 825.4025±0.0105; 5.0mmu (6ppm) lower than the theoretical value. Comparable data was obtained for vinblastin. The exact mass of protonated gramicidin-s is 1141.7138 u. In a single determination (Fig.1) the calculated mass was 1141.7057 u; 8.1 mmu (7ppm) lower than the theoretical value. Comparable data was obtained for Met-Arg-Phe-Ala.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

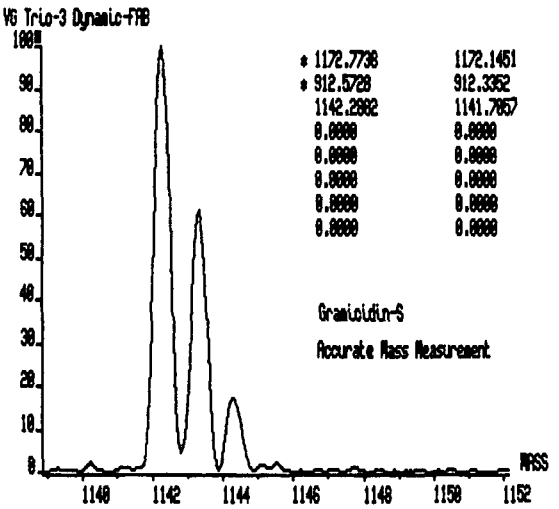

Figure.1. Mass spectrum of the protonated molecular ion region of gramicidin-s, (mass measured against cesium iodide; m/z 1172 and m/z 912). The experimentally determined mass was 1141.7057u; 8.1mmu (7ppm) lower than the theoretical value.

Discussion

The mass measuring accuracy and reproducibility obtained for the compounds studied was, as expected, comparable to that reported by using the same general approach with other types of ionisation [2,3]. Once the exact mass of an ion is obtained, algorithms are available to calculate possible molecular compositions. Although the correct composition may not be immediately obvious from the list of possibilities, identification is usually possible after employing the rules of spectral interpretation (eg. nitrogen rule, DBE) and judiciously considering additional chemical, chromatographic and spectral data.

ANALYSIS OF DATEM EMULSIFIERS USED IN BREAD PRODUCTION BY CAPILLARY SUPERCRITICAL FLUID CHROMATOGRAPHY/MASS SPECTROMETRY

D.E. Games[1], E. Lewis[2], A. Tomlinson[2] and S. Pleasance[1]
1. Department of Chemistry, University College, P.O. Box 78, Cardiff CF1 1XL, Wales.
2. Dalgetty UK Ltd., Station Road, Cambridge CB1 2JN, England.

The inclusion of emulsifiers in the breadmaking process is well established in the baking industry[1]. One of the most important classes of permitted emulsifiers for use in U.K. bread production is E472(e), diacetyltartaric acid esters of mono- and di-glycerides (DATEM (1)), which are used primarily as dough strengtheners in products where fine texture and volume are important. Its manufacture involves the addition of melted monoglycerides to a reaction mixture of tartaric acid and acetic anhydride in the presence of a trace of acid. The product contains varying amounts of free glycerol, fatty acids, acids, monoglycerides and their combinations. It is also known that DATEM is diluted with triglycerides.

Recently the composition and precise nature of the active species of this additive has generated much interest and a variety of methods for its analysis are being studied. Capillary supercritical fluid chromatography (SFC) has been used for the analysis of lipids and related materials[2,3]. We have used capillary SFC both with FID and mass spectral detection to study mixtures of model glycerides and fatty acids and then applied these techniques to study DATEM emulsifiers with varying degrees of functional properties.

Experimental

Capillary SFC/FID was performed on a 501 Lee Scientific system using an integral frit restrictor (50μm i.d.) with CO_2 as the mobile phase. Samples dissolved in chloroform, were introduced via a 100nl Valco injector and chromatographed on a SB methyl 8m x 100μm column at 150°C with a linear density gradient of 0.2 to 0.6 g/ml at 0.02g/ml/min. preceded by an initial isoconfertic period.

SFC/MS was effected using the pump and data system of the above system and combining to a Finnigan MAT 4500 quadrupole mass spectrometer using our recently described interface[4] which allows heating of the tip of the frit restrictor. Ammonia was used as the reagent gas for CI studies.

Results and Discussion

SFC studies of mixtures of mono-, di- and triglycerides gave good FID traces and DATEM samples gave complex chromatograms indicating the presence of many components. SFC/MS was next performed under CI and EI type conditions on both standard and DATEM samples. The TIC trace obtained under EI conditions for a DATEM sample is shown in fig. 1. This compares favourably with that obtained with FID and both good EI type and CI mass spectra were obtained. The ammonia CI mass spectra gave abundant $[M + 18]^+$ ions together with some structurally useful fragment ions, the spectrum for dipalmitin is shown in fig. 2. Use of this data, together with the EI spectra, enabled ready characterisation of the various standards.

Bases on these observations, we have identified a large number of compounds in the emulsifiers. The main components were found to be mono- and diacetylated esters of palmitate and stearate mono- and diglycerides. In addition, free fatty acids and small quantities of the proposed active stearinoyl and palmitoyl DATEM species were found. The ammonia CI TIC trace of a DATEM sample is shown in fig. 3 together with selected mass chromatograms of ammoniated molecular species.

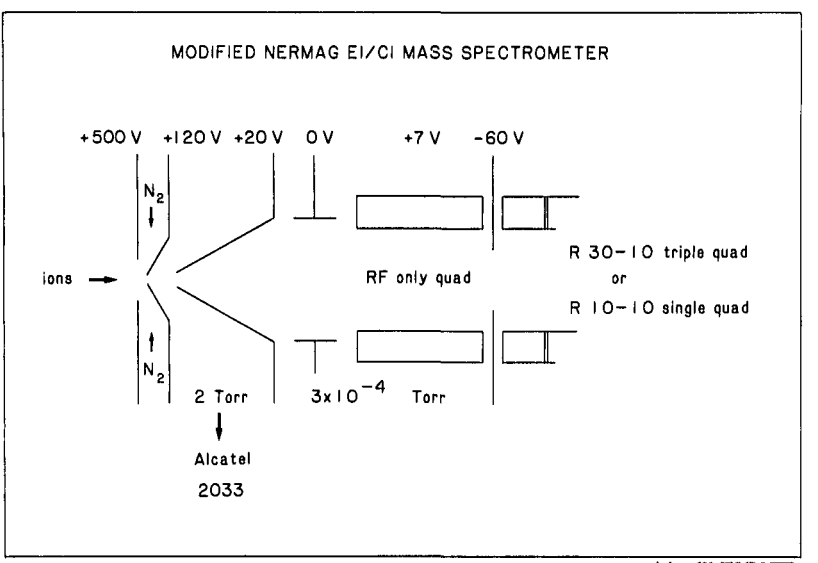
LC/MS with atmospheric pressure ionization using the NERMAG R 30-10 triple quadrupole mass spectrometer

A.P. Bruins
State University, Dept. of Pharmacy, 9713 AW Groningen, The Netherlands
C. Beaugrand
S.N. Nermag, 92500 Rueil Malmaison, France

One of the first publications on combined LC/MS described the use of an atmospheric pressure ion source (1). During the following ten years however, developments in API were mainly directed to air sampling.

Ion evaporation, electrospray, and ion spray are API techniques for mass spectrometric observation of ions already present in solutions. Coupled with liquid chromatography and capillary zone electrophoresis, these ionization methods working at room temperature are ideally suited for solving problems in the biomedical field, where most sample molecules are polar, ionic or thermolabile.

We have modified an existing commercially available NERMAG triple quadrupole mass spectrometer for LC/API-MS. Ions are drawn from the atmospheric pressure source through a nozzle into an intermediate pressure region, pumped by a 35 m^3/h rotary pump. A portion of the beam of ions plus neutrals is sampled through a conical skimmer into the original ion source housing pumped by the standard oil diffusion pump. The ions are



guided into the original analyzing quadrupole system by means of an additional RF only quadrupole assembly and associated focusing elements.

Ions are generated using the electrospray technique (2). A solution of 10 ng/ul of Safranin O was pumped at 5 ul/min (800 pg/sec) by a Jasco Familic 100N micro LC pump via a 50 um i.d. fused silica capillary into a 0.5 mm o.d. x 0.25 mm i.d. stainless steel capillary held at +4.5 kV. The ion sampling nozzle is protected against water vapor by a dry nitrogen gas curtain. Strong signals, adequate for source tuning an recording full scan spectra were observed in our first prototype when we used the aforementioned sample introduction rate of 800 pg/sec. No fragment ions are observed, as was the case in ion spray LC/API-MS (3). A 100 V difference in nozzle and skimmer voltage gave the best sensitivity. At 250 V and above we observed strong fragmentation by CID in the intermediate pressure region. An increased sensitivity should be feasible after optimization of the nozzle and skimmer diameters, their shape, their distance and the ion optics.

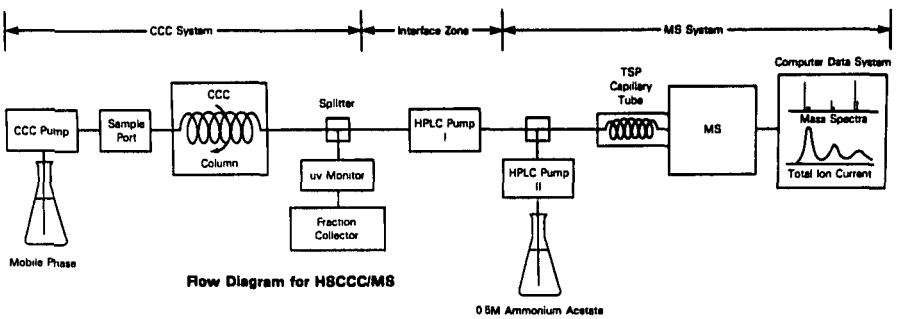
MASS SPECTROMETRY AS AN ONLINE ANALYSIS TECHNIQUE FOR COUNTER CURRENT CHROMATOGRAPHY.

L.K. Pannell, Lab. of Bioorganic Chemistry, NIDDK, NIH, Bethesda, MD 20892; T.Y. Zhang, Y. Ito, Lab. of Technical Development, NHLBI, NIH, Bethesda, MD 20892; and F.E. Chou, Pharma-Tech Research Corporation, Baltimore, MD 21212.

AIM: Gas and liquid chromatographs are both being routinely used as preseparative devices in conjunction with mass spectrometers. However, Countercurrent Chromatography (CCC) had not previously been interfaced to a mass spectrometer. The aim of this work was to perform this coupling and to present the initial results.

COUNTERCURRENT CHROMATOGRAPHY: During the past few years, CCC has become a more widely used separative technique and there are now at least two manufacturers. Excellent reveiws exist.

EQUIPMENT:



Flow Diagram for HSCCC/MS

A standard Finnigan TSP46 mass spectrometer equiped with a thermospray source was connected to a prototype "small-scale" countercurrent chromatograph developed by one of us (Chou). The CCC used a multilayer coil prepared from heavy wall #20 (0.85mm i.d.) PTFE tubing. The coil had a 2.5" revolutional radius operated at 1820 rpm and a solvent flow rate of 1.0 ml/min.

Countercurrent chromatography is a relatively low pressure technique and operates typically at 100 psi. Conversly, thermospray requires inlet pressures of 500-1000 psi and, at these pressures, the typical PTFE tubing used in CCC instruments would not survive. To surmount this problem, an open split interface was used consisting of a low volume HPLC "tee" joint in which 0.2 ml/min was run to waste (or an auxiliary detector) and the bulk used as the inlet for a first HPLC pump. A length of tubing was attached to the waste end of the "tee" to allow for the inlet piston volume of the HPLC pump. This pump could then send the liquid directly into the mass spectrometer through the thermospray interface or it could be "tee'd" with a second HPLC pump if a makeup or buffer solution was needed as was the case with most of the samples so far run. This is especially relevant where a buffer may effect the partition ratio of a compound in the two immiscible phases. With this post addition, we were able to take separations developed in the analytical laboratory and repeat them with the mass spectrometer as the detector. The advantage of obtaining real-time mass spectra over only spectrophotometry data need not be elaborated!

In the examples reported here, the solvent consisted of a hexane/ethyl acetate/methanol/water mixture and the lower (water/methanol) phase was used as the mobile phase; a buffer of 0.05% ammonium acetate (0.4 ml/min) was added by the second pump and "true" thermospray ionization used.

EXAMPLE 1: INDOLE DERIVATIVES

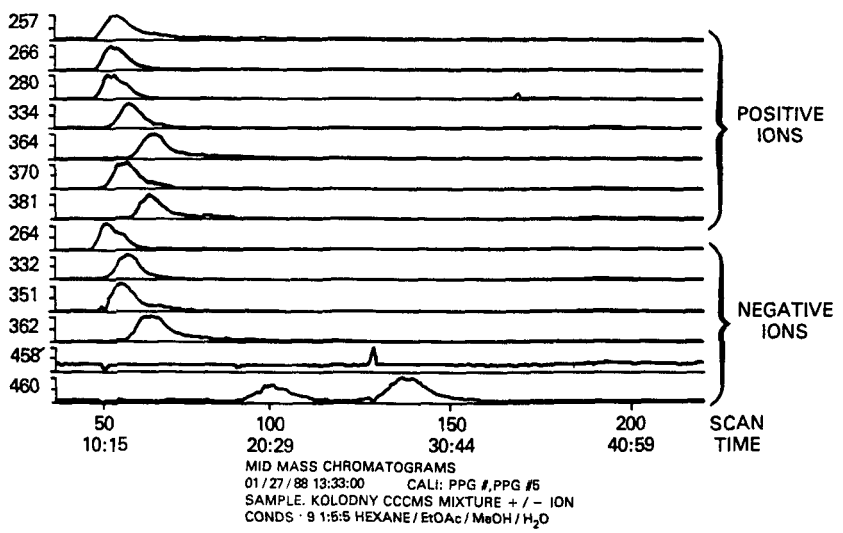
A mixture of indole-3-acetamide (mwt 174), indole-3-acetic acid (mwt 175) and indole-3-butyric acid were separated on a CCC instrument. When a similar separation was performed on the CCC-MS system, the total ion current (RIC) closely followed the UV profile and the compounds were easily identified by the protonated parent ions in their individual mass spectra.

EXAMPLE 2: ALKALOIDS FROM STEPHANIA TETRANDRA S. MOORE

This plant material was previously found to contain the two major alkaloids tetrandrine and fangchinoline with molecular weights 622 and 608 respectively. On countercurrent chromatography a separation was obtained and the two compounds were independently identified. An almost equivalent chromatogram was obtained on the CCC-MS system and clear protonated parent ions were observed in the spectra.

EXAMPLE 3: SYNTHETIC MIXTURE ANALYSIS

A post-doctorate fellow at NIH performed a reaction with possible products at masses 363,459 and 461: From an initial injection into the LCMS (no column), the ions of interest were determined and a dual positive/negative ion mass chromatogram obtained on the CCC-MS. As can be seen in the traces below, we were able not only to detect the compounds but to also show the resolution of the diasterioisomers on the CCC. These compounds had a weak UV absorption but from these results, a large scale purification of the useful product was possible.



SUMMARY:

A standard countercurrent chromatograph and thermospray mass spectrometer were easily connected to provide on-line mass spectrometry data from a countercurrent separation. Only simple hardware modifications were necessary from routine LCMS and these counld be performed in a matter of minutes.

PRELIMINARY STUDIES WITH AN ION CHROMATOGRAPHY MASS SPECTROMETRY SYSTEM

A.S. Al-Omair and J.F.J. Todd, Chemical Laboratory,
University of Kent, Canterbury, Kent, CT2 7NH, U.K.

Ion Chromatography (IC), is a novel analytical technique which permits the separation and determination of ionic compounds. The separation of ions is accomplished by utilizing ion exchange chromatography (IEC), ion pair chromatography (IPC) and ion chromatography exclusion (ICE). A major defect in IC is the lack of a universal detector; on the other hand mass spectrometry provides good detection and structural information for many classes of ions, organic and inorganic compounds.

In this study, the possibility of combining IC with fast atom bombardment mass spectrometry (FABMS) using a continuous flow probe has been investigated. The capacity of the system to handle certain modifiers, such as acids, bases and ion pair reagents, which improve the resolution of the IC, has been examined. The effect of such modifiers on the formation of the protonated molecular ion $[M+H]^+$, fragments and cluster ions has been studied.

A home-made IC has been used, and this consisted of a Waters 6000A pump, a Rheodyne injector model 7125 with 20µl sample loop, Hamilton ion separator columns, a Pye Unicam LC3 UV-detector and a pen recorder. The eluent of the IC was admitted to the FAB source through an SGE splitter (model MCVT-1/50) connected at the end of the flow cell fo the UV detector, and a home-made continuous flow probe fitted with a 0.075 mm vitreous silica capillary column. Positive ion FABMS spectra were obtained on an AEI MS9 double focusing mas spectrometer updated by VG analytical Ltd, using fast xenon atoms (2mA at 8KV).

Three groups of samples have been selected for this study. Inorganic anions (chloride and bromide), water soluble vitamins (ascorbic acid, thiamine hydrochloride, pyridoxine and riboflavin), and glucose derivatives (gluconic acid, glucose, and gluconolactone). In all experiments the eluent of the IC contained 5% glycerol.

1. Analysis of Inorganic Anions Utilizing IEC/FABMS.

A mixture containing fluoride, chloride, nitrite, bromide, nitrate and sulphate in aqueous solution was separated on a Hamilton PRP-X100 column of 4.1 mm I.D. x 250 mm, using 1 x 10^{-4} M potassium hydrogen phthalate as eluent at a flow rate of 1.5 ml/min, Fig. 1. Chloride and bromide have been selected for this study and were admitted to the FABMS. The mass spectra of these two ions showed some cluster ions in the form $[K_{n+1}X_n]^+$ up to n = 3, where X is the inorganic anion.

The formation of high molecular weight cluster ions ($n \geq 4$) could be observed for chloride if the concentration of the chloride was increased. High concentrations of sample require a higher column exchange capacity. However high exchange capacity resins require a highly concentrated eluent to maintain the high resolution of the IC. The disadvantage of increasing the concentration of the eluent, is that the mass spectra obtained contain high intensity background peaks.

2. Analysis of Water Soluble Vitamins by IPC/FABMS

The separation of ascorbic acid, thiamine hydrochloride, pyridoxine and riboflavin was performed using a 4.1 mm I.D. x 150 mm PRP-1 column, and 2 x 10^{-5} M hexane sulphonic acid in 50% V/V aqueous methanol containing 1% acetic acid as eluent, and was pumped through the system with a flow rate of 0.7 ml/min, Fig. 1. The mass spectra of riboflavin and thiamine showed that the molecular ion is more stable in it's protonated form, and that no peak was observed in the $[M+H+Na]^+$ region, Fig. 2. However, the molecular ions of pyridoxine and ascorbic acid showed stable molecular ions in the $[M+H+Na]^+$ form of about 20% and 10% relative intensity respectively of the protonated molecular ion $[M+H]^+$. This is may be related to their acidic property, and the existence of the Na^+ ion in the eluent.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

3. Analysis of Glucose Derivatives by ICE/FABMS

The analysis of gluconic acid, glucose and gluconolactone was performed using a 4.2 mm I.D. x 150 mm PRP-X300 IC column. The eluent was 1 x 10^{-4} M Na_2HPO_4 in water, and the flow rate was 0.3 ml/min. The mass spectra of gluconic acid showed no significant peak in the molecular ion region. Other sugars were found to be present in the two molecular ion forms $[M+H]^+$ and $[M+H+Na]^+$. Glucose was found to be more stable in the $[M+Na]^+$ form, and gluconolactone was found to have a considerable stability in the $[M+H+Na]^+$ form. This is may be related to the concentration of Na in the eluent, and also to the acidic properties of these two sugars.

IC/FABMS in it's three separation modes has proved to be a reliable technique for the analysis of three classes of ionic compounds although for successful results the chromatographic conditions have to be optimized.

In this study the conditions were optimized for the study of various known compounds, and more study is needed to evaluate the sensitivity and the reliability of the system to analyze unknown compounds.

For inorganic anions the formation of the cluster ions (e.g. $[K_{n+1}X_n]^+$) is observed, and thought to be governed by the sample concentration, column efficiency and eluent concentration. In the analysis of organic ions, the molecular ion in the form $[M+H+Na]^+$ may be governed by the existence of Na ions in the eluent, and the acidity of the compound itself.

DEVELOPMENT OF A THERMOSPRAY HPLC INTERFACE FOR FTICR

W.G. Millen, J.T. Meek, G.W. Stockton, M.L. Thomson and R.S. Wayne,
American Cyanamid Agricultural Research Division, Princeton, New Jersey, 08540

Summary - A thermospray LCMS interface was installed on an FTICR with an external ion source design. The thermospray source was capable of accepting a 2 cc/min flow from an HPLC column while maintaining a $7x10^{-8}$ torr pressure in the ICR cell. At this pressure a FWHM resolution of 47,000 was obtained at m/z = 289. Accurate mass measurements made with errors <2 ppm demonstrated that this instrument combination was successful.

Instrumental - The FTICR used for this work incorporates an external source, three cryopumps and a 7 Tesla magnet. The three cryopumps are mounted on 10 inch flanges and provide a high pumping speed (4000 l/sec H_2O, 1500 l/sec air) to each of the three differentially pumped chambers. The external ion source was built from an Extrel model C-50 ion source and quadrupole with the quadrupole operated in an RF-only mode to eliminate low mass reagent ions which would saturate the ICR cell. A standard thermospray LCMS interface, made by Vestec to connect to Extrel's electrical contacts, was modified by Vestec only to the extent necessary to be compatible with the 10 inch cross used for the source vacuum manifold.

Experimental - The system was tested using a conventional HPLC pump, column and solvents used in analytical separations work. The only concessions made in the operation of the LCMS system are that a high pressure detector cell is used for the in-line uv detector and that analyses are performed at the 1 cc/min optimum flow rate suggested for the thermospray ion source.

The FTICR's vacuum manifold was removed from the magnet and pressure measurements made in each of the vacuum regions while operating the thermospray system. Analyzer pressures of 3.6×10^{-8} and 6.9×10^{-8} torr were obtained at 1 and 2 cc/min solvent flow rates and demonstrated the basic capability of the system for producing high resolution mass spectra.

Sample Analyses - Samples of imazamethabenz (CAS 81405-85-8(mx)) and hydramethylnon (CAS 67485-29-4) were injected onto the thermospray LCMS/FTICR system and data acquired during the elution of each peak. Hexaethylene glycol was added to the solvent to provide a lock mass for monitoring space-charge-induced frequency shifts[1]. The spectra produced (Figures 1 & 2) show that high resolution has been maintained and that accurate mass analysis with errors less than 2 ppm are achieved on this LCMS/FTICR system.

A sample of Gramicidin S also was injected into the system and a FWHM resolution of 11,000 was obtained for its protonated molecular ion. An average error less than 2 ppm was obtained for the elemental composition of its protonated molecular ion; however, a standard deviation of 8 ppm may reflect the absence of a lock mass during the analysis of this sample.

Conclusions - A thermospray LCMS interface can be installed on an FTICR mass spectrometer with an external ion source design. The enhanced vacuum obtained from this design extends the usefulness of the FTICR for making accurate mass measurements to thermally labile compounds or to complex samples for which chromatographic separations are required.

NEW DESIGN OF A SPLITTER FOR FRIT-FAB LC/MS AND BATCH LIQUID INLET SYSTEM

T.Kobayashi, K.Matsuura, K.Otsuka, E.Kubota
Y.Itagaki, B.D.Musselman, and T.Higuchi
MSG JEOL LTD, 3-1-2 Musashino Akishima Tokyo 196 Japan

Introduction

FRIT-FAB LC/MS interface is a suitable analytical tool for mass spectral determination of thermolabile or nonvolatile compounds (1). In order to connect its interface to a conventional HPLC column, a new splitter has been developed. The performance of the splitter can control the effluent from the column at several micro liter per minute. Using this splitter the reproducibility and sensitivity of FRIT-FAB LC/MS is evaluated.

Principle and characteristics of the new splitter

Fig.1 shows an outline of the splitter and the interface. The splitter is installed at the column outlet. A pressure of several kg/cm^2 is applied to the column outlet by nitrogen gas. A part of effluent flows in a frit although most is exhausted to a drain through a needle valve. The frit flow introduced to the frit depends on the viscosity of the mobile phase and the resistance of the fused silica capillary tube to the frit, and can be controlled by V1. Fig.2 shows the relationship to the split pressure(p), column flow rate and the frit flow. The frit flow is constant over a column flow rate of 50 μl/min to 0.9 ml/min, and proportional to p. The minimum frit flow can be controlled to less than 1 μl/min.

Experimental

The equipment used was the JMS-DX303 mass spectrometer with a JMA-DA5000 data processing system(JEOL). The LC pump used was the TRI ROTAR-V(JASCO). Glycerol was used as the matrix for FAB ionization. LC/MS conditions were as follows ; the column was SFPAK ODS-5S25 1.7mm x 25cm(JEOL), the column flow rate was 150 μl/min and the frit flow was 5 μl/min(split ratio 1/30). The ionization chamber temperature was set at 50 ℃, and Xe gas of a primary beam energy of 4 Kev was selected.

Results and Discussion

Fig.3 shows the selected ion monitoring profile of m/z 363 M+H peak for hydrocortisol, replicated 300 ng(100ng × 3μl) injections to column for an hour. The chromatogram peak's shape was sharp and symmetrical. This indicates that there is no dead volume in the interface with the splitter. The reproducibility of the chromatogram peak intensity was 4.8% (n=19) as a coefficient of variation. Fig.4 shows the detection sensitivity was as high as S/N 10 with the selected ion monitoring profile of m/z 363 for 33 pg of hydrocortisol.

A DIRECT LIQUID INLET FOR TIME-OF-FLIGHT MASS SPECTROMETRY USING RESONANCE ENHANCED MULTIPHOTON IONIZATION

G.R. Kinsel, K.R. Segar, M.V. Johnston
Department of Chemistry, University of Colorado, Boulder, CO 80309

We have developed a direct liquid inlet suitable for use in a time-of-flight mass spectrometer with resonance enhanced multiphoton ionization (REMPI). REMPI offers several advantages for LC-MS:

1. Efficient generation of either soft or hard ionization.
2. Wavelength selective ionization based upon ultraviolet absorption properties. No solvent background will appear in the mass spectrum.
3. The potential for enhanced isomer distinction by selecting the optimum laser wavelength for ionization.

The liquid is pumped through a 45 um diameter fused silica restricting capillary and vaporized in a concentric flow of helium gas. The resulting mixture is then expanded through a 350 um diameter nozzle into the source region of the mass spectrometer. A pressure of 2 to 5 x 10^{-5} torr (depending upon the helium backing pressure in the nozzle) is maintained in the source region by a cryotrapped 6 inch diffusion pump. Further details concerning the inlet design can be found in the 1987 ASMS Conference Proceedings, pp. 405-406.

Figures 1-2 illustrate the inlet operation for a relatively nonvolatile compound, tryptophan. The spectrum in Figure 1 was taken using a glass nozzle heated to a nominal temperature of 165°C. This temperature is too low to thermally desorb tryptophan from a heated probe. (In fact, thermally desorbed tryptophan exhibits extensive sample decomposition.) The inlet can be operated for several hours at this temperature without clogging. There is no evidence of tryptophan precipitation in the restricting capillary, on the inner walls of the nozzle assembly, or at the nozzle orifice even after many hours of operation. In an effort to improve heat conduction to the liquid/gas mixture in the nozzle assembly, the glass nozzle was replaced by a brass nozzle. With the brass nozzle, tryptophan could be observed by heating to a nominal temperature of 135°C (Figure 2). These results suggest that the gas nebulized approach to liquid vaporization has great potential as a liquid inlet for mass spectrometry.

THERMOSPRAY AND NEGATIVE IONS.

PURE ELECTRON CAPTURE PROCESS BY DISCHARGE IONIZATION.

F. de Maack, G. Devant, M. Lesieur, C. Beaugrand.

SN NERMAG 49, quai du Halage 92500 RUEIL-MALMAISON (France).

The predictability of Thermospray (TSP) spectra is limited by several factors: among them, ionization process, source temperature, flow rate, repeller voltage, electrolyte and sample concentration.

In negative ion mode this situation is complicated by the additional possible occurence of two competitive ionization processes : deprotonation and electron capture, leading to two different molecular ions $(M-H)^-$ and M^- respectively.

Usually it is not possible to obtain pure electron capture process in presence of ammonium acetate at 1 mL/mn flow rate even with a 1000 eV Rhenium filament.

In this paper we report unambiguous spectra in negative ion mode on the antibiotic Chloramphenicol. This non-volatile and thermolabile compound has been studied in LC-MS successively with TSP ionization only and discharge ionization.

A pure TSP ionization is easily observed at a 1mL/mn flow rate of 0.1 M acetate ammonium and leads to M-1 species without fragmentation (Figure 1).

The TSP source is also equipped with a repeller and we demonstrated that this additional electrode at 400 Volts acts as a discharge and leads to the observation of "mixed" spectrum resulting from both competitive ionization processes.

In discharge-on mode, opposite to filament-on mode, a pure electron capture ionization leading to M^- species with extensive fragmentation can be obtained in presence of ammonium acetate (Figure 2).

These two resident ionization capabilities have been complementary used for molecular weight assessment of a potent antiparasitic agent namely AVERMECTIN B1a (Figure 3).

In some cases, e.g. Vitamin B_2 namely, Riboflavin, the discharge is the only ionization mode providing a valuable spectrum in LC/MS with the resulting fragmentation (Figure 4).

Thus we demonstrate that Electron Capture and Proton Abstraction, two competitive ionization processes in a classical TSP Source can be clearly separated.

The Electron Capture is the predominant ionization mode during the DISCHARGE operations even in presence of ammonium acetate.

The major effect of Repeller is an increase of signal intensity and at higher potentials, it is a key parameter for extensive fragmentation.

2) Kenan Laboratories of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514

The combination of liquid chromatography with mass spectrometry (LC/MS) is one of the most useful analytical methods currently available. Unfortunately, these two techniques are difficult to couple together in a manner where the full power of both LC and MS can be simultaneously utilized. This problem has stimulated the development of a variety of different LC/MS interfaces. The ideal LC/MS interface will allow the use of optimum LC conditions (flow rate and mobile phase composition) while still permitting the acquisition of the most useful classes of mass spectra [electron impact (EI), positive ion chemical ionization (PICI), and negative ion chemical ionization (NICI)].

Most LC/MS interfaces have difficulty in eliminating the large amount of vapor generated by the mobile phase which can result in high source pressures which, in turn, leads to chemical ionization of the analytes. While CI mass spectra give molecular weight information, the minimal amount of fragmentation that is found in CI spectra precludes obtaining structural information without resorting to MS/MS methodology. Only if the source pressure is sufficiently low will EI mass spectra be obtained. Towards this end many LC/MS interfaces resort to elaborate (and expensive) pumping/skimming and/or moving belt techniques to remove the mobile phase vapor. A very attractive alternative is to utilize an inexpensive LC method which not only has <u>very</u> low mobile phase flow rates (nl/min) but offers superior chromatographic separation efficiency - Open Tubular Liquid Chromatography (OTLC).

OTLC utilizes glass or fused silica capillary columns with an i.d. of from 2 to 20 microns and with lengths of from 1 to 10 meters. These columns have stationary phase coated/bonded on the capillary wall similar to capillary open tubular GC columns. Separation efficiencies of greater than 1,000,000 plates can be obtained with mobile phase flow rates of from 1 to 100 nl/min ([1]). This low flow rate permits direct introduction of the entire OTLC effluent into the MS source without significantly increasing the pressure of the source, and thus EI mass spectra can be directly obtained from the OTLC system.

OTLC columns have been successfully interfaced with MS using a probe which is introduced into the mass spectrometer via the direct insertion probe inlet ([2]). Tapering and heating the end of the OTLC column allows for the detection of compounds of low volatility and/or thermal stability while maintaining good chromatographic peak shape.

The utility of the OTLC/MS interface with quadrupole, ion trap, and magnetic sector instruments has been investigated. Both quadrupole and magnetic sector instruments were found to work well with the OTLC interface with a variety of different analytes and mobile phases (Figures 1 & 2). The magnetic sector instrument generally gave better results. It was able to successfully analyze several compounds which were not detected on the quadrupole instrument, such as adenine and iso-leucine, and also gave better S/N ratios for equivalent amounts of analytes. While a modified version of the OLTC/MS probe was successfully used with the ion trap instrument with non-polar compounds, the ion trap's intolerance for mobile phases containing methanol and/or water severely restricted the utility of the OTLC interface with the ion trap.

DEUTERIUM EXCHANGE AND ACTIVE HYDROGEN DETERMINATION IN MULTICOMPONENT ANALYSIS BY COMBINED LIQUID CHROMATOGRAPHY/THERMOSPRAY MASS SPECTROMETRY

Charles G. Edmonds, Steven C. Pomerantz, Fong Fu Hsu and James A. McCloskey
Department of Medicinal Chemistry, University of Utah, Salt Lake City, Utah 84112

Deuterium labeling of organic compounds plays an important role in mass spectrometry in studies of ionic reaction mechanisms, and in applications involving structural characterization. The on-line exchange of deuterium for protium during combined chromatography-mass spectrometry is advantageous because of its direct applicability to mixtures and because high exchange levels with minimum back exchange can be obtained. Directly combined LC/MS provides particular advantages in the analysis of polar compounds for which GC/MS is less well suited. Deuterium-protium exchange using DLI LC/MS was first reported by Henion (1). We report experimental details of thermospray LC/MS carried out in buffered D_2O, useful for studies of reactions associated with thermospray ionization and for structural characterization of constituents of multicomponent mixtures. Exchange levels of heteroatom-bound hydrogen at levels greater than 96% can be routinely achieved. H/D exchange using thermospray LC/MS, with $CH_3CO_2ND_4$-D_2O mobile phase and conventional flow reversed-phase HPLC has been used in this laboratory for several years (2), and the application of this method to the structure elucidation of new nucleosides from RNA has been previously reported (3). Experimental details will be published elsewhere (4). The maximum extent of exchange, measured using the disaccharide trehalose, is 97±1%D (n = 3). This is approximately the same as can be obtained with FAB from deuterated glycerol (5), although the FAB method requires care to avoid back-exchange during sample handling. Exchange levels using the LC/MS method are probably equivalent to the best levels obtained from chemical ionization with labeled reagent gases (6).

Deuterium exchange from a variety of substances is shown in Table 1, emphasizing cases in which some slightly acidic hydrogens nominally bound to carbon have undergone partial exchange. For example, exchange of enolizable hydrogen (22%) is observed in prostaglandin E_1. Additionally, exchange in the tripeptide leu-trp-met is observed and may arise from the imidazole portion of the molecule, mirroring similar exchange of aromatic hydrogens during chemical ionization with labeled reagent gases (6,7). Significant exchange of slightly acidic hydrogen was observed in the purine nucleosides, and is attributed to H-8, which can be quantitatively exchanged in solution by heating for several hours at neutral pH (pD). Partial exchange of H-8 (e.g., adenosine) was found to be generally reproducible from run to run, and relatively insensitive to changes of pD (over a range suitable for reversed-phase HPLC) and vaporizer operating temperatures (vaporizer tip 255-296°C, vapor 280-302°C). Some partial exchange of one hydrogen in cytidine takes place, as anticipated from the slightly acidic character of H-5 in solution.

The D_2O thermospray exchange method may be applied in studies of reactions associated with thermospray ionization, and as an element of structural characterization. An example was given by the differentiation of the isomers N^4,2'-O-dimethylcytidine (1) and 5,2'-O-dimethylcytidine (2), possible constituents of transfer RNA of thermophilic bacteria (3). LC/MS in D_2O of an enzymatic digest of nucleic acids revealed the unknown to contain four active hydrogens in the neutral molecule, in favor of 2.

Experience in applying this method to LC/MS analyses similar to those demonstrated above, involving 20- to 40-component mixtures, with many constituents chromatographically unresolved and in the nanogram range, has provided numerous examples of the utility of the exchange method in confirming and correcting assignments made on the basis of (protium) LC/MS data, and in providing useful deuterium shift data on new or unexpected components.

HYDROGEN-DEUTERIUM EXCHANGE STUDIES UTILIZING A THERMOSPRAY MASS SPECTROMETER INTERFACE

Marshall M. Siegel

American Cyanamid Company, Medical Research Division
Lederle Laboratories, Pearl River, NY 10965

SUMMARY

A routine and efficient technique.refered to as the "sandwiched slug injection technique", was developed for exchanging acidic hydrogen for deuterium, utilizing a thermospray mass spectrometer interface, to produce deuterium enriched deuteron-adduct molecular and fragment ions. Samples dissolved in solvents containing acidic deuterium atoms (D_2O/trifluoroacetic acid-d_1 or ammonium acetate-d_4) were introduced via slug injection into the thermospray interface sandwiched between slugs of the deuterated solvent. At all other times, the carrier solvent system introduced into the mass spectrometer consisted of a non-deuterium enriched mixture. Deuterium enrichments achieved were greater than 95%. Deuterium enriched deuteron-adduct molecular and fragment ions enabled the determination of the number of acidic hydrogens and aided in structural elucidation of model compounds of pharmaceutical interest.

EXPERIMENTAL

The spectra were obtained on a Vestec thermospray interface (Model 101) coupled to a Hewlett-Packard mass selective detector (Model 5970) and data system (Series 200 computer with ChemStation software). The interface temperatures were: control ~135 °C, tip 160-170 °C, block 280-285 °C and auxilary tip ~295 °C. These moderately high temperatures were chosen to induce thermal degradation and fragmentation [1]. For most of the experiments, the interface operated in the discharge ionization mode where a discharge electrode, maintained at 1 kV, was used to ionize the vapor exiting the vaporizer nozzle.

Two deuterated solvent systems were used in these studies. One consisted of D_2O/trifluoroacetic acid-d_1 (TFA-d_1) [1mL/3µL, pD ~ 1.3] where the TFA-d_1 served as an acid catalyst to enhance the exchange rate The second solvent system consisted of ammonium acetate (NH_4Ac) dissolved in the D_2O/TFA-d_1 solution to effectively produce 0.1 M ND_4Ac, a nearly neutral [pD ~ 5.8] buffered solution. (Similar experimental results were obtained when using 0.1 M ND_4Ac prepared by titrating ND_4OD with acetic acid-d_1.) To fully dissolve samples which were only partially soluble in these solvent systems, small amounts of acetonitrile methanol-d_1 and/or chloroform-d_1 were added until solubility was achieved. Solutions of the pure compounds were prepared in the deuterated solvents (~5mg/mL), thereby, exchanging the acidic hydrogen atoms in the compounds for deuterium.

A sample loop of 200 or 500 µL was used in which a sample volume of 2 - 15 µL was injected, preceded and followed by 50-200 µL and 100-200 µL, respectively, of deuterated solvent. At all other times, the carrier solvent system introduced into the mass spectrometer was a non-deuterium enriched mixture consisting of methanol/methylene chloride/water (48/48/4 v/v/v) flowing at 1.0 mL/min. This carrier solvent system was chosen since it behaves as a "universal solvent", thereby, minimizing the likelihood for blockage of the vaporizer probe. The mole fraction deuterium enrichments were computed using the "Average Mass Approach" developed by Blom and co-workers [2] for nominal mass data or by dividing the difference in average mass between the enriched and unenriched samples by the number of labile hydrogen atoms in the molecule.

RESULTS AND DISCUSSION

A variety of pharmaceutically important compounds were studied utilizing the sandwiched slug injection technique These compounds contained from 4 to 11 labile hydrogen atoms. As noted in Table I, the percent mole fraction enrichment of deuterium for the compounds ranged from 97.6% to 109.8%. A comparison of the unenriched and deuterium enriched discharge ionization spectra for VAAF and VAAF-d_6 are illustrated in Figure 1. The mass shift between the corresponding ions in the unenriched and enriched spectra correlate with the fragmentations illustrated with the structure in the figure. The key in getting these high deuterium enrichments is the sandwich of solvent around the sample The sandwiched slug injection technique optimizes the hydrogen-deuterium exchange process in both the condensed and gaseous phases. In the condensed phase, excess deuterium containing solvents and catalysts drive the exchange process to completion,

while, in the gaseous phase, the slugs of deuterium containing solvents, introduced before and after the sample, deuterate substances adsorbed on to the surface of the source thereby minimizing back exchange of deuterium for hydrogen. The net result is that the thermospray plasma remains rich in deuterium and more than 95% of the labile hydrogen atoms are exchanged with deuterium utilizing this technique.

If only a slug of the deuterium enriched sample is injected into the TSP system without the sandwich of deuterium enriched solvents, deuterium enrichment is only 40% to 50%. This is insufficient for structural elucidation because the ion distribution is very broad, making it virtually impossible to determine accurately the number of labile hydrogens. Although deuterium enrichment of the sample in the condensed phase is very high, the deuterium atoms back exchange in the gas phase with the hydrogen atoms present in the unenriched carrier solvent.

An interesting feature appearing in the spectra of ampicillin is the pair of abundant ions at m/z 195 and 196. The structures of these ions correspond to substituted ketenes generated from the [2 + 2] retro-cycloaddition (decomposition) of the β-lactam ring. Scheme I illustrates a possible gas phase mechanism for rationalizing the formation of the pair of ions. The hydrogen atom on the deuteron-adduct ketene group, readily undergoes exchange for deuterium via a neutral substituted alkynol, to produce the deuterium enriched ketene. This exchange mechanism is due to resonance stabilization of the delocalized charge associated with the deuteron-adduct ketene molecule.

SFC/MS ANALYSIS OF BIOLOGICAL SAMPLES WITH ELECTRON IONIZATION, Jack Henion, Per Olof Edlund, Edgar Lee, and Lee McLaughlin, Equine Drug Testing and Toxicology, Cornell University, 925 Warren Drive, Ithaca, NY 14850

The general acceptance of supercritical fluid chromatography (SFC) by analytical chemists appears to be dependent upon its successful combination with mass spectrometry (MS). The combination of these two analytical techniques (SFC/MS) could offer some of the following benefits over GC/MS and LC/MS: faster separations and better chromatographic efficiency then LC/MS, the ability to handle higher molecular weight and more thermally labile compounds than GC/MS, and more facile electron ionization then LC/MS. The latter feature is of particular interest to those who need appropriate structural information for the identification of unknown compounds.

There are two approaches to SFC/MS which parallel modern GC/MS and LC/MS. The first utilizes open tubular columns of somewhat smaller internal diameters than capillary GC/MS. The other uses packed columns of the same type used in modern LC/MS. Although we have evaluated both of these approaches, this paper will present data obtained from packed-column SFC/MS using supercritical carbon dioxide doped with methanol. The novel aspect of this work is the use of a heated, pneumatic nozzle and a two-stage momentum separator for enrichment of the expanded mobile phase prior to transfer of the analyte to the mass spectrometer electron ionization (EI) source. This approach provides full-scan (m/z 50-MW) EI mass spectra from an unmodified conventional EI mass spectrometer.

EXPERIMENTAL

A Hewlett-Packard Model 1084B HPLC system modified for SFC was connected to a homemade heated pneumatic nozzle "probe" which was positioned inside a homemade ambient temperature desolvation chamber. The latter was connected directly to a two-stage momentum separator which was pumped in the first stage by a 400 L/min rotary pump while the second stage was pumped by a 300 L/min rotary pump. The two-stage momentum separator was attached directly to a half-inch o.d. by three-eights inch i.d. tube which was inserted through the standard direct insertion probe vacuum lock of an unmodified Hewlett-Packard Model 5985B GC/MS system. The heated pneumatic nozzle was a modified homemade thermospray probe which accommodated a 50 micron i.d. x 40 cm fused-silica capillary housed in the central 0.010 in i.d. x 0.062 in o.d. stainless steel capillary tube. The central fused-silica capillary acted as a linear restrictor for transport of the carbon dioxide/methanol mobile phase mixed post-column with a make up liquid consisting of methanol, ethanol, or isopropyl alcohol. The flow of the supercritical fluid mixture was maintained at 0.8 mL/min while the make up flow liquid was maintained at 0.3 mL/min. A co-axial flow of helium nebulizing gas was maintained at 0.5 L/min in the annular space between the inside of the stainless steel central capillary tube in the probe and the outside of the central fused-silica capillary. The heated copper probe tip was maintained at 60 degrees during the course of this work. No additional heating was supplied to the desolvation chamber or the two-stage momentum separator. The EI ion source was maintained at 250 degrees.

RESULTS AND DISCUSSION

The packed-column SFC/MS system described in this work was used to obtain full-scan and SIM EI mass spectral data on a variety of compounds. These included coenzyme Q-10, stanozolol, several corticosteroids, 2,4-D and its methyl ester, in addition to several Irganox polymer additives and xanthine-related drugs. In addition, the identification of prednisolone and several of its metabolites were identified in a biological extract of equine urine.

Figure 1 shows, for example the EI packed-column SFC/MS TIC and mass spectrum for prednisolone identified in an ethyl acetate extract of an equine urine collected 2 hours post-administration of prednisolone to a horse. The extracted ion current profile for the base peak of this drug is observed at 5 min retention time and the EI mass spectrum is shown in the lower panel of Figure 1.

CONCLUSIONS

The packed-column SFC/MS system described provides access to EI mass spectra for moderately polar, thermally labile and relatively involatile organic compounds which may be isolated from biological samples. The system has operated for several months on a daily basis with no unusual adverse effects on the mass spectrometer. Conventional tuning procedures are used while ion source cleaning is no more frequent than with GC/MS techniques.

The most serious shortcoming of the present results is the low sensitivity obtained with compounds studied to date (1-5 micrograms on-column for good quality, full-scan SFC/MS EI mass spectra). There appear to be significant transmission losses within the two-stage momentum separator as evidenced by visible build-up of sample around the first skimmer of this device. This may result from inadequate pumping at the two stages of the separator and/or the formation of very small particles which lack the necessary momentum to be efficiently transferred through the separator under the SFC conditions used in this work. Work continues to significantly improve the sensitivity of this system. If the full-scan detection limits could be improved to the 20 ng level we believe this approach would be a very useful and rugged analytical technique.

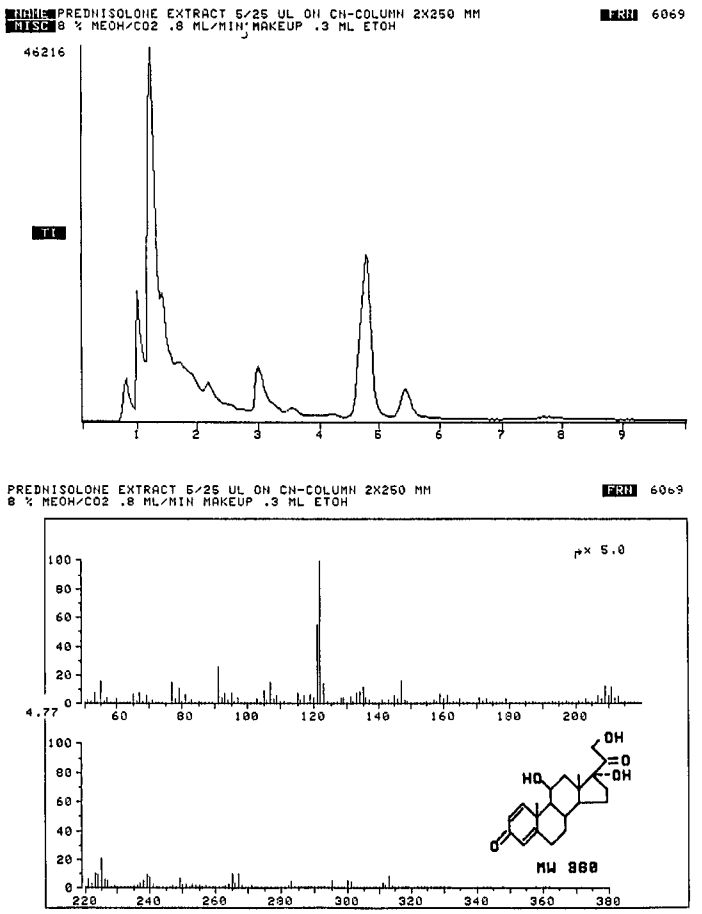

Figure 1. Packed-column SFC/MS full-scan EI mass spectrum of prednisolone (retention time 4.8 min) detected in the extract of an equine urine collected 2 hours after the administration of prednisolone. The peak at 5.4 min retention time is a metabolite, 20-hydroxy prednisolone.

APPLICATIONS OF SFC-MS TO TOXINS AND COMPOUNDS OF BIOLOGICAL INTEREST

H. R Udseth, H. T. Kalinoski, and R. D. Smith
Chemical Methods and Separations Group
Chemical Sciences Department
Pacific Northwest Laboratory, Richland, WA 99352

The principal applications of supercritical fluid chromatography (SFC) are for compounds that are thermally labile, of low volatility, and of low to moderate polarity. Many compounds of biological and pharmaceutical interest are defined by these criteria. Recently, applications of SFC and SFC-MS to the determination of lower molecular weight compounds of interest due to their biological activity were described (1,2).

As the technique of SFC has developed, CO_2 has become the most widely used mobile phase. Its low critical temperature, 32 °C, makes it an attractive choice for separation of thermally labile compounds. Unfortunately the solubility of many thermally labile compounds with biological activity in CO_2 is insufficient. Experience has shown that the addition of a small amount of modifier, usually 1 to 10% methanol or isopropanol, can dramatically increase the solubility of selected compounds.

The use of both packed and open tubular capillary columns in SFC has become an established as useful compliments. Most initial SFC work was done with packed columns. The initial development of SFC-MS, however involved the use of open tubular fused silica capillary columns due to their more easily addressed flow rates. These columns usually provide greater efficiency than packed columns, but when the efficiency needed for a given analysis is less demanding the speed and sample capacity of packed columns becomes advantageous. Techniques for using both types of column are now sufficiently well established that the optimum type of column for a given separation can be used.

For interfacing to mass spectrometry this desired flexibility in column choice is more difficult to accommodate due to the much higher flow rates typically used in packed columns. We have previously developed a High Flow Rate (HFR) interface that accommodates the higher flow rates of microbore packed columns which can also be used with larger diameter capillary columns at high flow rates and with splitless injection (3).

In this work we have examined selected compounds of moderate to high molecular weight with biological activity. We have used the HFR interface with CO_2 as the mobile phase with from 2 to 5% modifier. A standard gas chromatography (GC) oven was used to contain the capillary column. Both 20 m and 30 m X 100 µm i.d. capillary columns were used. They were coated with a 0.5 µm thick bonded and crosslinked stationary phase of 5% phenyl methylphenylpolysiloxane stationary phase. The 1 mm X 10 cm C-18 (5 µm particles Alltech Associates) microbore column was contained in the inlet probe so as to minimize the length of the transfer line.

One class of compounds potentially addressable by SFC-MS are cyclic peptides (4). These polar compounds require the use of polar fluid modifiers with CO_2 as the mobile phase. The ionic nature of the more hydrophilic portions of such polypeptides can sometimes be shielded, allowing solvation in supercritical fluid solvents. We used cyclosporin A as an example of such a compound. It is a cyclic undecapeptide which exhibits strong immunosuppressive properties.

The compound was successfully separated by SFC-MS using a microbore column using a 2% methanol modifier The compound was also successfully separated with a capillary column. With the capillary column 2% 2-propanol was adequate, whereas with the microbore column more polar methanol was needed. The mass spectra were identical in both cases. The protonated molecular ion (m/z 1203) dominates the spectra and the only other significant peak corresponded to the loss of the largest side chain.

Care must be taken in generalizing these results. Our attempts to chromatograph the cyclic heptapeptide microcystin-LR were unsuccessful even when the modifier content was increased to 5% and the temperature raised to 100 °C. Microcystin-LR is markedly more polar than cyclosporin A (having an amine residue on one of its side chains) which probably accounts for the difference in fluid phase solubility.

