INTRODUCTION

This volume represents the official record of the annual meeting and is designated as the Proceedings of the 40th ASMS Conference on Mass Spectrometry and Allied Topics.

The extended abstracts contained in the Proceedings provide brief descriptions of the research presentations made at the meeting and include both oral and poster contributions. In addition, reports from workshops and interest groups and the ASMS business meeting are included.

Special thanks are given to Hank Fales for overseeing the arrangement of the technical program and Judith A. Sjoberg and her staff of Professional Association Management for coordinating the printing and distribution of the Proceedings.

Alan G. Marshall
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 40th ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

Author(s); title; Proceedings of the 40th ASMS Conference on Mass Spectrometry and Allied Topics, Washington, DC, May 31 - June 5, 1992.

THE 40th ASMS CONFERENCE ON MASS SPECTROMETRY AND ALLIED TOPICS
May 31 - June 5, 1992

LISTING OF EXTENDED ABSTRACT TITLES BY SESSION vii

ABSTRACTS

Monday Orals

New Directions in Mass Measurement 1
Carbohydrates & Oligosaccharides/Pharmacology 12
MS/MS 39
Ion Molecule Reactions and CI "I" 65
MS in Hydrocarbon Research, In Memory of Thomas Aczel 91

Monday Posters

Fullerenes/Clusters 110
Ion Molecule Reactions & CI 138
Instrumentation 192
Polymers 261
Lasers/Matrix Assisted Laser Desorption 299
LC/MS 380
Surface Science for Organic & Thin Film Analysis 440

Tuesday Orals

Electrospray 469
Environmental Analysis-New Solutions to Old Problems 497
Instrumentation/Ion Dissociation Activation 507
Biochemistry 537

PDMS -Special Poster Session 564

Tuesday Posters

Electrospray 586
Environmental 647
FT/MS & Ion Traps 701
Fuels & Geoscience 752
Inorganic/Elemental/Isotope Ratios 776
Ion Activation & Dissociation 801
Pharmacology/Drugs I 852
Protein 925

Wednesday Orals

Environmental Mass Spectrometry 979
FT/MS & Ion Traps 997
Inorganic/Elemental/Isotope Ratios 1023
Ion Molecule Reactions/CI II 1043
Fullerenes & Mass Spectrometry 1067

Wednesday Posters
Biochemistry 1071
Computational 1133
Ion Molecule Reactions/CI II 1173
LC/MS 1250
MS/MS 1316
Reaction Mechanisms 1391

Thursday Orals
LC/MS & Thermospray/Particle Beam 1440
Fullerenes/Clusters 1466
Frontiers in Immunology 1492
Computational/Reaction Mechanisms 1496

Thursday Posters
Biochemistry II 1517
Carbohydrates & Oligosaccharides 1583
Electrospray II 1617
Environmental II 1687
FT/MS & Ion Traps 1727
Peptide Sequencing 1785
Pharmacology II 1841

Friday Orals
Lasers/Matrix Assisted Laser Desorption 1907
Proteins/Peptide Sequencing 1933
Spatially Resolved Organic Surface Analysis 1955

Plenary Lecture, By Jet on a Joyous Jag, John B. Fenn 1964
Recipient of 1992 Award for Distinguished Contribution to Mass Spectrometry

INDEX OF AUTHORS 1968

INDEX OF KEY WORDS 1997

MINUTES OF THE ASMS BUSINESS MEETING 2034

WORKSHOP AND INTEREST GROUP MEETING REPORTS
Young Mass Spectrometrists, "Introduction to Management" 2036
The Status of Federal Grants 2038
Isotopic Applications Interest Group 2040
Fuels & Geoscience 2041
Purchasing an Instrument: Perils & Pitfalls 2043
Present Issues in Elemental Analysis by Mass Spectrometry 2047

1992 ASMS MEMBERS AND CONFERENCE ATTENDEES 2048

ASMS BOARD OF DIRECTORS

President	Robert C. Murphy The Nat'l Jewish Center for Immunology & Respiratory Med. 1400 Jackson Street Denver, CO 80206
Vice President for Programs	Henry M. Fales National Institutes of Health Building 10, Room 7N 318 Bethesda, MD 20892
Vice President for Arrangements	Sanford P. Markey Nat'l Inst. of Mental Health Building 10, Room 3D40 Bethesda, MD 20892
Secretary	Brian Chait The Rockelfeller University 1230 York Avenue New York, NY 10021
Treasurer	P. Jane Gale Bristol Myers Squibb Post Office Box 191 New Brunswick, NJ 08903-0191
Member-at-Large (Publications)	Alan G. Marshall The Ohio State University 120 West 18th Avenue Columbus, OH 43210
Member-at-Large (Education)	Robert J. Cotter Johns Hopkins University Department of Pharmacology Baltimore, MD 21205
Member-at-Large (Measurements and Standards)	Michael T. Bowers Department of Chemistry University of California Santa Barbara, CA 93106
Past President	Ronald A. Hites SPEA 410 H Indiana University Bloomington, IN 47405
Executive Director	Judith A. Sjoberg 815 Don Gaspar Santa Fe, NM 87501 (505) 989-4517

INTEREST GROUP COORDINATORS

Academic Lab Managers	Thomas R. Sharp Pfizer Central Research (203) 441-5932
Biomedical Applications	Steven A. Carr Smith Kline & French (215) 270-6650
Computer Applications	David E. Smith Perkin-Elmer Nelson (408) 725-1107
Desorption Ionization	Richard Van Breemen North Carolina State Univ. (919) 747-2942
Elemental Analysis	Robert (Sam) Houk Iowa State University (515) 294-9462
Environmental Applications	Marcus Wise Oak Ridge Nat'l Laboratory (615) 574-4867
Fundamentals	Robert R. Squires Purdue University (317) 494-7322
History of Mass Spectrometry	Alfred L. Yergey NIH (301) 496-5531
Instrumentation & Ion Physics	Ben S. Freiser Purdue University (317) 494-5270
Isotopic Applications	E. L. (Larry) Callis Los Alamos Nat'l Laboratory (505) 667-9868
LC/MS & Related Topics	Ross C. Willoughby Extrel Corporation (412) 967-5708
Physical Organic	Douglas F. Barofsky Oregon State University (503) 737-1769
Surface Science	John A. Chakel Charles Evans & Associates (415) 369-4567
Young Mass Spectrometrists	John Stults Genentech (415) 266-1203

ASMS COMMITTEES

Asilomar Conference	Laszlo Tokes (chair) Syntex Research (415) 855-5713
	Arnie Falick J. Ronald Hass Alan G. Marshall Robert C. Murphy
Audit	Kelsey D. Cook (Chair) University of Tennessee (615) 974-8019
	Frank H. Field Peter J. Todd
Education	Robert J. Cotter (Chair) Johns Hopkins University (301) 955-3431
	Elizabeth Stemmler James A. Kelley Mark M. Ross Rodger L. Foltz
Measurements & Standards	Michael T. Bowers (Chair) Univ. of Calif. Santa Barbara (805) 893-2893
	John Bartmess Phillip C. Price Sharon Lias Anne Giordani
Nominating	Ernest Bonelli (Chair) Hewlett-Packard Instruments (415) 857-6028
	Jean Futrell R. Graham Cooks Michael Story Julie A. Leary
Sanibel Conference	Mark M. Ross (Chair) Naval Research Laboratory (202) 767-3148
	Jeanette Adams Vernon Reinhold Edward Chess Robert J. Cotter

MONDAY ORALS

Symposium: New Directions in Mass Measurement

FT/ICR/MS at the Extremes: High and Low Mass; Dynamic Range; CID Energy; Mass Accuracy; Ion Abundance Accuracy 1

Mass/charge Measurements with the Quadrupole Ion Trap 3

The Development of New Matrices and Instruments for Matrix-Assisted Laser Desorption 5

Fast, High Temperature and Thermolabile GC-MS in Supersonic Molecular Beams 6

Linear TOFMS Design Incorporating Post Source Pulse Focusing for Laser Desorption 8

Orthogonal Acceleration TOF-MS: Improved Sensitivity and Resolution with Gaseous Ion Sources 10

Carbohydrates & Oligosaccharides/Pharmacology

Analysis of Oligosaccharides by Liquid Chromatography Mass Spectrometry 12

Linkage Positioning in Sodiated and Permethylated Oligosaccharides Studied by Tandem Mass Spectrometry 14

Application of the Charge-Remote Fragmentation to Ceramide Structure Determinations 16

Characterization of Amorphous Water-Soluble Cyclodextrin Derivatives by Desorption Ionization Mass Spectrometry 18

Analysis of Disaccharides Using a Quadrupole Fourier Transform Mass Spectrometer 20

Mass Spectrometry of Bacterial Glycolipids: Structural Basis of Host Mimicry in the Surface Lipooligosaccharides of Human Mucosal Pathogens 22

Glycopeptide Mapping Using Capillary or Microbore HPLC Interfaced to an Electrospray Mass Spectrometer 24

Fluorescent Derivatives for Determination of Marine Toxins 26

PGH Synthase-Mediated Metabolism of 8,9-epoxyeicosatrienoic Acid 28

Correlation of Stable Isotope Enrichment of Leukotriene with Arachidonic Acid-Containing Phospholipids by Negative Ion FAB/MS/MS 30

Trace Detection of Drugs in Milk and Meat Using Direct Sampling ITMS 32

Identification of NHCC as a Urinary Metabolite of the Antineoplastic CCNU in Patients & in the Rat: Evidence for 34

the Formation of an Isocyanate Intermediate

Determination of Furfurals, Angelica Lactones and Phthalic Anhydride in Mainstream and Sidestream Particle/Vapor-Phase Cigarette Smoke 36

The Evaluation of Some Penicillins by ES LC/MS and by ES ITMS 37

MS/MS

Neutralization-Reionization with a Tandem Quadrupole Mass Spectrometer 39

The Neutral Products from Peptide Ion Fragmentations 41

Gas Phase Chemistry of Elusive Neutrals 43

Gas-Phase Fragmentation of Anionic Complexes of Ser- and Thr-Containing Peptides 45

Analysis of Isotope Distributions in Isotopomeric Peptides by High Performance Tandem Mass Spectrometry 47

Peptide Analysis by Hybrid Tandem Mass Spectrometry. The Case for Higher Collision Energy and RF Power 49

Capillary Electrophoresis Coaxial Continuous Flow FAB Combined with Array Detection Mass Spectrometry 51

Tandem Mass Spectrometry Combined with Nanoscale Separation Techniques: Capillary Electrophoresis and 75 id Packed Capillary LC 53

Tandem Mass Spectrometry of Matrix-Assisted Laser Desorbed Ions Using a Magnetic Sector/Reflectron Time-of-Flight (EB/TOF) Mass Spectrometry 55

Fundamentals of the MS/MS Experiment in an Ion Trap Mass Spectrometer 57

Tandem Mass Spectrometry of FAB-Desorbed Polycyclic Aromatic Hydrocarbons 59

Sequential Product Ion Spectra (MS3 and MS4) with Array Detection and Reaction Intermediate Scanning on a Four-Sector Instrument 61

Direct Sequential Analysis of Large Peptides by High Energy Collisional Activation of Multiply Charged Ions 63

Ion Molecule Reactions and CI

On the Ionization Energies of CCl3 and CF3 Radicals 65

Reactions of State Selected Co+ with CH3I 67

Probing the Unusual Kinetic Behavior and Ion Chemistry of Si2C2+ 69

Kinetics as a Probe of Host-Guest Chemistry in Ion-Molecule 71

Reactions: Molecular Recognition and Macrocyclic Effects

Energy Dependent Intramolecular Reactions of Crown Ether/Amine Complexes 73

Gas Phase Proton Transfer Reactions of Serinamide, Argininamide, and Histidinamide 75

Gas-Phase Reaction of Polyhalogenated Plasma Radical Species 77

Gas Phase Reactions of Sc+, Ti+, and V+ with Amines (Men,NH3-n) and Phosphines (MenPH3-n) 79

Charge Exchange Ion-Molecule Reactions as a Probe of Metastable Electronic States of Atomic Transition Metal Ions 81

The Gas-Phase Basicity of Polyglycines 83

A Classical Trajectory Investigation of the H2+/H2 Proton/Atom Transfer Reaction 85

Pulsed FT/ICR Chemical Ionization Mass Spectra of Organosilanes 87

Gas-Phase Ion Molcule Reactions of Biomolecules in Matrix-Assisted Laser Desorption with FTICR 89

Heavy Petroleum Hydrocarbons Characterized by On-Line LC/MS 98

Symposium: Mass Spectrometry in Hydrocarbon Research, In Memory of Thomas Aczel

Three-Plus Decades in Petroleum Mass Spectrometry and Memories of Thomas Aczel 91

Selective Detection and Quantitation in Mass Spectrometry: A Comparison of Relative Sensitivities for Low Voltage Electron Ionization and Benzene Charge Exchange 93

Mass Spectrometry and Buckyballs 95

Quantitative Measurement of Radical Intermediates by Molecular-Beam-Sampling-Mass-Spectrometry 97

Tentative Identification of High Molecular Weight Monocyclic Saturated Hydrocarbons by High Temperature GC Field Ionization Tandem Mass Spectrometry (HTGC-FIMS-MS) 100

Molecular Geochemistry: Application of Mass Spectrometric Techniques to Petroleum Exploration 102

FI/FDMS Characterization of Refinery Stream and Crude Oil 104

Characterization of Petroleum Contamination in Soil by Field Ionization/Probe Microdistillation/Mass Spectrometry 106

Field Ionization Mass Spectrometric Analysis of Lubricating Oil Additives 108

MONDAY POSTERS

Fullerenes/Clusters (Page 110 - 137); Ion Molecule Reactions & CI (Page 138 - 191); Instrumentation (page 192 - 260); Polymers (Page 261 - 298); Lasers/Matrix Assisted Laser Desorption (page 299 - 379); LC/MS (Page 380 - 439); Surface Science for Organic & Thin Film Analysis (Page 440 - 563)

Laser Ionization Mass Spectrometry of Fullerenes 110

High Performance Separation and Mass Spectrometry Characterization of Fullerenes 112

Fullerene Fluorination: Evidence for Product Instability at C60F48 114

Analysis of Fullerenes and Fullerene Derivatives by Laser Desorption FT/ICR Mass Spectrometry 116

Laser Desorption FT/ICR/MS: Platinum and Carbon Clusters from Carbon Electrode Materials 118

A SIFT Study of the Ion/Molecule Reactions of Fullerenes 120

On-Line LC/MS Detection of C60 and Larger Fullerenes 122

Ionization Potentials of Small Carbon Clusters (Cn,n=2-6) 124

Electron Affinities and Ion/Molecule Reactions of Carbon and Silicon Clusters 126

Inelastic Scattering and Endohedral Complex Formation in High-Energy Collisions of Fullerenes with He 128

Formation of Large Aluminum Cluster Ions by Direct Laser Vaporization of Aluminum Nitride 130

Mass Spectra of Mercury/Alkali and Noble Metal Complex Clusters 132

Electron and Chemical Ionization Mass Spectra of Some Transition Metal Acetates 134

Extent of Cluster Dissociation in DI. RRKM Calculations 136

Characterization of Extent and Relative Abundance of Electronically Excited Transition Metal Ions Produced by Laser Desorption 138

Reactions of M+ and CpM+ with 1,3,5-Trisilacyclohexane in the Gas Phase. First Observation of the Trisilabenzene Ligand 140

Studies of the Gas-Phase Reactions of Protonated Methanol with Methanol Using Oxygen-18 and Deuterium Labeling 142

Gas-Phase Chemistry of Bis(5-cyclopentadienyl)methyltitanium(+1) with Dihydrogen and Unsatruated Hydrocarbons 144

Ion-Molecule Reactions in the Structural Characterization of Ions 146

Bimolecular Reactions of the Molecular Ions of Simple Organic 148

Esters

Ion Molecule Reactions of Protonated Propylene Oxide and its Isomers with H2S 150

Ion Molecule Reactions of Distonic Radical Cations 152

Ion-Molecule Reactions of Dicoordinated Borocations with Alcohols, Ketones, Aldehydes and Bifunctional Organic Compounds 154

Reactions of Ar+ with Halocarbons and I+ with CF3I 156

Reactivity of Distonic Radical Cations with Self-Assembled Monolayer Surfaces 158

Hydrogen Bonding in , , -dialcohols 160

Determination of Relative Cation Affinities of Crown Ethers and Other Ionophores Using FTMS 162

Observation and Characterization of Gas-Phase Complexes of Alkali Metal Cations with Natural Ionophores 164

How do Electric Fields Effect Proton Transfer Reactions? 166

Effect of Halogenation and Metal Substitution on the Electron Affinities and Reactivities of Metalloporphyrins 168

Reactions of M+ and MCO+ (M=Cr, Mn, Fe, Co, Ni) with O2 and NO2 170

Proton Affinities of Peptides Assessed Using the Kinetic Method in an EBE Mass Spectrometer 172

Reactions of Propene and Cyclopropane Radical Cation with Neutral Ethylene: An Application of the Rf-Only-Mode Event to High Pressure Ion Chemistry in FTMS 174

Gas Phase Reactivity of Aromatic Hydrocarbon Cations Toward Imidazole 176

An Experimental Strategy for Studying Bimolecular Reactivity of Distonic Ions: Application of the RF-Only-Mode Event in FTMS 178

Nucleophile/Electrophile Ion/Molecule Reactions in a Quadrupole Ion Trap Mass Spectrometer 180

Classical and Non-Classical Forms of the C2H5+ Ion and Their Participation in the Ions RO+(C2H5)R′ 182

NICI Mass Spectra of Alkyl Esters of Dicarboxylic Acids 184

Ion-Neutral Complex-Mediated Decompositions of Ionized Dialkoxyalkanes 186

Mass Spectrometric Detections of Radicals in a CH4 Microwave Discharge Plasma by Usage of Li+ Ion Attachment Techniques 188

Ion-Molecule Reactions of Copper Cluster Ions with Alcohols and Hydrocarbons 190

Design and Construction of a Simple SFC/MS Interface 192

Modification of a Vestec Electrospray Ion Source for Ionspray Operation 193

Laser Desorption and Electrospray Ionization Interfaces for Capillary Electrophoresis with Tandem Time-of-Flight Mass Spectrometry 195

Implementation of Ion Spray on a Benchtop Saturn II Quadrupole Ion Trap 197

A Flow Injection Interface for Electrospray Ionization Mass Spectrometry with a Small Quadrupole Mass Spectrometer 199

An Atmospheric Pressure Chemical Ionization Interface for LC/MS on a Magnetic Sector Mass Spectrometer 201

Real-Time Mass Spectrometric Evaluation of Olfactometer Performance 203

Direct Thermal Analysis of Chewing Gums for Terpines, Sesquiterpines and BHT 205

Flow Injection Thermospray Mass Spectrometry for the Automated Analysis of Potential Agricultural Chemicals 207

Fast Neutral Beam Ionization FT/ICR Mass Spectrometry of High Molecular Weight Compounds 209

Analysis of Reactive Gases with Quadrupole MS and GC/MS 211

Mass Spectrometric Studies of Simple Olefinic Flames at Low Pressures 212

Fundamental Investigations with a New Atmospheric-Sampling Glow Discharge Ionization Source 214

A Glow Discharge Ion Source for the Analysis of Organic Compounds in Gaseous or Liquid Phase 216

Adaptation of a Triple Quadrupole Mass Spectrometer to Permit Glow Discharge Studies 218

A Microwave Induced Plasma Source for Trace Analysis 220

A Dual Ion Source to Produce Cs+ or I- Ions for Secondary Ion Mass Spectrometry 222

Pulsed Liquid SIMS on a Four-Sector Tandem Instrument with Array Detector 224

Relative Ion Yield Measurements in Liquid Matrix Assisted Secondary Ion Mass Spectrometry 226

Vaporization vs Thermal Decomposition in LD, Pulsed FAB, and Pulsed Rapid Heating Processes 228

Novel Monopole Operations of an Ion Trap Detector 230

Desorption of Ions from Glycerol Films by Backside Impact with Massive Cluster Ions 231

Operating Characteristics and Reliability of Channel Electron Multipliers in ICP-MS 233

Characteristics of High Gain Single Channel Electron Multipliers Under High Ion Dose Conditions 235

Enhanced Ion Detection Resulting from Reductions in the Surface Work Function 237

An Innovative Detector Design for the Ion Trap Mass Analyzer 239

Adjustable Multipole Elements in Sector Field Mass Spectrometers 241

Ion Trajectories and Focusing Properties of an Electrostatic Ion Mirror and a Solenoid Coil Represented by Transfer-Matrices 243

Analysis of 1-(2,6-difluorophenyl)-1H,3H-Thiazolo[3,4-a]benzimidazole (TBI) and Its Metabolites by Atmospheric Pressure Chemical Ionization LC/MS 245

Design of a Time-of-Flight Mass Spectrometer for a Plasma Source 247

Ion Optical Invesitgation of Deceleration Lens System 249

Design, Construction and Preliminary Operation Parameters of a Transportable Molecular Beam Mass Spectrometer with Quadrupole and Time of Flight Detectors 251

Analysis of Complex Biological Samples by Gas Chromatography/Time-of-Flight Mass Spectrometry with Time-Array Detection 253

Comparative Study of Alternative GC-FTIR-MS Methods 255

Supercritical Fluid Extraction for GC/MS Sample Preparation 257

Relaxation Spectroscopy with a Specially Designed Time-of-Flight Mass Spectrometer 259

A Precise Method of Determining Sample Temperature During Vacuum Pyrolysis 261

An Investigation of the Thermal Decomposition of Polyethylene Glycol, A Ceramic Binder, by Gas Chromatography Mass Spectrometry 263

Mass Spectrometry of Polymeric Hindered Amine Light Stabilizers 265

Mass Spectrometric Study of the Degradation of a Perfluorinated Copolymer by Nitrogen Tetroxide 267

The Use of Direct Insertion Probe Mass Spectrometry to Determine the Structures of Dialkyl Polysulfides 269

Applications of Desorption Chemical Ionization (DCI) Mass Spectrometry to Polymer Analysis 271

An Evaluation of the Desorption Chemical Ionization Mass Spectrometry of Organosilicon Polymers 273

Time of Flight Secondary Ion Mass Spectrometry of Polybutadienes 275

Static Secondary Ion Mass Spectrometric Analysis of Polymeric Materials Using a Magnetic Sector Mass Spectrometer 277

High Resolution TOF-SIMS Studies of Substituted Polystyrenes 279

Tandem Mass Spectrometry (MS/MS) of Poly(ethylene glycol) Hydrogen-Attachment Ions 281

Laser Microprobe Mass Spectrometry of Certain Synthesized Copper Complexes and Their Analogs Formed in the Laser Induced Plume 283

Study of Experimental Parameters for Laser Desorption FTMS Analysis of Nonpolar Polymers 285

cw-CO2 Laser Polymer Pyrolysis in a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer 287

Laser FTMS of Perfluorinated Polyethers 289

Matrix-Assisted Laser Desorption Ionization of Synthetic Polymers 291

Analysis of the Non-Soluble Ether Fraction of Baltic Amber 293

Surface Characterization of Polymer Films and Additives Using Time-of-Flight Static Secondary Ion Mass Spectrometry 295

New Calibration Compounds for Positive and Negative Ion High Resolution Fast Atom Bombardment Mass Spectrometry 297

Matrix-Assisted UV-Laser Desorption/Ionization MS Determination of the Loading Values for Anti-Cancer Drugs and Sugars Conjugated to Proteins 299

Can Protein-Cofactor Interactions be Determined by Matrix-Assisted LD-MS? 301

LD-TOF Mass Spectrometer Response: Comparison with Traditional Biochemical Methods 303

Matrix-Assisted Laser Desorption Mass Spectrometry of Proteins Isolated from Capillary Zone-Electrophoresis 305

Matrix-Assisted Laser Desorption Mass Spectrometry of Neuropeptides 307

Use of an Ion-Pairing Agent for Enhanced Sensitivity of LDMS Anaylsis of Oligonucleotides 309

Laser Ablation Mass Spectrometry for DNA Sequencing 310

Analysis of Oligonucleotides by Matrix-Assisted Laser Desorption Mass Spectrometry 312

Matrix Assisted Laser Desorption of Oligonucleotides 314

Characterization of Radiation-Induced Damage to Nucleic Acid Constituents by Matrix-Assisted Laser Desorption FTMS 316

The Analysis of Polymers by Matrix-Assisted Laser Desorption/Time-of-Flight Mass Spectrometry 318

Matrix-Assisted Laser Desorption Mass Spectrometry of Complex Oligosaccharides 320

Analysis of Porphyrin Mixtures Using Liquid Matrix-Assisted Laser Desorption Mass Spectrometry 322

Development of a UV-Laser Microprobe with Coaxial Optics for Laser Desorption, Sample Observation and Ion Extraction 324

Direct and Matrix-Assisted Laser Desorption on a Compact Time-of-Flight Mass Spectrometer 326

Construction and Performance of a Laser Desorption/Ionization TOF Mass Spectrometer System: Applications to Problems in Peptide, Protein and DNA Structural Analysis 328

Two-Laser Multiple Photon Dissociation in a Modified White - Type FTICR Cell 330

Comparison of Multiphoton, Single Photon and Electron Impact Ionization Mass Spectra of Laser Desorbed Neutrals 332

Matrix-Assisted Laser Desorption of Neutral Molecules Followed by Multi-Photon Ionization and TOF Mass Analysis 334

Analysis of Polycyclic Aromatic Hydrocarbons in Extraterrestrial Samples 336

The Degrees of Freedom Effect Revisited: A Comparison of Multiphoton Ionization and Electron Impact Mass Spectra 338

Vacuum Ultraviolet Laser Ionization Gas Chromatography/Time-of-Flight Mass Spectrometry 340

Laser Desorption - Laser Photoionization Time-of-Flight Mass Spectrometry Applied to the Direct Analysis of Polycyclic Aromatic Hydrocarbons in Soots 342

Mass Spectrometry of Polycyclic Aromatic Hydrocarbons: The Conflict of Photochemistry with Ion Ejection 344

Matrix-Assisted Laser Desorption Using a Magnetic Sector Mass Spectrometer 346

Matrix Assisted Laser Desorption in a Magnetic Deflection Mass Spectrometer 348

Problems with Mass Resolution in Matrix Assisted Laser Desorption TOF-MS and Practical Solutions 350

Design and Application of a Simple MALD-TOF Instrument 352

Laser Desorption vs Fast Atom Bombardment Which is Better? 354

Direct Measurement of the Kinetic Energy Distribution of Particles Generated by Matrix Assisted Laser Desorption 356

Determination of Post-Source Ion Kinetic Energies in Time-of-Flight Mass Spectrometry 358

Experimental Study of Ion Ejection Processes in Matrix Assisted Laser Desorption (MALD) 360

Comparison of Arrival-Time-Distributions of Mass Selected Ions Produced Using Matrix Assisted Laser Desorpton Ionization 362

Internal Energy of Matrix-Assisted Laser Desorbed Neutrals Probed by Single Photon Ionization 364

Comparison of Laser Desorption Kinetic Energy Effects on Detection by Time-of-Flight and FTICR Mass Spectrometry 366

Matrix-Mixtures for a Superior Performance of Matrix-Assisted Laser Desorption Ionization Mass Spectrometry 368

Substrate-Assisted Laser Desorption of Neutral Peptide Molecules 370

Experimental Studies on the Mechanism of Matrix-Assisted Laser Desorption 372

Evidence for Matrix Photochemistry Occuring During the Matrix-Assisted Laser Desorption Experiment 374

Investigation of Issues Related to the Preparation of Recombinant Proteins for Analysis by maLD/TOF-MS 376

High Resolution Matrix-Assisted Laser Desorption of High Molecular Weight Ions Using a Time-of-Flight Mass Spectrometer with Reflector 378

Strategies for HPLC-Accurate Mass FAB Measurements 380

Study of the Performance of Capillary Liquid Chromatography-Fast Atom Bombardment Mass Spectrometry Systems Using Pre-Column Addition of Viscous Matrices 382

Evaluation of the Chromatographic Boundaries within which Pre-Column Addition of Viscous Matrices can be Used in LC-FABMS 384

Changes in Selectivity Induced by Pre-Column Addition of Viscous Matrices in LC-FABMS Systems Using Ion-Pairing Chromatography 386

Capillary Liquid Chromatography/Continuous Flow Fast Atom Bombardment Mass Spectrometric Analysis of DNA Adducts from In Vitro Reaction Mixtures 388

Development of a Condensation Technique for TLC/FABMS 390

Nanoscale Separations of Biomolecules in Combination with Coaxial Continuous Flow-FAB Mass Spectrometry 392

Two-Dimensional Electroseparation Methods Coupled with Mass Spectrometry 394

The Detection of Abscisic Acid Sugar Conjugates in Plant Material Using Continuous Flow Packed Fused Silica Capillary Liquid Secondary Ion LC/MS/MS Using Reaction Monitoring 396

Monitoring of Drug Urinary Excretion by On Line Immunoaffinity Extraction/HPLC/Continuous Flow Fast Atom Bombardment 398

Identification of Isoflavonoid Conjugates in Alfalfa (Medicago Sativa L.) by Tandem LC/CF-LSIMS 400

Systematic Characterization of Electrospray Mass Spectrometry for Liquid Chromatography Mass Spectrometry Interfacing 402

Combined Liquid Chromatography/Electron Paramagnetic Resonance Spectrometry/Electrospray Ionization Mass Spectrometry for Radical Identification 404

Design and Performance Characteristics of a Particle Beam Interface and an Electrospray Interface 406

CE/ESI-MS in Small (<20 m) Diameter Capillaries 408

Comparison of Thermospray and Electrospray LC-MS Techniques for Analyses of Glycosides and Related Compounds 410

Ion Spray Liquid Chromatography/Mass Spectrometry from the Viepoint of the Liquid Chromatographer 412

High Flow Electrospray Interface for Liquid Chromatography/Mass Spectrometry 414

Confirmation of Danofloxacin Residues in Poultry and Cattle Liver by Microbore HPLC-Tandem Atmospheric Pressure Ionization MS 416

Analysis of Normal and Abnormal Hemoglobins by Liquid Chromatography/High Flow Electrospray Mass Spectrometry 418

LC-MS and LC-MS-MS Characterization of Lysophosphatidylcholines and Acylcarnitines Present in the Ischemic Region of Dog Hearts 420

Use of CE/ESI-MS to Investigate Solution and Gas Phase Protein Conformation 422

Improved Methods for the Determination of Veterinary Antibiotics Using Nanoscale Separation Techniques in 424

Combination with Electrospray Mass Spectrometry

Separation of Penicillins and Cephems by Nanoscale LC/ESI/MS Using 75 ID Packed Capillary Columns 426

Assessing Structural Alterations in Natural and Recombinant Proteins by RP-LC/ESI MS 428

DNA-Carcinogen Adduct Analysis by Ion-Spray Liquid Chromatography-Mass Spectrometry 430

Determination of the Macrolide Antibiotic Erythromycin A in Biological Matrices by LC-MS and CE-MS with Atmospheric Pressure Ionization 432

Electrospray Mass Spectral Analysis of the (N)- Arylazido- - Alanyl NAD+ Modified Bovine Heart Mitochondrial NADH Dehydrogenase 434

LCMS Analysis of Complex Synthetic Organic Molecules Utilizing Electrospray Ionization 436

An Atmospheric Pressure Chemical Ionization (APcI) Interface for LC Analysis of Drugs and Environmental Compounds 438

Hyperthermal Surface Ionization of Organic Molecules 440

Molecular Characterization and Spatial Analysis of Organic Surfaces by Time-of-Flight SIMS 442

Correlating Analyte Concentration with Fragmentation Behavior in Liquid SIMS 444

Time Dependence and Surface Phenomena of Secondary Ion Emission from Solution 446

The Dynamics of SN2 Reactions in the Gas Phase 1054

Gas-Phase Ion Chemistry of Distonic Radical Cations 1056

Ion-Molecule Reactions of Ionized Butenes in a Triple Quadrupole Mass Spectrometer 1058

Ion-Molecule Reactions of tert-Butyl Cation with Tertiary Alcohols 1060

Differentiation of Organic Nitroxyl and Hydroxylamine Analogues by Chemical Ionization Using Ammonia as Reagent Gas 1061

Selective Ion-Molecule Reactions of Biologically Active Lactones and Lactams in a Quadrupole Ion Trap Mass Spectrometer 1063

Isomers of C3H6N+ and the Interstellar Synthesis of C2H5CN 1065

Symposium: Fullerenes & Mass Spectrometry

Structures of Carbon Cluster Ions 1067

Aromatic Adducts and Reduction Products of Fullerenes Characterized by Mass Spectrometry 1069

WEDNESDAY POSTERS

Biochemistry (Page 1071 - 1132); Computational (Page 1133 - 1172); Ion Molecule Reaction (Page 1173 - 1249); LC/MS (Page 1250 - 1315); MS/MS (Page 1316 - 1390); Reaction Mechanisms (Page 1391 - 1439)

Gas Chromatographic-Mass Spectrometric (GCMS) Assay of Tissue Malonidialdehyde (MDA) and Ohter Aldehydes After Reduction to 1071

Stable Alcohols

Structural Analysis of Epoxy, Hydroxy Fatty Acids by Thermospray LC/MS/MS 1073

Quantitative Analysis of Vitamin K1 and Vitamin K1-Epoxide from Biological Samples by GC-NCI/MS 1075

Evaluation of Pentafluorobenzyl Esters of Substituted Fatty Acids in Structural Analysis 1077

Facile Determination of Alkyl-Branched Fatty Acid Methyl Esters by Tandem Mass Spectrometry 1079

Collision Induced Dissociation of LTB4 and Metabolites Derived from the Pentafluorobenzyl Ester Trimethylsilyl Ether Derivative 1081

Novel Fragmentation of Bispentafluorobenzoyl Esters (PFB)2 of 1-O-Alkyl- and 1-Acyl-2-Lyso-SN-Glycero-3-Phosphocholines and 1-Monoglycerides (1-MG) 1083

A Sensitive Assay for Estrogens in Human Plasma Using Gas Chromatography-Electron Capture Negative Ion Chemical Ionization-Mass Spectrometry (GC-ECNICI-MS) 1085

Enantioselective Metabolism of 14,15-epoxyeicosatrienoic Acid by Human Platelets 1087

Characterization of Vitamin D Metabolites by Static and Dynamic Fast Atom Bombardment Tandem Mass Spectrometry 1089

A General Method for the Simultaneous Analysis of Free Carnitine and Acylcarnitines by GC-MS of Their N-Demethylated Silylated Derivatives 1091

Mass Spectral Characterization of a Primary Hydroperoxy Cholesterol Ester from Oxidized LDL 1093

Immunoaffinity Extraction/GC-MS to Identify Cross-Reacting Compounds in Immunoassays: Evaluation of Antibodies Against Thromboxane Metabolites 1095

Characterization of Platelet Activating Factor Antagonists by Fast Atom Bombardment Mass Spectrometry 1097

Liquid Secondary Ionization Mass Spectrometric Analysis of Novel In Vivo Prostaglandin-Containing Glycerophospholipids 1099

New Approaches to Quantitative Mass Spectrometric Analyses of Lipid Mediators 1101

Pitfalls in Quantitative Analysis of PAF 1103

Pharmacokinetics of Phospholipids by High Dynamic Range, High Resolution FAB Mass Spectrometry 1105

A Gas Chromatography-Mass Spectrometry Assay for Lipid Peroxidation 1107

Membrane Probe for Quantitation of Nitric Oxide in Liquid Systems 1109

Structure Confirmation of Alfalfa Saponins by LSIMS and B/E LSIMS/MS 1111

GC/MS Analysis of Low Molecular Weight Organic Acids and Di-Acids in Aqueous Matrices 1113

Fundamentals of Short-Column GC/MS/MS and Applications to Anabolic Steroid Screening 1115

Tracheal Eicosanoid Measurements Using Microdialysis Sampling and GC/MS Detection 1117

Characterization of Angiotensin II Receptor Subtypes in Isolated Perfused Rat Kidney by Quantitative Analysis of Prostanoids 1119

Endogenous Biosynthesis of 20-Hydroxy-eicosatetraenoic Acid in Humans: Analysis by GC/Electron Capture MS 1121

Analysis of Urinary Nucleosides as Indicators of HIV Infection by GC/MS 1123

FAB/MS Analysis of Nucleoside Derivatives Used to Incorporate Oxidative Lesions into Synthetic Oligodeoxynucleotides 1125

New Strategies for RNA Structure Analysis by Mass Spectrometry 1127

Characterization of Two Novel Nucleosides from Trypanosomal mRNA Cap 4 Oligonucleotide 1129

Comparison of Assays on Thymine Glycol in Genomic DNA by EI vs PCI/MS/MS GC/MS 1131

Interface of a Commercial Visual Data Analysis Software Package to Mass Spectral Data Files 1133

The Use of Generalized Rank Annihilation Method for Mixture Analysis by Neutralization-Reionization Mass Spectrometry 1135

Computer-Assisted Interpretation of Copolymer Mass Spectra 1137

Utilizing an Apple Macintosh Computer for Transfer Display and Interpretation of Mass Spectral Data 1139

Determining Congener-Specific Polychlorinated Biphenyls in Human Serum by Using Isotope Dilution Mass Spectrometry: A Proposed Data Acquisition and Management Scheme 1141

Automated Writing of Selected Ion Recording (SIR) Descriptors and Plotting of Mass Peak Profiles from SIR Data 1143

Interfacing Spreadsheet and Word Processing Software to the VG 250 Data System 1145

Calculation of Pharmacokinetic Parameters Using PC Spreadsheet Macros 1147

Flexible File Format and Library for Storage of Mass Spectral Data 1149

Expanded Data Base of 200,000 Mass Spectra 1151

Testing and Optimization of Mass Spectral Search Algorithms 1153

Efficient Mass Spectra Library Presearch 1155

A User-Configurable Plotting Environment for Mass Spectral Data 1157

The Calculation of Fringing Fields of Quadrupoles 1159

Artificial Intelligence and Mass Spectrometry for Life Support Systems Monitoring 1161

Networking Mass Spectrometer Data Systems for Improved Productivity and Electronic Archival of Data 1163

Automated Alternating Positive Ion/Negative Ion FAB MS Data Acquisition for Routine FAB MS Samples & Automated Data File Processing/Data File Printouts Using a Finnigan MAT TSQ70 Mass Spectrometer/Data System 1165

Automated Data File Transfer from a Finnigan MAT TSQ70 Mass Spectrometer PDP1173 to a Central Vax Computer for Routine Data Archiving 1167

TOFWARE: A Windows-Based Data Acquisition System for Time-of-Flight Mass Spectrometry 1169

Deconvolution of Gas Chromatography/Time-of-Flight Mass Spectrometric Data: A Potential Alternative to Two-Dimensional Gas Chromatography/Mass Spectrometry 1171

Gas Phase Ion - Molecule Chemistry of Cycloheptariene Chromium Tricarbonyl (n6-C7H8Cr(CO)3) by FT-ICR Spectroscopy 1173

Competing Reactions in the Source of a Corona Discharge Atmospheric Pressure Ionization Mass Spectrometer 1175

Gas Phase Cl+ Affinities of Pyridines Determined by the Kinetic Method and MS3 Experiments in a Pentaquadrupole Mass Spectrometer 1177

Reactions of C2H4N+ and Substituted Analogs with Isoprene. Applications of MS/MS and MS/MS/MS in a Pentaquadrupole Mass Spectrometer 1179

Electrophilic Aromatic Chlorination in the Gas Phase 1181

Ion-Surface Reactive Collisions at Functionalized Alkyl-Monolayer Surfaces 1183

Molecular Recognition in the Gas-Phase 1185

Determination of Product Ion Structures Derived from the Reaction of Phenylium and Substituted Phenylium Ions with Neutral Reagent Gases 1187

The Gas-Phase Reactions of OH- with Acrolein and CH2=CCHO- with D2O: Evidence for Rearrangement in the Ion-Molecule Complex 1189

Negative Ion Chemical Ionization of Esters and Related Compounds 1191

SIFT Studies of Reactions of SiH+ 1193

The Proton Affinities of Some Diols Determined by High Pressure Mass Spectrometry 1194

Gas-Phase Ion/Molecule Reactions in a SCIEX TAGA 3000 1196

Ion/Molecule Reactions of SixDy+ with Disilane 1198

Thermal Energy Reactions of H3+ and H30+ with a Series of Small Organic Molecules 1200

A High Pressure Mass Spectrometric Re-evaluation of Proton Affinities of Fluorinated Benzenes [C6HnF6-n] 1202

Details of the Charge Transfer Reaction Between FeCp+ and Ethylene Oxide 1204

Low Pressure Glow Discharge Ionization MS/MS Analysis of Benzene and Toluene in Automobile Exhaust 1206

Gas-Phase Thermochemical Properties and Reactivity of the Bicarbonate and Bisulfite Negative Ions 1208

Development of a Stereochemical Protocol. Reactions and Competitive Dissociations of Pentacoordinate Silicon Ions 1210

Biradical Thermochemistry from CID Threshold Measurements in a Flowing Afterglow-Triple Quadrupole Instrument 1212

Measurement of Gas-Phase SN2 Reaction Rate Coefficients at Atmospheric Pressure Using the Photodetachment-Modulated

Pulsed Electron Capture Detector
The Unimolecular Chemistry of the Protonated Peptide Bond 1216

Application of a Sputtering Glow Discharge Ion Source to a Flowing Afterglow Study of Transition Metal Ion Chemistry 1218

Gas-Phase Proton Affinities of Small Peptides 1220

Bracketing Studies of the Gas Phase Basicities of the 20 Common -Amino Acids using Fourier Transform Mass Spectrometry 1222

Extent of Hydrogen Reduction in the Hydrogen Chemical Ionization Mass Spectra of a Series of Octaethylporphyrins and Tetraphenylporphyrins 1224

Gas-Phase Ambident Reactivity of N-Deprotonated Amides 1226

Chemical Behavior of the Gas-Phase Pentacoordinated Carbonium Ion C2H7+ 1228

Characterization of PAHs by Ion - Molecule Reactions in a Quadrupole Ion Trap 1230

Comparison of Proton to Ammonium Ion Affinities of Crown Ethers and Acyclic Analogs by the Kinetic Method 1232

Thermochemistry and Kinetics of Functional Group-Selective Ion-Molecule Reactions of Disubstituted Ethanes 1234

FT/ICR Mass Spectrometry: Reactions of Gas Phase Lanthanide Ions with Organic Molecules 1236

Nucleophilic Substitution Reactions in Difluorobenzene-Alcohol Mixed Cluster Ions 1238

Determination of Electron Capture Rate Constants Using a Pulsed High Pressure Mass Spectrometer 1240

A Study of the SN2 Reactions of Cl- with Methyl Bromide, Ethyl Bromide, iso-Propyl Bromide and n-Butyl Bromide at Atmospheric Pressure Using an Ion Mobility Spectrometry/Mass Spectrometry Apparatus 1242

Reactions of Benzenoid Ions with Atomic Hydrogen 1244

Isomerization of Alkylbenzenes by Electrostatic Activation During Gas-Phase Protonation 1246

A GC Artifact that Interferes with the Analysis of 1,4-Dioxane in Monoethylene Glycol--Who Says Mother Nature is Not Trying to Trick Us? 1248

On-Line SPE/Clean-Up/SFC-MS of Pesticides in Tissues 1250

Important Experimental Parameters in Thermospray and Particle Beam High-Performance Liquid Chromatography Mass Spectrometry 1252

A New Probe for Use with Thermospray Ion Sources 1254

Flow Injection-Photolysis-Thermospray-Mass Spectrometry 1256

Water is a Useful Calibrant for Thermospray Mass Spectrometry 1258

Analysis of Oligosaccharides Using a Thermospray Interface with Sodium Acetate Containing Mobile Phases 1260

HPLC/MS Analysis of Neutral Paper Sizing Agent Using Thermospray and Particle Beam Interfaces 1262

Separation and Characterization of Autoxidation Products of Alkylpyrroles by Thermospray High-Performance Liquid Chromatography/Mass Spectrometry 1264

Characterization of the Malondialdehyde Guanine Adduct (M1G) by Thermospray LC/MS 1266

Determination of Brodifacoum Rodenticide in a Food Sample Using Negative Ion Thermospray LC/MS 1268

The Identification of Low Level Impurities and Decomposition Products in Albuterol Sulfate by On-Line Linked Scanning and High Resolution Thermospray LCMS 1270

Identification and Confirmation of a Soil Metabolite of Bis(trichloromethyl)Sulfone by HPLC/Thermospray MS 1272

Thermospray LC/MS Characterization of Protein Adducts with Quinone Methides 1274

Direct Mixture Analysis by Thermospray Mass Spectrometry: Characterization of Commercial Juice Drinks by Factor Analysis of Thermospray Mass Spectra 1276

Quantitative Analysis of Amiprilose in Human Plasma by Flow Injection Analysis Using Thermosrpay MS and Selected Reaction Monitoring 1278

The Use of a Fluorinated Ion-Pairing Agent in the Analysis of Catecholamines by Thermospray LC/MS 1280

Development of Gradient Electrochromatography/ESI/Mass Spectrometry 1282

Parameters Affecting Resolution in Capillary Liquid Chromatography (LC) with Ultraviolet and Mass Spectrometric (MS) Detection 1284

Analysis of Cortisol Metabolites by LC-CRIMS 1286

Effect of Restrictor Heater and Ion Source Temperatures on Chemical Ionization Mass Spectra of Materials Following Supercritical Fluid Chromatography 1288

Chemical Ionization with a Particle Beam LC/MS Interface on an Ion Trap Mass Spectrometer 1290

The Use of a Solvent Saturated Nebulizer Gas to Improve Sensitivity in Particle Beam LC/MS 1292