Polyethers constitute another class of high molecular weight biologically active compounds of moderate polarity which may be amenable to analysis by SFC-MS. We analyzed the sodium salt of two ionic polyethers, maduramicin a (mol. wt. 938) and a related compound of mol. wt. 996 (5). These compounds are commonly referred to as ionophores. They are potent antibiotics that chelate with ions and transport them across cell membranes. We were not successful in using the microbore column, but 2% isopropanol in CO_2 at 60 °C allowed separation with the capillary column. The peaks showed substantial tailing and this coupled with the low transmission of the quadrupole at high m/z forced operation with reduced resolution (~ 500). The results nonetheless show the mass spectra are dominated by the protonated molecular ion. These results show that the salt is dissolved as an intact ion pair. Small salts are very insoluble in supercritical fluids, but when the hydrophobic region of the molecule becomes large enough the intact compound will often dissolve in fluids such as CO_2.

These compounds are generally thermally labile (~100 °C). This can be used to advantage by controlling fragmentation through changes in the tip heater. The result of raising the indicted temperature from 145 °C to 300 °C is to increase the fragmentation. This increase in fragmentation is potentially useful for compound identification. By raising the modifier content to 5% and the oven temperature to 100 °C the efficiency of the separation was substantially improved. This increase in signal allowed us to increase the resolution to unit mass. The nominal mass was set to 939. The isotopic pattern was clearly seen as was the lack of fragmentation. No decomposition was observed at these temperatures.

Our attempts to work with another polyether, brevetoxin (PbTx2, mol. wt. 894) were only partially successful. A spectra containing the molecular ion and a characteristic fragment loss was obtained, but at low resolution with low sensitivity.

Another class of compounds that is potentially addressable with modified supercritical fluids is unsaturated ring systems of moderate polarity. As an example we took a look at a series of cardio and vascular stimulants of decreasing solubility: khellin (mol. wt. 260), digitoxigenin (mol. wt. 374), digoxigenin (mol. wt. 390) and cymarin (mol. wt. 548). These separations used a 30 m capillary column with 5% isopropanol at 100 °C. Khellin was detected with excellent sensitivity and gave a spectrum that was dominated by the protonated molecular ion. The sensitivity for digitoxigenin was also good, but less than that for khellin. The eluting peak was symmetric with little tailing and the spectrum showed a small amount of fragmentation and adduct ion in addition to the protonated molecular ion. Digoxigenin had a sensitivity comparable to that of digitoxigenin and the eluting peak was similar in shape. The spectrum was still dominated by the $(M+H)^+$ ion, but showed much more fragmentation. Cymarin, which contains a sugar unit, is a more interesting case. Our previous experience with SFC of sugar containing compounds suggested that they would have very low solubility in these supercritical fluids. Cymarin, however was found to elute quite nicely. The spectrum showed considerable fragmentation and while the molecular ion was not the base peak, it was still prominent and the fragmentation gave useful information.

Although supercritical CO_2 has limited solvating powers, the addition of modifiers can extend its useful range substantially. Success with highly polar compounds is still problematical. However, if the polar regions can be successfully shielded by low polarity hydrophobic regions, then the possibility exists of solvation in modified fluids. This is clearly seen for the examples of the ionophores, where a large polyether ion pair has been successfully analyzed by SFC-MS. The stimulant cymarin is another clear example. It is difficult to generalize from these examples but it is safe to say that the application of SFC-MS will continue to grow on a case by case basis. Additional considerations relevant to direct injection SFC-MS are related to compound vapor pressure and to the particular interface design in regards to the flow restrictor region and effectiveness of heat transfer during the fluid expansion (decompression).

We thank the U. S. Army Medical Research Institute of Infectious Diseases for support of this work.

SUPERCRITICAL FLUID CHROMATOGRAPHY-MASS SPECTROMETRY (SFC/MS) USING A SIMPLE CAPILLARY-DIRECT INTERFACE

Steven B. Hawthorne and David J. Miller
University of North Dakota
Energy and Mineral Research Center
Grand Forks, North Dakota, 58202

The combination of supercritical fluid chromatography with mass spectrometry (SFC/MS) provides a powerful new approach to the separation and identification of non-volatile and thermally-labile compounds. In general, methods that have been used for interfacing SFC with MS require modifications of existing mass spectrometer interfaces and/or of the ion source which require dedication of the mass spectrometer to SFC/MS. We have developed a simple and effective SFC/MS interfacing method that requires no modification of a commercially-available quadrapole MS, and allows the mass spectrometer to be used for both capillary SFC/MS and GC/MS with a minimal conversion time.

SFC separations were performed using a Lee Scientific Model 501 supercritical fluid pump and split injections (split ratio ca. 1:20). All separations were performed using CO_2 as the carrier fluid at a temperature of 125 ^{o}C and a 10 meter J & W DB-5 or a Lee Scientific SB-phenyl-5 (50 µm i.d.) capillary column. Column pressure was maintained using an integral "Guthrie" restrictor. The restrictor was constructed to yield a gas flow rate of approximately 3 mL/min at 200 atm CO_2 resulting in a source pressure of approximately 5×10^{-5} torr. The physical strength of this restrictor allows the column to be installed and removed without breakage.

A Hewlett-Packard model 5988 GC/MS was modified for SFC/MS by simply installing the SFC injection valve on the outside of the chromatographic oven. The SFC column was then inserted through the interface transfer line until the column restrictor end just entered the ion source. After initial installation of the SFC injector, converting the instrument from GC/MS to SFC/MS and back is achieved simply by installing the appropriate chromatographic column. Since the 5988 allows columns to be changed without venting the source, the conversion can be accomplished in less than 20 minutes. Mass spectrometry was performed in the chemical ionization mode (CI) using methane as the reagent gas at a source pressure of approximately 0.3 torr with polydimethylsiloxane as the CI tuning compound.

The ability of the capillary-direct interface to yield good chromatographic peak shapes is demonstrated in Figure 1 by the SFC/MS total ion current chromatogram of PEG 600 (no background subtraction has been used for either Figure 1 or 2). Figure 2 shows that good sensitivity is achieved and that full scan (160-500 amu) spectra can be obtained at the low ng level. Selected ion monitoring (SIM) detection limits have also been determined for PAHs and oxy-PAHs, and are typically at the low pg level.

Several samples including natural and synthetic waxes, polycyclic aromatic hydrocarbons, triazine herbicide metabolites, polymers, and pine tree resins have been analyzed and these results demonstrate the usefulness of the capillary-direct interface method for SFC/MS analysis. Besides its simplicity, the interfacing method has an additional advantage in that a single instrument can rapidly be converted for either GC/MS or SFC/MS.

ANALYSIS OF HIGH MOLECULAR WEIGHT CARBOHYDRATES BY SFC-MS

D. M. Sheeley, J. C. Kuei, G. R. Her, & V. N. Reinhold
Harvard School of Public Health
Boston, MA 02115

Introduction

The application of FAB-MS and comparable soft ionization techniques (e.g. DCI and LD) has introduced the first hope of a sensitive method for studying carbohydrate structures. Unfortunately, for those techniques requiring a desorption matrix (FAB), a problem arises in the biased presentation of sample components, and it is not uncommon for selected samples to exhibit very poor sensitivity or not work at all. For DCI-MS, samples are always detected, but heat initiated desorption leads to pyrolysis of high molecular weight and nonvolatile materials, seriously limiting high mass analysis. An alternative technique not requiring an applied matrix or exhibiting sample suppression has been FAB desorption from a polyimide belt. However, this HPLC-belt interface device is expensive, appears to have high mass limitations, and is technically demanding.

The analysis of nonvolatile compounds by SFC presents an attractive alternative to existing LC-MS configurations. Although as yet unrealized, most significant is the flexibility provided to chromatographic and chemical ionization parameters by simple variations in the mobile phase. These factors, combined with reduced gas loads, ease of solvent elimination, and potential for encompassing greater sensitivity, will certainly make MS detection a major consideration in molecular characterization. This report describes a simple and direct SFC-CIMS interface applicable to derivatized oligosaccharides.

Experimental

SFC separations were performed on a model 501B supercritical fluid chromatograph (Lee Scientific, Inc.) equipped with a flame ionization detector, and a pneumatically actuated submicroliter (0.2 ul) injection valve (Valco Instrument Co. Inc.). Pump cylinder and injection valve temperatures were held at 0 deg C. Capillary columns had inner and outer diameters of 50 and 375 microns, respectively. The column was coated with DB-5, 0.2 um film thickness (J & W Scientific, Inc.). Mobile phase pressure and flow were maintained by fabrication of the integral restrictor described by Guthrie and Schwartz.

Chemical ionization MS was performed on a VG ZAB-SE instrument, operating at 8 kV using ammonia as the reagent gas. The ion source was modified for dedicated CI operation by removal of the columnating magnets, blocking all inlet ports, and use of narrower exit slits. The SFC column tip was introduced through the single DCI inlet and heated at the very tip (1 mm) by a resistance wire connected to and controlled by the DCI unit. With the exception of restrictor tip heating, all temperatures were maintained equal to that of the SFC oven.

Results and Discussion

In previous work, interface temperatures up to 250 degrees higher than that required for SFC separations have been reported. From these reports, usually involving low voltage quadrapole instruments, it was not always clear if there were high-mass limitations. In this application, we have attempted to address the question of heating requirements, analyte desolvation and ionization, sensitivity, and high mass limitations. To approach the latter concern, a comparison between FID signal (mass detection) and TIP plots (molar detection) obtained for permethylated glucose homopolymers suggests that the

ionization efficiency between low and high mass remains relatively constant. Under these SFC-CIMS conditions, each oligomer provided single molecular weight-related ions only, $(M+NH_4)^+$, with little indication of fragmentation. Investigation of a comparable glucose homopolymer, derivatized with trimethylchlorosilane to enhance chromatographic efficiency and increase the molecular weight, demonstrates that chromatographic fidelity is preserved in the interface with anomer separation still apparent at DP15. Moreover, the mass spectra of the latter eluting peaks again indicates that the molecular ion is the major contributor to the total ion current, Fig. 2. To examine the limits of sensitivity samples of permethylated cyclodextrin were studied at varying concentrations. A signal to noise ratio of 10:1 is obtained in the selected ion chromatogram of a 2 picomoles injection. These preliminary studies have provided an understanding of this application to high molecular weight biopolymer problems. Modifications are in progress to improve SFC coupling, higher mass analysis, and sensitivity.

STUDIES WITH PACKED AND CAPILLARY COLUMN SFC/MS

I.C. Mylchreest and D.E. Games
Department of Chemistry, University College,
P.O. Box 78, Cardiff CF1 1XL, U.K.

Packed and capillary column supercritical fluid chromatography (SFC) are complementary to both gas chromatography (GC) and high-performance liquid chromatography (LC) for the analysis of organic compounds. The former approach offers speed of analysis and method development, together with preparative capability. Whereas the latter provides better chromatographic efficiencies than LC and ease of interfacing to gas chromatographic detectors such as flame ionization.

We have effected packed column SFC/MS using a modified spray deposition device and moving belt LC/MS interfaces[1]. This approach provides both EI and conventional CI mass spectra and good retention of chromatographic efficiency. Packed column SFC/MS has also been developed using a modified Finnigan MAT thermospray source in the filament-on or discharge mode[2]. If only carbon dioxide is used as the mobile phase, charge exchange EI type spectra are obtained, whereas with modified CO_2 (e.g. methanol) solvent moderated CI mass spectra are obtained. For capillary SFC/MS, an interface was constructed which enables direct heating of a frit restrictor[3]. In this mode, charge exchange EI type spectra or conventional CI mass spectra are obtained.

Experimental

Packed column SFC was effected using a modified Hewlett Packard 1084B liquid chromatograph and capillary column SFC using a Lee Scientific 501 supercritical fluid chromatograph. Moving belt SFC/MS was performed on either a VG 70/70 E magnetic mass spectrometer or a Finnigan 4000. Thermospray filament-on or discharge SFC/MS was effected with a Finnigan 4000 or Finnigan MAT TSQ 70. For capillary SFC/MS, a Finnigan MAT ITD700[4], Finnigan 4000 and a Finnigan MAT TSQ 70 were used.

Results and Discussion

In capillary SFC/MS we have recently effected interfacing using an ion trap detector[4]. A directly heated frit restrictor was used for the interface and it was found that addition of helium gave good quality spectra with an increase in detection limits. Mixtures of polynuclear aromatic hydrocarbons were studied and good total ion current traces were obtained, together with library searchable spectra. In addition, collision induced dissociation experiments were successfully undertaken. Most of our studies in this area have been conducted with quadrupole mass spectrometers and studies of a dimethyl polysiloxane with a Finnigan MAT TSQ 70 have shown that informative mass spectra can be obtained to masses just in excess of 4000u. In addition, sensitivity studies of pyrene showed that EI type full scan spectra are obtainable at the 200pg injected level with 50pg being obtainable in the CI mode with methane.

Packed column SFC/MS using a moving belt interface has been used to study indole alkaloids in extracts from Catharanthus roseus and fermentation extracts containing milbemycin antibiotics. In both cases EI mass spectra provided molecular weight information and structurally useful fragment ions, enabling mono- and dimeric indole alkaloids and a range of milbemycins to be readily identified and new compounds located. SFC/MS studies of the indole alkaloids have also been undertaken using a thermospray source in the filament-on or discharge mode. Here spectra consisted mainly of $[M + 1]^+$ ions with few fragment ions. A mixture of isomeric alkaloids, tabersonine, catharanthine, vindoline and epivindolinine were studied and gave very similar mass spectra. Use of a TSQ 70 in the collisional activation mode, however, provided more informative spectra which readily enabled the compounds to be differentiated.

In an alternative approach to obtaining more structurally informative mass spectra from SFC/MS using the thermospray system, we have investigated the effects of variation of repeller voltages, discharge voltages and jet block temperature. Both variation of repeller voltage in the filament-on mode and increasing jet block temperature in the discharge mode yielded more fragmentation.

SFC/MS of ecdysteroids has also been studied. Here, best data was obtained using the thermospray system. The technique has been applied to the identification of these compounds in silene otites.

Analysis of Indole Alkaloids from Leaves of Catharanthus roseus by Means of Supercritical Fluid Chromatography/Mass Spectrometry

J. Balsevich*, A.J. Berry**, D.E. Games**, L.R. Hogge* and I.C. Mylchreest***, National Research Council of Canada, Plant Biotechnology Institute, Saskatoon, Saskatchewan,** Dept. of Chemistry University College, P.O. Box 78

Introduction: Separation and characterization of indole alkaloids in plant extracts can be a very difficult analytical problem because of the wide range of solubilities, molecular weights, and polarities of the components. Thin layer chromatography (TLC) has proven to be a useful method for their separation, while use of spray reagents in conjunction with TLC has proven a sensitive method for their detection. Reversed phase high pressure liquid chromatography (LC) using gradient elution has also been used with some success. Unfortunately both of these techniques have shortcomings. TLC spots obtained from polar compounds sometimes overlap. Furthermore, identification of unknown alkaloids separated by TLC is not possible using spray detection. Co-elution of components is also common when using LC for the separation of these compounds. Recently, supercritical fluid chromatography (SFC), a technology which is well suited to interfacing with a mass spectrometer, has been shown to be more efficient than LC and has proven effective in analyses of various polar compounds, including mixtures of ergot alkaloids (1). Accordingly, as a potentially useful means of directly obtaining pertinent information on the number and type of monoterpene indole alkaloids in a relatively small amount of complex sample, we sought to evaluate the use of a supercritical fluid chromatography/mass spectrometry system (SFC/MS) for the analysis of an alkaloid mixture obtained from the leaves of the medicinal plant Catharanthus roseus (Apocyn).

Experimental: SFC analyses were performed with a Hewlett Packard Model 1084B liquid chromatograph modified for SFC (2). An amino bonded 5 micron Spherisorb 100 x 4.5 mm column was used with CO_2 and a 5-15% gradient of methanol polar modifier as the mobile phase. Eluting peaks were detected at a wavelength of 290 nm. The column temperature was 65°C. Electron impact SFC/MS was performed by coupling the chromatograph to a VG model 70/70 mass spectrometer equipped with a moving belt LC/MS interface. The effluent was deposited on the moving belt by using a Finnigan MAT spray deposition device connected in-line via a "T" piece between the UV detector exit and the back-pressure regulator of the chromatograph (1). The belt speed was 3 cm/sec; the nosetip heater temperature was 250°C. The mass spectrometer was scanned from mass 850 to 85 every 2 sec. Thermospray SFC/MS was performed by coupling the chromatograph to a Finnigan MAT model 4000 GC/MS equipped with a modified Finnigan MAT thermospray LC/MS interface operated in the filament-on mode (3). The thermospray tip temperature was 160°C. The mass spectrometer was scanned from mass 150 to 850 every 2 sec.

Results and Discussion: The results of the SFC analysis of the leaf alkaloids of C. roseus were highly satisfactory both from the points of view of resolution and run time (ca. 8 min). The separations obtained on the amino bonded Spherisorb column (Fig. 1) yielded qualitative information comparable to that obtained via two dimensional TLC on silica gel. Compounds having very similar structures were well spaced. Desacetoxyvindoline (3), vindorosine (5), vindoline (6), and deacetylvindoline (10), complex Aspidosperma alkaloids differing only slightly from each other in their functional groups, were separated by a minimum 0.3 min (between 3 and 5) and a maximum of 1.9 min (between 3 and 10). Similarly, the pharmaceutically important bisindoles leurosine (11), 3', 4'-anhydrovinblastine (12), and vinblastine (14) were easily resolved and well separated from each other, even though they chromatographed as a group away from the majority of the "monomers".

One of the attractive features of SFC is the use of a large proportion of a highly volatile phase (CO_2 in our case) which makes interfacing the chromatograph to a mass spectrometer much less problematic than is the case with HPLC. Both EI and filament-on thermospray ionization were successfully employed in the SFC/MS system. Fig. 2 illustrates four representative EI mass spectra obtained via SFC/MS. With the exception of lochnerinine (1), whose spectrum contained some anomalous peaks (due to the presence of unknown alkaloid having M^+ 338) the spectra were of quality comparable to those obtained from the pure compounds.

The use of thermospray ionization in the SFC/MS system effectively enhanced the sensitivity for detection of the alkaloids. Since in the case of monoterpene indole alkaloids the ionization technique affords predominantly $(M + 1)^+$ ions with little fragmentation, a scan giving rise to a spectrum containing several significant peaks would

be indicative of the presence of several compounds of appropriate molecular weights. The spectrum (Fig. 3) obtained from the eluent proximate to peak 3 (Fig. 1) indicated the presence of components having molecular weights of 350 and 352 in addition to desacetoxyvindoline (M^+ 398).

Conclusion: SFC/MS is a very effective technique for obtaining useful information regarding the numbers and types of monoterpene indole alkaloids present in a complex mixture of plant leaf extracts such as those found in *Catharanthus roseus*. In principle, this system should prove equally effective in the analysis of indole alkaloids from other species of plants and/or plant cell cultures. Among the benefits noted were high resolution, short run times, and the production of high quality mass spectra.

PDMS OF ALPHA$_1$-PROTEASE INHIBITOR GLYCOPEPTIDES

M Alai, R Townsend, M. Hardy, Y C. Lee
Department of Pharmacology and Biology, Johns Hopkins University, Baltimore, Maryland 21205
C. Fenselau, Department of Chemistry, University of Maryland Baltimore County, Baltimore, MD 21228

Human α_1-protease inhibitor controls proteolytic processes in various tissue fluids by inactivating a number of serine proteases and its low plasma levels has been associated with the development of familial emphysema . This glycoportein is made of 394 amino acids in a single chain with no internal disulfide bridges and an approximate molecular weight of 53,000. One characteristic of α_1-protease inhibitor (α_1-PI) is production of multiple bands on acid (pH 4.9) electrophoresis or electrofocusing. This multiplicity has been attributed to a great extent to microheterogeneity in the carbohydrates attached. Consequently, the structure of the oligosaccharide chains in human α_1-PI has been the subject of numerous studies. Preliminary investigations revealed that this glycoportein contains two types of complex, N-linked oligosaccharides, bi- and tri-antennary, at the ratio of 3:1; bi:tri. The amino acid sequence of human α_1-PI indicated that there are only three putative sites for N-linked glycosylation, asparagine residues 46, 83 and 247; therefore, some varients must differ only in the arrays of bi- and tri-antennary oligosaccharides attached to each site. In this study it was our objective to characterize glycosylation site microheterogeneity by assessing mass heterogeneity at the three glycosylation sites of human α_1-PI. Asialoglycopeptides from human α_1-protease inhibitor were prepared by digestion with pronase, desialylation with Arthrobacter neuraminidase and chromatography on a Bio-Gel P-4 column. Two partially resolved peaks containing carbohydrates were obtained from this column, FP and BP. Both fractions FP and BP were derivatized using t-BOC-Tyr-2,4,5 trichlorophenyl ester and the resulting t-BOC-Tyr-asialoglycopeptides were purified by RP-HPLC and desalted on a Bio-Gel P-6 column, using 0.1 M ammonium acetate, prior to mass spectral analysis (1-5ug was used for PDMS analysis). Most of molecular ions were consistent with previously reported bi- and tri-antennary oligosaccharides. Fraction BP was found to contain mainly biantennary glycopeptides. The biantennary oligosaccharide structure on Asn-247 was identified in one of the RP-HPLC purified peaks of fraction BP. Our assignment of the structures to the ions was made by a combination of amino acid analysis, amino acid sequence around the glycosylation site and the proposed carbohydrate structures. Asparagine-247 seems to contain only biantennary oligosaccharides; whereas, in physiological variants of α_1-PI the usual biantennary oligsaccharides may be replaced in position 83, and to a lesser extent 46, by triantennary oligosaccharides. The triantennary oligosaccharides of sites 83 and 46 were identified in peaks F2 and F6, eluted from RP-HPLC purification of fraction FP. Two molecualr ions were observed from RP-HPLC purified fraction FP, that suggested the addition of another lactosamine unit to a triantennary oligosaccharide. Preliminary amino acid analysis as well as ^{1}H-NMR data support the presence of tetrantennary oligosaccharides in human α_1-protease inhibitor.

ANALYSIS OF DERIVATISED AND UNDERIVATISED OLIGOSACCHARIDES BY LC-MS AND LC-MS-MS

G. Lappin, V. Gould and *M. Rogers.

VG MassLab Ltd., Tudor Road, Altrincha, WA14 5RZ, UK. Phone 061 941 3552. Tlx 669964. *St Mary's Hospital Medical School, Paddington, London, W2 1PG, UK. Phone 01 725 1138.

There has recently developed a growing demand for the rapid analysis of biologically-active oligosaccharides. For example, they are known to be important in cell-cell interactions, antibody recognition and phytoalexin elicitation. Analysis of oligosaccharides by NMR methods are generally too insensitive. GC and GC-MS of derivatised oligosaccharides has molecular weight limitations. HPLC affords good separation at high molecular weight, for derivatised and underivatised oligosaccharides but collected fractions must be analysed separately. The coupling of HPLC and mass spectrometry provides all the advantages of HPLC, plus the on-line analysis of the oligosaccharides. Here we describe the positive ion thermospray spectra of peracetylated, permethylated and underivatised oligosaccharides. In addition, daughter ion data was obtained which provided further structural information.

Permethylated oligosaccharides (maltohexose, raffinose and stachyose) formed strong $[M+NH_4]^+$ ions. Peracetylated oligosaccharides (stachyose, melezituse, melibiose and raffinose) also produced strong $[M+NH_4]^+$ ions.

Daughter ion spectra were obtained from $[M+NH_4]^+$ parent of peracetylated melibiose and peracetylated melezituse. These spectra exhibited some characteristic ions eg. 331 (peracetylated GLU). Underivatised raffinose exhibited weak $[M+H]^+$ and $[M+NH_4]^+$ ions and several other fragment ions. The source temperature had to be increased from 230° to 280°C to obtain good sensitivity.

Using Selective Ion Recording (SIR), on the $[M+NH_4]^+$ ion, derivatised oligosaccharides were detected down to the 500pg level.

The antibiotic kanamycin was also studied (underivatised). This produced a strong 485 $[M+H]^+$ ion. Daughter ion spectra were obtained on this parent which produced further structural information.

POLYSACCHARIDE STRUCTURAL STUDIES USING LASER DESORPTION/ FOURIER TRANSFORM MASS SPECTROMETRY

Mildred L. Coates and Charles L. Wilkins
Department of Chemistry
University of California
Riverside, CA 92521

Earlier laser desorption/Fourier transform(LD/FT) mass spectra of polyhexoses(1) contained series of fragment ions whose masses corresponded to $[n(162)+X+K]^+$. Since 162 is the mass of the hexose repeating unit, we postulated that X corresponds to the mass of a sugar fragment resulting from a ring cleavage, with the ions in each series corresponding to a particular cleavage. The purpose of this study is to correlate these series with structural features and recently-proposed fragment ion structures(2-4).

The polysaccharides examined are cellulose, guar gum, locust bean gum, lichenan, laminarin, amylose, amylopectin, nigeran, dextran, chitin, and pectin. Spectra were obtained using a pulsed CO2 laser interfaced to a Nicolet FT-2000 mass spectrometer. Powdered polysaccharide samples were attached to the probe tip with double-sided adhesive tape. KCl was added to the samples by depositing a water/methanol solution onto the prepared tip and allowing the solvent to evaporate.

As in the previous study, the masses of the ions observed correspond to $[n(\text{repeating group})+X+\text{cation}]^+$. The mass of the repeating group is 162 for the polyhexoses, 203 for chitin, and 190 for pectin. For all compounds except pectin, the cation is K^+. The pectin sample is contaminated with sodium salts, so its spectrum is dominated by Na^+-attached ions, although K^+-attached ions are also present.

The relative importance of the ion series in a compound's spectrum seems to be more related to the linkages between the monosaccharides than to their identities. For example, LD/FT mass spectra are virtually identical for cellulose, guar gum, and locust bean gum, whose constituent monosaccharides, although different, are linked the same way. This correlates with the earlier observation(1) that LD spectra are not similar for cellulose, starch, and dextran, whose constituent monsaccharides (glucoses in each case) are linked differently.

It has been postulated that many ion series result from a ring or glycosidic cleavage in combination with one or more dehydration reactions(4). In accordance with this, some of the ions series discussed here are grouped into families consisting of the series believed to result from a particular cleavage alone and in combination with dehydration reactions.

B Family of Ion Series-B, A, Q, P

The B series(X=18) seems to arise from cleavage at the glycosidic linkage with proton transfer, to yield a saccharide and a dehydrosaccharide, with charge retention on the saccharide. The A series(X=0) might result from charge retention on the dehydrosaccharide or from B series ions which have undergone a single dehydration. A ions are abundant in the spectra of all the polysaccharides examined, while B ions are of low abundance, if discernable. This may reflect the favorability of dehydration reactions for saccharides. Q ions(X=144 for polyhexoses, 185 for chitin, and 172 for pectin) are usually present, though in low abundance. These may correspond to B ions which have undergone two dehydrations or A ions that have undergone one dehydration. P ions(X=126 for polyhexoses), corresponding to one more dehydration than Q ions, are

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

only present in the spectrum of laminarin.

F Family of Ion Series-F, D, N, L

The F(X=60) and N(X=120 for polyhexoses and 161 for chitin) series seem to be complementary, resulting from the same cleavage, but with charge retention on opposite ends of the molecule. D(X=42) and L(X=102 for polyhexoses, 143 for chitin, and 146 for pectin) series ions could result from the combination of F/N cleavages with dehydrations. Chitin has an acetylated amino group on C2. The masses of the F, D, N, and L ions in its spectrum indicate that the F and D ions do not contain C2, while the N and L ions do.

Other Ion Series-G, K

Observation of the G series ions(X=74 for polyhexoses and 120 for pectin) seems to be related to the (1-4) linkage, although they are not observed in the spectrum of chitin. Two G series ions are observed in the spectrum of pectin, a poly(methyl galacturonate). The masses of these ions suggest they contain C5 and C6. K series ions(X=90) seem to be related to the presence of the (1-3) linkage, although there is no evidence for any particular cleavage.

NOVEL O-LINKED OLIGOSACCHARIDES ISOLATED FROM HUMAN GASTROINTESTINAL MUCINS

A.M. Lawson, E.F. Hounsell*, S.B. Wilson, G. Cashmore, M. Stoll* and T. Feizi*;
Section of Clinical Mass Spectrometry and Section for Glycoconjugate Research, MRC Clinical Research Centre, Watford Road, Harrow, Middlesex. HA1 3UJ, UK.

Introduction: Human gastrointestinal mucins are glycoproteins (1-50 x 10^6 daltons) containing large numbers of heterogeneous oligosaccharides (~ 200 per subunit) each consisting of between 1 and 20 monosaccharides. These are O-linked to serine or threonine in the protein and during synthesis monosaccharides are added to step-wise by specific glycosyltransferases.

The function of mucins, and of the pronounced oligosaccharide heterogeneity, remains obscure although their potential capacity to interact with lectins on the surface of bacteria suggests an important protective mechanism of the mucosal epithelium.

The aim of the present study was to extend earlier work (1), on the major core-region oligosaccharides from gastrointestinal mucus of the human neonate (meconium) by characterising novel backbone sequences which are oligosaccharide antigens of onco-developmental type i.e. antigens of foetal origin which are expressed in adult neoplasia.

Experimental: Carbohydrates were liberated by mild alkali and sodium borohydride from glycopeptides produced by pronase digestion of glycoproteins. Following separation by Biogel P4 chromatography, fractions were individually chromatographed by HPLC on a ODS-Hypersil column and sub-fractions re-chromatographed on a APS-Hypersil column. Methylation analysis was carried out and positive ion FAB-MS (glycerol/thioglycerol) on approximately 0.5nM of permethylated purified oligosaccharides. Native oligosaccharides were analysed by negative ion FAB-MS (glycerol/thioglycerol). NMR ^{1}H spectra were obtained with a 500 MHz Bruker AM500 Spectrometer.

Results: Six of the oligosaccharide structures identified in meconium are listed in the Table. Molecular mass information was obtained from the -ve FAB spectra. The mass spectrum of oligosaccharide K2(4), for example, is shown in Figure 1 with its $[M-1]^-$ ion at m/z 1114 while ions at m/z 1098 and 952 indicate the presence of minor impurities. As little or no fragmentation of these compounds takes place in -ve FAB this is a useful means of detecting multiple components which cannot always be distinguished in the +ve FAB spectra of permethylated derivatives. Figure 2 shows the spectrum of the permethylated derivative of K2(4) which in addition to the $[M+1]^+$ ion at m/z 1410.7 has an intense fragment at m/z 464 (and m/z 432 from 464-MeoH) arising from the two possible cleavages of amino glycosidic bonds. GC-MS of the products of methylation analysis confirmed the monosaccharide composition and gave the linkages for each structure. Further characterisation including anomeric configuration was obtained by NMR.

Conclusion: As part of a continuing study the structure of a number of oligosaccharide moieties from gastrointestinal mucins have been determined. Several of these are of novel structure (e.g. K2(3), K2(4) and K6(3)) while some have been identified previously from other sources (e.g. K3(4), K4(3) and K5(3)2). K2(4) is particularly interesting having an unbranched GlcNAcβ1-6Gal backbone sequence in the absence of a GlcNAcβ1-3 substituent. This may represent a new biosynthetic step and questions the accepted specificity of GlcNAcl-6 transferases.

June 5-10, 1988, San Francisco, CA

Carbohydrate chains in mucins are highly heterogeneous and only by a combination of chromatography, ±FAB-MS, GC-MS and NMR can their structures be fully elucidated. Some of these structures are differentation and tumour associated antigens of monoclonal antibodies and are crucially important to immuno-chemical investigations.

EFFECTS OF CHEMICAL DERIVATIZATION OF OLIGOSACCHARIDES ON FRAGMENTATION IN LASER DESORPTION, PLASMA DESORPTION AND FAST ATOM BOMBARDMENT MASS SPECTROMETRY

M.F. Bean, W.B. Martin, T.J. Raley, Jr., C.M. Murphy and R.J. Cotter,
Department of Pharmacology, The Johns Hopkins University, Baltimore, MD 21205
C. Fenselau, Department of Chemistry, University of Maryland Baltimore County, Baltimore, MD 21225

Derivatization of oligosaccharides has been reported to enhance fragmentation in FAB-MS to provide more reliable data for sequence assignment, [1]. However, the utility of derivatization for other ionization techniques is not clear. This study was undertaken to compare the fragmentation using laser desorption, (LD), plasma desorption, (PD), and fast atom bombardment, (FAB) ionization methods of a variety of glucose and glucosamine oligosaccharides and to determine the effects of chemical derivatization on the two-bond ring cleavages that are characteristically observed in LD spectra of sugars.

The LD spectrum of N,N'-diacetylchitobiose is shown in Figure 1. MK^+ ions are observed at 463 amu and simultaneous cleavage of the O-C_1 and the C_2-C_3 bonds (type IV) and of the C_1-C_2 and C_3-C_4 bonds (type V) in the reducing sugar yield ions at 362 amu. Additionally, simultaneous cleavage of the C_2-C_3 and C_4-C_5 bonds (type VII) occurs to yield an ion at 302 amu. N,N',N"-triacetylchitotriose was studied to determine whether analagous LD type VII fragmentation would occur in the central sugar, however, no corresponding peaks were observed.

The PD spectrum of N,N',N"-triacetylchitotriose is shown in Figure 2, which shows that fragmentation arises chiefly from cleavage of the glycosidic linkage. A molecular ion is observed and oxonium ions are observed at 407 and 204 amu. The ion at 551 amu originates from a type IV or a type V cleavage of the reducing sugar.

The LD spectrum of maltotetraose is shown in Figure 3. The molecular ion, MK^+ is not observed, and unlike the triglucosamine above, two-bond ring cleavages occur throughout the molecule. Type IV cleavage in the reducing sugar and analogous ones in the next two sugars give peaks at 645, 483 and 321 amu (i.e., at 162 amu intervals). Since charge retention is on the distal portion, this series can be used to determine the sequence from the reducing end. Similarly, type VII cleavages result in the series at 585, 423, 261 and 99 amu. A third series at 627, 465 and 303 amu occurs 18 amu below the first. A fourth series was noted at 525, 363 and 201. Laser desorption of the peracetylated derivative, shown in Figure 4, illustrates that essentially all fragmentation is suppressed and only cationized molecular ions are observed. This was observed for LD of all the compounds studied, and was observed for LD of the permethylated derivative of stachyose as well.

The corresponding FAB spectrum is shown in Figure 5. MNH_4^+ molecular ions were observed at 1272 amu (PD produced MNa^+ ions at 1278 amu). Both FAB and PD of exhibit oxonium ions at 1195, 907, 619 and 331 amu. FAB and PD of the native sugar, however, produced little useful structural information. Thus, the sequence can be obtained by FAB and/or PD from the fully derivatized sample.

The LD spectrum of trehalose, a 1'-1 linked disaccharide, Figure 6, was studied to examine the behavior of a sugar with no reducing terminus. None of the characteristic two-bond LD fragmentations are observed; ionization is chiefly cationized molecular ions. LD of the peracetyled sugar showed the same results. However, both the FAB and PD spectra were simplified by peracetylation techniques - molecular ion species and oxonium ions were the major ions observed in contrast to complicated fragmentation in the corresponding spectra of the native sugar.

Thus, LD, FAB and PD provide complimentary fragmentation information useful for structurally elucidation of oligosaccharides. Derivatization improves sensitivity and fragmentation in PD and FAB, but suppresses fragmentation in LD. Clearly, LD is a viable alternative to derivatization to determine sequence information due to the extensive, more complex fragmentation observed.

FRAGMENTATION OF LIPOPOLYSACCHARIDE ANCHORS IN PLASMA DESORPTION MASS SPECTRA: THE LIPID A STRUCTURES FROM E. COLI, R. SPHAEROIDES, AND B. ABORTUS

R. Wang, L. Chen, R.J. Cotter; The Johns Hopkins University, Baltimore, MD 21205
N. Qureshi, K. Takayama; Veterans Administration Hospital, Madison, WI 53705

Lipid A (1) is a lipid component of lipopolysaccharides (LPS) which are amphipathic macromolecules found on the outer surface of the outer membrane of gram-negative bacteria. Lipid A has a basic structure (see Fig. 1) consisting of a mono- or diphosphorylated ß-1,6-linked D-glucosamine disaccharide, with four to seven fatty acids forming amide linkage (at 2 and 2' position of sugar) and acyl linkage (at 3 and 3' position of sugar). The different fatty acid composition appear to be related to toxicity.

Plasma desorption mass spectrometry has been used to elucidate the fine structure of lipid A's from various bacteria (Escherichia coli, Rhodopseudomonas sphaeroides (2), and Bacillus abortus). In the present study, the general fragmentation behavior of lipid A is reported.

Lipid A from E. coli and R. sphaeroids (only E. coli is shown)
MOLECULAR IONS (Fig. 2A) In positive spectra, both free acid and methylated lipid A yield intensive pseudomolecular ion $[M+Na]^+$. The free acid can catch two sodium ions from matrix to form $[M+2Na-H]^+$ ion while the methylated derivative can form $[M-CH_3+Na]^+$ ion.
MAJOR FRAGMENTS (Fig. 2B) The loss of ester-linked fatty acid forms the $[M-R_n]^+$, $[M-R_n+Na]^+$, $[M-R_n]^-$ ions. The oxonium ion is formed by cleavage of the bond between the distal and reducing sugar. These major fragments are very useful to determine the fatty acid composition and substitution positions.
FATTY ACIDS AND PHOSPHATE NEGATIVE IONS (Fig. 2C) The low mass region of PD negative spectra can be used to confirm phosphate and fatty acid compositions. All ester-bonds are cleaved to give free fatty acid negative ions ($R_1'^-$, $R_2'^-$, R_3^-). Note that background peaks are shaded.
ALKYL FRAGMENTATION (Fig. 2D) The low mass regions of positive spectra of all lipid A's exhibit a distinct fragmentation pattern which is characteristic to alkyl groups. These type of fragmentation may be the cause of peak broadening at high mass region.

Lipid A from B. abortus
The fragmentation pattern of tetra-amide-linked lipid A is distinct from previously mentioned lipid A with two ester linkages at 3- and 3'-positions. Instead of the normal cleavage at the ester bonds, cleavage of the C_1-O bond and the C_2-C_3 bond of the reducing sugar results in the loss of a portion of the molecule which includes the amide-linked fatty acid. The other fragmentation involves simultaneous cleavage of the C_4-C_5 and C_1-O bonds. The resultant ions can be used to establish the identity of R_1 and R_2.

Concluding Remarks
1. Plasma desorption mass spectrometry gives important information about the fine structure of lipid A. Negative spectra reveal the phosphate and O-linked fatty acid composition, while the major fragments in positive spectra provide direct information on the positions of the fatty acid chains.
2. Study of lipid A from E. coli and R. sphaeroides shows that major fragmentation in PD mass spectra involves only the cleavage of ester-linked fatty acyl groups, but not the amide-linked fatty acyl groups. Cleavage within the sugar ring is rarely observed. On the contrary, tetra-amide-linked lipid A from B. abortus shows specific fragmentations of the reducing end sugar.

CARBOHYDRATE ANALYSIS OF THE PRE-S(2) REGION OF HEPATITIS B SURFACE ANTIGEN

Mark E. Hemling[1], Steven A. Carr[1], Carine Capiau[2], and Jean Petre[2]
[1]Physical and Structural Chemistry L-940,
Smith Kline & French Laboratories, King of Prussia, PA 19406
and [2]Biological Division, SmithKline-RIT, B-1330 Rixensart, Belgium

The 226 amino acid long S protein of hepatitis B virus is the major surface glycoprotein of the infective agent. The development of vaccines against hepatitis B virus has focused on the immunogenic properties of the S protein, and two recombinant versions of this protein are currently available for use as vaccines. Using FABMS and selective chemical procedures we previously confirmed 85% of the sequence of the protein and identified the presence of an N-acetyl moiety on ca. 70% of the amino-terminal Met residues. Recently, an amino-terminally extended form of the S protein, designated pre-S(2), with 55 additional amino acid residues has been found in minor amounts in infectious particles and has been shown to be significantly more immunogenic in terms of antibody production in vivo than the S region alone. The gene for pre-S(2)-S HBsAg was cloned and expressed in yeast at SmithKline-RIT, and two major protein bands with molecular masses of 30 kDa (p30) and 33 kDa (gp33) were isolated by polyacrylamide gel electrophoresis (SDS-PAGE). The observed molecular mass of gp33 on SDS-PAGE was several kDa higher than expected based on the theoretical amino acid composition of the pre-S(2) protein. Treatment of the gp33 protein with endo-β-acetylglucosaminidase H resulted in a decrease in the apparent mass of the protein by SDS-PAGE suggesting that the mass difference was at least in part due to covalently bound oligosaccharide, probably of the oligomannose family.

Mass spectrometry was enlisted in this study to define the site(s) of attachment of carbohydrate and to determine the compositions and molecular heterogeneity of the carbohydrate at the various attachment sites. In order to study the structure of the pre-S(2) region separate from the rest of the S antigen molecule that we had previously characterized, we took advantage of the fact that the S antigen is refractory to tryptic digestion in the native state whereas the N-terminal pre-S(2) region is readily cleaved. Digestion of native pre-S(2)-S protein with trypsin in the absence of reducing agents should produce three tryptic peptides from the 55 amino acid long pre-S(2) region of the protein, consisting of 16, 2, and 30 amino acids. The 16 amino acid peptide Met_{-55}-Arg_{-40} contains the putative Asn-linked glycosylation site and two potential O-linked sites, while the 30 residue fragment Gly_{-37}-Arg_{-8} contains nine possible O-linked sites. FABMS of the tryptic digest of p30 yielded signals for the two larger peptides. Associated with each of these signals were peaks corresponding to glycosylated peptides containing one or two units of hexose, presumably O-linked.

FABMS of the tryptic digest of gp33 (ca. 40 nanomoles digested) yielded signals for the third tryptic peptide at m/z 2891 [$(M+H)^+$, average mass] with from one to six hexoses (incremental mass = 162) attached to Ser or Thr residues, but only weak signals which might correspond to the amino-terminal tryptic peptide could be detected (Fig. 1, top). Glycosylated peptides containing the Asn-linked glycosylation site were detected by analysis of HPLC fractions of trypsinized gp33. The RP-HPLC chromatogram of the tryptic digest was complicated due to the extensive heterogeneity of the carbohydrate components of the two glycopeptides and the similar retention behavior of the various glycopeptides. It should be noted that, unlike proteins, heterogeneity in the structures of carbohydrates attached to proteins is the rule rather than the exception. Peaks were observed at m/z 3634, 3796, 3958, and 4120 corresponding to peptide Met_{-55}-Arg_{-40} with two N-acetylhexosamine (HexNAc) and from eight to eleven hexose units. Of course, the exact distribution of these sugars among the three potential glycosylation sites present in this peptide (i.e., Asn_{-52}, Ser_{-51}, and Thr_{-50}) cannot be determined from this data. Similarly, signals were observed at m/z 4350, 4512, 4674, and 4835 corresponding to the peptide Gly_{-37}-Arg_{-8} with nine to twelve units of hexose attached From analysis of the fractions we concluded that Met_{-55}-Arg_{-40} has a total carbohydrate composition varying from $HexNAc_2Hex_7$ to $HexNAc_2Hex_{12}$ and that Gly_{-37}-Arg_{-8} is present with zero to thirteen hexose units attached at O-linked sites.

In order to unambiguously define the attachment site of Asn-linked carbohydrate we used the FABMS carbohydrate "mapping" strategy (1). Peptides containing Asn-linked carbohydrate are detected in this strategy by comparing the FABMS-derived peptide maps obtained before and after treatment of the glycoprotein with an endoglycosidase. The most generally useful enzyme for this purpose is peptide:N-glycosidase F (PNGase F) which cleaves the β-aspartylglycosylamine linkage of all known types of Asn-linked sugars and converts the attachment site Asn to Asp which weighs one dalton more. New peaks appearing in the mass spectra after treatment with the glycosidase correspond to formerly glycosylated peptides. Following digestion of trypsinized

gp33 with PNGase F strong peaks were observed at m/z 2255, 2417 and 2579 (Fig. 1, bottom) indicating that carbohydrate is N-linked to Asn_{-52} and that from two to four hexoses are attached via oxygen to Ser_{-51} or Thr_{-50}

The composition and molecular heterogeneity of the carbohydrate in peptide Met_{-55}-Arg_{-40} was examined by peracetylating a portion of the trypsin/PNGase F digest of gp33 which is a mixture of peptides and released carbohydrates. The peracetylated oligosaccharides were extracted from the acetylated peptides into an organic solvent and analyzed by FABMS These data establish that the Asn-linked site in peptide Met_{-55}-Arg_{-40} has a composition of $HexNAc_2Hex_n$ where n = six to nine. A working hypothesis for the structure of the glycopeptide Met_{-55}-Arg_{-40} based on these experiments is shown in Fig. 2. Work is progressing on defining the specific locations of the O-linked sugars in both of the tryptic peptides.

FAB MS/MS FOR ANALYSIS OF A COMPLEX MIXTURE OF LIPO-OLIGOPEPTIDES FROM NOCARDIA RUBRA CELL WALL SKELETON

M. Fujioka, F. Sentoh, S. Koda and Y. Morimoto
Analytical Research Laboratories, Fujisawa Pharmaceutical Co., Ltd.
2-1-6 Kashima, Yodogawa-ku, Osaka 532, Japan

Introduction: Lipopeptide(Peptidolipid or Lipoprotein) is one of the components of bacterial cell wall skeletons, but little is known about its biological function and structure, mainly due to its poor solubility and intrinsic complexities. The lipid moiety consists of a mixture of fatty acid homologues, and it blocks the N-terminus of the peptide moiety. Moreover the peptide moiety contains both D- and L- amino acids, and significant changes both in the fatty acid and amino acid compositions are often observed. We have isolated a lipopeptide fraction(ca. 5,000 daltons by GPC) from Nocardia rubra AN-115 cell wall skeleton(N-CWS) and initiated structure elucidation. Here we report the optimal FAB MS/MS conditions for the analysis of synthesized lipo-oligopeptides and application in determining of N-terminal sequences of the N-CWS lipopeptide.

Results and Discussion: A Finnigan MAT TSQ70(triple quadrupole mass spectrometer) equipped with an Ion Tech FAB11NF saddle field fast atom gun was used for this study. Since the N-CWS lipopeptide has been found to be rich in behenic acid as the lipid moiety, and Gly, Phe, Ala, Ile, and Val in the peptide moiety, behenylglycine(Beh-Gly), Beh-Gly-Phe, Beh-Gly-Phe-Ala were synthesized and used for optimizing FAB MS/MS conditions.

Among the eight matrix compounds examined in this study, 3-Nitrobenzyl alcohol provide the highest secondary molecular ion yield of the synthesized lipo-oligopeptides both in positive ion(+) and negative ion(-) modes except the case of Beh-Gly in the negative mode as shown in Table 1. No significant difference of secondary molecular ion signal duration, which is shown by lifetime of the secondary molecular ions in Table 1, was observed among the three matrix compounds which were chosen since they were superior to the others in respect to an ability of yielding higher signal abundance. It is definitely important for MS/MS experiments to have higher ion intensities, therefore 3-nitrobenzyl alcohol was recommended as the most suitable matrix compound for analysis of the lipo-oligopeptides

Nature of xenon and argon as a collision gas were studied to improve daughter ions yield and sequence imformation. There was no significant difference in the quality of the FAB MS/MS daughter ions spectra between by use of xenon and argon, however, higher collision energy of about 5eV was required in the case of argon compared with xenon.

The (-)FAB was found to yield higher secondary molecular ion abundance than the (+)FAB. Abundance and quality of sequence informative daughter ions generated by collisionally induced dissociation were compared between positive and negative ion modes. The (-)MS/MS is found to be superior to the (+)MS/MS. A plateau of ion intensities was observed in higher collision energy region when collision gas pressure was too low, therefore, higher colligion gas pressure was recommended as far as a sufficient abundance of parent ion intensity was maintained. The (-)FAB MS/MS daughter ions spectrum of Beh-Gly-Phe-Ala recorded at the condition optimized was shown in Figure 1.

A chloroform extractable materials from partial acid hydrolyzate of the N-CWS lipopeptide (in 6N-HCl at 110 ℃ for 30 min) was chromatographed on a silica gel thin layer plate (E. Merck; silica gel 60) using a mixture of petrorum ether, ether, and formic acid (40:30:3, by vol) as a developing solvent to revealed four fractions (Fraction 1 - 4). These fractions were lipids mixture or lipo-oligopeptides mixture, and subjected to the (-)FAB MS/MS analysis. The (-)FAB mass spectrum of the Fraction 4 from the N-CWS lipopeptide showed that this fraction might consist of a mixture of homologous lipo-oligopeptides. The (-)FAB MS/MS daughter and parent ions experiments of the Fraction 4 at the optimal condtions could establish Lipid-Gly-Phe sequence as shown in Figure 2.

CHARACTERIZATION OF AN ACIDIC EXOPOLYSACCHARIDE ISOLATED FROM AN *R. MELIOTI* MUTANT:

G.R. Her, S.Y. Chan, V.N. Reinhold, J. Glazebrook*, G. Walker*.
Harvard School of Public Health, Boston, MA 02115, and
*Massachusetts Institute of Technology, Cambridge, MA 02139.

Introduction

Our laboratory has recently provided unambiguous evidence that complex exopolysaccharides play crucial roles in the nodulation of alfalfa root hairs by the nitrogen-fixing bacterium *Rhizobium meliloti*. Briefly, we found that colonies of *R. meliloti* fluoresce under UV light when grown on medium containing calcofluor (exo^+). We isolated a large set of mutants generated by the insertion of the transposon tn^5 and showed that all of them failed to synthesize a complex acidic exopolysaccharide previously characterized by Aman, et al., (1). When alfalfa seedlings were inoculated with these exo^- mutants, nodules developed but no nitrogen fixation occurred. Thus, the presence of the exopolysaccharide appears to be required for successful invasion of developing nodules and for establishing an effective symbiotic relationship. A new mutant of *Rhizobium meliloti* isolated in this laboratory fails to synthesize the expected exopolysaccharide but does synthesize a modified structure which is effective in nodulation. Since this new exopolysaccharide can substitute for the previously known material in nodule invasion and symbiosis, the determination of its structure is a matter of extreme interest.

To approach this problem, sample composition, sequence, linkage, and substituent groups were determined. Glycosidic and substituent linkages were determined on the isolated polysaccharide and fractions of an enzymatic digest using both Hakomori (2) and Prehm (3) permethylation procedures. The sequence was established by a combination of FAB-MS (Fig. 1) and DCI-MS (Fig. 2) and NMR was used to determine all anomeric configurations. From these studies it can be concluded that this second exopolysaccharide has a very different structure compared to the wild type 1021 polysaccharide. The determined structure is a linear disaccharide repeating unit with an acetate group attached to glucose and a pyruate group attached to galactose as shown in Fig. 3.

PDMS ANALYSIS OF PEPTIDES, OLIGOSACCHARIDES AND GLYCOPEPTIDES

G. Scanlan, L. Benson, A. Tsarbopoulos, and I. Jardine

Mayo Clinic, Rochester, Mn.

The mass spectrometric analysis of INTACT complex glycopeptides, even to simply obtain unambiguous molecular weight information, but especially to obtain sequence and structural information, still presents a formidable challenge. In this poster is reported progress toward MS analysis of complex glycopeptides using 252-Cf-PDMS.

The model peptide substance P was used to optimize conditions for the routine, reproducible, and reliable PDMS analysis of peptides at the low picomole level. The amount of MNa^+ ions present using normal distilled water to apply the sample to the foil is dependent on the time the foil is allowed to stand before spin-drying. The salt-adduct ions can usually be washed from the NC using water or 0.1% TFA but losses of small peptides inevitably occur. The salt adduct problem can be alleviated by not only desalting the peptide, but also by using highly deionized water. Oxidation occurs more readily in smaller samples, i.e. 2 picomoles, but can be decreased by preparing foils under nitrogen or inserting them immediately into the vacuum system. Figure 1 demonstrates the usefulness of these techniques when looking at small quantities of Substance P. Figure 2 demonstrates the increased resolution and mass accuracy of Substance P using a PDMS-Time-of-Flight-Ion Reflectoer system.

Oligosaccharides can only be desorbed from NC coated PDMS foils with difficulty. The spectra usually consist of the MNa^+ ion even after sample cleanup or washing, but a few hundred picomoles of material are required. A dramatic change occurs when the oligosaccharide is permethylated and/or peracetylated. Sensitivity is increased to the sub-100 pmole level and fragmentation ions resulting from simple cleavages along the sugar chain become evident. Using the short fight path (15 cm) TOF system, the mass accuracy of the MNa^+ ion is fairly reliable , but the accuracy of the fragment ions is poor. The PDMS-TOF-ion reflector system solves this problem.

Analysis of the underivatized species (Tetra-antennary dodecasaccharide; Fig.3) required 5 nanomoles of material and gives a moderate MNa^+ ion signal (Insert in Fig. 3). In contrast, picomole amounts of the peracetylated analog provides an intense MNa^+ ion, accompanied by intense sugar fragment ions.

Prothrombin contains three asparagine-linked sugar chains per molecule. The complete structures of these sugars were previously determined as complex sialic acid containing isomeric oligosaccharides. To determine the precise location of these sugars on the prothrombin chain, the three complex glycopeptides were isolated after tryptic digestion of the molecule. Attempts to analyze these intact sialic acid containing glycopeptides by PDMS were initially unsuccessful. The oligosaccharide portion of the glycopeptides were then shortened using an endoglycosidase to leave only a GlcNAc-GlcNAc residue. Analysis of such molecules by PDMS produces an intense MH^+ ion similar to normal peptides (Fig. 4). When a standard sialic acid containing glycopeptide containing two terminal sialic acid residues and one amino acid (asparagine) was analysed no spectrum resulted. The molecule was derivatized using methylation (HCl/MeOH) then peracetylation, but still no spectrum was obtained using standard PDMS techniques. However, washing these derivatized samples with water and then CHLOROFORM resulted in spectra (Fig. 5). A complex prothrombin tryptic glycopeptide was then methylated, peracetylated, applied to a PDMS foil and washed in the above manner using water and CHLOROFORM (Fig. 6).

Department of Medicinal and Natural Products Chemistry
The University of Iowa
Iowa City, Iowa 52242

Heparin, a polydisperse sulfated copolymer of 1->4 linked glucosamine and uronic acid residues, has been used clinically as an anticoagulant for half a century. Despite a yearly use of over 50 million doses in the U. S. alone, heparin's exact chemical structure remains unclear. Heparin is depolymerized with heparin lyase and fractionated by HPLC into a small number of oligosaccharides. Five of these comprise approximately 86% of the mass. They are:

F1 : ΔIdoAp2S (1->4) -α- D-GlcNp2S6S

F2 : ΔIdoAp2S (1->4) -α- D-GlcNp2S (1->4) -α- L-IdoAp2S (1->4) -α- D-GlcNp2S6S

F3 : ΔIdoAp2S (1->4) -α- D-GlcNp2S6S (1->4) -β- D-GlcAp (1->4) -α- D-GlcNp2S6S

F4 : ΔIdoAp2S (1->4) -α- D-GlcNp2S6S (1->4) -α- L-IdoAp2S (1->4) -α- D-GlcNp2S6S

F5 : ΔIdoAp2S (1->4) -α- D-GlcNp2S6S (1->4) -α- L-IdoAp (1->4) -α- D-GlcNAcp6S (1->4) -β- D-GlcAp (1->4) -α- D-GlcNp2S3S6S

where ΔIdoA is 4-deoxy-α-L-threo-hex-4-enopyronosyluronic acid, GlcA is glucuronic acid and IdoA is iduronic acid (see Figure 1).

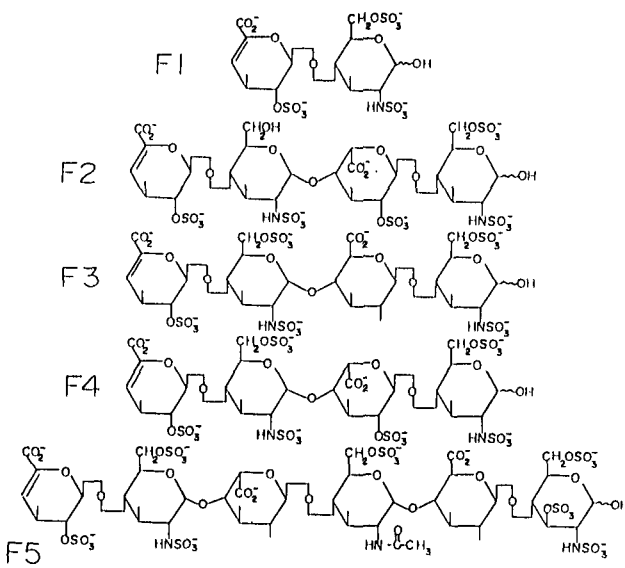

Figure 1

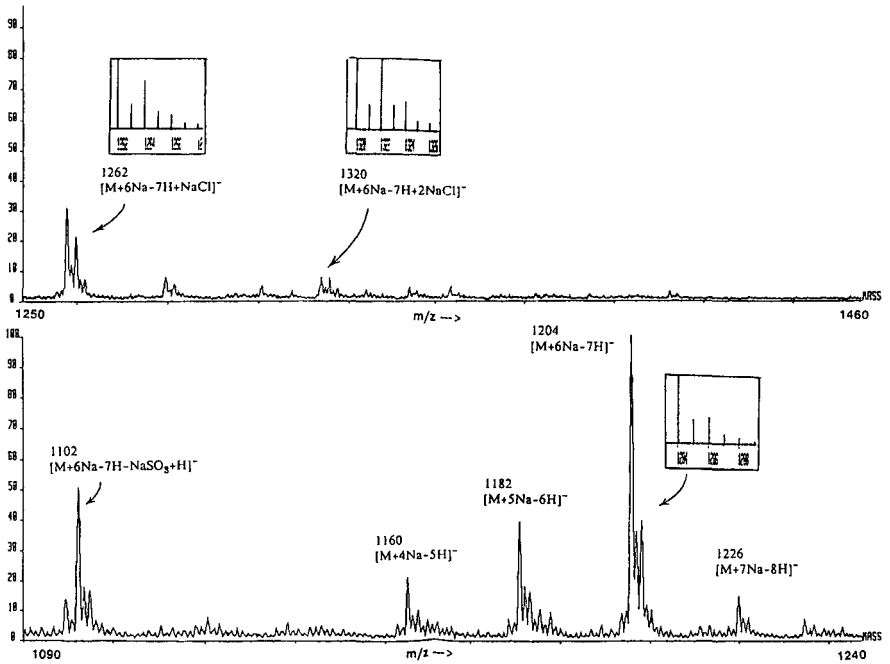

Figure 2

FAB-MS spectra have been reported for disaccharide F1[1] but not for higher oligosaccharides F2-5. In the case of polysaccharides, protonation often leads to cleavage of the glycosidic bond, thus the protonated molecular ion is not observed. In solution, the highly sulfated heparin derived polysaccharides contain up to ten negative charge sites. Clearly, analysis of these compounds should be performed in the negative ion mode. Owing to the potential (in solution) for formation of a molecule with several negative charges, a method for creating a species with a single negative charge without altering the character of the molecule is important.

Owing to the potential for multiple negative charge sites in solution (and gas phase), dodecylmethyl ammonium (DDMA) salts of F1-5 were made and successfully analyzed using plasma desorption (PD) MS (± 6 daltons).[2] Although analysis of these compounds by PDMS is feasible, oligosaccharide F5 (1603 daltons) as a DDMA salt has a molecular mass of 7510 daltons making analysis of even larger polysaccharides impractical.

Recently it has been reported that sodiated molecular ions can provide fragment ions for structural elucidation not obtained for the $[M+H]^+$ or $[M-H]^-$ molecular ions.[3] In addition, formation of sodiated molecular ions of sugars is commonly observed as the prominent molecular ion species, i.e., protonated molecular ions (or deprotonated in the negative ion mode) are often not observed.[4] Therefore negative ion FAB analysis was performed to detect ions of the type $[M+Na_x-H_{x+1}]^-$ (x = 1-10). These analyses were performed using a VG ZAB-HF with triethanolamine as the negative ion FAB matrix. Owing to the abundance of salts in the analyzed samples, sodium salts were not added to facilitate sodium adduct ion formation. As an example, the heparin compound F3 formed a $[M + 6Na - 7H]^-$ type molecular ion (see Figure 2). It is interesting to note that although the samples were considered pure, a considerable amount of NaCl was observed as $[M + 6Na - 7H + xNaCl]^-$ (x = 1-3) adduct ions.

Enhanced Separation and LSIMS Fragmentation of Chemical Derivatives of Oligosaccharides Containing 3-Deoxy-2-Keto-Octulosonic Acid (KDO)

Constance M. John and Bradford W. Gibson

Department of Pharmaceutical Chemistry, School of Pharmacy, University of California, San Francisco, CA., 94143-0446

The purification and structural determination of the oligosaccharide (OS) portion of the lipidoligosaccharide (LOS) of gram-negative bacteria, *e.g. Neisseria gonorrhoeae*, is complicated by heterogeneity and the presence of ionic components such as 3-deoxy-2-keto-D-*manno*-octulosonic acid (KDO) and phosphoethanolamine (PEA). Previously, we reported the primary structure determination of the OS of JW31R, a pyocin-resistant gonococcus strain, using a combination of liquid secondary ion mass spectrometry (LSIMS), GC-MS, and MS/MS techniques [1,2]. In order to improve the separation, sensitivity, and obtain more structural information, we prepared several chemical derivatives of OS containing KDO and investigated their MS and HPLC properties [3].

The OS portions of the LOS from *N. gonorrhoeae* JW31R were first released by acid hydrolysis (1% acetic acid, 2 hours, 100°C) and the water-soluble OS was separated on a Sephadex G-50 and Bio-Gel P-4 columns. Fractions from the P-4 column of the OS from JW31R were found to be heterogenous on the basis of refractive index detection and LSIMS analysis. Fraction 53, which contained at least 3 different OS components, was derivatized with p-amino-benzoic acid ethyl ester (ABEE) and reduced to the corresponding amine with $NaCNBH_3$ [3]. Reverse phase HPLC (Vydac C_{18} with H_2O/CH_3CN gradient) was used to purify the derivatized OS components and baseline separation was observed for most components. Analysis by negative ion LSIMS on a Kratos MS50 produced abundant deprotonated molecular ions with extensive fragmentation. Decarboxylation of KDO had also occurred in some of the derivatized OS during the reaction which improved the $(M-H)^-$ abundance by increasing the hydrophobicity of the OS (and presumably its surface activity).

To the contrary, the OS purified from the LOS of *S. typhimurium* TV 119 Ra reacted only slightly with ABEE. After extensive studies, we concluded that the reaction of the sterically hindered reducing terminus (KDO) with ABEE was not quantitative and that the yield was considerably lower with OS containing phosphate and PEA. After treatment of the *S. typhimurium* OS with HF to remove both phosphate and PEA, a much better yield of the derivatized OS was obtained. In addition, a number of well separated fragments of this OS were also present, presumably originating from partial acid cleavage during the HF treatment. Although this limited hydrolysis could be viewed as an unwanted side reaction of the HF cleavage, these smaller OS components gave abundant molecular ions by LSIMS and, therefore, became useful structural elements in determining the structure of the parent OS.

Nonetheless, the reaction of ABEE with KDO was still not quantitative and a more nucleophilic reagent was sought to derivatize these OS. For this purpose, *p*-hydrazino-benzoic acid ethyl ester, a stronger nucleophile, was synthesized and used to produce the corresponding hydrazones. Preliminary results indicated that the yield improved 3-5 fold and the resulting ABEE-hydrazones could be easily separated by HPLC in an identical fashion as for the ABEE derivatives. The LSIMS spectra of these hydrazone derivatives were equal to the best quality spectra of the corresponding ABEE derivatives.

Overall, the addition of hydrophobic UV chromophores to these OS provided excellent HPLC detection efficiency, separation, and LSIMS performance. The ABEE and ABEE-hydrazone OS produced fragmentation almost completely directed towards the reducing terminus. The ABEE-hydrazine reagent was found to be more nucleophilic and, therefore, more reactive with the reducing terminal KDO. It could be argued that the hydrazine-amino benzoates are preferable derivatizing agents to the amino benzoates for all types of oligosaccharides, since they are more reactive and no extraction steps are required prior to HPLC separation.

Applications and Further Developments of Liquid Chromatography - Fast Atom Bombardment - Mass Spectrometry (LC-FAB-MS) using a Continuous Flow Probe.

Alison E. Ashcroft, Kratos Analytical, Barton Dock Road, Urmston, Manchester, M31 2LD, UK
Alan A. Herod, British Coal, Coal Research Establishment, Stoke Orchard, Cheltenham, Glos. GL52 4RZ, UK
Gary Manton, ICI Wilton Materials Research Centre, PO Box 90, Middlesbrough, Cleveland, TS6 8JE, UK.

Introduction

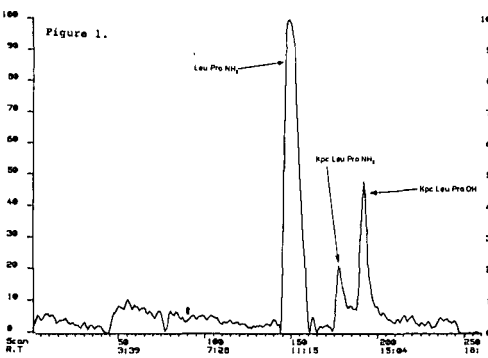
The development of Continuous Flow FAB[1] has resulted in a technique well-suited for on-line reaction monitoring[2] and LC-MS using both microbore and micro-LC columns[3]. The Continuous Flow FAB probe also provides for a rapid throughput of routine samples and facilitates the addition of salts and other additives to samples in order to establish the molecular weight by production of quasi-molecular ions.

Experimental

A Kratos Analytical Concept IS equipped with a Continuous Flow FAB probe and an Ion Tech FAB gun was used for this work. A Brownlee MPLC pump was employed to deliver solvents at the rates specified in the text. The LC columns and mobile phases used are discussed below.

Results and Discussion

Relatively polar materials such as peptides are amenable to reversed phase liquid chromatography. These types of samples are readily ionized by Fast Atom Bombardment, and an example of an on-line LC-FAB-MS analysis is shown in figure 1. The chromatogram shows the separation of three closely related neuropeptide derivatives achieved with a Brownlee RP-18, Spheri-5 column (1mm x 25cm) packed with 5µm particles using a gradient elution of 0 to 56% aqueous acetonitrile with a constant 0.1% trifluoroacetic acid and 5% glycerol. The flow rate of 40µl per minute through the column was split 1:8 to direct 5µl per minute to the ion source. A spectrum from the minor component, Kpc.Leu.Pro.NH_2, is shown in figure 2.



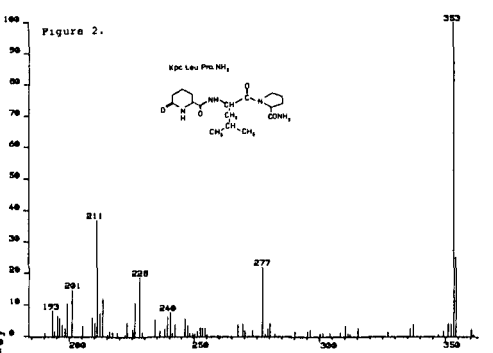


Figure 1. LC-FAB-MS: Neuropeptide mixture separated by reversed phase LC using a gradient of 0-56% aqueous acetonitrile with 0.1% trifluoroacetic acid and 5% glycerol.

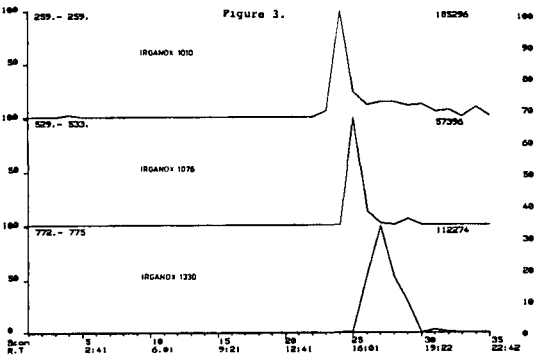
Figure 2. LC-FAB-MS: Spectrum of Kpc.Leu.Pro.NH_2 (mw 352)

Complementary types of LC have also been studied. Gel Permeation Chromatography (GPC) has a mechanism based on size exclusion whereby molecules are separated on passage through a porous phase by differences in their effective size ie. smaller solutes have access to a greater proportion of the total pore volume, and are retained for a longer time than larger solutes.

GPC has been used to separate mixtures of asphaltenes, lipids, phthalates etc. In this study, a PLgel GPC column (2mmx 30cm) of 100A pore size packed with 5µm particles was used to separate a mixture of three Irganox samples using FAB-MS as the detection system. Commonly used solvents for this type of column include tetrahydrofuran, toluene and chloroform. Initial studies with the continuous flow FAB probe indicated that both toluene and chloroform were suitable solvents to be used in conjunction with FAB-MS as they evaporated steadily into the ion source and produced few background ions in the mass spectrum. In comparison, tetrahydrofuran produced a high level of background ions and generally caused suppression of sample ions. Using toluene at a flow rate of 400µl per minute through the column with a split of 1:80 to direct 5µl per minute to the ion source, a separation of Irganox 1010, Irganox 1076, and Irganox 1330 was achieved (figure 3). A spectrum from Irganox 1076 is shown in figure 4.



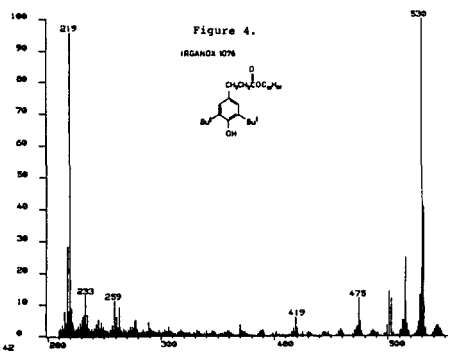


Figure 3. GPC-FAB-MS: Irganox mixture separated by GPC using toluene with 5% m-nitrobenzyl alcohol added.

Figure 4. GPC-FAB-MS: Spectrum of Irganox 1076.

Conclusion

The Continuous Flow FAB probe has been used as an LC-MS interface with both aqueous and organic solvent mixtures using both GPC and reversed phase HPLC columns.

SECONDARY ION MASS SPECTROMETRY OF SOLUTE PARTICLE BEAMS BY THERMABEAM LC/MS.

Ross C. Willoughby, James D. Buchner, andEdward W. Sheehan;
EXTREL Corporation, Pittsburgh, Pa. 15238.

Continuous introduction of sample into the ion source of the mass spectrometer with subsequent ionization using secondary ion mass spectrometry or fast atom bombardment ; namely, continuous flow FAB (1), has demonstrated several advantages over conventional FAB analysis. Among the advantages are: direct coupling to HPLC systems; enhanced sensitivity, reduced matrix requirements, and decreased background interferences. Unfortunately, present continuous flow FAB devices are limited to microbore flow rates; possibly requiring nonstandard LC hardware and columns; smaller column capacity; and injection volumes.

Introduction of solute in the form of a solvent-depleted solute particle beam intercepting a primary ion beam may result in an alternative approach to continuous sample introduction with secondary ion mass analysis. ThermaBeam LC/MS is a high enrichment particle beam introduction device that has show applications in both EI and CI modes. The objective of the present studies were intended to demonstrate the feasibility of producing FAB spectra by intercepting a primary ion beam (Xe) with a solute particle beam generated with ThermaBeam. The effects of matrix, temperature, and source geometry were studied.

Two experimental configurations were evaluated; a cross-beam and a target intercept (Figure 1). A Xenon saddle field source at 8 KV was used as the primary ion source. The targeted configuration yielded one to two orders of magnitude greater sensitivity than the cross beam experiments. Sample response was highly dependent upon the matrix additives. Most samples were analyzed with a thioglycerol matrix. Peak profiles were symetrical and tailing was not a problem unless the thioglycerol content in the effluent was significantly higher than ten percent. Sodium and potassium cation adducts were observed for many compounds presumably from impurities in the water.

The targeted configuration yielded FAB spectra that were comparable to those obtained under conventional FAB conditions. These experiments demonstrated that a high flow rate (to 2 ml/min) LC/MS interface is feasible for ionization with FAB. Matrix concentration in the effluent is extremely important for sensitive analysis and will probably require post column addition. Spectra were obtained for Substance P and a series of fragments, stachyose, vitamin B12, cobalamide, and PPG 600.

The Future of Mass Spectrometry: Part I

R. Graham Cooks
Purdue University
West Lafayette, IN 47907

This paper is prepared from the vantage point of the end of a six-year term of office in ASMS and is titled Part I in the hope that later parts will be contributed as the valedictions of future society Presidents. Having missed almost all technical presentations in the service of the society for a long period, one can at least claim a certain uniqueness of perspective in discussing the future of our subject. Here, this future is seen as dependent upon the strengths of both this Society and of the discipline which it represents. Continued interest in mass spectrometry and its wide use seem assured. Indeed, it is not unreasonable to expect ASMS membership to reach 9000 by 1998, the centennial year of mass spectrometry.[1]

Such growth calls for carefully considered changes in our meetings. We will not continue to be the intimate group that some of us persist in imagining us still to be. Smaller meetings, like the Asilomar conference, will surely play a more important role as primary research conferences. I look forward to the annual conference including an instrument exhibit, instrumentation being one of the common denominators of mass spectrometry. A delicate balance is necessary between fundamentals, instrumentation and applications for a discipline like mass spectrometry to thrive. The burgeoning use of mass spectrometry makes the task of education in the subject immensely important. The impact of mass spectrometry on the biological sciences can only be facilitated by a combination of education in mass spectrometry and carefully targeted research. Two areas in which mass spectrometry has a disappointing record are organic analysis and surface science. In both cases this is because only a fraction of available capabilities are employed. With the dissemination of ion traps of several types, one can see the prospect of organic chemistry done in the mass spectrometer, at last coming into its own. Recent developments in quadrupole ion trap instrumentation[2] are occurring at a particularly rapid rate. This year alone has seen ion injection from external sources, high order MS^n experiments, rate constant and thermochemical measurements, and combinations of MS/MS with photoionization and photodissociation.

Areas of greatest future research opportunity seem to lie at the interface with surface science on the one hand and the biological sciences on the other. For example, there is much to be done in developing techniques and elucidating phenomena associated with collisions of polyatomic ions at surfaces. Such efforts offer improved capabilities in tandem mass spectrometry through high internal energy transfer to the projectile ion, as well as opportunity to develop new methods of characterizing molecular adsorbates on surfaces. (Through reactive collisions in which the projectile ion reacts with groups on the surface and so allows their characterization by mass spectrometry). The use of ion beams for tailoring the chemistry of surfaces through soft-landing experiments[3] also stands ready for exploitation. Figure 1 shows a new UHV instrument[4] designed to characterize the scattering of organic ions at well characterized surfaces through angle, mass and velocity measurements on the projectile and emerging particles. The device is also designed to permit modification of surfaces through soft-landing of mass-selected molecular ions.

At the other extreme in instrumental complexity, a simple means has been developed for performing ion/surface collisions in standard quadrupole, sector or hybrid MS/MS instruments. This instrument modification calls for a device with an in-line geometry even though large scattering angles are employed in the ion/surface collisions themselves. Figure 2 shows a version of this device[5] incorporated into a hybrid instrument and Figure 3 shows the result of dissociating the protonated form of the peptide angiotensin in a double quadrupole SID instrument. Even at low collision energy (30 eV) extensive fragmentation of the peptide occurs.

The above examples provide clues to the future of mass spectrometry, there are many others which have been presented at this conference. At the beginning of the week, the very idea of producing organic molecules with 40 or 50 charges might have been thought bizarre, at next year's meeting half a dozen labs might report similar work. This time last year the coupling of mass spectrometry to one of the most widely used and promising separation methods - electrophoresis including capillary gas electrophoresis - was in the future. This week we heard several presentations on these already successful experiments. This week Martin Jarrold reported the deposition of mass-selected Si-clusters on surfaces, and then photographed them with scanning tunnelling microscopy. A year ago an elegant - if poorly named - SIMS method (flow FAB) was barely invented. Now it is being practised in dozens of laboratories. The first paper on MS/MS in the ion quadrupole ion trap appeared two years ago and already the field is exploding with activity. In several presentations at this meeting people treated pg amounts of samples and ppt detection as routine. These capabilities were in the distant future ten years ago. Thirteen years ago MS/MS - for mixture analysis - did not exist. Desorption ionization methods - SIMS and FAB - had not been applied to organic compounds and there was no way to couple LC and MS.

While it is not inevitable that mass spectrometry will thrive, I believe it is within our power to ensure that it does. For this to occur, we must do more than participate in and apply the types of developments just discussed. In addition,

- Individuals of the highest caliber must be willing to serve in the society.
- The effort on education of all mass spectrometry users must be maintained and strengthened.
- The balance between fundamentals/instrumentation/applications - this difficult balance - must be preserved.
- Finally, we need to improve the quality of our competitive interactions we need to be advocates of mass spectrometry, supportive of each other in the larger arena.

Common characteristics unite these developments:

- very rapid progress from concept to widely applied methodology
- ingenuity in implementation e.g. we have half a dozen ingenious methods for crossing the solution vacuum interface.
- daring: mass spectroscopists will tackle anything!

Whatever the exact form of the future in mass spectrometry surely these qualities will be carried forward - energy, ingenuity and daring. With human qualities like this the problems mass spectroscopists' tackle can be large indeed. Alessandro Manzoni suggested:

Truth as subject
Beauty as means
Utility as purpose

There could hardly be a more suitable motto for our science.

Exciting developments are occurring throughout mass spectrometry and we are fortunate that we can be counted amongst its practitioners. As we continue to practice our science, lets lend strength to each others efforts, a strong science can that way only become stronger to the advantage of all.

Given these attitudes we can hardly fail to succeed as we more to really high masses, really small instruments, really wide use of sensitive, mobile, on-line, instruments, and deeper insigts into chemical reactions, physical phenomena and biological structure and function.

ANALYTICAL CAPABILITIES AND APPLICATIONS OF FT/ICR MASS SPECTROMETRY

Alan G. Marshall

Dept. of Chemistry (and Dept. of Biochemistry)
The Ohio State University
120 W. 18th Avenue
Columbus, OH 43210

The analytical advantages and disadvantages of FT/ICR mass spectrometry[1] are considered briefly here. Because the device acts to convert mass into frequency, and because frequency is the most accurately measurable physical parameter, the ultrahigh mass resolution (~1,000,000 at m/z 200 at 3.0 tesla) of FT/ICR is limited only by pressure (since FT/ICR line width varies directly with ion-molecule collision frequency) and by the uniformity and magnitude of the electric field in the ion trap (see Grosshans et al. in this volume). Because ions can be trapped for prolonged periods (s or min or longer), ions can be characterized by their reactions with neutrals: the neutrals may be provided by the parent molecules themselves (self chemical ionization without the need (or complications from) an external reagent gas) or by pulsed introduction of collision or reagent gases (MS/MS). Moreover, because successive stages in an FT/ICR experiment are separated in time rather than (as in beam instruments) separated in space, the FT/ICR mass spectrometer is compact and can perform multistage experiments (e.g., MS/MS/MS···) without additional hardware (or cost!). A major advantage is that ion selection can be achieved essentially by means of *software* (e.g., stored waveform inverse Fourier transform techniques)[2] rather than by the *hardware* methods associated with conventional ion focusing and slits. Similarly, a variety of different ion-forming means (E.I., C.I., laser desorption, photodissociation, S.I.M.S., etc.) can all be adapted to the same detector without sacrificing performance of any one of the ionization methods. In particular, laser desorption FT/ICR is uniquely suited for analysis of mixtures of chemically dissimilar species,[3] because most organics desorb under the same experimental conditions. Since ICR excitation and trapping potentials are low (<100 V or so), and since there is no need to direct ions through a narrow slit, the ion source/detector can be operated for extended periods (several months) without the need for disassembly and cleaning. Because ICR experiments can be conducted at pressures ~1000 times lower than those of most other mass spectrometer ion sources, ICR is inherently more sensitive (in the sense of lower sample vapor pressure) for observation of low-volatility heat-labile species. Positive and negative ions may be detected in successive scans, simply by changing the sign of the trapping voltage. Detection is fast--data are generally acquired in 1 sec or less, even for very wide mass range and/or very high mass resolution.

A disadvantage of FT/ICR is its limited dynamic range. Because the detected signal is an image current induced by a coherently orbiting ion packet, the minimum number of ions that can be detected in a single scan is ~100. However, the presence of more than ~100,000 ions in the trap leads to Coulomb broadening and ion ejection. Therefore, the FT/ICR dynamic range is inherently limited to a factor of about 1,000 in a single experiment. However, selective ejection of abundant ions can improve that factor significantly, if two or more scans can be acquired.[4] A disadvantage of any computer-based mass spectrometer is that precision in determining mass (or ion abundance or peak width) is directly related not only to signal-to-noise ratio, but also to the number of data points per peak width. Thus, in order to realize the ultrahigh mass resolution available from FT/ICR, very large data sets (>256K) may be needed.

Accurate measurement of relative ion abundances by FT/ICR, although highly reproducible for a single set of conditions, can be sensitive to various experimental parameters--thus, it is important to compare relative peak areas under identical operating conditions. The low-pressure (~10^{-8} torr or less) requirement of FT/ICR requires differential pumping between the ion source (whether external or dual-cell) and the ion analyzer; as a result, FT/ICR has been interfaced satisfactorily to GC and FAB sources, but with less success for supercritical fluid or liquid chromatography effluents. As for all types of Fourier transform spectrometry, FT/ICR has the problem of foldover--i.e., signals whose frequency exceeds the Nyquist limit of the analog-to-digital converter will appear "aliased" or "folded-over" to incorrect frequencies. Foldover may generally be eliminated by appropriate (computer-selected) bandpass filtering. FT/ICR mass resolution decreases with increasing mass (as for any magnetic field based mass analyzer operated at its magnetic field imposed limit). Moreover, although experimental FT/ICR mass resolution closely approaches its theoretical limit[5] below about m/z 2000, experimental performance (particularly for F.A.B.-generated organic ions) drops well below that limit for ions of higher mass--causes and solutions are addressed in the paper by Grosshans et al. in this volume.

Several exciting new developments in FT/ICR are discussed in our own and other papers at this meeting. For example, our understanding of the origin of the upper mass limit for FT/ICR is improving, and there is reason to believe that new ion trap designs will lead to significantly improved performance at m/z > 2,000. Several research groups are developing new and/or better ways to adapt existing ion sources (e.g., F.A.B., S.I.M.S., plasma desorption, fast neutral beam) to FT/ICR instruments. The best evidence for the analytical advantages of FT/ICR is the good agreement between a best-fit exponential curve and the number of FT/ICR spectrometers shown below. The number of FT/ICR instruments worldwide is already double the number of continuous-wave ICR instruments (which were used mainly by academics for ion-molecule chemistry), due mainly to the analytical and industrial applications to polymers[3] and other areas.

ENERGY- AND TIME-RESOLVED MEASUREMENTS IN MASS SPECTROMETRY

Chava Lifshitz
Department of Physical Chemistry and
The Fritz Haber Center for Molecular Dynamics
The Hebrew University of Jerusalem, Jerusalem 91904, Israel

Two techniques for ion trapping have been employed by us in recent years: (1) Ion trapping in the space charge of an electron beam; (2) Ion trapping by RF voltages in a Cylindrical Ion Trap (CIT). These techniques allow time-resolved measurements to be made in the range of ion lifetimes from microseconds to milliseconds. They have been combined with energy resolved electroionization and photoionization measurements, respectively. These combinations have been applied to measurements of time-resolved appearance energies, ionization efficiency curves and kinetic shifts. Space charge trapping has also been combined with an MS/MS method called TRIMS (Time-Resolved Ion Momentum Spectrometry) and has been applied to determinations of time-resolved kinetic energy releases.

Figure 1 is a schematic drawing of the photoionization mass spectrometer and Figure 2 is a schematic drawing of the experimental setup which combines TRIMS with ion trapping in the ion-source by an electron space charge.

The primary reaction of the anisole cation-radical – elimination of formaldehyde has been studied by both techniques[1,2] in detail recently. The experimental time-resolved photoionization efficiency curves and kinetic energy releases (KERs) have been modelled by RRKM-QET calculations. An accurate long-time limiting threshold energy was determined for the reaction. The KERs were observed to be time-dependent due to varying contributions of two competitive mechanisms to the reaction.

RF QUADRUPOLE ION TRAPS - PAST, PRESENT AND FUTURE (?)

J.F.J. Todd, Chemical Laboratory, University of Kent,
Canterbury, Kent, CT2 7NH, U.K.

Although the rf quadrupole ion trap has its origins in the same patent as that which first described the quadrupole mass filter[1] its emergence as a viable commercial mass spectrometer has been only a recent event.

The history of the ion trap (see Table 1) has followed two essential parallel paths. On the one hand successive groups of physicists, originating with Dehmelt [2,3], have utilised the device in systems for studying the spectroscopy of trapped atomic ions and there is now an abundant literature involving this area of application[4]. At the same time the development of ion trap mass spectrometers has passed through three distinct periods: mass selective detection, mass selective storage and, latterly, mass selective ejection.

Table 1. The Ages of the Ion Trap

1953:-	First disclosure (Paul & Steinwedel)	Mass-selective Detection
1959:-	Storage of microparticles (Wuerker et al)	
1959:-	Use as a mass spectrometer by Fischer	
1962:-	Storage of ions for rf Spectroscopy (Dehmelt et al)	
1968:-	Ejection of ions into an external detector (Dawson & Whetten): use as a mass spectrometer	Mass-selective Storage
1972:-	Combination of 'Quistor' with quadrupole for analysis of ejected ions (Todd et al): Characterisation of the trap, CI, ion-molecule kinetics, etc.	
1980:-	Resonant ejection of ions (March et al)	
1984:-	Disclosure of 'Ion Trap Detector' (Stafford, Kelley, Syka, Reynolds & Todd)	Mass-selective Ejection
1987:-	MS/MS, CI, photo-dissociation, injection of ions, mass-range extension, etc.	

The earliest phase saw the ion trap acting as a combined source, analyser and detector, in which the presence of ions was characterised by sensing the motion characteristic of species with particular m/z values, in a manner not dissimilar to ICR. With mass selective storage, ions of specific m/z value were created and stored in the trap prior to ejection into an external detector[5]; a development of this system was the QUISTOR/Quadrupole tandem system for studying the physical and chemical behaviour of trapped ions. Each of these earlier systems contained drawbacks which gave the ion trap few apparent advantages over existing forms of analytical mass spectrometer. These problems have largely been overcome with 'mass selective ejection' [7]. Here ions are first created within the trap and then ejected by increasing the amplitude of the RF drive potential applied to the ring electrode such that the axial component of the motion of the ions becomes unstable. This occurs with increasing value of m/z, so that the detected ion signal corre-

sponds to a mass spectrum. It has been shown that the resolution and sensitivity of the device may be improved considerably by maintaining a background of helium buffer gas present in the trap at a pressure of ca. 10^{-3} Torr.

Using this basic technology a number of improvements and further developments have been possible, including the control of adverse space charge effects through 'automatic gain control' [8], MS/MS studies through the application of supplementary rf fields to excite the secular motion of mass selected ions [9], chemical ionization [10] and photodissociation [11]. At this point in time, therefore, it is of some interest to trace the manner in which the ion trap mass spectrometer has evolved, highlighting the landmarks, and to consider possible directions for the future.

COMPARISON OF THERMAL-ASSISTED AND PNEUMATIC-ASSISTED NEBULIZATION FOR ELECTROSPRAY LC/MS

Edgar D. Lee and Jack Henion, Equine Drug Testing and Toxicology, New York State College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Thomas Covey, Sciex, 55 Glencameron Road, Thornhill, Ontario, Canada L3T 1P2.

Electrospray has been demonstrated as a feasible LC/MS interface at eluent flowrates of 5 to 10 uL/min. These low flowrates are compatible with capillary columns or require splitting the majority of the chromatographic effluent from the mass spectrometer. The use of pneumatic-and/or thermal-assistance with electrospray has been investigated in our laboratory to increase the eluent flowrate to be compatible with larger bore HPLC columns.

The mass spectrometer used for these experiments was a Sciex TAGA 6000E triple quadrupole equipped with an atmospheric pressure ion source. The pneumatic-assisted electrospray interface used was the ion spray LC/MS interface (1). This interface was constructed of two concentric stainless steel capillaries held at a potential of ±3 kV. The applied potential and the assistance of nitrogen nebulizing gas which flows through the annular space between the two capillaries forms charged droplets from which the ions are emitted. The inner capillary, through which the chromatographic eluent flows was 100 um i.d. x 225 um o.d. and the outer capillary, with an inside diameter of 500 um, was tapered at the end to a diameter of 300 um. The linear velocity of the nebulizing gas was measured to be 216 m/sec at the exit of the co-axial capillaries. The thermal-assisted electrospray interface was constructed from a homemade thermospray probe. The central tubing in the probe was replaced with a 250 um i.d. tube through which a 100 um i.d. x 200 um o.d. stainless steel capillary was fed. The end of the capillary extended 3 mm beyond the end of the thermospray probe for the electrospray needle necessary to create a high electric field for nebulization. The thermospray probe and power supply were floated at a ±3 kV electrospray potential.

The ion spray LC/MS interface has increased the eluent flowrate of electrospray from 10 uL to 100 uL/min with a small loss in sensitivity. Operation at eluent flowrates compatible with standard bore columns (500 to 750 uL/min) can be used. However, the loss in sensitivity is greater than if a portion of the eluent is split off. The ion spray mass spectrum of 100 ng of the hexa-sulfonated azo dye, direct Red 80 (MW 1240), was obtained at a flow rate of 50 uL/min (Figure 1). The base peak at m/z 205 is the $[M-6H]^{6-}$ molecular ion. The other major ions are m/z 247, 309, 412, which correspond to the $[M-5H]^{5-}$, $[M-4H]^{4-}$ and $[M-3H]^{3-}$ molecular ions.

The thermal-assisted electrospray interface complements ion spray at flowrates greater than 100 uL/min. The thermal-assisted electrospray mass spectrum from 1 ug of the hexa-sulfonated azo dye, direct Red 80, (Figure 2) exhibited comparable total ion intensity to the ion spray spectrum for 100 ng (Figure 1). The thermal-assisted electrospray mass spectrum was obtained at a flowrate of 500 uL/min and probe temperature of 165°C. The same multiply-charged ions are present in the thermal-assisted electrospray mass spectrum as in the ion spray mass spectrum with the exception that in the thermal-assisted mass spectrum m/z 619, corresponding to the doubly deprotonated doubly charged negative molecular ion, is also present. The heat appears to drive the ionization to the lower charged species. This effect can also be seen with other analytes we have studied.

Evaluation and Optimization of Continuous Flow Fast Atom Bombardment Interface Between Open Tubular Liquid Chromatography and Mass Spectrometry

M.A. Moseley[1,2], J.S.M. de Wit[1,2], L.J. Deterding[1], K.B. Tomer[1] and J.W. Jorgenson[2]

2) Kenan Laboratories of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514

The combination of liquid chromatography (LC) and continuous flow fast atom bombardment mass spectrometry (CF-FAB/MS) has recently become the topic of active research (1-5) since both LC and CF-FAB/MS are very useful for the analysis of polar, nonvolatile and/or thermally labile compounds.

In the CF-FAB interfaces thus far demonstrated the matrix required for the FAB process is introduced either in the mobile phase and analyte solutions, or is added to the LC effluent post column. Introduction of the matrix into the mobile phase can compromise the chromatography and changing the matrix type or concentration may require reevaluation of the chromatographic conditions. Post column addition of the matrix may lead to significant chromatographic peak broadening, particularly with microbore or open tubular LC.

Therefore, an interface which circumvents both of these problems was designed (5) which uses coaxial flow of the LC and matrix in two separate fused silica capillary columns. In this "column-within-a-column" interface the LC capillary column (150 um o.d.) is inserted into a sheath capillary column (200 um i.d.). A 1/16" stainless steel "tee" (Fig. 1) is used to interface the sheath and LC capillaries. A syringe pump is used to flow the matrix solution coaxially in the sheath column around the capillary LC column, and mixing of the matrix and the LC effluent takes place only at the FAB probe tip. The matrix flow, and the LC flow are regulated separately, which allows for independent optimization of the operating conditions (composition and flow rate) for both the chromatographic and FAB processes. The matrix solution used in this work was 25/75 glycerol/water at a flow rate of 1.2 ul/min. The LC flow was approximately 100 nl/min, an order of magnitude less than the matrix flow, and the combined flows resulted in a source pressure of
2×10^{-5} torr.

The performance of the interface has been evaluated for a range of compounds in terms of chromatographic fidelity, reproducibility, and detection limits. This interface design was found to be suitable for use with open tubular LC columns and with ultra-microbore packed LC columns (50 um i.d.) (Fig. 2). We observed a detection limit of 8 pg (S/N ~ 4/1) (Fig. 3) for the (M+H)+ ion, and a MS/MS full scan detection limit of 640 pg (Fig. 4) for the tripeptide Met-Leu-Phe.

Continuous-flow fast atom bombardment mass spectrometry (CF-FAB) has been shown to have significant advantages in the direct analysis of aqueous solutions.[1] Our laboratory has previously shown that CF-FAB can be successfully applied to the analysis of peptides and peptide mixtures and can be utilized to obtain on-line kinetic measurements of enzyme reaction mixtures.[2] We have also combined microbore HPLC techniques to provide LC/MS capabilities for the analysis of peptides and small proteins.3 One area in which CF-FAB has not been applied to a significant extent is in the structural analysis of small molecules. Due to the nature of the low energy desorption process, FABMS normally yields spectra with very little fragmentation, and hence, very little structural information other than the molecular weight of the compound. In addition, the chemical noise due to the ions desorbed from the sample matrix is especially high in the low mass range, and complicates spectral interpretation of low molecular weight compounds.

The purpose of this study was to determine if CF-FAB could be successfully applied to the analysis of solutions of small molecular weight drugs (MW < 500) to yield both qualitative and quantitative information. The approach used was to combine CF-FAB with MS/MS techniques using a triple-stage quadrupole mass spectrometer. This combination allowed us to obtain collision-activated decomposition (CAD) mass spectra of the drugs after initial ionization by CF-FAB.

Samples were introduced into a Finnigan MAT TSQ 70 MS/MS system using a continuous-flow introduction inlet which was comprised of a 0.075 mm i.d. capillary and a Rheodyne Model 4010 injector fitted with a 0.5 μL loop. A Waters Model 590 pump was used to pump the carrier solution at a flow rate of 7 μL/min. The carrier solution was comprised of an aqueous mixture of 5% glycerol:15% acetonitrile:0.1% TFA. The sample and carrier solution was deposited on the normal FAB probe tip (Fig. 1), which is kept at 40°C. To aid flow from the probe tip, and maintain a stable surface, an absorbent pad of compressed cellulose is fitted to the probe tip adjacent to the sample surface. Collision-activated decomposition was effected using Ar as the collision gas at a pressure of 0.6-0.8 mTorr and a collision energy of 25-35 V. Mass spectral data was collected in the profile mode. Quantitative estimates were made using the integrated areas of selected ion chromatograms of significant daughter ions or the sum of significant daughter and surviving parent ions.

CF-FAB MS/MS was successfully used to obtain mass spectra from the following drugs or drug metabolites: benzoylecgonine, cocaine, codeine, morphine, penicillin G, pentobarbital, phenobarbital, phentolamine, and THC. Sensitivity and linearity studies were performed for benzoylecgonine, cocaine, penicillin G, and phentolamine. The minimum detection limits were determined to be 500 pg for benzoylecgonine, 250 pg for penicillin G, 50 pg for cocaine, and 50 pg for phentolamine. The range of reproducibility for repetitive injections of the different compounds was 5 - 15%, depending on the amount injected. Areas of selected ion chromatograms were linear for phentolamine and penicillin G for amounts injected from 250 pg to 50 ng (Fig. 2).

Experiments were also performed to determine if the CF-FAB MS/MS technique could be used to determine the presence of drugs in urine without prior sample clean-up procedures. Urine samples were spiked with either cocaine or benzoylecgonine (the primary cocaine metabolite) at concentrations of 0.1 - 10 μg/mL and injected directly into the mass spectrometer via the CF-FAB inlet. Both yielded the characteristic MS/MS spectrum at the 5 - 10 μg/mL level, and could be observed by selected ion chromatograms of the primary daughter ion down to 0.2 μg/mL and 1.0 μg/mL (100 pg and 500 pg injected), for cocaine and benzoylecgonine, respectively. Direct analysis of urine, however, resulted in poor reproducibility for repetitive injections which is attributed to the precipitation of salts and/or proteins in the capillary tubing of the CF-FAB inlet.

These experiments demonstrate that the combination of CF-FAB and MS/MS is useful for the structural identification of small molecular weight compounds such as drugs. The technique was demonstrated to be quantitative with standard errors of determination ranging from 5 - 15%. Sensitivity of the technique varied with the type of compound analyzed, but was in the picogram range for all compounds tested.

CONTINUOUS-FLOW FAB LC/MS ANALYSIS OF ACYLCARNITINES AND ACYL-COA COMPOUNDS USING MICROBORE HPLC COLUMNS

David S. Millington and Daniel L. Norwood
Division of Pediatric Genetics and Metabolism, Duke University Medical Center, Box 3028, Durham, NC 27710.

FAB-MS is a sensitive method for the analysis of acylcarnitines and acyl-coA thioesters (1). The recently developed continuous-flow FAB-MS interface is being applied in our research with three major objectives: 1. The analysis of acylcarnitine and acyl-coA mixtures from biological fluids by LC/MS. 2. The rapid, sequential analysis of urine samples for unusual acylcarnitines as a screening technique for metabolic disorders. 3. The development of in vitro enzyme assays by direct monitoring of substrate/product concentration.

Methods A standard pulse-damped HPLC pump (Waters 600-MS) was interfaced to a Valco CWI4 microinjector (100 nL loop) via a splitting 'T' (SGE MCVT 1:50), adjusted to provide a flow-rate of 5-10 µL/min. For direct injection of urine samples (25 µL, dried and methylated with 25 µL 3M MeOH/HCl at 65 °C for 10 min), the effluent was connected directly to the ion source of a VG Trio-3 triple quadrupole mass spectrometer by a length of fused-silica capillary. The manufacturer's interface probe and FAB/MS ion source (maintained at 50 °C) were employed. Acyl-coA thioesters were analyzed in the same manner, and MS/MS spectra were recorded using air as collision gas and with about 5 eV energy. For analysis of acylcarnitine standard mixtures, a "micro-LC" column (150 mm x 0.3 mm) packed with 5 µm C18 stationary phase (Alltech, Carnforth, UK) was employed and a non-linear gradient was used to effect the separation (Fig. 1).

Results The separation and analysis of free carnitine and its C2-C6 esters is shown by the TIC chromatogram in Figure 1. The high stability and sensitivity of the system were maintained despite the severe solvent gradient employed. The mass spectra of the individual components are dominated by (M+H)+ ions, enabling their detection at low pmol levels. For rapid screening of urine samples, it is sufficient to identify putative acylcarnitine signals without chromatographic separation. This was accomplished by analysis of 100 nL eqivalents of urine specimens after methylation (above) with an estimated detection limit for each acylcarnitine of 5 pmol (50 nmol/mL). The analysis cycle time, including syringe and injector flushing, was about 1.3 min. Since there was no evidence of memory effects, the method is apparently suitable for automation using an autosampler or laboratory robot.

The analysis of 0.8 nmol of propionyl-coA (MW = 823) is shown in Fig.2. In 2(a) and 2(b), the RIC profile and full scan mass spectrum at unit mass resolution are shown; and in 2(c), the CID mass spectrum from m/z 824 at reduced resolution (increased transmission) shows fragments at m/z 317 and 215 that contain the acyl group and is qualitatively similar to that previously reported by a metastable (B/E linked) scan on a magnetic sector instrument (1). The direct monitoring of these metabolites in mixtures at sub-nmolar concentration seems feasible.

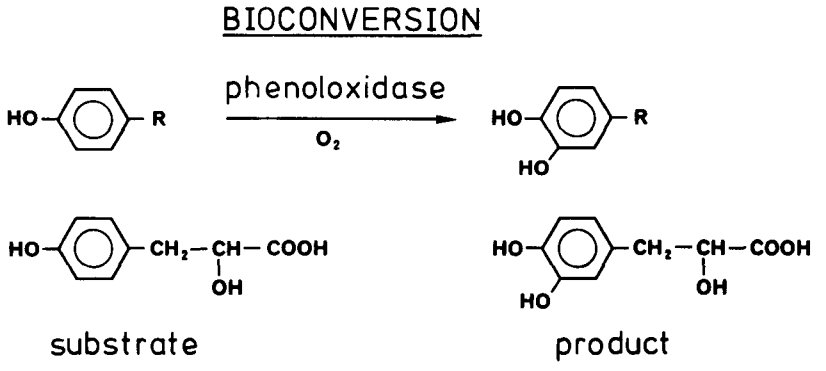
On line monitoring of nonvolatile products of biocatalytic reactions by mass spectrometric detection.

A.P. Bruins and N. Pras
State University, Dept. of Pharmacy, 9713 AW Groningen, The Netherlands

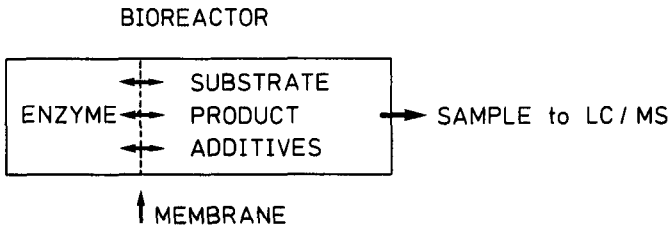
Mass spectrometers are used for process control and monitoring fermentations by measurement of volatile products .A sample from the head space inside the fermentor or a sample of volatile products that permeate through a membrane is introduced into the mass spectrometer.

On a laboratory scale, the quantitative and qualitative measurement of nonvolatile products of biocatalytic reactions is done by HPLC. Developments in LC/MS interfacing make mass spectrometric detection of such nonvolatile products feasible, by the direct introduction of a portion from the liquid phase of a biocatalytic reaction system into the LC/MS.

In our laboratory, an enzyme present in plant cells is used for the biocatalytic oxidation of substituted phenols to the corresponding catechols (1). Enzyme formulations employed for the oxidation of phenols are: a purified enzyme suspension; a plant cell suspension; plant cells entrapped in calcium alginate. In each system there are high molecular weight materials and particulate matter that cannot be introduced into the LC column and thermospray LC/MS interface.



To investigate the feasibility of on line LC/MS monitoring of fermentations a purified enzyme suspension was enclosed in a piece of dialysis tubing. A number of such "sausages" was immersed in an aqueous solution of a phenol, TRIS HCl buffer, and sodium ascorbate. Air was bubbled through. The substituted phenol migrates through the membrane, is oxidised, and the product migrates back into the bulk solution. We have in



fact created a two compartment system, where particulate matter (the enzyme suspension) is separated from a "clean" solution. A sample from the "clean" solution was injected into the LC/MS. The identity of substrate and product was readily confirmed from negative ion spectra and from daughter ion scans of $(M-H)^-$ ions.

The mass spectrometer was a Nermag R 30-10 triple quadrupole equipped with a Nermag thermospray source, a Vestec probe and controller. A Kratos Spectroflow 400 pump and Spectroflow 757 UV detector (high pressure cell) were used for HPLC.