Increased Sensitivity for LC/Particle Beam/MS 1294

High Temperature Vaporization in Particle Beam Liquid Chromatography/Mass Spectrometry Interfacing 1296

Surface Ionization in Particle-Beam Liquid Chromatography Mass Spectrometry 1298

The Determination of Components in Turmeric by Liquid Chromatography-Mass Spectrometry 1300

LC/MS Analysis of Estrone and Estradiol in Biological Specimens 1302

Particle Beam Liquid Chromatography/High Resolution and Tandem Mass Spectrometry of Several Drugs in Raw Plant Extracts 1304

Accurate Mass and MS/MS Analysis of a Pesticide Mixture by Particle Beam LC/MS 1306

Particle Beam LC/MS Analyses of Compounds of Environmental Interest using a Quadrupole Ion Trap Mass Spectrometer 1308

Automated Sample Analysis on the HP MS Engine Using Particle Beam Interface 1310

Qualitative Isotope Dilution Analysis Using Particle Beam LC/MS 1312

The Optimization of Particle Beam LC-MS Interface by Statistical Experimental Design 1314

Collision Cell Modifications on a Four Sector Tandem Mass Spectrometer 1316

Precursor Ion Scanning Utilizing a Four Sector Tandem Mass Spectrometer: - Application to Mixture Analysis 1023

The Characterization of Cationic Surfactants by LSIMS and FD Methods in Combination with Four Sector Mass Spectrometry 1320

MS3 Using Tandem Mass Spectrometry 1322

Use of a Multisector Hybrid Mass Spectrometer to Elucidate the Origin of an Artefact Peak Observed in Linked Scanning at Constant B/E 1324

Application of MS3 Experiments to Structural Characterization of Coenzyme A and Modified Adenine Compounds 1326

Multi-Analyzer Techniques Applied to the Identification of High Energy CAD Product Ions in Hybrid MS 1328

Sequential MS (MS3 and MS4) Studies of Water Loss from Peptide [M+H] + Ions: Further Evidence of Intra-Ionic Interactions 1330

The Tailing Signal on the Low Energy Side of the Main Beam in MIKES Spectra is Attributable to Source Phenomena 1332

Determination of Gas Phase Cation Affinities of Modified and Basic Amino Acids Using a Hybrid Mass Spectrometer 1334

Photodissociation in a Reflectron Time-of-Flight Mass Spectrometer 1336

Design and Construction of a Tandem Time-of-Flight Mass Spectrometer which Utilizes Laser-Induced Photodissociation 1338

A Novel Method of Performing MS/MS Experiments on a Laser Ionization Time of Flight Mass Spectrometer 1340

An Improved Instrument Design for the Measurement of Surface-Induced Dissociation Efficiency 1342

Measuring m/z 2 on a TSQ700: Instrument Modifications and Stability Studies 1344

Differentiation, Identification, and Quantitation of Platelet Activating Factor in Complex Phospholipid Mixtures Using FAB 1346

Triple Quadrupole Mass Spectrometry

Collision-Induced Dissociation of Brevetoxin PbTx-3 1348

Approaches to Enhancing Associative Ion-Molecule Reactions in a Triple Quadrupole Mass Spectrometer 1349

Collisional Activation Spectra of Macrolide Antibiotics: FAB/MS/MS, ESI/MS/MS and ESI Skimmer Induced Decompositions 1351

Collisional Activation Spectra of Penicillins and Cephems: ESI/MS/MS and ESI Skimmer-Induced Decomposition 1353

Collisional Activation and LC of Aminoglycosides Using FAB and ESI/MS 1355

Investigation of the Fragmentation of Singly-and Doubly-Charged Ions of Neuromuscular Blocking Agents Using Electrospray/Tandem Mass Spectrometry 1357

Application of FAB/MS/MS to the Analysis of Acylcarnitines for Drug Discovery 1359

Metal Ion Effects on Fragmentations of Complexes Between Alkaline Earth Metal Ions and Peptide Anions that Contain Protic Side Chains 1361

The Structure Elucidation of a New-Thiostrepton-Type Antibiotic, Sch 40832 1363

Structural Studies of Isepamicin and its Analogs with Fast Atom Bombardment/Tandem Mass Spectrometry 1365

Analysis of Sulfonated Dyes and Optical Brighteners by Continuous-Flow FAB and Tandem Mass Spectrometry 1367

Charge Remote Fragmentation in the Disulfide-Containing Peptide, [Pen]-Enkephalin, Under Fast Atom Bombardment-Collisionally Activated Dissociation Conditions 1369

Investigation of C-Terminal Amino Acid Effect on Fragmentation of N-Protected Tripeptides by Hybrid MS/MS 1371

Calibration Point for Measurement of MS/MS Spectra in Quadrupole Collision Cells 1373

Identification of Artefact Compounds in Plant Extracts with Fast Atom Bombardment/Tandem Mass Spectrometry 1375

An MS/MS Method for Distinguishing the Regioisomeric Phenolic Metabolites of GR38032 1377

Differentiation of Z-Blocked Diasteromeric Dipeptides by Fast Atom Bombardment Mass Spectrometry and Kinetic Energy Released Measurements 1379

Structural Characterisation of Glycosylceramides by Tandem Mass Spectrometry 1381

Mechanistic Investigations Into the Formation of N- 1383

Acetylcysteine Conjugates of 1,2-Dibromo-3-Chloropropane: Application of FAB/MS/MS and GC/MS

Mass Spectrometry of 2-Thienyl Substituted Betadiketonate Complexes of Some Transition Metals 1385

Mass Spectral Fragmentation Processes in Dinitroaromatic Compounds. An MS/MS CID Study 1387

Bidimensional Mass Spectrometry in the Identification of Biogenic Amines 1389

The Dimethylaminomethyl Radical. A Neutralization-Reionization and Theroretical Study 1391

The Elusive Dimethylhydroxylsulfinyl Radical. A Neutralization-Reionization and Theoretical Study 1393

Hypervalent Organic Ammonium Radicals by Neutralization-Reionization Mass Spectrometry 1395

The Unimolecular Reactions of Hypervalent and Hypovalent Species 1397

Fragmentation of Peptides Cationized with Metal Ions 1399

Comparison of Electron Ionization Fragmentation of Methoxy Cinnamates to Their Photochemical Reactions 1401

A MS Study of p-Phenylenediamine in Slow Oxidation Reactions 1403

Formation of Radical Cations in Liquid Secondary Ion Mass Spectrometry in a Series of Carbazoles 1405

LSIMS and ESMS of Disulfide Bonded Peptides 1407

Methylene Blue: A Comprehensive Study of the Variation of the Peak Intensities in the Molecular Ion Region with Experimental Conditions in LSIMS/FAB 1409

An Approach to the Evaluation of the True Effect of Experimental Parameters on the Oxidation-Reduction Observed in FAB/LSIMS 1411

Generation of Quasimolecular Ions in FAB Mass Spectrometry of Derivatized Glycosides and Nucleosides 1413

The Studies of Bulk and Surface Composition During Fast Atom Bombardment Mass Spectrometry 1415

Gas Phase Ion Molecule Reactions of Anions of Esters with Neutral Alcohols 1417

The Barrier to Methane Elimination from Ionized 2-Butanone: Theory and Experiment 1419

Fe+ Catalyzed [2+2+2] Cyclotrimerization of Alkynes and Nitriles 1420

Generation and Characteristics of Transition Metal-Silylene 1422

and -Silene Complexes

Mechanism of Unimolecular Dissociation of (CH3)SiH2+ and (CH3)Si(Cl)H+ 1424

Reactions of F2+ with Aromatic Compounds in an Ion Trap Mass Spectrometer 1426

Structure and Reactivity of Cyclopentadienyl Manganese Ions, RXC5H4Mn+, in the Gas Phase 1428

Fast-Atom Bombardment Mass Spectrometry of Peroxo Complexes of Molybdenum(VI) 1430

Mass Spectra of Liquid Crystals VII. Novel 1-Phenyl-4-Alkylcyclohexanol Derivatives and Various Fluorinated Compounds 1432

Selective Detection of Brominated Hydrocarbons by the Electron Capture Detector via Association Reactions with Silicon Tetrafluoride 1434

Adduct Ion Formation Pathways in Matrix Assisted Laser Deosrption Mass Spectrometry 1436

A New Tandem Mass Spectrometer with a Surface Induced Dissociation Cell 1438

THURSDAY ORALS

LC/MS & Thermospray/Particle Beam

An Improved Element and Isotope Selective Detector for HPLC 1440

Applicability of LC/TOFMS with a Pulsed Sample Introduction Interface for the Detection of Biochemicals and PAHs 1442

Detection of Nonvolatiles via Liquid Injection Into Atmospheric-Pressure DC and RF Glow Discharge Source/Mass Spectrometry 1444

Recent Developments in Packed Column SFC-MS and SFE-SFC-MS 1446

Continuous Flow FAB/MS: A Concept to Improve the Sensitivity 1448

Continuous-Flow Fast Atom Bombardment Liquid Chromatography-Mass Spectrometry of Oligonucleotides 1450

Charting of Rat Pituitary Peptides by Capillary Liquid Chromatography - Electrospray Mass Spectrometry 1452

Influence of Aerosol Drop Size on Response Factors and Linearity in Particle Beam Liquid Chmroatography/Mass Spectrometry Interfacing 1454

Mass Transport and Calibration in Liquid Chromatography/Particle Beam/Mass Sepctrometry 1456

Particle-Beam HPLC/MS and the Use of Stable Isotope Labeled Internal Standards for Quantitative Analysis 1458

Phase Transfer Catalyzed Derivatization of L-Tryptophan and L-Kynurenine and Their Quantification by Particle Beam LC-NCI MS 1460

Determination of Exchangeable Protons by Hydrogen-Deuterium Exchange Employing a Particle Beam LC/MS Interface 1462

Particle Beam LC-MS Spectra of Anionic Surfactants 1464

Application of Thermal Kinetics to Carbon Ion Clusters 1466

Fullerenes/Clusters

Mass Spectroscopy of Fullerene Encapsulated Metals 1468

Examination of Fullerene Growth and Doping by Laser Desorption FTMS 1470

Detection of C60 and C70 Fullerene Isomers Generated in Flames 1472

Formation of Fullerenes in MeV Ion Track Plasmas 1474

C60; A Radical Sponge as Determined by Electrospray, Laser Desorption, Fast Atom Bombardment, and Chemical Ionization Mass Spectrometry 1476

Proton Solvation in Multicomponent Clusters: Energy Effects and Evidence for Cyclic Structures 1478

Photoionization and Photodissociation of Solvated Metal Ions 1480

keV, MeV and Laser Induced Desorption of Fullerenes. Fullerenes MeV Beam 1482

Development of an Organic Cluster-Secondary Ion Mass Spectrometer 1484

Fullerene Distributions Determined by Laser Fourier Transform Mass Spectrometry: Laser Desorption vs Laser Ablation 1486

Desorption Ionization/Tandem Mass Spectrometry of Endohedral Complexes and Adducts of Fullerenes 1488

Laser Desorption FTICR Studies of Electrochemically-Modified C60 Thin Films 1490

Symposium: Frontiers in Immunology

Chemical Communication Between Cells Trying to Overcome a Viral Infection: Deciphering the Coded Messages by Tandem MS 1492

Modern Immunology: The Challenge of Carbohydrate Structure; Characterization by ESI-MS & CID 1494

Computational/Reaction Mechanisms

LAN Linking of Diverse GC/MS Data Systems to Produce Custom-Formatted Raw Data File Sets for Electronic File Transfer 1496

Automatized Analysis of GC/MS Data 1498

Robust Fitting Techniques Applied to FTMS Calibration 1500

A Graphic Interface for a Factor Analysis System with Mass Spectrometry Applications 1502

Computer-Aided Sequence Determination of Peptides; A Comparative Study of Structural Information Obtained from LSIMS and Electrospray Mass Spectra 1503

Structural Elucidation of Branched Oligosaccharides: MS/MS of Divalent Metal-Ion Coordinated Oligomers 1505

Implications of the Charge Site in Formation of "Charge-Remote" Radical Cations 1507

Further Investigation of the Fundamental Ionization Processes Involved in FAB/LSIMS Techniques 1509

Iron-Mediated [4+2] Cycloaddition of 1,3-Dienes with Alkynes 1511

Gas Phase Substitution of Halobenzenes by Amine Radical Cations - A Study by FT-ICR 1513

Determination of Metal to Nitrogen Binding in Nucleobase Complex Cations 1515

THURSDAY POSTERS

Biochemistry (Page 1517 - 1582); Carbohydrates & Oiligosaccharides (Page 1583 - 1616); Electrospray (Page 1618 - 1686); Environmental (Page 1687 - 1726); FT/MS and Ion Traps (Page 1727 - 1784); Peptide Sequencing (Page 1785 - 1840); Pharmacology (Page 1841 - 1906)

Profiling of Extracellular Products from Erwinia Amylovora by On-line Liquid Chromatography-Electrospray Mass Spectrometry 1517

Characterization of the Heterogeneous N-Terminal Fatty Acylation of Two Bovine Retinal Proteins; Reexamination of Myristoylation of cAMP-Dependent Protein Kinase 1519

Thermospray High Performance Liquid Chromatography/Mass Spectrometry Analysis of Protein Hydrolysate 1521

The Leucine Zipper Peptides: Ion Spray Mass Spectrometric Detection of Noncovlaent Dimers 1523

Structural Characterization of Guanylin: An Endogenous Activator of Intestinal Guanylate Cyclase 1525

Identification of Surface-Accessible Histidine Residues as Specific Cu(II) Binding Sites on the Dimerization Domain of a Transcriptional Regulatory Proteim Dimer by Matrix-Assisted UV LDTOF & Electrospray Ionization MS 1527

Mechanistic Characterization of Enzyme Catalyses and Inhibitions by Electrospray Ionization Mass Spectrometry 1529

Particle Beam FAB-MS of Trypsin Generated -Lactalbumin 1531

Peptides

Matrix-Assisted Laser Desorption Mass Spectrometric Analysis of Rat Liver Cytochrome P450 2B1 1533

Analysis by FAB-MS of the PKA and PKC Phosphorylation Sites in the Linker Region of Mouse P-glycoprotein 1535

Application of Mass Spectrometry for Identifying Modifications of Human Serum Albumin Exposed to Hydrogen Peroxide 1537

2-Fluoro-1-methylpyridinium Salts as Derivatization Reagents for FAB 1539

FAB/MS Analysis of Novel Synthetic Bolaamphiphiles and Their Interaction with Cations 1541

Structural Analysis, Biosynthesis, and Activities of a Novel Class of Antimicrobial Peptides from the Skin of Bombina Orientalis (or Asian Toad) 1543

Application of Capillary GC - Chemical Reaction Interface/Mass Spectrometry in the Investigation of Biochemical Pathways in Metabolic Disease 1545

Investigation of the Thermal Decomposition of C-13,N-15 Isotopic Labeled Algae with Pyrolysis Mass Spectrometry 1547

GC/MS Investigation of the Glutamic Acid to Proline Pathway in Lemna Minor Using 13C and 15N Isotopic Labeling 1549

Kinetic Analysis of Urea Compartments in End Stage Renal Disease Patients Using Stable Isotope-Labeled Urea 1551

Improved Measurement of Stable Isotope Ratios in CRIMS 1553

Tellurium Determination by GC-MS in Biological Samples 1555

Selenium Determination by GC-MS in Biological Samples 1557

Origin of Specific Ions Used in the Quantitation of Polyamine Aryl Imines of Use to Monitor Cardiac Allograft Rejection 1559

A Study of Volatile Fruit Flavour Biosynthesis Using Non-Invasive Deuterated Precursor Labelling Techniques 1561

Investigation of MeIQx (2-amino-3,8-dimethylimidazo - [4,5f] - quinoxaline) Metabolites in Human Urine 1563

Derivatization Schemes: Determination of Aldehydes in Biological Samples by GC/MS 1565

GC/MS/MS Identification and Quantitation of Metabolic 4-Acetyltoluene-2,4-Diamine From the F344 Rat 1567

Quantitative Determination of Ethylene Glycol Monobutyl Ether (2-Butoxyethanol) and Butoxyacetic Acid in Blood by Gas Chromatography with Electron Capture Negative-Ion MS 1569

Determination of Mercapturic Acid Metabolites of 1,3-Dichloropropene by GC/MS/MS 1571

Initial Investigations Into the Utility of MS-MS in the Detection of Changes in the Urinary Excretion of Glucuronides 1573

Pentafluorophenyl Boronic Acid: A New Derivatization Reagent for NCI/MS 1575

FAB MS and MS/MS Spectral Analysis of Benzo[a]pyrene-Peptide Conjugates 1577

Analysis of Amino Acids by GC-MS: Simultaneous Derivatization of Functional Groups by an Aqueous-Phase Chloroformate-Mediated Reaction 1579

Application of Ionspray LC-MS for the Detection of New Analogues of Dinophysistoxin-3 1581

Mild Periodate Oxidation and Core-Branching Pattern Analysis of O-Linked Glycoprotein Oligosaccharides 1583

On-Line Anion-Exchange Liquid Chromatography Thermospray Mass Spectrometry in the Analysis of Oligosaccharides 1585

Alkali Metal Ion Cationization of Carbohydrates 1587

Characterization of Phytoalexin Elicitors Derived from Hops 1589

Detection of Neoglycolipids by Matrix Assisted Laser Desorption Mass Spectrometry 1591

The GPI Anchor of the Scrapie Prion Protein 1593

Electrospray Analysis of Oligosaccharides 1595

Structural Characterization of the N-linked Oligosaccharides of Frog Opsin 1597

Carbohydrate Composition Analysis of a Glycoprotein by Laser Desorption Mass Spectrometry 1599

Comparison of the CID Spectra of a Series of Synthetic Complex-type Tri- and Pentasaccharides 1601

Carbohydrate Structural Characterization by SFC-MS and SFC-CID-MS 1603

Structural Characterization of Protein Anchors by ESI and Collision of Multiply Charged Parent Ions 1605

Extending Detection Limits with an SFC Solid Phase Injector, NCI and Focal Plane Detection 1607

Glycoforms of the HIV Envelope Glycoprotein gp120: Analysis of Glycans and Glycopeptides by ESI and SFC-MS 1609

Analysis of Complex Mixtures of Reducing End Derivatized Oligosaccharides by CF/FAB LC-MS 1611

Fast Atom Bombardment and Tandem Mass Spectrometry for Differentiation Between C-Glycosidic Flavonoids 1613

Unimolecular Decomposition of Metastable Oligosaccharide Cations in a Liquid Secondary Ion Source/Fourier Transform Mass Spectrometer 1615

Electrospray Ionization Mass Spectrometry for Natural and Radiation Induced Modifications in Histone Proteins 1617

Analysis of Cyclosporin A Using Electrospray Ionization and Fast Atom Bombardment 1619

Electrospray Ionization of Quaternary Ammonium-Linked Glucuronides and its Comparison to Mass Spectra Obtained by FAB 1621

Comparative Electrospray and FAB Mass Spectrometric Study of Lipophilic Neuropeptide Derivatives 1623

Analysis of Hydrophobic Peptides and Proteins by Electrospray Mass Spectrometry 1625

Application of Electrospray Mass Spectrometry to the Study of Chelator and Chelator Fragments in Mixed Hazardous Wastes 1627

Mass Spectrometric Characterization of HIV Protease 1629

Identification of Components in Waste Streams Using Electrospray and Tandem Mass Spectrometry 1631

Electrospray Ionization and Tandem Mass Spectrometry of Noncovalent Protein Complexes 1633

Refolding of Denatured Proteins in the Gas Phase: Evidences from Ion-Molecule Reactions and Scattering Collisions of Multiply-Charged Protein Ions 1635

Structural Characterization of Alkylated DNA Using Electrospray Ionization Mass Spectrometry 1637

Analysis of Human Calcitonin by Electrospray Ionization Mass Spectrometry 1639

Analysis of Vitamin D and its Metabolites: New Reagents for the Detection of Neutral Molecules by Electrospray Ionization 1641

Characterization of Large Metal Transition Complexes by LSIMS and ESMS 1643

Characterization of Cyclodextrins and Their Inclusion Compounds by LSIMS and ESMS 1645

Fragmentation Behavior of Lipid A's in Electrospray vs. Plasma Desorption Mass Spectrometry 1647

Optimized Lens Configuration Studies for a Two Stage Electrospray Ionization Mass Spectrometer Interface 1649

The Coupling of a Versatile Electrospray Source to an 1651

FT/ICR/MS at the Extremes: High and Low Mass, Dynamic Range, Mass Accuracy

Alan G. Marshall†, George M. Alber, Michael V. Gorshkov, Peter B. Grosshans, Shenheng Guan, Patrick A. Limbach, Michael A. May, Tom L. Ricca‡, Lutz Schweikhard, Troy D. Wood

Dept. of Chemistry (Dept. of Biochemistry†; Campus Chemical Instrument Center‡), The Ohio State University, 120 W. 18th Ave., Columbus, OH 43210.

We have determined the minimum (~150 for SNR ≈ 3/1 at 1 s observation period at 3.0 tesla) and maximum (>5,000,000) number of ions in a 1" cubic trap, by comparing the experimental signal with that calculated for one ion at the measured ICR orbital radius.[1] The dynamic range (~40,000 in a single spectrum) may be extended by selective SWIFT ejection of the most abundant ions, to allow accumulation of the less abundant ions.[2]

For thermal ions, radial loss sets the upper mass limit (see Figure 1).[3] The upper mass limit may be extended by elongating and/or screening the trap. In matrix-assisted laser desorbed (MALD), ions are produced with an approximately constant speed, independent of ion mass. Thus, higher-m/z ions have higher energy, and a higher trapping voltage is needed to trap them (in the absence of collisions).[4]

At the other m/z extreme, we report measurements of low-mass ions, e.g. O^{2+}, N^{2+}, D_3^+, D_2H^+, DH_2^+, DH^+, H_2^+, and H^+ (~107 MHz at 7.0 tesla), corresponding to m/z = 8,7,6,5,4,3,2, and 1 (see Figure 2 for a partial display).[5] At such high ICR frequencies, the relativistic shift in ICR orbital frequency is so large that it may be used to determine ICR orbital radius. Space charge may be reduced by dipole ejection at the trapping frequencies of unwanted ions, to reduce parasitic space charge shift in the ICR orbital frequency of the excited ions of interest. The radial magnetic field inhomogeneity, has been measured as a function of ICR orbital radius, r, for CO^+ ions (i.e., m/z high enough that relativistic differences in ion velocity for ions of slightly different r are negligible): $(dB/dr)/B = 2 \times 10^{-7}$ per cm. By measuring the ICR frequency over a period of months, we have determined the drift rate of our magnet, $(dB/dt)/B \approx 8 \times 10^{-10}$ per hour. Magnetic field drift thus has negligible effect on mass difference measurements for closely-spaced mass doublets.

Our precise measurement of the mass difference between H_2O^+ and OD^+ leads to a deuteron binding energy of 2,224,179(13) eV, and a deuterium atom mass of 2.014 101 764(13) u.[6] We are proceeding with other precise mass difference measurements leading up to the ^3H - ^3He mass difference, which is related to the rest mass of the electron neutrino.

NEW APPROACHES TO MASS(/CHARGE) MEASUREMENT: THE QUADRUPOLE ION TRAP

Scott A. McLuckey
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

The quadrupole ion trap is currently enjoying increasing attention as an analytical mass spectrometer. This attention is largely a direct result of the mass-selective instability method, a new approach to mass/charge measurement, introduced by Stafford et al. [1]. There are, however, many ways to measure the mass/charge of a charged particle with the Paul trap. This paper provides an overview of this variety of approaches and illustrates with selected examples.

Of course, one approach to using the ion trap in a mass spectrometry experiment is to use a separate mass spectrometer for the job of measuring mass/charge. This was done with many of the ion trap studies in the late sixties and seventies. The studies of Todd et al. [2], which involved the use of a quadrupole mass filter to measure the mass/charge ratios of ions ejected from the ion trap, are particularly noteworthy. However, because the ion trap itself was not used as a mass spectrometer, this approach is not discussed further here.

Ion trap mass spectrometry experiments either involve in-situ detection, in which the ions remain in the trapping volume during detection, or external detection, in which ions are ejected from the ion trap into a detector. The original mass spectrometry experiments employed in-situ detection. For example, Fischer's experiment [3] employed a tuned RLC circuit connected with the ion trap end-caps. Ions were successively brought into resonance with the RLC circuit by scanning the DC potential on the ring electrode at a fixed rf amplitude and frequency. These types of circuits are highly sensitive to load and therefore reflect the power absorbed by the ions. This approach is very similar to the tuned circuit experiments that were once common with ion cyclotron resonance (ICR) spectrometry. In the latter experiments, ions were brought into resonance by scanning the magnetic field. Rettinghaus' approach [4] also measured power absorption as ions came into resonance with a fixed frequency signal applied to the ion trap end-caps. A balanced bridge detector, however, was used in the detection circuitry. Such a detector has also been used by the ICR community.

In recent years, the ICR community has moved almost exclusively to measurement of the current induced in the "listening" plates by the coherent motion of ions excited by the appropriate frequency applied to the "excite" plates. This experiment is now commonly performed by applying Fourier transform methods to the image current transients resulting from the excitation of all ions in the ICR. Such a Fourier transform mass spectrometry (FTMS) experiment is also possible with the quadrupole ion trap. Syka and Fies [5] have demonstrated the image current measurement as part of an FTMS experiment with the quadrupole ion trap. In this case, the end-caps must serve as both the excite and listen plates. This experiment has not been vigorously pursued since the initial report. This is due, in part, to the fact that low pressures are required for long transients which, in turn, are required for adequate resolution. Low pressure operation runs counter to one of the main analytical advantages of the ion trap; i.e., the ability to operate at relatively high pressures.

Whereas the ICR community has used in-situ detection almost exclusively, the quadrupole ion trap community has almost always employed external detection. Methods that employ external detection can be classified broadly as either mass-selective stability or mass-selective instability. Dawson and Whetten were the first to use external detection [6] and did so using mass-selective stability. That is, only ions of a single mass/charge ratio were stored for each ionization event and these ions were subsequently ejected with a DC pulse applied to one of the end-caps. Griffiths and Heesterman have recently described a similar method but one which forces ions through the $\beta_z=1$ line for ion ejection [7]. Both approaches are analogous to the operation of the mass filter, which transmits ions of only a narrow range of mass/charge ratios at a time.

As indicated above, the mass-selective instability mode of operation has largely revolutionized ion trap mass spectrometry. This contribution of Stafford et al. is difficult to overestimate relative to the utility of the ion trap an analytical mass spectrometer. In this mode of operation, ions of a wide range of mass/charge ratios are formed (or admitted) and stored simultaneously. The mass spectrum is acquired ejecting the ions

in a mass/charge-dependent fashion. Ion storage is largely mass/charge-independent while ion ejection is mass/charge dependent. This is, of course, the reverse of the mass-selective stability mode. However, the mass-selective instability mode is much more analytically useful due to superior sensitivity. For example, with the conventional electron ionization method, the mass-selective instability mode enjoys two advantages. First, all ions formed in the ionization event are measured in a single scan whereas an ionization pulse for every mass/charge is required with the mass-selective stability mode. Hence, the mass-selective instability mode enjoys something of a Felgett advantage. The scan period in an ion trap experiment is analogous to the period for image current measurement in the FTMS experiment. A less widely recognized advantage of the mass-selective instability mode derives from a larger effective ionization volume on the a=0 axis than at the tip of the stability diagram. Therefore, for a given ionization pulse duration, more ions are formed from the analyte at a=0, the normal situation with mass-selective instability, than near to the tip of the stability diagram, usually the situation with mass-selective stability.

The mass-selective instability mode of operation, as it was first described, relied upon passing ions, from low mass/charge to high mass/charge, through the $a_z=0$, $q_z=0.918$ ($\beta_z=1$) point resulting in z-axis ejection. This was done by scanning the amplitude of the (fixed-frequency) drive signal. Any point along the $\beta_z=1$ and $\beta_z=0$ stability boundaries can be used to eject ions from the trap and through perforations in the end-caps. Examples of ion ejection at locations on stability boundaries other than a=0, $\beta_z=1$ have recently been shown by Todd et al. [8]. More recently, the use of a supplementary signal applied to the end-caps to eject ions at $\beta_z<1$ has been employed. This is often referred to as "resonance ejection". Most often, a fixed-frequency is applied to the end-caps while the amplitude of the drive signal is used to bring ions into resonance. This approach is reminiscent of the early power absorption measurements. However, in this case the supplementary signal is intended to eject ions from the ion trap. The resonance ejection method has been shown to be effective at extending the mass/charge range of the ion trap by ejecting ions at drive signal amplitudes much lower than those required to bring them to $\beta_z=1$ [9]. It has also been demonstrated that remarkably high resolving powers ($M/\Delta M > 10^5$) are possible using slow scan speeds and resonance ejection [10].

Ion traps, including both ICR and quadrupole, offer remarkable flexibility in the types of experiments that can be performed. The variety of approaches to mass/charge measurement listed above for the quadrupole ion trap illustrate this flexibility. However, they do not constitute all means for mass/charge measurement. We can therefore expect to continue to see more variations on the themes listed here as well as, perhaps, a new theme or two.

Understanding Matrix-Protein Interactions in Matrix-Assisted Laser Desorption

Ronald Beavis, Department of Physics, The Memorial University of Newfoundland, St. John's, Newfoundland A1B 3X7
beavis@beorn.physics.mun.ca

The least understood aspect of matrix-assisted laser desorption are the interactions between the matrix and the protein that result in an appropriate sample deposit. In this presentation, the crystal structure of several matrix materials were presented, including the newly determined structure of sinapic acid (3,5-methoxy-4-hydroxycinnamic acid). All of the matrix materials that have known crystal structures are monoclinic. They belong to the point group P2/m and the related space groups $P2_1/c$, $P2_1/a$ and $P2_1/n$. All of these structures contain dimers formed by hydrogen bonding of the carboxylic acid groups in a "head-to-head" fashion. These dimers are hydrogen bonded to adjacent dimers by hydroxyl groups. The dimers are arranged into extended sheets, with the hydrogen bonds in the plane of the sheet. The sheets are stacked so that van der Waals forces and steric constraints hold the structure together.

Sinapic acid was studied in detail, because of its current importance as a protein matrix. The crystal structure was solved using a Rigaku AFC6S diffractometer with graphite monochromatised MoKα radiation (λ = 0.071069 nm). The space group was $P2_1/n$. The structure contained very flat, hydrogen bonded sheets, with the methoxy groups oriented in the plane of the sheet. With the crystal structure solved, it was possible to assign the external faces of the physical crystals to crystal planes. The dominant crystal habit was monoclinic, hexagonal prisms with end pinacoids.

When a matrix-assisted laser desorption sample is prepared using sinapic acid as the matrix, the sinapic acid forms crystals covering the surface. The crystal habit is the same as the crystal used to determine the structure, although the crystals usually have a large [100] face, resulting in tablets with prominent pinacoids (the $[10\bar{3}]$ face). Therefore, if the protein and the matrix are intimately mixed, the protein must be inside of the crystal structure. The defect that results in the crystal from the incorporation of the protein must be quite large: the protein molecules form inclusions in the sinapic acid crystal.

The location of the protein molecules in sinapic acid crystals was determined by growing sinapic acid crystals from a mother liquor containing a low concentration of protein and Coomassie Brilliant Blue G 250 (a protein specific, anionic dye). When no protein was present in the mother liquor, no dye was incorporated into the sinapic acid crystals. With protein in the mother liquor, dye was included in the crystals in hourglass zones that terminated on the $[10\bar{3}]$ end pinacoid. These zones indicate that protein was included on the $[10\bar{3}]$ face during crystal growth and not on the other faces. The $[10\bar{3}]$ face is the external plane that corresponds to the flat, hydrogen bonded sheets in the crystal structure. This finding implies that the protein is included into the crystal by adsorption onto the $[10\bar{3}]$ face while that face is growing. The $[10\bar{3}]$ face is relatively non-polar, with no free donor hydrogen bonding groups, but it is relatively polarizable because of its high electron density.

The results of this study suggest that it is the crystal structure of a matrix material that determine its interaction with a protein, rather than the properties of individual matrix molecules. The cooperative nature of this interaction is reasonable considering the difference in molecular size between the protein and the matrix. The protein adsorption to the growing matrix crystal appears to be caused by a "hydrophobic" interaction: the adsorption of the protein results in an increased total entropy of the solvent/protein/surface system.

FAST, HIGH TEMPERATURE AND THERMOLABILE GC-MS IN SUPERSONIC MOLECULAR BEAMS

AVIV AMIRAV, SHAI DAGAN and ALBERT DANON
School of Chemistry, Tel Aviv University, Ramat Aviv 69978, Tel Aviv, Israel. Fax.: 972-3-6409293.

Supersonic molecular beams (SMB) sampling is characterized by several unique features including (a) High flow of up to 240 cc/min, (b) Ideal jet separation and centerline enrichment of heavy species, (c) Atmospheric pressure sample inlet, (d) Hyperthermal molecular kinetic energy which allows vacuum background filtration schemes and results in ultra fast ion source response time, (e) Molecular vibrational supercooling which results in a dramatic increase in the relative abundance of the molecular ion in electron impact (EI) ionization. Our mass spectrometer includes both fly-through EI ion source and hyperthermal surface ionization (HSI) ion source which is based on the very efficient ionization of hyperthermal molecules in the SMB upon their surface scattering.

A 50 cm short column serves as a fast GC column. This column is located between the sampling and vaporization oven (outside the vacuum system) and the supersonic nozzle, and allows carrier gas linear velocities up to 2000 cm/sec.

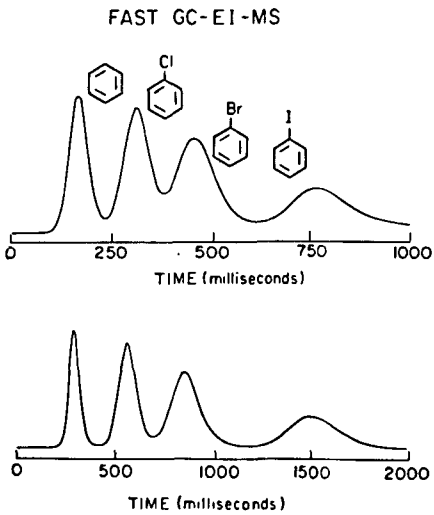

Fig.1 - Fast GC-MS

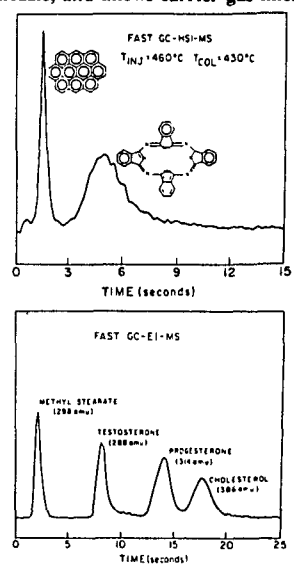

Fig.2 - High Temperature & Thermolabile GC-MS

In fast GC the imposition of time constraint on the total chromatography time results in a much higher optimal carrier gas linear velocities and the column length is irrelevant above a critical length. The combination of short column, high carrier gas linear velocity and ultra-fast ion source response time allow the GC-MS separation and quantification of simple mixtures in one second as shown in figure 1. The short time spent at the column combined with the unique tail free ion sources allow the GC-MS of thermolabile and relatively non-volatile molecules as demonstrated in figure 2. The hyperthermal surface ionization ion source is potentially the most sensitive ion source due to favorable ionization yield, enhanced molecular weight peak, lack of vacuum background noise and the high peak flux fast GC operation. In figure 3 a detection limit of 4 femtogram anthracene is demonstrated combined with 1 second elution time and 10 seconds repetitive injections. The fast GC-MS in SMB is ideal mostly in target compounds analysis even in highly complex mixtures as is demonstrated in figure 4. More information can be found in a review by A. Amirav, Org. Mass. Spectrom. 26, 1 (1991) and in A, Amirav and A. Danon, USA Patents Nos. 4845367 and 5055677.

Linear Time Of Flight Mass Spectrometer Design Incorporating Post Source Pulse Focusing For Matrix Assisted Laser Desorption Ionization

G.R. Kinsel*, J.M. Grundwürmer, M. Bönisch and J. Grotemeyer

Institut für Physikalische und Theoretische Chemie, TU München, Lichtenbergstr. 4, D-8046 Garching
*present adress : Texas A&M University, Dep.of Chemistry, College Station, Tx, 77843

Laser Desorption / Ionization is a successful method for introducing non-volatile molecules into the gas phase and is easily combined with a linear TOFMS for mass spectral analysis.

However a major drawback of the linear TOFMS, particularly severe for LD experiments, is the poor resolution of the detected ion signals. There is need for higher resolutions to be obtained, particularly when investigating high mass ion signals. Higher resolutions are required for improvements for distinguishing between various protonated, sodiated and/or adduct ions which may be formed during LDI.

Post Source Pulse Focusing (PSPF) is a method which is expected to improve the resolution of the ion signals in a linear TOFMS by applying a compressing voltage pulse to the ion packet of interest after accelerating the ions from the TOFMS source region using conventional electric fields [1, 2]. Results of theoretical calculations illustrate the gains in signal resolution which may be expected for a variety of ion formation conditions.

In addition initial investigations under direct LD/I and matrix assisted LD/I conditions all demonstrate the dramtic improvements in ion signal resolution which could be achieved using this simple technique. The spectra presented illustrate typical results obtained in these experiments for matrix assisted LD/I of insulin (spectrum 1) and cytochrome c (spectrum 2) with a resolution of 850 (FWHM). These spectra of insulin and cytochrome c show clearly seperated peaks of M-18,M, M+14 and M+28 ions. The static acceleration voltage was 15000 V. The pulsed field was 1,800 V 8.0 μs for insulin and 1,810 V 11.7 us after the ionization laser. Higher resolutions are expected with higher accelerating voltages and improvements in detector design.

ORTHOGONAL ACCELERATION TIME-OF-FLIGHT MASS SPECTROMETRY: IMPROVED SENSITIVITY AND RESOLUTION WITH GASEOUS ION SOURCES

JOHN COLES, MATTHEW STUTSEL and MICHAEL GUILHAUS
School of Chemistry, University of New South Wales, PO Box 1 Kensington NSW 2033 (Australia)

INTRODUCTION

With recent advances in the speed and performance of timing electronics, conventional TOF-MS would offer excellent mass resolution for a wide range of ion sources were it not for dispersions in: initial ion velocities (principally of thermal origin) known as velocity dispersion; initial distance from detector, known as spatial dispersion; and time that acceleration is initiated (gating).

Whilst numerous solutions have been proposed to correct individually for these dispersions, no approach hitherto has been established to prevent them from creating a corresponding dispersion in arrival times for isobaric ions when the analytically most useful gaseous ion sources are used.

The concept of orthogonal acceleration TOF-MS was developed to provide a solution to the resolution problem with gaseous ion sources and to allow coupling of TOF mass analysis with *any continuous ion source*. The theory of the TOF-oa instrument has been described previously [1,2]. The concept of the TOF-oa instrument can be explained as follows with reference to Fig. 1.

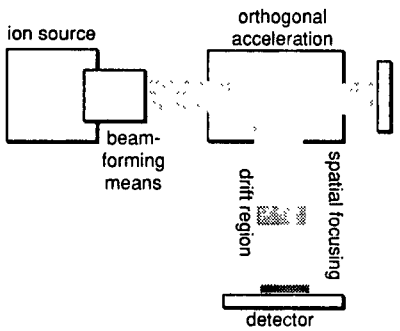

Figure 1

An ion source produces collimated beam of ions with relatively low kinetic energy (similar to those suitable for quadrupole mass filters). The ion beam is allowed to fill the extraction region of the orthogonal accelerator (oa). Ions near the middle of this region are sampled by application of a low-voltage, pulsed electric field, orthogonal to the beam. The ions have minimal initial velocity orthogonal to the beam and this allows the spatial dispersion to be corrected with classical spatial focusing. After sufficient time (c. 5μs) for the sampled ions to pass through the first grid, the low voltage pulse is turned off to allow the continuous beam to refill the extraction region.

Of particular significance in this configuration is the intrinsic sensitivity advantage of gating a low energy beam orthogonally: while the ions sampled from the continuous beam are moving at high energy down the flight tube, the orthogonal extraction region is refilling. The drift time and the refill time are about the same for the highest mass in the spectrum and so relatively high extraction efficiencies can be achieved. Another important advantage of orthogonal gating of a low energy beam is that the push-out pulse need not have a very fast rise-time and it can be of low amplitude (commensurate with the beam energy). It is only necessary to ensure that the ions between the push-out electrode and the first mesh do not leave that region until the pulse has stabilised at its maximum. This is a significant advance on conventional *in-line* gating methods.

EXPERIMENTAL

A TOF-oa prototype has been built with specifications similar to those given in the earlier theoretical study [1]. The ion source used is a VG 70-70 EI/CI source operating with an ion extraction voltage of 60 V and producing an ion beam with an energy of about 14 eV. Spectra were recorded with a LeCroy 9450 digital oscilloscope having 100 ps maximum time resolution. A custom-made pulse generator provided an 88 V push-out pulse, for sampling ions, and the trigger signal for the LeCroy 9450. The detector is a 25 mm diameter Galileo 3025 type N Chevron-pair microchannel plate. Detector H.T. and accelerating voltage were provided by a single supply . The detector and the inner flight-tube (insulated) were held at -2,900 V allowing the ion source to

operate with near ground potentials. Data was acquired into the memory of a Macintosh IIfx computer under the control of a LabVIEW II virtual instrumentation module for the LeCroy 9450.

RESULTS

Resolution Fig. 2 shows a portion of a spectrum of Xenon acquired with 400 duty cycles of c.100 µs each (40 ms total for the mass range 0-2200 amu). The resolution at *m/z* 132 is better than 2,200 (FWHM). At this *m/z* the pulse width from the detector accounts for a significant portion of the peak-width. We observed (Fig. 3) that a graph of peak-width, Δt, versus $\sqrt{(m/z)}$ is linear and intercepts the peak-width axis ($\sqrt{m} = 0$) at the detector pulse-width Δt_P. It can be shown that the slope of this relationship is directly related to the intrinsic resolution of the TOF analyser, $R = m/\Delta m$, based on the *arrival time* of ions (i.e., zero detector pulse width):

$$\Delta t = \Delta t_P + \frac{D}{2R}\sqrt{\frac{m}{2eV}} \qquad (1)$$

The underlying resolution (Fig. 3) is $m/\Delta m \cong 4{,}000$ (FWHM). This exceeds the predicted resolution by 25% [1]. Jitter and band-width limits in timing electronics as well as detector pulse-width contribute a constant $\Delta t_P = 2.3$ ns to the width of peaks. This limitation of the electronics degrades the resolution of a TOF instrument only at low mass, where it is generally not a serious problem, and has little effect at high mass where the resolution approaches its limit of c. 4,000 (FWHM).

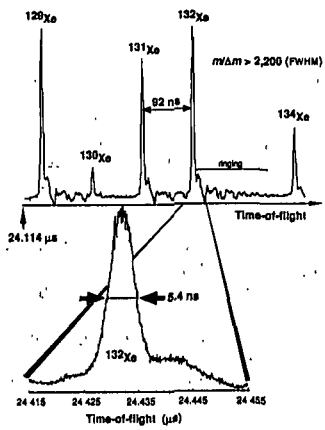

Figure 2

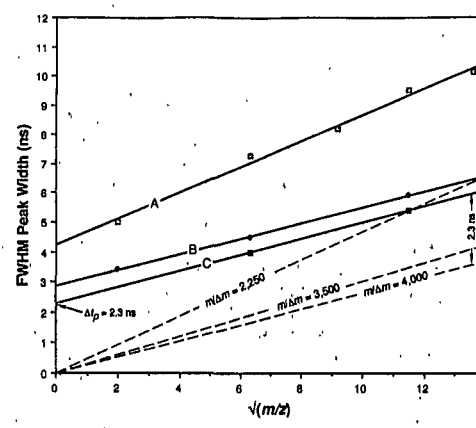

Figure 3

Speed and Sensitivity The spectrum shown in Fig. 3 is part of an acquisition with an *m/z* range from 0 to 2,200 obtained by averaging 400 transients, each of 100 µs duration. This represents a total acquisition time of 40 ms. A scanning mass analyser would be required to scan at a linear rate of 55,000 amu/s to cover the mass range in the same time. This result demonstrates the intrinsic speed of TOF mass analysis, and from the observed signal-to-noise ratio (ignoring the ringing which can be eliminated by proper impedance matching in the detection electronics) very high sensitivity is indicated. For an ion of *m/z* 2000 the TOF-oa prototype will detect nearly 200 times as many ions as an ideal scanning mass analyser covering the same mass range. Greater improvements in sensitivity are attainable with higher transmission grids which cause some decrease in resolution.

In a multidisciplinary research project on the development of instrumental techniques for the characterization of plant cell wall polysaccharides and oligosaccharides, chemically or enzymatically derived from the polysaccharides, among others, the potential of LC-MS was investigated.

Three aspects have to be studied in relation to LC-MS in carbohydrate characterization:

* ionization techniques to achieve molecular-weight and structural information for DP $\leq$ 10 oligomers.
* suitable LC technology compatible with available LC-MS interface technology. Because mostly aqueous solvent systems are used in sugar oligomer separations, thermosporay appears to be the interface of choice.
* techniques to obtain structural information concerning sugar type, linkage type and location, e.g., MS-MS.

Starting with thermospray, it was found that a wide variety of solvent composition do not provide molecular-weight information. For instance, with the widely used ammonium acetate, thermally induced ammoniolysis of the glycoside linkage takes place.

Subsequently, it was found that a mobile phase containing low concentrations of sodium or lithium acetate ($<10^{-3}$ mol/l) is compatible with thermospray interfacing without significant problems with vaporizer clogging or source contamination. Under these conditions, mono- and di- (when DP > 4) sodiated molecules are observed without fragmentation. In this way, rapid molecular-weight determination of oligosaccharides is possible.

A sodium-acetate containing mobile phase is compatible with either reversed-phase chromatography or high-performance anion-exchange chromatography, two techniques which can be used in sugar oligomer separation.

High-performance anion-exchange chromatography (HPAEC) is a powerful technique for the separation of oligosaccharides. Unfortunately, the elution order of oligosaccharides in complex mixtures is rather unpredictable. In this respect, on-line coupling of HPAEC to MS would be extremely helpful. Furthermore, a rapid molecular-weight determination of oligosaccharides in complex mixtures separated by HPAEC is also very informative in the investigation of plant cell

wall polysaccharides and in evaluation of enzymic methodology applied to plant cell wall polysaccharides.

In oligosaccharide separations by means of HPAEC-MS, a mobile phase consisting of 0.1 mol/l sodium hydroxide and a gradient of 0-50% 1 mol/l sodium acetate in 0.1 mol/l sodium hydroxide is applied. By means of a so-called anion micromembrane suppressor (AMMS) the sodium ions can be efficiently removed from the mobile phase as long as the sodium concentration does not exceed 0.4 mol/l. Using an AMMS on-line coupling of HPAEC-MS is possible using a thermospray (previously described by Simpson et al, Anal. Chem., 62 (1990) 248).

By means of HPAEC-MS, series of homologous sugar oligomers as well as complex mixtures of oligosaccharides derived from plant cell wall polysaccharides have been analyzed. Generally, oligosaccharides can be analyzed up to DP = 10, although for homologous ß-1,4-xylans peaks for DP=25 have been observed. The maximum DP value is limited by the sodium acetate concentrations needed for the elution.

Sodiation of oligosaccharides is also applicable in electrospray interfacing. In preliminary studies it appears, that electrospray show improved high-mass sensitivity. In a α-1,4-glucan mixture (maltodextrine), continuously infused into the electrospray system, peaks were detected up to DP = 24 (doubly-charged ion). On-line HPAEC-MS using an electrospray interface is currently under investigation.

Our laboratory is interested in the structural investigation of glycans originated from glycoconjugates. Typically, very low quantity of sample is available, so we are always looking for new sensitive methods that are analytically useful for our research. In the present work tandem mass spectrometry has been used to study the collision induced dissociation of alkali metal cationized and permethylated oligosaccharides.

Experimental. The low energy mass spectra were acquired on a triple quadrupole instrument (Finnigan TSQ 70) with collision energy ranging from 20 to 50eV. The high energy (4 keV) CID spectra were obtained on a four sector mass spectrometer (Kratos Concept II HH). Resolution of MSI was sufficient to select the C^{12} $[M+Na]^+$ ion into the collision cell. Thioglycerol saturated with NaI was used as the matrix.

Results. More than the enhancement of the FAB response, the interest to collide the $[M+Na]^+$ ions of permethylated oligosaccharides is based on the production of ions that are specific of the linkage position. These ions arise from two ring bonds cleavages within the sugar ring according to two decomposition ways (Figure 1). One interesting example of structural elucidation is illustrated in Figure 2 where each of the five interglycosidic linkages is identified. However, such useful CID spectra require specific experimental conditions. Indeed the yield of these diagnostic ions is strongly dependent on the collision energy and on the nature of the collision gas. The low energy CID spectra exhibit predominantly product ions arising from cleavage of the glycosidic linkages. Hence, only sequence informations are furnished by such a technique. The high energy (4keV) CID spectra show, in addition to the sequence ions, the diagnostic ions subsequent to multiple bond cleavages. Moreover, we have observed that the heavier target gas like argon or xenon were more efficient to induce their formation. These results are not surprising if one consider the strong stability of the sodium adduct. They are also consistent with previous observations : the heavier gas produce more effective collisions and induce less translational energy loss than helium.

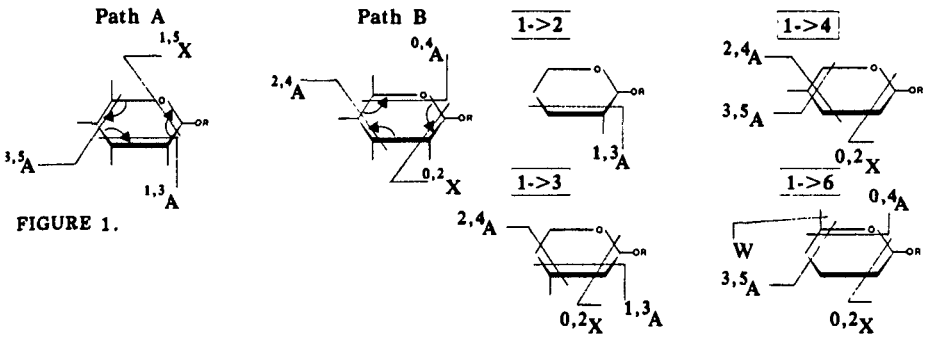

FIGURE 1.

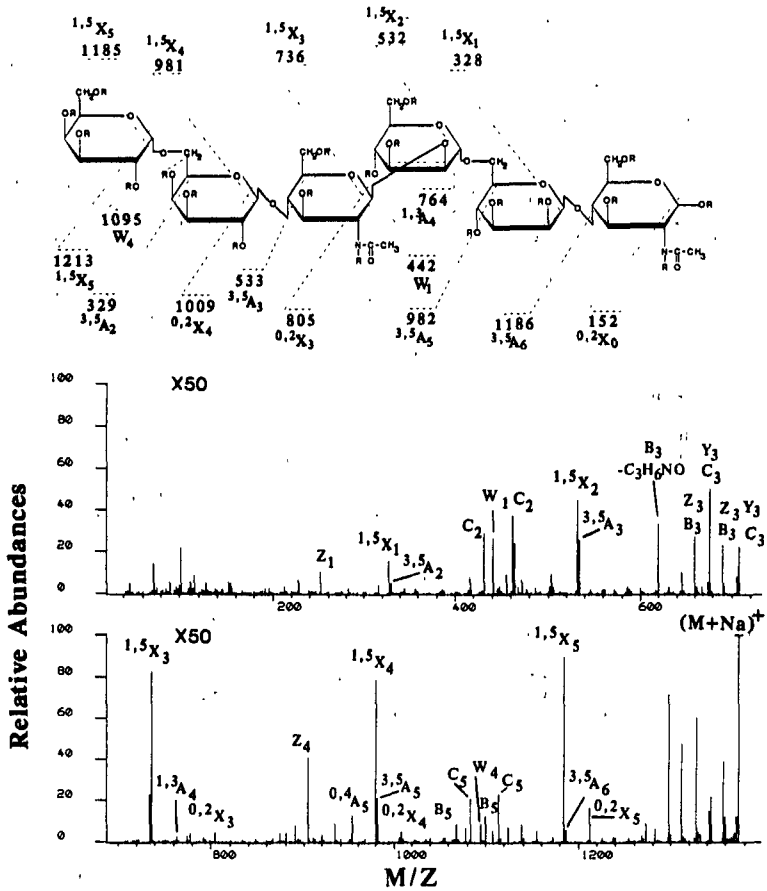

FIGURE 2. FAB CID tandem mass sepctra of $[M+Na]^+$=1375 for methylated Gal1-6Gal1-4GlcNAc1-2Man1-6Man1-4GlcNAc obtained on a four sector mass spectrometer with 4keV collision energy and argon as the collision gas. The peaks are labelled according to the nomenclature of Domon and Costello (1). The ions arising from the same site of cleavage at the glycosidic linkages are identically designated, either they result from H transfer or methoxy loss.

Application of the Charge-remote Fragmentation to Ceramide Structure Determinations

*Yoko Ohashi and Yoshitaka Nagai,
Frontier, RIKEN, Wako, Saitama, 351-01 JAPAN

Charge-remote fragmentation[1)](CRF) was applied to determine the location of double bond(s) in the ceramide portion of sphingolipids. Using a double-focusing mass spectrometer (HX-110), collision-activated dissociation (CAD) spectra in the(+)/(-)- modes FAB were taken applying the B/E-constant linked scanning technique. For multiply unsaturated ceramides, it was necessary to use EBEB tandem mass spectrometry (HX-110/HX-110).

As previously reported[2)], ceramides of d18:1 gave a daughter ion at m/z94 ($C_8H_8N^+$) and 80($C_5H_6N^+$)in the positive ion mode CAD when the LCB^+ ion $[CH_2C(NH_2)=CHR]^+$ was chosen as the parent ion. Compositions of these daughter ions require position of the unsaturation to be assigned at C4, as known for ubiquitous sphingolipids. The method is applicable to neutral small glycosphingolipids if a single double bond is contained in the long-chain base. Similarly, in the negative ion mode, the FAB daughter spectrum of $(M - H)^-$ of sulfatide showed the location of double bond in the most abundant fatty acid species c24:1 to be at C15, not only in the m/z values of daughters but also in the relative ion intensities which corresponded to those of vinylic and allylic cleavages[2)](Fig. 1). In this case, CRF occurred along the fatty acid chain and not along the long-chain base, because a CRF pattern was absent in the (-)FAB CAD spectrum of glucosylceramide (d19:3/c2:0)[3)]. The number of unsaturation in the fatty acid of c24:1 was, again, one.

On the other hand, multiply unsaturated long-chain bases failed to show clear-cut CRF patterns by CAD of the protonated LCB^+ ions except for the already described double bond at C4. Much alike to the cases of free alcohols[4)], addition of diluted solution of LiI to methyl linolenates, chosen as model isomers of polyunsaturated compounds, made the isomers clearly distinguishable from each other in the positive FAB daughter spectra. Similar treatment of polyene ceramides also much improved the positive daughter spectra, but still some ambiguity in the assignment of daughters was present owing to the inadequate resolution of the parent ion when the B/E constant linked scanning using a single unit of EB insrument was applied. Thus, we undertook MS/MS study using HX-110 mass spectrometers in tandem in the EBEB geometry.

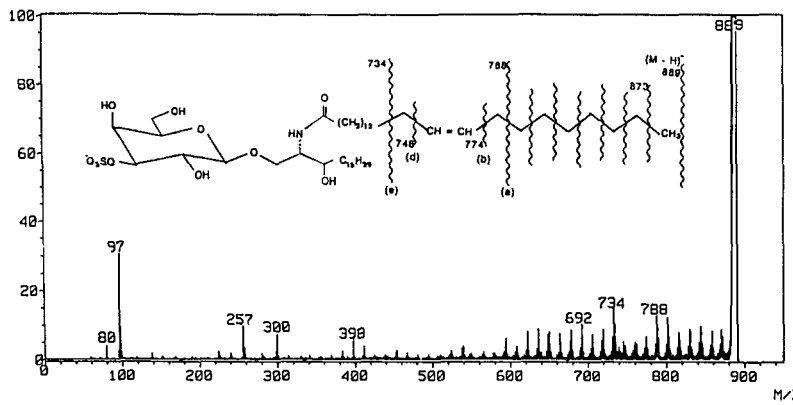

Fig.1 (-)FAB: Daughters of $(M - H)^-$ of bovine spinal cord sulfatide(d18:3/c2:0) and the CRF pattern. (triethanolamine).

A pair of glucosylceramides, d18:3/c:2 and d19:3/c:2, were chosen one more time to avoid the possible CRF originated from the fatty acyl chain. A trace amount of LiCl/aq. to the sample in matrix gave MLi^+ ions which were collisionally dissociated and the daughter ions were detected in the second mass spectrometer. Daughter ions detected by the B/E-constant linked scanning were predominated by charge-mediated fragment ions of high intensities, which prevented a full assignment of CRF ions of low intensities, now appeared clearly to be amenable to assign the second and third double bonds to be at C8 and C10, and location of a methyl group at C9, as reported previously.[3] Thus tandem mass spectrometry is essential when a multiple number of unsaturation is involved along the CRF series.

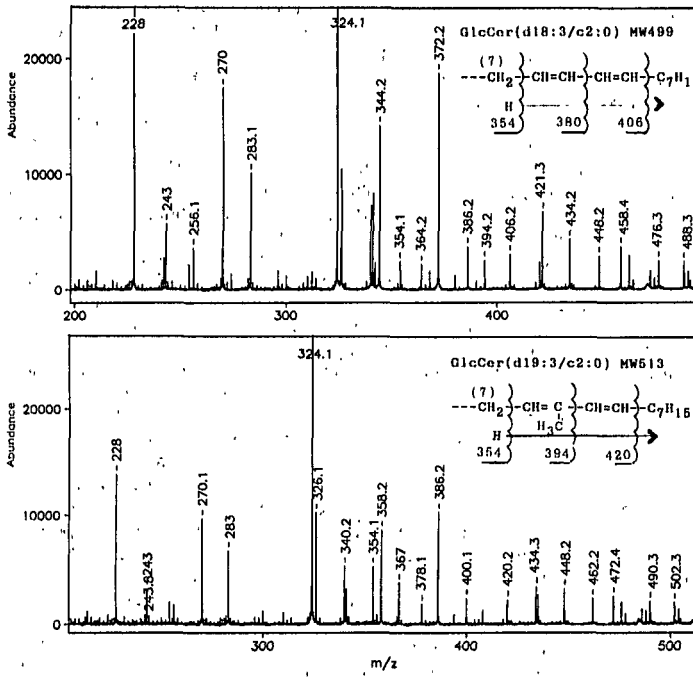

Fig. 2 (+)FAB MS/MS: Daughters of MLi^+s of GlcCer(d18:3/c2:0)(upper) and GlcCer(d19:3/c2:0)(lower), semi-synthesized from glucosylceramides of a starfish spermatozoa[3]. (3-nitrobenzylalcohol).

CHARACTERIZATION OF AMORPHOUS WATER-SOLUBLE CYCLODEXTRIN DERIVATIVES BY DESORPTION IONIZATION MASS SPECTROMETRY

Laszlo Prokai, Marcus E. Brewster[1], and Nicholas Bodor
Center for Drug Discovery, University of Florida
Box 100497, JHMHC, Gainesville, FL 32610.
[1]Pharmatec, Inc , P.O. Box 730, Alachua, FL 32615.

Cyclodextrins are oligomers of glucose which are produced by enzymatic (amylase) degradation of starch. Cyclodextrins are classified by the number of α-1,4-linked glucose units which occur in their molecular structure. Alpha (α)-cyclodextrin has six such units, ß-cyclodextrin (ß-CD) seven, and τ-cyclodextrin eight. In these carbohydrates, the C-1 chain conformation of the glucose monomers imparts to the molecule a cone-like structure in which the hydroxy groups are oriented on the exterior of a torus The narrower end of the cone contains the primary hydroxy functionalities while the wider face contains the secondary hydroxy groups. This arrangement makes the cyclodextrin exterior decidedly hydrophilic. The secondary hydroxy groups can, however, interact via hydrogen bonding to stabilize the crystalline lattice. Most importantly, the interior of the cyclodextrin cone is hydrophobic due to the presence of the skeletal carbons and ethereal oxygens which line the cavity The result of this architecture is a lipoidal microenvironment which can solubilize non-polar compounds. Taken as a whole, cyclodextrins are water soluble compounds which form reversible complexes with poorly water soluble molecules resulting in soluble molecular inclusion complex [1].

Its low water solubility and parenteral toxicity have prevented the widespread use of ß-CD, the most widely studied cyclodextrin. Several chemical modifications have been performed on ß-CD to increase its low water solubility and, therefore, its usefulness. Since the low solubility is due to in large part to intramolecular hydrogen bonding, methylation has been applied to disrupt this process. Another type of chemical modification is nonselective hydroxy- or dihydroxyalkylation. This chemical reaction generates amorphous mixtures of literally thousands of geometric and optical cyclodextrin isomers. This process has several advantages over simple alkylation. First, hydroxyalkyl cyclodextrins are in and of themselves water soluble and hydrophobic. Secondly, the nonselective nature of the modifications generates many chemically distinct species whose solubility is independent of even close structural analogs. The mixture produced is therefore highly water soluble and can be dissolved rapidly [2].

Since one of the intended major uses of chemically modified cyclodextrins (CMCD's) will be in pharmaceutical products, the most rigorous quality assurance standards must be met. Part of the requirements involves the structural and compositional characterization. CMCD's are complex mixtures and, therefore, the appropriate descriptive terms include the average degree of substitution, molecular weight and substituent distribution, and the extent of linear polymerization (for hydroxy- and dihydroxyalkyl CD's). Desorption ionization mass spectrometry is uniquely suited for the analysis of underivatized CMCD's. So far, ^{252}Cf plasma desorption (PD) mass spectrometry has been used for the determination of the average degree of substitution per cyclodextrin unit (n), the half-width of the distribution (w), as well as the distribution of the substitution degree on the glucose units after the hydrolysis of amorphous cyclodextrin derivatives [3].

We report the use of alternative ionization techniques (FAB, electrospray, thermospray) that are available to commercial sector (KRATOS MS80RFA - FAB) or quadrupole (VESTEC 200 electrospray-thermospray) instruments for 2-hydroxypropyl-ß-CD. The FAB mass spectrum that provides unit mass resolution of the molecular ions (Fig. 1) represents an improvement upon PD mass spectra. The symmetrical molecular weight distribution common for this type of derivatization is also readily discernible, and can be utilized to calculate n, w, etc. Similarly to PD, FAB ions are formed from the neutral molecules and the ambient sodium ions. The desorption of other species by mixing acids (formic acid, TFA, etc.) or other alkali ions (Li^+, K^+, Cs^+) to the 3-nitrobenzyl alcohol matrix could not be effected, or accompanied by significant suppression of the sample-related signal.

Electrospray mass spectrometry, on the other hand, has afforded the desorption of various species, depending on the composition of spraying solution. Protonated molecules ($[M+H]^+$ and $[M+2H]^{2+}$) were obtained from acid-containing solutions (water/MeOH, 1:1, containing 2-5 % AcOH),

although attachment of the ambient sodium to the molecules could not be completely suppressed. We have also been able to effect the desorption of a variety of cation adducts (with NH_4^+, Li^+, Na^+, K^+, Cs^+, and even Ca^{2+}), as exemplified in Fig. 2. Collision-induced dissociation of the protonated molecules and of NH_4^+ adducts by increasing the repeller to collimator voltage has also been possible. The process furnishes fragment ions that may be used for estimating the extent of clustering of substituents on a single glucose unit, and/or the extent of linear polymerization leading to oligoglycol side chains. The similarity of CID to partial acidic hydrolysis has also been observed.

Thermospray ionization was not applicable to the analysis of the underivatized 2-hydroxypropyl-ß-CD. We used this technique, following HPLC separation, for the characterization of the mixture of 2-hydroxypropyl-substituted glucose molecules obtained by acid-catalyzed hydrolysis (1 N HCl, 56°C, 4-10 days).

Analysis of Disaccharides Using a Quadrupole Fourier Transform Mass Spectrometer

James A. Carroll and Carlito B. Lebrilla
Department of Chemistry, University of California
Davis, California 95616 USA

The quadrupole Fourier transform mass spectrometer (QFTMS) allows for the use of low vacuum ionization sources such as fast ion bombardment (FIB) for the analysis of non-volatile species by FTMS. This instrument has proven useful for the analysis of saccharides.[1] Matrix peaks are minimal, even in the lower mass region, allowing the investigation of model disaccharides. Analysis of non-derivatized disaccharides shows a high degree of fragmentation, with peaks corresponding to loss of water and glycosidic bond cleavage.

The effects of alkyl derivatives on the fragmentation patterns of disaccharides was determined by comparing a series of singly-alkylated lactose derivatives with a ^{13}C-labelled lactose compound.[2] The presence of an alkyl group caused the charge retention to shift to the ring containing the derivative, even though the alkyl groups do not contain basic sites. This may be explained by differences in the relative basicities of the rings due to the presence of the derivative. The size of the derivative had little effect on the observed shift in charge retention. Larger alkyl groups caused an overall increase in the total amount of fragmentation of the lactose derivatives.

The negative ion spectra of disaccharides were also investigated. Cleavage occurs on the right side of the glycosidic oxygen for non-derivatized lactose in the negative ion mode and on the left side in the positive ion mode (Figure 1). This difference in the negative ion spectra may be caused by the fact that selective deprotonation occurs at the anomeric hydroxyl group. The localized charge then initiates fragmentation on the reducing end of the molecule. This is supported by the observation that when the anomeric hydroxy was replaced by a methoxy (methyl lactose) so that selective deprotonation no longer occured, cleavage was observed primarily on the left side of the glycosidic oxygen.

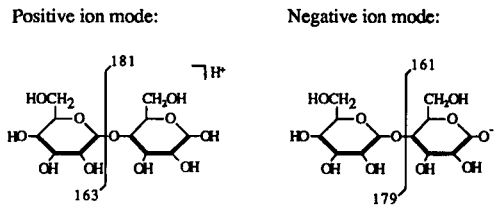

Figure 1: Different bonds are cleaved in the positive and negative ion modes (determined by analysis of ^{13}C-lactose, Sigma Chemical Co., St. Louis, MO USA).

It has been reported that ring cleavage products are observed in the collisionally activated dissociation (CAD) of negative ion disaccharide mass spectra obtained on sector-type instruments.[3] On the quadrupole Fourier transform mass spectrometer, these negative ion ring cleavage products are observed without CAD. The identity of the ring cleavage product observed is dependent on the linkage between the two monosaccharide units. In this way, linkage isomers can be distinguished. The ring cleavage may occur via a retro-aldol fragmentation mechanism proposed by Cotter and coworkers for the laser desorption time-of-flight mass spectra of saccharides[4] and by Leary and coworkers for the CAD mass spectra of lithiated disaccharides.[5]

A strategy for the CAD of externally produced ions has been developed for the FTMS. Parent ions were excited using an off-resonance pulse[6] with a frequency slightly below their natural cyclotron frequency. This served to excite the parent ions to higher translational energy while minimizing ion loss due to collisions with the cell plates. The amount of fragmentation was controlled by varying the amplitude and width of the excitation pulse (Figure 2).

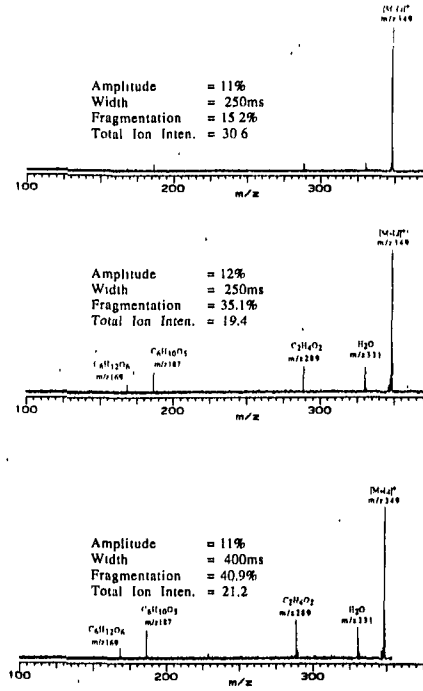

Figure 2: The CAD-FTMS mass spectra of lithiated lactose. The amplitude and duration of the excitation pulse were varied.

Various invasive diseases are caused by human mucosal pathogens, including *Neisseria meningitidis*, *N. gonorrhoeae*, *Haemophilus influenzae* and *H. ducreyi*. These gram-negative bacteria are uniquely adapted to man and occur nowhere else in nature. Colonization of the respiratory tract by *N. meningitidis* or *H. influenzae* can lead to serious disseminated infections including bacterial meningitis in young children. *N. gonorrhoeae* infects mucosal surfaces of the genital tract and in the absence of protective antibodies, gonococci can enter the bloodstream, survive and cause secondary infections. Genital ulcers caused by *H. ducreyi* infection have recently been identified as an independent risk factor in the transmission of human immunodeficiency virus (HIV). The virulence of mucosal pathogens is mediated by an array of surface antigens, including outer membrane proteins and glycolipids. The glycolipids consist of a membrane-associated lipid A moiety attached to a complex branched oligosaccharide.

Over the last few years, we have developed a comprehensive strategy to determine the structures of these surface glycolipids (or lipooligosaccharides) using a combination of liquid secondary ion mass spectrometry (LSIMS), MS/MS, methylation analysis, high pH anion exchange chromatography and NMR [1,2]. More recently, we have found electrospray mass spectrometry of the 'intact' LOS to be particularly valuable to provide an overall look at the heterogeneity of the LOS preparations before any chemical work-up is performed. These electrospray spectra provide information that cannot be obtained by mass spectrometric analysis of the lipid A and oligosaccharide moieties that are produced after mild acid hydrolysis. For example, in the MS/MS analysis of the oligosaccharide fractions from *H. ducreyi* LOS , we found that an anhydro KDO sugar was present in all samples [2,3]. Electrospray analysis of the LOS (after mild hydrazine treatment to remove O-acyl fatty acids and increase the water solubility of the LOS) clearly showed that that there was an extra phosphate group. Further experiments confirmed that this phosphate group is attached to KDO but undergoes β-elimination during the mild acid hydrolysis step required to release the oligosaccharide from the lipid A moiety.

The electrospray data also showed that H. ducreyi LOS is highly sialylated. Normally we can not observe the presence of sialic acid in the oligosaccahride fraction due to the high lability of this group to the acid hydrolysis step. However, mild hydrazine does not effect release of sialic acid, and the electrospray spectra clearly showed a large specie that was 271 Da larger in mass than the previously identified specie (see Fig. 1).

The LOS structures we have determined show structural homology to human glycosphingolipids. This suggest a mechanism by which the bacteria may mimic host glycolipids to evade the host immune system and/or to attach to specific host cell surfaces via carbohydrate lectin-type interactions. Further work is in progress to address this speculation.

The mapping of proteins by mass spectrometric analysis of enzymatic or chemical digests is a well documented technology. Initially, work was limited to the analysis of small peptides by EI or CI, a method that was time consuming and labor intensive even for small proteins. The development of FAB and LSIMS extended the mass range of analysis to much larger peptides, but the collection, concentration and analysis of individual HPLC fractions was still a lengthy process. Recently, much effort has been put into attempts to analyze protein digests using the on-line technique of HPLC/MS. One of the most promising of these technologies is the combination of electrospray mass spectrometry (ESMS) with HPLC.

This report concerns our attempts to extend the utility of this method to the analysis of picomole and sub-picomole amounts of such digests. Fetuin, a 48000 Da molecular weight glycoprotein containing both N- and O-linked glycosylation sites, was used as a test protein in these studies. Following standard procedures, the protein was treated with vinylpyridine and digested with trypsin. The resulting peptides were separated on a microbore column (1.0mm i.d. x 100mm, ABI) directly interfaced to a VG Biotech electrospray mass spectrometer. Mobile phases used were 0.1% TFA in water (Solvent A) and 70% acetonitrile/30% water/0.08% TFA (Solvent B). Gradients were run from 0-70% Solvent B at 0.5 or 1.0 %/min. Ultraviolet detection at 215nm was accomplished using an ABI model 783A detector equipped with a LC Packings U-Z View flowcell with a 7-8 mm pathlength for high sensitivity. The mass spectrometer was scanned from 300-2000 Da with a total scan time of 6 seconds.

Our initial results were promising but limited to a detection limit of 10-40 picomoles of injected digest, with only marginal sensitivity for peptides eluting with less than 20% Solvent B. Based on literature reports (1,2), it was decided to modify the composition of the column effluent by adding a solvent with better electrospraying characteristics to the liquid stream before the mass spectrometer (MS). This was accomplished by adding the electrospray enhancing solvent with an ISCO syringe pump via a 3.0μL mixing tee positioned between the UV detector and the MS. After testing various solvents, a 1:1 mixture of 2-methoxyethanol:isopropanol was selected as the postcolumn addition solvent based on sensitivity and spray stability improvement. It was mixed with the column effluent 1:1. An additional increase in sensitivity was noticed by limiting the flow rate at the MS to 3-4μL per minute (compared to 8-12μL/min used previously). A splitting tee was placed in line between the mixing tee and the MS to allow the microbore columns to be used at their optimum flow rates of 40-50μL/min. This is also useful for the collection of peaks for off-line sequencing techniques.

2. Chowdhury, S.K. and Chait, B.T., *Anal. Chem.*, 63, 1660-1664 (1991).

Using this new system configuration resulted in increases in sensitivity sufficient to analyze digests of fetuin at sub-picomole levels. Figure 1 is a plot of the UV absorbance (top) and base peak intensity (BPI, bottom) versus time for an injection of 10 picomoles of fetuin digest onto a microbore column. Since the split ratio was 1:20, the amount of sample entering the MS corresponded to 500 femtomoles. Figure 2 shows the mass spectrum obtained for a N-linked glycopeptide, with the multiply charged species labeled A4, A5 and A6. Since this peptide was found to be present as three glycoforms this spectrum actually represents less than 500 femtomoles of material. All results were obtained with the MS instrument resolution set to give peak widths of 1.25 daltons at half height. Further increases in sensitivity could be obtained by degrading this resolution.

This new system has subsequently been used for the analysis of a variety of glycoprotein and protein digests at the levels shown above. It has also proven useful for the identification of minor components in protein-adduct formation studies when larger amount of digests are injected. The ultimate goal is to extend this on-line technique to MS/MS analysis of peptide mixtures by electrospray. Current work in this lab is being applied to this end.

Fluorescent Derivatives for the Determination of Marine Toxins

F. Aladar Bencsath, and Robert W. Dickey
Food and Drug Administration, Fishery Research Branch,
P.O. Box 158, Dauphin Island, Alabama 36528

Sensitive liquid chromatographic methods with fluorometric detection were used in our laboratory for the analysis of polyether marine toxins such as okadaic acids. The analyses could be verified by off-line chemical ionization mass spectrometry (CI-MS) which required an additional derivatization step following collection of the eluting material. The fluorescent pyrenacyl and pyrenylmethyl derivatives used for these chromatographic analyses did not provide useful spectra under fast atom bombardment (FAB) conditions thus prohibiting the use of the continuous-flow FAB method.

Recently, highly fluorescent reagents (fluorescamine, fluorescein, coumarin compounds) were developed and used for labelling carboxyl, hydroxyl, amino, etc. groups on biologically important molecules. These novel, commercially available reagents are successfully utilized for the detection of minute amounts of materials in liquid chromatographic (LC) and capillary electrophoretic analyses.

Reagents carrying tertiary or quarternary amino groups were often used formerly by several investigators to increase the ionization yield with FAB. We found that dimethylamino coumarin reagents form highly fluorescent derivatives with polyether antibiotics and marine toxins of the polyether family (nigericin, maduramycin, okadaic acid, brevetoxin) that produce intense molecular ions with FAB. Using continuous-flow FAB, a nanogram level of sensitivity can be achieved with these derivatives.

For labelling the carboxylic group, bromomethyl diethylamino coumarin reagent was used, and for labelling hydroxyl groups, diethylamino coumarin carbonylnitrile and carbonylazide were used. These hydroxyl labelling reagents seemed to react under mild conditions only with unhindered primary and secondary hydroxyls groups. Since most polyhydroxylated polyether marine toxins have only a very limited number of unhindered hydroxyl groups, this derivatization method will probably be adequate for sensitive LC/MS analysis of such compounds.

Introduction

8(S),9(R)-epoxyeicosatrienoic acid (EET) is a major metabolite of the rat kidney cortex and it is a vasoconstrictor when infused into the rat renal artery (1). However, the vasoconstriction is abolished in the presence of PGH synthase inhibitors such as indomethacin (1). This raises the possibility that 8(S),9(R)-EET is metabolized by PGH-synthase to a vasoconstrictor substance. In separate experiments we have shown that 8,9-EET enantiomers are metabolized by human platelets and that the formation of several of the metabolites is inhibited by PGH-synthase inhibitors. The structures of these metabolites have now been elucidated using a combination of EI and electron capture negative ion chemical ionization (EC) MS.

Results and Discussion

Two metabolites (metabolites 1 and 2) were isolated from incubations of [1-^{14}C]8(S),9(R)-EET with human platelets. Metabolite 1 was identified as the diol that arose from the action of epoxide hydrolase on the EET. Metabolite 2 was a conjugated diene based on its UV spectrum (λ_{max} 235 nm). The EC mass spectrum of its PFB,TMS derivative showed an intense [M-PFB] negative ion at *m/z* 407, which was consistent with the attachment of a single hydroxyl group to the EET molecule. GC/EIMS of metabolite 2 as its ME, TMS derivative revealed that the site of hydroxylation was C-11. There was an intense fragment ion at *m/z* 225, resulting from an α-cleavage. After hydrogenation, this fragment ion appeared at *m/z* 229 providing evidence that the structure of metabolite 2 was 11-hydroxy-8(S),9(R)-EET (11,8(S),9(R)-HEET). We have previously identified HEETs as metabolites of 12(R)-HETE (2) and they have also been observed in the metabolism of 5,6-EET (3). The formation of metabolite 2 was completely inhibited by indomethacin or aspirin and this suggested that it was a product of PGH-synthase rather than a lipoxygenase.

Analysis of the supernatant from incubations of [1-^{14}C]8(R),9(S)-EET with human platelets revealed the presence of three metabolites (metabolites 3-5). Metabolite 3 was the diol derived from the action epoxide hydrolase on the EET. Metabolite 4 was a conjugated diene (λ_{max} 235 nm). Its ME, TMS derivative had an identical EI mass spectrum to metabolite 2 (Figure 1). Hydrogenation caused a similar shift in the fragment ion from *m/z* 225 to *m/z* 229 (Figure 2). This suggested that metabolite 4 was 11,8(R),9(S)-HEET, a diastereomer of metabolite 2. Metabolite 5 was also a conjugated diene (λ_{max} 235 nm). GC/EIMS analysis of its ME, TMS-derivative was consistent with the assignment of its structure as 15,8(R),9(S)-HEET. In particular, there was a fragment ion at *m/z* 351, which is typical of an α-cleavage at C-15. This fragment ion was shifted to *m/z* 357 on hydrogenation, providing confirmation that the molecule had undergone hydroxylation at C-15. The formation of metabolites 4 and 5 was inhibited by indomethacin and aspirin.

8,9-EET was an excellent substrate for PGH synthase from ram seminal vesicles. Three major products were observed and they corresponded to the PGH synthase-dependent metabolites obtained in the incubations of 8,9-EET with human platelets. This confirmed that the platelet products were indeed formed from PGH-synthase and that 8(R),9(S)-EET selectively underwent oxygenation at C-15. The configuration of the hydroxyl group in the 11,8,9-HEETs was confirmed as 11(R) by synthesis of the pure HEET diastereomers using vanadium catalyzed epoxidation of 11(R)-hydroxyeicosatetraenoic acid (HETE).

Supported by NIH grant DK38226.

Correlation of Stable Isotope Enrichment of Leukotriene with Arachidonic Acid-Containing Phospholipids by Negative Ion FAB/MS/MS

Kathleen Kayganich and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street
Denver, CO 80206

The biochemistry of arachidonic acid (AA) has been studied extensively primarily because of the potent biological activities of its oxidative metabolites (eicosanoids) such as leukotrienes and prostaglandins. The major stores of AA in cells are the glycerophospholipids (GPL) and over thirty different arachidonate-containing GPL molecular species exist in typical mammalian cells. Following stimulation, AA is released from GPLs and is readily converted to eicosanoids. Whether or not a specific AA-GPL serves as precursor to eicosanoid production is as yet unknown. Our goal has been to investigate this question by enriching cellular AA-GPL with a stable isotope label and correlating the isotopic enrichment of the possible precursors with the isotopic enrichment of eicosanoids released upon stimulation of the cells. Negative FAB ionization and tandem mass spectrometry has been used to measure the isotopic enrichment of individual AA-GPL molecular species within complex mixtures of molecular species. Isobaric endogenous molecular species can present interference when analyzing isotopic enrichment of minor species within complex mixtures. To circumvent this problem either additional chromatography must be used to separate the phospholipid molecular species or a stable isotope label must be introduced that increases the masses of the molecular species of interest above that of any of the endogenously occurring species. We have concentrated on the latter approach, employing a multiply ^{13}C-labelled linoleic acid (18:2) to produce isotopically enriched AA-GPLs. Labelled 18:2 is converted by the cell to labelled AA through elongation and desaturation pathways. By adding labelled 18:2, rather than labelled AA, we avoid problems associated with the addition of large quantities of labelled AA which can be used directly for eicosanoid synthesis by the cells.

EXPERIMENTAL

Cell culture. Virally-transformed murine bone marrow-derived mast cells were incubated in culture medium ($1x10^6$ cells/ml) with 5 uM D_4-18:2 or 9 uM $^{13}C_{17}$-18:2 for 24 or 48 hr at 37°C. D_4-18:2 was a kind gift from Professor H. Sprecher, Ohio State University. $^{13}C_{17}$-18:2 was isolated by RP-HPLC (ODS, 5 um, 25 cm x 4.6 mm, 75% CH_3CN/25% H_2O/0.4% HOAc, pH 2.8) of saponified (1:1 MeOH/2N NaOH, 1 hr, room temp.) lipid extract from algae grown in a $^{13}CO_2$ environment purchased from MSD Isotopes, St. Louis, MO.

Lipid isolation. Glycerophospholipids (GPL) were recovered from mast cells by $CHCl_3$:MeOH:buffer (1:1:1) extraction. Normal-phase HPLC (hexane:isopropanol:H_2O, 60:80:6.6 to 60:80:14 in 20 min) was used to separate lipid classes (neutral lipids, glycerophosphoethanolamine (GPE), glycerophosphoinositol (GPI), glycerophosphoserine (GPS), and glycerophosphocholine (GPC)).

Mass spectrometry. Collision induced dissociation (CID) of the $[M-H]^-$ ions from FAB of GPE, GPI, GPS, and the $[M-CH_3]^-$ ions from GPC AA-containing molecular species was employed to measure the isotopic enrichment of the AA-GPL. An abundant carboxylate anion at m/z 303, corresponding to cleavage of the esterified AA is produced upon CID of AA-GPL molecular species. Isotopically labelled AA-GPL produce carboxylate anions at m/z 307 (D_4-AA) or m/z 320 ($^{13}C_{17}$-AA). The ratios of the abundance of the ion at m/z 307 (or m/z 320) to m/z 303 produced by CID of the respective parent ions from the labelled and unlabelled molecular species were obtained using selected reaction monitoring.

RESULTS

Results from initial experiments using D_4-18:2 are shown in figure 1. These isotopic enrichments were calculated by subtracting the ratio of m/z 307 to m/z 303 obtained by selected reaction monitoring of each AA-GPL in control cells (no label added) from that ratio obtained from cells following incubation with D_4-18:2.

The control ratios were from 25% to 150% of the ratios obtained from the labelled cells. The major contribution to the high ratios in control experiments was from molecular species containing eicosadienoic acid (20:2), which yields a carboxylate anion at m/z 307 upon CID. Isotopic enrichments of AA-GPL obtained by subtraction of the control cell ratios assume that the ratio of m/z 307 to m/z 303 in the cells incubated with labelled 18:2 remains constant. A decrease in the ratio of m/z 307 (from 20:2) to m/z 303 throughout the labelling period would cause error in the calculation of isotopic enrichment. The negative values obtained for isotopic enrichment for GPI species in figure 1. illustrates this point.

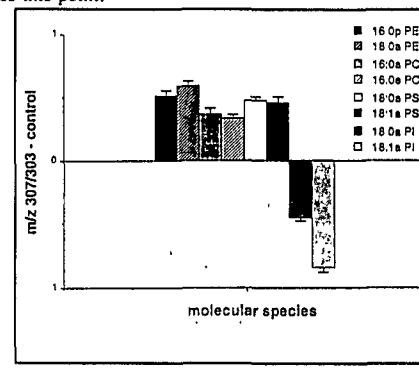

Figure 1 - Ratio of m/z 307 to m/z 303 by selected reaction monitoring of major AA-GPL from mast cells labeled 48 hr with 5 μM D_4-18:2, (n=3) less ratio from unlabeled control cells.

Results from subsequent experiments in which $^{13}C_{17}$-18:2 was added to cell cultures instead of D_4-18:2 are shown in figure 2. The control ratios for m/z 320 to m/z 303 from selected reaction monitoring of AA-GPLs are small (5% to 30%) in comparison to the ratios obtained for AA-GPL from labelled cells. The ratios obtained from the control cells reflect the signal-to-noise limitation in the measurement of minor molecular species within these complex mixtures of GPLs.

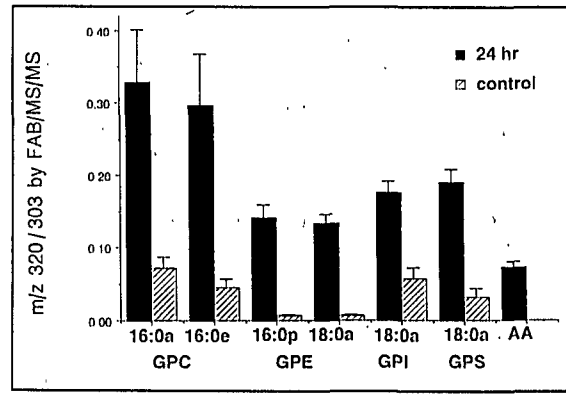

Figure 2 - Isotopic enrichment of major AA-GPL from mast cells labeled for 24 hr with 9 μM ^{13}C-18:2 (n=5) as measured by selected reaction monitoring to obtain ratio of m/z 320 to m/z 303 for each species.

CONCLUSIONS

Addition of D_4-18:2 produces molecular species that are isobaric with endogenous 20:2-containing molecular species. Contributions from these species interfere with the calculation of the isotopic enrichment of the AA-GPLs, especially if the levels of these 20:2-GPLs change upon addition of the labelled 18:2 to the cells. The use of the $^{13}C_{17}$-18:2 alleviates this problem because no endogenously occurring molecular species are isobaric with these labelled species.

Trace Detection of Drugs in Milk and Meat Using Direct Sampling ITMS*

Michelle V. Buchanan, Larry C. Water, Jinghai Xu, and Stacy-Ann Rossi
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Quantitative, specific and rapid detection methods are necessary for trace determination of drugs in physiological media as a means of assessing human dosimetry. Typical methods, however, require extensive sample preparation or lengthy chromatographic separations prior to analysis. We have developed methodologies based on thermal desorption ion trap mass spectrometry (TD/ITMS) which will allow small samples to be analyzed in a few minutes with minimal sample preparation. For compliance evaluations, in particular, this would allow more samples to be tested to ensure the safety of animal products for the consumer. Two anthelmintic drugs, phenothiazine and piperazine, were the compounds targeted for detection in milk using the developed methodologies.

A specially designed thermal desorption inlet was interfaced directly with a Finnigan MAT ion trap mass spectrometer. The ITMS is equipped with all of the electronic components necessary for the selective ionization or storage of ions in the analyzer cell as well as performing collision induced dissociation tandem mass spectrometry. The thermal desorber is continuously purged with 50 mL/min of helium, which transports volatilized materials into the ITMS via a capillary open split interface with a fixed split ratio of approximately 16:1. The thermal desorber is heated to a maximum temperature of about 250 °C in 30 seconds.

New software has been developed to allow for simultaneous detection of multiple compounds in the MS/MS mode of operation, including one or more target analytes and a deuterated internal standard for more accurate quantitation. The dual scan function method, requiring the use of the scan editor program, was determined to be the most reliable method for monitoring multiple compounds. With this method, multiple parent to product ion transitions could be monitored for both the analyte and internal standard resulting in more accurate quantitation and identification capabilities. A calibration curve for phenothiazine and d_8-carbazole (internal standard) is shown in Figure 1, demonstrating the linearity of the dual scan function method.

Rapid sample preparation schemes including Tenax tumbling, solid phase filtration/desorption (SPD), and solid phase extraction (SPE) were investigated. The lowest limits of detection (5 ppb in milk) were obtained using a C18 solid phase extraction column requiring approximately 30 to 45 minutes for preparation of multiple samples. Using the solid phase filtration/desorption apparatus supplied by Toxilab, about 50 ppb detection limits could be achieved with a 5 minute sample preparation. Extraction efficiencies for these methods ranged from 36% (SPD) to 52% (SPE).

Figure 2 is a desorption profile for a 10 ppb milk sample using isobutane chemical ionization and desorption of 10 μL of extract from a C18 filter disk. The top ion profile is for the sum of the two product ions for the internal standard, d_8-carbazole. The MS/MS fragment ions at mz/ 167 and m/z 199 are shown in the bottom traces for the analyte, phenothiazine. Note that the entire desorption process occurs in under 2 minutes resulting in rapid sample turnaround times. Overall, TD/ITMS has considerable promise as a routine method for the analysis of targeted drugs in milk. We are currently extending this methodology for the detection other drugs, including piperazine, and to the analysis of other physiological media, including tissue, urine, and saliva.