IMPROVEMENTS IN A PARTICLE BEAM LC/MS INTERFACE

A. Apffel and R. Nordman; Hewlett-Packard Company, Palo Alto, California 94304

During the last several years, experiments using particle beam based interfacing techniques between High Performance Liquid Chromatography and Mass Spectrometry have excited attention because of their potential advantages with respect to existing interface techniques, such as the generation of library searchable electron impact spectra, excellent sensitivity, reproducibility and ease of use.

The Particle Beam LC/MS system consists of three basic components; an aerosol generator, a desolvation region and a momentum separator. Following initial feasibility studies (reported last year), an in-depth investigation into the performance characteristics of each of these subsystems has lead to a redesign of the system resulting in significant improvements in the instrumentation, particularly in the quantitative performance and the ease of use. The purpose of this paper is to summarize these improvements

PB LC/MS is based on earlier work on "MAGIC" (Monodispersed Aerosol Generation Interface Combining LC and MS) done at Georgia Institute of Technology[1]. The development of MAGIC LC/MS utilized a cross-flow pneumatic nebulizer and emphasized the requirements for narrow droplet size dispersion. The current system utilizes a co-axial pneumatic nebulizer which results in a major improvement in sensitivity, nebulization gas consumption and ease of use.

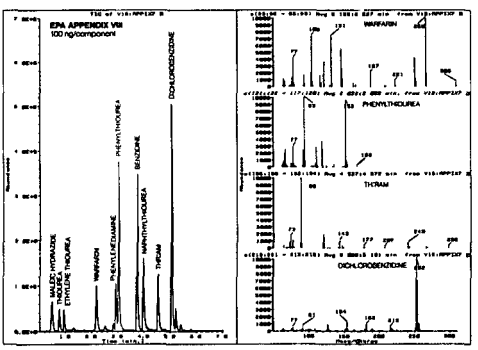

Figure 1. Analysis of 10 EPA Appendix VIII compounds at the 100 nanogram level

In our earlier prototype temperature stability of the desolvation chamber had adverse effects on reproducibility. Optimization of the dimensions and thermal characteristics in the current system has lead to excellent reproducibility (<3% rsd) under a wide range of conditions Finally, modeling of the fluid dynamics of the momentum separator has lead to increased sensitivity.

The Particle Beam LC/MS system can operate with all commonly used HPLC mobile phases (with the exception of non-volatile buffer systems) at flow rates between (0.1 and 1 ml/min. Both electron impact and chemical ionization modes can be used, resulting in typical detection limits of 10-100ng for full scan acquisition. The system shows applicability to a wide range of problems not amenable to GC/MS analysis.

CHARGE EXCHANGE REACTIONS WITH WATER IN THE DETECTION OF PERFLUOROCARBONS BY THERMOSPRAY LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

S. K. Huang, M. McLoughlin and D. H. Klein
Adamantech inc., 1501 Blueball Ave., Linwood, PA 19061-0895

Perfluorocarbons (PFC's) are thermally and chemically stable materials. They are resistant to microbiological or chemical oxidations. In 1966, Clark et. al. (1) found that perfluoro- tetrahydrofuran equilibrated with oxygen at atmospheric pressure could support the respiration of a mouse. Since then, applications of perfluorochemical emulsions for human therapeutics have been explored.

Valuable information about PFC mixtures could be obtained by an analytical method which determines the composition of the mixture in terms of molecular weight groups, rather than in terms of individual isomers(2). Several packed GC columns were tried but found not useful in achieving the separation of PFC's into different molecular weight groups clearly. Therefore a procedure for liquid chromatographically separating these PFC's clearly into different molecular weight peaks, each of which consists of isomers of a single molecular weight has been developed. This was achieved by using a 4.6mm x 25 cm column with a Fluorodecyl bonded stationary phase and 100% THF as a mobile phase. A Hewlett-Packard Model 5988 LC/MS system equipped with a Vestec thermospray interface was used for this work. Table 1 is a compilation of experimental results for the detection of PFC's. It can be seen that LC/MS detection of PFC's requires the presence of water with filament turned on in the negative ion mode. The best condition in terms of sensitivity and resolution was obtained by the postcolumn addition of 0.1 N ammonium acetate (NH_4OAc) aqueous buffer, or of water only, through a low dead volume tee; addition of water or aqueous buffer directly to the mobile phase resulted in degradation of the separation. The mobile phase was pumped at 1 ml/min, and buffer or water was added to the column effluent at 0.5 ml/min with the stem temperature was taken at 25% less than the vaporizer exit temperature, and at a source temperature of 280° C. Figure 1a shows the total ion chromatogram (m/e 17-600) resulting from injection of a mixture of 60ug each of perfluoro-cyclohexane, perfluoro-methyl cyclohexane, perfluoro- 1,3-Dimethyl cyclohexane, perfluoro decalin and perfluoro-1-methyl decalin, with thermospray LC/MS detection and Figure 1b is the chromatogram of the same mixture using a refractive index(RI) detector. The ions detected are $M^{-\bullet}$ and $(M-F)^-$. It has been reported that proton transfer, anion attachment, and electron capture are responsible for the negative ion thermospray detection(3). Since there was almost no signal detected when THF alone was used as the mobile phase (Table 1), the contribution of the direct electron attachment process to the detection of PFC's is minor. Furthermore, the observations that when water is added to the system the detection of PFC's becomes sensitive, and that the background of the total ion chromatograph shows abundant mass peaks representing $(H_2O)_m(OH)_n^-$ (m=0-4, n=4-6) suggest the charge exchange mechanism. To test this hypothesis, an experiment was performed on perfluoro-toluene. Because the electron affinities of $\bullet OH$ and $C_6F_5CF_3$ are 43.6 ± 2.7 kcal/mole and 39.2 ± 6.9 kcal/mole respectively, $\bullet OH$ should not transfer charge to perfluoro-toluene. This was shown to be the case. Thermospray LC/MS of perfluoro-toluene gave a negligible peak at the same retention time at which the RI detector gave a large peak.

In the experiments reported here, there is no preionization of PFC's as described by Dodd and no chemical ionization of PFC's by the primary reagent ions (here NH_4^+) through gas phase ion/molecule reaction in direct thermospray ionization. This can be ascribed to the inertness and stability of the PFC's. The detection limit of PFC's in thermospray LC/MS can be improved by a factor of 10 when single ion

monitoring (SIM) technique is employed. This is much less effective than in the case of GC/NICI/MS, where the improvement of sensitivity can be as high as 500. Because PFC's appear to be shielded from electron attack by the surrounding THF molecules (The THF molecules are effective shields because they are electrophobic, as shown by the low baseline signal obtained when THF alone is entering the ion source), and because water has no affinity for the PFC's, the intensity of the detected negative ion PFC is limited by the surrounding THF molecules. Therefore greatly increasing the water content in the inlet system does not result in more sensitive detection of the PFC's.

Analysis of Middle Mass Peptides by Thermospray LC-MS and LC-MS/MS

Patrick J. Rudewicz, Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

Introduction Since most thermospray (TSP) LC-MS analyses have been done on quadrupole mass spectrometers having mass ranges less than 1800 u, there have been a limited number of applications using TSP for peptide and protein structure determination. Previously, the molecular weights of middle mass (2000 to 4000 u) peptides ionized by TSP had to be determined using multiply charged ions. However, with the latest generation of quadrupole mass spectrometers having extended mass ranges of 4000 u, middle mass peptides can now be analyzed directly by TSP LC-MS.

Experimental These experiments were done using a Finnigan MAT TSQ 70® triple quadrupole mass spectrometer equipped with a Finnigan MAT TSP LC-MS ion source. The HPLC system consisted of two Waters (Milford, MA) 510 HPLC pumps and a Waters 680 gradient controller. The TSP conditions were: source block 190°C; vaporizer 85°C; aerosol 155°C. The mobile phase was 80% methanol/20% 0.1 M ammonium acetate at a flow rate of 1.2 ml/min. For the LC-MS/MS experiments, the collision gas was xenon at 1.5 milliTorr and the collision energy was 25 eV. The sample was introduced continuously into the ion source at a rate of 0.5 nmole/sec, and the parent ion beam was transmitted with a 5 u window. The scan time was 30 sec. The tryptic digest of bovine lactoglobulin A was purchased from Applied Biosystems (Foster City, CA).

Results and Discussion Previous work in our laboratory has demonstrated the potential of TSP LC-MS for the analysis of peptides with molecular weights between 2000 and 4000 u (1,2). Full scan centroid data have been shown for low nanomolar amounts of peptides such as melittin (M_r 2844) and glucagon (M_r 3480). The spectra contained abundant singly protonated molecular ions and the doubly charged species, MH_2^{+2} and $(M+H+Na)^{+2}$. Centroids of molecular ion clusters, recorded at reduced resolution to enhance sensitivity, provided average molecular weight data.

TSP LC-MS As a preliminary evaluation of this methodology for the on-line LC-MS analysis of peptide mixtures, a tryptic digest of bovine lactoglobulin A (MW 18,367) was analyzed. The mixture was eluted from a 3 cm C-8 column using isocratic conditions of 80% methanol/20% 0.1 M ammonium acetate. A mass spectrum displaying the total ion current summed across the entire elution volume is shown in Figure 1. Abundant molecular ions are present for most of the expected tryptic fragments. In the 2000 to 3000 u range, a singly protonated molecular ion for tryptic fragment, T_4, a 20 residue peptide, is present at m/z 2313. The doubly charged ion at m/z 1157 corroborates the molecular weight of this fragment. The presence of a disulfide linkage connecting T_5 and T_{18} is indicated by the ion at m/z 2777.

TSP LC-MS/MS To produce structural information, daughter ion spectra can be obtained on either the singly or doubly protonated molecular ions of peptides (2). As an example, the CID spectrum of the protonated molecular ion of substance P is shown in Figure 2. The principal fragmentation pathways involve cleavage of the -CHR-CO- bonds and the -CO-NH- bonds with charge retention by the N-terminal fragments, A and B type ions, respectively. It has been our experience that CID spectra of peptides up to mass 600 ionized by TSP can be recorded at unit resolution within the time frame of a chromatographic peak. Higher mass peptides, especially above mass 1000, however, require continuous introduction into the TSP source and transmission of the entire molecular ion cluster through the first quadrupole.

FUNDAMENTAL STUDIES OF SOLUTION-PHASE AND GAS-PHASE REACTIONS IN ELECTROCHEMISTRY/THERMOSPRAY/TANDEM MASS SPECTROMETRY

Kevin J. Volk, Anna Brajter-Toth, and Richard A. Yost
University of Florida, Gainesville, FL 32611

The on-line coupling of an electrochemical cell with thermospray/tandem mass spectrometry (EC/TSP/MS/MS) can provide valuable redox information on a variety of compounds because it is capable of providing molecular weight and structural information of intermediates and products formed in redox processes. After the initial redox reaction has taken place, the intermediates produced during the electrooxidation of uric acid and 6-thiopurine can undergo a variety of chemical reactions (Figs. 1,2) such as hydrolysis, ammonolysis, methanolysis, and other substitution reactions depending on the composition of the mobile phase and the thermospray operating parameters. Here we report the results of our work to determine if such reactions occur in the thermospray probe, source or both.

Our studies were divided into the following categories:

Gas-Phase Studies

Reagent Gas Added	Mobile Phase
1) none	0.1M NH_4OAC
NH_3	0.1M HOAC
2) none	0.1M NH_4OAC/CH_3NH_2
CH_3NH_2	0.1M NH_4OAC
3) none	0.1M NH_4OAC/CH_3OH
CH_3OH	0.1M NH_4OAC

Solution Phase Studies

1) Tip temperature studies
2) Source temperature studies
3) Mobile phase composition

The effect of tip temperature on intermediate formation (mobile phase consists of 0.1M NH_4OAC) can be seen in Figures 3 and 4. These plots indicate that ammonolysis reactions are related to processes which occur inside the vaporizer probe. Unlike the tip temperature studies, source temperature studies did not indicate the presence of temperature dependent chemical reactions. When 0.1M acetic acid is used as the mobile phase and NH_3 is added to the source, only hydrolysis reactions are detected (i.e. no ammonolysis reactions occur for either compound studied). Similar reactions occur inside the vaporizer probe when methylamine and methanol are present in the mobile phase; but do not occur when the these same gases are introduced in the TSP source.

The electrooxidation of 6-thiopurine is thought to be very similar to the chemical oxidation (Figure 5). The inability to detect the dimer by EC/TSP/MS at pH ~7 is consistent with the disproportionation process. Although the sulfinic acid is not detected by EC/TSP/MS, we believe that once formed, it undergoes reactions inside the probe (hydrolysis, ammonolysis, etc.) to

form the observed products, purine, adenine, and hypoxanthine (Figure 2). Gas-phase studies also support the dimer disproportionation process because the dimer can be detected using a mobile phase consisting of 0.1M HOAC with ammonia added to the TSP source. Under the conditions which allow the detection of this dimer, neither hypoxanthine nor adenine are formed. These studies indicate that many of the observed reactions do not occur in the TSP source, but occur inside the vaporizer probe.

DEVELOPMENT OF NEW SOFT IONIZATION TECHNIQUES BASED ON PROPERTIES OF SUPERCRITICAL FLUIDS

S. V. Olesik, L. A. Pekay, Department of Chemistry, The Ohio State University, 120 West 18th Ave., Columbus, OH. 43210

The ideal "hyphenated" technique of chromatography - mass spectrometry for high molecular weight, highly polar compounds has the following properties:

1) The separation process is highly efficient.
2) The interface between the chromatography and mass spectrometer is easily made.
3) The ionization process is capable of ultra-soft ionization, as well as, highly controlled energetic ionization.
4) The interface and the ionization process is well suited for use with high-performance mass spectrometers such as magnetic sector instruments and FT-ICR.

None of the present soft ionization techniques share all these attributes. Fast atom bombardment (FAB) is plagued by high background signal and the inability to interface easily to highly efficient separation techniques. In FAB, liquid electrospray, and thermospray the monovalent ions produced are present as solvated ions in solution. High molecular weight nonpolar compounds are very difficult to analyze by any of these techniques.

We are developing a new ionization technique that should have many of the properties desired of an ideal ionization technique. Supercritical Fluid Assisted Ionization depends, as the name implies, on the properties of the supercritical fluid controlling the ionization process.

The fundamental gas-phase chemistry that forms the basis of supercritical fluid assisted ionization will be described. In addition, a detailed description of the new instrument will be included. Finally, preliminary results will be presented.

Pyrolysis-GC-MS and Fast Atom Bombardment Mass Spectrometry : a useful tool for structure elucidation of complex organic molecules.

Vangaever F., Hendrickx A., Decuyper M., Hancke N.

R&D Analytical Laboratory Agfa-Gevaert,
Septestraat 27, B-2510 Mortsel, Belgium

Mass spectrometry is well suited for structure determination of submilligram amount of pure material. Electron impact ionization was used as such in our laboratory for many years for probing a variety of chemicals used in the photographic industry.

The advent of a simple desorption-based ionization method like Fast Atom Bombardmen mass spectrometry makes nowadays possible the study of, mass-spectrometrically speaking difficult molecules (highly polar and even charged samples most often in a mass range above 500 dalton). Although tremendous achievements have been realized, a major drawback of FAB is the nearly abscence of abundant fragment ions. The occurrence of some minor fragmentation is further compromised by the fact that more often the fragment-ion signals are buried into the matrix background, which cannot be subtracted properly or reliably. Of course, running electron impact mass spectra on the same compound is the solution of this problem, at least for those samples which sustain the evaporation step. In the absence of MS-MS facilities, an alternative approach was used to complement FAB and EIMS data for cyanine dyes (I,II), color-forming compounds (III), and polyethylene oxide surfactants (IV,V). From extensive applications with cyanine dyes some useful fragmentation rules have been derived. These fragmentation reactions are a dealkylation, a retroreaction, a hydrolysis sequence, and the formation of small stable molecules. Basically, PY-GC-MS helps in determining the structure of unknowns b converting intractable parent molecules to many simple daughter molecules (see Fig. 1 for compound II). These daughter molecules reveal substructural features which enable the formulation of plausible candidate structures. Those candidates can be validated b referring to easily accessible reference compounds, commonly used in the synthesis of cyanine dyes. Extension to the structure determination of chromogenic compounds (coupling agents) and to oligomeric monoalkylated polyethylene oxide surfactants shows that PY-GC-MS is useful complementary technique for FAB and EI mass spectrometry.

CHARACTERISTICS OF MULTIPOLE COLLISION CELLS

J.E.P. Syka, Finnigan MAT, San Jose, California, 95134; I. Szabo, University of Lund, Lund, Sweden.

Tandem quadrupole mass spectrometers and hybrid sector quadrupole instruments generally use RF-only quadrupole collision cells, which are simple to construct and provide efficient collection of daughter ions. However, the ion transmission through RF-only quadrupoles is strongly dependent on operating parameters such as the applied RF voltage and the axial component of ion kinetic energy (collision energy), requiring the instrument operator to control these parameters carefully if reproducible results are to be obtained. Extensive theoretical calculations (1) suggest that collision cells constructed from higher order multipole fields (hexapole, octopole, etc.) might not exhibit such dependence on operating parameters. Calculations indicate that higher order multipoles have wider stability regions than the quadrupole and, thus, should allow observation of a wider mass range of daughter ions generated from a given parent-ion. Higher order RF-only multipole collision cells have already found use in studies of ion fragmentation energetics, where kinetically correct results are critical (2,3,4). The flat-bottomed, pseudo potential trough generated by the higher order multipole fields adds precision to the determiniation of parent-ion kinetic energy. This paper describes a study undertaken to determine the suitability of higher order RF-only multipoles (hexapoles, octopoles) for incorporation in MS/MS instruments designed for general analytical use.

A study was conducted in which linear quadrupole, hexapole, and octopole RF-only collision cells of identical length and field radius, r_o, were successively installed in a suitably modified TSQ^R 70 tandem quadrupole mass spectrometer. The ion q value (Mathieu stability parameter) corresponding to the stability limit, q_{max}, for the RF-only hexapole and octopole were measured. A measured stability limit for the RF-only quadrupole of q_{max}=0.908 was used as a reference. The measured q_{max} for the RF-only hexapole was ca. 1.5, which compared well to the predicted value of 1.7 (5). However, the measured q_{max} for the RF-only octopole was ca. 1.4, which does not agree with the predicted value of 7.7 (6). This deviation is probably due to the very restricted range of initial radial displacements and velocities of the ions used in the calculations. This extension of the stability limit translates into about a 10% increase in the observable daughter ion mass range and about a 30% reduction in the region at the low end of the daughter mass range that is not observable. Figures 1, 2, and 3 show the effect of ion axial kinetic energy on the transmission of uncollided ions for the RF-only quadrupole, hexapole, and octopole collision cells. The local maxima and minima observed in the intensity vs. kinetic energy characteristics for the RF-only quadrupole are absent from the intensity vs. kinetic energy characteristics of the RF-only hexapole and octopole. However, the RF-only hexapole and octopole have somewhat lower relative transmission at elevated ion kinetic energies. At low kinetic energies, there was no measurable difference in absolute transmission between the three collision cell designs.

Determination of the variation in the intensity of m/z 231, 181, 131, and 69 daughter ions of a m/z 231 parent-ion for a changing parent-ion q show that local maxima and minima are absent from the intensity vs. parent-ion q characteristics of true daughter (fragment) ions for the RF-only quadrupole as well as the RF-only hexapole and octopole collision cells.

The combination of somewhat extended stability regions and more uniform transmission characteristics for unreacted ions makes using RF-only hexapole or octopole collision cells modestly advantageous in comparison to using the conventional RF-only quadrupole collision cells.

OBTAINING MOLECULAR ION AND STRUCTURAL INFORMATION OF PERFLUOROCARBONS BY MASS SPECTROMETRY

Sunkwei Huang
Adamantech, Inc., 1501 Blueball Ave., Linwood PA 19061

Identification of perfluorocarbons (PFC's) can be achieved in several ways: electron attachment (EA) at near zero electron energy, negative ion chemical ionization (NICI) and electron ionization (EI). EA may provide both molecular weight and structural information. However, as the molecular size of PFC's is increased, the dissociative electron attachment process becomes insignificant and thermal electron attachment becomes the major pathway, possibly due to the rapid distribution of excess energy among the many vibrational degrees of freedom of the molecule. CH_4-NICI in general gives only molecular ion information. On the other hand, EI of perfluoroalkanes yields little or no molecular ion and very abundant low mass fragment ions such as CF_3^+ (m/z 69), $C_3F_5^+$ (m/z 131) and $C_4F_7^+$ (m/z 181), which are not structurally characteristic. EI on perfluoroalkenes very often gives more high mass fragments, but it still yields little or no molecular ion information. An exception was observed for perfluoro-cyclopentene, which gives a sizeable molecular ion upon EI. Typical examples are illustrated in Figure 1. Decreasing the electron energy and lowering the ion source temperature do not increase the abundance of the molecular ion, but instead degrade the sensitivity of detection.

Structural information may be obtained by CAD experiments on the molecular ion generated by EI of the sample. Figure 2 illustrates the CAD result of perfluoro-1,3-dimethyl adamantane (F-DMA) from high energy collisions. Low energy CAD below 30 eV gave the same result. However, negative ion mode CAD did not yield structural information and the result is similar to of NICI. Experimentally, CF_3^+ is found to be the most abundant peak between 5 and 70 eV of electron energy in EI. Therefore, it appears that most of the molecular ion and $(M-CF_3)^+$ ions are formed with large amounts of internal excitation, even at the low electron energies, and undergo further fragmentations to produce low mass fragments such as CF_3^+. In CAD, collision energy is added to the relatively stable molecular ion. In this case, the effective energy transfer during the high energy collisions must be small so that $(M-CF_3)^+$ and other high mass ions are more stable relative to CF_3^+.

It is therefore likely that the CAD technique can be employed to acquire the structural information of PFC's. However, most PFC's give little or no molecular ion upon EI. If the formation of abundant CF_3^+ in EI indeed results from the bombardment of energetic electrons, then the energy deposition distribution can be modified by thermalizing the electrons by letting electrons collide with reagent gases. It was found that the employment of helium provided spectra similar to EI but with more high mass fragment and some molecular ion formation. The employment of methane as the reagent gas resulted in a great formation of $(M-F)^+$. On the other hand, when nitrogen or air was used, abundant molecular ions as well as structural information were obtained (Figure 3). The mass spectrum of a given PFC can be easily changed by mixing different proportion of regent gases. The mass spectra obtained this way did not change between the electron energy of 55 eV and 230 eV, except that at higher electron energies, lower mass fragments are favored and high mass fragments and the molecular ion were formed with one a.m.u higher than in the case of low energies. This could be ascribed to the radical reactions with residual hydrogen on the wall of the ion source. It appears that there are at least three mechanisms operative in producing the above results. They are electron thermalization (He case), high pressure charge exchange (air or N_2 case) and ion molecule reactions (CH_4 case).

INTERNAL ENERGY DEPOSITION BY COLLISIONAL ACTIVATION IN FOURIER TRANSFORM MASS SPECTROMETRY

R. B. Cody*, D. A. Weil
Nicolet Analytical Instrument
5225 Verona Rd. Madison, WI 53711

Parent ion kinetic energy is a dominant factor in determining the nature of collisional activation spectra in Fourier transform mass spectrometry (FTMS) [1]. In order to best use FTMS for collisionally activated dissociation (CAD) it is important to understand how parent ion internal energies are affected by collision energies, pressures, collision times, etc. Breakdown curves (i.e. plots of fragment ion abundance vs. collision energy) provide a great deal of information about how such factors affect ion fragmentation.

FTMS breakdown curves have been reported for several compounds, by observing the variation of fragment abundance with collision energy [1]. While informative, these early studies were limited to low kinetic energies by cell size and magnetic field strength; maximum energies were 40 to 60 eV. Further, these studies employed a static collision gas and a single-cell geometry. Under these conditions, ions may collide with the target gas during excitation, or may undergo ion-molecule reactions with sample neutrals following activation.

More modern FTMS instruments are free of these limitations. Higher magnetic field strengths and larger cells provide access to much larger kinetic energies (in the low keV range). Pulsed valve introduction of the collision gas coupled with a differentially-pumped dual-cell geometry avoids problems with collisions during excitation, or subsequent ion-molecule reactions. Therefore, it is of interest to reexamine energy deposition by collisional activation with a state-of-the-art Fourier transform mass spectrometer.

We report here breakdown curves for n-butylbenzene, iron pentacarbonyl, tetraethylsilane, and anthracene. Collision energies employed range from less than 1 eV to greater than 1 keV. Comparisons with previous data and data collected with other types of mass analyzers show many similarities. Internal energy distributions estimated by the method of Wysocki, Kenttamaa and Cooks show reasonable agreement with those reported for hybrid instruments under multicollision conditions [2].

However, some striking differences are also observed. For example, in the previous study [1] the ratio of abundances for m/z 91/92 in the CAD spectrum of n-butylbenzene reached a maximum at 2.5:1 for both the FTMS and hybrid (BQQ) instruments. This contrasted with a the much higher ratio (7:1) observed for photoexcitation studies. In the present study, the ratio of m/z 91/92 is very high. To our knowledge, our present observed ratio of 25:1 is the highest value reported for any activation method.

For collisional activation of the molecular ion of tetraethylsilane, the breakdown curves obtained for FTMS agree at low energies with those obtained using other instruments. However, we observe Si+ at higher collision energies above 100 eV; also, the EtSi+ fragment is not present in the FTMS spectra.

At high energies, collisional activation spectra of anthracene show extensive fragmentation, characteristic of high internal energy deposition. The chief difference between the FTMS spectrum and previously reported spectra is the absence of fragments due to CHn losses, and in the relatively smaller abundance of the doubly charged ion in the FTMS spectrum.

June 5-10, 1988, San Francisco, CA

High energy collisional activation spectra of iron pentacarbonyl show very high internal energy deposition; the spectra are dominated by Fe+ rather than Fe(CO)4+, as in previously reported spectra.

These differences between FTMS CAD and spectra reported for other analyzers may be attributed to several factors. FTMS CAD operates under multicollision conditions. This increases both internal energy deposition and fragmentation efficiency, but makes it more difficult to determine the exact collision energy. FTMS CAD is associated with long ion lifetimes, and is less sensitive to scattering angle.

CHEMICAL IONIZATION AS A POST-IONIZATION METHOD FOR LASER-DESORBED NEUTRALS.

I. Jonathan Amster, Donald P. Land, John C. Hemminger, and Robert T.McIver, Jr.; Chemistry Department, University of California, Irvine, CA 92717.

Introduction. Laser desorption is a popular desorption-ionization method for the analysis of nonvolatile compounds. Typically, these experiments are performed in a direct ionization mode in which the laser is used to desorb and ionize the sample in one step. However, laser desorption produces far more neutrals than ions. Post-ionization of these neutrals (that is, ionization as a subsequent step to laser desorption) offers the possibility of enhancing sensitivity and allows the choice of a variety of ionization methods. Multiphoton ionization has been used recently as a post-ionization method for laser-desorbed neutrals of high molecular weight species. Electron post-ionization has been used in our laboratory for the analysis of molecular adsorbates on surfaces present at submonolayer concentration. Chemical ionization has also been reported as a post-ionization method (LD/CI) [1]. However, this early experiment lacked sensitivity as a result of combining a pulsed ionization technique of low duty cycle with the scanning mass analyzer of a sector mass spectrometer. A considerable sensitivity enhancement should be possible by adapting this post-ionization method to a simultaneous mass analyzer, such as a Fourier transform mass spectrometer (FTMS).

Experimental. The results are obtained using an FTMS instrument with a 12" electromagnet (B = 1 Tesla). An excimer laser (Lambda Physik EMG 103 MSC) is used for desorption at wavelengths of 193 nm, 248 nm, and 350 nm. Typical desorption conditions use a laser pulse of 0.3 mJ focused to a 0.25 mm^2 spot size, giving a power density of 1 MW/cm^2. These low power conditions cause desorption of neutrals, without direct formation of ions or cations. All spectra are recorded from a single laser shot at the sample. The sample substrate is platinum for most experiments. Macor with a 100 nm overcoat of gold is used for the peptide and thymidine experiment. The samples are applied to the substrate by evaporation of dilute solutions (thymidine, tetrapeptide), vacuum sublimation (acridine), or by condensation onto a liquid nitrogen cooled sample holder while in the FTMS vacuum system (acetophenone). A 30-ms burst of methane admitted with a pulsed valve creates reagent ions at 10^{-3} torr peak pressures. Ion detection occurs 1 second later when the pressure has dropped to about 10^{-8} torr.

Results. Laser desorbed neutrals from a 30 monolayer thick sample of acetophenone frozen onto a Pt substrate are protonated by methane reagent ions made and stored in a Fourier transform mass spectrometer. The FTMS instrument is used to select CH_5^+ or $C_2H_5^+$ from the reagent ions generated from methane, allowing control of the amount of fragmentation observed in the spectrum. Acetophenone protonated by CH_5^+ produces a mass spectrum in which the molecular ion has a relative abundance of 50%, whereas ionization with $C_2H_5^+$ gives the molecular ion as the base peak of the spectrum. Laser desorption of 9-pentadecylacridine followed by methane chemical ionization produces a strong protonated molecular ion (Fig. 1b), whereas electron ionization produces only fragment ions (Fig. 1a). The first reported attempt to combine chemical ionization with laser desorption in a FTMS instrument [2] was unsuccessful, using thymidine as a test compound. However, we are able to produce an LD/CI spectrum of thymidine, in which the molecular ion has a 10% relative abundance. This method demonstrates exceptionally good sensitivity for a laser desorption method. Ten monolayers of the tetrapeptide Val-Ala-Ala-Phe produce the LD/CI mass spectrum shown in Figure 2 from a single laser shot, and the amount of material desorbed from the 0.25 mm^2 spot is 4 pmol. Since the signal-to-noise ratio in Fig. 2 is approximately 130:1, the detection limit for LD/CI in an FTMS instrument should be in the submonolayer regime, suggesting applicability to surface analysis problems.

BUTYLBENZENE RADICAL CATION THERMOCHEMISTRY FROM PEPICO EXPERIMENT USING SYNCHROTRON RADIATION; COMPARISON WITH ION ENERGY MEASUREMENT IN LOW ENERGY CAD

Tomas Baer, University of North Carolina, Chapel Hill, NC 27599, USA
Odile Dutuit, Université Paris-Sud, 91400 Orsay, France
Hélène Mestdagh and Christian Rolando,
Ecole Normale Supérieure, 24 rue Lhomond, 75231 Paris Cedex 05, France

As pointed out by many workers butylbenzene radical cation is ideally suited for experiments on dependence of fragment distribution with ion internal energy. Butylbenzene ion (m/z 134) has indeed two major decomposition pathways leading respectively to m/z 91 and m/z 92 ion; the former arises from a simple bond cleavage, the latter from a rearrangement. Fragment distribution is strongly dependent on the internal energy of the parent ion. Providing this dependence is reliably known, measurement of the 91/92 ratio gives access to the internal energy of the fragmenting ion under any given conditions.

Considering the dispersion of the literature data, it appeared interesting to study the fragmentation of butylbenzene by the PEPICO method, using synchrotron radiation as light source. The abundance curves obtained for parent and fragment ions (Figure 1) allowed to get reliable values of the 91/92 ratio on a wide internal energy range, and to compare the results with literature data (Figure 2). In addition, the measured 92/134 ratio gave access to the absolute dissociation rate to m/z 92 ion as a function of parent ion internal energy. This dependence was fitted using a RRKM-QET model (Figure 3). Extrapolation of the corresponding curve to high internal energy range, combined with the experimental 91/92 ratios, allowed to obtain m/z 91 ion production rate (Figure 4). The best fit of this rate corresponds to a high activation energy (1.6 eV) and a positive activation entropy (+14.6 J/K), as expected for a simple bond cleavage; on the contrary, a lower activation energy (0.99 eV) and an important negative activation entropy (-29 J/K) were found for the formation of m/z 92 ion, involving a rearrangement.

These data were compared to those obtained by the measurement of parent and daughter ion kinetic energy in low energy CAD using the modified "double" RF-only collision cell of a tandem quadrupole mass spectrometer. The dependence of fragment ion kinetic energy with parent ion kinetic energy allows to estimate the average internal energy transfer, Q, from Ar collision gas to the parent ion, for each type of fragmentation separately. Whereas the kinetic energy of m/z 92 ion is close to the maximum value allowed by momentum conservation, corresponding to a low Q value, the average kinetic energy of m/z 91 fragment is close to the minimum value allowed, corresponding to a high Q value (Figure 5). This is in agreement with increasing 91/92 ratio with internal energy of parent ions, as well as with the higher activation energy of m/z 91 ion production.

Carbohydrate-containing macromolecules are found in abundance in all living organisms. These include: a) exclusively carbohydrate polysaccharide polymers, b) glycoproteins, proteoglycans and peptidoglycans, c) glycolipids and lipopolysaccharides, d) teichoic acids, and e) nucleic acids. It is now well established that complex carbohydrates are essential in biological recognition, as hormones, as structural polymers and as energy reserves. The use of desorption mass spectrometric approaches, such as FAB and DCI, to sequence oligosaccharides derived from these biopolymers is well documented[1]. FAB spectra usually show only glycosidic bond cleavages, and the oligosaccharide has to be reduced prior to mass spectrometric analysis for sequencing to be unambiguous[1]. Furthermore, derivatization (permethylation or peracetylation) is normally required. Unfortunately, both methods may remove base- or acid-labile substituents that may be present.

Our laboratory has a long standing interest in bacterial capsular polysaccharides (CPS) which are antigenic. They can be considered in terms of repeating units and consist of simple monosaccharide residues and labile substituents. CPS biopolymers are often of high molecular weight (>40,000 daltons) and therefore generally are not sufficiently volatile for study directly by mass spectrometry. By the use of specific bacteriophage-borne enzymes the CPS can be degraded to oligosaccharides corresponding to the repeating units[2]. Such oligomers are commonly tri- to hepta-saccharides and consequently have molecular weights which are well within the mass range of modern ionization techniques.

The following example illustrates the use of positive and negative ion LDI-FT-ICR mass spectrometry for the complete sequencing of an *underivatized* pentasaccharide. This oligosaccharide is derived from bacteriophage degradation of *Klebsiella* serotype K44 bacterial CPS. The complete sequence can be deduced from each of the positive ion and negative ion spectra. LDI-FT-ICR spectra of the *underivatized* pentasaccharide showed intense fragmentation resulting from glycosidic bond cleavage and ring rupture. The presence of both ring cleavage ions and glycosidic bond cleavage ions allows, without the necessity of a prior reduction step, unambiguous sequencing of oligosaccharides.

From the positive ion spectrum two ring cleavage routes were observed; a) the M-series fragments with cationic attachment to the reducing end[3], and b) the N-series fragments with cationic attachment to the non-reducing end[3]. Two types of M-series fragments were observed. The non-reducing end terminal glucuronic acid, gave a $C_2H_3O_2$ ring fragment, while the adjacent 2-linked rhamnose gave a C_2H_3O ring fragment. As M-series fragments only contain C-1 and C-2 from the ring cleaved residue, the oxygen difference is likely to be the glycosidic oxygen of a 2-linked residue. Two N-series fragments were also observed. The reducing end 4-linked terminal glucose gave a $C_4H_7O_2$ ring fragment, while the adjacent 3-linked glucose gave a $C_4H_9O_3$ ring

fragment. This may indicate that 3-linked residues give a $C_4H_9O_3$ fragment whereas 4-linked residues give a $C_4H_7O_2$ fragment. Dehydration of high molecular weight oligosaccharides is, however, very facile and further work is required to confirm these observations.

Four distinct ring cleavage fragmentation pathways were observed in the negative ion spectrum which we label Q_α, Q_β, R_α and R_β. The Q_α and Q_β-series fragments have the negative charge residing on the reducing end[4]. The R_α and R_β-series fragments have the negative charge residing on the non-reducing end[4]. For the Q_α and Q_β-series, the sub-monosaccharide unit correlated with the anomeric configuration of the ring cleaved residue, i.e. the α anomers gave a C_2H_2O fragment while the β anomers gave a $C_2H_2O_2$ fragment. For the R_α and R_β-series, the sub-monosaccharide unit correlated with the anomeric configuration of the monosaccharide residue adjacent to the ring cleaved residue. In this case, the α anomers gave a $C_2H_4O_2$ fragment while the β anomers gave a $C_2H_2O_2$ fragment.

It could also be argued that the two carbon fragments arising for both Q and R fragment series may indicate the configuration of the highest-numbered chiral carbon, i.e. a D- or L-series sugar, rather than the configuration of the anomeric carbon. The fragmentation of a monosaccharide ring, however, is more likely to manifest itself as either a neighbouring-group effect or as a representation of the stereochemistry of the fragment centre, rather than a reflection of the stereochemistry of a relatively distant group, i.e. C-5 in this case.

In conclusion, high resolution LDI-FT-ICR mass spectrometry can unambiguously sequence *underivatized* oligosaccharides. Tentative additional information on the linkage positions can be obtained from the positive ion spectra, while the anomeric configuration of the individual monosaccharide residues can be deduced from the negative ion spectra.

THE USE OF ^{252}Cf PLASMA DESORPTION MASS SPECTROMETRY FOR THE ANALYSIS OF SYNTHETIC PEPTIDES AND PROTEINS

Brian T. Chait
The Rockefeller University
New York, N.Y. 10021

Over the past several years there has been a dramatic increase of interest in the area of synthetically produced peptides and proteins. These materials find widespread utility in areas as diverse as the raising of antipeptide sera of predetermined specificity against a receptor protein, the development of synthetic peptide based vaccines, and the development of a fundamental understanding of the relationship of protein structure to function. At the Rockefeller University, we have found through the detailed examination of about 800 synthetic proteins and peptides originating from 15 different laboratories in the U.S.A. that plasma desorption mass spectrometry (PDMS) provides an enormously useful, easy, and definitive method for assessing the accuracy of peptide synthesis [1].

The most useful and most easily obtained single piece of information from the PD mass spectrum is the molecular weight (MW) of the compound. In a stepwise peptide synthesis, the identity of each added amino acid is known and so a measured MW which is found to agree with the MW calculated for the desired synthetic product provides a relatively good verification that the material has been correctly assembled. Conversely any disagreement which is observed between the measured and calculated MW's of the synthetic product immediately indicates that an error or undesired modification has occurred. PDMS is also a powerful tool for determining the homogeneity of the desired synthetic product. The strength of the method resides in its high resolving power compared with more commonly employed techniques like HPLC and its ability to provide masses of undesired side products. Fig. 1A shows the results of an HPLC analysis of a purified 39 residue cytochrome-C fragment synthesized by Kent and Selk at the California Institute of Technology where the analysis was made using a C4 reverse-phase column. The dominant chromatographic peak looks quite symmetrical and sharp and one might predict that the synthetic product is homogeneous. Inspection of the mass spectrum obtained from the material (Fig. 1B) shows that this is not the case. The desired material is present - its experimentally determined MW agrees with the predicted MW to within 0.3 u - but so is a substantial amount of a second compound having a MW 114.0 u lower which suggests that a deletion or deletions involving asparagine occurred during the synthesis. The peptide was thus carefully resynthesized and the mass spectrum from this second synthesis is shown in Fig. 1C. The peak corresponding to the deletion peptide is now no longer present in the spectrum demonstrating that this second synthesis yielded a pure product. A great many other errors can and do occur during solid phase synthesis. These errors range from operator or machine related errors to relatively subtle chemical modifications of the peptide during and after synthesis. We have found that the majority of these can be detected by PDMS [1]. The importance of the use of this technique can be gauged from our rather staggering finding that almost half of the 800 purified synthetic peptides and proteins that we examined were found to have a MW different from that calculated for the desired target material or to contain significant amounts of unwanted peptide side products.

We also found PDMS to be very useful for the analysis of fully protected synthetic peptides containing as many as 50 amino acid residues; for the analysis of unusual peptide containing molecules which cannot readily be analyzed by techniques such as Edman sequencing or nuclear magnetic resonance; for studying the folding and thiol oxidation of synthesized proteins; and for evaluating and optomizing details of the synthetic chemistry [2].

TAGA 6000E QA/QC ANALYSIS PROCEDURES AND THE ASSOCIATED DATA GATHERED DURING FOUR, TWO WEEK BLOCKS OF INDOOR AIR ANALYSES AT THE LOVE CANAL EMERGENCY DECLARATION AREA (EDA)

Thomas H. Pritchett, U.S. EPA Environmental Response Team
Edison, NJ 08837

David Mickunas & Mark Bernick, Roy F. Weston, Inc. (REAC)
Edison, NJ 08837

INTRODUCTION

The U.S. EPA Environmental Response Team was tasked to perform indoor air analyses in the Love Canal Emergency Declaration Area as part of the overall EDA habitability study. The analytical results, in conjunction with results from concurrent soil and dioxin sampling programs, will be used by the New York State Department of Health to determine the overall habitability of the EDA. The sampling took place over four, two week phases which represented the various meteorological seasons. During each phase different sampling shifts were utilized to spread the analyses over the full 24 hours of a day. Each first floor and basement room for every structurally sound residential building in the EDA was sampled whenever possible. The air habitability decision will to be based upon the presence or absence of two sets of indicator compounds (LCICs): chlorobenzene and chlorotoluenes. From the results o a previous pilot study, only a very small percentage of the houses were expected to contain any LCICs. Because of the political nature of the final habitability decision, it was determined that the TAGA data would have to stand up to severe technical reviews by multiple parties.

DATA QUALITY OBJECTIVES

The QA plan which was developed for this program had several goals. The plan had to ensure 1) that the TAGA would have sufficient sensitivity throughout the whole program; 2) that the generated data would be reliable and defensible; 3) that the instrument was performing within defined specifications; 4) that any quantitation errors due to calibration drifts were known and defined; and that the accompanying documentation was 100% complete and consistent.

Eight data quality objectives (DQOs), five of which were directly relate to the instrument's performance, were defined. The instrument related DQOs were 1) accuracy of $\leq$ 25% error, 2) precision of $\leq$ 25% relative standard deviation, 3) LCIC detection limits of $\leq$ 4 ppb, 4) response factor decay between consecutive calibrations of $\leq$ 15%, and sampling lin transport efficiencies of $\geq$ 85%.

PROCEDURES, RESULTS AND DISCUSSION

The TAGA's accuracy was measured by using 6 Liter Summa canister externa performance evaluation samples (daily starting in phase 3), by 16 Liter precision canisters (on alternate days starting in phase 2), by 16 Liter external audit canisters (once per phase), and by internal control standard gas cylinders (daily for all phases). All Summa canisters were provided by Northrop Services, Inc. and the standard gas cylinders were obtained from Scott Specialty Gases. In addition, at the end of each analytical day the TAGA was challenged with a spike of the LCICs at a concentration within 2 ppb of the reported quantitation limits.

The samples, which contained the LCICs at concentrations ranging from 10 - 35 ppm, were analyzed by diluting the sample to 5 - 15 ppb through a mass flow controller into an ambient air sample stream flowing past the TAGA inlet at approximately 1500 ml/sec.

For chlorobenzene the reported errors from these analyses had average absolute percent errors of 5.6%, 5.9%, 14.9%, 6.6%, 9.5%, 10.0%, 3.6%, 13.5%, and 4.4% for the internal control analyses in phases 1-4, for the 6 Liter Summa canister P.E. sample in phases 3 & 4, and for the 16 Liter Summa canister precision samples in phases 2-4, respectively. For chlorotoluene these average absolute percent errors were 4.9%, 5.4%, 13.7%, 8.4%, 10.4%, 13.4%, 3.4%, 16.6%, and 10.6%. Only once did a percent error exceed the 25% (-26.4%) and on that day the two other measurements were within the required 25%. The percent error from the quantitation limit verifications never exceeded 25%.

To minimize the effect that the TAGA's calibration drifts had on the analysis accuracies, new calibrations were performed prior to entering each house. Whenever an investigation was initiated because of the presence of an LCIC in the house, a new calibration was performed immediately after existing. An intermediate set of response factors, which yielded symmetrical error bars, were then calculated from the two sets of response factors (RF_1 & RF_2). This intermediate response factor (RF_i) was calculated as follows:

$$RF_i = 2 * (RF_1 * RF_2) / (RF_1 + RF_2)$$

The TAGA's precision was measured using the results from the 16 Liter Summa precision canister analyses and from the internal control standard analyses. The highest RSD measured for any set of samples during the program was 17.9%.

The TAGA detection limits through the program ranged from 0.4 to 3.7 ppb for chlorobenzene and from 0.4 to 4.2 ppb for chlorotoluene. The detection limit averages for all four phases were 0.8 and 1.0 ppb for chlorobenzene and chlorotoluene, respectively. Only once did a detectio limit exceed 4.0 ppb and the house for which it applied was sampled four additional times during the study.

Although the TAGA response factors did vary throughout each day (typically increasing as the day progressed), the response factor decay (or decrease) only exceeded 15% twelve times during the study. In every case appropriate corrective actions were taken and the decay was either stabilized or reversed.

The sampling line transport efficiencies were measured twice daily. Thi measurement was made by diluting the LCIC standard downstream of the sampling lines, the bulk of which were outside the bus exposed to ambien temperature, at a concentration of 3 - 6 ppb and then averaging the signal for over thirty measurements. The standard gas was delivered through a mass flow controller to a three-way valve and then to the ambient air stream. Once the downstream average was obtained, the three way valve was reset to deliver the standard gas upstream of the sampling lines and the signal was then averaged for another thirty measurements. The ratio of the upstream signal average versus the downstream average defined the transport efficiencies. For the full study the measured transport efficiencies ranged from 88.6% to 122% for chlorotoluene and from 90.7% to 120% for chlorobenzene. During phase 1 a heated 200' sampling line, which was maintained at 70°F, was used while in phases three through four unheated sampling lines were used. The transport efficiencies with the heated lines averaged 100.2 $\pm$8.5% and 100.8 $\pm$5.8% for chlorotoluene and chlorobenzene, respectively. With the unheated lines the transport efficiencies averaged 97.7 $\pm$5.3% and 98.5 $\pm$4.2%. When the unheated lines were used, the outside ambient temperatures were recorded but no correlations were found between the transport efficiencies and ambient temperature.

OPTIMIZATION OF THE GCMS METHODOLOGY TO MONITOR MULTIPLE LABELED ANALOGS OF ARGININE AND ORNITHINE.

Van Langenhove, A; ENSECO/Erco Laboratory, 205 Alewife Brook Pkwy, Cambridge, MA 02138. Marks, L M, Lin, V K, Hoerr, R A, and Young, V R; MIT Clinical Research Center, 40 Ames Street, Cambridge, MA 02139.

The most straightforward method to evaluate whole body amino acid kinetics in men is to measure the isotopic enrichment of plasma amino acids following a single dose or continious infusion of a stable isotope labeled amino acid tracer. The stable isotope enrichment of plasma amino acids can then be determined with a high degree of sensitivity and accuracy by GCMS analysis.

We are proposing a new and elegant stable isotope tracer approach for the study of arginine metabolism and nutrition in healthy adult humans. Our approach is based on an intravenous infusion of ^{15}N-guanidino-5,5-$^{2}H_2$-arginine together with 13C-ornithine and the monitoring of the stable isotope label in plasma for both amino acids (Fig. 1).

We have been evaluating different derivatization methods and mass spectrometric ionization techniques for the analysis of arginine and ornithine. The conventional amino acid derivatization methods (N-perfluoroacyl, alkyl esters) work well for ornithine. For arginine, however, these methods do not give satisfactory results. We have found two major problems associated with the derivatization of arginine: (i) either incomplete derivatization, or (ii) breakdown of arginine into ornithine. These two problems become intertwined when one tries to derivatize arginine because the guanidino group from arginine can only be acetylated under vigorous reaction conditions.

We also evaluated the procedure described by Nissim et al. (1). The authors' report reproducible formation of N-tetra-TFA arginine in studies with guanidino-^{15}N-arginine in plasma. Our attempts to duplicate this procedure were only partially successful. We were able to form a TFA derivative (presumably the tetra-TFA-arginine) and the EI mass spectrum showed ions that were appropriate for our purpose (i.e. ions that retain the stable isotope label and are not involved in C-5 hydrogen rearrangement processes). For ornithine, a di-TFA derivative was obtained (Fig. 2). Repeated attempts to form a TFA derivative for arginine were, however, unsuccessful.

Another approach to make a GC-amenable derivative for arginine would be conversion of arginine into delta-N-(2-pyrimidinyl) ornithine by condensation with malonaldehyde or acetylacetone (2,3). This ornithine derivative could then be further esterified and trifluoroacetylated to permit its analysis by GCMS. Data obtained so far using this technique are quite encouraging. The reproducibility of the technique is superior to the previously investigated methods. The EI mass spectra of delta-N-(2-pyrimidinyl)-n-propyl di-TFA ornithine and n-propyl-di-TFA ornithine are presented in Fig. 3. Selection of appropriate ions that retain the stable isotope label is not so straightforward as for the TFA derivatives. For the arginine derivative most of the ion current is carried by ions that contain the pyrimidinyl moiety (e.g. m/z 192). Formation of these ions can involve hydrogen rearrangements and involvement of the C-5 deuterium atoms in this rearrangement process. The ion at m/z 347 is a likely candidate. We could monitor m/z 347/348 for the enrichment of 13C in the C-5 position of arginine, m/z 347/349 for the enrichment of 15N2 in the guanidino moiety and m/z 351/347 to follow the course of the proposed arginine tracer of $^{2}H_2$-$^{15}N_2$ arginine. For the ornithine derivative we could monitor the m/z 127/126 for enrichment of ^{13}C at the C-5 position and m/z 128/126 for the $^{2}H_2$ at the C-5 position. The abundances of these ions are low and, also, the ion cluster around m/z 126 could be subject to interferences from plasma because of its low m/z value.

Further chemical ion work will be necessary to deliver the most appropriate ions to monitor for the stable isotope labeled analogs we have available for these studies. Our previous experience with both positive and negative CI analysis of other amino acids suggests that fewer hydrogen rearrangements occur and that there are ions present at high m/z values in

abundance. Mass spectrometric analysis of deuterated ornithine and arginine should actually provide us with information about such fragmentation processes.

Although the formation of delta-N-(2-pyrimidinyl)-n-propyl di TFA ornithine is a reproducible process, we still observe to a small extent the breakdown of arginine into ornithine. Therefore, we are now focusing our efforts on reducing the harshness of the derivatization procedure in particular, the steps where acid and elevated temperatures are involved. We are at the same time looking into the incorporation of a preparative HPLC step which would separate arginine from ornithine and at the same time provide an initial clean-up of the plasma sample. Arginine and ornithine could then be analyzed separately by GCMS and if any breakdown of arginine into ornithine occurred, appropriate corrections could be made.

QUALITATIVE AND QUANTITATIVE ANALYSIS OF ACYLCARNITINES IN HUMAN PLASMA AND TISSUES BY FAB-MS

Fumio Inoue, Diane Gale and David S. Millington
Duke University Medical Center, Division of Pediatric Genetics and Metabolism, Box 3028, Durham, NC 27710.

A number of inherited metabolic disorders can present with Reye-like or sudden infant death (SIDS) syndromes. The most striking example is the medium-chain acyl-coA dehydrogenase deficiency (MCAD), in which the toxic metabolite octanoic acid accumulates during catabolic episodes and can result in rapid deterioration and death. The retrospective identification of MCAD and related disorders of fat catabolism in a substantial population of SIDS cases has been undertaken with the objectives of defining the incidence of these disorders and identifying families "at risk" for affected siblings. The diagnostic value of urinary acylcarnitine profiling by FAB-MS has been demonstrated. Here we describe methods for the analysis of acylcarnitines in post-mortem tissue and plasma and their applicability to screening for inherited metabolic disease.