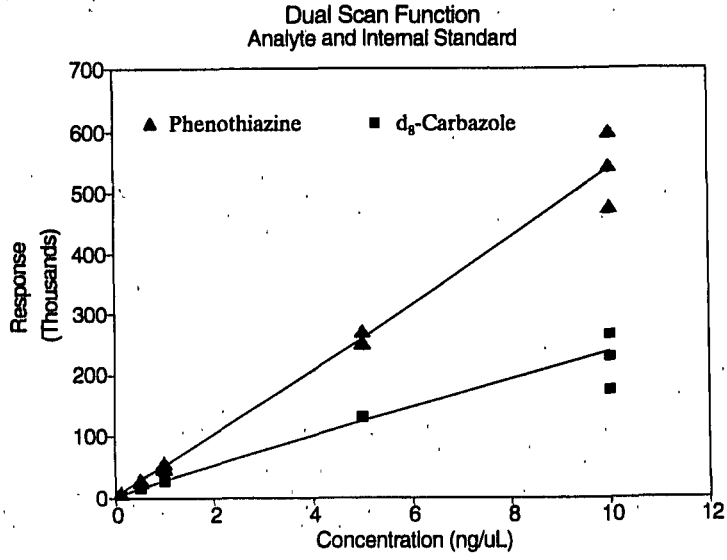

Figure 2

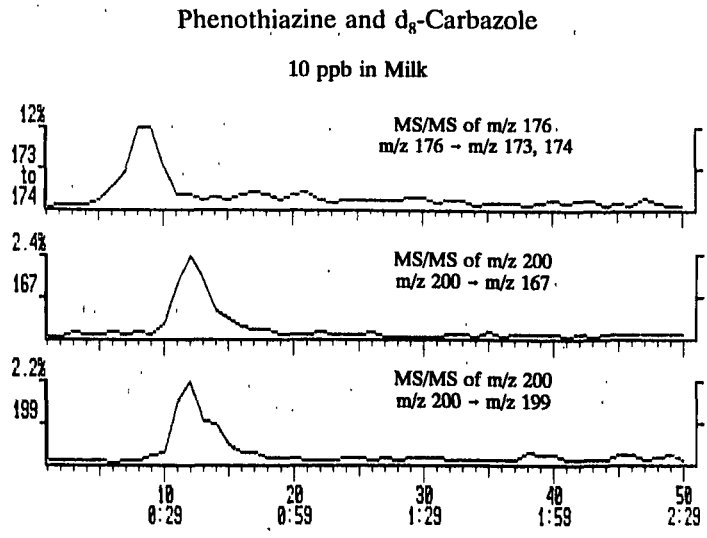

Identification of *N*-acetyl *S*-[(4-hydroxycyclohexyl)carbamoyl]cysteine (NHCC) as a urinary metabolite of the antineoplastic 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU) in patients and in the rat: Evidence for the formation of an isocyanate intermediate. Anthony Borel and Frank Abbott, Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C., Canada, V6T 1Z3.

Introduction

The pharmacological activity of CCNU is thought to be mediated by its decomposition products, namely an alkylating diazonium hydroxide and a carbamoylating isocyanate (1). Although the alkylation of DNA has been proposed to account for chemotherapeutic activity of nitrosoureas, the role of the isocyanate is not precisely clear. Isocyanates are reactive electrophiles which covalently inactivate crucial enzymes (2), and have been speculatively associated with the pulmonary toxicity of nitrosoureas (3,4). We present herein, the first reported structural characterization of a metabolite of a nitrosourea, namely NHCC, which provides evidence for the *in vivo* formation of a potentially toxic isocyanate intermediate.

Experimental

NHCC was synthesized from 4-aminocyclohexanol (5). Treatment of the latter with *p*-nitrophenylchloroformate afforded the carbamate ester. Nucleophilic displacement of *p*-nitrophenoxide from the ester by the thiolate of *N*-acetylcysteine at pH8.5 afforded NHCC. NHCC was characterized by LC/MS/MS on a Waters 600E HPLC interfaced *via* a heated nebulizer (400°C) to a Sciex API *III* MS/MS. CAD in the second quadrupole was induced with argon at a collision energy of 40eV. Patients were orally administered CCNU at 130mg/m^2 and urine collected for up to 12h. Male Sprague-Dawley rats were dosed i.p. with the drug at 130mg/kg and urine collected for 18h. Urine was deconjugated with glucuronidase/sulfatase, extracted with ether, concentrated to dryness *in vacuuo*, reconstituted in MeOH, centrifuged, and the metabolite NHCC purified by HPLC. Chromatography was performed on a Hewlett Packard 1050 HPLC connected in sequence to a Beckman Ultrasphere ODS 5*u*, 250x4.6mm column, variable wavelength detector (210nm) and a Gilson FC-80K fraction collector. The mobile phase MeCN:10mM NaH_2PO_4, pH4.0 (4:96) was delivered at 1mL/min, and fractions were collected around t_R 8.2min which coincided with the retention time of an authentic standard of NHCC. The purified metabolite was analyzed by direct injection LC/MS/MS.

Results

MS conditions favoured MH^+ m/z 305 for synthetic NHCC with virtually no thermally induced fragmentation. CAD of m/z 305 afforded daughter ions m/z 164$(NAC+H)^+$, m/z 146 $(NAC-H_2O+H)^+$, m/z 122$(cys+H)^+$, m/z 99$(C_6H_{10}OH)^+$, m/z 81$(C_6H_9)^+$, m/z 76$(gly+H)^+$ and m/z 43$(CH_3CO)^+$. HPLC of a mixture of *cis*- and *trans*-NHCC revealed that the isomers co-eluted at t_R 8.2min. NHCC was identified as a metabolite of CCNU in rats (Fig.1) and in a patient (Fig.2) in the Q1 scan of urine at HPLC fraction t_R 8.2min by MH^+ m/z 305 and $(M+NH_4)^+$ m/z 322, and by the daughter ion spectrum of m/z 305 which was characteristic of synthetic NHCC.

Conclusion

NHCC was formed as a urinary metabolite in man and in rats and provides evidence for the *in vivo* exposure to the reactive electrophile (4-hydroxycyclohexyl)isocyanate. The formation of NHCC is envisioned to occur through sequential cytochrome P-450 oxidation of the cyclohexyl ring of CCNU (6), decomposition to the isocyanate, carbamoylation of the thiol group of glutathione (GSH) and metabolism of the GSH conjuate *via* the mercapturic acid pathway to the *N*-acetylcysteine (NAC) conjugate.

Determination of Furfurals, Angelica Lactones and Phthalic Anhydride in Mainstream and Sidestream Particulate/Vapor-Phase Cigarette Smoke

Earl L. White

R.J. Reynolds Tobacco Company
Bowman Gray Technical Center
Winston-Salem, NC, 27102

2-Furfural, 3-furfural, α-, β-, γ-angelica lactones and phthalic anhydride are all suspected pyrolytic products of sugars, which occur naturally in tobacco. 2-Furfural is a lachrymator with some reported CNS effects. 3-Furfural, α-angelica lactone, δ-angelica lactone, γ-angelica lactone and phthalic anhydride are known irritants whose chemical, physical and toxicological properties have not been thoroughly investigated. Analytical methods for the determination of these compounds in smoke usually employ gas chromatographic separation with detection by FID and/or mass spectrometry. The purpose of this study was to develop methodology for the quantitative determination of these compounds in mainstream and sidestream particulate/vapor-phase (MSPP, MSVP, SSPP & SSVP) smoke and to validate methodology for smoke collection.

MSPP, MSVP, SSPP and SSVP smoke samples were all collected simultaneously with MSPP and SSPP smoke samples being collected on Cambridge filter pads under FTC smoking conditions. Vapor-phase smoke was cold trapped in midget impingers that contained acetone with $^2H_4$-2-furfural and $^2H_4$-phthalic anhydride internal standards (IS). A Fishtail Chimney smoke collection system was used to collect both SSPP and SSVP smoke. Cambridge filter pads were extracted with acetone-IS solution. An aliquot of the smoke condensate extract was analyzed by multidimensional gas chromatography/mass spectrometry. Precolumn separation was performed on a DB-5 capillary column (0.54 mm X 15 m, 1.0 μm film thickness) which was held at 50°C for 1 min, then programmed to 250°C at 10°C min^{-1} and held for 10 min. The analytical column was a DB-1701 capillary column (0.32 mm X 30 m, 0.25 μm film thickness). The analytical column oven temperature was held at 35°C for 2 min, then programmed to 55°C at 3°C min^{-1} and held for 0.5 min, then to 250°C at 15°C min^{-1}.

No breakthrough was observed during sampling for MSPP, SSPP or MSVP smoke components. However, for SSVP smoke samples, approximately 3-5% of most compounds were detected in a second midget impinger placed in series. Extraction efficiencies with standard deviations were 90.1±5.4, 90.2±3.7, 93.8±1.5, 100.7±5.8 and 93.4±1.5 for 2-, 3-furfurals, α-, γ-angelica lactones and phthalic anhydride, respectively. No authentic δ-angelica lactone standard was commercially available, however, this compound was found as a contaminant in the α-angelica lactone standard at 2.3%. Therefore, all values for this compound are estimates. Minimum detectable quantities were found to be 10 ng/cig for all compounds except phthalic anhydride which was 15 ng/cig. Accuracy of the method was determined by the method of standard addition. The precision was found to be 4.08±0.08, 0.77±0.02, 0.71±0.02, 0.68±0.11 and 0.16±0.02 for 2-, 3-furfurals, α-, δ- and γ-angelica lactones, respectively as determined by eight repetitive injections of a MSPP smoke sample. Since phthalic anhydride was not detected in the MSPP sample, no precision data is presented for this compound. Smoke samples from non-filter, full flavor, full flavor low tar, and ultra low tar cigarettes were analyzed. With the exception of phthalic anhydride (found in MSVP only), and γ-angelica lactone (which was not found in MSVP and SSVP), all other compounds were detected in all phases of smoke samples from non-filter, full flavor and full flavor low tar cigarettes. Essentially no 3-furfural, δ-angelica lactone or γ-angelica lactone was detected in MSPP and MSVP smoke of ultra low tar cigarettes. Phthalic anhydride was only detected in the MSVP smoke as the anhydride. This compound is readily converted to phthalic acid in the presence of water.

The Evaluation of Some Penicillins by ES LC/MS and by ES ITMS

*D.J. Grindstaff [1], M.H. Allen [1], and R.D. Voyksner [2]
1.Vestec Corporation, 9299 Kirby Drive, Houston, TX 77054
2.Analytical and Chemical Sciences, Research Triangle Institute,
P.O. Box 12194, Research Triangle Park, NC 27709

Penicillins are a class of drugs commonly used for their antimicrobial activity against both gram-positive and gram-negative organisms in veterinary applications as well as in human medicine. Analytical methods must be developed to confirm the presence of B-lactam antibiotics at the ppb level to insure human food safety. Electrospray MS was used for the specific detection of three penicillins (ampicillin, amoxicillan, and cloxacillan) in order to establish precise analytical methods for their their detection and to compare the obtained the spectra form CID in a quadrupole mass spectrometer to that obtained on a ITMS with MS\MS capabilities.

We have observed $[M+H]^+$ ions (*m/z* 350 for ampicillin, *m/z* 366 for amoxicillan, and *m/z* 436 for cloxacillan) and fragment ions. One fragment ion at m/z 160 was common for all B-lactams. This ion was formed by the cleavage of the B-lactam ring. These ions proved sufficient to confirm the presence of the antibiotics. Even though the electrospray ionization process exhibited primarily $[M+H]^+$ ions under the conditions of 10 volts on the repeller, we have obtained several structurally confirming fragment ions which were generated by (1) maximizing the collision activation dissociation (CAD) in the quadrupole electrospray source[1] by increasing the repeller voltage to 24 volts and (2) by utilizing the MS/MS capabilities of the ITMS. The fragment ions arise from both the loss of functional groups and/or the further clevage of the B-lactam ring. By either technique at least three fragment ions were produced for each compound. This changed the base peak of the spectrum to that of a fragment ion instead of the protonated intact molecular ion. Figure 1a shows the resulting spectra for ampicillan under the conditions of a 10 volt repeller voltage for the spectrum obtained on the quadrupole mass spectrometer and the resulting spectrum obtained for ampicillan under MS only conditions for the ITMS. Both spectra show only intact protonated molecular species. Figure 2a shows the resulting spectra obtained under the conditions of a 24 volt repeller setting for the quadrupole MS and MS\MS conditions for the ITMS. Both exhibit clevage of the B-lactam ring resulting in the m/z 160 ion and the m/z 106 ion. The spectra are quite similar showing the ability of the quadrupole MS to fragment these small molecules resulting in spectra very similar to that of the MS\MS capabilities of the ITMS. Both methods are very useful in obtaining structually significant fragment ions from the B-lactams studied.

Figure 1a

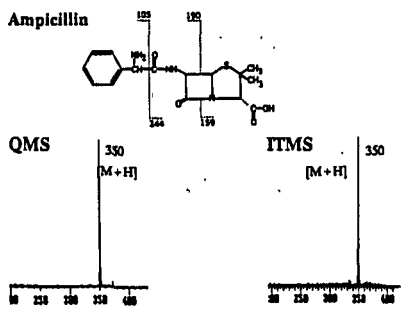

Figure 1b

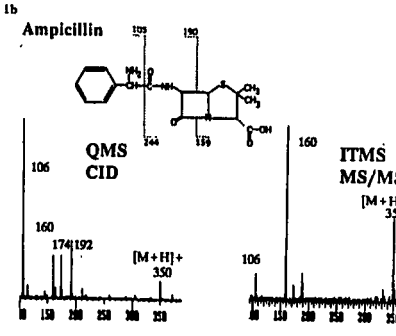

Low levels of the penicillin residues were detected by Electrospray microbore LC/MS on the quadrupole system by monitoring both intact protonated molecular ion and the identified characteristic fragment ions. These measurements were made using the isocratic conditions of 55/45 water/CH3CN with 2% Acetic Acid. A flow rate of 25 uL/min was used for all separations using an LC Packings 1 mm i.d. x 100 mm C_{18} column with a 3 um particle size. Figure 2a shows reconstructed ion chromatograms for the molecular ions from amoxicillan, ampicillan, and cloxacillan acquired with a repeller voltage of 10 volts. Primarily only intact molecular ion species exist with a small amount of ring clevage to produce the shown m/z 160 ion. Figure 2b shows reconstructed ion chromatograms for the molecular ions and characteristic fragment ions for each of the three penicillins evaluated. Amoxicillan demonstrated the ions m/z 349 [M-H2O+H]+, m/z 114, m/z 208, and the characteristic ion for all three m/z 160. Ampicillin demonstrated the ions m/z 350 [M+H+], m/z 160, m/z 106, and m/z 192. Cloxicillan, the last compound to elute demonstrated a very small amount of intact molecular ion under the 22 volt repeller condition but exhibited a strong m/z 160 and m/z 277 which are both produced by the clevage of the B-lactam ring,

Neutralization-Reionization with A Tandem Quadrupole Mass Spectrometer

Frantisek Turecek*, Ming Gu and Scott A. Shaffer
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

A novel tandem quadrupole acceleration-deceleration (QADQ) mass spectrometer has been designed and constructed for neutralization-reionization ('NR') studies.[1] The instrument is equipped with electron impact (a), chemical ionization, and Cs-ion gun ionizers and allows a variety of scans and collisional activation experiments. In a standard 'NR' mode the precursor ion is selected by a quadrupole mass analyzer as MS-I (b), accelerated to a keV kinetic energy (c) and neutralizaed in a floated collision cell (d). Ions are separated by conduits (e, f) floated at positive potentials and the neutrals transmitted to a reionization cell (g) floated at a variable keV potential. Ions formed by reionization are decelerated (h), filtered by kinetic energy (i), mass analyzed by a second quadrupole analyzer (j) and detected as electrons after impinging on a conversion dynode (k). The ion source, collision cells, ion conduits, and MS-II part are differentially pumped (Figure 1).

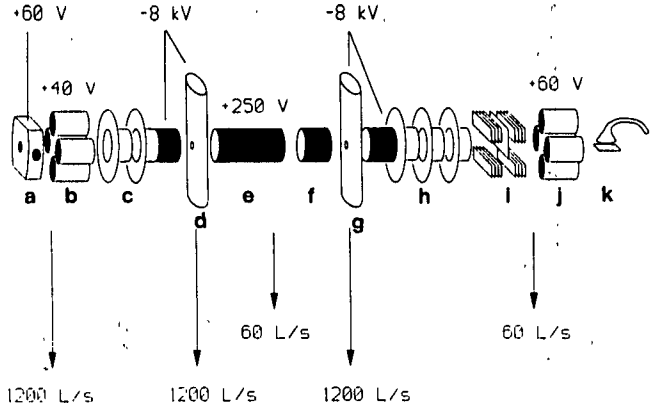

Figure 1. Quadrupole acceleration-deceleration mass spectrometer.

The MS-II part achieves unit mass resolution as demonstrated for 'NR' spectra of various ions including aromatic hydrocarbons, phenol, aromatic amines, and organosulfur derivatives. Mass resolution has little dependence on the kinetic energy release in the formation of the fragment ion.

Neutralization-collisional-activation-reionization ('NCR') experiments with the QADQ instrument are carried out by admitting helium in the floated conduit e. These show substantial efficiency in dissociating neutral intermediates as will be demonstrated for organosulfur molecules.[2,3] Efficient neutral dissociation is made possible by the long (63.5 cm) collisional path, and the large acceptance angle of the MS-II ion optics.

Reionization in the field gradient between **e** and **f** of thermal gaseous molecules by keV neutral beams is also observed, although with limited sensitivity. Collision-induced dissociative ionization (CIDI) is monitored by linked scan of the quadrupole analyzer (**j**) and the decelerating lens (**h**) set to a fractional potential.

Decoupling of the deceleration lens and quadrupole analyzer scans allows precursor neutral and survivor ion scans. For the former, **b** is set to an RF-only mode, and **j** is set to transmit an ion corresponding to the selected neutral. Scanning **h** then allows passage of reionized neutrals formed from neutral and ionic precursors of different masses, as illustrated with the PO precursor scan (Figure 2a). The substantial differences in neutral stabilities and reionization efficiencies for isobaric ions of different elemental composition (e.g. PO, CH_2SH, and CH_3O_2 at *m/z* 47) show potential for type-selective monitoring in mixtures.

For survivor ion scans, **b** is operated in an RF-only mode, and **h** voltage is set to transmit reionized precursors, while **j** is scanned. The survivor ion spectra show potential for isomer differentiation as demonstrated with hexenes, hexadienes (Figure 2b) and hexenols.

DETECTION AND CHARACTERIZATION OF THE NEUTRAL FRAGMENTS FROM BIOMOLECULAR IONS VIA NEUTRALIZATION-REIONIZATION MASS SPECTROMETRY

Marcela M. Cordero, Scott V. Boyle, and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron OH 44325-3601

Tandem mass spectrometry (MS/MS) is an established, powerful technique for the determination of the structures and sequences of biomolecules. Conventional MS/MS spectra, usually acquired by collisionally activated dissociation (CAD), contain only the ionic fragments formed during the unimolecular dissociation of the ionized biomolecule. The coproduced neutral fragments can, however, also be detected and characterized by using neutralization-reionization mass spectrometry (NRMS). Here NRMS is applied to several protonated oligopeptides in order to establish the identity of their neutral dissociation products and thus clarify proposed fragmentation mechanisms and evaluate the new structural information.

The CAD spectrum of protonated Ala-Ala is dominated by the N-terminal *a* fragment (100%), formally generated by elimination of the C-terminal alanine ($C_3H_7NO_2$) and of CO. After reionization, these neutral products are identified in the corresponding NR spectrum (Fig.1a). This spectrum contains $CO^{+\cdot}$ as well as ions characteristic of alanine, confirming postulations that the latter is lost as a complete $C_3H_7NO_2$ unit, not as the isobaric combination of small stable molecules, such as $H_3N + C_2H_4 + CO_2$. The reference spectrum of alanine used in the comparison was obtained by reionizing the Ala molecules liberated from the proton-bound dimer, viz. $[Ala]_2H^+ \rightarrow [Ala]H^+ + Ala$ (Fig.1b).

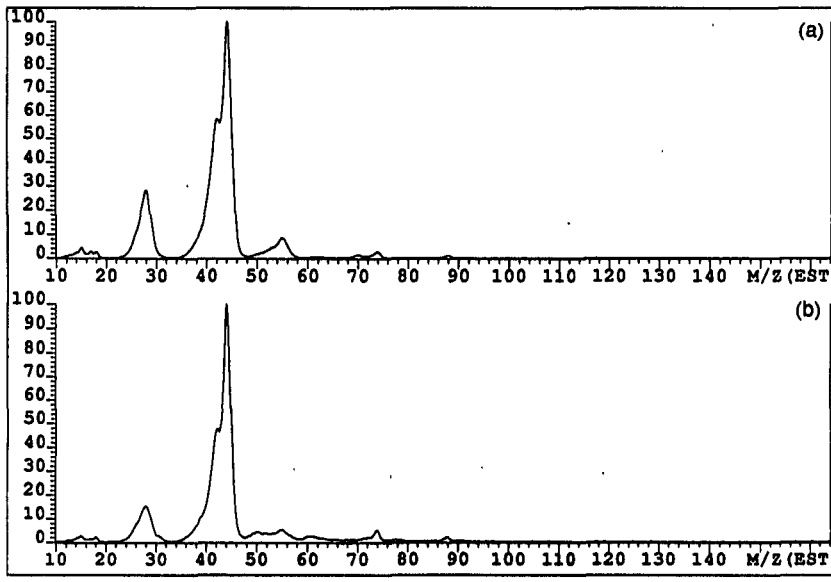

Figure 1. (a) +NR+ He/O_2 spectrum of protonated Ala-Ala. (b) Alanine reference spectrum.

The CAD spectrum of $[Ala-Ala]H^+$ also contains a sizable C-terminal *y* fragment (12%) arising by loss of a C_3H_5NO unit from the N-terminus; C_3H_5NO has been proposed to have the structure of an aminoketene ($H_2N-C(CH_3)=C=O$) or of an aziridinone (*cyclo*-[HN-$CH(CH_3)$-CO]). The NR spectrum indicates liberation of the latter and, hence, transfer of the amino-H upon *y* fragment formation. This is corroborated by the CAD and NR spectra of $[Ala-Ala-\alpha,\alpha'-d_2]H^+$, which do not show D-transfer. Similar results were obtained in other labelling studies [1,2].

The CAD spectrum of MH^+ from the tripeptide Ala-Ala-Ala includes diagnostic a_1/a_2, b_1/b_2, and y_1/y_2 fragments. Comparison of the corresponding NR spectrum with reference NR spectra of pure Ala (vide supra) and Ala-Ala (generated via $[Ala-Ala]_2H^+ \rightarrow [Ala-Ala]H^+ + Ala-Ala$) shows that most of the smaller N-terminal fragment ions (a_1, b_1) originate directly from MH^+ by elimination of entire dipeptide units. Similarly, experiments with the tetrapeptide Ala-Ala-Ala-Ala reveal that a substantial portion of its a_1/b_1 and a_2/b_2 fragments are formed from MH+ by losses of complete tripeptide and dipeptide units, respectively; the remaining fraction is produced from the larger sequence ions by consecutive cleavages of smaller neutral molecules (alanine itself or its aziridinone).

In addition to such mechanistic insight, detection of the neutral CAD products can also provide valuable structural information. E.g., dissociation of protonated val-gly-ser-glu and val-gly-asp-glu leads to the same a_2/b_2 fragments by elimination of different neutral dipeptides. The corresponding NR spectra reflect the structural differences by displaying abundant ions at *m/z* 60 for the former (a_1 fragment from reionization of ser-glu) but *m/z* 88 for the latter (a_1 from reionization of asp-glu), as shown in Figs. 2a and 2b.

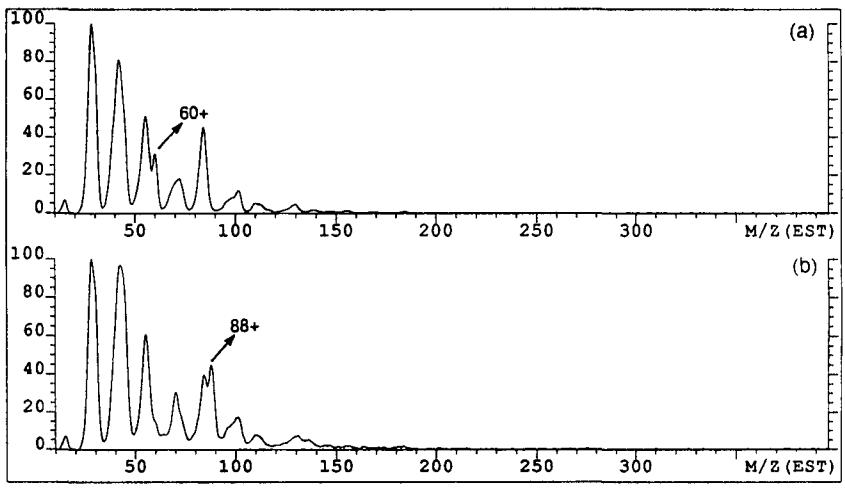

Figure 2. +NR+ He/O_2 spectra of (a) protonated val-gly-ser-glu and (b) protonated val-gly-asp-glu.

GAS PHASE CHEMISTRY OF ELUSIVE NEUTRALS

Chrys Wesdemiotis, Michael J. Polce, Jinnan Cai, and Sarka Beranova
Department of Chemistry, The University of Akron, Akron OH 44325, U.S.A.

Molecules with extra or missing valencies, which are difficult to study by conventional bench experiments, can be formed and characterized in the gas phase by neutralization-reionization mass spectrometry (NRMS). With this MS/MS technique, solitary neutrals are produced by charge-exchange from the corresponding mass-selected ions. The stabilities and unimolecular reactions of the neutrals are then probed by the mass spectra obtained after reionization. NRMS's capabilities are demonstrated here for polysubstituted radicals, diradicals, and hypervalent radicals; such species have unpaired electrons and can be important intermediates in thermal and photochemical reactions.

Neutralization of even-electron cations provides a convenient route to variously substituted radicals. E.g., from protonated formamide, $HO-HC=NH_2^+$, the amino-hydroxy-methyl radical, $HO-HC^{\cdot}-NH_2$, is accessed. This radical is bound by only ~36 kJ mol-1 in respect to dissociation into $H^{\cdot}$ + $O=HC-NH_2$. For comparison, the energies required for $H^{\cdot}$ elimination from the monosubstituted $CH_3CH^{\cdot}OH$ and $CH_3CH^{\cdot}NH_2$ are >3 times larger, namely 118 and 117 kJ mol-1, respectively. The substantially lower thermodynamic stability of the disubstituted radical is reflected in its neutralization-reionization (+NR+) spectrum (Figure 1a). This shows a weak recovered parent cation and extensive fragmentation into formamide, whose reionization yields dominant $O=CHNH_2^{+\cdot}$, HCO^+, $CO^{+\cdot}$, and $NH_3^{+\cdot}$ fragments (Figure 1b). The abundances of HCO^+, $CO^{+\cdot}$, and $NH_3^{+\cdot}$ in Figure 1a are much higher than in the reference +NR+ spectrum of formamide+· (Figure 1b). The additional fragments could originate from neutralization of the ion-dipole complexes $HCO^+\cdots NH_3$ = $CO\cdots NH_4^+$, formed upon protonation of formamide if the proton is attached to the nitrogen instead of the oxygen atom of the amide functionality.

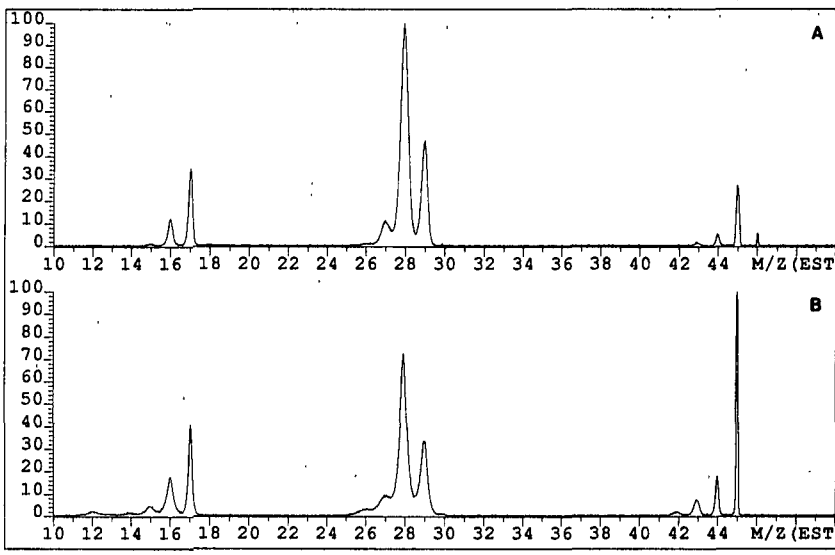

Figure 1. +NR+ Xe/O_2 spectra of (A) protonated formamide and (B) formamide radical cations, produced by isobutane chemical ionization and 70 eV electron impact, respectively.

The diradicals $^{\cdot}CH_2CH_2OCH_2^{\cdot}$, $^{\cdot}CH(CH_3)OCH_2^{\cdot}$, and $^{\cdot}CH_2CH_2CH(OH)^{\cdot}$, which represent ring-opened forms of four- and three-membered rings, can be produced by reduction of the well known distonic radical cations $^{\cdot}CH_2CH_2OCH_2^{+}$, $^{\cdot}CH(CH_3)OCH_2^{+}$, and $^{\cdot}CH_2CH_2CH(OH)^{+}$, respectively. Reionization into positive and negative ions provides evidence that all three diradicals represent true intermediates with sizable barriers towards both fragmentation as well as rearrangement to more stable closed-shell isomers via ring-closure and/or H-atom migrations. This is confirmed by semiempirical MO calculations. A large fraction of the 1,4-diradical $^{\cdot}CH_2CH_2OCH_2^{\cdot}$ decays by simple C-O bond rupture to $CH_2{=}CH_2 + O{=}CH_2$. In contrast, the 1,3-diradicals, which would necessitate isomerizations to yield stable closed-shell fragments, do not dissociate noticeably within the microsecond time scale of the NR experiments. Reionization into anions shows that $^{\cdot}CH_2CH_2OCH_2^{\cdot}$ and $^{\cdot}CH_2CH_2CH(OH)^{\cdot}$ can produce surviving molecular anions, whereas $^{\cdot}CH(CH_3)OCH_2^{\cdot}$, in which both radical centers are next to an oxygen atom, can not. The most likely structures of the observed molecular anions are $^{-}CH_2CH_2OCH_2^{\cdot}$ and $^{-}CH_2CH_2CH(OH)^{\cdot}$, which depict a β-substituted ethyl anion and a γ-substituted propyl anion, respectively.

Simple, hypervalent ammonium radicals have been studied extensively by neutralization techniques. While $NH_4^{\cdot}$ and $CH_3NH_3^{\cdot}$ are unstable (lifetime <<150 nsec), the perdeuterated isomers $ND_4^{\cdot}$ and $CH_3ND_3^{\cdot}$ can survive long enough (≥ 1 μsec) to be experimentally detectable. The higher stability of the perdeuterated species has been attributed to the significantly lower zero point vibrational energy associated with N-D versus N-H bonds. In such a case, persubstitution with even heavier elements should lead to a similar stabilizing effect. This is indeed confirmed with the tetramethyl ammonium radical. Neutralization of $(CH_3)_4N^+$ with trimethylamine (TMA) yields the incipient $(CH_3)_4N^{\cdot}$, which upon O_2 reionization gives rise to the +NR+ spectrum of Figure 2. The presence of a sizable recovered parent cation in this spectrum proves that $(CH_3)_4N^{\cdot}$ can survive intact and must, therefore, represent a bound species with its ground state lying well below the corresponding dissociation threshold. With $(CH_3)_4N^{\cdot}$, the non-hypervalent resonance structure $(CH_3)_3N{:}\cdots{}^{\cdot}CH_3$ is feasible, in which the dipolar trimethyl amine and the polarizable methyl radical are held together by London dispersion forces.

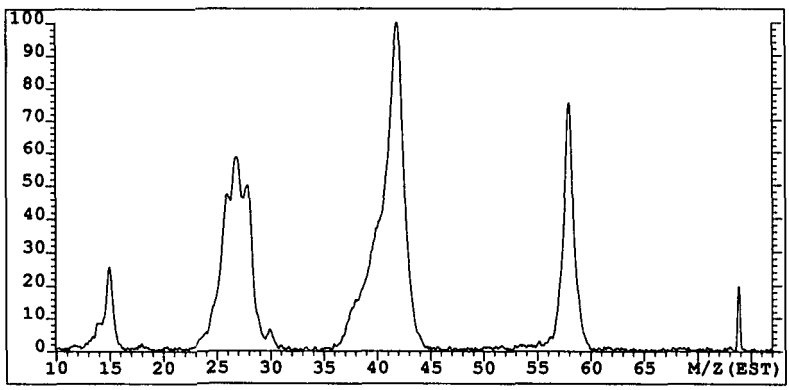

Figure 2. +NR+ TMA/O_2 spectrum of $(CH_3)_4N^+$ from FAB ionization of $(CH_3)_4N^+Br^-$.

GAS-PHASE FRAGMENTATIONS OF ANIONIC COMPLEXES OF SER- AND THR-CONTAINING PEPTIDES

Lynn M. Teesch and Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.

Recently, the first study of anionic complexes between peptides and alkaline earth metal ions was reported (1). Collision-induced decomposition (CID) of $(M + Cat^{2+} - 3H)^-$ complexes that contain aprotic amino acids produces $(x_{n-m} + Cat^{2+} - 2H)^-$ and $(y_{n-m} + Cat^{2+} - 2H)^-$ sequence ions and other ions that include the C-terminus. In contrast, peptide complexes that contain the protic amino acids His, Tyr, Trp, Asp, or Glu fragment to give unique N-terminal $(c_{n-m} + Cat^{2+} - 2H)^-$ sequence ions. Formation of $(c_{n-m} + Cat^{2+} - 2H)^-$ ions requires that a protic amino acid side chain and two adjacent amide nitrogens be available for deprotonation and complexation with the alkaline earth metal ion. This initial study of anionic complexes provided further evidence of intramolecular chelation between peptides and alkaline earth metal ions.

If the peptide complex contained either Ser or Thr, however, the predominant decomposition would be via cleavage of the Ser or Thr side chain (loss of 30 or 44 u, respectively). Here, we present fragmentations of anionic complexes of tetra- and larger peptides that contain Ser and Thr. Both negative ion fast atom bombardment (FAB) and CID were used to study the $(M + Ca - 3H)^-$ and $(M - H)^-$ ions of several peptides. Fragmentations that result from loss of either 30 or 44 u are also ion source reactions. CID of $(M + Ca - 3H - R)^-$ fragment ions (R = 30 or 44) formed in the ion source are the same as CID of analogous peptides in which Gly has been substituted for either Ser or Thr. The similarity of decompositions is shown in the CID spectra of the $(M + Ca - 3H - 44)^-$ fragment ions of AYTPAA (Fig. 1A) and of the $(M + Ca - 3H)^-$ ions of AYGPAA (Fig. 1B).

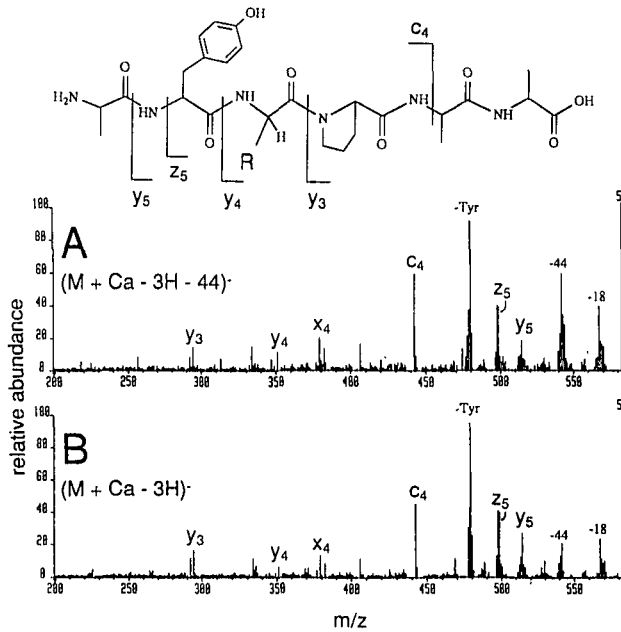

Fig.1 CID spectra of (A) $(M + Ca - 3H - 44)^-$ fragment ions of Ala-Tyr-Thr-Pro-Ala-Ala, and (B) $(M + Ca - 3H)^-$ ions of Ala-Tyr-Gly-Pro-Ala-Ala. R is -44 or $-CH(OH)CH_3$ in (A) and -H in (B).

The similarity of the fragmentations suggests that the losses of 30 and 44 u involve side chain cleavages via a mechanism that requires transfer of hydrogen from the hydroxyl group of the side chain carbonyl oxygen group of the Ser or Thr residue (Scheme I). Thus, the resulting $(M + Ca - 3H - R)^-$ ion is a calcium-peptide complex that now contains Gly.

Analogous losses of either 30 or 44 u are observed in the FAB and CID spectra of $(M - H)^-$ ions of tetra- and larger peptides that contain either Ser or Thr, and the resulting ions likewise contain Gly. The analogous chemistry of $(M + Ca - 3H)^-$ complexes and $(M - H)^-$ ions suggest that the $(M - H - R)^-$ ions decompose similarly to $(M + Ca - 3H - R)^-$ ions. Thus, the charge site is distant from the site of the reaction. This differs from the previously proposed idea that the chemistry involves charge-mediated ion-dipole complexes (2).

A mass spectrometric method for determining the extent of succinylation at each lysine in a protein has been developed. To minimize desorption differences, the remaining free lysines were derivatized with d_4-succinic anhydride. The protein was then digested with suitable proteases and the resulting products partially fractionated by high performance liquid chromatography before being subjected to mass spectrometry on a JEOL HX110/HX110. Figure 1 shows the FABMS of the peptide N-terminal peptide which has two lysines at positions 3 and 9. The two clusters of peaks correspond to d_0,d_4 and d_4,d_4. No d_0,d_0 cluster is seen. Figure 2 shows the MSMS of the tallest peak in the d_0,d_4 cluster of a shorter version of the N-terminal peptide: AcATKAVC*VLKG [1-10] with lysine-3 d_4-succinylated, lysine-9 d_0-succinylated and cysteine-6 carbamoylmethylated. No evidence for d_4-succinylated lysine-9 was found. The two clusters observed are d_4,d_0 and d_4,d_4. The percent d_0 at lysine-3 for this peptide is 0 while the percent d_0 at lysine-9 is 44.

The source of the protein whose peptides we have examined for percent succinylation at each lysine was polyethylene glycol (PEG) derivatized bovine superoxide dismutase (SOD). PEGated enzymes have prolonged plasma half-lives (1) and are under study as possible therapeutic products. PEG-SOD's heterogeneity makes it a challenge to characterize. When the PEG is attached to the protein via a succinyl group, base treatment removes the PEG leaving succinyl groups on the lysines where the PEGs had been attached. To complete the succinylation of the protein, we used pH 9 succinylation with d_4-succinic anhydride. Products from endoproteinase Asp-N, *S. aureus* V8 protease, trypsin, and α-chymotrypsin digestions have been analyzed. As the data shown in Figures 1 and 2 are interpreted, the percent PEGation of SOD is not the same at each lysine in PEG-SOD.

PEPTIDE ANALYSIS BY HYBRID TANDEM MASS SPECTROMETRY. THE CASE FOR HIGHER COLLISION ENERGY AND RF POWER.

Caroline D. Bradley[1], Jonathan M.Curtis[1], Peter J. Derrick[1], and Barry Wright[2]
[1]Institute For Mass Spectrometry and Dept. of Chemistry, University of Warwick,Coventry,U.K.
[2]Kratos Analytical, Barton Dock Road, Urmston, Manchester, UK.

Hybrid tandem mass spectrometers combine the advantages of high resolution and high mass range of a double-focusing instrument (MS1) with the unit mass resolution and relative simplicity of a quadrupole mass analyser (MS2) for fragment ion analysis. Typically, when used as tandem instruments, hybrids employ laboratory collision energies (E_{lab}) of less than 100eV, resulting in an effective upper mass limit of 800-1000 for hybrid MS/MS spectra[1]. This is due to insufficient internal energy uptake by the projectile ion, possibly as a result of the centre-of-mass collision energy (E_{com}) being too low. Hence it is desirable to raise E_{lab} to match those of four-sector instruments (typically 1-10keV) where the upper mass limit (for peptides) is approaching 3kDa.

It has been clearly demonstrated by Alexander et al [2], that the use of higher values of Elab in RF-only quadrupoles necessitates a corresponding increase in the RF-amplitude(V_{RF}) in order to achieve satisfactory transmission. The effect of raising the RF-amplitude is to increase the focusing action of the RF-only quadrupole so that the number of half-cycles of secular motion undergone by an ion travelling through the quadrupole can be raised to one. This corresponds to a maximum in ion transmission where the beam profile at the quadrupole entrance is imaged at the exit [3]. Ion-optical modelling for CID processes in RF-only quadrupoles [3], has predicted that efficient transmission of high mass precursor and fragment ions is possible if V_{RF} is high enough(perhaps kV) and the quadrupole is sufficiently long.

Using the above ideas, a new RF-only quadrupole was installed in a Kratos Concept IHQ hybrid mass spectrometer (EB-qQ geometry). It employs 200mm long hyperbolic-section rods with an inscribed radius of 4mm, and an RF-power supply capable of delivering 1000V zero-to-peak at 1.2MHz. In this version, values of E_{lab} up to 500eV were possible.

The $[M+H]^+$ ion of the peptide dynorphin A fragment 1-9 (YGGFLRRIR, m/z 1137) is shown as a test case, since it was shown to give a poor yield of fragment ions in a previous study on a commercial instrument [1] at E_{lab} = 30 or 100eV. The benefits of higher collision energy and V_{RF} are immediately apparent form the figure. At E_{lab} = 100 eV the introduction of Ar collision gas does not greatly enhance the fragmentation over the unsatisfactory level evident in the unimolecular spectrum. The dominant fragment ions (b_2, y_3'', b_6, b_7 and b_8+H_2O) mainly reflect the location of the basic residue arganine and tyrosine. In striking contrast, at E_{lab} = 400 and 500eV the spectra contain sequence ions across the mass range many of which are not present in the unimolecular spectra. Of particular significance are the appearance of side-chain cleavages w_5 (loss os isopropyl radical from Leu side-chain of z_5+1) and d_7 (β cleavage of an Arg side-chain from a_7+1) since such cleavages are generally not seen in low-energy CID spectra due to insufficient energy deposition on collisional activation[4]. Abundant immonium ions are also seen.

The results shown for dynorphin A represent a great improvement on previously published hybrid spectra, but are inferior to CID spectra at E_{lab} = 4keV obtained on a four-sector instrument which contained a number of extra w and v ions. However, it was found that by reducing E_{lab} to 400 eV so that E_{com} was the same as on the hybrid, similar results were obtained on the two instruments, apart from some known differences due to ion optics. On the other hand, making E_{com} the same by changing collision gas from Ar to He whilst maintaining E_{lab}=4keV resulted in the four-sector spectrum still containing more fragment ions. Hence E_{com} is by no means the only factor controlling CID processes, as will be discussed elsewhere[5].

The results shown for Dynorphin A are typical of the improvements to be gained at higher values E_{lab} for peptide precursor ions of relative molecular mass above about 800. Even in cases where apparently satisfactory low-energy spectra could be obtained previously, often as a result of pre-collision internal energy [1] (eg Gramicidin S, m/z 1141), additional fragmentations could be observed at E_{lab} > 400eV. Experiments using peptides of RMM > 2000 have indicated that at E_{lab} = 400-500 eV, there is sufficient internal energy uptake to induce fragmentation. Thus it is hoped that a further increase in V_{RF} could extend the useful range of the hybrid even further.

Capillary Electrophoresis Coaxial Continuous Flow FAB Combined with Array Detection Mass Spectrometry

R. L. Cerny, J. M. Y. Wellemans and M. L. Gross, Midwest Center for Mass Spectrometry, University of Nebraska, Lincoln, NE 68588-0304 and L. J. Deterding and K. B. Tomer, Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P. O. Box 12233, Research Triangle Park, NC 27709

Capillary Electrophoresis (CE) is a separation technique based on the differential migration of charged analytes in an electric field. The flow profile associated with CE is piston-like rather than parabolic such as is found in pressure driven separation techniques. This leads to very high separation efficiencies with plate counts in excess of 1,000,000 having been reported. A corollary to this high separation efficiency is that the peaks in CE are extremely narrow (in time), especially at low levels of analytes. When coupled to scanning mass spectrometers this leads to missed peaks in the full scan mode and insufficient time for data acquisition during MS/MS experiments. For instruments capable of simultaneous detection, however, the narrow peaks associated with CE can be advantageous. The sample is presented in a very tight band resulting in abundant ion production, albeit of short duration.

We have interfaced an ISCO Model 3850 CE unit with a VG ZAB-T four sector mass spectrometer equipped with a 15 cm channel electron multiplier array. The design of this instrument allows for acquisition of a large portion of an MS/MS spectrum simultaneously. In addition, the integrating capability of the array detector permits full utilization of the sample ions produced.

The interface consists of a coaxial continuous flow FAB probe (1) using a 13 micron capillary for the CE separations. With this design the matrix and analyte interact only at the probe tip so there is no compromise of separation conditions. In addition, the probe tip, which is at the accelerating potential of the mass spectrometer, serves as the "ground" for the CE separations. This eliminates the dead volumes and band broadening that are associated with transfer lines or junctions.

CE separations were obtained using a 1 m column with a potential drop of 22 kV (power supply operated at 30kV minus accelerating potential of 8 kV)). The buffer system was 0.005 ammonium acetate at a pH of 8.5. The FAB matrix was 25% glycerol in water adjusted to a pH of 3.5 by the addition of heptafluorobutyric acid. This system results in separations of negatively charged peptides and detection of positively charged (protonated) ions.

The mass spectrometer was operated at 8 kV. Ions were desorbed by using Cs^+ gun operated at 30 kV. FAB spectra were obtained using 1 sec/decade scans. MS/MS data were obtained by floating the collision cell at 4 kV. This results in simultaneous detection of a mass range of 1.21:1 with a resolution of 1500 to 2000. He was used as the collision gas at 70% attenuation of the parent ion. The array exposure times were 1 sec.