Methods Blood plasma (0.2 ml) or frozen tissue (0.2-0.4 g) containing 3-30 nmol total acylcarnitine was homogenized with MeOH (2.0 mL). Deuterium-labeled internal standards were added for quantification when appropriate. After centrifugation, the supernatents were applied to cartridges containing 0.6 g C-18 reverse-phase packing, prewashed with MeOH. The cartridges were eluted with 80% MeOH (4 ml), then with pure MeOH (4 ml). After concentration to 1 ml (N_2) and washing with hexane (3 x 2 ml), the eluate was evaporated and the residue methylated with 50 µl MeOH-HCl (3 N) at 65 °C for 10 minutes. After a further wash with hexane (3 x 1 ml) an aliquot of the residue (2 µl) was analyzed by FAB/MS in a glycerol matrix using a VG 70S mass spectrometer. Signals corresponding to putative acylcarnitine methyl ester cations were further analyzed by HRMS and MS/MS as described previously.

Results Acylcarnitine profiles of a normal plasma control, and of blood samples obtained post-mortem from children with propionic acidemia and with MCAD deficiency (diagnosed retrospectively) are shown in figure 1 a, b and c respectively. In figure 2a the diagnostic "MCAD" metabolite octanoylcarnitine (M^+ = 302) was detected in a post-mortem liver specimen from another child dying of SIDS but not in a normal control liver (2b). Subsequently, MCAD deficiency was also diagnosed in a surviving sibling before symptoms developed, enabling preventive therapeutic intervention. By spiking with known amounts of internal standards, e.g. octanoyl-d_9-carnitine, M^+ = 311 (methylester), it was possible to quantify individual acylcarnitines by HRSIM to levels as low as 5 nmol/g.

The results suggest that blood and tissue obtained at autopsy can be successfully analyzed for disease-specific aclycarnitines by FAB-MS. Routine screening for inherited diseases presenting as SIDS is now possible, and can be improved by use of the continuous-flow FAB-MS device as a rapid sample introduction system.

IDENTIFICATION AND QUANTITATION OF URINARY ADIPIC ACID METABOLITES BY GC/MS

Shiow-Jen Jin and Kou-Yi Tserng
VA Medical Center and Dept. of Pharmacology, Case Western Reserve Univ., Cleveland, OH 44106

Dicarboxylic aciduria, an increased urinary excretion of adipic (DC6), suberic (DC8), and sebacic (DC10) acids, is often resulted from enhanced fatty acid oxidation or inhibited fatty acid metabolism. These acids are produced from medium chain monocarboxylic acids, most likely dodecanoic (MC12) or decanoic (MC10) acids through microsomal omega-hydroxylation and cytosol oxidation. The dicarboxylic acids (DC10 or DC12) are then activated to CoA derivatives, which are then transported to mitochondria or peroxisomes for further beta-oxidation to DC8 and DC6. It is not known whether DC6 can be metabolized further to DC4 (succinic acid) to provide a gluconeogenic pathway from fatty acids, since the direct product-precusor relationship have never been demonstrated. Through the use of gas chromatograph-mass spectrometry, we have identified 3-hydroxyadipic acid 3,6-lactone and trans-2-hexenedioic acid, two intermediates produced in the further beta-oxidation of adipic acid in human urine.

METHODS

URINARY ORGANIC ACID ANALYSIS WITH DUAL COLUMN GC AND GC/MS - Urine sample was spiked with pentadecanoic acid as internal standard, acidified and extracted with solvent mixture of ethyl acetate and diethyl ether. The combined extract was dried and derivatized with BSTFA/TMCS or BSA/d_9. This trimethylsilyl derivative was analyzed with a dual capillary column gas chromatography and a gas chromatography-mass spectrometer. The column temperature was maintained initially at 60 °C and programmed to increase at a rate of 4 °C/min to a final temperature of 250 °C. A repetitive scanning mode was used for compound identification. The eluent from the capillary column was repetitively scanned from m/z 49 to 550.

SYNTHESIS OF AUTHENTIC SAMPLES - 3-Hydroxyadipic acid 3,6-lactone was synthesized from the reduction of 3-oxoadipic acid with sodium borohydride. The resulting 3-hydroxyadipic acid was cyclized to the lactone upon acidification. Trans-2-hexenedioic acid was synthesized from oxidation of 1,3-cyclohexadiene.

RESULTS

In SPB-1 capillary column, a major peak eluted before and another eluted after adipic acid when the urine sample was derivatized as trimethylsilyl derivatives(Fig. 1). The former unknown(Fig. 2b) had highest mass at m/z 201, suggesting a molecular weight of 216. Other diagnostic ions at m/z 188, 157, and 85 and the shifting of masses obtained from its TMS-d_9 derivative suggested the possible structure of this compound as 3-hydroxyadipic acid- 3,6-lactone. The latter eluted unknown(Fig. 2a) had highest mass at m/z 273, suggesting a molecular weight of 288. Other mass fragments occurred at m/z 198, 183, 170, 155, and 139. This compound was identified as 2-hexenedioic acid. The trans configuration was suggested since its eluting sequence came after adipic acid. All structural assignments have been confirmed by comparison with synthetic authentic samples(Table 1).

CONCLUSION

(1) From the correlation between the excretion of lactone and adipic acid(Fig. 3), as well as the knowledge of the degradative pathway of dicarboxylic acid, it appears that 3-hydroxyadipic acid 3,6-lactone is derived from adipic acid through beta-oxidation(Fig. 4).
(2) The obligatory intermediate, t-2-hexenedioic acid, in this pathway was also identified and no other hexenedioic acids could be detected in human urines.

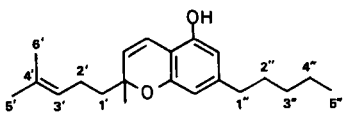
A GC/MS INVESTIGATION OF IN VITRO METABOLITES OF CANNABICHROMENE AND CANNABIGEROL IN SEVERAL SPECIES.

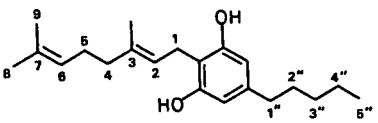
D.J. Harvey and N.K. Brown,

University Department of Pharmacology, South Parks Road, Oxford, OX1 3QT, UK.

Although metabolism of the major cannabinoids from marihuana, delta-9-tetrahydrocannabinol, cannabidiol and cannabinol, has been well studied, metabolism of some less abundant constituents such as cannabichromene (CBC, I) and cannabigerol (CBG, II) has received little or no attention.



I



II

CBC, although of low relative concentration it is, nevertheless, the second most abundant cannabinoid in some high delta-9-THC marihuana originating from the USA. CBG has been used to treat glaucoma. This paper reports the in vitro metabolism of these cannabinoids.

Liver microsomes were prepared from mice, rats, rabbits, cats, guinea pigs, gerbils and hamsters and incubated with the two cannabinoids for 1 hr at 37°C. Metabolites were extracted with ethyl acetate, concentrated by chromatography on Sephadex LH-20 and converted into TMS and [$^2H_9$]TMS derivatives for examination by GLC and GC/MS. For GLC, a Hewlett-Packard 5890A gas chromatograph fitted with a 50 m x 0.3 mm OV-1 fused silica capillary column was used with peak integration employing a Hewlett-Packard 3390A recording integrator. GC/MS data were recorded using a VG 70/70F mass spectrometer (70 eV) fitted with a 25 m x 0.2 mm OV-1 fused silica capillary column terminating inside the ion source.

Metabolites from CBC were mainly monohydroxy compounds. Their mass spectra were all similar because of ready formation of the chromenyl ion following loss of the methylpentenyl chain. However, the mass of this ion differentiated metabolites hydroxylated in the pentyl chain (m/z 391) from those hydroxylated in the methylpentenyl chain (m/z 303). Metabolites hydroxylated in all positions of the pentyl chain were detected and were identified by retention time and by the presence of weak diagnostic fragments (1,2) in the spectra of the 1"- and 3"-hydroxy compounds. Metabolites hydroxylated at the terminal methyl groups of the methylpentenyl chain were identified by NMR. Other metabolites were the 3',4'-epoxide and its derived diol. Most of the species gave similar metabolites but in different proportions.

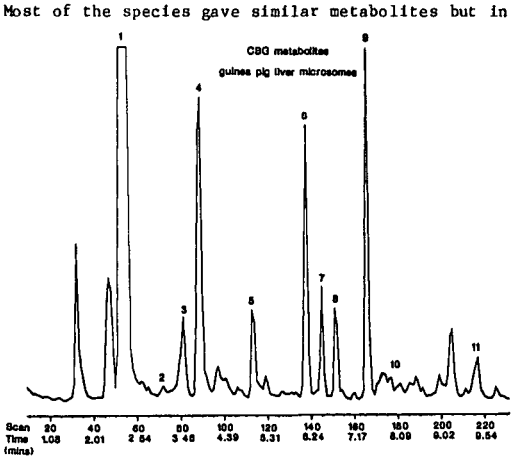


Fig. 1. Limited ion chromatogram (m/z 300-700) of metabolites of CBG isolated from guinea pig liver microsomes.

Metabolism of CBG was similar and consisted mainly of hydroxylation. Fig. 1 shows a limited ion chromatogram (m/z 300-700) of the metabolites from the guinea pig. The mass spectrum of unmetabolized CBG TMS ether (Fig. 2) gave prominent ions at m/z 337 (tropylium ion from cleavage of the C-1 - C-2 bond), 377 (cleavage at C-3 - C-4), 391 (cleavage at C-5 - C-6) and 403 (cleavage at C-5 - C-6). In the mass spectra of the TMS derivatives of metabolites hydroxylated in the pentyl side-chain, all of these ions shifted by 88 mass units. In addition, these metabolites gave rise to prominent diagnostic fragment ions allowing the metabolites to be identified as 1"-OH-CBG [peak 2, diagnostic ion, m/z 417 (100%)], 2"-OH-CBG [peak 5, m/z 14[illegible] (100%)], 3"-OH-CBG, [peak 6, m/z 404 (100%), see Fig. 3], 4-OH-CBG [peak 7, m/z 117, (21%)] and 5"-OH-CBG (peak 10, identified by retention time).

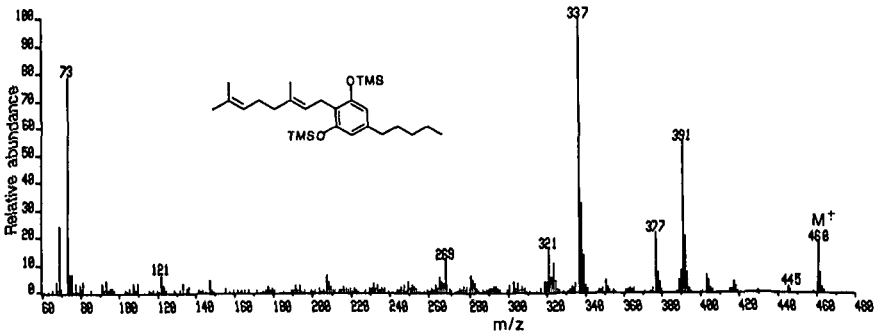

Fig. 2. 70 eV Mass spectrum of the TMS derivative of CBG.

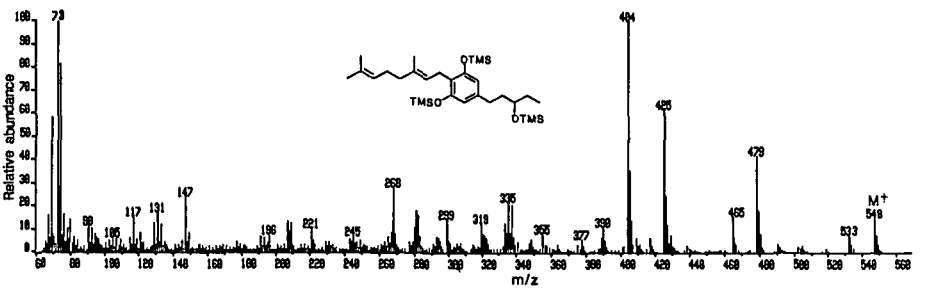

Fig. 3. 70eV Mass spectrum of the TMS derivative of 3"-hydroxy-CBG.

Metabolites hydroxylated in the other chain (carbons 1'-10'), peaks 8 and 9, had similar spectra in which the fragment ions present in the spectrum of CBG-TMS ether had not shifted in mass. This indicated hydroxylation at C-8 and C-9 with the trans-hydroxy metabolite, 8-OH-CBG, being the major metabolite (peak 9). Ions containing the terminal carbon atoms of the chain and the OTMS group were present at m/z 156, 157, and 169. Peak 4 was produced by CBG-6,7-epoxide (M^+, m/z 476) and its derived diol was was also identified (peak 11). The mass spectrum of the latter compound was dominated by the ion at m/z 131 produced by cleavage of the C-6 - C-7 bond. Peak 1 in Fig. 1 is CBG. Most of the species produced these metabolites although in different relative proportions. The cat produced a considerable concentration of a hydroxylated dihydro-CBG (M^+ m/z 550) identified as the 6,7-dihydro analogue of the 8- and 9-hydroxy metabolites (both give the same dihydro compound). The presence of the hydroxy-methyl group was confirmed by the ion at m/z 103.

This work was supported by the Wellcome Trust and NIDA.

METABOLISM STUDY OF ETHYLCYCLOHEXANE IN MALE FISCHER RATS BY GC/MS

Kyung O. Yu[a], M. Paul Serve[b], Jacqueline Roberts[b], and Gayle A. McDonald[c]

[a] Toxic Hazards Division, Harry G. Armstrong Aerospace Medical Research Laboratory, Wright-Patterson Air Force Base, OH 45433.
[b] Department of Chemistry, Wright State University, Dayton, OH 45431.
[c] Northrop Services, 101 Woodman Drive, Dayton, OH 45431.

Petroleum products are widely used in our society and hydrocarbons are the principal class of components in petroleum products (gasoline, cleaning solvents and lubricants). The relationship between exposure to petroleum-derived hydrocarbons and renal toxicity in male rats is a fairly recent finding (1,2). Exposure of unleaded gasoline in rats and mice showed the occurance of the dose-related degree of kidney damage in male rats. This kidney insult appeared to be sex and species-specific. Since unleaded gasoline is composed of many hydrocarbons, studies to correlate specific chemical structure with the nephropathy are underway.

Cyclic compounds such as cyclohexane and methylcyclohexane do not appear to produce hyaline droplet nephropathy in proximal tubular epithelium of male rats while a branched chain hydrocarbon substituent (e.g. isopropyl or t-butyl group) attached to the cyclohexane ring produces the nephrotoxicity. The objective of this study is to determine how the ethyl group moity in cyclohexane ring would affect the oxidative metabolic pathway and cause the renal damage in the male rats.

Eight male Fischer 344 rats (283 $\pm$ 10g) were dosed by gavage with 1.0 mL/kg ethylcyclohexane every other day for 14 days. Rats were placed in metabolism cages for the first 48 hours following initial dosing for urine collection. Urine was also collected from water-treated rats (N = 4). Food and water were freely available. Aliquots of urine were ajdusted to a pH of 4.4 and hydrolyzed by β-glucuronidase/aryl sulfatase at 37°C overnight. The samples were filtered through Clin-Elut using methylene chloride as the eluent. Concentrated methylene chloride extracts were analyzed by GC and GC/MS. TMS-derivatives were made by reaction of urine extracts and BSTFA (Pierce chemical Co). Mass spectra and GC retention time of the urinary metabolites were compared with those of synthesized or purchased compounds. All spectra were obtained on HP 5985 quadrupole mass spectrometer equipped with capillary columns (Carbowax 20M 25 meter or DB-1 30 meter for TMS-derivatives). Heluim gas was used as carrier gas ($\bar{\mu}$ = 25 cm/sec), and both injection port and ion source were 200°C. The column temperature was programmed from an initial oven temperature of 100°C held for 1 min, with the program rate of 5°/min, to the final temperature of 180°C held for 1 min.

Urinary metabolites identified by GC/MS are 4-ethyl cyclohexanol, 2-hydroxy-4-ethyl cyclohexanone, cis-diols (2^c-hydroxy-4^c-ethyl cyclohexanol, 2^c-hydroxy-4^t-ethyl cyclohexanol) and trans diols (2^t-hydroxy-4^t-ethyl cyclohexanol, 2^t-hydroxy-4^c-ethyl cyclohexanol). GC trace of the urinary metabolites showed that thermally stable trans-diols are the major metabolites. No attempts were made to assign which diol eluted first in cis-diols or trans-diols.

Monohydroxylation, oxidation to keto alcohol and dihydroxylation were the metabolic pathways for ethylcyclohexane in male rats exposed by gavage. Histopathology showed the mild hyaline droplet formations which were not detected in the proximal tubule of the rats exposed to cyclohexane or methylcyclohexane.

IDENTIFICATION OF URINARY ARGININOSUCCINIC ACID IN ADULT TYPE CITRULLINEMIA BY FAB MS/MS

Masahiro Matsumoto, Yoshito Inoue, Takashi Ohkura,
*Kimio Isa and Isamu Matsumoto
Department of Biochemistry, Institute of Human Genetics,
Kanazawa Medical University, Uchinada, Ishikawa 920-02, Japan,
*Faculty of Education, Fukui University, Fukui 910, Japan

Citrullinemia or citrullinuria is caused by a hereditary deficiency of argininosuccinic acid (ASA) synthetase. ASA synthetase is located in the liver, brain, and kidney of mammals, and its precursors are citrulline and aspartic acid. Adult type citrullinemia patients are deficient in ASA synthetase in the liver, but not in the kidney.

The quantification of citrulline is done routinely using an amino acid analyzer. ASA is undetectable in healthy normal urine and serum, and can only be detected in urine, blood, and cerebrospinal fluid of patients with argininosuccinase deficiency, argininosuccinic aciduria.

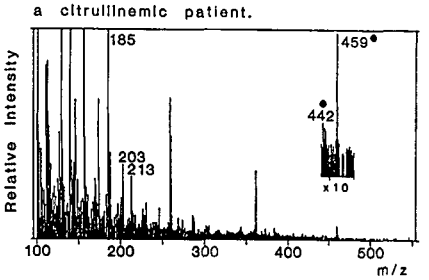
Recently, we detected moderatory intense peaks having the same retention time as ASA by amino acid analysis of urine of a patient with citrullinemia, and analyzed the component by FABMS and/or FAB MS/MS.

Urine specimens were dried under reduced pressure and derivatized to butyl esters by 15%-boron trifluoride n-butanol solution, and applied to FABMS and/or FAB MS/MS.

Quasi-molecular ions ($M+H)^+$ of ASA butyl ester (m/z 459) were detected in the urine from the patient with adult type citrullinemia, but the peak was less intense than that in argininosuccinic aciduria. This was further confirmed by E-B-E type FAB MS/MS. The collision induced decomposition spectra obtained by focussing the ion beam of m/z 459 showed major peaks of m/z 442 in both samples from patients with argininosuccinic aciduria and citrullinemia.

A possible explanation for this contradictory finding is that the ASA synthetase deficiency in the liver caused the accumulation of excess amounts of citrulline, which was then circulated into the kidney and utilized for the synthesis of ASA as ASA synthetase in the kidney has normal activity, which results in the accumulation of ASA.

The FAB mass spectrum of urine from a citrullinemic patient.



The ions of 459 and 442 are derived from ASA tri-butylester. Other numbers are derived from citrulline butylester.

ASSESSMENT OF HEXOSE MONOPHOSPHATE SHUNT ACTIVITY IN NEOPLASTIC CELLS

[1]T.P. Krick, [2,3]S.L. Mitchell, [1,3]B.D. Ross and [2,3]M. Garwood
[1]Department of Biochemistry, University of Minnesota, St. Paul, MN
[2]Department of Radiology, University of Minnesota, Minneapolis, MN
[3]Gray Freshwater Biological Institute, University of Minnesota, Navarre, MN

Introduction

The hexose monophosphate shunt (HMPS) provides pentose sugars and NADPH for the synthesis of nucleic acids and lipids, respectively. Since malignant cells of the central nervous system have been shown to have increased HMPS activity relative to normal cerebral tissue [1] and some chemotherapeutic agents affect nucleic acids and the HMPS [2], it is important to be able to gain a better understanding of the activity of this pathway. We present a mass spectrometric method for sequential measurements of the relative contribution of the HMPS to glucose metabolism.

Materials and Methods

C6 glioma cells were grown to confluence in sterile flasks in supplemented Ham's F-10 medium. Prior to the test, the flasks were rinsed with Krebs-Ringer Bicarbonate buffer (KRB) and allowed to metabolize endogenous carbon sources for one hour. Prior to the addition of the test media, the flasks were again rinsed. The test media were KRB with 5.5 mM 1-^{13}C-glucose (KRB-Glu) for control or KRB-Glu with either 0.001 mM phenazine methosulfate (PMS) or 1.0 mM KCN. Eight ml of media was added to the flasks and changed at time points of 1, 2, 3, 5, 7, 9 and 12 hours.

One half ml of each sample with 0.05 ml of U-^{13}C-lactate at a concentration of 0.2384 mg/ml added to some samples was used for mass spectrometric analysis. The U-^{13}C-lactate was added as an internal standard for total lactate determination in samples involving PMS since PMS oxidizes the NADH used in the enzymatic measurement of lactate [3]. The samples were converted to trimethylsilyl (TMS) derivatives in a solution of 25 µl pyridine and 40 µl bis (trimethylsilyl)-trifluoroacetamide with 1% trimethylchlorosilane which was heated to 50° C for 15 minutes prior to injection [4,5]. Seven and a half ml of each aliquot were lyophilized and reconstituted in 0.5 ml deuterium oxide for NMR analysis.

Determination of the HMPS activity depends on the determination of the [3-^{13}C-lactate]/[3-^{12}C-lactate] ratio due to 1-^{13}C-lactate metabolism. The fraction of glucose metabolized to lactate which was metabolized by the HMPS (X) was calculated by the equation, $X = (3-3R)/(3+2R)$, where R is the [3-13C-lactate]/[3-12C-lactate] ratio [6-8].

Mass spectrometric analyses were done on a KRATOS MS-25 gas chromatograph-mass spectrometer coupled to a DS-55 data system. A DB-5 fused silica column (30 m x 0.32 mm) with a 0.25 µm film thickness was used with helium as the carrier gas.. Selected ion monitoring was performed on the m/z 219 through m/z 222 ions which correspond to the molecular ions of the TMS derivatives minus a methyl group. Each sample took approximately 15 to 20 minutes to run.

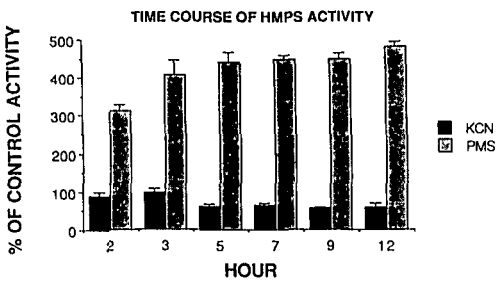
NMR analyses were done on a Nicolet Magnetics NT-300 (7.05T) spectrometer. The [3-13C-lactate]/[3-12C-lactate] ratios were determined by quantitating the areas of the resonances of the lactate methyl proton satellites due to carbon-13/proton interaction and the resonances of the methyl protons on carbon-12 by spectral

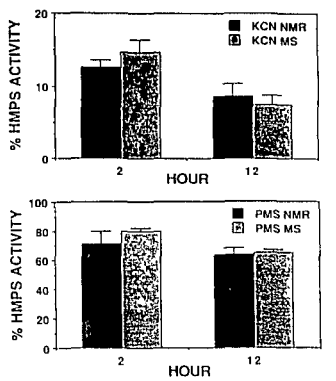
deconvolution using the Nicolet "NMCCAP" routine. Each sample took up to 5 hours to run.

Lactate determinations were done by two methods. An enzymatic method utilizing lactate dehydrogenase for the oxidation of lactate and the concomitant reduction of NAD^+ to NADH. The increase in NADH concentration was determined by a spectrophotometer at 340 nm [3]. Since PMS oxidizes the NADH which is produced in this reaction, this method was not suitable for samples with PMS. U-13C-lactate in a known concentration was added to these samples prior to derivatization and total lactate was determined by the ratio of the m/z 219 and 220 peaks to the m/z 222 peak (as corrected for natural abundance) which correspond to U-^{12}C-lactate and 3-^{13}C-lactate from the metabolism of the 1-^{13}C-glucose and the U-^{13}C-lactate.

Results and Discussion

The HMPS activity was determined for control cells as well as cells treated with PMS or KCN for 12 hours. Individual measurements were made at 1, 2, 3, 5, 7, 9 and 12 hours with a curve being formed of varying activities (fig. 1). After 12 hours of incubation with PMS the HMPS activity was increased to 350% of control activity. Cells cultured with KCN had an activity decreased to only 41% of control after 12 hours. A comparison of the activities as derived from the mass spectrometric and NMR data (fig. 2) revealed no significant difference by Student's t-test.





These results demonstrate that this mass spectrometric method correlates well with the previously reported NMR method for sequential monitoring of HMPS activity in cultured cells but takes less sample (0.5 ml vs 7.5 ml) and less time per sample (15-20 minutes vs 5 hours) for analysis than the NMR method.

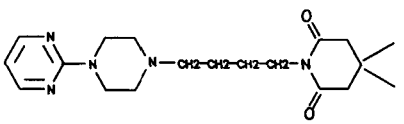
SIMULTANEOUS QUANTITATION OF GEPIRONE AND 1-PP IN HUMAN PLASMA BY CAPILLARY GAS CHROMATOGRAPHY-MASS SPECTROMETRY:

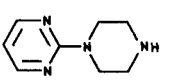
M.A. Sciacca, J.P. Shea, G.F. Duncan, H.C. Faulkner, III, R.H. Farmen and K.A. Pittman, Department of Metabolism and Pharmacokinetics, Bristol-Myers Company, Pharmaceutical Research and Development Division, Syracuse, N.Y. 13221.

Gepirone (I), 4,4-dimethyl-1-[4-[4-(2-pyrimidinyl)-1-piperazinyl]butyl]-2,6-piperidinedione, is a potential anxiolytic and antidepressant agent currently undergoing Phase III clinical trials. 1-PP (II), 1-(2-pyrimidinyl)-piperazine, is a major metabolite of gepirone.

(I)



(II)



A GC-MS assay was developed and validated to simultaneously quantitate gepirone and 1-PP from human plasma. Analytes were extracted from plasma using C-18 extraction columns. The columns were conditioned with methanol and tris buffer (20 mM, pH 7.3), followed by addition of a 1 ml plasma sample. Columns were then successively washed with buffer and 1 ml of a methanol:water (2:3) mixture followed by analyte elution with 2 ml of 1% triethylamine in acetonitrile (1). After extraction the metabolite and its deuterated internal standard were derivatized with pentafluorobenzoyl chloride to their corresponding amides. The 1-PP derivatives, gepirone and the gepirone internal standard, 5-fluorobuspirone, were then reconstituted in 0.11% triethylamine in toluene (v/v) and injected. Samples were analyzed by capillary GC with automated splitless injection. The HP 5970 MSD was set to monitor the molecular ions of 1-PP and d4-1-PP, M/Z 358 and M/Z 362, followed by the gepirone common ion at M/Z 251 and then the 5-fluorobuspirone common ion at M/Z 277. The lower limit of quantitation, 0.1 ng/ml for both compounds, was determined on 1 ml plasma samples from ten different sources.

Standard curves were linear from 0.1-25 ng/ml when relating the ratio of gepirone and 1-PP to their respective internal standards with the concentration of analyte added to human plasma.

Figure 1 is a selected ion chromatogram of a processed 1 ml plasma standard spiked with 25 ng of gepirone and 1-PP and about 5 ng of the internal standards. The GC conditions employed helium as the carrier gas, with a 10m DB-5 column, 0.18 mm ID, 0.4 um film thickness, (J&W Scientific). The GC oven temperature was held at 150°C for 1 min, increased to 315°C at 25°C/min, and was held at final temperature for 5 min. Interface and injector temperatures were 270°C.

Figure 2 shows gepirone and 1-PP kinetics in a fasted subject given a 20 mg gepirone tablet.

The main advantage of this assay over previous methods (2,3) was the simultaneous quantitation of gepirone and 1-PP, saving both analyst and GC-MS time, with no loss in assay performance. The solid-phase extraction was efficient and simple. Plasma sample volume requirements were also reduced from 4 mls to 1 ml. This assay is currently being used to generate pharmacokinetic data for gepirone and 1-PP in humans.

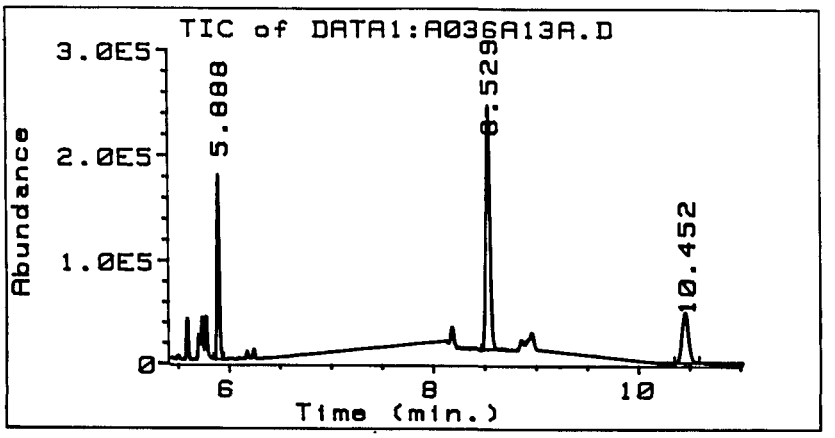


Figure 1. Peaks: 5.8 min. = 1-PP and d_4-1-PP; 8.5 min. = gepirone; 10.4 min. = 5-fluorobuspirone.

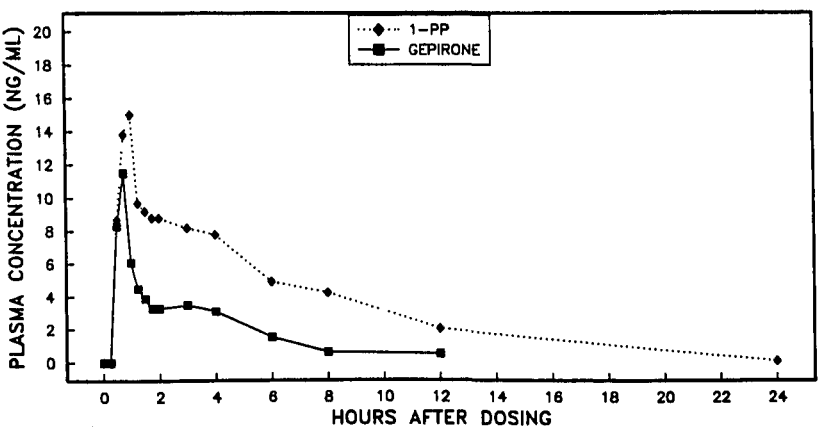

Figure 2.

METABOLIC PROFILING OF VALPROIC ACID IN PATIENTS USING NEGATIVE ION CHEMICAL IONIZATION GCMS. Frank S. Abbott, Kelem Kassahun, Roland Burton and Kevin Farrell. Faculties of Pharmaceutical Sciences and Medicine, University of British Columbia, Vancouver, Canada, V6T 1W5.

Valproic acid (VPA) is a major antiepileptic drug widely used in the treatment of a variety of seizure types. VPA is metabolized in the body by a combination of mitochondrial, microsomal and cytosolic enzymes to produce at least 16 known metabolites. It is believed that several of the metabolites contribute to both the therapeutic and toxic effects of the drug. Partly because of their large number and the wide concentration range at which they are found in biological fluids, quantitation of VPA metabolites represents a significant analytical challenge. Published methods[1-3] for the assay of VPA metabolites either do not have the necessary sensitivity to quantitate the trace unsaturated metabolites or are not complete in terms of including important metabolites. Here, we report the development of a negative ion chemical ionization (NICI) GCMS method for the simultaneous quantitation of VPA and 14 of its metabolites in one chromatographic run. The assay was employed for metabolic profiling of VPA in pediatric patients on VPA monotherapy and combined therapy with other antiepileptic drugs.

Serum (trough) and overnight urine samples were obtained from 26 patients receiving VPA only and 33 receiving VPA in combination with carbamazepine and/or clobazam. Four internal standards were employed in the assay; di-([3,3,3-^{2}H]propyl)acetic acid ([$^2H_6$]VPA), [3,5,5-^{2}H]3-heptene-4-carboxylic acid ([$^2H_3$]2-ene VPA), [3',3',3'-^{2}H]2-propyl-3-oxopentanoic acid ([$^2H_3$]3-keto VPA) and 2-methylglutaric acid. Serum (100-250 uL) or urine (250 uL) to which internal standards had been added was acidified (pH 1.5-2.0) and extracted with 2x500 mL ethyl acetate. The concentrated extract (200 uL) was derivatized to give the pentafluorobenzyl (PFB) esters. The PFB derivatives were then treated with N-methyl-N-trimethylsilyl-trifluoroacetamide to silylate metabolites containing hydroxyl groups and the 3-oxo moiety. Finally a 1 uL aliquot of the derivatized sample was injected into the GCMS in the splitless mode. The instrument used was a Hewlett-Packard 5987A GCMS fitted with a DB-1 column, 30 m x 0.32 mm (I.D) with a film thickness of 0.25 uM. Operating conditions in the negative ion mode were: ionization energy, 200 eV; source prssure, 1 torr; source temperature, 200°; reagent gas, methane.

The NICI GCMS properties of the PFB esters and O-TMS-PFB derivatives of hydroxy and 3-oxo metabolites proved to be suitable for the simultaneous analysis of VPA and 14 of its metabolites. The PFB derivatives of the hydroxyl metabolites chromatographed poorly on the DB-1 column and sensitivity was poor. Trimethylsilylation of the hydroxyl groups after PFB derivatization, however, greatly improved both peak shape and sensitivity of detection. The use of the DB-1 column enabled the complete resolution of 4-ene VPA from VPA as well as the separation of the monounsaturated metabolites as seen in Fig. 1A. PFB derivatization also resulted in baseline separation of the geometric and/or positional isomers of the diunsaturated metabolites (Fig. 1B).

Quantitation was performed by monitoring the intense $[M-181]^-$ ions. Correlation coefficients were typically greater than 0.99 for all standard curves. The method showed good precision with a day to day variation of less than 15% for all 15 analytes. Trace metabolites, including 4-ene VPA, (E)-2,4-diene VPA and (E,Z)-2,3'-diene VPA were readily quantitated from 100 uL of serum. The major metabolites in serum were found to be (E)-2-ene VPA, (E,E)-2,3'-diene VPA and 3-keto VPA (Table 1). The putative toxic metabolite, 4-ene VPA, was present at low levels (mean = 0.20 ug/mL).

The serum concentrations of 4-keto VPA and 5-OH VPA were significantly higher ($p<0.05$) in the VPA + carbamazepine group compared to the monotherapy group. There was no significant difference in metabolite profile between monotherapy and combined therapy with clobazam. In urine, the unsaturated metabolites were excreted mainly as conjugates, while the oxo metabolites were predominantly excreted in the free form. The hydroxy metabolites and 2-PGA were found in urine in both the conjugated and free forms.

The serum levels of the the unsaturated metabolites including the putative toxic metabolites, 4-ene VPA and (E)-2,4-diene VPA, were higher relative to that of VPA in a single case of VPA-induced liver toxicity. This, however, reflects the elimination characteristics of these metabolites since the sample was taken three days after the withdrawal of therapy. Thus it does not appear that the concentrations of the toxic metabolites were abnormal in this case of VPA-induced liver toxicity.

In summary, a NICI GCMS method has been developed for the simultaneous quantitation of 14 VPA metabolites. The assay demonstrated good reproducibility and sensitivity enabling the accurate determination of trace metabolites in small serum samples. The ω and ω-1 pathways of VPA appeared to be induced when VPA was given in combination with carbamazepine while clobazam apparently had no effect on the VPA metabolite profile.

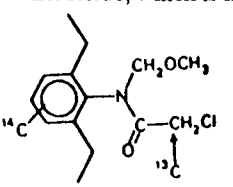
St. Louis, Missouri 63198

Alachlor [2-chloro-N-(2,6-diethylphenyl)-N-(methoxymethyl)acetanilide] **1** is the active ingredient in LASSO ® herbicide, which is manufactured and sold worldwide by Monsanto Company.



1

Alachlor metabolism was studied in cell-free kidney and liver enzyme preparations from rats, mice, and monkeys. Such *in vitro* studies were useful in elucidating the initial and intermediary pathways of alachlor metabolism (Scheme 1), and in determining species and gender differences in the metabolites produced.

Dual ^{13}C/ ^{14}C-labeled alachlor was used as a substrate in order to monitor metabolic transformations by HPLC/RAD and mass spectrometry. Metabolites were normally produced in the range 1 μg to 5 μg, and mass spectral techniques were essential for structure elucidation. Relatively volatile products were analyzed by GC/MS and by direct probe MS. Nonvolatile metabolites such as sugar and peptide conjugates were analyzed by FD/MS and HPLC/MS.

Two primary routes of alachlor metabolism were found in liver and kidney microsomal preparations from rats, mice, and monkeys: 1) alachlor was conjugated with glutathione by nucleophilic displacement of chlorine. and subsequently transformed via the mercapturic acid pathway; 2) alachlor was oxidized to alcohol derivatives which were subsequently converted to glucuronides. Further enzymatic conversions of initial metabolites produced 2.6-diethylaniline, which underwent aryl hydroxylation followed by sulfation to form 4-amino-3,5-diphenylsulfate.

In summary, the same products of alachlor metabolism were produced by liver and kidney microsomal enzymes from rats, mice, and monkeys. However, there were significant differences between species in the rates of metabolism, which may correlate with differences observed in the distribution and ultimate disposition of alachlor *in vivo*.

Analysis of Drugs of Abuse in Hair by Tandem Mass Spectrometry

David A. Kidwell, Chemistry Division
Naval Research Laboratory, Washington, DC 20375

Introduction

Analysis of hair for drugs of abuse has several advantages over urinalysis. Drugs have been shown to be stable in hair and non-leaching for long periods of time whereas they are rapidly cleared from urine. Unlike urinalysis, hair analysis can be repeated with many samples at various times if the analytical results are questioned. Hair analysis also provides a long-term profile of drug use to aid as an independent check on an individuals veracity.

Most hair analysis has been by extraction of the drug and its detection in the extract by radioimmunoassay or GC/MS.[1-4] Extraction is time consuming and requires 30-40 pieces of hair. A more rapid and sensitive analytical procedure based on pyrolysis CI/MS/MS has been developed. Tandem mass spectrometry eliminates the tedious washing and extraction steps, can be preformed on single hairs, and can examine metabolites as well as the parent drug. To demonstrate this technique, cocaine and its metabolites and PCP were examined in human hair.

Methodology

Several hairs were weighed. One or two hairs were cut into 0.5 cm pieces, the sections placed in a solids probe cup, and the cup heated at 110°C for 1 minute in air to dry prior to analysis. For longitudinal sectional analysis, five strands of hair were cut at 1 cm points. Instrumental conditions for the Finnigan TSQ 70 were:

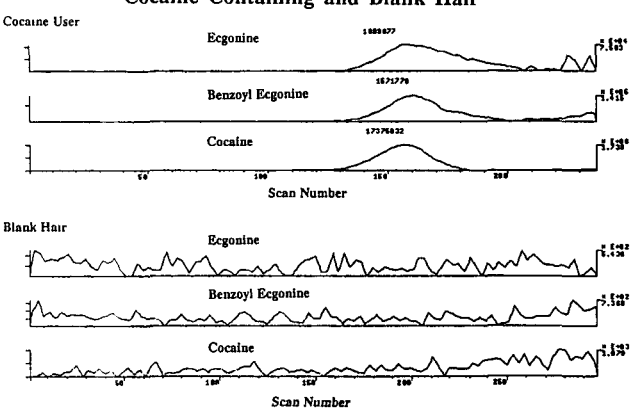
Isobutane CI gas at 1.6 torr
Argon collision gas at 1 mtorr
Collisional energy -20V (cocaine)
-18V (PCP)
Probe Heating: Initial at 50°C; 0.5 minute
Ramp to 250°C; 0.5 minute
Hold at 250°C; 2 minutes

Parent spectra of m/z 182 (cocaine), m/z 168 (benzoylecgonine) and m/z 82 (ecgonine) were taken in SIM mode. Cocaine was quantitated with external standards. Daughter spectra of m/z 244 (PCP) and m/z 258 (p-methyl PCP, the internal standard) were taken in SIM mode. Sensitivity for all materials was less than 50 pg.

Results

Typical desorption profiles for cocaine and its metabolites and blank hair are shown in Figure 1. Levels of cocaine and metabolites from different users are given in Figure 2. Hair from only one PCP user was available. Only PCP was found (at 16 ng/mg hair); no metabolites of PCP were detected. The desorption profile was very similar to that for cocaine, shown in Figure 1.

Figure 1 - Typical Desorption Profile for Cocaine Containing and Blank Hair



Precautions

Although an excellent filter, a tandem mass spectrometer can be overwhelmed in certain cases. In early work the hair was heated to 350°C. Interferences in some blank hair were observed. When two ions were monitored, as in PCP, high heating temperature produced both ions in approximately the correct ratio. A lower heating temperature resulted in much improved signal/noise ratios. In addition, cleaning of the ion source must be performed frequently when the hair is heated too hot.

Mechanism of Drug Incorporation

Once drugs are incorporated into hair they are not removed under normal cleaning conditions. Drugs may be bound to hair by covalent binding, ionic binding, or Van der Waals forces. Covalent binding cannot be considered for cocaine or PCP since no parts of the molecule are available for binding. Binding through Van der Waals forces also is unlikely since cocaine and its metabolites are highly water soluble and neither water nor organic solvents remove the cocaine.

To test an ionic binding mechanism, hair was soaked in solutions of PCP and washed in various solvents. As shown in Figure 3, the PCP is tightly held in the hair and only removed with acid or base. PCP is rapidly taken-up by hair and only slowly released. Hair soaked in drugs mimics hair from drug users. However, the metabolites are not present. Preliminary experiments indicate that cocaine is not degraded in hair to the metabolites in the presence of base. Thus, the presence of metabolites is an indication of drug use.

Conclusions

Analysis of cocaine and PCP in the hair of drug users is rapid and easy by tandem mass spectrometry. Metabolites of cocaine are readily observed and are in lower concentrations than cocaine. Hydroxy metabolites of PCP were not observed. Since drugs may be tightly bound to hair by exposure in solution, hair analysis must be approached with caution. Analysis for metabolites may be one means of confirming drug use.

Determination of Volatile Organic Compounds in Human Blood By Purge and Trap Combined with Gas Chromatography/Mass Spectrometry

F.L. Cardinali, J.M. McCraw, and J.S. Holler

Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services, Atlanta, GA 30333

A number of recent findings suggest continuous, low-level human exposure to many volatile organic compounds (VOCs). The main concern of many health scientists is the adverse health effects that may be associated with such exposure. Several of these compounds are known human carcinogens. Others are suspected human carcinogens, that is they have been shown to cause cancer in animal testing programs. Individual VOCs have been associated with neurological and immunological health problems along with adverse reproductive outcomes. Many VOCs are thought to be associated with a new occupational health problem, associated with energy-efficient buildings, known as "sick-building syndrome."

The objective of our program is to measure the extent of exposure in the general population. In this program we will examine blood samples from over 1,000 individuals in conjunction with the third National Health and Examination Survey (NHANES III). By doing this, we will establish reference values that may be used in evaluating the degree of exposure to VOCs.

The analytical approach is purge and trap sample desorption combined with gas chromatography/mass spectrometry(GC/MS). The purge apparatus is a Tekmar LSC 3 with a 25 mL sample vessel operated in the needle sparging mode. Sample vessels are treated with Antifoam B to minimize foaming problems associated with this type of sample. A 10-mL blood sample is purged for 15 minutes by using the helium carrier gas, followed by a 4-minute heating cycle to desorb from the Tenax trap. A Tekmar Model 1000 capillary interface is used to cryofocus the volatiles before they are introducted onto the capillary column, a Vocol column (Supelco, Inc.; Bellefonte, PA) 60M x 0.75mm with a 1.5um film thickness. The capillary column is maintained at 40 ^{o}C for 5 minutes, then increased at 8°C per minute to 170°C and held at the final temperature for 10 minutes. The instrument used for detection is a Finnigan 1050 GC/MS system operating in the full scan mode scanning from 40u to 200u at 0.5 second per scan. Quantifcation is accomplished by using a group of isotopically labeled internal standards which are added to the sample before it is analyzed.

A typical chromatogram is depicted in Figure 1. Detection limits for most compounds are in the range of 100-500 ppt. Preliminary results suggest that the compounds observed depend on recent individual exposure. Use of home deodorizers, wearing clothing that has been dry cleaned, and use of laboratory solvents results in characteristic compounds being observed in the profile of volatiles in the blood.

Use of trade names is for identification only and does not constitute endorsement by the Public Health Service or the Department of Health and Human Services. This research is supported by funds from the Comprehensive Environmental Response, Compensation and Liability Act trust fund.

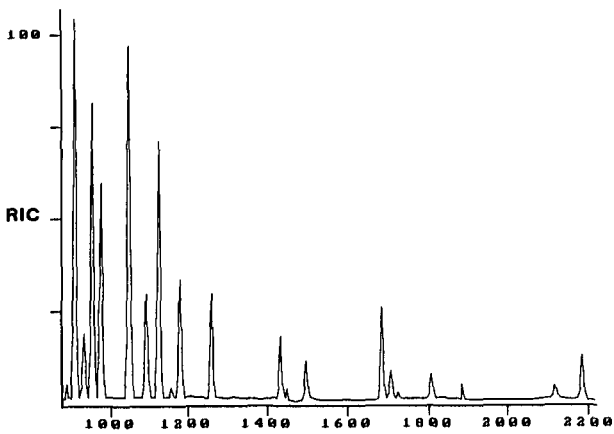

Figure 1. Typical reconstructed ion chromatogram obtained in purging human whole blood. Compounds observed include internal standard mixture spiked at the 3 ppb level.

DETERMINATION OF MUTAGENIC HETEROCYCLIC AMINES BY ON-COLUMN INJECTION GC/MS,

Lise H. Rovin*[1], Robert T. Rosen[2], Thomas G. Hartman[2], Joseph Ziv[1], and Joseph D. Rosen[1], Food Science Department[1] and Center for Advanced Food Technology[2], Cook College, New Jersey Agricultural Experiment Station, Rutgers University, New Brunswick, New Jersey 08903

The mutagenic activity detected in basic extracts of cooked muscle meats and several model systems involving amino acids, reducing sugars, and water has been attributed to a relatively small number of highly active structurally related heterocyclic amines[1]. The compound 2-amino-3-methylimidazo-[4,5-f]quinoline (IQ) and its analogues 2-amino-3,4-dimethylimidazo[4,5-f]quinoline (MeIQ), 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline (MeIQx), 2-amino-3,4,8-trimethylimidazo[4,5-f]quinoxaline (4,8-DiMeIQx), and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) have been shown to be potent mutagens which are formed at trace levels (ppb) in some cooked foods via a Maillard reaction. Another analog, 2-amino-3,7,8-trimethylimidazo[4,5-f]quinoxaline (7,8-DiMeIQx) has also been detected in model systems.

The method most frequently used for their determination is HPLC with mass spectrometric single ion detection. The HPLC mass spectral data was difficult to confirm due to lack of significant fragmentation and the presence of high levels of coextracted interfering compounds[2]. In our investigation, on-column injection capillary GC/MS analysis was used to detect and quantify trace levels of IQ formed in a model system and in commercial beef extract. This is the first time GC or GC/MS has been successfully utilized for the determination of these non-derivatized mutagens in beef and model systems. Murray et al[3] successfully used bistrifluoromethylbenzyl derivatives in the electron capture negative ion chemical ionization mode.

With proper cleanup procedures, the reproducibility of this technique is high due to lack of interfering coextracted compounds. By use of mass chromatography, the molecular weights of the mutagens of interest can easily be detected. We have demonstrated that IQ can be detected in model systems as well as in beef extract using GC/MS following efficient extraction and purification procedures. This procedure can be used for analyses of mutagenic and carcinogenic heterocyclic amines in other systems that are of interest and help in assessing the public health risk associated with various methods of cooking meats.

THE DETERMINATION OF CHLORDIAZEPOXIDE AND ITS MAJOR METABOLITES IN URINE AND POSTMORTEM TISSUES BY CAPILLARY COLUMN GC/MS

Li Yulan Yao Xi Gao Lisheng He Yi Xu Wan

Institute of Forensic Science, Ministry of Public Security,
P. R. CHINA.

Chlordiazepoxide is one of the benzodiazepine hypnotics. Since it is rapidly effective with fewer side effects, it has been used very extensively as hypnotic and anxiolytic agent. However it is potentially toxic. Abuse and misuse may give rise to considerable societal problem.

Chlordiazepoxide is metabolized to biologically active tranquilizer.

This paper describes an analytical method that can be used to identify chlordiazepoxide and its major metabolites, N-desoxydemoxepam and 2-amino-5-chlorobenzophenone, in the decomposed postmortem tissues and urine.

5g postmortem tissues (or 40ml urine) was extracted with 50ml diethyl ether at pH. 9 for three times. The collected organic phase was dried by a anhydrous sodium sulfate and evaporated by K-D evaporator. The residue was dissolved in ethanol (0.2ml). It was purified and separated by using TLC on the silica gel GF with a solvent mixture of cyclohexane-ethyl acetate-isopropyl alcohol (14:2:2) as developer. The eluates from this initial treatment were subjected to futher purification by running them in methanol respectively. They were analyzed by inserting them on the direct probe of mass spectrometer or by GC/MS on the Finnigan Mat 1020 GC/MS in the EI mode. SE-54 column (30m x 0.25mm) was used with column temperature programming from 180°C (for 1 min) at 25°C/min to 270°C (for 20 min).

Organism sample can be easily analyzed using this method for the qualitative identification of chlordiazepoxide and its metabolites. Fig.1 shows a RIC of purification sample from the decomposed postmortem tissues. The mass spectrums of scanning number 343,551 speaks are shown in Fig.2.3. They are 2-amino-5-chlorobenzophenone and N-desoxydemoxepam in accordance with forward library search. They have characteristic peaks which are formed by lossing H and CO from molecular ion and giving the fragment ion at m/e 230

,269 and 202,242 respectively. Under electron impact base peak of N-desoxydemoxepam can be decomposed further by loss of CH≡N group, and then it gives fragment ion at m/e 215.

Chlordiazepoxide is an unstable drug. Under the GC/MS analytical conditions thermolysis has been observed. Since oxygen was lost by heating, deoxychlordiazepoxide was detected(Fig.4). When injection port temperature decreased to 200°C, thermolysis disappeared.

This method has the main merit of overcoming the difficulty in lack of standard sample. It has been successfully used in identification of the chlordiazepoxide and its metabolites from decomposed postmortem tissues and urine. The detection limit is 15ng for chlordiazepoxide.

DETERMINATION OF TRACE VOLATILE N-NITROSOCOMPOUNDS IN FRESH MEAT, FROZEN MEAT AND PUTRID MINCE BY GC AND MATCHING TECHNIQUE

*Yang Yinghua, Ding Jahua, Song Jehuai, Jiang Yunfei,
Shu Lizong, Liu Guixin, Wang Ping, Wu Xia
(Sanitation and Antiepidemic Station of Jilin Province, China)
(*Jilin Import and Export Commodity Inspection Bureau, China)

It has been known that N-nitrosocompound is a kind of strong carcinogens, and it is very important to study its aetiology of carcinogenesis.[1,2] Interational Agency for Research on Cancer (I.A.R.C.) has paid attention to the research since 1969, but there is a few of reports in china.

Because foods to be analysed contain trace of N-nitrosocompounds, high selectivity is required. In 1973, Fine et al.,[3] introduced Thermal Energy Analyser which greatly increased reliability of screening method and became an effective routine technique for analysis of N-nitrosocompounds, but dinitrocompound and something else shall interfere with the determination, so it can not meet the need of the identification. A combined GC/MS technique for the detection of N-nitrosocompounds opens up the wide way. Only retention time of GC,is not enough to determine N-nitrosocompound qualitively and quantitatively, and the results must be confirmed by MS, which was suggested in the conferences of 1973, 1977 IARC.