Shown in Figure 1 are the single ion electropherograms of the protonated molecular ions of 37 fmol Met-Leu-Phe and 23 fmol Phe-Leu-Glu-Glu-Ile. This separation demonstrates the performance of the interface with separation efficiencies of 37,000 and 23,500 theoretical plates respectively.

1. Moseley, Deterding, Tomer, Jorgenson, *Anal. Chem.*, **63**, *109* (1991).

The MS/MS spectrum obtained using the array detector of 250 fmol of Met-Leu-Phe separated by CE is shown in Figure 2. All of the expected major fragment ions are observed with good S/N. The ions of *m/z* 26 and 318 are fragment ions from a matrix background ion of the same nominal mass as the protonated peptide.

The MS/MS spectrum shown in Figure 3 is of 75 fmol of Met-Leu-Phe. Ions resulting from the matrix background have been subtracted. Most of the major ions are still identifiable in the spectrum. It is evident, however, that at these levels the analysis would be more useful for confirmation than structure determination.

As the importance of mass spectrometry in the analysis of biological samples continues to increase, the mass spectrometrist is faced with ever decreasing sample size combined with increasing sample complexity. We have combined two high efficiency sample separation methods, capillary electrophoresis (CE) and nanoscale (75 μ id) capillary liquid chromatography (NCLC), with mass spectrometry. Both of these separation techniques are characterized by short analyte elution times (1 to 20 seconds) and relatively low loading capacities (femtomole for CE and low picomole for nCLC are typical) as well as high separation efficiencies.

To obtain as much structural information about the analyte as possible, MS/MS data should also be obtained in addition to full scan data. The short elution times and low loading capacities of the nanoscale techniques, however, place severe constraints on the combination of these techniques. We have successfully combined both nanoscale packed capillary LC and capillary electrophoresis with tandem magnetic sector mass spectrometry (VG ZAB 4F) using coaxial-continuous flow FAB (1,2).

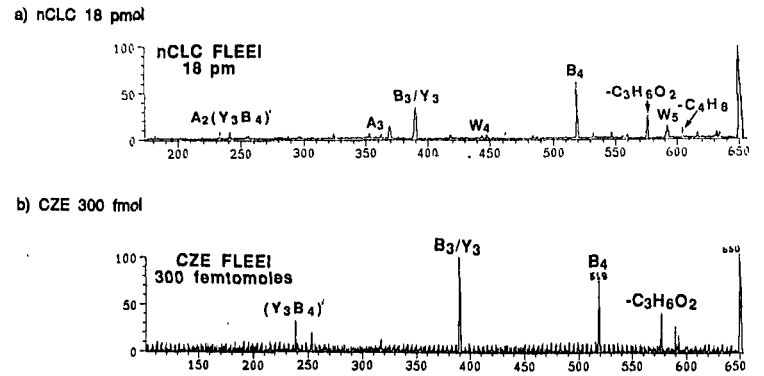

Fig. 1

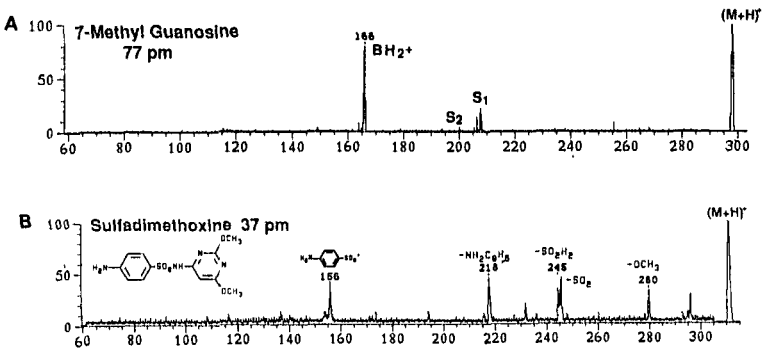

Fig. 2

MS/MS detection limits in the low picomole range have been obtained for components separated by nCLC and in the mid femtomole range for analytes separated by capillary electrophoresis. The MS/MS spectra of a typical peptide, FLEEI, obtained from 18 pmoles by nCLC introduction and from 300 fmoles by CE introduction are shown in Figure 1. Examples of the MS/MS spectra of low picomoles other types of analytes, a nucleoside and a sulfonamide, introduced by nCLC are shown in Figure 2.
We have also interfaced nCLC separations with electrospray ionization on a hybrid tandem mass spectrometer (a Kratos Concept ISQ). We have obtained MS/MS detection limits for singly charged peptide analytes comparable to those obtained from the tandem sector instrument. The MS/MS spectra of morphiceptin, 18 pmol by CF-FAB and 25 pmol by ESI, are illustrated in Figure 3. The detection limits are higher for peptides which are observed as both a singly and a doubly protonated molecule. The MS/MS spectrum of the $(M + 2H)^{2+}$ of (Sar[1], Gly[8])Angiotensin II (Figure 4) is an example of the MS/MS spectrum of a doubly charged peptide ion obtained via nCLC introduction.

Matrix-assisted laser desorption ionization (MALDI) has greatly impacted molecular weight mass spectrometry of peptides and proteins, but the potential of MALDI, in combination with tandem mass spectrometry, for structural characterization is far less developed. In part, the slow adaption of MALDI as an ionization method for tandem mass spectrometry can be attributed to incompatibilities of scanning instruments to pulsed ionization/excitation sources. In previous work we demonstrated femtomole and sub-femtomole detection levels of small peptides with MALDI and magnetic sector/reflectron-time-of-flight (EB/R-TOF) tandem mass spectrometry.[1] More recent work with the EB/R-TOF instrument has focussed on instrument development and improvements of the signal-to-noise of the data.[2] For example, we have examined the metastable ion spectra of ions formed by MALDI in an attempt to evaluate the utility of EB/R-TOF type instrumentation for performing structural mass spectrometry of large molecules with particular emphasis on ultra-high sensitivity. Concurrently we are comparing data obtained with the EB/R-TOF instrument with data obtained using Fourier-transform ion cyclotron resonance (FTICR) mass spectrometry. The comparison of ICR and TOF tandem mass spectrometry experiments and data will be the focus of an up-coming manuscript.

Figure 1 contains metastable ion spectra for leu-enkephalin $[M+H]^+$ ions (formed by Cs^+ liquid-SIMS) obtained using neutral-ion correlation (spectrum A) and neutral-ion correlation/pile-up rejection (spectrum B). Pile-up rejection is a method for eliminating signals due to "false coincidnece" counts.[2] Pile-up rejection improves the signal-to-noise ratio by a factor of five and reduces the data acquisition time by a factor of six. Clearly, pile-up rejection provides a major improvement in the metastable ion spectra, and a corresponding improvement is observed for the CID spectrum. It is now clear that tandem mass spectrometry experiments can be performed on samples where the primary ion count rate is as low as 100-500 primary ions per second. The limiting factor for detection of low level signals is the contribution to the primary ion signal by background ions from the matrix.

The EB/R-TOF instrument has also been used to study metastable ion decomposition of ions formed by MALDI. The preliminary studies were performed to development the methods and are focussed on small biomolecules. Figure 2 contains metastable ion spectra for adenosine monophosphate and val-gly-gly [M+H]+ obtained by using Cs+ liquid-SIMS and MALDI (337 nm). The l-SIMS data was recorded using neutral-ion correlation/pile-up rejection; however, the MLADI data was obtained without the aid of pile-up rejection. Consequently, the S/N for the MALDI/metastable ion spectra is not as good as that for l-SIMS. Nonetheless, the data from these preliminary experiments clearly illustrate the potential of the EB/R-TOF instrument for tandem mass spectrometry studies of ions formed by pulsed ionization, in particular MALDI.

Future work in this area will focus on metastable ion and CID studies of larger biomolecules ionized by MALDI and implementation of pile-up rejection with MALDI.

Introduction.

Ion trap mass spectrometry is becoming a valuable tool for performing MS/MS experiments to investigate ion-molecule reactions and to obtain structural information about organic molecules. The MS/MS experiment in an ion trap mass spectrometer is performed by applying a resonant excitation voltage to the endcap electrodes which causes ions to gain kinetic energy in the axial direction. This gain in kinetic energy can result in ion ejection, or the kinetic energy of the parent ion can be converted into internal energy, via collision with a target gas thereby promoting ion dissociation and the formation of product ions. Resonant excitation thus leads to ion ejection and ion dissociation and the appearance of the resulting MS/MS spectrum depends on which process dominates.

The kinetic energy of the parent ion is related to the power absorbed, and is thus affected by the resonant excitation voltage (tickle voltage), the duration that the resonant excitation voltage is applied (tickle time) and the power lost by collisions with the target gas. Another factor that can affect the ion's kinetic energy is the q value. According to the pseudo-potential well model of ion motion, the maximum kinetic energy that an ion can have and remain stable increases with increasing well-depth, which is proportional to q^2. Experiments were thus performed to evaluate the effect of the q value, tickle voltage, tickle time and the presence of a target gas on ion ejection/dissociation of four model ions, as a means to better understand the resonant excitation process.

Experimental.

The ion trap experiments were performed on a Finnigan Ion Trap Mass Spectrometer. Parent ions of xenon (m/z 132), N,N-dimethylaniline (m/z 120), perfluorotributylamine (m/z 131) and butylbenzene (m/z 134) were chosen as model ions because they are similar in mass and thus have similar power absorption from the resonant excitation voltage, and because N,N-dimethylaniline, perfluorotributylamine and dimethylaniline differ in their degree of fragmentation. The neutral species were introduced into the ion trap through a batch inlet system resulting in sample pressures about 10^{-6} torr. The parent ion of these compounds was isolated by ramping the radio-frequency voltage on the ring electrode (mass selective instability mode). In certain cases, a resonant excitation voltage was simultaneously applied to the endcap electrode to isolate the parent ion from ions of higher mass (axial modulation). The rf voltage was then lowered and the MS/MS experiment was performed by applying a resonant excitation voltage to the endcap electrodes after the frequency on the endcap electrodes was adjusted to obtain resonance between the parent ion and the applied voltage. The experiments were performed in the absence and presence of helium by increasing the resonant excitation amplitude in 30 mV intervals until ion ejection/fragmentation was complete for times of 5 ms, 10 ms, 20 ms, 30 ms or 50 ms and q values of 0.1, 0.2 or 0.3. Beam experiments were performed on a VG SEQ hybrid (EBQQ) mass spectrometer to determine the critical energy of the product ions of N,N-dimethylaniline, butylbenzene and perfluorotributylamine.

Results and Discussion.

In the absence of helium, about 50% of the m/z 132 ion was ejected at 150 mV at q=0.3, 100 mV at a q=0.2 and 50 mv at q=0.1. In the presence of helium, the tickle voltage required to initiate ion ejection of xenon increased as the q value was increased (30 mV at q=0.1; 90 mV at q=0.2 and 270 mV at q=0.3). The duration that the resonant excitation amplitude was applied (5 ms - 50 ms) did not affect ion ejection at any of q values in the presence or absence of helium. The differences in ion ejection that occur at the q=0.1, q=0.2 and q=0.3 arise because the kinetic energy needed to eject an ion increases with well-depth. At q=0.3, the ions are cooled by collisions with helium which results in lowering their kinetic energy, thus requiring a greater resonant excitation amplitude for ion ejection.

Dissociation of N,N-dimethylaniline, perfluorotributylamine and butylbenzene can occur in the absence of helium. Under these conditions ion ejection was the predominant process. Dissociation occurs at q=0.1, 0.2 and 0.3 for N,N-dimethylaniline and butylbenzene and at q=0.2 and q=0.3 for perfluorotributylamine. The normalized relative intensity of the product ions, however comprise less than 1% of the total ion current for dimethylaniline and perfluorotributylamine and less than 10% of the total ion current for butylbenzene.

The resonant excitation amplitude at which the onset of ion ejection was observed increases as the q value was increased and when helium was present compared to when helium was absent. This is an expected result because, as previously stated, the kinetic energy of the ion needed to affect ion ejection increases with well-depth, and because the kinetic energy of the parent ion is lowered by collisions with helium.

Ion ejection was the predominant process at q=0.1 in the presence of helium for all the compounds investigated. Dissociation occurs for the parent ion of N,N-dimethylaniline and butylbenzene at q=0.2 but at this q value, ion ejection dominates for perfluorotributylamine. In general, ion dissociation was enhanced at q=0.3 compared to q=0.2 for N,N-dimethylaniline and butylbenzene. For N,N-dimethylaniline, ion ejection/dissociation occur simultaneously and the onset occurs at 120 mV at q=0.2 and q=0.3. At q=0.3, onset of dissociation of the m/z 131 parent ion of perfluorotributylamine occurs at about 300 mV and ion ejection is initiated when about 400 mV are applied to the endcap electrodes. For butylbenzene, initiation of ion ejection/dissociation occurs at 60 mV at q=0.2. At q=0.3, the onset of ion dissociation occurs around the same tickle voltage (30 mV) but ion ejection does not occur until a voltage of greater than 1000 mV is applied. Neither the onset of ion ejection/dissociation nor the intensity of the product ions was affected by the duration that the resonant excitation amplitude was applied for the m/z 120 parent ion of dimethylaniline. In contrast, the onset of ion dissociation was decreased from 420 mV to 120 mV and the normalized intensity of the m/z 69 product ion was increased from 11% to 50% when the tickle time was increased from 10 ms to 50 ms.

Summary.

The kinetic energy of xenon is lowered by collisions with helium so that a greater resonant excitation voltage is needed to induce ion ejection at q=0.3 in the presence of helium. The critical energy for the appearance of the m/z 92 and m/z 91 product ions is less than for the product ions of N,N-dimethylaniline and perfluorotributylamine. Thus, ion dissociation of butylbenzene occurs at a lower resonant amplitude than the other compounds. At q=0.3 and in the presence of helium, the m/z 134 parent ion is able to dissociate before ion ejection occurs at a resonant excitation amplitude of 1000 mV. Application of resonant excitation voltages greater than 1000 mV cause ion ejection to become the predominant process. The critical energy for the appearance of the m/z product ions of N,N-dimethylaniline is greater than for the product ions of butylbenzene but less than the critical energy for the formation of the m/z 69 product ion of perfluorotributylamine. Thus, the onset of ion dissociation occurs at a higher resonant excitation than for butylbenzene (120 mV) but less than the resonant excitation amplitude to initiate ion dissociation of perfluorotributylamine (300 mV). The m/z 120 parent ion of N,N-dimethylaniline is less effective in dissipating the absorbed power by collisions with helium and ion dissociation and ion ejection occur simultaneously. The power lost by collisions is greater for perfluorotributylamine than N,N-dimethylaniline but less than for butylbenzene. Hence, the onset of ion ejection occurs at a resonant excitation amplitude about 280 mV greater than for N,N-dimethylaniline even though it takes 180 mV more for the onset of ion dissociation.

These results indicate that, in addition to the experimental parameters, the critical energy for dissociation is an important parameter but also the efficiency of the transfer of kinetic energy to either internal energy or kinetic energy of the target affect ion ejection and ion dissociation. The well-depth at which the resonant excitation is performed will be important in determining the relative rates of ion dissociation and ion ejection.

TANDEM MASS SPECTROMETRY OF FAB-DESORBED POLYCYCLIC AROMATIC HYDROCARBONS

Chhabil Dass

University of Tennessee, Memphis, 956 Court Avenue
Memphis, TN 38163

Recently, the use of FAB-MS for characterization of several polycyclic aromatic hydrocarbons (PAH) was described (Dass, 1990). An impact of a fast atom beam produces radical cations ($M^{+\cdot}$) and protonated molecules (MH^+) both, with no evidence of fragment ions. Ionization of PAHs by FAB was facilitated by use of an aprotic liquid matrix, sulfolane (Dass, et al., 1988). The use of glycerol or other protic matrices does not produce meaninigful data. In that study, it was further observed that the $[MH^+]/[M^{+\cdot}]$ ratio is a compound-specific parameter.

Polycyclic aromatic hydrocarbons are carcinogenic and are widely found in combustion products. Therefore, highly structure-specific techniques are required for their analysis. Of critical importance is differentiation of isomeric PAHs because carcinogenicity is attributable to a specific isomer only.

Because the ions sampled in MS/MS for collision-activated dissociation (CAD) experiments have internal energies below the threshold for first dissociation, it is most likely that those mass-selected ions may retain the structure of their neutral precursor. Coupled with the fact that FAB is a soft ionization technique, it should be possible to distinguish the FAB-desorbed PAHs by CAD spectroscopy.

This study was aimed to test that premise. CAD spectra of anthracene (**1**)/phenanthrene (**2**) (MW=178 Da), fluoranthene (**3**)/pyrene (**4**) (MW=202 Da), and chrysene (**5**)/tetracene (**6**)/benz[a]anthracene (**7**)/triphenylene (**8**) (MW=228 Da) were obtained. A VG AutoSpec Q mass spectrometer was used for these experiments. The front end of this hybrid mass spectrometer is of EBE design, and can be used as a stand-alone tandem mass spectrometer for high-energy collision experiments. The precursor ion was mass-selected in the III field-free region and its product ion spectrum was acquired by MIKES technique (i.e., by scanning the second ESA). The above-mentioned PAHs were dissolved in sulfolane and bombarded by a beam of Cs^+ ions of 35 keV energy. The desorbed ions exited the ion source at a potential of 8000 V. Collision activation was accomplished using He as the collision gas.

Figure 1 illustrates MIKE spectra of the $M^{+\cdot}$ ions of **3** and **4**. That data and the data obtained using the MH^+ ions as the precursor are compared in Table 1. It is evident that MIKE spectra of $M^{+\cdot}$ and MH^+ both can distinguish fluoranthene from pyrene.

Table 2 lists the MIKE data for **1** and **2**. Once again, MIKES spectrum of the $M^{+\cdot}$ ions of **1** differs from that of the corresponding spectrum of **2**. These differences are, however, accentuated further when the MH^+ was chosen as the precursor.

The data for the four isomers of MW 228 Da are included in Table 3. In this example, the MIKE spectra of the $M^{+\cdot}$ and MH^+ ions of **5** and **6** are identical but differ from the corresponding spectra of **7** and **8**. The MIKE data of **7** and **8** also are not exactly identical. **7** exhibits increased loss of methyl radical.

The low-energy CAD of the $M^{+\cdot}$ of pyrene using quadrupole section as the second stage mass analysis did not produce many fragment ions. This observation is consistent with high stability of fused benzene rings PAHs.

It is, therefore, concluded that FAB-MS coupled with tandem MS can distinguish a few isomeric PAHs.

Sequential Product Ion Spectra (MS^3 and MS^4) with Array Detection and Reaction Intermediate Scanning On a Four-Sector Instrument. Kevin D. Ballard[1], Simon J. Gaskell[1], Richard K.C. Jennings[2], Jim H. Scrivens[2], and Richard G. Vickers[3]. [1]Baylor College of Medicine, Houston, TX; [2]ICI Wilton, Cleveland, UK; [3]VG Analytical, Manchester, UK.

Sequential mass spectrometric (MS^n) experiments are useful in a variety of different types of studies. The most widely employed such experiment involves obtaining an nth generation product ion spectrum, which is a spectrum of the decomposition products of an $n-1^{th}$ generation intermediate, itself derived via specified pathways from the chosen precursor ion. Such a spectrum can be represented as

Precursor -> 1st gen. intermediate -> ... -> $n-1^{th}$ gen. intermediate -> n^{th} gen. products.

Any inefficiency in the formation of the intermediates results in a decreased yield and therefore reduced signal intensity for the final product ions. This can be a particular problem under high energy CAD conditions, where fragmentation yields are often low. Consequently, attempts at multi-stage mass spectrometry under high energy CAD conditions can give unsatisfactory results when a conventional point detector is employed. Because array detection dramatically improves the sensitivity of detection for ion currents of low abundance, the use of array detection is expected to enhance the quality of data obtained during sequential mass spectrometric experiments under high energy CAD conditions. Accordingly, we have implemented a variety of sequential product ion "scanning" experiments, including MS^3 and MS^4, using a BEBE instrument with array detection (a VG ZAB-T). These experiments employed well characterized peptides as model compounds. The corresponding experiments were previously established on a BEqQ hybrid (a VG ZAB-SEQ), where the final stage of decomposition occurred under low energy CAD conditions. (The initial stage(s) of decomposition occurred under identical conditions on the two instruments.) The results from the hybrid were used as a basis of comparison for the results under high energy CAD with array detection.

A second objective of these studies was to establish reaction intermediate scanning on the four-sector instrument. On a four-sector, the reaction intermediate scan could be used to examine reaction pathways where both stages of decomposition occur under high energy CAD conditions, with acceptable resolution of all of the species involved. Again, data from experiments previously established on the hybrid were used as a basis for assessing the corresponding data from the four-sector.

RESULTS On the BEBE instrument, the use of the array greatly enhanced the signal-to-background ratio for second and third generation product ion spectra, as compared to the use of the point detector on that instrument. For the peptides employed, the fragmentation patterns observed in the sequential product spectra were qualitatively similar on the four-sector and on the hybrid, although the relative abundances varied between the high and low energy CAD regimes. An exemplary MS^4 sequential product spectrum, depicting the $[M+H]^+ \rightarrow B_4 \rightarrow A_4 \rightarrow$ products reaction sequence for leucine-enkephalin from the BEBE instrument using the array, is shown in Figure 1. Observed differences between this spectrum and that representing the $[M+H]^+ \rightarrow A_4 \rightarrow$ products sequence (not shown) suggested that ions derived from particular fragmentation pathways may be predisposed to fragment further through pathways unique to those ions.

Figure 2 shows a reaction intermediate scan for leucine-enkephalin obtained under unimolecular decomposition conditions from the BEBE instrument, depicting the $[M+H]^+ \rightarrow$ intermediates $\rightarrow A_4$ reaction sequence. (This spectrum was obtained using the point detector.) The first stage of decomposition occurred in FFR1, with the second stage occurring in FFR3. An alternative mode of reaction intermediate scanning, employing FFR1 and FFR2 for the two fragmentations, has also been implemented on both the ZAB-SEQ hybrid and the ZAB-T four sector instruments. The results obtained on the two instruments in this mode of operation were virtually identical, in keeping with the identity of the energetics and time scale during the two experiments.

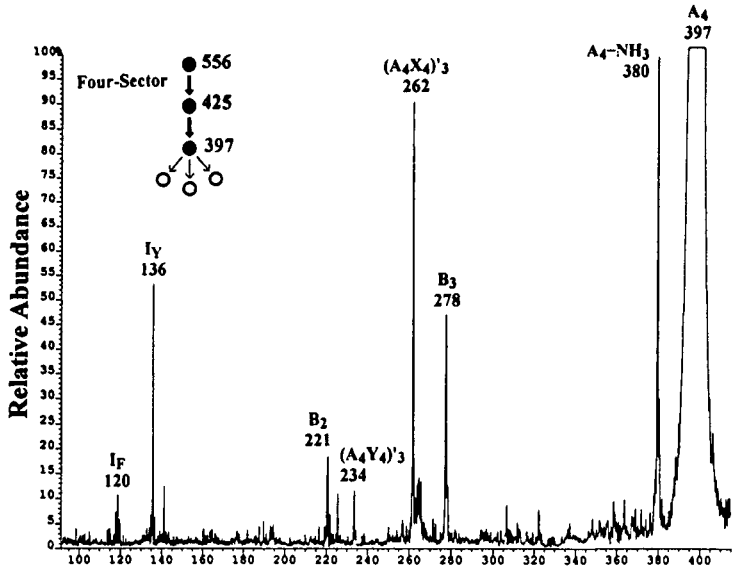

Figure 1. Third generation product spectrum (MS^4) of leucine-enkephalin, showing the $[M+H]^+$ --> B_4 --> A_4 --> products reaction sequence from the BEBE/array instrument.

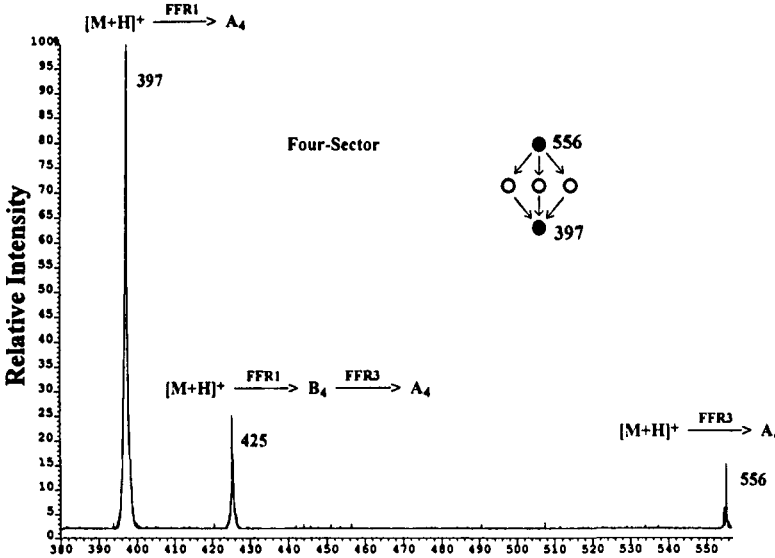

Figure 2. Reaction intermediate scan for leucine-enkephalin from the BEBE instrument, showing the $[M+H]^+$ --> intermediates --> A_4 reaction sequence (spectrum obtained with the point detector).

Direct Sequential Analysis of Large Peptides by High Energy Collisional Activation of Multiply Charged Ions

Ron Orlando
Suntory Institute for Bioorganic Research
Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka 618 Japan

In the sequential analysis of peptides, MS/MS offers several advantages over more traditional methods. However, very few singly charged peptide ions over 3 kDa have been successfully sequenced by MS/MS.[1] Possible explanations for this size limitation are that the amount of energy deposited by collisional activation (CA) is inversely related to the size of the precursor ion and that the dissociation rate decreases as the size of the analyte grows.

Alternatively, very large (66 kDa) multiply charged ions have been fragmented by low energy collisions.[2] Unfortunately, only limited sequence information is obtained from these experiments as fragments appear from confined regions of the analyte. In addition, interpretation of these spectra is hampered by the wide variety of variously charged fragment ions.[2] By providing both higher collision energies and resolutions, tandem four sector mass spectrometers appear to offer several possible solutions to the CA analysis of multiply charged ions, which is the focus of this study.

The fragment ions observed in the high energy CA spectra of doubly protonated peptides are identical to those produced by CA of singly charged ions, as shown by the analysis of the doubly charged ß-peptide, Figure 1. The low *m/z* region contains immonium ions that identify nearly one half of the amino acids present. In addition, fragments arise from back bone cleavages throughout this peptide, and provide virtually complete sequence information. High energy collisions produce fragments from combined side chain and backbone cleavages allowing leucine/isoleucine differentiation even from these large peptides.

Similarly, high energy CA of doubly protonated human parathyroid hormone fragment 1-44 produces fragmentation from virtually all regions of this peptide and allows nearly complete sequence identification. In contrast, low energy CA of this sample permitted only approximately one third of the sequence to be confirmed.[2] Consequently, high energy collisions appear to provide substantially more comprehensive sequence information than low collision energies.

With the size of these peptides, identification of the fragments' charge state would be rather complicated, if not impossible, in the case of an unknown sample. To aid in this task, the resolving power of MS 1 was degraded so that all isotopic variants of the precursor could be analyzed simultaneously. Therefore, charge state determinations could be made from isotopic spacing, provided that the resolution in MS 2 is increased sufficiently to resolve these peaks.[3] This ability simplifies spectral interpretation and is expected to be of particular use in the sequence determination of unknown samples.

On the Ionization Energies of CCl_3 and CF_3 Radicals

Pierre Ausloos and Sharon G. Lias*
National Institute of Standards and Technology
Gaithersburg, Maryland 20899

Values of the ionization energies of the CCl_3 and CF_3 radicals based on direct ionization of the radicals and on appearance energies of the CCl_3^+ and CF_3^+ ions from a variety of precursors are usually higher than values derived from ion/molecule bracketing studies in which these ions are formed as products.

(1) $H_3O^+ + CFCl_3 \rightarrow CCl_3^+ + H_2O + HF$ $IE(CCl_3) \leq 7.9 \pm 0.1$ eV[1]

(2) $HCN^+ + CF_4 \rightarrow CF_3^+ + HF + CN$ $IE(CF_3) \leq 8.3 \pm 0.2$ eV[2]

In such studies, thermochemical data is derived by assuming that only exothermic (or marginally endothermic) reactions are observed.

Because of the wide range of values for these ionization energies in the literature, and because of the discrepancies between the results of ion/molecule bracketing studies and ionization or appearance energy measurements, a different approach, bracketing of charge transfer reactions of the CCl_3^+ and CF_3^+ ions has been used to establish the ionization energies of these radicals. Reactions such as:

(3) $CCl_3^+ + M \rightarrow M^+ + CCl_3$

(4) $CF_3^+ + M \rightarrow M^+ + CF_3$

(where M is a compound with a well-established ionization energy) were examined in a Fourier transform ion cyclotron resonance spectrometer (ICR). The CCl_3^+ and CF_3^+ ions were generated in CCl_4 and CF_4, respectively. The reactant compounds, M, were mainly aromatic molecules, and were added in low concentrations to insure that the reactant halomethyl ions were thermalized prior to reaction.

The CCl_3^+ ion was found to transfer charge to naphthalene (IE = 8.13 eV) but not to anisole (IE = 8.21 eV), allowing an estimate of the ionization energy of the radical of 8.15±0.05 eV. This value is fully consistent with the value of 8.109±0.005 eV obtained in a resonance enhanced multiphoton ionization study of the CCl_3 radical[3].

The CF_3^+ ion transfers charge to p-chlorotoluene (IE = 8.69±0.02 eV) with a low probability (5%), but not to p-fluorotoluene (IE = 8.79±0.01 eV). This results indicates an ionization energy for the radical of 8.7±0.1 eV, within error limits of the value of 8.60±0.07 eV obtained in a recent guided ion beam study[4].

The low ionization energy values derived from reactions (1) and

(2) could be attributed, as pointed out before[1], to the formation of weakly bonded $[CX_3^+ \cdot HF]$ or $[CX_3^+ \cdot H_2O]$ products instead of the separated products as written above. Another possibility, pointed out in a study of negative ion reactions[5], is that the large positive entropy change associated with two-to-three-body reactions permits the observation of reactions which are substantially endothermic.

Based on the ionization energy values derived in this study, reaction (1) as written, is endothermic by 17±4 kJ/mol. The occurrence of reaction (1) was confirmed and the rate constant was determined to be $k_{Rn}=5\times10^{-10}cm^3molecule^{-1}sec^{-1}$. When H_3O^+ was replaced by H_3S^+, however, no reaction was observed; the dissociative proton transfer involving H_3S^+ is endothermic by 31±4 kJ/mol, 14 kJ/mol more than the reaction involving H_3O^+.

Other apparently endothermic two-to-three body reactions have been observed using the NIST Fourier transform ICR spectrometer. For example, the reactions:

(5) $AsH_4^+ + t\text{-}C_4H_9Br \rightarrow t\text{-}C_4H_9^+ + HBr + AsH_3$

$k_{Rn} = 1 \times 10^{-9} cm^3\ molecule^{-1}\ sec^{-1}$ $\Delta H^\circ = +23$ kJ/mol

(6) $CH_3OH_2^+ + t\text{-}C_4H_9Br \rightarrow t\text{-}C_4H_9^+ + HBr + CH_3OH$

$k_{Rn} = 0.2 \times 10^{-9} cm^3\ molecule^{-1}\ sec^{-1}$ $\Delta H^\circ = +27$ kJ/mol

were observed to occur with a high efficiency, while the reactions:

(7) $AsH_4^+ + 2\text{-}C_4H_9Cl \not\rightarrow 2\text{-}C_4H_9^+ + HCl + AsH_3$ $\Delta H^\circ = +35$ kJ/mol

(8) $CH_3CHOH^+ + t\text{-}C_4H_9Br \not\rightarrow t\text{-}C_4H_9^+ + HBr + CH_3CHOH$ $\Delta H^\circ = +42$ kJ/mol

do not occur. In no case, has a reaction with an apparent endothermicity greater than about 35-40 kJ/mol been observed. This does not exceed the value of $T\Delta S$ associated with two-to-three body reactions, which at a temperature of 350K is about 40 kJ/mol. If instead these are exothermic reactions in which an ion/molecule complex is the initial product, one can assign an upper limit of 40 kJ/mol to the binding energy of the possible ion/molecule complex products.

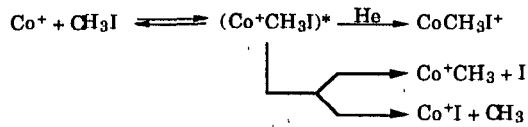
Reactions of State Selected $Co^+ + CH_3I$

*Petra A.M. van Koppen, Paul R. Kemper and Michael T. Bowers
Department of Chemistry, University of California, Santa Barbara, California 93106

Introduction

The growing use of mass spectrometric techniques for probing the kinetics, dynamics and thermochemistry of organotransition-metal reactions stems in part from the importance of transition metal centers as catalysts in various molecular transformations. Such reactions have been shown to be complex and usually extremely dependent on the metal ion electronic state. It is therefore important to carry out state selected reactivity studies.

Recently we have developed a "chromatographic" technique[1] to determine the electronic state distribution for transition metal ions, enabling us to study state selected reactions. Here we apply this method to reactions of state selected Co^+ with CH_3I.



Observed rates for adduct formation as well as CH_3 and I elimination channels were found to be strongly dependent on the electronic configuration. Information regarding the mechanism of the reactions is provided by measuring the temperature dependence of the rate coefficients. Modeling the experimental results with statistical phase space theory allows us to probe the thermochemistry of the reactions.

Experiment and Theory

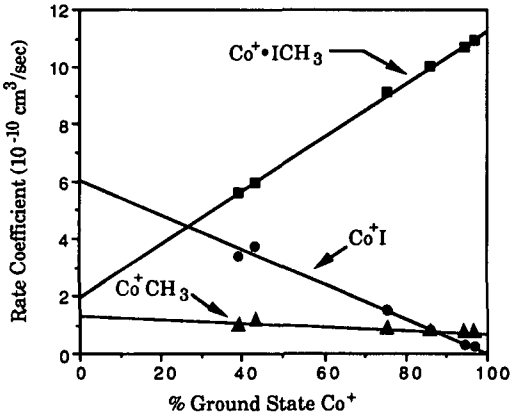
The cobalt ions are formed by electron impact on either $Co(CO)_3NO$ or $CoCp(CO)_2$ or by surface ionization of $CoCl_2$. The ions are mass selected in a double focusing mass spectrometer, decelerated to a kinetic energy of 2 - 3 eV, and are focused into a reaction cell containing 4 torr of He buffer gas and ~ 1×10^{-4} torr of the CH_3I reactant neutral. The ions, which are quickly thermalized by collisions with He, drift through the cell due to a uniformly applied electric field. Ions that exit the cell are quadrupole mass analyzed and collected. Low drift fields are used to ensure thermal conditions. The reaction time is obtained by pulsing the ion beam into the reaction cell. The cell temperature is variable from 80 to 600K.

The electronic state distribution of the cobalt ions is determined by a "chromatographic" technique which we have recently developed.[1] The Co^+ electronic state population is a function of both the electron energy and the precursor used, and can be varied from 36% to 97% ground state. This allows us to study reactions of Co^+ as a function of electronic state population. Extrapolation to 100% ground and excited state Co^+ yields their absolute rates of reaction.

The experimental reaction efficiencies for the elimination channels were modeled using statistical phase space theory. The parameters are well defined for these reactions with frequencies and geometries obtained from ab initio calculations.[2] The only unknown parameters are the heats of formation of the $CoCH_3^+$ and CoI^+ product ions. By modeling the experimental reaction efficiencies, the overall heats of reaction and the corresponding bond energies are determined for these species.

Results and Discussion

The rates of reaction as a function of % ground state Co^+ reacting with CH_3I at 300K are shown in Figure 1. Extrapolation to 100% ground state Co^+ or 100% excited state Co^+ (0% ground state Co^+) yields the absolute rates of reaction.



The reaction efficiency for adduct formation is much greater for the ground state Co^+ than for the excited state. Unlike ground state Co^+ which has a $3d^8$ electronic configuration, the excited state of Co^+ ($4s3d^7$) contains a repulsive 4s electron which decreases the binding energy of the adduct. For the elimination channels the excited state is more reactive. CoI^+ is the dominant channel for the excited state and is essentially absent for the ground state at 300 K. Only a small increase in reactivity for the excited state relative to the ground state is observed for the $CoCH_3^+$ channel. The experimental branching ratios for ground and excited state Co^+ for the elimination channels are consistent with those calculated using statistical phase space theory.By theoretically modeling the experimental reaction efficiencies, the bond energies for $CoCH_3^+$ and CoI^+ were obtained:

$$D_0^0\ (Co^+\text{–}CH_3) = 52.9 \pm 2 \text{ kcal/mole}$$
$$D_0^0\ (Co^+\text{–}I) = 50.6 \pm 2 \text{ kcal/mole}$$

The corresponding heats of reaction are + 2.3 and + 4.6 kcal/mole for the I and CH3 elimination channels respectively. The bond energy determined for $CoCH_3^+$ is in good agreement with literature values : Armentrout and coworkers.[3] find a value of 50.3 ± 3 kcal/mole, and Bauschlicher et al.[4] calculates a lower limit of 48 kcal/mole.

The temperature dependence of the rate constants were measured for both the ground and excited electronic states of Co^+. A negative temperature dependence was ovserved for adduct formation for both the ground and excited state. A positive temperature dependence was observed for both elimination channels for ground state Co^+. This result is consistent with the derived endothermicities for these reactions. For the excited state, a negative temperature dependence was observed for both elimination channels; these reactions are exothermic and a negative temperature dependence implies the formation of a complex in the mechanism as shown in the reaction scheme.

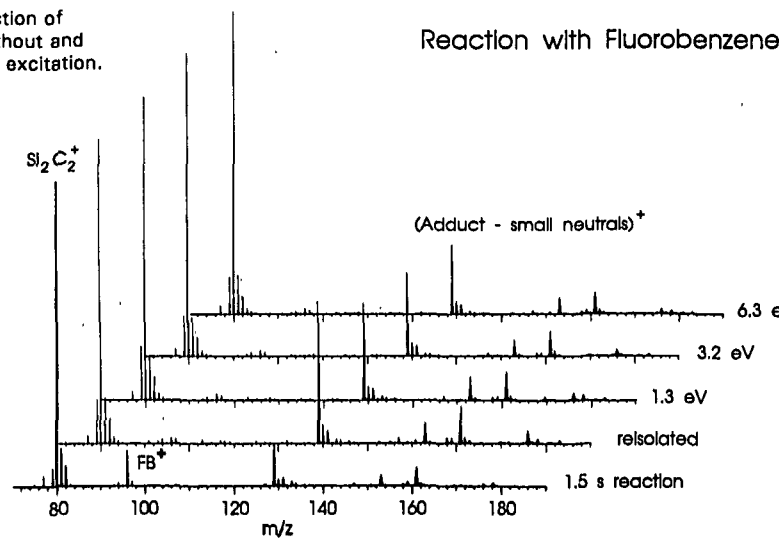
PROBING THE UNUSUAL KINETIC BEHAVIOR AND ION CHEMISTRY OF $Si_2C_2^+$

Denise C. Parent

Chemistry Division/Code 6113
Naval Research Laboratory, Washington, D. C. 20375-5000

Introduction. Recent work in this laboratory has investigated the formation of silicon carbide cluster cations (SiC_y^+, y=0-8 and $Si_2C_y^+$, y=0-6) and their reactivity with acetylene [1]. The disilicon carbide cations exhibit unusual, nonlinear kinetics: initially the reaction is slow and yields the CH_2 addition product; as the reaction proceeds it becomes more rapid and adduct formation is observed. These observations suggest the following questions: Are the $Si_2C_y^+$ ions produced with excess energy and in what mode? What process is occurring at shorter reaction times? Are different isomers involved in the reaction? This communication attempts to provide answers for $Si_2C_2^+$ specifically.
Methods. The experimental apparatus consists of a Nicolet FTMS-1000 data system modified to operate with SWIFT, a 3-Tesla superconducting magnet and a home-built vacuum system with a 1 x 1 x 2-inch cell. The frequency-doubled output (532 nm, ~2 mJ/pulse) of a Nd:YAG laser was used for direct laser vaporization of the sample pellet, which was composed of silicon and graphite powders. Trapped ions were mass-selected and reacted with various neutral gases using standard methods.
Charge Transfer Reactions and the Effect of Kinetic Energy. Preliminary experiments revealed that $Si_2C_2^+$ charge transfers with substituted benzenes having ionization potentials (IP) greater than the 8.2 eV IP of Si_2C_2 [2]. Using charge transfer bracketing [3], the IPs of both the "initial" and "relaxed" populations of $Si_2C_2^+$ were determined. The "initial" population was found to have an IP lying between 9.25 and 9.45 eV, while the "relaxed" population gave an IP value between 8.04 and 8.44 eV. Thus the $Si_2C_2^+$ initially isolated contain at least 1 eV of excess energy. Further experiments (shown in Figure 1) were carried out with fluorobenzene (FB, IP=9.20 eV) as the neutral reagent. After mass-selection, the $Si_2C_2^+$ were reacted with FB for 1.5 s, yielding FB^+ and other products. The remaining $Si_2C_2^+$ were then reisolated and again allowed to react with FB for 1.5 s. No FB^+ was observed from the reaction of the reisolated cluster ions, demonstrating that the $Si_2C_2^+$ were now

Fig. 1. Reaction of $Si_2C_2^+$, without and with kinetic excitation.



"relaxed". The "relaxed" cluster ions were then translationally excited (lab frame kinetic energy of 0.7 to 6.3 eV) before reacting with FB. No FB^+ was observed, thus establishing that kinetic energy does not induce the initial charge transfer reaction.

Activation of $Si_2C_2^+$. To study the short-time behavior of the $Si_2C_2^+$/acetylene reaction, Ar or SF_6 buffer gas was added to the ICR cell. Figure 2 shows the effect of adding SF_6. (Similar curves were obtained with Ar or C_2H_2 alone.) With acetylene, the average number of collisions required to reach the onset of the linear decay ("activation") was found to be ≈ 6 collisions. Ar and SF_6 were equally efficient in "activating" $Si_2C_2^+$ but were only one-third as efficient as acetylene. With its many low-frequency vibrational modes, SF_6 is considered to be a good quencher of rotational/vibrational energy. Since Ar is equally effective, this suggests that the excess energy is not in the rotational or vibrational modes.

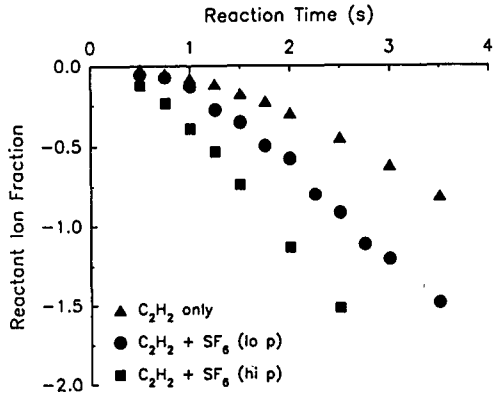


Fig. 2. Effect of added SF_6 on the reaction of $Si_2C_2^+$ with acetylene.

^{13}C Labelling. Using ^{13}C labelled $Si_2C_2^+$ or acetylene, the initial ion products observed are due to carbon exchange between the $Si_2C_2^+$ and the acetylene (as shown below), with no other chemical change. The final ion product, $Si_2{}^{12}C_2^+$, can be formed sequentially (as shown) or directly.

$$Si_2{}^{13}C_2^+ + {}^{12}C_2H_2 \rightarrow Si_2{}^{13}C^{12}C^+ + {}^{12}C^{13}CH_2 \rightarrow Si_2{}^{12}C_2^+ + {}^{13}C_2H_2.$$

This carbon exchange process is most likely responsible for the high "activation" efficiency of acetylene. It is also consistent with the previous conclusions that the excess energy is not kinetic or rotational/vibrational. Relaxation of an excited electronic state, with or without concurrent isomerization, appears to be the first step in the reaction of $Si_2C_2^+$.

Ion/Molecule Chemistry. Reactions with 2- and 3-carbon unsaturated hydrocarbons, as well as substituted benzenes, were also studied. A brief summary of some results follows. $Si_2C_2^+$ dehydrogenates ethylene to acetylene with carbon exchange/carbon scrambling being observed. Ethylene and acetylene are the major neutral products from reaction with allene and propylene. Carbon scrambling is observed in some products but not others. Methyl-substituted benzenes predominantly yield the adduct accompanied by methyl loss. $Si_2C_2^+$ abstracts one or two O^- from nitro-substituted benzenes, to form silicon oxide species. The chemistry of halogenated benzenes and hydrocarbons is dominated by formation of silicon halides.

Summary. DLV produces $Si_2C_2^+$ with at least 1 eV of excess electronic energy, as confirmed by the charge exchange and "activation" experiments. The larger ions in the $Si_2C_y^+$ series also exhibit nonlinear reaction kinetics and undergo carbon exchange with acetylene. Though they were not investigated in as much detail, they presumably are also formed with excess energy. The existence of isomers of differing reactivity, though possibly an important part of this puzzle, has not been proven. $Si_2C_2^+$ is a highly reactive species: formation of small stable neutrals or silicon oxides and halides drives the chemistry.