We studied and compared four kinds of MS methods for the determination of them in 1981:[4] (1) low resolution EI SIM (2) high resolution EI peak matching (3) low resolution CI SIM (4) high resolution peak matching. Results showed that low resolution CI SIM method is also reliable. The method described here is based on above method using to high resolution peak matching technique which can be used to determine N-nitrosocompounds in food.

All experiments were carried out on a JMS-D_{300} Mass spectrometer. Experimental conditions are as follows: glass column, 2M×1.8mm packed with 15% PEG-20M+1% KOH, Chromosorb W, AW DMCS(80-100Mesh); Helium as a carrier gas; Electron impact source (EI); Resolution 7000;ionization voltage 70V; ionization current 300μA; ion source temperature 180°C. When the instrument became stabe, 1μl of N-nitrosodimethylamine (NDMA) standard solution was injected and retention time were determined, then PFK (68.9952) and NDMA base peak (74.0480) was matched, the matching value was 1.07323. The peak height was read out from the oscilloscope at NDMA retention time, in order to avoid error from instrument, a calibration was made using a standard solution. Finally calculate the content of N-nitrosamine in samples according to peak height of

standard and samples from the oscilloscope, the equation is $C_1 = H_1/H_2 \times C_2 \times 1000/N$ where H_1: sample peak height(mm); H_2: standard N-nitrosamine peak height(mm); C_2: standard N-nitrosamine concentration (μg/ml); N: concentration factor; C_1: sample concentration (ng/ml).

table 1: The contents of four volatile N-nitrosamines in fresh meat and over frozen meat

Sample	No	NDMA	NDEA	NDPA	NPYR
fresh meat	1	-	-	-	-
	2	-	-	-	-
	3	-	-	-	-
	4	0.5	-	-	-
	5	-	-	-	-
	6	0.5	-	-	-
	7	0.8	-	-	-
	8	0.6	-	-	-
	9	0.5	-	-	-
	10	-	-	-	-
frozen meat	1	0.8	-	-	-
	2	-	-	-	-
	3	1.4	-	-	-
	4	1.4	-	-	-
	5	0.7	-	-	-
	6	-	-	-	-

	8	0.8	-	-	-
	9	0.8	-	-	-
	10	-	-	-	-

table 2: The content of NDMA, NDEA, NDPA, NPYR and (TVB-N) formed during putridity of mince

storage time (day)	storage tem. (°C)	NDMA (ppb)	NDEA (ppb)	NDPA (ppb)	NPYR (ppb)	TVB-N (mg/100g)
1	room tem.	0.6	-	-	-	2.410
3	"	0.8	-	-	-	5.455
4	"	0.8	-	-	-	6.330
5	"	7.7	-	-	-	9.745
6	"	8.6	0.6	-	-	15.895
8	"	18.1	0.7	-	-	30.770

NDMA were detected in both fresh meat and over-stored frozen meat, the ratio of detection are 50%, 70% and X are 0.3ppb, 0.7ppb,respectively. The ratio and X in over-stored frozen meat is higher than in fresh meat. This is probably due to nitrosation of over-stored frozen meat. The content of NDMA in pork mince had only a little change within the first 4 days. After 5 days, the amount of NDMA suddenly increased to 7.7ppb (TVB-N 9.7mg/100g) from 0.8ppb (TVB-N 6.3mg/100g), after 8 days, the the amount of NDMA reached 18.1ppb (TVB-N 30.8mg/100g). It was shown the amount of NDMA increased along with the putridity degree of meat.

QUANTITATION OF TRICHOTHECENE MYCOTOXINS BY MS/MS: A COMPARISON OF ISOTOPICALLY LABELED INTERNAL STANDARDS WITH AN EXTERNAL STANDARD PROCEDURE.

Pawlosky R.J., Wen Y., Abbas H.K., and Mirocha C.J.
The University of Minnesota, Dept. of Plant Pathology
St. Paul, MN 55108

An advantage of tandem mass spectrometry over that of single stage instrumentation is in the analysis of trace substances occurring in complex backgrounds. Trichothecene mycotoxins, are known to be produced by various species of Fusarium inhabiting stored grain. The quantities of the mycotoxins are small compared to the backgrounds in which they are found thus are suitable candidates for trace analysis by MS/MS. Sampling biological fluids of humans or animals for trichothecenes T-2 or the metabolite HT-2 establishes the link in alledged mycotoxicoses.

Multiple Reaction Monitoring (MRM) relies on the collision activated decomposition (CAD) processes of tandem MS/MS. Thus specific sets of reactions are followed by the selection of parent ions with MS I and sequential jumping of daughter ions by MS II. In the analysis of T-2 and HT-2 toxin and their deuterated counterparts three specific reactions were monitored with MRM (figure 1). These reactions produced a high degree of specificity and sensitivity owing to the efficient conversion of the parent ions to the various daughters.

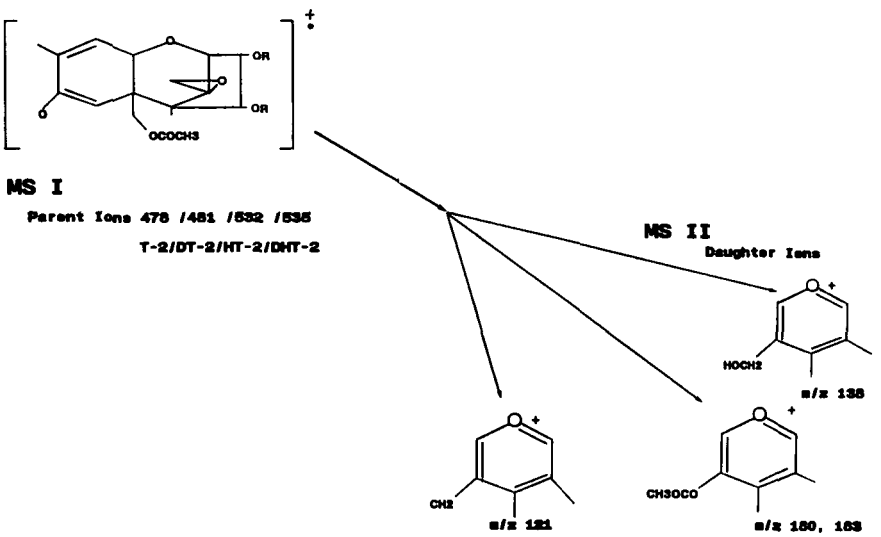

figure 1.

The results of the T-2 and HT-2 analyses are presented in figure 2. The four graphs represent quantitation of the mycotoxins with an external standard procedure as well as using a deuterated internal standard. Blood was amended with the toxins at levels of 20, 10 and 1 ppb and triplicate injections were made of each sample. When using the external standard for quantitation the results were consistantly lower than those obtained using the ISTD. The scatter for both sets of experiments based on standard deviation and coefficient of variance were about the same suggesting reproducibilty of sample handling in the entire series of experiments. Deuterated internal standards are the best choice in the analytical procedure because they provide a means of quantitation based on the dynamic state of the CAD process and duplicate the reactions of the analytes.

METABOLISM OF 3,4-METHYLENEDIOXYMETHAMPHETAMINE (MDMA) IN THE RAT: IDENTIFICATION OF METABOLITES WITH AN ION TRAP DETECTOR.

H.K. Lim and R.L.Foltz; Center for Human Toxicology, University of Utah, Salt Lake City, Utah 84112

MDMA has recently been shown to cause selective degeneration of serotonergic neurons in the brains of rats and monkeys, as indicated by the alteration of neurochemical and histological parameters (1). In an effort to understand the mechanism of MDMA-induced neurotoxicity, we have investigated the metabolism of MDMA in the rat, using mass spectrometry with ion trap detection to identify metabolites in vivo and in vitro.

The methanol positive ion chemical ionization (PCI) total ion current chromatogram of TFA-derivatized urine from dosed rats contained eight peaks that were absent in control urine (Fig. 1). Only peaks A, C, D, and E were present in sufficient quantity to permit the acquisition of EI mass spectra, although PCI mass spectra were obtained for all eight peaks. The major metabolite in rat urine, peak C, was identified as 4-hydroxy-3-methoxymethamphetamine from its EI (Fig. 2) and PCI mass spectra (Fig. 3). The identities of all the chromatographic peaks are shown in Table 1. MDMA, MDA, and the 3-O-methyl phenolic amine metabolites were consistently detected in all the specimens examined. The EI mass spectrum of a new metabolite produced in liver and brain tissues in vitro (Fig 4) identified it as 3,4-dihydroxymethamphetamine Other metabolites present in the 10,000 x g liver incubate included 4-hydroxy-3-methoxymethamphetamine, MDA, and 3,4 methylenedioxyphenylacetone ; the major liver metabolite was MDA. In the 10,000 x g brain incubate, the major metabolite was the 3,4-dihydroxymethamphetamine, but MDA, 4-hydroxy-3-methoxymethamphetamine and 4-hydroxy-3-methoxyamphetamine were also found. The structures tentatively assigned to MDMA metabolites were confirmed by comparison of their EI and PCI mass spectra and relative retention times with those of synthetic reference compounds.

The biotransformation pathways for MDMA that we have identified in the rat include O-dealkylation, N-demethylation, deamination, O-methylation, and O-conjugation (Fig. 5). The demonstration that the brain can biotransform MDMA , the neurotoxic MDA being one of the metabolites, provides presumptive evidence for the involvement of metabolites in MDMA-induced neurotoxicity.

IDENTIFICATION OF THE METABOLITES OF 4'-METHYLTHIOPROPRANOLOL IN THE DOG BY GC/MS AND HPLC/MS

Carol A. Haney GC/MS Lab N.C. State University, Raleigh, NC and

Charleston, SC.

Structural modifications of a drug molecule can result in important alterations of its metabolism, especially if the modification is at a metabolically important site. Propranolol, the most commonly used beta receptor block, is extensively metabolized in dog and man (1,2). Its metabolism follows three major pathways: ring oxidation, predominently at the 4'-position, N-dealkylation, and glucuronic acid conjugation. Of these pathways, ring oxidation is quantitatively the most important. This study evaluated the effects a methylthio substitution has on the metabolism of this drug when placed in the metabolically active 4' position of propranolol. Liquid scintillation spectrometry allowed for quantitation and mass spectrometry was used for the identification of Phase I and Phase II metabolites.

4'-Methylthiopropranolol (MTP), 10 mg/kg, was given together with 14C-MTP orally to dogs. The 0-48 hr urine, which contained 50% of the total dose, was extracted with ethyl acetate first at pH 9.8 to yield basic, possible phenolic and neutral metabolites, then at pH 2 for acidic metabolites. Based on the total radioactivity in urine, the basic and acidic fractions contained 48.6 $\pm$ 2.8% and 21.6 $\pm$ 3.7%, respectively (mean $\pm$ S.D.;N=3). The pH 9.8 and pH 2 extracts were each separated into their respective components by HPLC/UV. Structure identification of these metabolites was accomplished by GC/MS (positive CI) after derivativization with N,O-bis(trimethylsilyl)trifluoroacetamide with 1% trimethlychlorosilane in pyridine (basic metabolites) and N,O-bis(trimethylsilyl)trifluoroacetamide with 1% trimethylchlorosilane in pyridine following methylation with diazomethane (acidic metabolites). The third fraction, containing non-extractable metabolites, was analyzed directly by HPLC/MS.

The base extractable metabolites were identified as MTP, MTP-glycol, deisopropyl-MTP, and the sulfoxide (-SO) and sulfone ($-SO_2$) metabolites of these metabolites (Table 1). Identification of these metabolites was confirmed by GC/MS of synthetic standards. In the acidic fraction, over 75% of the radioactivity was related to the naphthoxylactic acid metabolites of MTP, and its sulfoxide and sulfone metabolites (Table 1). Three additional acid metabolites, representing less than three percent of the total urine radioactivity, were not identified.

Using DEAE-Sephadex anion-exchange and reverse-phase HPLC/UV chromatography, the major metabolites contained in the nonextractable fraction (30.0 $\pm$ 6.5% of the total urine radioactivity) were separated and purified. These metabolites were identified by HPLC/MS and enzymatic hydrolysis (β-glucuronidase) as consisting of the glucuronic acid conjugates of MTP, MTP-SO, MTP-SO_2, and MTP-glycol-SO_2. The results of this study showed that methylthio substitution at the 4'-position dramatically alters its metabolic profile, shifting the primary route of metabolism from ring oxidation to that of sulfur oxidation.

STRUCTURE ELUCIDATION OF A SERIES OF ACETOGENINS BY MASS SPECTROMETRY

David L. Smith, Ya-mei Liu, Yu-hua Hui, J. Kent Rupprecht, Ahmad Alkofahi, Ching-jer Chang, and Jerry L. Mclaughlin
Department of Medicinal Chemistry and Pharmacognosy
Purdue University, W. Lafayette IN 47907

Tetrahydrofuranoid acetogenins are a new class of higher plant compounds that are characteristic of the plant family Annonaceae. Because these long-chain polyketide derivatives are showing a number of promising biological activities, there is considerable interest in isolating and characterizing acetogenins. Although proton and carbon magnetic resonance spectroscopy has been used to identify the presence of selected functional groups, mass spectrometry has been used to determine the connectivities of these functional groups. This is because the functional groups are joined by saturated hydrocarbon chains which are indistinguishable by NMR, and because the amount of material is often limited.

Although the methane and isobutane CI mass spectra of acetogenins usually have prominent MH^+ ions from which the molecular weights can be determined, the EI spectra have few high mass ions, and are of limited use for structure elucidation. In addition, the relative abundances of many peaks in the EI spectra are not highly reproducible, and often depend on the sample size and rate of heating. Since a probe temperature of approximately 300 °C is required for vaporization, thermal degradation, including intramolecular rearrangement, is likely. The EI spectrum of the trimethylsilyl (TMS) derivative has a good balance of low and high mass peaks from which major features of the structure can be determined.

The usefulness of the EI spectra of the TMS derivative is illustrated below for a new acetogenin, gigantecin, which was isolated from the stem bark of Goniothalamus giganteus. It is important to note that this investigation has made extensive use of the biological activity of crude and fractionated extracts to lead us to the pure bioligically active components, such as gigantecin. The scheme summarizing the proposed fragmentation of this derivative is given in Figure 1. The mass shift for the deuterated derivative is used with exact mass information to determine the elemental compositons of the fragments. The mass shifts found upon hydrogenating the double bond in the γ lactone, 0 or 2, differentiate ions which contain the γ lactone. The molecular ion (926), as well as fragments corresponding to the loss of CH_3 (911) and TMSOH (836), confirm that the gigantecin has a molecular weight of 638.

The elemental composition of all fragments indicated in Figure 1 have been determined from their exact masses. Fragment ions with TMS groups frequently undergo loss of TMSOH, forming new ions which undergo further fragmentation. This has been verified from the daughter ion spectra (E/B linked scans) of

several structurally diagnostic fragments, as indicated by the arrows in Figure 1. For example, the daughter ion spectrum of the fragment at m/z 573 shows two consecutive losses of TMSOH to give the ion at m/z 393, as well as further losses to give ions at m/z 367, 297, and 271. The structures of the ions at m/z 585 and 655 were also confirmed from their daughter ion spectra.

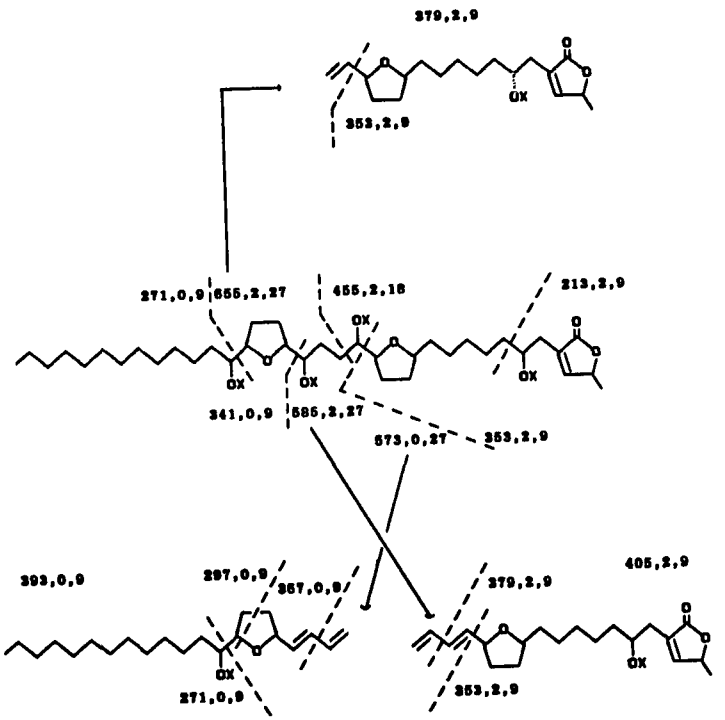

Figure 1 The fragmentation scheme of the TMS derivative of gigantecin. The mass shifts for the hydrogenated and TMS d_9 derivatives are also given.

DIRECT DETERMINATION OF TNT METABOLITES IN ANIMAL AND HUMAN BODY FLUIDS BY MS/MS

Li Zhong-Min, and Deng Lin
Beijing Institute of Technology
Beijing, P.R. China

A rapid method for characterizing TNT metabolites in human body fluids is needed in research on occupational disease such as hepatitis and cataract caused by TNT dust and vapor. We have studied, by the MS/MS technique, numerous samples such as rabbit urine, rat serum, urine of several workers who are working in TNT related factories, and some urine samples of patients who are in the hospital. A series of CI mass spectra and daughter ion spectra for real samples have been obtained and identified by comparison to authentic compounds. All data were obtained on a Finnigan MAT TSQ 45B triple stage quadruple tandem mass spectrometer with a direct inlet probe.

The results show that 2,4-diamino-6-nitrotoluene (2,4-DA), 2,6-diamino-4-nitrotoluene (2,6-DA), 4-amino-2,6-dinitrotoluene (4-A), and 2-amino-4,6-dinitrotoluene (2-A) are present in rabbit urine. The 2,4-DA, 2,6-DA, 4-A, 2-A, and parent TNT are present in rat serum. The 2-A, 4-A, 2,2', 6,6'-tetranitro-4,4'-azotoluene (4,4'-AZ), 2,4-DA, 2,6-DA, and 4-hydroxyamino-2,6-dinitrotoluene (4-HA) are present in the urine of workers. And 4-A, 2-A, 2,4-DA, 2,6-DA, and original 2,4,6-TNT have been identified in patient urine.

The secondary reduction metabolite of TNT is 4-HA which can not be treated by acidification because of the tendency to form 4,4'-AZ. It also can not be analyzed by GC because of the thermal instability. Fortunately, it can be analyzed very well by MS/MS methodology.

Figure 1a shows the positive ion chemical ionization CAD MS/MS spectrum obtained for the MH^+ from authentic compound 4-HA. Figures 1b, 1c, 1d show the CAD MS/MS spectra of parent ion M/Z 214 from the urine samples of worker B, C, and D who are working in TNT related factories.

The results indicate that the 4-HA is present in the urine of the three workers. And the CAD spectra show that M/Z 197 and M/Z 196 results from loss of $OH^{\cdot}$ and H_2O causing by ortho-effect. The M/Z 168 and 167 are formed by loss of NO_2 and NO_2H from the parent ion M/Z 214. The fragments M/Z 121, 122 are formed from loss of NO_2 and NO_2H and two molecular NO_2 respectively.

The results also show that 4,4'-AZ and parent TNT are present in the urine of the workers. The fragments can be observed in Figure 2 and 3.

The conclusion is that the TSQ MS/MS technique is a rapid, specific, and sensitive method for characterizing TNT metabolites in human body fluids. The urine samples were presented by professor Xian Yin-Lin and Mr. Yao Ming.

COMPUTERIZED INTERPRETATION OF THE MASS SPECTRA OF ACYCLIC ORGANIC COMPOUNDS

M.J. Bertrand and D. Zidarov
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, P.O. Box 6128, Station A,
Montreal, Quebec, Canada H3C 3J7

The application of computer science to the problem of molecular structure elucidation is an active area of research and new approaches are continuously proposed in the literature. Presently, the computer assisted identification of organic compounds is achieved by i) spectral comparison using a library of reference spectra, ii) use of an expert system including information from one or several analytical techniques or iii) using a combination of the above approaches. This work describes an algorithm that has been developed in order to study the feasibility of synthetizing and ranking the most probable structures of acyclic organic compounds corresponding to experimental mass spectral data.

The approach that is presented essentially involves the construction of a close system of rules and chemical constraints and is based on the hypotheses that i) all or almost all simple cleavages occur in the fragmentation of the molecule, ii) there is at least one sequence of fragment ions that corresponds to one or several acyclic structures for which the sum of the ion intensities in the mass spectrum ΣI is maximized and iii) to each candidate structure can be assigned a probability of coincidence that is not strictly proportional to ΣI. The algorithm using mass spectral data such as exact mass, isotopic peak ratios (if available) and a list of mass-intensity obtained from the high energy collision activated spectrum produces a list of the most probable acyclic structures that correspond to the data.

The generation of the most probable structures from the experimental data proceeds in four steps that are the i) generation of empirical formulae, ii) decomposition of the empirical formulae in sets of superatoms, iii) synthesis of chemical structures from the superatoms and iv) the scoring and ranking of the most probable structures. The generation of empirical formulae is done using the exact mass and isotopic peak ratios (if available) and the empirical formulae obtained are in agreement with the nitrogen rule, an integer number of insaturated sites, and several other chemical composition constraints. The empirical formulae that are retained are then decomposed into sets of saturated and unsaturated superatoms using a base of 74 functional groups that are linearly independant. This process is done by solving equation [1] in which X_i and Y_j refer to the frequency of occurence of the unsaturated and saturated superatoms i and j.

$$C_xH_yO_zN_t \equiv \Sigma X_iS_i + \Sigma Y_iS_j \qquad [1]$$

The sets of superatoms that have been obtained in the proceeding step are used to construct acyclic structures using the molecular topology of pseudo-alkanes where the nodes represent superatoms. At each stage of the construction of the structures, which is done using a backtrack algorithm, predictable ions from the substructures are matched with ions present in the spectrum. Substructures with bad correlations are terminated and the others are scored. The 20 highest scores are retained and ranked in order of probability by considering ion intensities and the presence of consecutive predicted fragments in the spectrum.

The basic functionning of the algorithm can be understood by considering the example shown in figure 1. In the example, the collison activated spectrum of decyaldehyde $CH_3(CH_2)_8CHO$ and the exact measured

mass were given to the program as input. The algorithm found one empirical formula $C_{10}H_{20}O$ which was consistant with the constraints given. In the second step, it is seen that this formula can be decomposed in 72 sets of superatoms of which only a few are shown (the number in parantheses are the frequencies of appearance of each superatom). Then, using the sets of superatoms, the algorithm generates 250 structures that fit the data and on the figure the structures with the five highest scores are shown. The actual structure of decyaldehyde is ranked as first candidate indicating the potential of the approach.

In view of these encouraging results, several refinements are being added to the program with the aim that it will be useful in the interpretation of MS/MS spectra with or without the use of a search data base.

SPECTRAL EXAMINATION TOOLS: IDENTIFICATION OF LOW MASS ION SERIES AND STABLE NEUTRAL LOSSES USING ACCURATE MASS INFORMATION

R. B. Cody
Nicolet Analytical Instruments
5225 Verona Rd., Madison, WI 53711

When interpreting electron ionization mass spectra, mass spectrometrists use various kinds of information. Low mass ion series are a valuable indicator of general compound classes or functional groups. High mass fragments resulting from stable neutral losses provide information about specific structural features.

Identification of such characteristic ions can be automated. For example, low resolution information about ion series and neutral losses are used by McLafferty's STIRS program [1] in comparing an unknown spectrum with library spectra to identify substructures present in the compound.

Through high resolution measurements the reliability of an interpretation algorithm can be greatly improved. We report here the use of two computer programs based upon accurate mass information: one program identifies functional groups based upon low mass ion series, and the other identifies neutral loss fragments and relates them to specific substructures. These "spectral examination tools" are not intended as a comprehensive methodology for interpreting spectra, but are useful aids for identifying features of the mass spectrum and can supplement other interpretive methods.

The basis for these programs is found in the appendices to McLafferty's "Interpretation of Mass Spectra"[2]. We extended the information to include accurate mass information, additional ion series, and constraints on the number of peaks that must be identified for a given series. The programs were tested on electron ionization spectra of pure compounds, a synthetic mixture, and a complex hydrocarbon oil.

The low mass series program searches the spectrum for alkyl series (peaks differing by methylene groups), peak lists (peaks that do not differ by a fixed mass), or user-defined series. To be recognized, ions in the series must meet criteria for accurate mass measurements, minimum number of peaks that constitute a given series, and consecutiveness (e.g. two nonconsecutive peaks are not recognized as a series).

Low mass series analysis of 18 pure compounds showed characteristic functional groups for each compound. Analysis using accurate masses was found to be much more reliable than analysis using nominal mass data. Analysis of a synthetic eight component mixture showed at least one characteristic functional groups for each component. A hydrocarbon oil was found to contain alkanes, alkenes, cyclic hydrocarbons, and also terpenes and alkylbenzenes. The presence of the latter was not reported by the manufacturer, but was confirmed by FTIR analysis. Ion series analysis was also performed on a laser desorption spectrum of a hydrocarbon wax, with electron postionization of desorbed neutrals. Molecular weight distributions were determined from molecular ions of alkenes and dienes.

Neutral loss analysis was found to complement series analysis for all compounds where a molecular wight was known or suspected. However, interpretation of these results requires more skill on the part of the operator, and is slightly less reliable than series analysis, since identifications were based on individual peaks, rather than groups of peaks.

STRUCTURE ELUCIDATION USING SUBSTRUCTURE IDENTIFICATION RULES ON MS/MS DATA

K.J. Hart, P.T. Palmer and C.G. Enke
Department of Chemistry, Michigan State University
East Lansing, Michigan 48824

The development of ACES (Automated Chemical structure Elucidation System) represents the first attempt to fully exploit the huge data space available from MS/MS instrumentation (i.e. triple quadrupole mass spectrometer). Substructure information is obtained by a pattern recognition/ artificial intelligence program called MAPS (Method for Analyzing Patterns in Spectra). The program has two functions. The first function is to generate substructure interpretation rules and the second function is to apply the rules obtained to MS/MS data of an unknown compound. This software was recently modified to produce two types of rules which can be used to predict the presence and absence of substructures in an unknown. The rules are referred to as inclusion (presence) and exclusion (absence) rules.

Both types of substructure identification rules were generated with and without intensity data. There has been some debate as to the reliability of intensity data in daughter spectra due to instrumental variations. Additionally, the environment of a substructure plays a role in the relative intensity of the corresponding fragment ions (i.e. the influence of a heteroatom). Since the MAPS rules are generated from a training set containing substructures in a variety of environments, it was decided to classify the intensity of an ion as strong, medium or weak. This type of classification is often referred to as a "fuzzy set".

The recall and reliability of the MAPS rules was evaluated by applying each rule to the MS/MS data of each training set compound. It was found that the intensity data improved MAPS inclusion rule performance while exclusion rules performed better without intensity data. The exclusion rules performed better without intensity information because it is the absence of highly diagnostic features which are characteristic of the absence of a particular substructure. The uniqueness of the features found in the inclusion rules with an associated intensity were higher than those without an associated intensity leading to better performance.

Sixteen compounds not found in the training set were analyzed using the MAPS inclusion rules. No false positives (incorrect inclusions) occurred in eight of the sixteen compounds. Of the false positives in the other eight compounds, six involved the benzyl and/or the phenol substructure. One reason for these false positives may be the composition of the training set which contains alarge numer of phenols and few benzyl containig compounds. Also, the rule generation process remains under development. Current work is aimed at determining the most reliable combinations of features found in a rule in an

attempt to reduce false positives. The exclusion rules were applied to data for the same compounds. No false positives (incorrect inclusions) were observed using these rules. Exclusion rule results can be used to eliminate specified substructures from consideration before or after structure generation.

Recently, ACES has been modified to include automated structure generation and substructure searching of training set structures. GENOA, a structure generation program originally developed at Stanford University has been updated to include a file interface with MAPS and a molecular formula generation program (MFG). The MAPS and MFG software provide the information (i.e. substructural constraints and molecular formula(e)) required by GENOA. The updated GENOA software runs a structure generation session for each molecular formula found to be consistent with MS/MS data of an unknown. The resulting candidate structures are stored in files with a specified analysis reference name.

The results are then summarized with the use of a structure checking program (STRCHK) included with GENOA. The STRCHK program has been modified to sum the substructure search results for more than one molecular formula. The STRCHK program was also modified to perform automated substructure searching of a library of training set structures. The substructures found in the training set structures are passed to the MAPS software for use in developing spectral feature / substructure correlations. These correlations eventually become the MAPS rules.

The tabulated results from STRCHK will be used by a program under development that will correlate the substructures in the results file with MAPS rules taken under different experimental conditions (i.e. chemical ionization and multiple collision CAD). If a rule exists that will confirm or eliminate the presence of a substructure, the system will recommend to the user that the experiment be run. These experiments are referred to as ancillary experiments. Reduction of the number of possible molecular formulae is another area where the system could recommend an ancillary experiment. Measurement of isotopic ratios in the daughter spectrum of the M+1 ion has been shown value in characterizing the elemental composition of 13C containing compounds. Soft ionization of the compound of interest is often required to obtain a reasonably intense M+1 ion.

The development of the ACES software will continue with the addition of a greater variety of training set compounds. The software itself will be updated to optimize the reliability and recall of the rules generated by MAPS and to provide suggestions for ancillary experiments.

Improved selectivity in selected ion monitoring by using multiple magnet positions.

Coles, A, Moncur, J and Moore, C.
Kratos Analytical, Barton Dock Road, Urmston, Manchester M31 2LD,

PCDDs and PCDFs unfortunately tend to occur in complex matrices containing many other chlorinated species, therefore SIM at a resolving power of 10,000 (10% valley definition) or greater is generally recommended in the analysis of these compounds[1].

In order to ensure that the correct mass is accurately centred onto the collector, the magnetic field is kept static and the ESA voltage (E) and accelerating voltage (V) are altered so as to focus the desired m/z value ion beam through the analyser. For all polychlorinated dioxins and furans to be monitored E and V must be reduced by at least the fraction of the two extreme masses, in this case m/z 303.90162 from TCDF and m/z 471.77501 from the internal standard ^{13}C-OCDD. As a reduction in V results in a corresponding reduction in sensitivity, the relative intensities of the higher mass ions (for example from HeCDD and HeCDF) will be significantly lower than those for the low mass ions. This is illustrated in Figure 1 which shows the total (summed) response obtained from the analysis of a fly-ash sample[2]. This drop in sensitivity is reduced if the ions to be monitored are divided into groups, and the magnetic field strength optimised at the start of each group.

The individual ions within each group are still monitored by V and E adjustment (the most accurate method) but now the mass range required within each group is much less, for example only m/z 407.78176 to m/z 437.81399 for the hepta series. An experiment of the type shown in figure 1 can be used to select the required start and stop times for each group, and a lock mass is used to ensure that peak tops are monitored.

The results shown in Figure 2 have been obtained in the analysis of the same fly-ash sample shown in Figure 1. In this case, using separate ion groups, the relative intensities of each group of PCCDs and PCDFs are more accurately represented. In this experiment 8 ions have been monitored in each group, two from dioxin, two from furan and two each from the fully ^{13}C labelled internal standards. Figure 3 shows the results of one of the 5 groups monitored - the pentachloro series - expanded in full.

Quantitation of the unlabelled isomers was performed using the ^{13}C labelled standards, and the quantitation report for the PeCDD and PeCDF isomers is shown in table I.

These data were acquired on a CONCEPT IS mass spectrometer operated at 10,000 R.P. (10% valley definition) with a 1 second cycle time. This short cycle time ensures chromatographic resolution is maintained.

With longer cycle times, ultimate sensitivity is increased and a detection limit of 10 fg of TCDD has been achieved (figure 4)

IMPROVED PEAK DETECTION SYSTEM FOR GC-MS ANALYSES WHICH INCORPORATES THE KRATOS DS-90 STANDARD PEAK DETECTION ALGORITHMS:

J. H. Garrett, J. G. Solch, L. A. Harden, and T. O. Tiernan;
Department of Chemistry and Toxic Contaminant Research Program,
Wright State University, Dayton, Ohio 45435.

The peak detection routines supplied with most GC/MS data systems are generally adequate for delineating isolated ion peaks but are less successful as the peaks broaden or overlap with other peaks. When Selected-Ion-Monitoring of many masses is used as the basis for the identification and quantitation of an analyte in an unknown, the ratios of the intensities of these ions must be within a specified range, consistent with that observed for the pure analyte standard. Frequently, the delineation of one ion to another does not match precisely enough and degrades the quantitation of an analyte or fails to identify the analyte because the ratio is out of the specified range. The peak detection algorithm used in Kratos DS-90 was chosen to be modified because it contained a very good kernel from which to create a more powerful routine that would improve the identification and quantitation of wide-spread analytes in a normal GC/MS run.

The most important item in improving the general peak detection routines is in incorporating the normal peak width of an analyte into the algorithm. From the peak width, one can determine the background noise of each particular ion in the window in which an analyte or its isomer components elute. The background noise is found by segmenting the above window into increments of the normal peak width and finding the increment in which the ion intensity of an ion changes the least. The background noise is then the difference of the highest ion intensity in the increment minus the lowest ion intensity in the increment. Once the background noise is found for each ion, a value for the minimum peak area of each ion is determined and also a fairly reliable S/N value is given for each peak of an ion. An accurate baseline value (the difference between two scans that signifies noise) is also determined for each ion from the background noise of that ion. This baseline value significantly improves the ratio of isolated low S/N peaks. Peak width is also invaluable in determining the leading and trailing edges of a peak when convoluted with other peaks.

Many other rules were also implemented that dealt with the following items. The trailing edge of a peak is terminated when the height drops below a certain level and its slope essentially becomes horizontal. The baseline cannot be drawn at an extreme angle or found at too high of an ion intensity above a previous baseline point. Slight irregularities in a peak's shape are ignored so as not to delineate a peak at an incorrect position. In the presence of changing chemical noise background, baseline values were changed to reflect the change in chemical noise.

The delineations with the improved peak detection algorithm shown in Figure 1 are markedly better than with the DS-90 peak detection algorithm shown in Figure 2. Table 1 shows the results from a GC/MS run that involved looking for the chlorinated dibenzofurans and dibenzodioxins. The ratios and identification of isomers identified in this run that involved very low levels of the analytes showed a marked improvement over the DS-90 implementation.

The above results have shown that additions to an existing peak detection algorithm can significantly improve the identification and quantitation process. Refinements to the routine will proceed as the need arises, e.g. the presence of incorrectly delineated or unidentified peaks.

HIGH VOLTAGE AND MAGNETIC SCANNING FOR MIXTURE AND TYPE ANALYSIS USING A PERSONAL COMPUTER

T.A. Wittstruck and T.J. Eskew
Measurement and Analysis Systems, Inc.
Bellefonte, Pa 16823

OBJECTIVE

In the course of upgrading magnetic mass spectrometer systems used in petrochemical laboratories, we sought to develop an automation system to completely control data acquisition, in either magnetic or high voltage scanning modes. Data analysis would then be performed by operator specified Mixture or ASTM Type Analysis methods. To achieve this, a highly-prompted program was written in IBM/Microsoft BASICA to acquire and store data on disk, followed by the appropriate analysis. This program was compiled and linked to increase its speed of operation.

THE PROGRAM

After a brief "setup" during which the operator specifies whether the operation is for Magnetic or High-Voltage scanning, and whether Mixture or Type analysis is to be performed upon the data, the program is menu-driven. From the Main menu, various routines may be accessed that, for example, allow changing scanning parameters, storing the changed values in a disk-file, scanning by one of several modes, listing out the acquired data, re-analyzing old data, etc.

Each of the scanning modes utilize a variable-time-constant filter and peak-detection algorithm. With Faraday-cup collectors, the minimum practical electrometer time constant is about 20 ms, and the digital volt meter (DVM) integration time for each "raw" data point is also typically set at 20 ms (or at 16 2/3 ms if a significant 60-Hz modulation is present). As many as possible of the required computer operations (data storage, digital filtering, peak detection, exponential-scan generation, graphic presentation) are completed within this 20-ms interval. The operations which must take place outside this interval (data transfer and DVM triggering) require about 5 ms. Thus, the data rate is 40 readings/second, with 80% of the time given to actual integration of the ion-beam signal.

The optimum digital filter for a rectangular peak is simply the moving average of N consecutive readings, where N matches the width of the peak. We have found that this filter also gives good results for trapezoidal or Gaussian peaks with random noise in the peak amplitude (1). Since the scan is precisely exponential, the required value of N is independent of mass, and is computed as a function of operator-specified scan half-life and slit-widths.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

Peak detection is based on the digital-filter output. The algorithm searches for the following three events, in sequence:

(1) The first derivative of the filter output must rise above a threshold;
(2) The output must pass through a maximum which exceeds an operator-specified threshold; and
(3) The output must fall below a certain fraction of its maximum.

If these events occur within a certain maximum-expected peak width, a peak is reported. If the first event has not occurred, the baseline is updated by a weighted factor.

The scanning modes available from the Main menu are Peak Profile, Scan for Background, Scan for Sensitivity, Scan for Analysis, Iterative Scanning, and Manual Scan. When using any of the first six modes, the spectrum is displayed on the CRT, in real time. At the conclusion of the scan the display may be graphically printed before proceeding. In the Manual-scanning mode, only the real-time mass and intensity are digitally displayed. However, in this mode, scanning direction can be reversed and/or the scan-rate changed at any time.

Using the Iterative Scanning routine to acquire 10 consecutive scans of the spectrum of n-Butane, we found that the scanning algorithm gave reproducibility for the intensity of m/z 43 that varied by +/- 0.38% over a 20 minute duration (after accounting for the expected intensity decrease arising from sample pressure drop during this time).

For Mixture Analysis of the mass spectral data, a list of 29 components has been specified. For each component, a characteristic mass is specified. A 29x29 matrix is then constructed, consisting of the intensities at each of the masses for each of the components (some will obviously be zero), normalized to that at m/z 43 for n-Butane. The routine Scan for Sensitivity is used for this purpose. A separate sensitivity matrix is required for High-voltage or Magnetic scanning. This matrix is used, with the Gauss-Seidell method, to determine the composition of a mixture using the routine Scan for Analysis. Prior to data analysis, an optional background subtraction may be performed, using spectra acquired and stored by the routine Scan for Background. A typical mixture analysis of the acquired data requires about 5 seconds, after which a report of the analysis is printed.

Type analyses may be performed, based on published ASTM methods, for (1) Low-Olefin gasoline, (2) Middle Distillates, (3) Gas-Oil Saturates, or (4) Gas-Oil Aromatics.

A GENERAL METHOD FOR ACCURATE MASS MEASUREMENT OF AMMONIA CI SPECTRA USING PFK INTERNAL REFERENCE.

William F. Haddon, D. S. Millington, R. E. England, C.A Elliger and G. D. Manners.

Western Regional Research Center, USDA, 800 Buchanan St., Albany, CA. and Dept of Pediatrics, Duke University, Box 3028, Durham, NC 27710 (DSM).

Introduction. Ammonia is often the reagent gas of choice for structural analysis of newly isolated compounds by mass spectrometry becuase its use uniquely provides molecular weight values in many cases. This report describes the use of PFK to record high resolution positive NH_3CI spectra by a method that avoids the use of non- standard CI conditions[1] or specially tailored reference compounds.[2]

High resolution NH_3 CI measurements have provided essential data for identification or confirmation of over 20 unusual ergostane-type steroids from insect -resistant petunia plants[3] and from series of macrocyclic jatrophane diterpenes isolated from the noxious weed *Euphorbia esula* (leafy spurge).[4] Among the common reagent gasses, only NH_3 gave molecular weight information consistently for about 50 compounds and synthetic analogs in these series of samples.

Experimental. Spectra were recorded at 5-7000 mass resolution using a VG 70/70-HS mass spectrometer scanned at 5 sec./decade or faster for full- scan spectra in CI mode at 1000 µA. total ionizing current and 100 eV. Adjustment of NH_3 pressure is critical. After admitting PFK via the batch inlet, we increase the NH_3 pressure until the intensity ratio for m/z 331:329 is about 1, making certain the direct probe is in the position to be used for subsequent introduction of samples. Under these conditions, the reagent gas spectrum has intensity values NH_3^+, 10%; NH_4^+, 100%; $NH_3NH_4^+$, 1%. It may be necesarry to increase the pressure in the inlet system with N_2 or Argon.

Results and Discussion. Significant changes occur in the PFK spectrum as NH_3 pressure increases to a value appropriate for CI measurements, as shown in Fig. 1. The more saturated PFK ions, including m/z 369,343 and 331 (C_7F_{15}, C_8F_{13} and C_7F_{13}) rapidly decrease with increasing NH_3 pressure, with concomitant increases in m/z 386,360 and 348; in contrast, less saturated ions, for example those at m/z 341 or 329 ($C_{11}F_{11}$, $C_{10}F_{11}$) are unreactive toward NH_3 and display no measureable change in absolute abundance. The increased abundance of m/z 348, 360 and 386 arises from the presence of nitrogen-containing ions from reaction of PFK ions and neutral ammonia. Such peaks are unsuitable reference points for mass assignments because they are doublets with unreactive PFK ions. Ions at m/z 329,331,341,434,355 and 367 remain single peaks in the presence of NH_3. The optimum pressure is that at which these ions retain measureable abundance.

Surprisingly the quality of CI spectra obtained in the presence of PFK is excellent. Figure 2 illustrates this fact by comparison of a spectrum of petuniasterone A recorded with PFK in the ion source and under the usual CI conditions. Major PFK ions are subtracted in the high resolution spectrum in the lower part of the figure.

Mass measurement accuracy below 3 ppm (1 std. dev.) was obtained for peak matching of jatrophane samples above m/z 700, as shown in the Table. For full scan spectra, the error has been 3.8 ppm based on measurements on about fifty samples.

Conclusions. The method described has the advantages of convenience, accuracy and integrity of spectra . As such, it routinely provides compositional identification for both molecular and *fragment* ions in CI spectra. Such measurements have often been inconvenient previously.

Computer Program for the Interpretation of CID Mass Spectra Obtained from Peptides of Unknown Sequence

R.S. Johnson and K. Biemann
Department of Chemistry, Massachusetts Institute of Technology
Cambridge, MA 02139

In order to efficiently use CID mass spectral data of peptides, automated methods of interpretation are needed that can be carried out on a time scale similar to that required for the actual experiment. In addition to keeping up with the rate at which data is generated, such automation ought to increase the likelihood of arriving at all sequences that account for most of the ions found in a spectrum (and possibly indicate ambiguities in the CID data).

Past efforts at such programs were directed mostly towards the interpretation of FABMS spectra of single component samples, but, nevertheless, could be used for interpreting CID mass spectral data. One approach (1,2) has been to identify small portions of a peptide sequence (usually referred to as subsequences). Those subsequences that account for the greatest numbers of observed fragment ions are then extended by at least two amino acids at a time to form new sets of subsequences. Eventually subsequences reach a point where they may account for the mass of the peptide, whereupon they are stored as possible sequences of the peptide. A second approach (3-5) involves the generation of all permutations of all amino acid combinations that account for the molecular weight of the peptide. For each of these permutations, scores are assigned based on matches between the calculated m/z values of the expected fragments and those appearing in the spectrum of the unknown. All of these programs, however, have been too slow to use routinely, unless amino acid compositions (3,4) or exact mass measurements (5) were used to limit the CPU time. Acquiring such information both adds to the analytical effort, and eliminates one of the major advantages of tandem mass spectrometry, namely, the ability to work with mixtures. For one of these algorithms (2), the CPU time could be shortened by limiting the number of fragment ions used as input (an input of < 20 fragment ions required 1-3 hours), which is clearly not satisfactory for the large number of fragment ions found in CID mass spectra.

The algorithm described here most closely resembles the subseqencing approach described by Ishikawa and Niwa (1), except that in this program the initial set of subsequences encompasses the C-terminus and are extended one amino acid at a time towards the N-terminus. Furthermore, additional ion types (and differences between FAB and CID fragmentations) not known to these authors were incorporated into the algorithm. Ions of type a_n, b_n, c_n, d_n, v_n, w_n, x_n, y_n, z_n, and z_n+1 are identified in the subsequencing routine, and up to 300 subsequences can be accomodated before eliminating the least likely candidates. The only required input is a list of the mass and relative abundance values from the CID spectrum, the mass of the $(M+H)^+$ ion, and the mass of the C-terminal modification (e.g., amide), if present; amino acid compositions or exact mass measurements of the $(M+H)^+$ ion are not necessary. The program accomodates modified amino acids and N-terminal blocking groups. Unlike most of the other programs, the mass of the N-terminal blocking group is not required as input. Once the subsequencing routine is finished, the list of completed sequences are subjected to a final scoring procedure (a further difference between this program and that of reference 1). In this last step, scores are assigned based on the ions found in the subsequencing routine, plus the nonsequence-specific immonium and acyl internal fragment ions, "secondary" d_n and w_n ions, R-group losses, as well as those ions resulting from loss of H_2O from product ions containing Ser or Thr. The scores are equal to the sum of intensities of ions identified divided by the sum of all intensities in the input data.

The entire procedure requires only 1-5 minutes of CPU time on a VAX 11/750 computer. The program has been used on hundreds of peptides of known and unknown sequences; the results from twenty such peptides are shown in Table I.

Table I: Results obtained on twelve peptides of known sequence and eight of previously unknown sequence. <E indicates pyroglutamic acid; C* indicates carboxymethylated cysteine.

	Sequence	Number of Fragment Ions	CPU Time	Score	Rank[1]
1.	<ELYENK (neurotensin 1-6)	54	2:32	0.92	1(1)

COMPUTER AIDED PEPTIDE SEQUENCING (CAPS) BY FAB MASS SPECTROMETRY

K. Ishikawa and Y. Niwa
National Chemical Laboratory for Industry, Tsukuba, Ibaraki 305, Japan

It is generally difficult to predict amino acid sequences of unknown peptides from their FAB or FAB MS/MS spectra. We proposed a method CAPS (Computer Aided Peptide Sequencing) (1) which allows us to analyse peptides much larger than 1000 u within a reasonable cpu time and to have a set of probable amino acid sequences which are consistent with observed FAB spectra to varying degrees. Another feature of CAPS is that there is no need to pick sequence ion peaks out of the spectrum; all the ions observed are equally taken into account in the analysis so that one can exhaust the possibilies expected from the whole spectrum.

The method has been applied to 22 known linear peptides composed of 5 to 13 amino acid residues The correct sequences were always found at the top of the candidate sequences with prior knowledge of amino acid composition (Table 1(a)) Without prior knowledge of amino acid composition, the correct sequences were still found among the candidates at high rank (Table 1(b)). α-Mating factor (MW=1682.8) was the peptide whose correct sequence was missing in 100 candidates (designated by "101-" in the table). A part of the correct sequence "WLKLK" was, however, included in all the candidates of high rank (Table 2). In general, candidates at high rank partly reproduced the correct sequence. As was the case for α-mating factor, sequences near peptide terminals were sometimes ambiguous. This is because ions in the higher mass region are often low in intensity and spectra in the lower mass region are crowded with background ions. As a whole, the degree of success in the sequence elucidation strongly depends on the quality of the spectrum used in the analysis.

The difficulty will be further complicated in the case of cyclic peptides since they have much more possible fragmentation pathways than linear peptides (2, 3). Fig. 1 shows the FAB CID spectrum of $[M+H]^+$ (m/z=1043.6) of an unknown cyclic peptide isolated from the substances produced by a strain of *Bacillus subtilis* which inhibits the hypal growth of rice blast fungus, *Pyricularia oryzae* (4, 5). The CAPS analyses of the spectrum were made with prior knowledge of its amino acid composition; it was a octapeptide composed of each one mole of Pro, Ser, Tyr, Gln, 3-amino-tetradecanoic acid (Ata) and 3 moles of Asn. Daughter ions were assumed to be formed by successive and/or competitive losses of amino acid residues from the C-terminal of the linear acylium $[M+H]^+$ resulting from a cleavage of a certain peptide bond. There are 8 cases as to which peptide bond will be ruptured; Scheme 1 illustrates the case where the bond cleavage has taken place between A_1 and A_8. Thus the CID spectrum may be a superposition of, at the maximum, 8 different daughter ion spectra. The CAPS analysis will pick the amino acid sequence of predominant acylium $[M+H]^+$ out of 6720 (8!/3!) possible sequences. The sequence of the most predominant acylium $[M+H]^+$ was deduced to be

H_2N-(Pro, Asn)-Ser-Ata-Asn-Tyr-Asn-Gln-CO^+ (A)

where the order of Pro and Asn was uncertain since the observed CID spectrum gave no daughter ions formed by the bond cleavage between them. Although most ions observed were interpreted in terms of this structure, there still remain several ions of considerable abundance as marked in Fig. 1. The spectrum was again analyzed by CAPS after eliminating the ions related to the amino acid sequence (A). The sequence of the second most predominant acylium $[M+H]^+$ was deduced to be

H_2N-Asn-Tyr-Asn-Gln-Pro-Asn-(Ser, Ata)-CO^+ (B).

On the basis of the structures (A) and (B), the amino acid sequence of the peptide can be represented by

Pro-Asn-Ser-Ata-Asn-Tyr-Asn-Gln (C).

The FAB mass spectrum of the acid hydrolysate of the peptide confirmed this conclusion. The amino acid sequence (C) and the origin of the peptide strongly suggest that it is Iturine A-2 (6, 7).

COMPUTER IDENTIFICATION OF BACTERIA VIA MS WITH CI

D.C. Conway and Humberto Lopez, Department of Chemistry, and
J.M. Quarles, Jr., Department of Medical Microbiology and Immunology,
Texas A&M University, College Station, TX., 77843

The object of this research is to develop a rapid method for the identification of bacteria by MS using CI to reduce fragmentation. Time consuming steps such as solvent extraction or making derivatives are to be avoided. The analysis of the bacteria growth medium was complicated by the formation of ion clusters in the low temperature ion source [1]. Therefore, it was decided to pyrolyze the bacteria, but at lower temperatures than is the case with the well-known Curie point method. At lower temperatures pyrolyzates produced by higher activation energy reactions are strongly hindered, and spectra can be taken over several temperature ranges for one sample. The bacteria pyrolysis spectra are more complex than those obtained from the growth media, but this permits the use of more sophisticated data analysis techniques.

The bacteria were grown for 16–18 hrs, killed in 70% ethanol solution, separated by centrifugation, and stored in 70% methanol. A small aliquot of this mixture containing 1 mg of bacteria was placed in a 0.04 ml stainless steel cup and dried in an unheated vacuum oven. Then 0.03 ml of H_2O was added, the mixture stirred, and dried again. The cup was heated in a direct inlet probe, and the pyrolyzates were carried by a gas stream in 0.1 sec through a heated inlet tube at 170–180°C to the MS. (High tube temperatures reduce the formation of ion clusters.) Ions were produced by a 1 kHz pulsed electrical discharge ion source, which was mounted downstream of the MS inlet. The CI gas was CH_4 at 0.56 Torr pressure with a small amount of added H_2O, so the CI reagent ions were mainly $H_3O^{+\cdot}$. The mass spectra were taken for 2 min from 330–390°C. The data were digitized on a microcomputer (Zenith–158 PC) to produce mass intensities as a percentage of the total ion intensity. The data were then analyzed on an IBM 3090 computer.