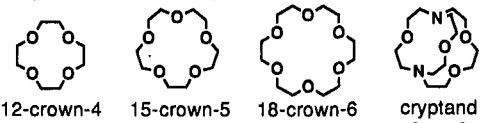
KINETICS AS A PROBE OF HOST-GUEST CHEMISTRY IN ION-MOLECULE REACTIONS: MOLECULAR RECOGNITION AND MACROCYCLIC EFFECTS

David V. Dearden, In-Hou Chu, Hong Zhang, and Qizhu Chen

Department of Chemistry
The University of Texas at Arlington
Arlington, TX 76019-0065

Introduction. Host-guest interactions in condensed media are governed by the relative sizes and/or shapes of the reacting species, and often are dominated by non-covalent bonding. For example, the crown ethers selectively bind alkali metal cations in solution, with complex stability constants strongly dependent on the relative sizes of the cations and the binding cavities of the crowns. Stability constants for the crowns are typically about 2 orders of magnitude larger than those of their acyclic analogs. This has been termed the "macrocyclic effect." Similar size-specific chemistry is relatively unexplored in the gas phase. We have examined the reaction kinetics of the simple prototypical crown ether-alkali metal cation host-guest system in the gas phase, with the goals of gaining a better understanding of non-covalent cation attachment processes and of developing this chemistry as an analytical probe for determining the conformational structure of ions.



12-crown-4 (12C4) | 15-crown-5 (15C5) | 18-crown-6 (18C6) | cryptand [2.1.1]

Experimental. Our experiments employed an Extrel FTMS-1000 ion cyclotron resonance mass spectrometer. Alkali metal cations were generated by laser desorption of the appropriate nitrates or chlorides from a stainless steel probe inserted through a vacuum lock and placed adjacent to the trapping cell. An open-geometry trapping cell, with the RF excitation capacitively coupled to the trapping plates (based on the design of Laude et al.),[1] facilitated easy optical access to the cell interior and the probe. Ligands were introduced either through a variable leak valve (in the case of volatile materials) or via a temperature-controlled solid probe which was warmed to obtain the desired ligand vapor pressure. Pressures, typically in the range 5×10^{-8} - 5×10^{-7} Torr, were measured with a Bayard-Alpert ionization gauge calibrated using the literature rate constant for self-CI of acetone. Ions of interest were isolated using either conventional RF-chirp or SWIFT ejection (SWIFT from Tom L. Ricca Associates). Reactant and product ion intensities were monitored as a function of time, and rate constants were extracted assuming pseudo-first order kinetic conditions. Simultaneous study of two or more ionic reactants was used to guarantee that each ionic species experienced the same neutral ligand pressure environment.

Results and Discussion. The formation of 1:1 metal:ligand complexes is a rapid ion-molecule reaction, which is almost certainly radiatively stabilized. The rate constants exhibit an approximately linear dependence on $1/\mu^{1/2}$, where μ is the reduced mass of the collision pair, suggesting that the reactions proceed at nearly the rates predicted from collision theory. 15-Crown-5 reacts more rapidly than 12-crown-4, consistent with the fact that the former is larger and more polarizable.

Subsequent reaction of the 1:1 complexes with an additional neutral ligand, to form 2:1 complexes, is characterized by very interesting size dependence.[2] 12-Crown-4 reacts rapidly with all the alkali

metal cations, with Na^+ having the largest rate constant. 15-Crown-5, on the other hand, was not observed to react with Li^+, although reaction with the other alkali metal cations was rapid. The fastest rates for formation of $(15C5)_2M^+$ occurred for K^+. 18-Crown-6 was not observed to react with Li^+ or Na^+, reacted only slowly with K^+, and reacted more rapidly with Rb^+ and Cs^+. When the rate constants are plotted against the ratio of cation radius to ligand cavity radius (Figure 1), the data for all three ligands falls roughly on the same curve, dramatically emphasizing the size-dependent nature of these reactions.

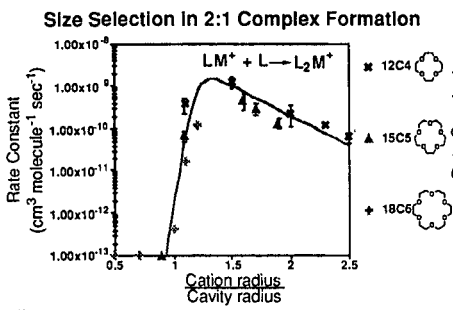


Figure 1.

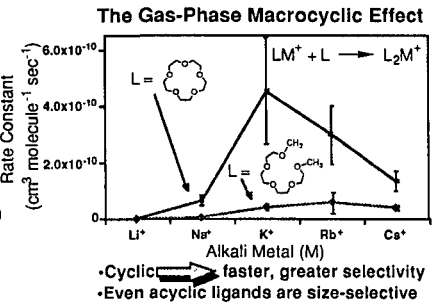

Figure 2.

Comparison of 2:1 complex formation rate constants for 15-crown-5 and its acyclic analog, tetraglyme, (Figure 2) reveals a macrocyclic effect: cyclic ligands react more rapidly, and with stronger size dependence, than the acyclic ligands.[3] Interestingly, even the glymes show size dependence, but the fastest rates occur for larger cations. The additional flexibility of the acyclic ligand probably enables it to better encapsulate larger cations than can the cyclic crown.

The same techniques were used to study the interactions between alkali metal cations and the cryptand [2.1.1], which is a bowl-shaped ligand with a negatively-charged interior. [2.1.1] was not observed to form metal-bound dimers with Li^+ or Na^+, but readily forms 2:1 complexes with K^+, Rb^+, and Cs^+. 18-Crown-6 abstracts the latter three cations from their 1:1 $[2.1.1]:M^+$ complexes, but does not abstract Li^+ or Na^+ on the time scale of our experiment. Both findings suggest that Li^+ and Na^+ reside within the ligand bowl in the complexes, but that the other alkali metal cations reside outside the bowl. Molecular mechanics calculations, using the AMBER force field, corroborate these findings, predicting low-energy structures with Na^+ primarily in the bowl, but K^+ complex structures with the metal, too large to fit within the cavity, poised on top of the ligand.

Energy Dependent Intramolecular Reactions of Crown Ether/Amine Complexes

Simin Maleknia, and Jennifer Brodbelt
Department of Chemistry & Biochemistry
University of Texas at Austin, Austin, TX 78712

Crown ether macrocylces have been selected as receptor models to show properties of molecular complexation and structural recognition in solution (1). Because, the interactions of host/guest complexes are highly influenced by solvation effects, recent mass spectrometric investigations have been focused on cavity-size dependent reactions of crown ethers in the gas phase (2). This investigation focuses on the intramolecular interactions of primary amines with crown ethers in the gas phase. Ion complexes of crown ethers with ammonium, methylammonium, hydrazines and sulfonylhydrazines were generated by the LSIMS technique from a solution of polyethers and the amine substrates. Collision induced dissociation (CID) results of the complexes are compared to CID spectra of the protonated polyethers to determine new dissociation reactions that arise from multiple interactions of the hydrogen bonds between the amine donors and oxygen receptor sites. MS/MS experiments were performed by the use of a JEOL HX110/HX110 tandem mass spectrometer (located at MIT, Cambridge, MA) equipped with a variable voltage collision cell.

These complexes show two different dissociation pathways at laboratory energies of 7 and 0.4 KeV. At the lower collision energy, the dominant dissociation pathway is the loss of ethylene oxide units from the protonated crown ether. Additionally, a metastable ion for the decomplexation process is observed. High energy collision activation results in the formation of odd electron, acyclic fragments from the macrocyclic *host* while the *guest* cation is retained. These fragments are listed in Figure 1 for CID mass spectra of 18-crown-6/NH_4^+. As the size of the cavity increases the abundances of this new series of fragments increase compared to the fragments from the loss of ethylene oxide units (*m/z* 133, 177, ...). The predominant intramolecular dissociation reaction for hydrazine and methylhydrazine complexes is the loss of hydroxymethylene radical (31u). Table 1 shows that as the size of the cavity increases this fragmentation pathway dominates over the intramolecular proton transfer reaction. For ammonium and hydrazinium complexes, dissociations within the host molecule occur. In contrast, complexes with methanesulfonyl- and tosyl-hydrazines dissociate by homolytic cleavages of the sulfur-nitrogen bonds resulting in fragments of (crown ether + N_2H_4)$^+$.

Collisional activation results show that intramolecular dissociation reactions of the ion complexes are energy dependent, and the higher order effect of hydrogen-bonding interactions is cavity-size dependent. The association energy of complexation influences the dissociation pathways of the *host/guest* complexes.

GAS PHASE PROTON TRANSFER REACTIONS OF SERINAMIDE, ARGININAMIDE, AND HISTIDINAMIDE

R. D. Kinser and D. P. Ridge
Department of Chemistry and Biochemistry
University of Delaware
Newark, DE 19716

Our investigation of proton transfer reactions of amino acid amides as models of gas phase chemistry of polypeptides and proteins was expanded to include serinamide (SA), histidinamide (HA), and argininamide (ArgA). Reactions of these compounds (or their conjugate acids) with various reference bases (or their conjugate acids) were studied with FTMS. While serinamide•HCl yielded sufficient vapor phase SA (as measured by the electron impact mass spectrum) when admitted to the FTMS on the heated probe, it was not possible to generate adequate populations of HA or ArgA by treating the dihydrochlorides of histidinamide and argininamide in the same fashion. However, ample quantities of protonated HA and protonated ArgA were generated by laser desorption (CO_2 laser; 10.6 μm) of the respective dihydrochlorides.

Proton transfers from various reference compounds to serinamide indicated that there was one dissociative proton transfer pathway open to excited protonated SA: loss of ammonia and CO. A barrier to this fragmentation is indicated by the absence of any fragments from reaction of SA with protonated methanol and protonated ammonia. Dissociative proton transfer was observed in reactions of SA with protonated hydrogen sulfide, suggesting limits on the barrier of:

$$44 \text{ kcal} < E_b < 55 \text{ kcal}.$$

A proton affinity of 225.6 kcal/mol was determined for serinamide by the bracketing method. Deuteron transfer from $C_2D_5^+$ to serinamide, threoninamide, and tyrosinamide yielded products representing D loss as well as D inclusion, suggesting that either there is not a preferred single site of protonation or that H/D exchange rates are more rapid than decomposition. Evaluation of the H-only product/deuterated product ratios indicated that the hydroxyl group of the R-group is not involved in the protonation of these three amino acid amides.

No products were observed for reaction of laser-generated HAH^+ with pyridine or 2-picoline. Proton transfer was observed from HAH^+ to tripropylamine and tributylamine; reaction of HAH^+ and triethylamine yielded the proton bound mixed dimer. Based on these reactions and the proton affinity of triethylamine (Gorman, Speir, Turner, Amster; **JACS,** in press), a proton affinity of 239.6 kcal/mol has been assigned to histidinamide. This is ~11 kcal/mol greater than the proton affinity of histidine (Gorman, et al., **JACS,** in press), suggesting the possibility of disolvation of the proton by two basic sites in histidinamide.

Evidence for proton transfer from laser-generated $ArgAH^+$ to tripropylamine, triethylamine, and 2,6-lutidine was obtained under a variety of experimental conditions. Although the quench delay after the laser shot (0.1 sec to 20 sec) and the reaction time (10 sec to 60 sec) were varied, complete conversion of $ArgAH^+$ to protonated amine was not observed. Reactions of $ArgAH^+$ with 2,6-lutidine were observed in the presence of 2.4E-6 torr argon or 4E-6 torr benzene. These results are initially suggestive of formation of excited $ArgAH^+$. The $ArgAH^+$ signal persisted at long reaction times even in the presence of tributylamine. From these results, 243 kcal/mol has been set as the lower bound on the proton affinity of argininamide.

Gas-Phase Reaction of Polyhalogenated Plasma Radical Species

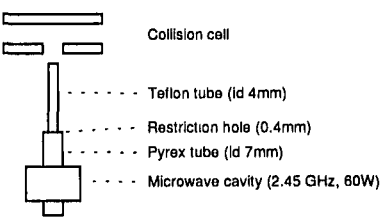
Hélène Mestdagh, Christian Rolando, Michel Sablier,

Ecole Normale Supérieure, Département de chimie,
URA 1110 du CNRS, Laboratoire de l'Activation Moléculaire, Laboratoire associé à l'Université P. et M. Curie, 75231 Paris Cedex 05, France

Contrary to ion-molecule reactions, reactivity of free atoms with ionic complexes is not well documented. However such reactions are involved in many fields: (i) chemistry of the interstellar medium where free atoms are abundant (ii) chemistry of the atmosphere, in particular concerning CFCs (iii) combustion (iv) generation of new organetallic species (v) modeling of catalysis processes.

In our experiment ions are generated in the EI/CI source of a multiquadrupole MS/MS/MS instrument. A microwave device is used to form atomic and/or radical species from gases. These atoms pass through a teflon tube to minimize recombination and are injected in a collision cell of the apparatus (fig.1).
Recently investigations have been done about reactivity of iron carbonyl cations with atomic hydrogen and nitrogen*.

Figure 1:



Microwave discharge detail

We have investigated the reactivity of atomic and radical species produced from halocarbon gases CY_nX_m (n=0-3; Y= H, F; X= F, Cl, Br; m= 4-1) in the microwave discharge. Ar^+, Cl^-, $Fe(CO)^+$ have been choosen as ion probes since:

- Ar^+ affords positive charge transfer and could be assimilated to electron impact.

- Cl^- allows negative charge transfer and is roughly equivalent to electron capture.

- whereas $Fe(CO)^+$ must have afforded carbene detection.

table 1: Major species obtained from CF_3Br and $CHBr_3$ (underlined ions are the main products)

Reactant	discharge	Ion Probe		
		Ar^+	$Fe(CO)^+$	Cl^-
$CBrF_3$	off	CF_2Br^+	CF_2Br^+	no reaction
	on	$\underline{CF_3}^+$, Br_2^+ Br^+	$\underline{BrCO}^+$ $FeBr^+$	$\underline{Br}^-$ Br_2^-, Br_3^-,CF_3^-
$CHBr_3$	off	$\underline{CHBr}^+$, CBr_2^+	$CHBr_2^+$	no reaction
	on	$\underline{Br}^+$, Br_2^+	$\underline{FeBr_2}^+$, $FeBr^+$	$\underline{Br}^-$, Br_2^- $BrCl^-$ $BrCl_2^-$

It seems difficult to quantify and characterize the species contained in the plasma from the results quoted in table 1. However it appears that in the case of CF_3Br , $Br^\cdot$ is mainly formed whereas in the case of $CHBr_3$, the observed species is molecular Br_2 (possibly excited). Among the others halogenated hydrocarbon, two main classes of compounds can be distinguished:

- CF_3Br and $CFCl_3$ which yield preferentially $Br^\cdot$ and $Cl^\cdot$ respectively
- $CHBr_3$, CH_2Cl_2, $CHCl_3$, CCl_4 which yield excited molecular X_2.

Comparative studies with a mixture of Argon/Br_2 is under investigation to definitively identify the composition of the halogen plasma.

Gas Phase Reactions of Sc^+, Ti^+, and V^+ with Amines (Me_nNH_{3-n}) and Phosphines (Me_nPH_{3-n})

Asgeir Bjarnason and Ingvar Arnason
Science Institute, University of Iceland, Dunhaga 3, IS-107 Reykjavik, Iceland

INTRODUCTION

Reactions of metal ions with various organic compounds in the gas phase have been extensively studied in recent years. Inorganic compounds have received less attention. We have undertaken a systematic study of the reactions of transition metal ions with ammonia and phosphine as well as mono-, di-, and trimethyl amines and phosphines. In this presentation we will discuss the results obtained for the highly reactive first three transition metal ions, Sc^+, Ti^+, and V^+. Deuterated samples of the amines and the phosphines were synthesized and used in this study to give insight into the mechanisms of the reactions.

EXPERIMENTAL

The experiments were done by employing an EXTREL FTMS-2000. Metal ions were generated by laser desorption from pure metal foils and cooled by the use of a buffer gas. Double resonance studies were performed to verify all reactions paths.

RESULTS

Dehydrogenation is the main reaction in most cases, although elimination of CH_4 is sometimes observed for the mono-, di-, and trimethyl derivatives. Both primary and higher order reactions were investigated but due to space constraints only the reactions with methyl phospine and methyl amine will be discussed here.

Primary reactions with methyl phosphine:

1. $M^+ + CH_3PH_2 \rightarrow MCH_3P^+ + H_2$ M = Sc, Ti, V
2. $M^+ + CH_3PH_2 \rightarrow MCHP^+ + 2H_2$ M = Sc, Ti

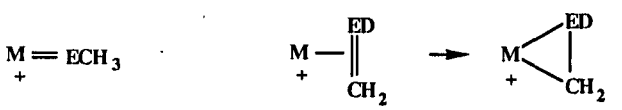
Same reactions with methyl amine, except one additional reaction channel:

3. $M^+ + CH_3NH_2 \rightarrow MNH^+ + CH_4$

Different behavior is observed, however, with the labelled compounds:

	Elim. of	Sc^+	Ti^+	V^+
CH_3ND_2	D_2/HD	80/20	70/30	60/40
CH_3PD_2	D_2/HD	90/10	100/0	100/0

Elimination of D2 results in the formation of M=ECH3 (E = N, P). Elimination of HD, presumably results in the formation of a double bond between C and N or P.



Loss of D_2 Loss of HD

Secondary and higher order reactions:

Ti+ reactions taken as an example:

$TiCH_3P^+ + CH_3PH_2$	--->	$TiP_2^+ + [C_2H_6 + H_2 \text{ or } 2CH_4]$	40%
		$TiCH_2P_2^+ + [CH_4 + H_2]$	50%
		$TiP_2H_2^+ + C_2H_6$	10%

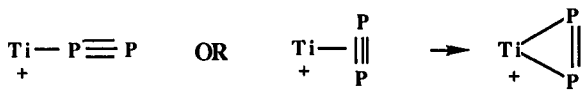
TiP^+ reacts on with the neutral methyl phosphine according to:

TiP_2^+ ---> TiP_3H^+ ---> TiP_4^+ ---> TiP_5H^+ ---> TiP_6^+

The secondary reactions in the amine case were different, and no series analogous to the one above was observed.

Collision-Induced Dissociation (CID) was performed on most major product ions in an effort to gain insight as to their structure.

TiP_2^+ ---> $Ti^+ + P_2$



TiP_4^+ ---> $TiP_2^+ + P_2$

---> $TiP_3^+ + P$

---> $Ti^+ + P_4$

NO !! TiP_4^+

$TiCH_2P_2^+$ ---> $TiCH_2^+ + P_2$

---> $TiP_2^+ + CH_2$

---> $TiCP_2^+ + H_2$

Charge Exchange Ion-molecule Reactions As A Probe of Metastable Electronic States of Atomic Transition Metal Ions

*Vincent J. B. Oriedo and D. H. Russell
Department of Chemistry
Texas A&M University
College Station, TX 77843

Studies of gas phase ion-molecule reaction chemistry of transition metal ions provide fundamental insights into many areas of chemistry. For example, gas phase ion-molecule chemistry studies have provided insights in understanding reaction energetics and thermochemical properties of transition metal containing species. Recent studies in our group and several other groups have focused on state-specific reaction chemistry of transition metal ions. State-specific studies require sensitive and reliable methods for probing the extent of electronic excitation and also measuring the relative distribution of the excited states of the reactant metal ions (M^+) formed by various ionization methods. Studies of charge exchange ion-molecule reactions of M^+ with transition metal carbonyls, e.g., $Fe(CO)_5$, $Cr(CO)_5$ etc. have shown that these reactions are a sensitive probe of metastable electronic states of atomic transition metal ions.[1]

In this paper, we focus on dissociative and non-dissociative charge-exchange reactions of Cr^+, Fe^+ and Co^+ formed by electron impact ionization of $Cr(CO)_6$, $Fe(CO)_5$ and $Co(CO)_3(NO)$ respectively. It should be noted that these experiments was performed in a differentially pumped two-section ICR cell. The reactant M^+ is produced in region 1 of the two-section cell. M^+ is then isolated using ion-ejection techniques and partitioned to region 2 where it is allowed to react with $M(CO)_y$ for 100 milliseconds.

$$(1)\quad Cr^+ + Cr(CO)_6 \longrightarrow Cr + Cr(CO)_y^+ + (6\text{-}y)CO \qquad y = 3 - 6$$

$$(2)\quad Cr^+ + Fe(CO)_5 \longrightarrow Cr + Fe(CO)_y^+ + (5\text{-}y)CO \qquad y = 2 - 5$$

$$(3)\quad Cr^+ + Cr(CO)_6 \longrightarrow Cr_2(CO)_x^+ + (6\text{-}x)CO \qquad x = 3 - 6$$

$$(4)\quad Cr^+ + Fe(CO)_5 \longrightarrow CrFe(CO)_x^+ + (5\text{-}x)CO \qquad x = 3 - 5$$

$$(5)\quad Co^+ + Fe(CO)_5 \longrightarrow Co + Fe(CO)_y^+ + (5\text{-}y)CO \qquad y = 1 - 5$$

$$(6)\quad Co^+ + Fe(CO)_5 \longrightarrow CoFe(CO)_x^+ + (5\text{-}x)CO \qquad x = 1 - 3$$

Cr^+ produced by electron impact of $Cr(CO)_6$ reacts with $Cr(CO)_6$ and $Fe(CO)_5$ according to reactions 1 to 4. Reactions 1 and 2 are endothermic for ground state Cr^+. Based on collisional relaxations studies, ionic-cluster fragments (reactions 3) corresponding to x = 5 and 6 are due to reactions of the ground state Cr^+. Likewise, Co^+ reacts with $Fe(CO)_5$ according to reactions 5 and 6. On the basis of collisional relaxation studies and low ionizing beam energy results, $CoFe(CO)_3^+$ ionic cluster fragment is formed by reactions of ground state Co^+. The charge-exchange products (reactions 5) are endothermic for the ground state Co^+. Charge exchange reaction of Fe^+ with $Fe(CO)_5$ have been reported

elsewhere[1].

Table 1 compares excited states population of Cr^+, Fe^+, and Co^+ determined by dissociative and nondissociative charge exchange ion-molecule reaction chemistry data with previously reported values.[2-4] For Cr^+, we estimate that 80% of the ions are produced in excited states when Cr^+ is formed by 70 eV EI of $Cr(CO)_6$. This data agrees well with results reported by Armentrout *et. al., i.e.*, 80% of Cr^+ ions produced by 50 eV EI of $Cr(CO)_6$ are in excited states. Ridge *et. al.* have also reported that 75% of Cr^+ ions produced by 70 eV EI of $Cr(CO)_6$ are electronically excited. The results for Fe^+ also agrees fairly well with those reported by Armentrout *et. al.*. Both these studies (ion-molecule reaction chemistry data and Armentrout's) estimate that the majority of excited Fe^+ ions are in states higher than the first excited state [$^4F(3d^7)$]. Results for Co^+ formed by 30 eV compares well with Bower's results, i.e. approximately 64% of Co^+ ions are produced in excited states.

In conclusion, dissociative and nondissociative charge-exchange ion-molecule reactions can be used as a sensitive and reliable probe of the extent and distribution of electronic states of transition metal ions produced by electron impact ionization.

Gas-Phase Basicities and Sites of Protonation of Glycine Oligomers (Gly_n; n=1-5)

Carlito B. Lebrilla and Jiangyue Wu; Department of Chemistry; University of California; Davis, CA 95616

The hydrogen bonding interaction of specific base sites in large biologically important macromolecules are fundamentally important. In peptides and proteins, the interactions play an active role in the secondary (and tertiary) structures as well as in the function of these compounds. In mass spectrometry, the new ionization methods for the analysis of peptides nearly all rely on some form of cation (usually proton) coordination. Thus the determination of inherent gas phase basicities are important in both biological chemistry and analysis. Recent efforts in our group have focused on developing the external source Fourier transform mass spectrometry instrument for the determination of gas-phase basicities of amino acids and peptides. Experimental results are presented for glycine oligomers and compared to theoretical (AM 1) calculations to provide insight into the position of protonation in peptides.

An external source FTMS recently built in our laboratory was used for all experiments and is described in earlier publications.(1) Protonated peptides are produced in the external source using fast ion bombardment (FIB, Cs^+) and glycerol or thioglycerol matrices. The ions are transported, using a single set of quadrupole ion guide, into the analyzer cell. A background pressure of reference base (3 to 4 x 10^{-8} torr) is maintained in the analyzer chamber throughout the experiment. The protonated peptide is isolated by using a series of ejection pulses. The last of these pulses eject protonated reference base molecules which form from the reaction of neutral base with other protonated species in the analyzer cell. Table 1 lists the results of the reactions of poly glycines with a series of reference bases. From these results we assign a gas-phase basicity of 205.8 Kcal/mole for glycine and 212.4 Kcal/mole for Gly_n (n=2-5).

Semi-empirical calculations using AM1(4) (an MNDO type program specifically parametrized for hydrogen bonding) have been performed to determine the reason for the similarity of the polyglycines and their GB differences from the glycine monomer. The lowest protonated structure for both mono- and diglycine corresponds to protonation of the terminal amino group with intramolecular coordination to the adjacent carbonyl group. The increase in basicity observed for diglycine is due to the enhanced basicity of the carbonyl oxygen in the amide of the diglycine. Eliminating this interaction by rotating the amino group away from the carbonyl oxygen in diglycine increases the energy by 6.3 Kcal/mole or a similar magnitude to the experimental gas-phase basicity values between glycine and diglycine (6.6 Kcal/mole). Other binding sites are higher in energy but point to a mechanism for proton motion in the peptide. Protonation of the amide oxygen is higher in energy by 3.1 Kcal/mole while protonation of the amide oxygen with coordination to the other carbonyl oxygen is higher in energy by only 2.3 Kcal/mole. Thus proton motion may proceed via the carbonyl groups of the peptides.

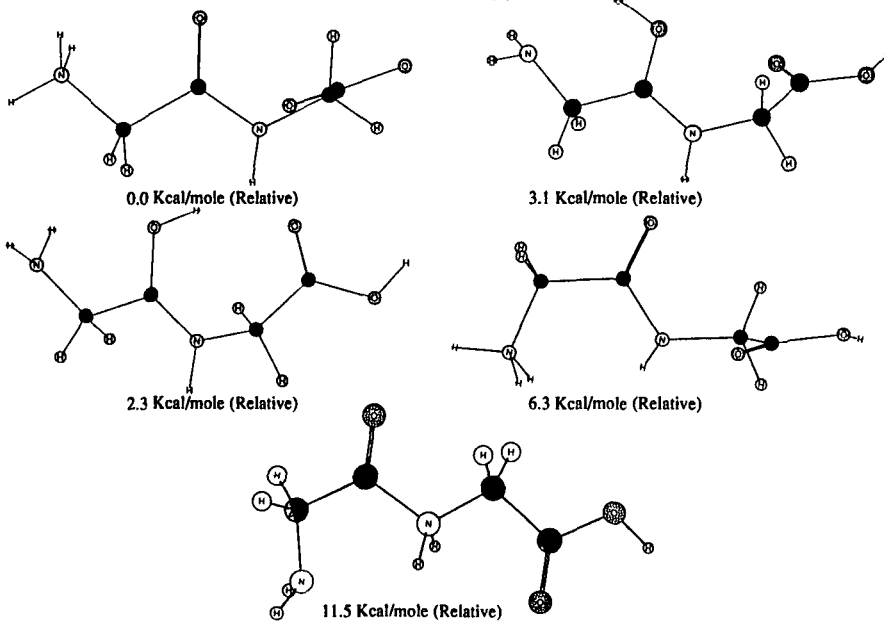
AM1 Calculation of Diglycine



Classical Trajectory Calculations of The H_2^+/H_2 System

C.A. Picconatto and G.I. Gellene, Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556.

Last year at this meeting we presented evidence that symmetry restrictions could inhibit reactivity in systems that consisted of identical reactants in different electronic states of which the title system is the simplest example. The rate of the H_2^+/H_2 proton/atom transfer reaction and its isotopic variants have been determined by several groups over the years with the results summarized in Table I. The results seemed to indicate an enhanced reactivity for nonidentical reactants (i.e. H_2^+/D_2 and D_2^+/H_2) in agreement with the predicted symmetry restrictions.

Reaction Rate for $H_2^+ + H_2 \rightarrow H_3^+ + H$ and its isotopic variants at 300 K

D_2^+/H_2	1972	3.0 ± 0.6	1.85	1.77

To further test for the presence of symmetry restrictions in this reaction, classical trajectory calculations were performed using a potential which included the permanent quadrupole moment and full polarizability tensor of H_2. The results of these calculations, which are listed in the last column of Table I, do not support the importance of a symmetry restriction at 300 K because the reactions of identical reactants are observed to proceed at the classical collision rate. A detailed treatment of the symmetry restriction indicates that the strength of the restriction can be related to the extent to which the orbital angular momentum (l) is conserved in the collision. Although the anisotropy in the potential prevents l from being rigorously conserved, calculations show that it becomes increasingly conserved as the translational temperature is lowered. Thus it is possible that the symmetry restriction may manifest itself at low temperature. To test this possibility, an H_2/D_2 mixture was ionized and the low pressure the D_2H^+/D_3^+ ratio was determined at 300 and 115 K. These experimental results were compared to the predictions of the classical trajectory calculations under the reasonable assumption that the D_2H^+/H_2D^+ product branching ratio from H_2^+/D_2 and D_2^+/H_2 reactants is identical and temperature independent below 300 K. If the symmetry restriction does become more important at low temperatures, the measured D_2H^+/H_2D^+ should larger than the predictions of the classical trajectory calculations. The comparison is shown in Table II. Although, the experimental ratio is slightly larger than the theoretical ratio, the difference is not sufficient to be certain that the symmetry restriction is operating. Measurements at still lower temperatures will be required to obtain the final answer to this question.

Table II. Temperature dependence of D_2H^+/H_2D^+ product ratio

	Experimental	Classical Trajectories
$\dfrac{\left(\frac{HD_2^+}{D_3^+}\right)_{T = 115\ K}}{\left(\frac{HD_2^+}{D_3^+}\right)_{T = 300\ K}}$	1.06 ± 0.04	1.00 ± 0.04

Independent of the question of a quantal symmetry reaction restriction, the investigation of the kinetics of this reaction on the H_2 rotational state revealed a classical mechanism for isotopic fractionation which would operate at low temperature and thus may be astrophysically relevant. It was observed that the ion-quadrupole interaction enhanced the reactivity of only the J = 0 neutral molecules. At low temperature in the absence of a catalyst, the H_2 rotational distribution is 25% J = 0 and 75% J = 1 because of the inefficiency of changing nuclear spin. Alternatively, HD has no nuclear spin constraint and readily relaxes completely to J = 0 at low temperature. This leads to an enhanced reactivity for HD at low temperature with a corresponding increase of D in the product ions. The temperature dependence of this effect is shown in Figure 1, where enhancement is defined by:

$$\text{Enhancement} = \frac{\left(\frac{DH_2^+}{H_3^+}\right)_{obs}}{\left(\frac{DH_2^+}{H_3^+}\right)_{stat}} \times 100$$

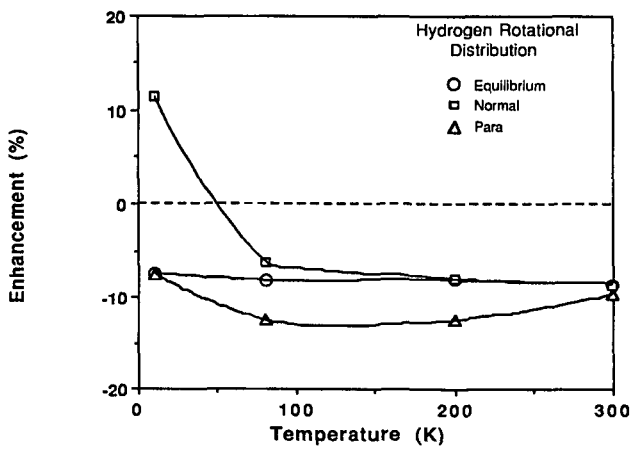

Figure 1. Enhancement of H_2D^+ as defined in equation (1).

PULSED FT/ICR CHEMICAL IONIZATION MASS SPECTRA OF ORGANOSILANES

* Ivan Haller and Edward D. Babich,
IBM Research Division, T. J. Watson Research Center,
Yorktown Heights, New York 10598.

We report here on the systematics of C.I. mass spectra and ion-molecule reactions of some saturated, olefinic, cycloaliphatic, and aromatic organosilanes. A major motivation for us was to have a methodology for the analysis of mixtures of volatiles formed in pulsed electron stimulated decomposition reactions of organosilane polymers.[1]

Selected ions from a pulse of reagent gas were trapped in an FTMS cell and allowed to react[2] with a subsequent pulse of the organosilane analyte. Reagent ions used were CD_5^+, $C_2D_5^+$, $CD_3OD_2^+$, CD_3CND^+, and their non-deuterated counterparts. Figure 1 compares the electron impact and C.I. mass spectra, using several reactant ions, of diethylmethylsilane. As with all organosilanes investigated, we find that reaction with $CD_3OD_2^+$ is sufficiently exothermic to proceed with collisional rates but results in minimal fragmentation compared to C.I. with protonated ions of reagents with lower basicity. Since in the reactions of $CH_3OH_2^+$ with all organosilanes investigated we only observe even-electron (odd m/z) product ions, any even mass number ion appearing in $CD_3OD_2^+$ C.I. must have an odd number of deuterium atoms incorporated thereby greatly simplifying its identification.

In Figure 2 we compare the fraction of total ionization appearing as quasi-molecular ions, i.e. the ions derived from the parent peak with 0-3 hydrogen atoms lost in electron impact, and the $(M+2)^+$ and $(M-1)^+$ peaks in $CD_3OD_2^+$ chemical ionization. In E.I., significant intensity occurs only in aromatic silanes and a few trialkyl silanes. In C.I., $(M+2)^+$ ions [or $(M+1)^+$ for non-deuterated reagents] were observed with those silanes in which

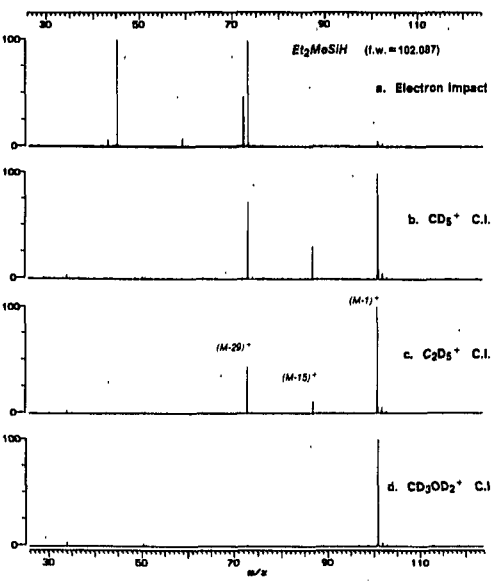

Fig. 1. Et_2MeSiH mass spectra with various ionization methods.

deuteron transfer to an allyl, acetylenic, or phenyl substituent can occur or by opening of a strained silacyclobutane ring. In all compounds containing Si-H bonds $CD_3OD_2^+$ C.I. results in dominant $(M-1)^+$ peaks.

The $CD_3OD_2^+$ C.I. spectra are also valuable in the analysis of quaternary organosilanes as the strictly even-electron fragmentation patterns are systematically different from electron impact fragmentation patterns. Table I presents, for 3 groups of compounds, the observed intensity ratios for ions arising by loss of methyl to loss of a larger substituent from silicon. In mixed tetraalkylsilanes the C.I. spectrum always exhibits a preferential loss of the lower mass substituent, i.e. it shows a characteristic $(M-15)^+$ peak, whereas the E.I. spectrum is dominated by the uninformative m/z=73 peak. We also observe that vinyl and alkynyl substituents on silicon are lost in chemical ionization with a greater probability than is methyl. This again complements the behavior observed in electron impact ionization. In allyl and phenyl substituted silanes the branching ratio depends less on the ionization method.

In summary, we find $CD_3OD_2^+$ a superior C.I. reagent for organosilanes due to optimal energetics, simple procedures, and simple interpretations. Complementing E.I. ionization, it produces strong quasimolecular peaks except with tetraalkylsilanes in which case the most abundant ion arises always by the loss of the lowest mass substituent.

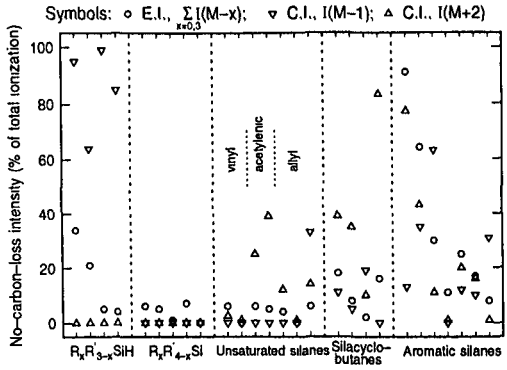

Fig. 2. Quasimolecular ions of organosilanes in E.I. and $CD_3OD_2^+$ C.I.

TABLE I. Branching ratios for the loss of methyl vs. the loss of other substituent from silicon in $CD_3OD_2^+$ C.I. and electron impact ionization.

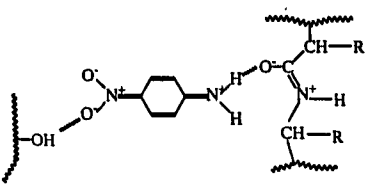
STRUCTURAL MASS SPECTROMETRY IN MATRIX-ASSISTED LASER DESORPTION IONIZATION WITH ION DETECTION BY FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRY

T. Solouki, J. V. B. Oriedo, and D. H. Russell
Department of Chemistry
Texas A&M University
College Station, Texas 77843

Matrix-assisted laser desorption ionization (MALDI) has greatly expanded the scope of biological mass spectrometry, especially with regards to the analysis of peptides and proteins. Very recently we reported MALDI/FTICR data for peptides with molecular weights of 1000-3000 that suggested the problems with MALDI/FTICR are related to the kinetic energy of the laser desorbed ions.[1] In addition, we showed that [M+H]+ ions of bovine insulin (MW 5734) could be detected if the MALDI process were performed in a confined volume that allowed collisional relaxation of the ions/neutrals prior to trapping in the ICR cell. Wilkins and co-workers have also recently reported success with MALDI/FTICR of peptides and proteins of up to 30k daltons molecular weights.[2] MALDI/FTICR is now developed to the level that structural mass spectrometry of large molecules is a realistic objective. In this paper we report feasibility of using selective and "proper" matrix molecules to induce fragmentation of analyte molecules for structural mass spectrometry.

It has been our experience that the matrices used for MALDI affect internal energies of the laser desorbed analyte ions and some matrices induce fragmentation of analyte molecules. Many of the organic compounds that are useful as matrices for MALDI have interesting solid-state chemistry in terms of their "interactions" with polar molecules (e.g., peptides) via hydrogen bonds as both hydrogen donor and hydrogen acceptors through different functional groups. A reasonable interacting structure of a matrix (in this case 4-nitroaniline) and peptide molecule is depicted below:



If the interaction between matrix and analyte molecules are site specific, the ionic dissociation products of the analyte may reveal information about both primary and secondary structures of the analyte molecule. Fig. 1 a, and b contain MALDI/FTICR mass spectra for alpha melanocyte stimulating hormone (MW 1665) with 4-nitroaniline (a) and alpha-cyano-4-hydroxycinnamic acid (b) as matrices with all of the variables (*e.g.* laser power, matrix:analyte ratio, etc...) kept constant. When alpha-cyano-4-hydroxycinnamic acid is used as the matrix substantial amount of

fragmentation is observed. Time-of-flight data obtained in similar conditions suggest that analyte ions dissociate in time scales longer than a micro second ,*i.e.*, only molecular ion of the analyte is observed. The fragmentation pattern of the alpha melanocyte is depicted in Fig. 2. It is interesting to note that this tri-deca peptide hormone contains hydrogen accepting amino acids in the C terminus while the N terminus contains predominately hydrogen accepting amino acids.

We plan to investigate the chemistry of both ground and excited states of matrix molecules in an attempt to design novel matrix molecules for structural mass spectrometry by chemical and photochemical processes. We also plan to compare data obtained from time-resolved TOF/MALDI and FTICR/MALDI experiments on larger biomolecules.

Three-Plus Decades in Petroleum Mass Spectrometry and Memories of Thomas Aczel

H. E. Lumpkin
Exxon Research and Engineering Co., Baytown, Tx
(Retired), 1600 Deep Wood Dr., Round Rock, Tx 78681

My role in today's symposium is two-fold--to remind you of some of the background to modern hydrocarbon research and to honor the memory of Thomas Aczel. Mass spectrometry in the U. S. petroleum industry began when Consolidated Engineering Corp. of Pasadena, Ca. (CEC) marketed the first commercial instrument, installed in the research laboratories of the Atlantic Refining Co., Philadelphia, Pa. in 1942. The instrument gave repeatable spectra and was initially used in the analysis of individual gases in refinery streams, replacing a laborious low-temperature distillation procedure. Oil and chemical company researchers quickly recognized that the MS was a major analytical advance and by World War II's end many laboratories were utilizing one or more mass spectrometers.

In the fall of 1945, still in military uniform, I was hired as a mass spectroscopist by Humble Oil & Refining Co., Baytown, Tx. I had never heard of a mass spectrometer. For most of my 35 years with Humble (later Esso then Exxon) I was directly in charge of the mass spectrometry laboratory in Baytown. Although my primary work was in analysis and characterization, I, along with many others also used mass spectrometers for spectra-structure correlations, ionization potential measurements, ion-molecule reactions, carbon isotope ratios and geologic age dating. Time, space, and memory constraints will prevent me from telling you of the many people, instrumental advances, procedures, and sample types that I encountered in my career. But I want to relate a few things that happened to me or that I heard of so you will get a flavor of what it was like a few years ago.

Here is the situation in Baytown in 1945. CEC had just installed a Model 21-101 and the Research and Development Laboratory was expecting delivery of two Westinghouse units. Humble was assemblying a team to begin operation of these instruments. What were we doing with two Westinghouse mass spectrometers? It seems that early on CEC had required purchasers to sign a contract giving CEC rights to any discoveries made with their instruments. In order to break this hold several companies, including Humble, had pooled their efforts to design and build a competitive instrument. The result was the Westinghouse Model LV, a 90-degree sector instrument. Many procedures were developed on it, including the initial work at low ionizing voltage.

The CEC 21-101 had a curved 180 degree stainless steel analyzer tube inserted into a glass envelope evacuated by a mercury diffusion pump. In spite of liquid nitrogen and dry ice traps there was always the easily recognizable doubly-charged mercury isotopes appearing in the spectra. They were good mass markers. The inlet system had two glass reservoirs fitted with specially ground stopcocks. Every Friday evening it was the job of the chemist to cycle the traps, vent the instrument with helium and regrease the stopcocks. Unfortunately, one evening I allowed the helium from a cylinder to exceed atmospheric pressure in the reservoirs and a precious stopcock bore was expelled to the tile floor with a disastrous result. Months later I would still be reminded of this forgetable episode.

When hydrogen, nitrogen, oxygen, carbon monoxide, carbon dioxide and water are included in an analyses for the light hydrocarbon gases, an 18-20 component simultaneous equation is required. Assemblying calibration data from runs on "pure" compounds, correcting spectra for contaminants, arranging a matrix, and inverting the matrix with the Crout method on a Frieden or Marchant electro-mechanical calculator was a 2-3 day job. This was before computers.

Most of us know of the effect of ionization chamber temperature on the spectra of hydrocarbons. The 21-101 initially did not have a temperature control mechanism and as a result many recalibrations were required. CEC eventually installed an external parabolic mirror focussing the light from an incandescent bulb through the glass envelop onto the source. It worked. I have a 21-101 source here that you may examine at the intermission.

The transition from gases to gasolines, naphthas and heavier stocks occurred naturally in most of the petroleum laboratories. We built our own inlet systems, devised capillary dippers, microburets, constant volume pipets, gallium valves, fritted discs, and solids inlet systems in order to charge and pump out increasingly more complex samples. But we reduced the complexity of the samples with batch distillation, thermal diffusion, and separation over silica and aluminum gels so that hydrocarbon and sulfur

and oxygen heterocompounds were identified in petroleum fractions. This was done long before high resolution instruments made it easier.

There is one more device, now extinct, that I would like to mention. This was the Electrical Computer manufactured by CEC. It was about the size of a motor oil drum and featured a manually rotatable turret and 132 10-turn helipots. Up to 10 simultaneous equations could be solved in about 15 minutes by an iterative method using a null balancing procedure on a small oscilloscope display. It was a great success--no inversion of matrices was necessary.

The recording system on early instruments was electrometer tube, amplifier, recording oscillograph featuring light beam galvanometers on light sensitive paper. Any lab had to have a dark room near by. It was a great boon when digitizing equipment became available. First there was the CEC Mascot Digitizer; then Texas Instruments produced a fine machine that measured signal amplitude and accelerating voltage and printed peak height and mass. From this to punch cards and then to dedicated computer with data acquisition and reduction were natural technological steps.

The early years in mass spectrometry were filled with small steps, giant strides (a popular 1960's term), innovations, and discoveries that are a foundation for the work being reported in this symposium.

In February, 1959, Thomas Aczel was hired by Humble in Baytown and was shortly assigned to the mass spectrometer group. He was my colleague, confidant, and friend; Burnaby Munson and I were groomsmen at his and Molly's wedding, I vouched for him at his naturalization hearing, and I attended the bar mitzvahs of their sons Joseph and Stephen. Thomas wasted no time in launching his career in the field--a career rich in publications and presentations. At that time Humble R & D was conducting research in catalytic oxidation of aromatics and we published a series of papers (1960-62) on the "Correlation of Mass Spectra with Structure in Aromatic Oxygenated Compounds" with Thomas as the senior author. I will not forget the day in December, 1960 when he saw his first publication in print. He was happy, delighted, and excited and invited my wife and me to have a grand dinner with him in Houston.

During his early single days in Baytown it seemed he seldom missed a movie at the Brunson Theatre. He did this to improve his English language skills--it was part of the Americanization of Thomas Aczel.

Thomas had a zest for life and new experiences. He was deprived of sweets during the war and in post-war Italy and tried to make up for it in America. As we strolled down the Boardwalk in Atlantic City, N. J., in June, 1960, during the ASTM E-14 meeting (his first extended professional trip for Humble) he had a snow-cone, cotton-candy, an ear of corn-on-the-cob, and bought a sack of salt water taffy. He had a great time and so did I just observing him. We toured Washington, D. C. on the week-end before returning to Baytown.

Thomas was not mechanically inclined. One day when we were office-mates we each received a new rolling swivel arm-chair which could be adjusted for height by rotating a collar on a grooved shaft. After I figured out how it worked, I adjusted mine and Thomas asked me to adjust his, which I did. A few weeks later a prankish idea came to me and about 1 or 2 times a week I would raise Thomas' chair seat by a small increment. After 2 or 3 months he was sitting sidewise or with his knees spread--the chair was too high for him to get his knees under the desk. He finally realized the situation and calmly remarked that he thought his chair was too high and asked me to lower it. I happily complied as I was becoming remorseful. I never told him of the practical joke I had pulled on him, but I think he knew.

One day he told me of his imprisonment in a Nazi concentration camp, of the loss of his mother, of his release by Gen. George Patton's troops, and his return to his former home in Nagykanizsa, Hungary and on to Trieste, Italy, where his uncle and aunt lived. He said he had never told anyone except his wife Molly of these experiences. Some years later he gave an invited paper at a symposium in Germany and remarked to me on his return how he felt about going back to Germany--the first time a prisoner, this time an honored guest.

I need not repeat Dr. San Hsu's tribute to Thomas Aczel, describing his career and listing his honors. Thomas and my relationship is not unusual--it is the old story of the student surpassing the teacher in accomplishments and acclaim. During my retirement of the last 12 years he would call often, even during the last week before he died. I particularly recall his excitement when he called me in 1989 to tell me in advance of public notification of his upcoming ACS National Award in Petroleum Chemistry. He very graciously gave me credit for being his mentor.

It has been my joy to participate in this symposium honoring the memory of Thomas Aczel.

Selective Detection and Quantitation in Mass Spectrometry: A Comparison of Relative Sensitivities for Low Voltage Electron Ionization and Benzene Charge Exchange

Burnaby Munson
Department of Chemistry and Biochemistry
University of Delaware, Newark, DE 19716

Low voltage electron ionization (EI) mass spectrometry was developed in the 1950's for the quantitative analyses of unsaturated compounds in complex mixtures.(1) The technique has been used extensively since that time, particularly for the analysis of aromatic hydrocarbons in complex mixtures with paraffins and cycloparaffins.(2) As with other techniques for the quantitative analysis of complex mixtures, sensitivities are needed for each compound in the mixture. Since each isomer and each member of a homologous series is seldom (if ever) available, direct experimental values for these sensitivities are frequently not known. Consequently, estimation and extrapolation procedures are needed.

The low voltage EI sensitivities depend strongly on the electron energies, which are maintained at sufficiently low values to eliminate (almost) fragmentation of the alkylaromatic hydrocarbon molecular ions. In the low electron energy range, the sensitivities are approximately linear functions of the electron energy. However, reproducible control of the electron energy can be achieved and relative standard deviations of sensitivities of only a few percent have been reported.(2d) The relative molar sensitivities for alkylbenzenes depend strongly on the number of substituents. The molar sensitivities for isomeric C_9-alkylbenzenes vary by a factor of about 3.5 and the sensitivity for hexaethylbenzene is 7.6 times the sensitivity for dodecylbenzene.(2c) Relative molar sensitivities for alkylbenzenes increase only slightly with increasing chain length.

Mixtures of approximately 20% C_6H_6 in He at pressures of about 0.3 torr contain predominantly $C_6H_6^{+\cdot}$ ions, with only small amounts of $C_6H_7^+$ and other ions. Because the ionization potentials of alkylbenzenes and olefins are lower than the ionization potential of benzene, the charge exchange reactions of $C_6H_6^{+\cdot}$ ions with alkylbenzenes and olefins are exothermic and expected to be fast. Because the ionization potentials of paraffins and cycloparaffins are higher than the ionization potential of benzene, the charge exchange reactions of $C_6H_6^{+\cdot}$ with paraffins and cycloparaffins are endothermic and are expected to be very slow.

Rapid charge exchange of alkylbenzenes with $C_6H_6^{+\cdot}$ ions in these He/C_6H_6 mixtures is observed to give simple (essentially one peak) mass spectra similar to the spectra produced by low energy electrons. The relative sensitivities of alkylbenzenes in C_6H_6 charge exchange are not sensitive functions of the experimental parameters of the high pressure experiments. The relative sensitivities are not obviously dependent on the structure or degree of substitution of the alkylbenzene isomers. The relative sensitivities of isomeric C_9- and C_{10}-alkylbenzenes vary only by ± 15%,

approximately the same as the reproducibility of these experiments. Relative molar sensitivities increase slightly (if at all) with increasing molecular weight.(3)

Early work on low voltage EIMS showed that the relative sensitivities of olefins also depended strongly on the structures of the olefins. (1) Relative molar sensitivities for olefins in C_6H_6 charge exchange do not depend strongly on structure. (3)

The Langevin theory for calculating the rate constants of reactions of ions with non-polar molecules can be used to calculate the relative rate constants and, therefore, the relative molar sensitivities for alkylbenzenes in benzene charge exchange. The calculated relative molar sensitivities are in good agreement with the experimental values over the molecular weight range studied. The theoretical model predicts an increase in relative sensitivity with increasing molecular weight that is not obvious in the experimental data. The predicted increase in relative sensitivity between ethylbenzene and hexamethylbenzene is only 14% and the relative standard deviations of the individual measurements are 8 - 15%. Consequently, the lack of any observed trend in relative sensitivity with increasing molecular weight may result from a lack of data over a sufficiently wide range of molecular weights.

MASS SPECTROMETRY AND BUCKYBALLS

D. M. Cox, C. S. Hsu, S. K. Chowdhury
Exxon Research and Engineering Co.
Route 22 East, Clinton Township, Annandale, NJ 08801

In the last couple of years, the research on fullerenes and their derivatives has increased dramatically because of their unique structures and potential applications in diverse areas of science and technology. As a result, there is a growing need for analytical techniques to characterize them. Mass spectrometry has been playing an important role in the characterization of fullerenes and their derivatives. Several MS techniques were employed in our laboratory including desorption chemical ionization (DCI), plasma desorption (PD), field desorption (FD), liquid secondary ion MS (LSIMS), and thermospray (TSP).

For bare fullerenes electron capture DCI, FD, LSIMS and TSP all produce molecular ions with little fragmentation. However PD of fullerene deposits not only desorb parent fullerenes and but also generate higher fullerenes that were not originally present in the sample. An example is given in Figure 1 which shows a PD spectrum of a thick deposit of pure C_{60}. In our previous work, negative ion (electron capture) CI was found to be at least an order of magnitude more sensitive than positive ion CI for fullerenes. Extensive fragmentation and formation of multiply charged ions were observed when fullerenes were thermally desorbed and ionized by a high energy electron beam (70-eV) [1].

Higher sensitivity in negative ion CI than positive ion CI are also observed for fullerene derivatives, such as phenylated and methoxylated fullerenes [2]. For thermally labile compounds, such as C_{60}-monooxide, thermospray is a preferred method. The non-direct heating by TSP reduces the thermal decomposition of the C_{60}-monooxide and produces more than 60% of intact molecular ion, compared to less than 5% when using DCI and FD (Figure 2).

For relatively non-polar functionalized fullerenes, FD operated at a positive ion mode is another method of choice. This soft ionization technique yields mainly molecular ions of the analytes. Figure 3 shows FD spectra of hydrogenated (3a) and 1,4-cyclohexadiene-derived fullerenes (3b), respectively. In the hydrogenated fullerene, addition of one to 12 hydrogen atoms to fullerene were observed. In the cyclohexadiene derivative, 1 to 5 cyclohexadiene units were found to be added to the fullerene molecule.

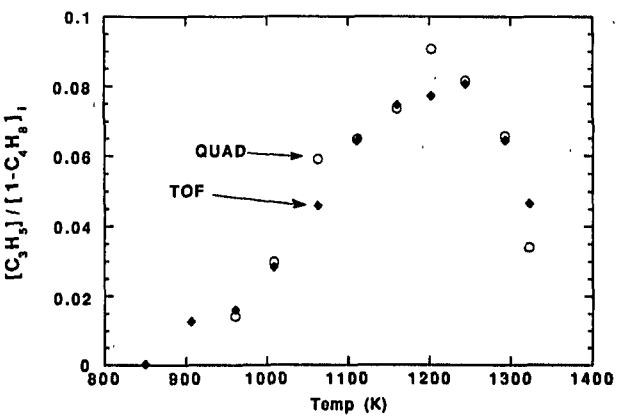
QUANTITATIVE MEASUREMENT OF RADICAL INTERMEDIATES BY MOLECULAR-BEAM-SAMPLING-MASS-SPECTROMETRY

Xian Zhong, Joseph W. Bozzelli and Anthony M. Dean
Corporate Research Labs, Exxon Research and Engineering Company,
Annandale, NJ 08801

Complementary advances in theory and experiment have provided significant new insights into the complex chemistry occurring during high temperature pyrolysis and combustion. Detailed models have been developed for reactions in flames and engines as well as hydrocarbon pyrolysis. Such detailed models are generally considered to be more reliable if they can successfully describe the behavior of reactive intermediates, since these are usually much more sensitive to subtle details of the chemistry than either the reactants or products. In particular, accurate knowledge of the concentration-time profiles of these intermediates provide a rigorous test of the accuracy of the proposed kinetic model. We demonstrate methods for accurate and quantitative determination of these (free radical) intermediates, as well as the stable species, in this talk. These data should allow further validation of detailed reaction mechanisms as well as provide key insights to reaction pathways.

A molecular-beam-sampling apparatus utilizing both a time-of-flight mass spectrometer with ultraviolet (VUV) photoionization and a quadrupole mass spectrometer with electron impact ionization is described. These systems are used to analyze reactants and products, as well as reactive intermediates, from flow tube experiments at reduced pressures and elevated temperatures. It is shown that the quadrupole signal sensitivity can be predicted using literature cross sections which are based upon the atoms and their hybridization within the various molecules. Measurements of the VUV photoionization sensitivities for stable species led to development of a group additivity approach to predict cross sections. This approach was extended to reactive intermediates, using the quadrupole measurements of methyl as the basis. Detailed comparisons of quadrupole and TOF data shows very good agreement between the two techniques, for both stable species and reactive intermediates. Typical data for formation of the allyl radical during pyrolysis of 1-butene is shown in the figure below. The minimal fragmentation obtained with the VUV source makes this the preferred technique for accurate species concentration measurements for many molecules and radicals.

Effect of Temperature on the Allyl Radical Concentration during 1-Butene Pyrolysis



HEAVY PETROLEUM HYDROCARBONS CHARACTERIZED BY ON-LINE LC/MS

C. S. Hsu, K. Qian, W. K. Robbins and S. C. Blum
Exxon Research and Engineering Company, Route 22 East, Clinton Township
Annandale, New Jersey 08801

Many technical challenges are present in the characterization of heavy petroleum fractions due to the complexity of these fractions and limitations in analytical technology. Recent endeavors in combining liquid chromatography and mass spectrometry (LC/MS) enable us to address important science issues and obtain previously unattainable results in petroleum fractions boiling between 650-1050°F.

Using a moving-belt interface and low voltage electron-impact ionization high resolution mass spectrometry, on-line LC/MS takes advantage of the unique characteristics associated with LC and MS to differentiate between aromatics and naphthenoaromatics, and to distinguish between aromatic hydrocarbons and hard-to-resolve sulfur compounds[1]. The combination of these two fundamentally incompatible analytical techniques enhances the capabilities of either technique.

To effectively process enormous amounts of high resolution mass spectral data obtained from on-line LC/MS, we have developed an innovative data analysis procedure including the use of the Kendrick mass scale, indigenous mass calibrants, and nominal mass series groupings for the determination of compound type distributions in each of LC elution regions. Thus, the elution characteristics of every individual compound classes within each LC peak can be delineated from scan-by-scan analysis[2].

We have applied on-line LC/MS with the newly developed data analysis procedure to study the molecular transformation and composition changes in a hydrotreating process of a thermally cracked petroleum distillate. The changes in compound type and carbon number distributions of the feed and product appearing in each LC peak can be studied in great detail. An example is given in Figure 1 which compares the distributions of hydrocarbon series, in the diaromatic, triaromatic and tetraaromatic LC elution regions, of a feed and its hydrotreated product. There is a net gain in diaromatics mainly hydroaromatic compounds, accompanied with a net loss in tetraaromatics. From the changes in compound type distributions we can draw a chemistry associated with the process, shown in Figure 2. The changes in each homologous series can also be discerned. Figure 3 shows the carbon number distribution of the CnH2n-18 series (phenanthrenes) in the triaromatic region. There is a net loss of unsubstituted or lightly substituted phenanthrenes, and a net gain of higher or longer alkyl substituted phenanthrenes. The increase of higher phenanthrenes could be attributed by hydrogenolysis of thiophenes and/or hydrogenation followed by ring opening of more condensed aromatic hydrocarbons, shown in Figure 4.

Gross changes in different classes of compounds can also be obtained from the analysis. Figure 5 compares the overall distributions of hydrocarbons and heterocompounds in each LC elution region. As intended, the hydrotreating reduces the amounts of monosulfur compounds in all LC regions substantially although some residual compounds are detected. The other heterocompounds in the feed are more narrowly distributed with oxygen compounds mostly in the diaromatic and triaromatic regions and nitrogen compounds abundant in the tetraaromatic and polar regions. Upon hydrotreating most of the hydroaromatic hydrocarbons formed in the monoaromatic, diaromatic and tetraromatic regions. Disulfur and oxygenated compounds are almost completely removed, while certain amounts of monosulfur and nitrogen compounds survive from hydrotreating.

Thus, on-line combination of LC with high resolution mass spectrometry provides a powerful analytical technique to monitor the changes at molecular level of heavy hydrocarbon processing.

Introduction

High molecular weight hydrocarbons can potentially serve as "biomarkers" to aid in geochemical studies. This investigation explores the possibility of using HTGC-FIMS-MS to provide information about the exact structures of co-eluting high molecular weight cyclic and acyclic components previously identified in a Rangely Field, Colorado, crude oil.

Experimental Section

These studies were carried out using a J&W 15-m , 0.32 mm i.d., 0.1 µm film thickness DB-1 fused silica capillary column connected directly to the Field Ionization source of a VG-Analytical Autospec-Q mass spectrometer with EBEQQ geometry. Samples analyzed are described below.
Altamont 180R is a saturate fraction of a Utah crude oil. It was spiked with n-C36, n-C50, and n-C60. Cut #12 was isolated from Rangely Field Colorado crude oil using distillation LC, urea adduction,and HPLC described elsewhere[1].

Results and discussion

Figure 1 is a GC-FIMS total ion chromatogram of Altamont 180R and the summed mass spectrum of the GC trace. The summed spectrum closely resembles FI spectra of this material admitted by a direct insertion probe. Figure 2 shows the HTGC/FIMSMS daughter ion mass spectra of co-eluting C_{38} monocyclic and C_{39} acyclic components in the highly fractionated Cut #12 from Rangely Field , crude oil.

The mass spectrum for the C_{38} monocyclic with a M^+ -29 and a base peak at m/z 97 suggests a methylcyclohexl at one end connected to a long carbon chain with branching at $C_{24,25}$, perhaps an ethyl group. The C_{39} acyclic mass spectrum shows a base peak at m/z 71 suggesting an isoprenoid group, with an ethyl loss similar to the monocyclic.

Molecular Geochemistry: Application of Mass Spectrometric Techniques to Petroleum Exploration

G. H. Isaksen [1], A.G. Requejo[1], and C.S. Hsu[2]
[1]Exxon Production Research Co. Houston, TX; [2]Exxon Research & Engineering, Clinton, NJ

Molecular Geochemistry is an important tool in petroleum exploration for assessing key variables such as thermal evolution of geologic samples and the association of oils with their corresponding source rocks. This paper provides an overview of the application of GC/MS and GC/MS/MS techniques in molecular geochemistry. These analytical techniques are essential for the analysis of chemical fossils commonly referred to as *biological markers* or *biomarkers*. Biomarkers are organic compounds whose basic skeleton can be linked to a known natural product. They exist in the geological environment because their skeleton undergoes only minor alteration as a result of diagenetic processes.
GC/MS with selected ion monitoring (SIM) is routinely employed to characterize distributions of two common classes of hydrocarbon biomarkers; steranes (base peak m/z 217) and triterpanes (base peak m/z 191). Analyses of sterane and triterpane distributions from source rock samples deposited in widely varying sedimentary environments allows the delineation of "end-member" molecular distributions, an approach referred to as *organic facies* assessment. These can be used to assess the origin of oils in exploration areas where the source rock distribution is uncertain.
An emerging application is the assessment of organic facies using tandem mass spectrometry. This approach is useful where biomarker concentrations are exceedingly low or where interferences from other hydrocarbons preclude the use of GC/MS. The most common approach involves GC/MS/MS that links molecular ion and characteristic ions. In addition to organic facies assessment, biomarkers can provide information on the degree of thermal alteration a rock sample or crude oil has undergone. This is important in identifying regions where hydrocarbon source rocks are generative, as well as the stage of generation. This approach requires an understanding of precursor-product relations and the interconversion of stable and labile isomers of biomarkers. Quantitative analysis of steranes and triterpanes using GC/MS has been used to shed new light on these maturity-related interconversions.

When employing biomarkers for assessment of organic facies it is of interest to know not only the molecular distribution that typifies each "end-member" environment, but also why the observed differences exist. Such understanding is gained by making the link between geochemistry and biochemistry. Knowledge of the types of organisms that inhabited each environment as organic-rich rocks accumulated permits reconstruction of depositional environment, allowing explorers to highgrade which portions of sedimentary basins have the potential to be prospective for oil and gas generation. The illustrations show how quadrupole GC/MS analysis of steranes (m/z 217) allow determination of C_{27} through C_{29} steranes, but give limited information on which types of C_{30} steranes (parent ion m/z 414) are present. The types of C_{30} steranes present in extracts from organic rich rocks or oils provide information on algal precursors, and thus help with the reconstruction of paleo-depositional environments. GC/MS/MS analyses show that C_{30} des-methyl steranes predominate in this example, whereas C_{30} A-ring methylated steranes are minor constituents. These steranes originate from different types of algae. With such detailed molecular information we are also able to closely tie a crude oil to the source rocks from which it was generated; important for computer modelling of the sedimentary basin's hydrocarbon system.

FI/FDMS CHARACTERIZATION OF REFINERY STREAM

*T.P. Fan, H. Siegel, L.L. Sterna
*Shell Development Bellaire Research Center, Houston, Texas
Shell Development Westhollow Research Center, Houston, Texas

FI/FDMS combined with HPLC fractionation was used to characterize vacuum distillates of CAT Cracker Feed. This is part of an effort to improve the accuray and precision of aromatic analysis for refinery streams. Major economic incentives exists to improve refinery feedstock selection. Since the aromatic carbon content is an major criteria, accurate and precise determinations of aromatic carbon in various feed and product streams becomes critically important.

Due to the complexicity of refinery streams and the lack of standard mixtures, a CCU feed was selected and fractionated based on boiling point (distillation) and polarity (HPLC). Each of these fractions, with a limited number of class of compound, were then characterized by both NMR and MS techniques. These well characterized fractions were then used as standards for the calibration of other methods such as UV. The fractions with AEBP below 865 degrees F were analyzed by GC/MS, while the 865 - 1100 degrees F fractions, not ameanable for GC/MS analysis, were analyzed by FI/FDMS.

All of the FI/FD analysis were carried out using a VG ZAB-HF mass spectrometer and 11-250 data system. HPLC fractions including the saturates, mono-, di-, tri-aromatics and polars, of the distillation cuts at AEBP 865, 885, 906,938,980, 1087, and >1087° F were analyzed. The FI/FD spectra of HPLC fractions of ABEP 906-938° F distillation cut is shown in Figure 1. Also obtained from the spectra were the distribution of carbon number, compound type (Z number), and average molecular weight. For example, the distribution of high molecular weight biomarkers with 4 and 5 rings were clearly observed in the saturate fraction. The calculated average molecular weight of all the fractions are shown in Table 1.

The aromatic carbon content in each HPLC fractions, as well as in the total CCU feed can be calculated based on an assumed aromatic carbon/mole and the averaged molecular weight. The aromatic carbon content obtained from FI/FD agrees remarkably well with those obtained from carbon-13 NMR analyses. The aromatic carbon content of monoaromatics in each of the AEBP cuts are shown in Table 2. The results demonstrated that FI/FDMS provides information concerning bulk as well as composition of heavy petroleum fractions not available otherwise. It is a valuable tool for characterizing heavy petroleum fractions from refinery streams as well as from crude oils.

Characterization of Petroleum Contamination in Soil by Field Ionization/Probe Microdistillation/Mass Spectrometry

Ronald D. Grigsby

IIT Research Institute
National Institute for Petroleum and Energy Research
P.O. Box 2128, Bartlesville, OK 74005

In this investigation, soil thought to be contaminated with crude oil was sampled between an oil well and a lake situated on rural property in northeastern Oklahoma. The well was located about 100 feet uphill from the lake. Samples were taken one foot below the surface at specified locations, which included the edge of the lake. The soil consisted of sandy loam of varying degree of wetness.

No sample preparation was undertaken other than drying overnight in a desiccator followed by pulverization to increase the surface area. Field ionization mass spectra were acquired at 3000 resolving power on a Kratos MS-50 mass spectrometer. A field desorption emitter was used for ion formation. Samples were loaded into a quartz, direct introduction probe, which was programmed over a temperature range from sub-ambient to greater than 400 ^{o}C. Spectra were processed as a function of probe temperature to provide molecular-ion distributions whose masses were classified according to nominal-mass Z series.

Interpretation of the data reveals a pattern of petroleum contamination that decreases as a function of distance from the well site to the edge of the lake. Hydrocarbons are readily distinguishable from naturally occurring organic substances found in the soil. This is evident by comparing Figure 1 with Figures 2 and 3. Figure

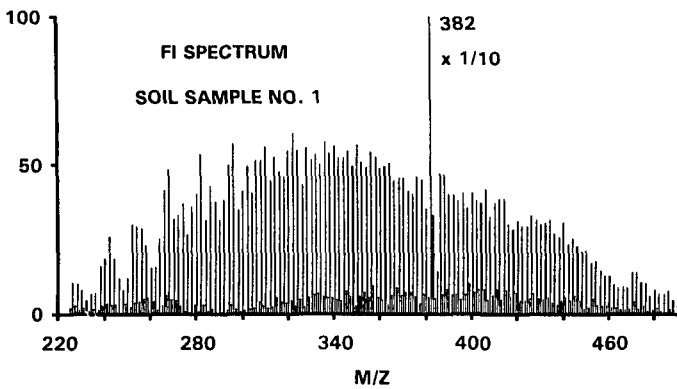

Figure 1. Field ionization mass spectrum of soil sample taken six feet from the well site. Peak at m/z 382 represents the molecular ion of quinquephenyl, used as an internal standard.

1 shows a molecular-ion distribution for aliphatic and aromatic hydrocarbons extending over a range from approximately 220 to 500. This pattern is seen to be much weaker in Figures 2 and 3, which show mostly molecular ions for organic substances found naturally in the soil.

The results show that the method is useful for providing a detailed characterization of petroleum in soil as a function of distance from the source of the contamination. A high concentration was found in the immediate vicinity of the well. This did not extend beyond a radius of 25 feet. Therefore, the lake was found to be free of pollution.

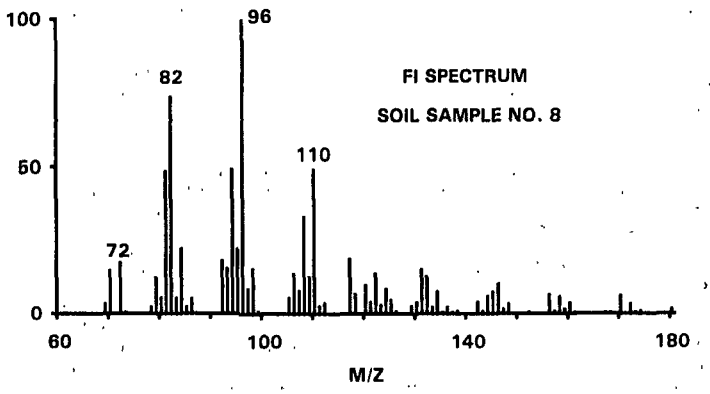

Figure 2. Field ionization mass spectrum of soil sample taken 19 feet from the well site. Low mass region.

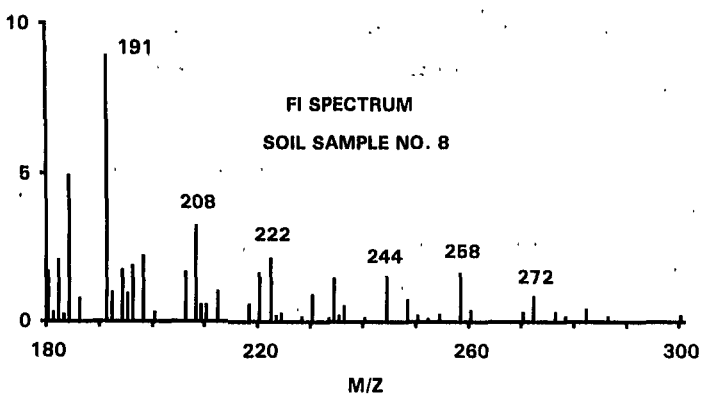

Figure 3. Field ionization mass spectrum of soil sample taken 19 feet from the well site. High mass region.

FIELD IONIZATION MASS SPECTROMETRIC ANALYSIS OF LUBE OIL ADDITIVES

Michael T. Cheng and Felicia F. Simpson
Chevron Research and Technology Company
Richmond, California 94802

Lubricating oil generally contains detergents, anti-oxidants, wear inhibitors, dispersants, and others. These compounds range from low to high molecular weight, and from non-polar to polar. Each class of compound is present in low concentration (percent level), and they are usually complex mixture of isomers and homologs. These conditions render the mass spectral analysis of the additive a challenging task. Electron ionization GCMS is not satisfactory, because the high molecular weight additive are not volatile enough to be gas chromatographed. Direct insertion EI of the mixture produce mass spectrum far too complex for interpretation, and molecular ions are not always observed. This report describes a field ionization mass spectrometric (FIMS) method for the analysis of these additives. The advantages of FIMS are the following: 1. Most of the ion current is due to the molecular ions. 2. It is insensitive to isomers. Therefore, the spectra are generally simple, composing of distributions of molecular ions of the homologs.

The mass spectra were obtained on a VG 70VSE double focusing mass spectrometer, and all of the samples were introduced via the direct insertion probe. The sample was first separated into a high and a low molecular weight fraction. Then each one was separated into four fractions according to polarity. Since each fraction was then examined by GCMS or FIMS, each fraction dose not have to be pure. Figure 1 is a FI mass spectrum of a low molecular weight, medium polarity fraction, containing detergents and anti-wear agent. Clearly, the detergents are based on nonyl-phenols, which has been treated with sulfur. The three ring compounds at m/z 846 and m/z 720, and the two ring compounds at m/z 596 and m/z 502 are not observed in GCMS. The peak at m/z 546 is due to butyl zinc dithiophosphate, an anti-wear agent, the cluster is due to the isotopes of the zinc atom. Assuming each peak in the FI spectrum is a molecular ion, then, there are clearly some unidentified species. The FIMS data can sometimes be used in a semi-quantitative fashion. For example, a fraction containing mixture of diarylamine anti-oxidants were analyzed by both FIMS and by electron ionization GCMS. Not only all of the compounds observed in the GCMS are also observed in the FI mass spectrum, but also, the relative concentration of each component as indicated by GCMS is approximately the same as that indicated by FIMS. Figure 2 shows the spectrum of a proprietary dispersant found in the high molecular weight, medium polarity fraction. This spectrum not only demonstrates the high mass capability (at least up to 2000 AMU) of direct insertion probe FIMS, but also shows the correct distribution of the oligomers, which was confirmed by electro-spray mass spectrometry.

In conclusion, field ionization mass spectrometry of mixtures offers an advantageous alternative to GCMS, and sometimes an additional dimension. A GCMS run usually requires about forty minutes, whereas a direct probe FIMS can be obtained in about ten minutes. And also, less volatile compounds that do not gas chromatograph can sometimes be analyzed by direct probe FIMS. Because only molecular ions are observed in FI mass spectra, one can interpret spectrum of mixture without too much difficulty. However, all this is based on the assumption that some structural information is known about the sample in question.

Laser Ionization Mass Spectrometry of Fullerenes

Filippo Radicati di Brozolo, Eugene P. Marsh, Ronald H. Fleming and Robert W. Odom, Charles Evans and Associates, 301 Chesapeake Drive, Redwood City, CA 94063.

Fullerenes (C_{60}-C_{70}) exhibit intense absorption bands in the UV, at 216, 264 and 339 nm, respectively (1), which are close to commonly available laser wavelengths, for example that of a frequency-quadrupled Nd:YAG laser (266 nm). Thus it is expected that fullerenes will be efficiently vaporized and ionized in a laser ionization mass spectrometer using such a laser.

In our search for efficient analytical techniques for fullerene detection, we have performed laser ionization with time-of-flight mass spectrometric analysis of fullerenes, using both one step UV laser (266 nm) ablation/multiphoton ionization and two step UV laser (266 nm) desorption followed by VUV (118 nm) single photon postionization. Ionization using a single VUV photon is known to be a "soft" form of ionization which enhances the yield of parent ions and monomer units (2).

We used the LIMA-2A instrument at CHARLES EVANS & ASSOCIATES with pulsed UV laser (266 nm) to analyze fullerenes. Typical mass range examined was 0 to 1000 amu. Low ablating laser power levels were used ($\leq 5\times10^7$ W•cm^{-2}); typically 200 mass spectra were acquired and summed. Initial samples examined were commercially obtained fullerenes of various degrees of purity. Both single laser ablation/ionization and postionization experiments were carried out. Both types of analysis confirm the prediction of efficient vaporization and ionization of fullerenes. We observed relatively intense signals at m/z 720 and less intense at m/z 840, with several other peaks in the vicinity exhibiting 24 amu separation (3) (Figure 1). We interpret these signals as fragments of the C_{60} and C_{70}, created by the laser irradiation. The VUV postionization spectrum exhibits only the two major signals of C_{60} and C_{70}, without molecular fragmentation (Figure 2). In the case of single laser ablation/ionization, we propose that the mechanism that produces fullerene signals is resonant multiphoton ionization (REMPI) (4). This selective mechanism explains why low mass C cluster ions are generally not observed along with the fullerenes, since they have much higher ionization potentials. From a practical point of view, the single laser ablation/ionization analysis is much simpler to implement and exhibits higher sensitivity than the single photon post ionization technique. This technique is therefore preferable when the goal is to establish the presence or absence of fullerenes. On the other hand, the VUV postionization technique is preferred in those cases where it is important to avoid any molecular fragmentation, for example when there is a need to measure relative intensities of individual fullerene species.

A particularly interesting result is the observation of fullerenes in a micrometeorite crater from the NASA Long Deployment Exposure Facility (LDEF). This crater has a high C level associated with it, and is interpreted as having been produced by the impact of a C-rich micrometeoroid (5).

In single laser ablation/ionization analyses of selected regions of LDEF crater #31, we observe fullerene signals, mainly C_{60}^+ with lower levels of C_{70}^+. This finding is unexpected, since up to now the search for fullerenes in extraterrestrial materials has not been successful (6). We rule out instrumental artifacts, having tested the LIMA 2A instrument with a carbon target under a variety of laser power conditions, without detecting fullerene signals. We also rule out laboratory contamination of the sample, since (a) this crater was always under controlled conditions from the time it was cored from LDEF, (b) its companion, crater #74, does not exhibit fullerene signals, and (c) fullerene distribution decreases radially outward from crater 31 suggesting a crater ejection origin. Experiments conducted at the NASA Ames Vertical Gun Facility show that a) fullerenes survive impacts into Al at least up to 6 km•s^{-1}; and b) fullerenes are <u>not</u> formed by impact of other C species such as diamond, graphite or amorphous carbon. Hence, we conclude that the fullerenes were carried by the C-rich projectile that formed LDEF crater #31. This is the first finding of extraterrestrial fullerenes and may force a revision of our current thinking of carbon chemistry in the solar system.

High Performance Separation and Mass Spectrometry Characterization of Fullerenes

M.R.Banks[1], A.C.Jones[1], I.Gosney[1], P.R.R.Langridge-Smith[1], Y.Ghaemi[2], T.J.Ormsby[2] and D.S.Jones[3]

[3] Kratos Analytical, Barton Dock Road, Manchester, UK

Introduction

Since the isolation of appreciable quantities of fullerenes by Kratschmer and Huffman [(1)] in 1990, research effort worldwide has spiralled exponentially in an attempt to characterise this new class of carbon compounds. These molecules are arranged as polyhedra with hexagonal and pentagonal faces. Preparation is relatively straightforward using carbon electrode contact-arc in an atmosphere of helium. This tends to produce a complex mixture consisting mainly of C_{60} and C_{70}. These products can be separated relatively inefficiently by use of flash chromatography using silica [(2)], alumina [(3)] or graphite [(4)]. Analysis is carried out, off-line, on these crudely separated fractions. However, a novel HPLC stationary phase called "FullereneSep" is now able to separate components far more efficiently than was previously possible. This poster describes in detail the coupling of this separation technique to mass spectrometry using the Kratos particle beam interface.

Experimental

The fullerene samples used in this work were prepared by contact-arc vaporization in a helium atmosphere using a single bench-top reactor modelled on the design published by Koch and Wudl [(5)]. Column chromatography of toluene soluble extract from the reactor on neutral alumina with hexane /toluene gradient afforded the fraction used for this analysis.

HPLC was carried out using a 150 x 46 mm ID "FullereneSep" column. The separation is achieved isocratically using soluble phase of n-hexane at 2 ml/min. Components were monitored by UV detection prior to mass spectrometric analysis. This is shown in Figure 1.

LC-MS of Fullerenes

A Kratos particle beam interface was used to couple the HPLC to the mass spectrometer. Nebuliser and desolvation temperatures were optimised to give best sensitivity and chromatographic peak profiles. A Kratos CONCEPT I H mass spectrometer with electron impact source performed the analysis at 1000 resolution The mass spectra were obtained by scanning from m/z 1000 to 100 at 3 seconds per decade.

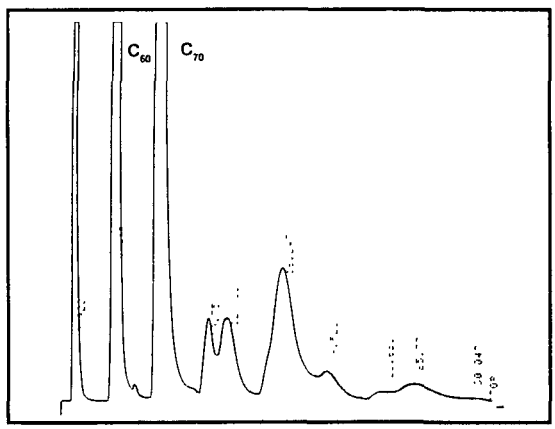

Figure 1 UV chromatogram of fullerene mixture

Source temperature was set at 350° C and electron energy set to 80eV. Most data was acquired in nominal mass format but spectra from the high temperature probe analysis were collected as raw data profiles and processed using a MACH 3 data system.

Good quality spectra were obtained from the two major components - viz. C_{60} (Figure 2) and C_{70}. Both exhibit very prominent multiply charged ions. In both cases the 2+ and 3+ charge states are more abundant than the singly charged molecular ion. The spectrum of C_{60} even shows evidence of the 4+ ion at m/z 180. One further feature of both mass spectra is that C_2 losses from the molecular ion are quite pronounced at this ionisation energy. These product ions give rise to a whole series of multiply charged ions at lower m/z values in the spectrum.

We have separated and identified a higher molecular weight component, C_{76}. The spectrum is shown in Figure 3, which shows molecular ion at m/z 912 and double charged species at m/z 456.

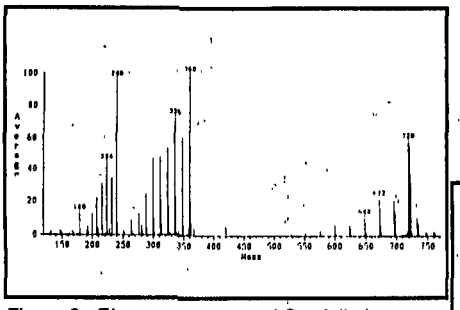

Figure 2: EI mass spectrum of C_{60} fullerene

Chromatographic peak profiles recorded by the mass spectrometer are considerably broader than those of the UV detector. This is most likely to be caused by the very low volatility of C_{60} and C_{70} even at a source temperature of 350°C. Vapour pressures of these species at various temperatures have been measured independently by Abrefah et al [6].

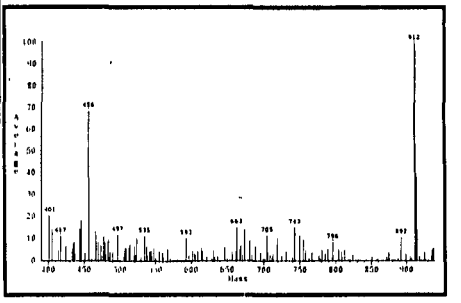

Figure 3: EI mass spectrum of C_{76} fullerene

We have investigated the behaviour by heating the sample on a high temperature probe to 750°C. This work would indicate that a source temperature in excess of 500°C is required to achieve rapid evaporation from the ion source. Almost certainly, band broadening does not originate from the particle beam interface which is kept at relatively low temperatures (80°). Transport of material through this differentially pumped region is as solvated species rather than as a gas phase process.

Conclusion

LC-MS in conjunction with the new "FullereneSep" column and a particle beam interface is a feasible approach to the mass spectrometric analysis of fullerene mixtures. However, a new generation of high temperature ion sources will be essential for gas phase ionisation investigations. We believe this will improve chromatographic integrity and increase sensitivity, especially for higher molecular weight species.

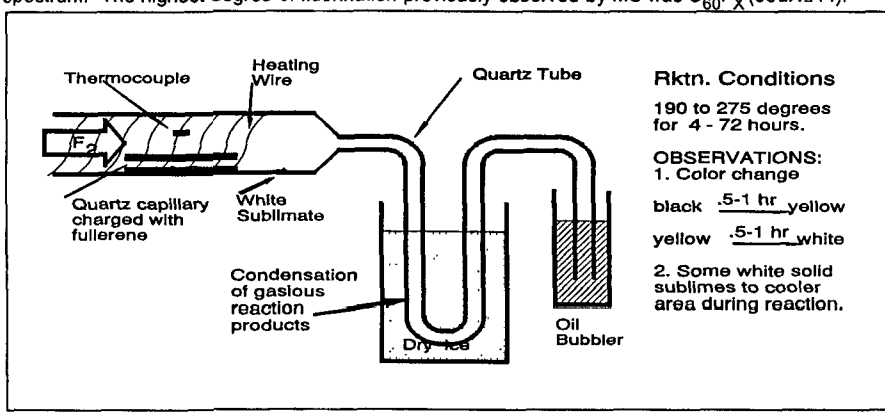
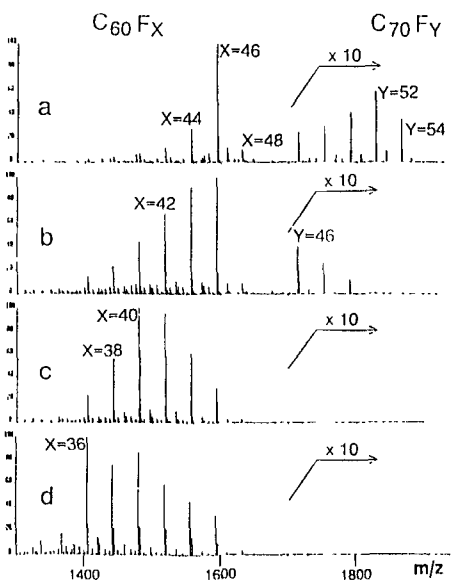
FULLERENE FLUORINATION: EVIDENCE FOR PRODUCT INSTABILITY AT $C_{60}F_{48}$.

A. A. Tuinman*, P. Mukherjee, J. L. Adcock, and R. N. Compton
Department of Chemistry, The University of Tennessee, Knoxville, TN 37996.

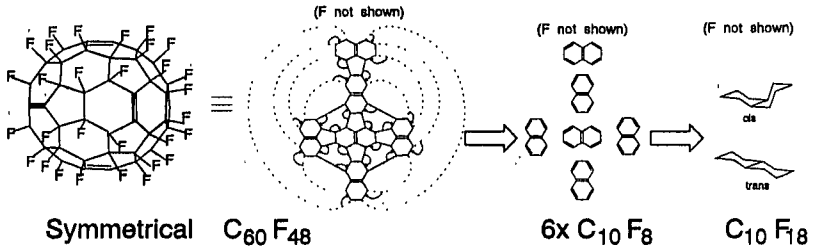
Several authors have reported highly substituted products resulting from addition of hydrogen or halogens to fullerenes. The degree of substitution varied with the nature of the substituent: $C_{60}Br_2$[1], $C_{60}Cl_{24}$[1], $C_{60}H_{36}$[2], and $C_{60}F_{60}$[3] representing the highest numbers of substituents reported for each type. The perfluoro-C_{60} was not identified by MS, but relied on the appearance of a single ^{19}F peak in the NMR spectrum. The highest degree of fluorination previously observed by MS was $C_{60}F_X$ ($30 \leq X \leq 44$).[4]





The white residue from the reaction of $C_{60} + C_{70}$ (9/1) contains $C_{60}F_X$ ($36 \leq X \leq 48$) and $C_{70}F_Y$ ($46 \leq Y \leq 54$), as illustrated in spectrum **a**. The white sublimate (see Fig. of reaction vessel) shows the same spectrum. On prolonged storage *as a solid* this composition does not change. On prolonged storage *in C_6F_6 solution* (air, ambient temp., ambient light) the sample changes as illustrated by spectra **b** (6 days storage), **c** (12 days storage), **d** (28 days storage). The $C_{70}F_Y$ cluster shifts to lower mass after one week, and looses intensity. Gone after 2 weeks. The $C_{60}F_X$ cluster shifts to lower mass and appears to lose absolute intensity with time. These changes may result, in part, from loss of F_2 increments ("reverse fluorination"). However, total disappearance of $C_{70}F_Y$ seems to require skeletal breakup. SKELETAL BREAKUP ALONE can explain the changes, if the more highly substituted fullerenes disintegrate more rapidly, leaving a relative overabundance of the less substituted molecules.

In addition to slow degradation of the solid fluorination products on storage in solution, there is evidence of formation of volatile products during the fluorination itself. Examination by electron capture-MS, MS/MS, and GC-MS of the condensate in the dry ice U-tube (see reactor drawing) unequivocally shows the presence of small amounts of perfluorodecalin. This may have been formed by skeletal breakup of a highly fluorinated intermediate (*e.g.* $C_{60}F_{48}$). The scheme below represents a possible mechanism for decomposition.



Symmetrically substituted $C_{60}F_{48}$ may fragment to 6 x $C_{10}F_8$ by (concerted ?) rehybridization of 24 sp^3 to sp^2 orbitals in a sort of "super retro Diels-Alder" mechanism. Driving forces for the reaction would be: 1) Relief of the F - F steric strain inherrent in $C_{60}F_{48}$ and 2) Formation of thermodynamically favoured aromatic compounds (perfluoronapthalene). In the fluorination reactor the napthalenes would further react to perfluorodecalin (*cis* and *trans*) which was specifically detected by GC-MS of the reaction condensate.

CONCLUSIONS: 1) Extended reaction of fullerenes (C_{60} and C_{70}) with gaseous F_2 provides fluorinated fullerenes detectable by EI-MS up to $C_{60}F_{48}$ and $C_{70}F_{54}$. 2) Although apparently stable in the solid state, $C_{60}F_X$ and $C_{70}F_Y$ decompose slowly in C_6F_6 solution, possibly via skeletal breakup. 3) During the reaction of C_{60} with F_2 at elevated temperature, volatile products are formed which may be trapped by cooling. 4) A significant constituent of the resulting condensate is perfluorodecalin. 5) A mechanism for the conversion of $C_{60}F_{48}$ to 6 x $C_{10}F_8$ is proposed to account for the observed perfluorodecalin.

Laser desorption FT/ICR mass spectrometry is ideally suited to the analysis of bare and derivatized carbon clusters and fullerenes, particularly metallofullerenes. LD/FT/ICR/MS on arc-welds of graphite doped with lanthanum oxide (carbon:lanthanum = 60:1 atom ratio) shows (see Figure 1) that abundant $La@C_n^+$ clusters can be produced, most prominently $La@C_{60}^+$ and $La@C_{82}^+$. $La@C_n^+$ clusters from n = 64-112 are clearly observed, as are even-numbered C_n^+ clusters extending to n = 122. When La_2O_3 and fullerene-rich soot are admixed and laser desorbed, no $La@C_n^+$ clusters are observed, clearly indicating that these species are formed by the arc-welding process and *not* by a laser desorption process in the mass spectrometer. These results agree with previous results [1,2], except that we do not observe clusters containing multiple lanthanum atoms.