Four types of bacteria were studied, Escherichia coli, Staphyloccus aureus, Listeria monocytogenes 1706, and Listeria monocytogenes ATCC 9115. Data were taken for 3 batches of the first two bacteria. All the mass spectral data were divided into 7 classes, 4 groups that are standards (knowns) and 3 groups from the last batches that are unknowns. The 4 groups of standard spectra, one for each type of bacteria, were analyzed by stepwise discriminant analysis. By this process 56 mass lines were chosen to give the largest differences between the 4 types of bacteria.

Canonical discriminant analysis yields linear combinations of the mass intensities, the canonical variables, which emphasize the differences between the classes. When canonical discriminant analysis was performed for the 4 classes of knowns, the first and second canonical variables were the same (to 0.002%) for the

members of each class. When the 7 classes of data were analyzed the same way with the 56 masses, the first and second canonical variables shown in the figure below were obtained. The unknowns (squares) are from the last batches grown. In order to keep the intragroup variances of the canonical variables for the unknowns reasonably small, the intragroup variances for the knowns are forced to be larger than when only the knowns were analyzed.

It is encouraging that knowns from 1–3 batches of bacteria and the corresponding unknowns for the last batch cluster together. However, the unknowns and knowns must come from different batches to prove the procedure viable, work presently in progress.

TOF-SIMS DATA SYSTEM

Jeffrey R. Wyatt, Richard J. Colton, and Steve M. Hues
Naval Research Laboratory, Code 6110, Washington, DC 20375-5000.

Time-of-flight Secondary Ion Mass Spectrometers require high speed digital data acquisition and processing capabilities. During the last few years several groups have constructed specially designed data acquisition systems for this purpose.[1-5] We have recently constructed such a data system solely with commercially available components. It is based upon off-the-shelf CAMAC modules that are controlled by a MicroVAX-II computer.

The mass spectrometer is a reflection time-of-flight instrument. The primary ion pulse is 2-5 nsec long and mass resolution is greater than 2000. Depending on the mass range, secondary mass spectra are 50-200 μsec long. Currently the only multihit time-to-digital (TDC) converter comparable with our system is the LeCroy Model 4208. It can measure up to eight events (ions of different flight time per spectrum) with a time resolution of one nsec. Our system cannot distinguish more than one ion simultaneously (within 3 nsec) striking the detector.

Since it is possible to measure flight times to one nsec, a mass spectrum could contain up to 200,000 points. Due to the small number of events per spectrum, it is desirable to operate the mass spectrometer at as high a repetition rate as possible. These requirements meant that we chose a computer more powerful than an IBM-PC AT. In particular we needed a computer capable of handling efficiently data arrays having greater than 64,000 elements. We wanted a computer with a well-established software base. Thus we selected a MicroVAX-II computer.

The data system is depicted in Figure 1. The computer is interfaced to the CAMAC crate using a Kinetic Systems Model 3920 crate controller and Q-bus interface. Timing pulses are generated using a Kinetic Systems Model 3655 timing generator. Pulses from the timing generator are used to pulse the primary ion gun, clear the TDC, start the TDC, and stop the TDC. Secondary pulses are amplified with a Phillips model 774 amplifier and detected with a Phillips 704 discriminator. The output from the discriminator is used as input for the LeCroy Model 4208 multihit TDC. The sequence of timing pulses is shown in Figure 2.

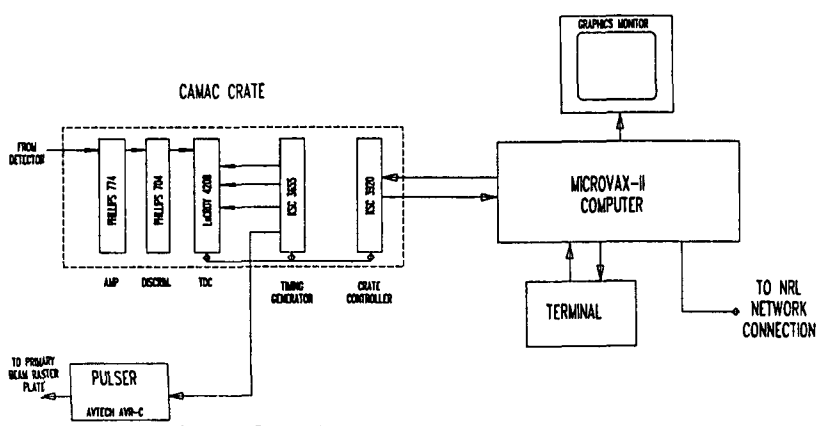

Figure 1. Schematic of the data acquisition system.

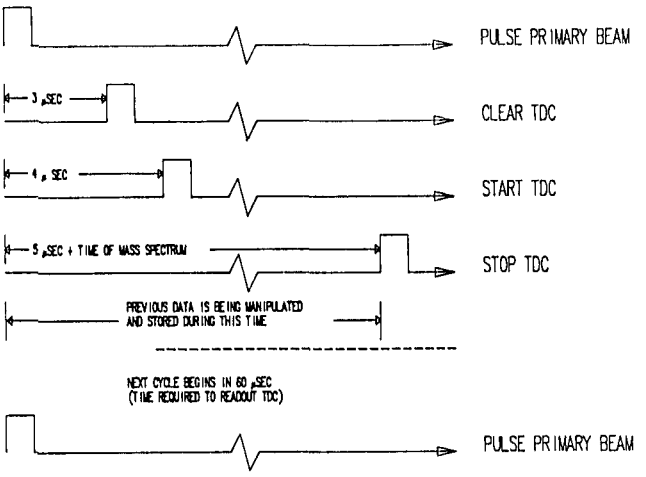

Figure 2. Diagram of the pulse timing.

The principal timing limitation of the system is the time required to readout the TDC. Nine μsec are require to read each channel; thus 72 μsec are required for all eight channels. Approximately 50 μsec are required to manipulate and store the data; this operation is performed while the next spectrum is being acquired. Therefore spectra 100 μsec long can be acquired a rate of 6 kHz. The data acquisition program pauses about 20% of the time to permit a lower priority plotting program to run.

Data are continuously plotted using a DEC VSV21 graphics board driving a color CRT. Plots of the data update several times a second. The rate of plotting depends upon how many points of data need to be reduced to the 500 points shown on the screen. Other information displayed on the screen includes the mass of the ten most intense peaks, low, middle, and high masses, total spectra acquired, and total ions detected. The data can be displayed logarithmically if desired. Hard copies of the data are plotted on the Chemistry Division computer which is connected to the Microvax by a network. A third program is used to control the other programs and interface to the operator. All of the other computer operations can be performed while data is being acquired. All of the software is written in FORTRAN; and thus is easily modified for unique experiments.

USE OF AN HP-1000 GC/MS DATA REDUCTION ENVIRONMENT AND LOTUS/1-2-3 FOR THE RAPID EVALUATION OF LOW-LEVEL PCB ANALYSIS DATA

by
D. E. McKenzie and B. Mason Hughes
Environmental Sciences Center
Monsanto Company
St. Louis, Missouri 63167

ABSTRACT

Two important considerations in the analysis of complex mixtures are accuracy of the reported results and data reduction costs. The present poster describes a significant step in completely automating the data reduction for the analysis of samples containing polychlorinated biphenyl (PCB) congeners which greatly impacts both of these areas Specific analysis windows are determined from the analysis of a commercially available PCB window standard. Selected Ion Monitoring (SIM) data for each homologous class of PCB isomers is used for the low-level analysis of these congeners. This approach is both rapid, and can be easily modified to expand the analytes beyond the specific PCB congeners of interest It also allows for the inclusion of quality control steps, such as the use of ^{13}C-containing surrogate compounds, with little additional time required for extensive reporting of these results.

Background

Polychlorinated biphenyls are defined as a class of compounds which have from one to ten chlorine atoms attached to a biphenyl moiety. A total of 209 congeners with empirical formula $C_{12}H_{10-X}Cl_X$ comprise the PCB family. These compounds have been analyzed by a number of methods. The two most common analysis approaches for low level PCB analyses use GC/EC (gas chromatography with an electron capture detector) or GC/SIM-MS (gas chromatography with selected ion monitoring mass spectrometry). GC/SIM-MS is the more specific analysis method of the two. However, at least one order of magnitude more data is generated using this analysis technique. Therefore rapid, accurate, cost effective data analysis methods are needed in order to make full use of this more specific information. This paper deals with the instrumental and data analysis methods which have been developed for rapid, cost effective analysis of low-level PCB concentrations using capillary GC/SIM-MS.

Instrumental Analysis

The instrumentation used for this type of analysis, along with operating parameters, is listed in the following table.

Instrumentation	Operating System	Instrument Parameters	
HP-5985/5987	*RTE-VI*	*Run Time:*	*15 - 40 min.*
		Multiplier Voltage:	*1800 - 2800 eV*
Column and Chromatographic Conditions		*Dwell Times:*	*100 - 500 msec/mass*
30-meter (0.32 mm) f.s. J&W DB-5 (0 25 uM)		*Electron Energy:*	*70 eV*
Column Temperature Program: 50(4)/8/300		*Scanning Mode:*	*Selected Ion Monitoring*
Injection Type Splitless			

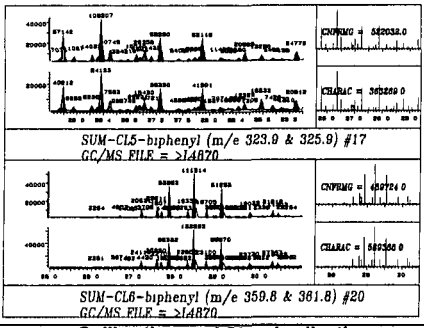
Analysis Approach

Prior to analysis, appropriate retention time windows for each PCB isomer class must be determined since all masses are not monitored during the total analysis. This is accomplished by the analysis of a commercially available standard which contains the first and last eluting PCB isomer in each chlorine class. This window standard contains: 3- and 4-Cl-biphenyl, 2,6- and 4,4'-Cl_2-biphenyl, 2,4,6- and 3,4,4'-Cl_3-biphenyl, 2,2',6,6'- and 3,3',4,4'-Cl_4-biphenyl, 2,2',4,6,6'- and 3,3',4,4',5-Cl_5-biphenyl, 2,2',4,4',6,6'- and 3,3',4,4',5,5'-Cl_6-biphenyl, 2,2',3,4',5,6,6'- and 2,3,3',4,4',5,5'-Cl_7-biphenyl, 2,2',3,3',5,5',6,6'- and 2,3,3',4,4',5,5',6-Cl_8-biphenyl, 2,2',3,3',4,5,5',6,6'- and 2,2',3,3',4,4',5,5',6-Cl_9-biphenyl, and Cl_{10}-biphenyl.

Once the selected ion monitoring data is collected using the proper retention time windows, the HP-1000/RTE-VI operating system "organizes" the data by producing a graphical output which shows peak integration areas (by solid fill), reduced chromatograms of the M^+ and $(M+2)^+$ chromatograms, and tabular information which is stored in an ASCII file. Graphic outputs similar to those shown in Figure 1, are visually scanned by a trained mass spectroscopist for integration errors, and the ASCII file is corrected using EDIT/1000, when required. The ASCII file for each sample is then transferred to a personal computer by the use of the AdvanceLink program.

A Lotus/1-2-3 template file with "user defined" menu items is then used for further calculations. Menu items allow for the importing of the ASCII files for each sample and standard. From the standard file, the template calculates average response factors for each PCB isomer class. From each sample file, the template calculates the concentration for each set of geometric isomers and sums each isomer class to calculate total PCB concentrations for each sample. The user is prompted to input sample identifications, extract volumes, and sample weight information from which the total PCB concentrations are automatically calculated

Figure 1. Example of Graphic Outputs Produced from the Analysis of Cl_5- and Cl_6-biphenyl Congeners.



Calibration and Standardization

Quantitative: An internal standard quantitation technique is used to calculate analyte concentrations. Average relative response factors are determined for each chlorine class from the analysis of standard solutions containing various PCB congeners. The calculations, using internal standard methodology, are given by the formula:

$$AC = (AA)/[(ARRF)(ISA)]$$

where:

AC = *analyte concentration*
AA = *analyte characteristic mass area*
ARRF = *analyte relative response factor*
ISA = *internal standard area.*

Total PCB concentrations can be calculated in two ways:
1) If a PCB formulation can be identified from the patterns of PCB congeners, then selected PCB isomers or classes of isomers (i e. all Cl_4-biphenyl isomers) are used to quantify the formulation concentration. Relative Response Factors are calculated using the concentration of the total formulation in the above equation.
2) If no unique PCB formulation is present, then the total PCB concentration is calculated by using standard solutions containing known amounts of monochlorobiphenyl through decachlorobiphenyl congeners. Relative Response Factors for each chlorine class are calculated using the above equation. The RRFs for the corresponding PCB isomer classes are used to calculate total PCB isomer concentrations of each class in unknown samples.

Qualitative: The ratio of characteristic mass response to confirming mass response must be within 20% of those measured for the authentic standard. For PCB congeners between Cl_1-biphenyl and Cl_5-biphenyl, the characteristic and confirming masses are the molecular ions containing all ^{35}Cl isotopes and one ^{37}Cl isotope. For PCB congeners between Cl_6-biphenyl and Cl_9-biphenyl, these masses are the molecular ions containing one ^{37}Cl and two ^{37}Cl isotopes. For Cl_{10}-biphenyl, these masses are the molecular ions containing two ^{37}Cl and three ^{37}Cl isotopes. The following table summarizes the masses monitored for the analysis of internal standard, surrogate standards, and monochlorobiphenyl through decachlorobiphenylphenyl congeners.

Table 1. Summary of Characteristic and Confirming Masses Used for Low-Level PCB Analyses.

Analyte	Characteristic $(M)^+$	Confirming $(M+2)^+$
anthracene-d_{10}	188	190
Cl_1-biphenyls	188	190
4-Cl-biphenyl-$^{13}C_6$	194	196
Cl_2-biphenyls	222	224
Cl_3-biphenyls	255.9	257.9
Cl_4-biphenyls	289.8	291.8
3,4,3',4'-Cl_4-biphenyl-$^{13}C_{12}$	301.8	303.8
Cl_5-biphenyls	323.9	325.9
Cl_6-biphenyls	359.8	361.8
Cl_7-biphenyls	393.8	395.8
Cl_8-biphenyls	427.7	429.7
2,2',3,3',5,5',6,6-Cl_8-biphenyl-$^{13}C_{12}$	439.7	441.7
Cl_9-biphenyls	461.6	463.6
Cl_{10}-biphenyl	497.6	499 6
Cl_{10}-biphenyl-$^{13}C_{12}$	509.6	511.6

Conclusion

Lotus/1-2-3 can be a very effective means of simplifying data reduction of complex mixtures. In the present example, each menu item is actually macro driven and contains 25-100 individual Lotus/1-2-3 commands. While this type of data manipulation could be accomplished manually, the data analysis time would be increased dramatically. However, in order to use this approach for data analysis, one must:

1) Plan carefully in order to anticipate the major properties of the template file,
2) Break down the data analysis steps into specific analysis steps so that one can maximize the amount of information in a minimum amount of time and steps, and
3) Incorporate error detection with the inclusion of graphic outputs which show peak areas and ratios of characteristic to confirming ion intensities for the rapid detection and correction of errors when they occur.

Burroughs Wellcome Co.
Research Triangle Park, North Carolina 27709

The mass spectrometry facility at Burroughs Wellcome Co. decided to implement a local area network (LAN) for its data systems for three reasons:

1. The amount of data generated by three mass spectrometers can easily exceed the storage capacity of the dedicated instrument data systems within a few working days. With a need to access this data over a period of several weeks, access to large central disk storage was desired.
2. The computer facility at Burroughs Wellcome Co. is much better equipped to handle the long term storage of data generated by our group that falls under the Good Laboratory Practices (GLP) of the FDA and EPA. Therefore efficient transfer of this data to their storage media was desired.
3. The use of remote terminals and personal computers for analyzing data has become essential for report writing and for efficient use of mass spectrometer data system CPU time. Networking was the method that allowed much wider access to the mass spectrometer data systems.

The Automation Group at BW has in place a network system that meets these needs. The system is an ethernet system using DECNET® as the local area network protocol. This system also has in place a DECserver® 200 system that allows for remote terminal access to any DECNET® system computer via RS232 lines at 19200 baud. In order to connect our computers to this network, each mass spectrometer data system was supplied with a DECQNA® interface board and a copy of the DECNET® software. A PDP 11/70 is used for extra disk space and as a host for the archiving and auxiliary storage of mass spectral data upon request. A VAX can also be used for extra disk storage space when the need arises. The transfer of data from one computer to another is conducted via the Network File Transfer (NFT) program of DECNET®. The archival storage of data on the PDP 11/70 is accomplished under a program entitled ARCHIVE which resides on the PDP 11/70 system. This program is called when the user wishes to archive data for future reference under GLP guidelines. The program copies the file to a special disk area from which tape back-up of the file is accomplished. This program was written in-house by the automation group to archive data acquired by chromatography and scintillation counter microcomputer data systems. Other vendor-written archiving software is available for VAX computer systems. This program allows the archiving of any data in the users storage area of the PDP 11/70. The command ARCH is used to call the program. Under program control the user can archive data, review the list of files awaiting archiving, and delete files from the archive list. Archiving of files is accomplished with the full range of wildcard options available under RSX 11M. Alternately the system operator for the PDP 11/70 can request ARCHIVE to automatically archive any file residing in the users storage area once a week. To retrieve archived files, the user simply requests that the operator copy the desired file to his work area from tape storage. A master list of file names stored on tape is kept by the operator under system control and can be searched to give the tape location of any file. The use of remote terminals within the LAN of BW has provided access to mass spectrometry data from virtually any type of microcomputer or terminal available. With the use of office Macintosh computers to cut and paste graphical data into reports, there is faster turn-around time in report and manuscript writing.

UTILITY PROGRAMS FOR FACILITATING CONTRACT LABORATORY PROGRAM DATA PACKAGE PREPARATION*

E. Y. HWANG AND R. J. WINGENDER

To participate in GC/MS analysis of environmental pollutants for the Contract Laboratory Program (CLP), laboratories are required to maintain an intense quality control (QC) program. Several companies supplying GC/MS equipment have developed specialized software that presents sample results and quality control data in a specific format required by the EPA. We are using the Formaster II software in conjunction with our Finnigan 4021 GC/MS system for the analysis of semivolatile target compounds and have found that, in day-to-day operations, the exclusive use of the Formaster software is not cost effective. To sustain productivity without compromising QC, we developed utility programs to supplement the Formaster software.

1. Initial Calibration (IC) and Continued Calibration (CC)

After the instrument has been tuned to DFTPP specifications as required by the EPA, calibration standards are injected to check system performance. The minimum average relative response factors for the four semivolatile System Performance Check Compounds (SPCC) (N-nitroso-di-n-propylamine, hexachlorocyclopentadiene, 2,4-dinitrophenol, and 4-nitrophenol) must be greater than 0.05. Thirteen other compounds are referred to as the Continued Calibration Check Compounds (CCC):

Acenaphthene	4-chloro-3-methylphenol
1,4-dichlorobenzene	2,4-dichlorophenol
Hexachlorobutadiene	2-nitrophenol
N-nitroso-di-n-phenylamine	Phenol
Di-n-octylphthalate	Pentachlorophenol
Fluoranthene	2,4,6-trichlorophenol
Benzo(a)pyrene	

Analysis of these compounds must have a relative standard deviation (RSD) of less than 30% in the initial calibration and a percent difference of less than 25% in the continued calibration. The actual sample analysis cannot commence until these criteria have been met. Formaster is capable of doing both the initial and continued calibration checks. However, the processes involved to produce calculated results are extremely time consuming because the quantitation list for all 67 target compounds must be edited and updated, and because ASCII files must be created before the data can be transferred to the personal computer on which the Formaster is resident, and then read into the Formaster program after proper headings are typed in.

The IC and CC program has been written as an alternative way to check the initial and continued calibration data. The printed results, formated similarly to the EPA Form VI and Form VII, can be produced within five minutes of the termination of the last standard run. The program is capable of calculating the response factor, average response factor, standard deviation, percent RSD, and percent difference of all compounds of interest or just the SPCC and CCC compounds. It is also flexible enough to be used in different aspects of organic analysis (volatile, semivolatile, and/or PCB/pesticide) through input format modification.

In addition, we have established the capability of transferring all the quantitation data from the personal computer to a VAX, where additional manipulation of data or calculations can be performed.

2. Limit of Detection of Individual Target Compounds

Limits of detection (LOD) are calculated by assuming that a minimum of 1000 counts is needed for the primary ion of any compound to satisfy the requirements for qualitative verification. All but nine compounds on the semivolatile list require a 20 ng calibration standard for the LOD calculation. (The LOD for the nine compounds that require a four-point calibration is computed from the 50 ng calibration standard.) Our utility program reads in data from both the 20 ng and 50 ng standard runs, isolates the nine compounds (marked with an asterisk), and does appropriate calculations. The LOD is presented in three ways in the output: as the minimum quantifiable amount in ng of the specified compound, in μg/L (assuming a one liter water sample was analyzed following the CLP procedure), and in μg/kg [assuming a 30 g (dry) soil sample was analyzed following the CLP procedure].

3. Elution Order of the Semivolatile Compounds

CLP protocol requires that every single peak on the chromatogram from the daily standard be identified and labeled. Our utility program sorts the compounds according to their respective order of elution (in ascending order of scan number) and prints out compound names (including internal standards and surrogate standards), target ions, scan number, and elution time.

This listing eliminates the laborious task of hand-labeling every single chromatographic peak on the reconstructed ion chromatogram.

4. Tentatively Identified Compounds (TICs)

Compounds not on the target compound list are quantitated by using the nearest internal standard free of interference. Area counts from the total ion chromatogram are used for both the compound to be quantitated and the internal standard. A relative response factor (RRF) of 1.0 is assumed. Because the Finnigan IDOS software does not reference the correct internal standard for the TICs and does not give the RRF a default value of 1.0, all TIC quantitative calculations are incorrect. Our utility program corrects this problem and outputs two files. One file lists the internal standards as in the regular quantitation report; this list is included in the data package with the results of a library search. The other file has the internal standards deleted and read into the Formaster program in order to generate Form I TICs.

OPTIMIZATION OF GC/MS DATA ANALYSIS USING HEWLETT PACKARD MACRO PROGRAM ENHANCEMENTS

John T. Cody and Dragoslav T. Marcovich
Air Force Drug Testing Laboratory, Brooks AFB TX 78235-5000

The ability of GC/MS data systems to manipulate raw data to produce sophisticated detailed reports has reached impressive proportions even with relatively small bench top computer systems. The need to process data accurately, reliably and rapidly is of paramount importance in a laboratory environment where large numbers of samples are processed. This is of particular significance when the data produced by the laboratory is routinely used in the legal environment.

The ability to generate files containing user defined variables which can then be used for further processing and evaluation of subsequent samples is realized using options found in version 3.2 of the HP ChemStation software. This allows for generation of truly customized reports which can ultimately save not only time in data reduction and analysis but storage space in an archival system. Program load time is substantially reduced by the ability to "compile" macro programs allowing for rapid loading into memory thus reducing system overhead time.

Custom annotation of chromatographic data allows for a data report which is easily understood by individuals not familiar with the data system being used. This is of critical importance for data which is reviewed and presented in legal proceedings to individuals who are generally not intimately familiar with looking at GC/MS data. These capabilities allow for the generation of a complete report which contains all pertinent data from a sample in as compact and easy to read a format as possible (See Figure 1).

The ability to create files which contain calibration and ion ratio data makes it possible to quantitate unknown samples in the Data Editor program, thus eliminating the need to use the Report program. This capability also allows the quantitation portion of the sample data output to indicate only what is deemed by the user as important rather than being forced to work around the manufacturer's standard format. Ion ratio comparison with the standard can also be accomplished within the Data Editor.

Creation of files also gives the user the ability to capture only the data which is critically important for archival purposes. In addition, summary files can be created to hold results for an entire analytical run in a format which can be sent to another computer system (i.e., a laboratory information management system).

In earlier versions of the ChemStation software, the ability of the system to generate a customized report was available, but required a cumbersome and complex sequencing macro as well as numerous internal checks to ensure the proper data was being evaluated at each step along the process. This, with the advent of version 3.2, is not only easier but allows for more customization. The potential for bar code reading and numeric variable input of data by the user makes the potential power of this release even more powerful.

DEVELOPMENT OF NOVEL ON-LINE TECHNIQUES FOR GC/MS AUTOMATION IN ENVIRONMENTAL LABORATORIES

G. E. Prill and J. V. Headley
Research & Methods Development Group, Chemistry Wing
Alberta Environmental Centre,
Bag 4000, Vegreville, Alberta, Canada T0B 4L0

The diversity of samples, the large number of analytical services required and the urgency with which information is demanded, have focused the attention of environmental laboratories on automation. The complexity of GC/MS analyses has presented an obstacle to on-line laboratory information management and most laboratories generate GC/MS reports manually. Automatic data input necessitates a communication software package or suitable on-line GC/MS software. This paper reports the development and application of the latter.

The software consists of a series of executable procedure files, developed for Hewlett Packard RTE GC/MS instrumentation equipped with 'AQUARIUS' software (1).

The novel feature of the software is the utilization of on-line sample 'log-in' information to facilitate:

(a) the analysis of outstanding samples
(b) computer assisted data reduction and data validation
(c) the generation of customized analytical client reports and
(d) the generation of an on-line sample 'log-in' data base.

The software is softkey driven and makes extensive use of Edit 1000, RPN and system level commands. Sample 'log-in' information is stored in user designed globals utilizing a 'running' log-template. The latter saves the 'log-in' information of the last sample, a useful feature for batch analyses and multiple 'log-in' entries. Procedure files format the 'log-in' information using a naming convention to automatically append work files, edit text files and update the sample information data base. The sample data base supports up to three linked pattern searches.

An example of a worklist for outstanding samples is illustrated in Figure 1. This worklist contains the information required to assist with the set up of a batch data acquisition file linking the sample to the appropriate laboratory naming convention.

Examples of autogenerated quality control charts for monitoring sample extractions and instrumental performance are described elsewhere (2). The work files and listings described are automatically appended and scheduled during the 'log-in' process.

Application of the software described provides high volume GC/MS laboratories with automated generation of workfiles and on-line information management. This software is used routinely in our laboratory for the analyses of extractable and volatile priority pollutants, PCB's and hydrocarbons.

A STRUCTURED MACRO LANGUAGE FOR CONTROLLING GC/MS DATA REDUCTIONS

B.N.Colby and P.W.Ryan
Pacific Analytical, Inc.
1989 B Palomar Oaks Way
Carlsbad, CA 92009

and

P.H.D'Arcy and I.Buttler
VG Masslab Ltd.
Tudor Road, Altrincham
Cheshire WA14 5RZ

Procedure languages have become critical to GC/MS users over the past ten years for efficiently linking software modules into semi-intelligent data reduction processes and for generating customized report formats. As our level of reliance on these user generated procedures has increased, the need for software maintenance and quality assurance (QA) has become critical. In the software industry QA is been addressed through adherence to documented coding protocols and source code review, and software maintenance is dealt with through the use of structured programming languages, named variables, and through extensive use of "commenting" in the source code.

To the end described above, a structured macro programming language has been developed for controlling GC/MS data reduction. It includes:

- Arithmetic and Logical operators,
- User assigned numeric and string variables,
- Structured program control constructs,
- Numeric and string handling functions,
- File, system global and keyboard input functions,
- Printer, screen and file output functions,
- Source code comment delimiters, and
- Single step and error code logging for debugging.

A full set of arithmetic and logical operators for use with user assigned variables. These variables are assigned using the assignment operator, "=". Control structures include IF, IF ELSE, CASE and DO WHILE statements. Program control is achieved using the CALL, EXIT, RETURN and CANCEL commands. Functions are provided for numeric manipulation, string handling and cross conversion between string and numeric. Additional functions provide for formatted writing to the screen, creating windows and accepting formatted input from the keyboard with a prompt on the screen. Disk files can be created, read from, written to and modified in both ASCII and dBase III formats. Full access is provided to the GC/MS system globals as a mechanism to pass information between applications program modules.

Each line of a macro is parsed in turn, The first check is for keywords. These are acted on immediately and the results passed to the applications programs as if it were interactive keyboard input. The parsing sequence is as follows:

1. Find the first non-whitespace character in the macro.

2. If it is a double quote, pass all following characters up to the next double quote. Proceed with step 1.

3. If it is a "(", ignore it and all following characters up to and including the following ")". Proceed with step 1.

4. Temporally store this and all character up to the next whitespace character.

5. If the stored character sequence evaluates to a keyword or an arithmetic expression, process it and subsequent characters as required by the command, Proceed with step 1.

6. Pass the first character of the sequence, then proceed with step 1.

An example of a macro written in this macro language is provided below.

THE PC AS A VIABLE ALTERNATIVE TERMINAL FOR THE INCOS DATA SYSTEM

Frank M. Benoit, Health and Welfare Canada, Ottawa, Ontario Canada K1A 0L2.

The Incos data system is based on custom software which is not very flexible, particularly in the preparation of comprehensive quantitative analytical reports. For example, standard INCOS cannot calculate directly the concentration of analytes in the original sample nor combine the results from a batch of samples into one report. Since the inception of INCOS, tremendous advances in computing power have been made, particularly in the area of personal computers. PC systems have available an extensive software library from which many programs can be used to enhance the output from INCOS.

In order to exploit the wealth of PC software, communication between the INCOS and PC systems must be established. In our laboratory we linked the "second terminal" port of INCOS to the serial port of a PC and used a 4010 Tektronix emulator program called PCPLOT to communicate to INCOS. Other terminal emulation programs can be used provided that 4010 graphics are supported. If only ASCII text is transferred, then any terminal program can be used. Crosstalk XVI and Procomm were used successfully to capture text but were incapable of displaying graphics. With the PCPLOT link all the features of the original Tektronix terminal were available with a few exceptions :

1. The PC monitor displayed 22 lines whereas INCOS transmitted 40 lines of text per page. The additional information caused the page to scroll off the top of the screen; the scroll was halted with "control s" and restarted with "control q".
2. A mouse and second PC serial port are recommended for control of the 4010 crosshairs; the "arrow keys" were very slow.

Hence, the PC is a less expensive, viable alternative for the replacement of a Tektronix 4010 terminal. However, the major benefit from this arrangement is the capability to transfer data from INCOS to the PC which is warranted when:

1. It is possible to transfer the data. Not all data accessible to INCOS can be transferred. As a rule the PC can capture any data that INCOS can transmit to the screen. Data that is directed from within an INCOS program to other peripherals such as the printer cannot be diverted to the monitor and hence cannot be captured by the PC.
2. The PC software can import INCOS data for manipulation. For example, the transfer of graphics such as mass spectra to the PC is possible but of limited value unless there is access to software that can import and manipulate INCOS graphics.
3. The manipulation of data using the PC software improves upon the treatment available under INCOS. The quality of INCOS graphics produced by the PC printer is lower than the INCOS printout and hence of little benefit.

Data management and reporting are two of the main weaknesses of INCOS. The quantitative output from INCOS requires additional manipulation to produce the final result. On the other hand, spreadsheet programs such as LOTUS 1-2-3 can import raw data from INCOS and perform a wide variety of calculations to produce quantitative results in a form that can be inserted easily into a final report. We have used two approaches in transferring quantitative data from INCOS. In one approach, the quan list, generated by quantitation of all the peaks in the appropriate regiona of the RIC, is edited in EDQL to exclude all but the relevant data; an entry must exist for each analyte which is identified subsequently by its position in the data list. In the second approach, the quan list is generated by a reverse library search and each entry is labelled with the library name and entry number. This label is used during data manipulation to direct the data to the appropriate location in the worksheet. In this way, target compound analysis, where the target compound may be absent, can be managed.

INCOS data were imported as ASCII files into Lotus 1-2-3 by combining the /File Import Text and /Data Parse commands. The /FIT command imported data as lines of text which were stored in discrete cells. The /DP command converted the data into discrete columns from which the relevant data was extracted. A macro was designed in a Lotus 1-2-3 worksheet to import the raw data from multiple files, calculate the concentrations of each target analyte identified in the sample, normalize multicomponent analytes and prepare the results in tables suitable for insertion in the analytical report.

In our laboratory we analyze routinely indoor air samples in batches of 5 to 15 samples per batch. These samples are screened for 30 target compounds, as well as photocopier fluid residues which consist of a complex collection of aliphatic hydrocarbons in the C_{10} to C_{12} range. The 22 major components in the photocopier fluid mixture provide a characteristic pattern of peaks in the RIC. It is not possible to use quantitative pattern recognition within INCOS because INCOS cannot compare quantitative RIC data from separate datafiles. However, Lotus 1-2-3 can manipulate imported INCOS data from multiple datafiles within one worksheet. Furthermore, statistical operations such as average concentrations in standard solutions, range of concentrations in field samples, differences in the patterns of photocopier residues, correction for incomplete sample recovery, and standard deviations etc. which are not available within INCOS can be carried out easily within Lotus 1-2-3. Of greatest importance is the capability to design and modify the quantitative operations within Lotus 1-2-3 to suit the needs of the analyst.

Using a Lotus macro, the import and data manipulation processes described above took 6.3 s per datafile with an Epson Equity III+ operating at 12 MHz or 26 s per file with an Epson Equity II operating at 7.2 MHz.

The use of the PC as a terminal for the INCOS data system allows access to the raw quantitative data which enables the application of more powerful computational operations than are available under INCOS. The flexibility available with the PC overcomes many of the restrictions and limitations imposed by INCOS.

THE USE OF PC-COMPATIBLE COMPUTERS TO PULL AND FURTHER REDUCE DATA FROM A SCIEX TAGA 6000E MASS SPECTROMETER/MASS SPECTROMETER

Thomas H. Prichett, U.S. EPA Environmental Response Team,
Gmae Loy and Steve Bottemley, Response Engineering and Analytical Contract.

The U.S. EPA Environmental Response Team (ERT) decided to develop PC-based software to perform the additional data reduction required by the developing Quality Assurance/Quality Control (QA/QC) protocols because of the limitations of the current Sciex software and computer hardware. By replacing one of the Sciex 6000E's terminals with a PC-compatible computer, this PC-compatible computer was used as a smart terminal. Data was captured off the PC-compatible's screen as ASCHII files in MS-DOS with a communication package, XTALK MK4. The ASCHII files were later imported into LOTUS 1-2-3 and parsed into a suitable LOTUS data format. Depending on the LOTUS spreadsheet, data was used for either calibration calculations or QA/QC calculations.

Figure 1 illustrates a sequence of events in capturing flag and intensity data for calibrating the instrument. At event 1, both systems (the TAGA's 6000E Plessey minicomputer and the PC-compatible computer) started at their respective operating systems. At event 2, the TAGA program called Airmon was loaded and several cylinders of different standards were run for intensity and flag data. Event 3 shows a LOTUS spreadsheet, Flags.wk1, making the request for a flag table by writing to an ASCHII file called Filename.dat. Once XTALK is loaded, Filename.dat is read and XTALK dumps the flags and operating parameters into a Plessey file called Mixdat.dmp. The LOTUS spreadsheet, Flags.wk1, remains in resident memory while XTALK is active. Event 4 shows XTALK capturing the Mixdat.dmp file from the Plessey system to a MS-DOS file called MD.dat. Event 5 shows Flags.wk1 importing MD.dat and parsing the sequence numbers of the flag table into LOTUS data format. Another request is made for intensity data of TS ion pair tables. Event 6 shows XTALK being loaded and TS tables being downloaded from the Plessey to the PC-compatible computer. Event 3 through Event 6 is repeated until all of the TS files for each cylinders has been downloaded. Event 7 shows another Lotus file being loaded to do calibration calculations.

These software and hardware techniques became necessary because Airmon, a TAGA program, was unable to calculate the RFs of ion pairs. Airmon had the advantages of monitoring 128 ion pairs and, once the RFs were loaded back into the program, it was able to calculate ion pair concentrations in real time. Similar software techniques were used to calculate the RFs and load RFs data back into Airmon.

By extending the capabilities of the TAGA with a PC-compatible computer, it can be noted that :

1. The tedious operation of data manipulation is removed from human intervention.

2. More time is spent sampling, which allows the TAGA to be more productive.

3. Most of the data can be reduced before leaving the field.

4. Rapid data manipulations provides the project manager with essential information for decision making processes.

5. Modification of spreadsheet macros and communication package macros is possible in the field without long development time.

In conclusion, using a PC-compatible computer to access and reduce data could be a powerful method for extending as well as being cost effective.

Sequence of Events to Capture Flag and TS Table

AN IMPROVED VERSION OF THE NBS/EPA/MSDC MASS SPECTRAL DATA BASE, EVALUATION OF THE QUALITY INDEX, AND DATA BASE SOFTWARE FOR AN MS-DOS PERSONAL COMPUTER

Stephen E. Stein and Sharon G. Lias, National Bureau of Standards, Office of Standard Reference Data, Gaithersburg, MD 20899

William L. Budde, U. S. Environmental Protection Agency, Office of Research and Development, 26 W. Martin Luther King Drive, Cincinnati, OH 45268

D. Thomas Terwilliger and Ann L. Behbehani, Computer Sciences Corp., 26 W. Martin Luther King Drive, Cincinnati, OH 45268.

The purpose of this work was to evaluate the 43,005 spectra electron impact (EI) data base and the efficacy of the quality index (QI) which is used to select, from multiple spectra of the same compound, a single spectrum for the data base; and, to implement the data base on an MS-DOS personal computer with software to retrieve and display spectra.

In a previous report of the status of the data base (1), eleven quality factors (QFs) which are used in the QI calculation were evaluated, and new definitions established for some of them. The QI was used to select a 43,005 spectra data base from the archive collection, and a number of the selected spectra were compared with alternative spectra of the same compound in the archive file. As a result of this analysis, several additional QF definition changes were made.

An additional quality factor, QF12, was added to the QI definition to assess the high mass limit of spectra. The quality factor for illogical losses (QF3) was revised to not penalize spectra of low molecular weight hydrocarbons which show losses of multiple hydrogens. The quality factor for detection of spectra with a high air background (QF10) was modified to require the presence of both masses 28 and 32. Quality factors for electron energy (QF1) number of ions (QF5), low mass limit (QF6), calibration date (QF8), and saturation (QF11) were modified slightly. The mean values and standard deviations of the newly defined QFs for the 43,005 spectra data base are as follows:

Quality Factor	QF	Mean	S
Electron energy	QF1	0.9614	0.0733
Ions above M+	QF2	0.987	0.0918
Illogical losses	QF3	0.9824	0.0925
Isotope abundance	QF4	0.9628	0.0819
Number of ions	QF5	0.8953	0.1406
Low mass limit	QF6	0.9572	0.0879
Sample purity	QF7	0.9109	0.0302
Calibration	QF8	0.9536	0.0129
DFTPP refernnce	QF9	0.9017	0.0095
Presence of air	QF10	0.9887	0.0487
Saturation	QF11	0.9769	0.0647
High mass limit	QF12	0.98	0.0634

The most recent changes in the QI algorithm caused the selection of 636 alternative spectra from the archive collection. A careful manual inspection of the 636 pairs of spectra revealed that the alternative spectrum was of better overall quality in only about half of the cases. In the remaining cases, the best spectrum probably was not selected by the revised algorithm.

For example, the spectrum (QI = 589) of hydrazinecarboximidamide with a major ion at mass 46 was selected over an otherwise identical spectrum (QI = 576) of the compound without an ion at mass 46. This ion could only be formed in fragmentation processes which, considering thermochemistry and ion structure, are unlikely. But the atoms present in the parent compound can be combined on paper to form an ion of mass 46. The spectrum with the mass 46 ion is favored by QF5 which penalizes spectra with a smaller number of ions. A very much more sophisticated QI algorithm would be required to rationally distinguish spectra of this type.

Similarly, two spectra of dichloroacetyl chloride were assigned QIs within two points of one another. The spectrum with the higher QI value contained ions at masses 41 and 44, which can only originate from an impurity. We conclude that the QI, at the present level of sophistication, is useful in the automated selection of one EI spectrum when several of the same substance are available. But, the QI must be used with caution, and when the QIs of spectra are within about 10%, the final selection should include the judgement of an expert mass spectroscopist. An effort, based on this approach, is currently underway to improve the overall quality of the data base.

The 43,005 spectra data base was installed on a MS-DOS compatible personal computer (PC), and software developed to retrieve and display spectra. The data base may be searched by Chemical Abstracts Service (CAS) Registry Number, CAS name or other names, internal spectrum identification number, molecular formula, molecular weight, and by the abundances of major ions. More sophisticated searches detailing the presence (or absence) of selected ions may be designed using various options and constraints provided in the search software, including limiting the peak search by molecular weight or elemental composition. Typical searches are completed in 5-15 seconds.

Several thousand spectra are being evaluated for use in the next data base release. Donations of spectra are solicited from laboratories. Computer programs are available, or under development, to assist laboratories in the submission of spectra in machine readable form in a standard format.

DEVELOPMENT OF A PROPOSED NATIONAL REFERENCE SET OF ELECTRON IMPACT GC/MS RELATIVE RESPONSE FACTORS FOR THE U.S. ENVIRONMENTAL PROTECTION AGENCY'S CONTRACT LABORATORY PROGRAM

by
A. D. Sauter and J. J. Downs, A. D. Sauter Consulting, Henderson, NV 89014; P. Isaacson, Viar and Co., Inc., Alexandria, VA 22314; D. Bottrell, U.S. EPA, EMSL/LV, Las Vegas, NV 89114; D. Youngman, Lockheed Engineering Management Science Corp., Las Vegas, NV 89114; and J. Fisk, C. Dempsey, and A. Carasea, U.S. EPA OERR, Washington, D.C. 20460.

Relatively recent efforts of Mitchum, Tondeur, Fisk, Telliard (1, 2, 3, 4) and others have called to question qualitative and quantitative aspects of the DFTPP criteria published in 1975 (5). Despite the widespread use of these criteria in environmental applications of GC/MS, the impact of these criteria has **never** been definitively tested to establish the qualitative and quantitative consequences of being "in" or "out" of tune. Various tune requirements can add cost to environmental analysis and prohibit the utilization of various types of mass spectrometers in environmental applications of GC/MS. In addition, DFTPP provides limited information for the analysis of higher molecular weight environmental compounds of developing interest. In this regard, a reference set of electron impact GC/MS response factors has merit. Because of these considerations, an interlaboratory study was designed and testing has begun to definitively establish the quantitative and qualitative effects of the old DFTPP criteria on the ability of various GC/MS <u>systems</u> to perform quantitative and qualitative analysis, while developing a reference set of EI GC/MS response factors for the U.S. EPA's Contract Laboratory Program.

Elements of the study include common analytical standards, floppy disc data submission, and an explicit set of directions for the participants. GC/MS data is acquired for 93 organic compounds for seven separate injections, under five different sets of "warped" tunes. Output from the study yields 3255 response factors and 6510 qualitative factors <u>per laboratory</u>. Hence, informative (2-D and 3-D) ways to display the data are useful in understanding the technical consequences of tune (see Figures 1 and 2).

To date, three sets of data have been produced and are currently undergoing study. **Preliminary** indications are:

* Acceptable GC/MS data quality as measured by response and qualitative factors can be achieved outside traditional tune boundaries.

* Suppression of "low" mass sensitivity can greatly increase quantitative uncertainty, as many GC/MS RF values go non-linear.

* For the analytes studied, qualitative library matching and ranking output is largely tune independent except at tune extremes (i.e., when "low" or "high" mass sensitivity are greatly suppressed compared to the old tune).

AN ELECTRONIC MASS SPECTRAL DATA BOOK

Kogoro MAEDA and Hirotaka ROKUSHA
Electrotechnical Laboratory, 1-1-4 Umezono, Tsukuba, JAPAN

We have noticed for a long time a new trend in the future usage of computer system and emphasized an importance of personal use mode in a small system by microcomputers equipped with large scale storage peripherals. As one of the examples on this theses, we have presented here a new system on mass spectral data base of about 40,000 compounds in a 16 bit microcomputer system with a 20 M bytes hard disk system. Several series of tests have proved so far that the new system is certainly quite good enough for handling a large amount of the data base in a small system and effective as a desk top system for personal use, and further as an electronic data book.

The mass spectral data used are NBS/NIH/EPA/MSDC MSDB edited in 1983, and numerical and character string data in MT were extracted and compiled in FD's in total 17.8 M bytes in a microcomputer system. The terms selected from the MT are: Spectrum number, CAS number, Molecular weight, Chemical formula, Compound name, and a group of Peak heights for all M/Z values.

The computer system used is a combination of PC-9801-UX41 of NEC, Japan, a 4 M bytes RAM disk and a CRT, minimum constituents, but quite an ordinary combination.

Many programs and indices have been developed and compiled for handling the extracted data, and arranged finally into one total system for effective handling of the data base. The whole software systems are written in BASIC compiler language and they run all on MS-DOS Ver.3.1. Searches are available so far for CAS number, Molecular weight, Chemical formula, Base peak and all M/Z values with Peak heights. Any arbitrary combinations are also possible between the two units from the above five operations.

All of the searches can be performed in very short times. For example, only one compound can be picked up from about 40,000 candidates by key-ining a CAS number almost in less than one second, quite a short time. Results of the searching operations can be displayed as tables or mass spectral charts. Mass range for the charts is from m/z 1 to m/z 1800 in six diagrams with unit mass range 300. Two scenes on the same CRT are used for the display, and the two displays on the screen can be changed very quickly from one to the other by pushing the "TAB" key. Table displays also can be changed quickly in the unit of 20 lines by "ROLL UP" and "ROLL DOWN" keys. These efficient replacements on the CRT are quite effective for looking through the candidates found by the searching operations. All the results of the searching operations performed and searching conditions are always displayed as a total list on the CRT. This list is quite effective for following the logics of the searching operations performed.

The present system can be used for many purposes, not only for simple candidate searchings but also for finding rules between compound structures and the mass spectra. In a previous report, we revealed that a clear correlation does exist for the structures and the base peak m/z values for hydrocarbons: that is, when the hydrocarbons are represented as C_nH_{2n-m}, all the base peaks apear for a group of compounds having special m-values always greater than a specific m-value. For example, base peaks m/z 67, 81 and 95 are always found for hydrocarbons C_nH_{2n-m} having the m-values greater than 2. For the case of m/z 79, the base peak is found only for the compounds C_nH_{2n-4}. These rules were revealed for 1813 hydrocarbons extracted from EPA/NIH Mass Spectral Data Book in 4 volumes published in 1978.

The MSDB used here contains 3086 hydrocarbons and the present system has been used in order to confirm whether or not the correlations found previously are still right for more number of the hydrocarbons. To confirm this, we can use the operation No. 8 in the present MENU, AND operation between base peak (BP) and chemical formula (CF). By simple operations, we can find quite instantly the total number is 332 for the compounds having m/z 79 as base peak. Then the system goes to the next stage. By keying "C/H", we obtain the results in 2 - 3 seconds and find the total number of hydrocarbons is 3086, then we can proceed the final stage, AND operation between these two results. The AND operation takes 2 - 3 seconds between the numbers 332 and 3086, and finally we are tought from the system that the number of the candidates required is 123. From the first operation to the final, the total operation takes only 15 - 25 seconds including the key-in operations. Time for display of the results as a list is about 20 seconds, and we take in all about one minute to find all the hydrocarbons having m/z 79 as the base peak. By looking though the list, we could confirm the correlation is still right. All the procedures took several minutes only in all, quite a short time. If we have to do the above procedures by using 6 volumes of MSDB, we will have to consume several hours or more. This is the reason why we call the present system as an "Electronic" Data Book.

As for the compound name search, we sorted all the CAS names by the first capital letters in 26 groups from A- to Z-group, and we can pick up all the compounds having a same first capital letter arbitrarily, then we can see instantly a list of strings of the common first parts of the names with the selected capital letter in next scene on the CRT. If we can find there a string of the same first part as that of compound name required, we have the third list on molecular weight, chemical formula and molecular name for all the compounds having the same first part. By picking up one from the list, we finally obtain all the information on the compound required. The present scheme is quite useful for finding other groups of names together similar to the candidates. Some more experiences, however, are necessary for more convenience. Updates are now in progress.

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

AMERICAN SOCIETY FOR MASS SPECTROMETRY
BUSINESS MEETING

San Francisco Hilton
San Francisco, California
June 8, 1988

President Gerry Meisels called the meeting to order at 11:35 a.m. He announced that the first item of business was the 1988 Research Awards. The representatives of the two participating companies and the grant recipients were asked to come forward. Dr. Denley B. Jacobson of North Dakota State received his award from Dr. Michael Harvey of VG Instruments, and Dr. Mark A. Smith of the University of Arizona was given his award by Dr. Robert Finnigan of Finnigan-MAT.

Susan Weintraub presented the Secretary's report. She asked for any additions or corrections to the 1987 Business Meeting minutes which were printed in the Bound Volume of the 35th Annual Conference. There were no recommended changes to the minutes, and it was moved, seconded and unanimously passed that the minutes be accepted.

The results of the 1988 ASMS elections were then displayed. The new Board Members will be: Vice President for Programs, Robert Murphy; Treasurer, Michelle Buchanan; Member-at-Large (Education), Michael Story; Member-at-Large (Measurements and Standards), Rodger Foltz. Thanks were also expressed to the candidates who were not elected - Tom Cairns, Alan Marshall, Robert Dunbar and Kenneth Standing.

Next, the list of winners of the 1988 Student Travel Awards was shown. The recipients were: Charles S. Christ, Jr., University of Florida; Rick A. Flurer, Indiana University; Mark E. Hail, University of Florida; Peter Haroldsen, Baylor College of Medicine; Kathleen A. Kayganich, Michigan State University; Gary R. Kinsel, University of Colorado; James N. Kyranos, Northeastern University; Leo M. Lech, Purdue University; Matthias Mann, Yale University; Chad C. Nelson, University of Utah; Ron Orlando, University of Delaware; Jian-Dong Shao, University of North Carolina; Elizabeth A. Stemmler, Oak Ridge National Laboratory; and James E. Vath, Massachusetts Institute of Technology. Weintraub explained to the audience that according to current policy regarding the stipends, only one student per advisor is eligible for an award.

In concluding the Secretary's report, it was announced with regret that two members had passed away during the past year - Terry E. Sharp and John D. Connell.

The Treasurer's report was presented by Kelsey Cook. He explained that the society's financial health is excellent and that we have an amount sufficient for 1 year's expenses maintained in reserve. In addition, our expenses for the past year were somewhat less than our total income, allowing our reserves to increase by approximately $36,000. Cook continued by showing a slide which compared assets, expenses, income and reserves for 1985 through 1987. He concluded with an illustration of conference expenses and showed that these expenses have increased each year. Cook explained that in recent times more emphasis has been placed on the scientific program, with the result that expenses for speakers have increased while expenditures for catering have decreased. There were no questions from the audience.

Gary Glish, the Vice President for Arrangements, was next to report. He announced that to this point, there were 1796 registrants for the 36th Annual Conference. In response to earlier questions about the current situation with the ACS meeting being held at the same time as the ASMS Conference, Glish explained that the ACS selected their dates after we had already made our final arrangements.

Details about the upcoming social event were presented, and Glish gratefully acknowledged the efforts of Julie Leary. He also requested suggestions for future social activities. Glish continued by saying that the spouses's program had been very successful this year, and he thanked Lou Story for her assistance.

Glish next explained that the site for the 1989 Conference had been changed from Toronto to Miami Beach, because the hotel in Toronto was planning to initiate major renovations of the meeting space. He added that the facilities at the Fontainbleau in Miami Beach were exceptionally good.

Plans for the 1990 Conference in Tucson were covered next. Glish indicated that there would be 2 main hotels, with shuttle buses operating between them. Tentative arrangements for 1991 have also been made; it is likely that the meeting will be held at Opryland in Nashville on May 19 - 24. There were no questions about Conference arrangements.

Ron Hites, the Vice President for Programs, spoke next. He acknowledged the assistance of the Program Review Committee (T. Cairns, R. Caprioli, G. Glish, P. Hemberger, G. Meisels, R. Murphy, M. Ross and S. Weintraub, with Judith Watson as an ex officio member) and explained that the interests of these people covered a wide range of disciplines in mass spectrometry. In the initial review process about 60 abstracts were rejected, of which approximately 40 were later accepted after revision. He then showed an overview of submitted papers and compared the statistics for 1988 with those of 1987. The popularity of posters was evidenced by an increased number of abstracts requesting the poster format in contrast to a decline in oral presentations. In conclusion, Hites showed that there has been approximately an 8% per year increase in the number of papers presented. No questions were raised.

Willard Harrison serves as the ASMS Board Member-at-Large who is responsible for the Bound Volume. He reported that he anticipates that there will be about 1400 pages in the volume for this year and added that the cost to the society for each volume has decreased from 1987; this is due in great part to the work of Judith Watson.

Harrison then announced that the Board of Directors of ASMS had voted to change the title of what has been informally known as the "Bound Volume" to include the word "Proceedings". This year's issue will be called "Proceedings of the 36th ASMS Conference on Mass Spectrometry and Allied Topics". He continued by saying that growth of the Proceedings at the current rate might necessitate a change to a more convenient format.

The Member-at-Large with the responsibility for Education, Chris Enke, gave his report next. He described the results of a questionnaire about educational resources in mass spectrometry at academic institutions. From the responses it was evident that not only would additional material be beneficial, but also, implementation of some form of clearinghouse for instructional items would be of great value. Enke next explained about the Education Committee's current efforts to prepare a brochure on mass spectrometry; the brochure is designed to help people who are not in the field and will present information about various techniques and applications of mass spectrometry.

Enke then discussed a change in the organization of the Education Committee, saying that the new ASMS Board Member-at-Large with responsibility for Education, Mike Story, will be the chairman of the Education Committee. Enke then gave special thanks to Harry Hertz for his hard work in past years as the chairman of this committee.

Enke next listed the short courses which were offered immediately prior to the 1988 Conference. He explained that there were 120 attendees at the courses and that there had been a waiting list for places in these courses. In conclusion, he announced that the Fall Workshop would be entitled "Environmental Applications of Mass Spectrometry". It will be organized by Ron Hites and Ron Haas and is scheduled to be given during the week of October 17, 1988.

Paul Goodley, the Member-at-Large responsible for Measurements and Standards, reported on that committee's activities and described their upcoming workshop on quality criteria for mass spectral databases. He also said that efforts were currently underway to compile a glossary of terms used in mass spectrometry. He then mentioned that a modification of the JCAMP-DX data format for mass spectral data transfer between PC's was under consideration. Goodley completed his report by explaining that the Measurements and Standards Committee was being reorganized in a manner similar to the Education Committee, and that the new ASMS Board Member-at-Large, Rodger Foltz, would be the Measurements and Standards Committee chairman.

President Gerry Meisels gave his report next. He related his views on the exciting and interesting years he has spent with the ASMS Board, and he predicted a great future for mass spectrometry in response to the challenge of rapid changes in science and technology. He described various growth areas of the society and explained that eventually the annual ASMS Conference will have so many attendees that a convention center will have to be used for the scientific sessions. Meisels reviewed several changes that have taken place over the past few years - for example, affiliation with the Asilomar Conference and removal of the last formal ties with ASTM E-14 - all as evidence of the broadening of ASMS, which must continue to examine how to provide services which will meet the needs of the members. Meisels said that many of the society's activities are directly dependent on action of the ASMS Board of Directors, and he thanked them all collectively. He expressed particular gratitude to Judith Watson and said that the society couldn't function effectively without her. Meisels then thanked the representatives from Japan and China for their participation in making the 36th Conference a special Pacific Rim international meeting. In recognition of the Board members who were leaving office, he asked Graham Cooks, Kelsey Cook, Chris Enke and Paul Goodley to come forward. Meisels presented plaques to each person and thanked them individually for their efforts.

Meisels next asked for comments from the floor. Anne Giordani brought up two issues. She expressed interest in having a salary survey conducted and related her feelings on the need for child care arrangements at the annual conference. Meisels responded by saying that the Board will look into these matters. William Sherman then announced that he unfortunately had to report that another member, David Carroll, had passed away during the year.

In conclusion, Meisels urged the society members to speak with people on the ASMS Board concerning any other questions that may arise. There being no further business, the meeting was adjourned at 12:30 p.m.

TERMS TO USE IN YOUR RESEARCH PRESENTATIONS

The following terms occur in ASMS presentations frequently. The translation, given in *italics*, tells what the speaker really means.

It has long been known that.... *I haven't bothered to look up the the original reference.*

...of great theoretical and practical importance *...interesting to me*

While it has not been possible to provide definite answers to these questions... *The experiments didn't work out, but I figured I could at least get a publication out of it.*

The XYZ system was chosen as especially suitable to show the predicted behavior. *The fellow in the next lab had some already made up.*

Three of the samples were chosen for detailed study. *The results on the others didn't make sense and were ignored.*

High-purity... *Composition unknown except for the exaggerated claims of the supplier.*

...handled with extreme care throughout the experiments. *...not dropped on the floor.*

Typical results are shown. *The best results are shown.*

Although some detail has been lost in reproduction, it is clear from the original spectrum that... *It is impossible to tell from the spectrum.*

The agreement with the predicted curve is excellent. *...fair* ...good *...poor* ...satisfactory *...doubtful* ...fair *...imaginary* ...as good as could be expected *...non-existent*

The most reliable values are those of Jones. *Jones was a student of mine.*

It is generally believed that... *A couple of other guys think so too.*

It might be argued that... *I have such a good answer to this objection that I shall now raise it.*

Much additional work will be required before a complete understanding... *I don't understand it...*

Correct within an order of magnitude *Wrong*

It is to be hoped that this work will stimulate further work in the field. *This paper isn't very good, but neither are any of the others on this miserable subject.*

Thanks are due to Joe Hoe for assistance with the experiments and to John Doe for valuable discussions. *Hoe did the work and Doe explained what it meant.*

Preliminary experiments have shown that... *We did it once but couldn't repeat it.*

A survey of the earlier literature.. *I even read through some of last year's journals.*

Careful statistical analysis... *After going though a dozen books, we finally found one obscure test that we could apply.*

We are excited by this finding. *It looks publishable.*

We have a tentative explanation. *I picked this up in a hospitality suite last night.*

We didn't carry out the long-term study. *We like to go home at 5 P.M. What do you think we are, slaves?*

We say this with trepidation. *I don't know anything about this.*

We have repeated So-and-so's experiments in our lab. *Brother, were we surprised!*

Academic Lab Managers Interest Group Report

Richard W. Kondrat
Department of Chemistry
University of California, Riverside
Riverside, CA 92521

The group held a workshop in order to inform the mass spectrometry community about the academic resources available to researchers. A summary of the capabilities of NIH and NSF funded facilities was prepared prior to the workshop. Each attendee received a copy of the results which were then summarized by Dr. Tom Sharp. Additional information was given to each attendee concerning Biomedical Research Technology Resources (booklet provided by Dr. C. Halloway of NIH). Sufficient copies were available such that extras were left for general distribution following the workshop. Representatives from many of the facilities were introduced and spoke about their facilities. A distinction became evident concerning what types of analytical problems are dealt with at the various facilities. At the end of the workshop, Dr. Cotter from MAMS, suggested we publish our survey of capabilities in Rapid Communications in Mass Spectrometry. Also, Dr. G. Eigendorf (University of British Columbia) informed us that our list of Canadian facilities was far from complete and pointed out several such facilities. It was concluded that our interest group should disseminate and update the information presented at the workshop on an ongoing basis via the SPECNET electronic bulletin board.

Following the workshop, an interest group meeting was held. The decision was made to follow up on Dr. Cotter's suggestion, as well as to update our listing of Canadian facilities. Members were encouraged to use SPECNET and examples were provided as to its utility. A new interest group coordinator was elected - Dr. Tom Sharp of Texas A&M University. Suggestions on future symposia, workshops, etc., were solicited.

Report of the Biomedical Interest Group

This report is based on comments of members at the Interest Group Meeting on Monday, June 6 and those made throughout the meeting to the coordinator.

Generally, it was felt that the meeting was well organized and ran smoothly. The schedule of events was quite full and in a few instances where workshops and interest group meetings ran over, some minor difficulties were experienced with the set up of the sessions which followed. It was suggested that contributed oral papers be limited in the future to decompress the schedule. Nevertheless, overall, the meeting was reviewed quite positively.

Suggestions for the 1989 meeting for symposia included quantitative analyses using soft ionization methods with emphasis on compounds other than peptides, and coupling of separations techniques to MS other than LC. Workshop suggestions included LC/MS basics using soft ionization methods, and electrophoresis/MS applications. These workshops should cover elementary aspects of theory and practical how-to-do-it tips and procedures for those interested in starting separations and measurements with these techniques.

Members are encouraged to send in additional suggestions for the 1989 meeting, particularly those involving biomedical interest, to the vice president for programs or to the biomedical interest group coordinator. Our group consists of a wide diversity of interests and applications, and our input is vital to the Board in preparing next year's meeting. If you feel there are areas not well represented and which you think are vital to the society, please write and give us your thoughts.

"Analysis of Drugs and Drug Metabolites by Tandem MS"

A Workshop Sponsored by the
Biomedical Applications Interest Group

The identification of drug metabolites is in many ways an ideal problem for the application of MS/MS techniques. In part, this is due to the fact that metabolites usually retain structural features of the parent drug, and because most drugs are metabolized by similar biochemical pathways. Recent advances in instrumentation have made sophisticated MS/MS techniques accessible to research groups that are directly concerned with the identification and quantification of drugs and their metabolites within complex biological sample matrices. This workshop was organized to discuss the increasing use of tandem MS by metabolism research groups, and to address the practical aspects of these techniques. Featured speakers included John Coutant (Merrell-Dow Pharmaceuticals), Simon Gaskell (Baylor College of Medicine), Bill Seifert (University of Texas Medical School), Roger Foltz (Center for Human Toxicology, University of Utah), and Bob Strife (Procter & Gamble). Speakers were requested to stress the practical aspects and potential drawbacks of the various techniques in use in their laboratories. The workshop was very well attended, with over 300 participants.

John Coutant outlined the use of the triple quadrupole for rapid identification of metabolites, particularly in combination with thermospray ionization. Issues such as the need for sample clean-up vs. direct mixture analysis, the limitations of thermospray as an ionization technique, and the 'success rate' of MS/MS in solving real problems were addressed in a lengthy question and answer period.

Simon Gaskell discussed the use of MS/MS for metabolite identification and quantification using FAB ionization with a hybrid (BEQQ) instrument. Examples that were discussed included the identification of glutathione conjugates using precursor ion or neutral loss scans, and the quantification of sulfate esters using precursor ion scans. The need for sample cleanup was stressed, and the advantages of immunoaffinity columns for this purpose were demonstrated. The continued need for stable isotope analogues was also stressed, both for quantification purposes (as internal standards) and to assist in distinguishing drug-related materials from endogenous compounds (*eg.*, the use of "isotope twinning" techniques).

Bill Seifert discussed the use of 'flow-FAB' as a means of sample introduction for trace analysis and quantification. Practical advice on operation of this increasingly popular means of sample introduction was provided, and examples of results obtained using a triple quadrupole were shown.

In spite of the obvious suitability of tandem MS for drug and drug metabolite identification, the very high cost of conventional MS/MS instruments continues to inhibit their widespread adoption. This is especially true of applications where large numbers of samples are the norm, such as with clinical and other drug development studies. Accordingly, the last two speakers were invited to discuss the capabilities of potential 'low cost' MS/MS devices.

Roger Foltz gave an introductory talk on the practical aspects of the use of the ion trap mass spectrometer for drug analysis. The capability of this device for high sensitivity, selective chemical ionization was illustrated with a number of examples.

Bob Strife then discussed the concept of doing MS/MS in time rather than in space (as in multiple sector devices) using an ion trap equipped for MS/MS operation. After first presenting a brief introduction into the theory and practical aspects of this device, a number of examples were presented which illustrated the very high intrinsic sensitivity and specificity afforded by MS/MS.

In summary, all of the speakers provided examples which demonstrated that MS/MS offers unique advantages and capabilities for identifying and quantifying drugs and their metabolites. It was stressed, however, that when solving real problems on unknowns, MS/MS should be viewed as an extension of rather than a replacement for existing analytical techniques.

ASMS Education Committee Report

ASMS once again sponsored a series of short courses on the weekend preceding the Annual Conference. As in prior years, course evaluations received from the students indicated that the courses were very successful with most students achieving their goals. This year's short courses and organizers were as follows: Interpretation of Mass Spectra - James Kelley; Quantitative Mass Spectrometry - Al Yergey; Intrepid Ion Chasing: SIMION Style - David Dahl; Fast Atom Bombardment Mass Spectrometry - Ken Busch; Practical MS/MS Analysis - Rick Yost.

The Education Committee also sponsored a Symposium and a Workshop at the 36th ASMS Conference. The Symposium, entitled "Mass Education - Introductory Lecturers from ASMS Educational Programs", drew large attendance and provided introductory lectures on Mass Spectrometric Approaches to the Analysis of Biopolymers by Chuck McEwen, Principles of Isotope Dilution Mass Spectrometry for Quantitative Analysis by Al Yergey and Practical MS/MS Analysis by Jodie Johnson and Rick Yost.

The Committee Workshop entitled "Ethics Issues in the Technical Workplace" was organized by Al Yergey. Working on a case study, workshop participants were asked to confront some of the moral and ethical issues which face us as scientists.

As a formal committee of the American Society for Mass Spectrometry, the Education Committee does carry on activities throughout the year. During the past year, members of the committee were Ann Goetz, Paul Goodley, Al Yergey and Harry Hertz. With primary responsibility accepted by Ann Goetz, the committee worked on an introductory brochure for scientists in research areas who could benefit from mass spectrometric measurements. The brochure, to be made available during the coming year, will provide an overview of problem areas where mass spectrometry can provide assistance and an overview of mass spectrometric instrumentation and techniques.

The committee also sent a questionnaire to all members of the Society requesting information on mass spectrometry courses presented at their institutions. Paul Goodley coordinated this activity. He is currently evaluating the many responses received and developing a mechanism for accumulating and organizing the instructional materials offered to ASMS by respondents.

During the coming year, in addition to completing the introductory brochure, the ASMS Education Committee will its attention on preparing a short course package to be made available to local discussion groups. This package will include a complete instructional kit from one of the ASMS basic short courses and will give the instructions needed for local discussion groups to use their own faculty in putting on the short course.

Mike Story will become chairman of the ASMS Education Committee in July. He will welcome suggestions from ASMS members on educational activities which ASMS can provide its members and the scientific community.

Respectfully submitted,

Harry S. Hertz

Ethics in the Workplace

This workshop was organizes to provide a forum for the discussion of some issues that involve the people of science as well as the science that they do. It was organized around the format of dicussion, in a small group format, of a hypothetical case study concerning a problem that has occurred in laboratories in virtually any setting. Issues addressed were responsible reporting of observations, ability to reproduce work, and some of the personality clashes that occur under those circumstances.

The basis for addressing solutions to the problem were suggested by the very able discussion leaders, Sondra Ford and Carlos Ramos of FMC Corporation, who were kind enough to offer their time to the Society for this purpose. The bases for ethical decisions given were:

When Making an Ethical Decision:

Choose the Alternative That Has:

* Most benefits

*Fewest Harms

*Respects Rights

*Distributes Benfits Fairly

*Distibutes Burdens fairly

Ask:

- Will the Choice Stand Up to Public Scrutiny?

- Will the Choice Stand the Test of Time?

Approximately 30 people participated

Organizer: A.L. Yergey

ENVIRONMENTAL INTEREST GROUP REPORT
SAN FRANCISCO 1988

The Environmental Interest Group held its annual meeting prior to the workshop on "New Ionization Techniques for Environmental MS". A report on this workshop is included in this volume. The meeting began with approximately 300 attendees, but soon this number swelled to about 700. A number of subjects were suggested for workshops and/or symposia for next year, including:

- Environmental Applications of MS/MS, including water, soils and atmospheric samples. (This was the topic of a workshop sponsored by this group at the Denver meeting in 1987).
- Chemometric Techniques in Conjunction with Environmental Analysis by Mass Spectrometry
- Preparing for the Next Generation of Environmental Contaminants
- QA/QC in Environmental MS
- Air Monitoring by MS

The Group was asked about possible changes they would like to see in the format of the meeting and only one comment was received concerning the overlap of interesting sessions during the week. Otherwise, no complaints or suggestions were offered.

NEW IONIZATION TECHNIQUES FOR ENVIRONMENTAL MS

A Workshop Sponsored by the
Environmental Applications Interest Group

This workshop was organized to examine new ionization techniques which have utility for environmental problems. Featured speakers were Marc Wise (Oak Ridge National Laboratory), Jack Henion (Cornell University), Eric Grimsrud (Montana State University), and Dave Jamieson (National Research Council of Canada). A large audience of about 700 also participated actively in the discussion.

Marc Wise discussed the use of a glow discharge source for the direct analysis of volatiles in soils and water. Analysis is conducted either by monitoring the headspace over the sample or by purging the sample directly into the source, which is operated at 0.2 torr. Potential applications of this source include use as a continuous air monitor, for targeted compound analysis in water and soil (especially as a field instrument) and as a potential CLP equivalence method. The advantages of this technique include rapid sample turnaround (less than 2 minutes), part per billion (ppb) sensitivity, linear response, and good accuracy and precision.

Jack Henion discussed several ionization techniques for the analysis of polar environmental analytes in conjunction with liquid chromatographic separation. Topics discussed included use of an ion spray interface for analysis of low ppb levels of mono- and disulfonated azo dyes and the analysis of higher molecular weight dyes (including Direct Red 80 with a molecular weight of 1240) using thermal assisted electrospray. Phenoxyacetic acids were analyzed using capillary zone electrophoresis (CZE) directly interfaced to the mass spectrometer. The main problem encountered with CZE is the need to balance the sample load of the separation technique with the detection limits of the mass spectrometer. This requires the use of single ion monitoring to avoid overloading the chromatographic column. Using CZE and single ion monitoring, detection limits of less than 1 pmole per component were achieved. CZE with MS/MS was used to analyze waste water extracts for Acid Yellow 49.

Eric Grimsrud discussed the good and bad points of high pressure electron capture mass spectrometry. Besides electron capture reactions, this source can also produce altered neutrals formed by reactions with positive ions, radicals and surfaces, which can then undergo electron capture to produce additional ions. Directions for further research included investigation of buffer gases, ion source materials, ion source volumes and ion/electron density.

Dave Jamieson concluded the workshop by discussing the use of negative ion mass spectrometry for better selectivity and sensitivity. Methane and water have been used as a buffer gas with negative ion chemical ionization (NICI) to analyze polychlorinated biphenyls in marine sediment samples. Oxygen enhanced NICI gives isomeric information on PCBs. Recently carbon dioxide has been used as a buffer gas for the analysis of polycyclic aromatics hydrocarbons in marine sediments and has been shown to differentiate isomers.

INTEREST GROUP REPORT
FUNDAMENTALS

The symposium on Cluster Ion Mass Spectrometry, sponsored by the Fundamentals Interest Group and organized by Mark Ross, attracted approximately 70-100 delegates over a three hour period during which five interesting and authorative accounts of different aspects of cluster ions were covered. The theme was continued on the following morning when a number of shorter papers on related topics were presented.

The group also sponsored two lunchtime workshops: "Making Metal Ions", organised by Doug Ridge and "Aspects of Photoionisation" organised by David Lubman. In each workshoip, 5-6 "volunters", reviewed appropriate parts of the subject and presented recent data, giving a useful snapshot of some of the themes of current interest in these two topics. Despite a very full program leaving little time for lunch, each workshop attracted over 50 delegates and discussion had to be curtailed to make way for the afternoon sessions.

The Business Meeting was held before the first workshop and continued briefly at the end of the second workshop. Since suggestions for symposia, plenary speakers and workshops form the floor were rather fragmented, delegates were asked to provide suggestions in writing either to Doug Ridge (who will assume responsibility for the group over the next two years) or to myself. For symposia in particular, this produced a gratifying response. Concern was exppressed on several occasions during the conference that the influence of the Fundamentals Interest Group on the meeting is diminishing and there is certainly a need to try to attract back to ASMS meetings those working on fundamental aspects of ion chemistry and physics who no longer see the annual congress as a meeting they wish to attend. Possible topics for symposia which were suggested were (i) Ions and Spectroscopy and/or Lasers and Mass Spectrometry; (ii) Ionisation Processes & Ion Dynamics; (iii) Applications of Mass Spectrometry to Atmospheric Chemistry; (iv) A Comparison of Gas Phase and Condensed Phase Ion Chemistry; and (v) The Interaction between Experimental and Theoretical Gas Phase Ion Chemistry. Other topics, perhaps more suitable for plenary lectures or workshops, include: (i) High Temperature Chemistry and Vaporisation of Species; (ii) Reaction of State Selected Species; (iii) Ion Activation Processes; and (iv) Ionospheric Chemistry relevant to the Space Shuttle. These suggestions, together with names of possible contributors, will be forwarded to the ASMS Board.

FUNDAMENTALS WORKSHOP: MAKING METAL IONS

Workshop Coordinator: Douglas P. Ridge

The workshop dealt with techniques for generating gas phase metal ions for chemical studies.

Terry McMahon from the University of Waterloo described the adaptation of an electron impact high pressure source to laser desorptive ionization. A XeCl excimer laser pulsed at 1 Hz was used. There are quartz windows on both the source housing and the source. The source window is a 5 cm lens that focused the laser onto the metal target. Shot to shot reproducibility is good and strong signals are observed. A multichannel analyzer collects the ion intensity as a function of time. Equilibrium constants for solvation of Cu^+ by Xe, N_2 and H_2O have been obtained already. In each case the second ligand is bound more strongly than the first.

John Allison from Michigan State reported evidence concerning the formation of excited states. Ni^+ reacts differently depending on the compound from which it is formed. Reactions with C_6H_5I, $C_6H_5CHOHCH_3$ and $C_6H_5CH_2OH$ were examined. Ni^+ was formed by electron impact on $Ni(CO)_4$, $Ni(PF_3)_4$ and NiCpNO. 70 eV electrons were used. Distinctly different product ratios were observed especially for Ni^+ from NiCpNO.

Steve McElvaney from Naval Research Laboratory described two methods for generating clusters. In one method metal powders are pressed into a pellet with a matrix of boron nitride or graphite. The pellet is then placed in an ICR cell and exposed to a pulsed Nd YAG laser at either the fundamental or the first harmonic. W and Ta in graphite matrices give metal carbide clusters $M_nC_m^+$. In Ta both n and m can be 10 or more. CID on the carbide clusters give a characteristic C_3 loss. A second ionization method also involves laser oblation. In this case the target is a rotating rod in the throat of a pulsed nozzle for a supersonic expansion. Clusters grow from metal atoms ejected from the metal surface into the cooling expansion. Ionic clusters then result from photoionization of the neutral clusters. Bi clusters formed by SIMS and LDI were compared and found to be similar. Ion emission resulting from the first harmonic of the Nd YAG laser and the

fundamental were compared. Recent spectra of ions obtained from Ag in a graphite matrix were shown.

Rob Freas from the University of Houston described results from sputtering metal ions from surfaces. 8 kV Xe atoms bombarded metal foils, metal salts and metal oxides. The yield was 1 to 10^3 particles per Xe atom. Ti foil gives titanium oxide clusters even after several hours of sputtering. This is the result of the reactivity of Ti and contaminants in the vacuum system. When bombarded in the presence of O_2 in a CI source ions of stoichiometry $Ti_nO_{2n-1}^+$ are formed almost exclusively. The distribution of vanadium oxide clusters obtained in a similar experiment agreed with a simple theoretical model. Preliminary spectra resulting from sputtering from a superconducting Ba containing ceramic were shown.

Tim McMahon from Purdue described several experiments with laser oblation of ions into an ICR cell. A Nd YAG laser is focussed on metal targets in the wall of the cell. The targets have holes in them parallel to the laser beam. The beam passes through the holes and the resulting ions emerge into the cell. Glass windows are used. A Nicolet FTMS 2000 has been adapted to bring the laser beam down the axis of the cell so that it impinges vertically on the target ejecting ions into the cell. An external source has also been used to inject metal ions into an ICR cell. The ions formed in the source travel along magnetic field lines into the source. At this point the injection efficiency is low and unreliable. All of the first row transition metal atomic ions and a number of second and third row atomic ions have been formed this way.

Historical Interest Group Business Meeting - - 6-JUN-88 San Francisco

The meeting was convened at 1:00 PM with 60-70 persons present.

Those in attendance were assured that the outgoing chairman, Bob Kiser, was on his way to good health and was looking forward to joining us again in Miami in 1989.

A sign-up sheet was passed among the attendees soliciting help for the coming year. A group of attendees indicated willingness to provide time and energy to accomplish goals of the historical interest group between now and next year's meeting. Those members are listed below for the benefit of those unable to attend the meeting, and for those interested in knowing more about our activities.

Historical Interest Working Group:

Lyn Bear	NBS	Gaithersburg MD
K. L. Busch	Indiana U	Bloomington IN
P. Chastagner	E I duPont	Aiken SC
R. G. Cooks	Purdue	West Lafayett IN
Fred Elder	Xerox Corp	Webster NY
Jean Futtrell	U of Delaware	Newark DE
Leonard Ingram	Miss. Forest. Lab.	Mississippi State MS
Charles Judson	U of Kansas	Lawrence KS
Bob Kiser	U of Kentucky	Lexington KY
Robert Madden	Extrel Corp	Pittsburgh PA
Fred McLafferty	Cornell U	Ithaca NY
Vince Saltamach	Columbia U	New York NY
Bill Sherman	Washington U	St Louis MO

The ASMS Proceedings has more specific address and phone information if anyone wishes to contact any of these individuals regarding the activities of the historical interest group.

As Chairman for the next two years, I presented to the attendees a plan for historical interest group activities which centered on the collection of information about three specific phases of mass spectrometry:

* Its practitioners
* Its scientific and technological development
* Its instrumentation

The intention is to collect information in these areas since the Society has neither the physical nor financial resources to collect equipment. The group has already embarked on the collection of information on practitioners of mass spectrometry as suggested by Bob Kiser. Small questionnaires were placed in the Spectaker and also provided at the meeting itself, asking individuals to provide the historical interest group with information about how they became involved with mass spectrometry. Approximately 200 responses were collected prior to the meeting and 200 more were collected at the meeting. In addition, a display of photographs of individuals and instrumentation was set up at the meeting on Sunday for the perusal of attendees. Accompanying the display was a request for the loan of photographs of people and/or equipment which would be copied and returned to the contributor. Anyone wishing to loan such material can get more information by contacting me at the phone number listed below.

The collection of information about practitioners will continue throughout the year and efforts to collect information in the other two areas outlined above will be started. In particular, anyone having old advertising literature, manuals or other material on instrumentation from the past is encouraged to contribute such material to the historical interest group for its archives as it becomes obsolete. If you are thinking about pitching it, pitch it to the Historical Interest Group! Based on the response during the coming year, the group will mount a more elaborate display of memorabilia and historical artifacts at the meeting in Miami.

The Workshop consisted of short oral presentations by Charles Judson and Vince Saltamach on some of the history of mass spectrometry which they had witnessed first hand. Charles spoke on the early era of commercial mass spectrometry when Consolidated Engineering Corporation was developing the instrument which eventually became the CEC 103 series of instruments. Vince spoke on the various instruments which were developed at Columbia University in the years before and during the Manhattan project. Pictures and information about each of these topics were posted on poster boards and after the brief oral presentations, the workshop evolved into a miniature poster session with the attendees participating in a lively exchange for the remainder of the time allotted for the workshop.

Respectfully submitted,

Michael A. Grayson

McDonnell Douglas Research Laboratories (314) 233-2541

Presented at the 36th ASMS Conference on Mass Spectrometry and Allied Topics
June 5-10, 1988, San Francisco, CA

INSTRUMENTATION AND ION PHYSICS INTEREST GROUP MEETING AND WORKSHOP REPORT

The Instrumentation and Ion Physics Interest Group sponsored the symposium entitled "Ion Trapping: Methods and Applications" held on Friday, June 10 and a workshop entitled "Practical Aspects of Lasers with Mass Spectrometry" held on the evening of Monday, June 6. A short interest group meeting preceded the workshop on Monday where a number of suggestions for topics of future symposia, workshops, and plenary/introductory lectures were offered. Among these were:

- -Formation and analysis of multiply charged ions
- -Ion optics calculations
- -Lasers in mass spectrometry
- -Interfaces in hyphenated techniques
- -Detection systems
- -Molecular beam techniques and sampling ions from high pressures

Other good suggestions were also made that better fit under the purview of other interest groups and have been forwarded to the Board for consideration.

An audience in excess of fifty was present throughout the evening workshop which centered on the types of lasers used today in mass spectrometry and their relative merits. Four speakers gave short presentations with particular emphasis on the important considerations involved in applications with which they were familiar. Each speaker was asked to target the presentation at people relatively unfamiliar with the use of lasers in mass spectrometry experiments. Dr. David Lubman (University of Michigan) led off the workshop with a general discussion of today's commonly used lasers in relation to the photoionization of polyatomic ions. Dr. Douglas Goeringer (Oak Ridge National Laboratory) followed by expanding on some of the previously presented material with emphasis on the photoionization of atomic species for isotope ratio measurements. Dr. Robert Hettich (Oak Ridge National Laboratory) discussed laser desorption of biomolecules in a Fourier Transform mass spectrometer along with photodissociation. Dr. Mark Ross (Naval Research Laboratory) concluded the presentations with a discussion of photodissociation in a beam-type mass spectrometer. The positive feedback from the workshop audience (along with the good attendance) indicates a continued strong interest in lasers among mass spectroscopists. For this reason, another symposium in the rapidly growing area of lasers in mass spectrometry may be appropriate at either next year's meeting (as suggested above) or the following meeting.

ISOTOPE RATIO INTEREST GROUP REPORT

Approximately 50 people attended the business meeting of the Isotope Ratio Interest Group held Tuesday, June 7, 1988.

The group felt that the name Isotope Ratio Interest Group should be changed to Isotopic Applications Interest Group to accommodate a broader range of scientific disciplines. We therefore recommend that the name Isotopic Applications be adopted for next year's meeting.

The Isotopic Applications Group felt that this year's presentation format for inorganic topics (elemental, surface, and isotopic) worked very well. We hope that the format of symposium, regular oral session, and posters can be continued in future meetings. There is strong feeling within our group that oral sessions should be continued at future ASMS meetings, as opposed to an all poster format. Some suggested topics to be included in an isotopic symposium in 1989 include biomedical tracers, geochronology, nuclear materials, environmental analysis, and accelerator mass spectrometry.

A major issue that all isotope ratio mass spectroscopists will soon face is the availability of isotopically enriched materials. The production of enriched isotopes in the U.S. has fallen off in recent years making these materials harder to find for different elements or enrichment levels. This issue might be addressed at a workshop for the 1989 meeting.

The Isotope Applications Group now has a member mailing list that includes about 100 names and addresses. Our group has found this list useful to keep informed about ASMS events; we hope that the mailing list will help to establish stronger communications among us for larger issues, such as the production of enriched isotopes. To receive a copy of or add your name to the mailing list, please send your name and address to:

ISOTOPE RATIO INTEREST GROUP WORKSHOP
ISOTOPE RATIO MASS SPECTROMETRY--A LOOK TO THE FUTURE

Approximately 50 people attended the workshop for the Isotope Ratio Interest Group held Monday evening, June 6, 1988.

The purpose of the workshop was to address the future of isotope ratio mass spectrometry--what advances in instrumentation are desired and what may be new areas of application. The featured speakers, Linus Barnes (NBS), Guenter Lugmayer (U.C. San Diego/Scripps Institute), and Dick Perrin (Los Alamos), presented an overview of their research to demonstrate the limits of today's instrumentation and isotopic measurements.

Linus Barnes described the development of analytical methods for neodymium and strontium. NBS is obtaining isotopic analysis of picogram samples of neodymium with part-per-million errors. With strontium, the instrumental errors have all but been eliminated, and the remaining problems are related to sample preparation and standards. Some of the drivers behind Linus' work include smaller samples, higher accuracy, faster/automated analyses, and multi-element determinations.

Guenter Lugmayer discussed the applications of isotope ratio mass spectrometry to geochemistry and cosmochemistry. Guenter pointed out that high-purity standards and high-precision thermal ionization mass spectrometers are the important tools of the trade and that the cardinal points in isotope ratio MS are (1) sensitivity, (2) sample/spectral purity, and (3) external precision and accuracy.

Dick Perrin showed applications of isotope ratio mass spectrometry to geochemistry and nuclear chemistry. Dick described some imaginative schemes for incorporation into future instruments. These included an element selective ionization system, an isotope selective detection system, and an automated closed-loop separation system. The concept of the closed-loop separation system interfaced to an automated thermal ionization mass spectrometer invoked the lively, heated, and spontaneous discussion that is the hallmark of the Isotope Ratio Interest Group.

The workshop adjourned into informal discussion groups and enjoyed refreshments graciously provided by Finnigan MAT.

Committee on Measurements and Standards
Meeting on Qualities Desirable in Mass Spectral Data Collections
Organized by: F. McLafferty and S. Lias
Chaired by G. Meisels

The meeting opened with a description of both NBS-EPA and Wiley data collections by S. Lias (NBS). The first contains 43,000 compounds, the second over 130,000 some of which are duplicates. Both are available in hard copy and computer format and they have been combined in a joint publication which will be available about August, 1988. Each is searched by its own system, the PBM-STIRS routines being used in the Wiley collection. These search routines were not discussed further at this meeting, which was concerned with the quality of data collections. Lias discussed certain difficulties in using the various forms of "quality index" to screen spectra. McLafferty agreed that it is a problem. He has each spectrum in the Wiley collection entered in his database by students and then checked by PBM-STIRS. When difficulties are encountered he personally checks the spectrum, changing obviously erroneous peaks McLafferty gave a brief discussion of the history of the Wiley collection and discussed some of its features. It has many more spectra, partly because even highly abbreviated spectra, usually found in papers where mass spectrometry is not the key feature, are included. McLafferty found that such spectra, in spite of their shortcomings, tend to improve the quality of the search which uses only 15-27 of the most important (not necessarily most abundant) peaks.

McLafferty stressed the importance of collections prepared from spectra run by practicing mass spectrometrists since they are likely to be of higher quality and more general interest. He then read the results of a questionnaire he recently sent out to a small number of spectrometrists. As expected, everyone appears to want both quality and quantity but heuristic approaches to providing the former are not sufficiently trustworthy. Discussion of this point led to general agreement that ASMS should convene a committee of referees to inspect new spectra before they are submitted to either data collection. (This has been done; the temporary chairman is Richard W. Crawford). On this same point M. Grayson requested that the committee before a standard form for submission of spectral data. This will be done and Meisels agreed to publish it in a future issue of the Spektaker. Lias stated that NBS would accept data in any ASCII format. McLafferty added that he would accept data in any form, but not from unknown materials. A meeting to discuss the format issue, especially the JCAMP format used for infrared spectra (J.Applied Spec. 1988) was scheduled for Thursday evening (see report of Computer Applications Interest Group).

On the question of subset collections, McLafferty saw no difficulty in such a division provided the subset was sufficiently well defined. He requested the Committee's assistance in this. Discussion followed concerning FAB, EI, and CA collections. These spectra are known to be highly dependent on instrument conditions. Since such spectra are generally used for very specific purposes on well defined samples, it was considered that they would not be included at present. However, about 1000 collision activated spectra are available from McLafferty, provided

the requester will promise to send 50 of his own. He mentioned that these spectra when run through the PBM system required such wide windows that they would be of questionable value.

On the question of sources of new spectra, regional mass spectral facilities were mentioned as one possibility. K. Bieman pointed out that in his experience most of these are other El spectra and he questioned their general quality. Other centers reported more use of El spectra, however.

Some discussion centered on the incorporation of "physics" into the data base, i.e. low electron voltage changes, etc. McLafferty mentioned that his search algorithms already did attempt to take into account such matters as peak skewing due to GC peak elution, etc.

R. Foltz wished to know more characteristics of the users of these collections. What fraction is environmental, drug firms, etc.? It was agreed that this would be of great importance in future considerations of the committee and an effort should be made to determine this point.

QUANTITATIVE ANALYSIS OF PEPTIDES

Pharmacology Interest Group Workshop Report
(Formerly Quantitative Organic Analysis)

This workshop considered analytical aspects of the quantitative analysis of peptides by mass spectrometry and was intended to be an extension of the afternoon symposium organized by Dr. Dominic Desiderio titled "Measurement of Peptides". There were approximately 100 in attendance.

The name of the interest group was changed last year from "Quantitative Organic Analysis" to "Pharmacology" with the subject area of the interest group defined as "The structural and quantitative analysis of drugs and their metabolites, and of endogenous bioactive compounds and their metabolites." An unscientific sampling of the membership strongly indicated that the subject area directly overlapped with the "Biomedical Interest Group" and that "Pharmacology" was an inappropriate name. Several suggestions for a more appropriate name were made with "Biochemical Quantitation" having the most support. It is therefore proposed that this new name be adopted for this interest group.

The workshop began with Dr. Dominic Desiderio, University of Tennessee, describing the overall analytical scheme used in his laboratory to discover and quantify biologically active peptides in the mammalian central nervous system. Briefly, the scheme employed solid phase ODS extraction, LC purification, limbic system receptor assay and FAB-MS-MS analysis using a double-focusing MS of reverse geometry. Quantitative analysis of methionine-enkephalin (YGGFM) in cerebospinal fluid was described in detail. Early studies used structural analogue and carboxyl ^{18}O-internal standards. Since exchange of carboxyl ^{18}O is a potential problem, ^{13}C-internal standards (specifically $^{13}C_6$-methionine-enkephaline) are presently being used. Methionine-enkephalin in CSF was quantitated by FAB-MS-MS utilizing the $YGGFM^+ \rightarrow YGGF^+$ parent-daughter pair and monitoring m/z 431 and 425. The CSF sample milieu was described as a simpler matrix than tissue, however, quantitative measurements are complicated by the lower concentration of methionine-enkaphalin present in CSF. The method was described as highly sensitive with calibration data points routinely attainable in the fmole level (standards alone). Addition of HCL and glutathionine to the FAB matrix was observed to increase the molecular ion intensity by a factor of three.

Dr. Carol Lisek of the Mayo Clinic described her work in collaboration with Dr. Ian Jardine on the quantitative analysis of substance P ($PPLPQQFFGLM-NH_2$) in feline spinal cord using continuous flow FAB-MS. The sample preparation consisted of the addition of a deuterated internal standard to the biological matrix, solid phase extraction and immunoaffinity chromatography purification. The immunoaffinity purification was described as critical to successful analysis. LC-MS analysis utilized microcolumn LC/dynamic FAB-SIM-MS, monitoring MH^+ of substance P and MH^+ of $^2H_8$-substance P (1348.7/ 1356.7) using a VG 30-253 quadupole. The limit of detection using this system was observed to be 0.1 pmole (3:1 S:N). A major limitation with this approach is the limited injection volume (0.1μ l injector loop) since a mimimum of 10μl solvent is required to dissolve the purified sample. Members of the audience suggested that it should be possible to use multiple injections and adsorption of the sample at the beginning of the column and then increase the percent organic solvent to chromatograph the sample. It was also suggested that a requirement of 10 l solvent to dissolve the sample could be related to non-specific adsorption at the immunoaffinity purification step and that a more specific elution (e.g. displacement with an analogue) should allow smaller solvent volumes to be used.

Dr. Simon Gaskell of the Baylor College of Medicine presented an overview of some of the general considerations for any quantitative analytical method. The key considerations described were sensitivity, accuracy, precision and intermethod comparability (if possible). Key considerations for accuracy are the degree of selectivity of the method and the demonstration of spiking parallelism. It was noted that both interassay and intra-assay precision should be determined. It was suggested by a member of the audience that a more detailed discussion of quantitative analysis fundamentals would be an appropriate subject for a future workshop. Preliminary studies quantitating leucine-enkephalin and bradykinin using FAB and MS-MS with a hybrid instrument (VG ZAB SEQ) were also described.

SOLIDS AND SURFACE ANALYSIS INTEREST GROUP REPORT

Approximately twenty-five members of this interest group met Thursday, June 9, from 8:00-10:00 PM to conduct the annual business meeting and participate in the workshop, "Organic Ion Imaging-Problems and Prospects". Members were informed of the decision to divide the present interest group into three new interest groups, namely Inorganic and Elemental Analysis, to be chaired by G. Hieftje, Desorption Processes to be chaired by P. Todd, and Surface Science, with the chair to be named. Volunteers for successor/new chair positions, and recommendations for next years' program were solicited. Recommendations for next year's workshops/symposia included:

Radiation Damage in Organic and Semiorganic Materials
Solutions to Sample Charging Problems
Multichannel detectors and Mass Analyzers
Mass Spectrometry of Laser Ablated Surfaces
Desorption/Ionization of Langmuir-Blodgett Films
Inorganic Elemental Desorption and Surface Science

It is recognized that these topics would fall under the purview of different interest groups that will be formed for next year's meeting. Recommendations for next year's plenary lectures included:

Medical Community Needs That Might Be Met by Imaging Mass Spectrometry
History and Present Capabilities of the Ion Microprobe

The workshop that followed was moderated by P. Todd, and consisted of brief presentations and discussions led by Tom Brenna (IBM), Ken Busch (Indiana), Greg Gillen (NBS), and Robert Odom (Charles Evans and Associates).

Tom Brenna discussed crucial aspects of sample preparation and instrument control for generation of atomic secondary ion images from biological tissue. Many of the lessons learned from determining elemental distributions by using SIMS are directly applicable to organic ion imaging. He pointed out that sample preparation methods that fix spatial distributions best are the most difficult to perform and are the techniques that disrupt physical morphology most. Failure to employ the more demanding preparation techniques has led to misinterpretation of the resulting images. A second point made graphically by Tom was that by changing a single variable in the focusing of a Cameca ion microscope, he was able to create from a single sample, a series of complementary images. That is, a high intensity Ca^+ region appeared in one image where in a subsequent image, that same region yielded a low intensity Ca^+ signal. This led him to state that given the state of the art, secondary ion images would best be presented using single bit picture elements (e.g., white or black) indicating whether a particular ion is detected from that region or not, respectively. Shading and color enhanced imaging can lead to misinterpretation.

In apparent contrast to the results presented by Tom Brenna, Ken Busch discussed the conflicting needs of rigorous sample preparation and high sample throughput. There are many problems to be solved at all levels of sample preparation sophistication and spatial resolution capability. Information generated (and desired) from SIMS of TLC plates, for example, is different from that generated from biological tissue samples. Retention indices and sample identification are the main issues, rather than detailed spatial resolution. Ken also noted that the number of samples he handles regularly precludes extensive sample preparation; nonetheless, very useful information can be obtained from images produced from TLC/SIMS without extensive sample workup. The important issue for the analyst to remember is that the particular information required determines the rigor of the imaging experiment. It was the general consensus that with spatial resolution between 1 μm and 1 mm., sample preparation requirements could be mitigated and still permit a number of important biochemical problems to be addressed.

Greg Gillen discussed his finding that characteristic organic secondary ion mass spectra could still be discerned even after substantial primary ion dose. It is well-known that organic secondary ion emission appears to decay exponentially with time and primary ion dose. At some point before reaching zero characteristic emission, signal decay ceases. Steady-state emission follows. This is because the primary ion beam also sputters damaged material as it erodes the surface of an organic sample, leaving at least some analyte molecules undamaged. The apparent rate of secondary ion decay decreases with decreasing primary ion kinetic energy provides evidence for this hypothesis. This knowledge could be used in conjunction with the known high depth profile resolution of SIMS to produce organic ion images with spatial resolution of 100 Angstroms or so.

Robert Odom addressed the fundamental differences between obtaining organic SIMS images from pure samples dispersed on grids, and from biological samples where analytes exist as trace components of complex mixtures. Even using exceptionally well-characterized experimental conditions, he noted that generation of organic secondary ions from tissue samples can lead to ambiguous interpretation. For example, images of secondary epinephrine-characteristic ions could be generated from grids loaded with epinephrine. The distribution obtained from actual adrenal tissue was inconclusive, even though the image of the tissue sample was clear. He argued that additional information and research on effects of sample thickness and sample charging will be necessary to make micron-level spatial resolution organic SIMS a useful analytical technique.

WORKSHOP

Use of Mass Spectrometry in Space

Chairman: Carla M. Wong-- NASA Ames Research Center, Moffett Field, CA 94035
Panel: Richard A. Yost-- University of Florida, Gainesville, FL 32611
Steve L. Durfee-- Somatogenetics Instruments, Inc., Broomfield, CO 80020
George Wood-- NASA Langley Research Center, Hampton, VA 23665

(Attendance ~ 100)

The purpose of this workshop was to bring to the attention of the mass spectrometry community some of the very complex analytical problems facing NASA, some of the differences in the working environment that have to be addressed in the solution of these problems and some of the ideas currently being considered. This report is a summary of all information provided in either written or oral form for the workshop.

The most conspicuous use of mass spectrometers in space has been in the analysis of the terrestrial and planetary atmospheres. This activity has spanned more than forty years. It has included rocket-borne experiments with recoverable cryogenic sampling systems to analyze the rare-gas concentrations and atmospheric composition as a function of altitude; Balloon and satellite borne mass spectrometers to determine gas and aerosol composition in the stratosphere and charged particle composition of the ionosphere and magnetosphere; Lunar and Planetary mass spectrometers to analyze the atmospheres of the Moon, Venus, and Mars; and, Energetic ion mass spectrometers to analyze the coma of Halley's Comet. Mass spectrometry will continue to have a predominate role in these applications, both in the forthcoming Galileo mission to Jupiter and in proposed terrestrial studies. An example of the latter is the Downward-deployed Tethered Satellite Program (DOWNTEST), in which instrumented platforms will be deployed downward on long tethers from the Space Shuttle or from expendable launch vehicles in order to obtain atmospheric science and hypersonic aerothermodynamic data at altitudes above 90 km. This will, for the first, time provide a significant quantity of data in the upper half of the region often referred to as the "Ignorosphere". This region, which lies between 55 and 150 km, is too high to be accessed by balloons or research aircraft and too low for orbiting satellites, and has so far been studied only with sounding rockets and to a lesser extent by the re-entering space shuttle. Mass spectrometers will be used on these tethered satellites to measure both the free-stream composition and density, and the composition of the gases in the boundary layer associated with the satellite surface. Both neutral and charged species will be measured over an extended period of time and over dramatically changing experimental conditions as the satellite slowly descends since the orbiting host vehicle will be capable of providing station-keeping, steady state data which will include diurnal variations in composition, density, and solar flux, can be obtained over periods of several orbits.

Of no lower importance are the less conspicuous applications of mass spectrometry in space related activities. Mass spectrometers have been used to monitor gas composition in ground-based research facilities; in studies of spacecraft materials; and, in monitoring the natural atmosphere in the Space Shuttle during fueling operations. They have been used to identify and quantitate outgassing products from materials to be used in the inhabited areas of the spacecraft and will be critical to the development and implementation of life-support systems for long term manned missions on the Space Station and the expedition to Mars. In addition to meeting analytical and control function requirements, while at the same time assuring long term reliability, the instrument system will have to meet the power, weight, and volume constraints imposed by the spacecraft or space station, for which there is a great deal of competition from other on-board systems. These life-support applications will therefore require challenging new developments in instrument configuration and performance, and in automated operation and data reduction methods.

A recent research area has shown that MS/MS capabilities of the ion trap are extremely promising for rapid, sensitive, and selective trace detection for life-support applications. In particular, evaluation of the sensitivity and dynamic range of the ion trap in the MS mode (using automatic control of the ionization time) and of the efficiency of the MS/MS mode suggest that the ion trap may well become the most sensitive MS/MS instrument ever. Another plus for space

applications is that ion trap tandem mass spectrometry offers ease of computer integration for automated control, testing and decision making. Optimization of instrumental sensitivity and resolution involves only electronic, not mechanical, adjustments. Alternating between operational modes (ionization type, ion polarity, MS/MS scan mode) can therefore be accomplished rapidly as the analytical results dictate. Similarly, testing of the instrumental performance (mass calibration, resolution, sensitivity) can be automated. MS/MS with a quadropole ion trap offers an ideal opportunity for instrumental optimization, evolution of analytical protocols, and decision-making by artificial intelligence.

Traditionally, this intelligence and knowledge for decision-making has been provided by highly trained scientists (typically a Ph.D. mass spectrometrist). If such an individual is not to be continually stationed on board the space station, then these requirements will have to be met by telemetry to experts earthside or by artificial intelligence/expert systems on the station.

Artificial intelligence/expert systems have been demonstrated for on-line analysis with real-time optimization (tuning) of instrumental parameters of triple quadropole tandem mass spectrometer; and, recently the first commercial tandem mass spectrometer to implement expert system tuning was introduced. One of the earliest artificial intelligence systems developed, heuristic DENDRAL, was designed to elucidate molecular structure from mass spectrometry; and, recently AI techniques have been expanded to include MS/MS data. The challenge is to extend AI/expert system approaches to the entire analytical process from instrument control to decision-making (screening and confirmation).

Another possible techniques to be considered because of compactness, high speed, and ease of sample preparation is Curie-point pyrolysis for analyzing mixtures and non-volatiles. An added advantage is that computerized methods of pattern recognition may be readily applied to the data, which permits a high level of interpretation by relatively inexperienced interpreters or by artificial intelligence (AI) software. Pattern recognition methods would be necessary to provide data which the AI could then interpret and act upon. The pattern recognition would not make decisions, but would place the data in a state such that a decision could be made.

There is a large body of literature describing the successful analysis and interpretation of highly complex organic mixtures using pyrolysis mass spectrometry (Py/MS) with computerized pattern recognition. Recent work has involved the identification of several species of bacteria which amply illustrates the power of this technique, and, which could be very useful in analysis of manned space environments.

In one experiment, four species of *Mycobacteria* were cultured, applied to Curie point wires, analyzed by Py/MS and interpreted by Principal Component Analysis. Each of the species could be distinguished from the others. In other experiments, two variants of a mycobacterium, which differed with respect to virulence, were distinguished.

In a third set of experiments, forty mixtures were prepared of four species of bacteria (*Proteus vulgaris, Pseudomonas fluorescens, Escherichia coli* and *Enterobacter aerogenes*), pollen and atmospheric particulates. It was possible to determine the relative concentrations of each component in the mixtures, and to identify the species of bacteria in every case despite the varying concentrations of pollen and particulate background. In these experiments, the mass of the bacteria in the mixtures was about one-third of the total mass; by using tandem mass spectrometry this fraction could be significantly lowered.

In summary, recent developments in mass spectrometric instrumentation, analytical methods and data interpretation show great promise for space applications.

Young Mass Spectrometrists Interest Group Report

The Young Mass Spectrometrists Interest Group held a workshop entitled "Write It Right" at its traditional time of Sunday evening with suitable refreshments (provided by the Group's benefactor, John Wiley & Sons) to kick-off the ASMS Conference in an appropriate manner. The subject of the workshop was proposal writing, and the attendance was approximately 120, demonstrating the importance of this topic. A group of distinguished ASMS members talked about different aspects of obtaining funding based on extensive experiences. First, Graham Cooks and Ken Busch spoke from the vantage points of senior and junior academicians, mainly on NSF proposals. Next, Sue Weintraub explained how NIH shared instrumentation grants can be obtained. Bob Cotter then talked about both NIH and NSF funding procedures. Finally, Paul Goodley offered an alternative funding source through a little-publicized Hewlett-Packard program. The format then became question-and-answer, with great interest displayed especially by the younger members as noted by the copious note-taking. In summary, the key elements to a successful proposal include knowing your funding source desires and requirements, an organized and well-written proposal and learning from rejection. The suggestions for next year's workshop include a follow-up on proposal writing with representatives of the funding agencies, careers for mass spectrometrists and a collaborative workshop with the History Interest Group.