Fullerene soot components have been separated by reverse-phase HPLC and analyzed by LD/FT/ICR/MS. Analysis of these fractions shows pure C_{60} (Figure 2), C_{70}, and other higher mass fullerenes, confirming that these fullerenes were not generated by laser desorption or any other process in the mass spectrometer, provided that "thin" films are used (see Figure 3a for a benzene extract of fullerene-laden soot). However, we observe massive, even-numbered positive ion carbon clusters beyond C_{400} (Figure 3b) and negative ion clusters beyond C_{250} for "thick" film benzene extracts of fullerene-laden soot or open-column LC fractions of pure C_{60}! The qualitative effect of the giant carbon cluster formation did not vary with laser fluence for the irradiances tested. Formation of these giant clusters is proposed to occur by a nucleation process on or near the probe tip surface in the laser plasma. Work is underway to determine how thick the sample must be before production of giant clusters occurs.

Negative ion LD/FT/ICR mass spectra of benzene extracts from glassy carbon arc-welds clearly indicate that the fullerenes C_{60}, C_{70}, and C_{84} are the primary species formed by the arc-welding procedure, just as with graphite arc-welds. Also, we have observed numerous doubly-charged fullerene anions, in addition to those discovered previously for C_{60} and C_{70} [3,4]. These anions have been identified by isotope ratios and distribution patterns as well as by shifts in ion cyclotron frequency (ν_+) with trapping potential. Carbon Clusters and Fullerenes from Carbon and Platinum Electrode Materials: Laser Desorption FT/ICR/MS

Michael A. May,† Michael E. Huston,†
Matthew R. Callstrom,† and Alan G. Marshall†,#

Departments of Chemistry† (and Biochemistry#), The Ohio State University,

Carbon cluster ions from "low temperature" glassy carbon-6 (GC-6),[1,2] platinum doped glassy carbon-6 (Pt/GC-6),[3] glassy carbon-25 (GC-25), highly oriented pyrolytic graphite (HOPG), and polycrystalline graphite have been investigated by pulsed laser desorption Fourier transform ion cyclotron resonance mass spectrometry (LD/FT/ICR/MS). As described below, microstructural differences between these carbon electrode materials are observable by LD/FT/ICR mass spectrometry. GC-6 was synthesized by heating poly(phenylene diacetylene) to 600 °C. Platinum(0) clusters were incorporated into GC-6 by heating a platinum-butadiyne precursor to 600 °C to yield GC-6 doped with ~1 atom% platinum (Pt/GC-6). Films of Pt/GC-6 exhibited electrocatalytic activity comparable to pure platinum with respect to H^+ and O_2 reduction.

Pt/GC-6 gave ion signals for Pt^+, PtC^+, and C_{14}^+ to C_{36}^+ by LD/FT/ICR/MS (see Fig. 1). No higher mass platinum cluster ions, such as Pt_2^+, were observed in the mass spectra of Pt/GC-6 for laser fluences up to 1.3 x 10^{10} W cm^{-2} (Nd:YAG laser, 1064/532 nm). GC-6 yielded carbon cluster distributions (see Fig. 2) similar to those found in the mass spectrum of Pt/GC-6. The mass spectrum of GC-25 (see Fig. 3) gave similar carbon cluster distributions compared to Pt/GC-6 and GC-6 in positive-ion mode, except that GC-25 gave a weak ion signal above C_{28}^+.

In negative-ion mode, laser desorption of Pt/GC-6 yielded carbon clusters from C_6^- to C_{19}^-, and C_{21}^- to C_{27}^- (odd). Under similar conditions, GC-6 yielded C_6^- to C_{21}^-, and C_{23}^- to C_{33}^- (odd). The mass spectra of Pt/GC-6 and GC-6 each gave prominent C_nH^- peaks relative to C_n^- (n= 8, 10, 12). By comparison to the two GC-6 materials, carbon clusters above C_{13}^- were less abundant for conventional GC-25. In addition, GC-25 gave relatively weak C_nH^- peaks (n= 8, 10, 12).

Two other solids, polycrystalline graphite and HOPG, were also examined in order to determine whether graphite is distinguishable from glassy carbon by LD/FT/ICR/MS. In contrast to glassy carbon, we find that: (1) polycrystalline graphite gave C_{60}^+ and other fullerene cations, (2) basal plane HOPG typically gave strong C_{60}^- and C_{70}^- signals, and (3) polycrystalline graphite and basal plane HOPG each gave significant C_9^+ to C_{13}^+ peaks. This work was supported by NSF (CHE-9021058, CHE-9007132) and The Ohio State University.

A SIFT Study of the Ion / Molecule Reactions of Fullerenes

Gholamreza Javahery, Simon Petrie, Jinru Wang and Diethard K. Bohme
Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, Ontario, Canada M3J 1P3.

The recent discovery[1] and synthesis[2] of the prototypical fullerene, C_{60}, has precipitated a great number and variety of studies of the chemical and physical nature of this novel class of carbon allotropes. Mass-spectrometric detection of the ion C_{60}^+ in graphite laser-ablation studies[1] gave the first indication of the existence of the fullerenes, and the reactivity of such ions is of interest and importance for several reasons. Fullerene ion / molecule chemistry is postulated to occur within sooting flames and within interstellar space. Fullerene ions can provide insight into the effects of very high symmetry and charge delocalisation upon reactivity. A uniquely high range of charge states - from 5+ to 6- - has been reported for C_{60} species under various conditions: fullerenes provide a convenient model for the reactivity of multiply-charged species, and permit a comparison between the reactivities of different charge states having essentially identical geometry. We have recently begun a Selected-Ion Flow Tube (SIFT) study of the reactions of $C_n^{+\cdot}$ and C_n^{2+} (n = 60, 70) with various neutrals, and of various ions with C_{60}.[3-10]

The reactions were studied in a selected-ion flow tube which has been described previously.[11] All reactions were studied at a temperature of 294 ± 3 K and within the pressure range 0.35 - 0.4 Torr of helium buffer gas. $C_n^{+\cdot}$ and C_n^{2+} were generated in the ion source by electron bombardment upon C_{60} / C_{70} vapour (from heating of a C_{60} / C_{70} mixture, obtained from Strem Chemicals Co., containing 2-12% C_{70}) entrained in argon. For reactions of the form $X^+ + C_{60}$, the neutral C_{60} was introduced into the flow tube in an uncalibrated fashion by heating solid C_{60} (>99% pure) entrained in argon. Because of the nature of C_{60} introduction, rate coefficients for reactions of ions with C_{60} could not be determined.

A brief summary of the results to date is as follows:

The reactions of $He^{+\cdot}$ and $Ne^{+\cdot}$ with C_{60} and C_{70} occur without fragmentation of the fullerene cage. The major product channel of these reactions is apparently charge transfer. A minor channel (>10% and >5% respectively) is the production of the dicationic species C_n^{2+}, most probably by a novel process of charge transfer electron detachment.[3]

The ions C_{60}^+, C_{60}^{2+}, C_{70}^+, and C_{70}^{2+} all undergo efficient association with atomic hydrogen, with the sequential addition of at least 3 (for C_{60}^+) and 4 (for C_{60}^{2+}) hydrogen atoms.[4]

Charge transfer from C_{60}^{2+} does not occur in a fashion anticipated from the measurement of $IE(C_{60}^{+\cdot}) = 11.39 \pm 0.05$ eV.[12] 'Bracketing' experiments, by McElvany et al[13] and by ourselves[5] indicate that charge transfer from C_{60}^{2+} to a neutral X does not occur for neutrals having IE(X) ≥ 9.69 eV. The absence of charge transfer in the range 9.69 - 11.39 eV is consistent with the requirement for additional energy resulting from the Coulombic repulsion between two monocationic product ions initially produced in close proximity.[5] Similar arguments have been made previously,[14-18] and similar energetic constraints apply for the occurrence of proton transfer from dications, such as in the reaction of $C_{60}NH_3^{2+} + NH_3$.[7]

The presence of activation energy barriers to charge-separation reactions (such as charge transfer, hydride abstraction and proton transfer) favours the occurrence of association reactions in many reactions of fullerene dications. Such reactions are additionally favoured by the possibility for

increased charge separation made possible by the attachment of a moiety to the spherical fullerene cage. This effect is most pronounced for reactions of fullerene dications with relatively large unsaturated hydrocarbons, which permit an increase in charge separation by several carbon-carbon bond lengths.[8] Such factors would also prevail in the association of dications with other fullerene molecules: however, our studies of reactions of fullerene dications with aromatic and fullerene neutrals indicate that only charge transfer (which is highly exothermic for all such reactions) occurs in these reactions.[8]

These results have several implications for interstellar and circumstellar chemistry. The formation of C_{60}^{2+} in the reaction of $He^{+\cdot}$ + C_{60} indicates that dications are likely to be present within both diffuse and dense interstellar clouds as a result.[3] The association reactions of fullerene ions with atomic hydrogen[4] lends support to the proposals[17] that variously hydrogenated 'fulleranes' are likely constituents of the interstellar medium. Association reactions of fullerene cations with ammonia and amines, and of fullerene dications with unsaturated hydrocarbons, suggest the formation of functionalised fullerenes within dense interstellar clouds.[8]

INTRODUCTION

Mass spectrometric method is one of the most important and useful technique that can characterize carbon fullerenes. We have investigated fullerenes using on-line LC/MS. The purpose of these experiments are as follows:

(1) To characterize heavy fullerenes such as C76,C78,C82 and C84 using LC/MS.
(2) To analyze fullerenes in solvents which allow high sensitive detection.
(3) To make clear the problem of aggregation and fragmentation in FAB or SIMS ionization which allow the clear interpretation of normal mass spectrum.
(4) To interpret the mass spectrum of very heavy fullerenes extracted by quinoline/pyridine.

EXPERIMENTAL

1. Chromatography: A Yokokawa LC-100 gradient systems with a 150x4.6 mm ODS column was employed under the condition of the column flow rate of 1 mL/min and a linear gradient of toluene and acetonitrile from 40:60 v/v to 90:10 v/v in 60 minutes. A m-nitrobenzyl alcohol was used as a FAB matrix to assist in FAB ionization. The 2 % of toluene solution was delivered using the second pump and mixed at the exit of the UV detector.
2. Mass Spectrometer: A JEOL SX 102A mass spectrometer of reverse geometry with data system DA 7000 was used for mass separation and detection. Frit FAB ion source was connected with a liquid chromatography on-line. Samples were ionized on frit surface bombarded by xenon atoms of 6kev energy. A syringe pump (Harvard Apparatus Model 22) was also used to analyze small amount of sample dissolved in arbitrary solvent. The flow rate was 5μL/min. Mass spectra were acquired at every 5 seconds with a mass range of 400 to 2200 daltons at 8 KV accelerating potential.

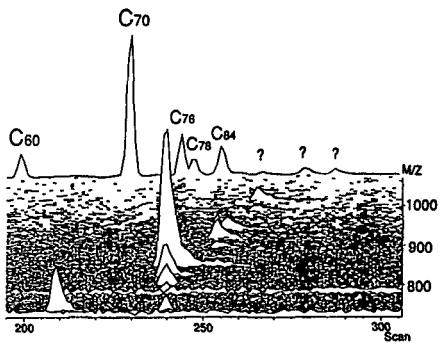

Figure 1. 3D-plot of mass chromatogram of sample A

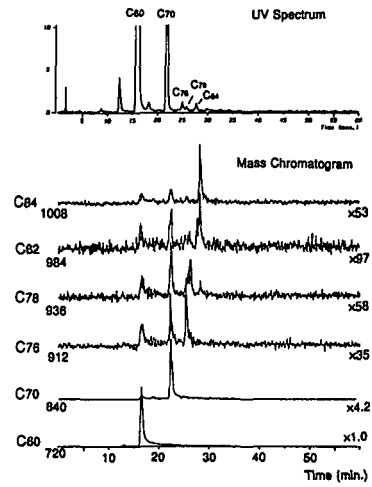

Figure 2. Mass chromatogram of sample B

3. Fullerene sample preparation:
The fullerene-rich carbon soot was prepared by the contact arc method[2]. Sample **A** containing mainly heavier fullerenes than C70, such as C76, C78, C82, C84 extracted by toluene; Sample **B** containing mainly C60, C70, and small amount of C76, C78, C84 extracted by toluene; Sample **C** containing only C60 extracted by toluene; Sample **D** containing very heavy fullerenes extracted by Quinoline/Pyridine[3].

RESULTS AND DISCUSSION

Figure 1 shows the 3D-plot of mass chromatogram of sample **A**. Carbon fullerenes of C70, C76, C78, C82 and C84 can be clearly separated and identified from their mass spectra.
Figure 2 is the mass chromatogram of sample **B**. It should be noted that C76, C78, C82 and C84 peaks consist of two origins. One is the component which are originally contained in the sample and the others are the components which are produced during ionizing processes through aggregation or fragmentation. Fullerenes higher fullerenes such as C76, C78, C82 and C84 are produced from C70 not from C60 in spite of much lager amount of C60 is contained in the sample **B**. For the case of C82, major components are produced through fragmentation from C84. By investigating this mass chromatogram, the relationship between heavier fullerenes will be investigated.
In order to make clear the aggregation and fragmentation process of fullerenes during ionization process, pure C60 was analyzed through the same LC/MS condition. It can be seen that smaller and larger fullerenes were created and detected . We recognized that heavier component at mass range 1400 can be seen at the same retention time, though its intensity ratio C140/C60 is about 1/100. These heaver elements are explained to be produced by collisional attachment of two C60 fullerenes. Figure 4 is the normal SIMS spectrum of very heavy fullerenes contained in sample **D**. The intensity ratio of C140/C60 of Figure 4 is 20 times bigger than those from Figure 3. This suggest that the sample **D** contains very heavy fullerenes. We got the following conclusions.

(1) Larger fullerenes up to C84 could be analyzed by LC/MS on-line from low concentrated solution.
(2) Aggregation and fragmentation phenomena occur though in small ratio during FAB or SIMS ionization. Some of C76, C78, C82 and C84 fullerenes are post-produced from C60 or C70.
(3) Sample **D** contains very heavy fullerenes since such high intensity distribution can not be explained by only aggregation or fragmentation of smaller fullerenes.
(4) On-line LC/MS technique is a unique and powerful methods to characterize heavy fullerenes.
(5) A syringe pump is useful and high sensitive apparatus for liquid sample measurements.

Ionization Potentials of Small Carbon Clusters (C_n, n=3-6)

R. Ramanathan and J.R. Eyler
Department of Chemistry, University of Florida
Gainesville, FL 32611-2046

Over the last two decades, carbon clusters have been of interest to both theoretical and experimental groups. Small carbon clusters have been of particular interest because of their importance in combustion processes, interstellar space and comet tails. The ionization potentials (IP's) of clusters are one of their most important physical properties. Accurate determination of IP's of small clusters can lead to a better understanding of reactivity and configuration. Previously, our group has determined IP's of carbon clusters containing from 6 to 24 atoms and from 48 to 200 atoms with an uncertainty of few tenths of an eV by using the charge-transfer bracketing technique (1-2). Charge-transfer bracketing is done by monitoring the occurrence or non-occurrence of charge transfer reactions with neutral reagents of known IP.

In Fourier transform ion cyclotron resonance (FTICR) mass spectrometric studies it is possible to approximate quite closely the adiabatic IP values. In FTICR, during a "thermalizing" period, ions undergo many ion-molecule collisions (≥100) with the thermalizing gas and lose most of their internal energy. During a charge transfer reaction delay period the ionic cluster is neutralized by gaining an electron from a neutral reference compound. In this work, IP's of small carbon clusters (C_n, n=3-6) have been determined using the charge transfer bracketing technique.

All experiments were performed using a 2 Tesla FTICR mass spectrometer equipped with a Nicolet FTMS 1000 data station. The carbon clusters were produced by focusing the fundamental (1064 nm) output of a Nd:YAG laser onto a graphite plug mounted behind the back trap plate of the cell. The laser beam was focused with a 7.63 cm focal length quartz lens through the front and back trap plates onto the graphite plug. The energy per pulse was 5-15 mJ.

The pulse sequence used in these experiments was as follows: A quench pulse was first applied to both trap plates to eject any ions present in the cell. The laser was then triggered and a pulsed valve was opened during the beam time. Next, a 900 ms delay time allowed the ions to be thermalized by ion-neutral collisions with argon (peak pressure 6.6×10^{-6} Torr). This delay time also allowed the thermalizing gas to be pumped out of the vacuum chamber. A series of ion ejection sweeps was then used to isolate the cluster cation of interest. After the cluster ion was isolated, a variable reaction time allowed the charge-transfer reaction to take place. Ions were excited and detected by standard chirp excitation and broad band detection.

The carbon cluster distribution was observed to depend on the laser energy. For small carbon clusters containing 10 atoms or less, clusters with an odd number of atoms were found with higher intensity. Table 1 compares our IP's with some previously reported experimental and theoretical values. There is generally poor agreement with earlier theoretical and experimental <u>vertical</u> IP's. The IP for C_3 determined in this study was found to be higher than the experimental <u>adiabatic</u> IP's reported in the literature. The C_4 experimental adiabatic IP reported previously agrees very well with the IP obtained in this study. The IP of C_5 fits the trend of generally decreasing IP's with cluster size observed in our previous studies (1-2). The IP of C_6 reported here agrees very well with the IP of C_6 bracketed by our group using the same technique but with a different laser and different reference compounds.

Several interesting side reactions were observed in addition to the charge transfer reactions. These side reactions caused some difficulties in bracketing the IP's. However, they gave some insight into the reactivity of the carbon clusters. These side reactions indicate that the even and the odd clusters react differently. During the reaction with N_2O, the odd numbered clusters formed C_nO^+ and $C_nO_2^+$ and even numbered clusters formed $C_{n-1}O^+$ and $C_{n-1}O_2^+$. Time plots for these side reactions are shown in Figure 1. The small carbon clusters also showed some differences in their reactivity with benzene. All four clusters underwent charge transfer with benzene. However, the odd numbered clusters reacted with $C_6H_5^+$ and $C_6H_7^+$ formed during the reaction period but the even numbered clusters did not react.

Table 1
Comparison of previous experimental and theoretical IP's with the IP's detemined by charge-transfer reactions and FTICR-MS

C_n	This work	vIP(exp.)	vIP(theory)	aIP(exp.)
C_3	12.97±0.1	9.98-11.61[3]	11.4[4]	12.1[5]
C_4	12.54±0.35	9.98-11.61[3]	10.5[4]	12.6[5]
C_5	12.26±0.1	9.98-11.61[3]	10.7[4]	
C_6	9.70±0.2

Electron Affinities and Ion/Molecule Reactions of Carbon and Silicon Clusters

James E. Bruce and John R. Eyler,
Department of Chemistry, University of Florida,
Gainesville FL 32611-2046.

Clusters of atoms, especially those of carbon atoms, have been the subject of countless experimental and theoretical investigations in recent years. The variation of physical properties observed as the number of atoms in the cluster is altered has been a key factor in the investigations of cluster bonding and structure. Mass spectrometry has played a vital role in these studies involving both positive and negative ions. A number of previous cluster studies from this laboratory have used a charge transfer technique to bracket ionization potentials of carbon, metal, and other clusters[1]. We now have extended this approach with another ladder of reference compounds to bracket electron affinities (EA's) of laser-generated clusters.

All the cluster anions discussed here were formed by laser ablation or laser desorption and trapped in a Fourier transform ion cyclotron resonance mass spectrometer with a typical trapping voltage of -1 or -2 volts. The negative ions of C_{60} and C_{70} were produced by CO_2 laser desorption from a commercially available extract of carbonaceous soot, enriched in C_{60} and C_{70}. The anions were trapped in the analyzer cell, where they were allowed to react by electron transfer with reagents of known electron affinity[2]. By allowing the anions to react successively with various electron transfer reagents and observing which reagents underwent transfer and which did not, the electron affinities of C_{60} and C_{70} were successfully bracketed. Smaller cluster anions of carbon (C_4^-, C_5^-, and C_6^-) and silicon (Si^- and Si_2^-) were studied in a similar manner; however, these clusters were produced by Nd:YAG laser ablation of a graphite or silicon target, respectively. A 2 second thermalization period with argon (5×10^{-6} Torr) was introduced before any of the reactions used to bracket a cluster electron affinity were followed.

The results of the electron affinity bracketing experiments are summarized and compared to previous determinations (threshold photodetachment spectroscopy for Si_2 and ultraviolet photoelectron spectroscopy for all carbon clusters) in Table I. Agreement for the larger carbon clusters is good; however, the bracketed values for all the small clusters of silicon and carbon are lower than previously determined values by 1.3 to 2.4 eV. No definite explanations for the differing results have been given; some possibilities are trapped electrons, background interferences from ions such as H^- and OH^- and excited states of the cluster anion.

Quite frequently, side reactions are observed during the charge transfer bracketing experiments. These reactions can obstruct the determination of ionization potentials and electron affinities by this technique; however, they can sometimes provide information relevant to ionic and neutral structures.

Hydrogen atom abstraction reactions were observed for the even numbered carbon cluster anions (C_{2n}^-, for n= 2 to 6) when reacted with the electron transfer reference compound 3-nitrotoluene. The products $C_{2n}H^-$ and $C_{2n}H_2^-$ were observed from sequential hydrogen atom abstraction from 3-nitrotoluene. The odd numbered carbon cluster anions showed no such reactivity. Investigation of this behavior with phenol as an H· radical source resulted in abstraction of only a single hydrogen atom for the even cluster anions (again, no hydrogen atom abstraction for the odd numbered clusters). The isolation of C_6^- followed by its reaction with phenol, shown in Figure 1, provided an explanation for this observation. C_6^- reacts with phenol by hydrogen atom abstraction, similar to the 3-nitrotoluene case, to produce C_6H^-. However, a second abstraction is not observed because proton transfer from phenol (a fairly strong Brønsted-Lowry Acid) to C_6H^- occurs to produce (presumably) the neutral C_6H_2.

The electron affinities of laser-generated clusters were successfully estimated by the electron transfer bracketing technique. The agreement with previous data is excellent for the larger clusters and poor for the small clusters of carbon and silicon. The results from hydrogen atom abstraction reactions suggest that the even numbered carbon cluster anions are linear; no examples of abstraction of more than two hydrogen atoms were observed. The much greater reactivity of even numbered cluster anions, as compared to that of the odd numbered clusters, suggests that the even clusters possess more radical character than the odd clusters. This fact may possibly indicate an alternation between acetylenic (even) and cumulenic or cyclic (odd) structures for the carbon cluster anions from C_4^- to C_{12}^-.

Table I. Electron affinities determined by electron transfer bracketing experiments.

Cluster	Present EA/eV	Previous EA/eV
Si	<0.69	1.385±0.005[3]
Si_2	0.90±0.13	2.176±0.002[4]
C_4	1.3±0.19	3.70[5]
C_5	1.5±0.18	2.80[5]
C_6	1.5±0.18	3.10[5]
C_{60}	2.6±0.21	2.6 - 2.8[6]
C_{70}	2.6±0.21	2.6 - 2.8[6]

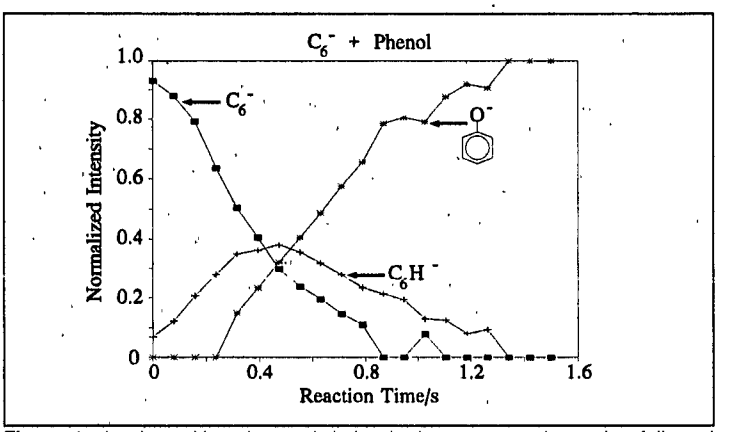

Figure 1. Ion intensities observed during hydrogen atom abstraction followed by proton transfer for C_6^- with phenol at 3.3 x 10^{-7} Torr.

Inelastic Scattering and Endohedral Complex Formation in High-Energy Collisions of Fullerenes with He

John H. Callahan, Richard C. Mowrey and Mark M. Ross
Chemistry Division, Naval Research Laboratory
Washington, D.C. 20375-5000.

Since the original postulation of its icosahedral structure by Smalley and Kroto in 1985, C_{60} (also known as buckminsterfullerene) has fascinated investigators in a variety of fields. With the publication of a synthetic method for the bulk production of C_{60}, there has been an explosion of research interest in this molecule. A number of intriguing experimental results have been published, including work in the area of mass spectrometry. For example, at a workshop at the 1991 ASMS meeting, Schwarz and coworkers reported a remarkable result.[1] They showed that high energy collisions of C_{60}^+ with He resulted not only in the expected formation of collision-induced dissociation (CID) products such as C_{56}^+ and C_{58}^+ (C_2 loss is the main fragmentation pathway for C_{60}), but also in the formation of products such as C_{56}^++4 and C_{58}^++4. Careful experiments with ^{3}He showed that the products were $C_{56}He^+$ and $C_{58}He^+$, most likely formed by the uptake of He by C_{60}^+ during the collision. Subsequent experiments in our laboratory were able to directly observe the $C_{60}He^+$ product;[2] the product ion shifts in kinetic energy by an amount equal to the center-of-mass collision energy, consistent with kinematic arguments. $C_{60}He^+$ was also observed by the Gross group[3] and the Schwarz group[4]. Gross and coworkers were able to show in very detailed studies[5] that similar effects can be observed with Ne, Ar and D_2, that C_{70}^+ can take up two He atoms, and that all of the fragments (e.g. C_n^+ or C_nHe^+) in the high energy collision process arise from the $C_{60}He^+$ precursor. Gross and coworkers also showed that inelastic scattering processes can be observed in the collision spectrum.[5] More recently, the Anderson group has studied reverse processes, in which ions such as He^+, Li^+ and C^+ undergo collisions with C_{60} and are taken up in the collision.[6]

We have been interested in modelling the dynamics of endohedral complex formation and inelastic scattering in high-energy collisions of C_{60}^+ with He. Molecular dynamics calculations have been used previously in this laboratory to model the impact of C_{60}^+ on various surfaces such as hydrogen terminated diamond and graphite.[7] These simulations predicted some of the behavior later observed in collisions of fullerene ions with surfaces.[8] These techniques were used in these studies to model interactions between C_{60} and He in high-energy collisions. Intermolecular forces between carbon atoms were calculated using an empirical many-bodied potential. The functional form of the potentials is based on the Tersoff bond order expression; the potential can properly describe bond-breaking and bond-formation and is chemically realistic. The interactions between He and C_{60} were modelled by a screened Coulomb interatomic repulsive potential. To facilitate the calculation, the collision process was modelled by directing He at C_{60} with energies such that center-of-mass collision energies (E_{cm}) were identical to those obtained in high-energy collisions of C_{60}^+ with He. Multiple trajectories were calculated at various collision energy at various impact parameters, where the axis of symmetry was taken through the center of the 5 or 6-membered rings in the fullerene; increasing impact parameter corresponds to an increasing distance from the axis of symmetry. The results of the simulations were compared to experimental results obtained on a reverse-geometry hybrid mass spectrometer (BEqQ configuration).

Figure 1 shows the results of a 5-keV collision of C_{60}^+ with He. Figure 1a is the conventional MIKE scan obtained when He is present under near-single collision conditions (approximately 20% main beam attenuation). Figure 1b shows the same energy scan with the analyzer quadrupole set to transmit m/z 720, and the inset in Figure 1a is the same scan with the quadrupole set to transmit m/z 724. The results show that a $C_{60}He^+$ product is formed, with a kinetic energy that is reduced by E_{cm}, consistent with kinematic arguments. We have compared the experimentally determined trapping efficiencies at various collision energies with that predicted by the simulations. The simulations predict a higher overall efficiency at a higher collision energy. This may be in part due to the fact that the simulations can only be carried out over a timescale of hundreds of femtoseconds, while decomposition lifetimes for a molecule such as C_{60}^+ are on the order of μsecs. The dynamics simulations probably overestimate the amount of $C_{60}He^+$ that actually survives. The simulations also give some insight into how the trapping process occurs. Low-energy, low-impact parameter collisions can be successfully trapped, largely because He gives up some energy to C_{60}^+ as it passes through the ring. He subsequently has insufficient energy to pass through the rear ring. On the other hand, high-energy low-impact parameter collisions result in He passing through both the front and rear rings. High-energy, high-impact parameter collisions can also result in trapping. Here He is deflected into the interior of C_{60}, and subsequently possesses insufficient

energy to pass through the rear. Conversely, low-energy, high-impact parameter collisions result in recoil, as He rebounds from a direct impact with He.

The simulations also provide insight to the inelastic scattering behavior observed in figure 1b. As explained by Gross and coworkers, the "foot" in figure 1b results from collisions in which He is inelastically scattered by C_{60}^+. The onset of the "foot" can be explained through kinematic arguments as a case where the initial interaction between He and C_{60}^+ is through a largely elastic collision between one or two carbon atoms and He. This is corroborated by the molecular dynamics simulations, which show that scattered He has trajectories largely explained by highly elastic collisions with a small part (e.g. one or two carbon atoms) of C_{60}. Moreover, the simulations also show that the foot should shift toward the elastic scattering limit with decreasing collision energy, as has been observed experimentally. This result suggests that less energy can be taken up as internal energy as the collision velocity decreases, probably because of a mismatch between the change in momentum in the collision and the available vibrational modes for internal energy uptake.

FORMATION OF LARGE ALUMINUM CLUSTER IONS BY DIRECT LASER VAPORIZATION OF ALUMINUM NITRIDE

*Stephan B. H. Bach[1], Stephen W. McElvany, Ngai Wong[2] and Denise C. Parent**

Chemistry Division/Code 6110
Naval Research Laboratory, Washington, D. C. 20375-5000

Introduction. Direct laser vaporization (DLV) is a simple technique for producing elemental clusters in a Fourier transform ion cyclotron resonance (ICR) mass spectrometer (FTMS). Advantages of this technique are that it uses no buffer gas, thus differential pumping is not required, and that the ions are formed *in-situ* without the need for ion injection optics. Disadvantages include possible internal excitation in the clusters and the limited applicability of DLV. Generally only elements that have molecular species in the vapor phase (*e.g.* C, Si and other main group elements) form clusters and these are usually small (carbon is unusual in this respect). The observation of aluminum cluster anions containing up to 50 atoms produced by DLV of an aluminum foil [1] remains the exception. (It is worth noting that cations were not observed in those experiments.) In this work we have taken another approach and used metal nitrides as the solid target for DLV.

Methods. The experimental apparatus consists of a Nicolet FTMS-1000 data system modified to operate with SWIFT, a 3-Tesla superconducting magnet and a home-built vacuum system with a 1 x 1 x 2-inch cell. The frequency-doubled output (532 nm, ~2 mJ/pulse) of a Nd:YAG laser was used for DLV of the aluminum nitride pellet. The pellet, mounted on a solids probe, was in close proximity to one of the trapping plates. In some experiments, a pulsed valve was opened at the time the laser was fired, allowing argon into the cell. This pulse of argon served to thermalize the clusters.

Abundance Distributions. Aluminum cluster cations and anions were produced by DLV of an aluminum nitride pellet. A pressure burst was also observed coincident with the laser firing; electron ionization showed that it was composed of N_2. This large pressure burst may act as a buffer gas to stabilize the nascent clusters. Figure 1 shows the cation mass spectrum for clusters containing 10-62 atoms (clusters with 3-9 atoms were ejected). Magic numbers in the cation cluster distribution are 7 (not shown) and 14. Figure 2 shows the anion mass spectrum for clusters containing 3-42 atoms. Magic numbers in the anion cluster distribution are 3, 7, 9 and 13. Except for small $Al_xN^{\pm}$ species, nitrogen-containing clusters are not observed.

Reaction with Oxygen. In order to characterize the cation clusters, we studied the reaction of selected clusters with oxygen for comparison with previous work [2]. Beam studies have shown that the

Fig. 1. Al_x^+ ($x \geq 10$) produced by DLV of AlN.

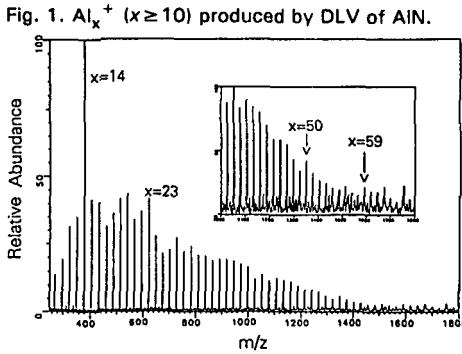

Fig. 2. Al_x^- produced by DLV of AlN.

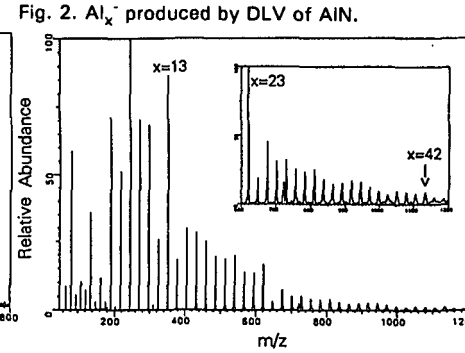

reactions of Al_x^+ with oxygen, though exothermic, have small barriers in the entrance channel [3] and do not occur at thermal energy. For $x \geq 5$ the dominant process appears to be [2]

$$Al_x^+ + O_2 \rightarrow Al_{x-4}^+ + 2Al_2O$$
$$\hookrightarrow Al_{x-5}^+ + Al.$$

We did not observe any reaction of the thermalized cluster cations with 17, 19 and 25 atoms. Only upon kinetic excitation of the cations did we observe reaction products. The main product in each case was Al_{x-5}^+. (We also performed collision-induced dissociation and verified that this was not a CID product.) The lower pressures and longer times of the FTMS, compared to the beam experiments, allows the initial Al_{x-4}^+ product, which may contain several eV of internal energy, to fragment further. The similar behavior of the DLV-produced clusters and those formed in a molecular beam (MB) source suggests that the DLV clusters are not significantly hotter (internally excited) than the MB clusters.

Reaction with Ammonia. *A portion of the* nascent cation cluster distribution was also reacted with ammonia, as shown in Figure 3. Adduct products, $Al_x(NH_3)^+$, are seen for $x = 10$-22 while larger clusters appear to be unreactive [4]. Comparing the top and bottom panels of Figure 3 we see that Al_{13}^+ and Al_{17}^+ are strongly depleted and thus especially reactive. Since the clusters were not mass-selected in this experiment we cannot rule out fragmentation processes that might distort the apparent reactivities. A study of neutral aluminum clusters reacting with ammonia [5] found that the NH_3 is only weakly bound (physisorbed) to the aluminum cluster. If this is also the case for the cation clusters, then fragmentation would not be expected to occur. The apparent large variations in the probability of adduct formation and the probable weak interaction suggest that ammonia may be useful as a sensitive probe of cluster structure, as it was for silicon cation clusters [6].

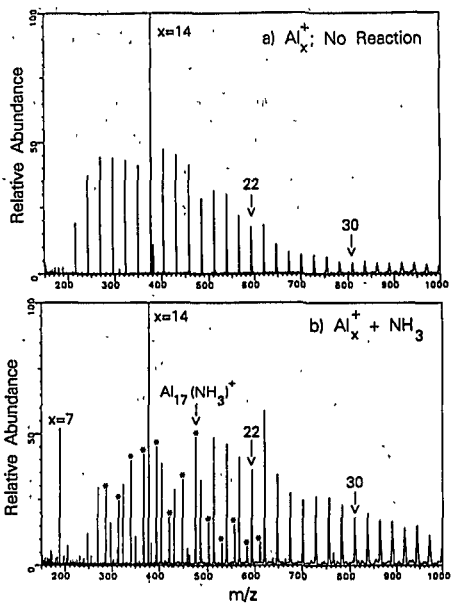

Fig. 3. Reaction of Al_x^+ with NH_3.

Summary. We have seen that at least one metal nitride is a suitable target for producing metal cluster ions by DLV. This is the first report of the formation of large homogenous metal clusters from a heterogenous material. The reactivity of the thermalized cation clusters is comparable to that of cold clusters obtained from molecular beam sources.

[3]Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139

INTRODUCTION: We investigated the structure of mercury, mercury/alkali and mercury/noble metal clusters. It is theoretically expected that small mercury clusters have the structure based on van der Waals force since the bond length of the mercury dimer is 30% longer than those of bulk metal mercury. The transition from van der Waals to metallic in mercury clusters was observed by measuring the dependence of photon energy on ionization efficiency by Bréchignac et al[1]. We tried to prove such a transition from the intensity pattern of mass spectra obtained using two sector type MS and a linear time of flight MS. Very large clusters of mercury/cesium were observed up to m/z=240,000. How the structures of mercury/complex clusters are changed depending on the type of metal atom included and the size of clusters are discussed.

EXPERIMENTAL: The experimental details are given in a following table.

Type of MS	Ionization Method	Observed Cluster Ions	Samples
GEMMY(sector)[2]	15kev Cs^+ bombardment	$(Hg)_nCs^+$	mercury
CQH(sector)[3]	8keV Xe^+ bombardment	$(Hg)_nAg^+$,$(Hg)_nCu^+$,$(Hg)_n^+$	mercury/noble metal amalgam
VESTEC VT2000(TOF)	laser, 266, 337nm	$(Hg)_nAg^+$,$(Hg)_n^+$	mercury/silver amalgam

RESULTS and DISCUSSION:

A: Mercury/Cesium Cluster

Figure 1 shows a mass spectrum of $(Hg)_nCs^+$ obtained the gland scale mass spectrometer (GEMMY). Dominant cluster ions were $(Hg)_nCs^+$. Other types of cluster ions such as $(Hg)_n^+$,$(Hg)_nK^+$ are less than 1%. The magic numbers of $(Hg)_nCs^+$ at n=12,18,22,25,28,31,.., are quite similar to those of rare gas clusters[4], namely, relating to the double icosahedral structure (DIC). Above n=40, an undulation of ion intensity was observed. Total numbers of valence electrons in mercury clusters at the local minima, which equals twice times of cluster size, agreed with theoretical shell closing numbers calculated based on metal bonding force.

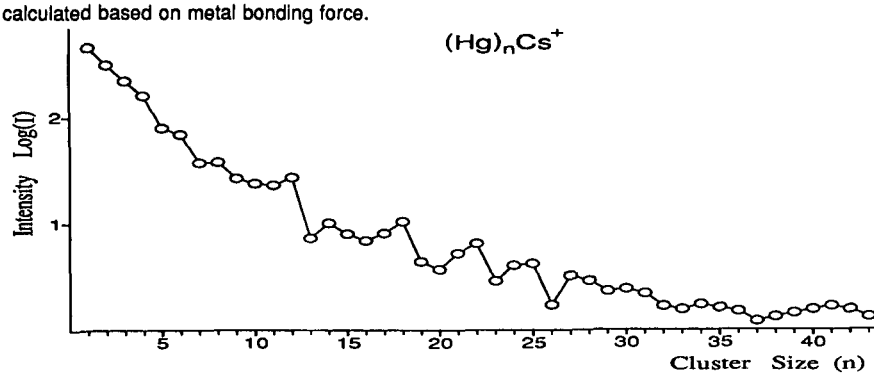

Figure 1. Mass spectrum of$(Hg)_nCs^+$ up to cluster size 43.

B: Mercury/Noble Metal Clusters

Figure 2 shows mass spectra of $(Hg)_nAg^+$ obtained using a sector MS and a time-of-flight/MS. The major magic number of $(Hg)_nAg^+$ were observed at n=4,10,22 in both spectra. The minor magic numbers were also observed at n=15,17,26 in the mass spectrum obtained by CQH MS. The size distribution of $(Hg)_nCu^+$ clusters is quite similar to those of $(Hg)_nAg^+$ clusters. However $(Hg)_nAu^+$ clusters were not observed under the similar preparation of mercury/gold amalgam to that of mercury/silver. Only bare mercury clusters were detected. These new magic numbers may suggest the possibility of new geometrical structure of mercury/noble metal clusters.

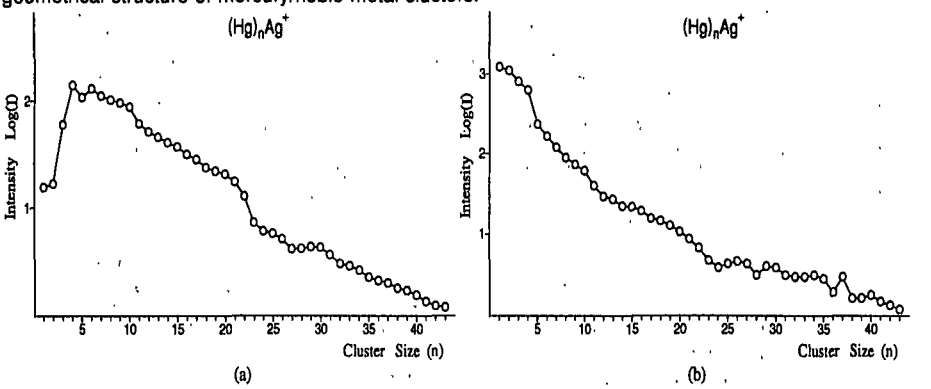

Figure 2. Mass spectra of $(Hg)_nAg^+$. **a**: SIMS Sector MS, **b**: LD TOF

C: Supershell of Mercury Cluster

Figure 3 shows a mass spectrum of $(Hg)_nCs^+$ up to m/z=240,000 obtained using GEMMY. We obtained following to two evidences. [1] Plot of the cube root of the shell closing number obtained from local minima of mass spectrum against the shell index falls on two straight lines with the same slope. [2] Transition from one straight line to another one occurs around cluster size n=500. We conclude the supershell structure in divalent metal clusters $(Hg)_n$ was confirmed from above two points.

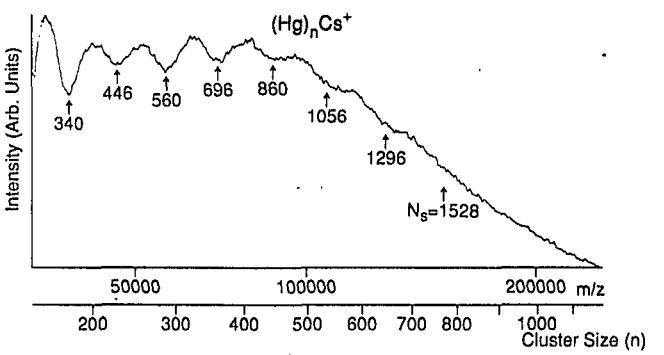

Figure 3. Mass spectrum of $(Hg)_nCs^+$ up to cluster size 1200 (m/z 240,000).

ELECTRON AND CHEMICAL IONIZATION FOR SOME TRANSITION METAL ACETATES

Y. Cao and K. L. Busch
School of Chemistry & Biochemistry
Georgia Institute of Technology, Atlanta GA 30332-0400

Introduction:

Numerous methods have been used to elucidate the structures of metal clusters. Mass spectrometry has proved to be an important technique for determination of the structures of these cluster ions. In this study, electron ionization and negative chemical ionization mass spectra of the acetates of molybdenum, cadmium, silver, lithium, sodium and potassium and mixtures of these compounds have been investigated by using an in-beam direct chemical ionization probe. Complex cluster ions are formed under incident high pressure conditions by heating the DCI probe rapidly. As a result of gas phase ion-molecule reactions, these cluster ions have masses higher than the molecular weight of the acetate itself. Both temperature and pressure strongly affect the nature and abundances of the cluster ions. The DCI/NCI mass spectra reported here for the metal acetates contribute the first such report of their mass spectra.

Results and Discussion:

EI and CI spectra for three transition metal acetates have been studied in both positive and negative ion modes. Normal positive EI or CI condition cannot break the bond between two molybdenum atoms. Only a few cluster ions have been observed for molybdenum acetate. Clusters contain up to five cadmium atoms have been observed for cadmium acetate. Some previously unreported higher mass cluster ions from silver acetate have been seen in this study.

A negative chemical ionization study for these three transition metal acetates has been pursued. For molybdenum acetate, the base peak appears at m/z 670, and corresponds to $[Mo_4(OAc)_5]^-$. A much cleaner spectrum has been obtained for cadmium acetate in the negative ion mode than its positive DCI or DEI spectrum. $[Cd(OAc)_2]^-$ at m/z 232 appears to be the base peak. $[Cd(OAc)_2CH_3]^-$, $[Cd(OAc)_2C_2O]^-$ $[Cd(OAc)_3]^-$ $[Cd(OAc)_5CH_3]^-$, $[Cd_2(OAc)_5]^-$, $[Cd_3(OAc)_4C]^-$ and $[Cd_3(OAc)_7]^-$ also appear in the spectrum (Figure 1). The largest cluster ion that can be observed has a mass higher than 900, and is likely $[Cd_5(OAc)_7]^-$, but the signal is weak. In the NCI/DCI spectrum of silver acetate. $[Ag(OAc)_2]^-$ at m/z 225 is the most abundant peak. Other negatively charged ions are at m/z of 181, 283, 392, 450 and 558, which correspond to ions $[Ag(OAc)\cdot CH_3]^-$, $[Ag(OAc)_3H]^-$, $[Ag_2(OAc)_3\text{-}H]^-$, $[Ag_2(OAc)_4]^-$ and $[Ag_3(OAc)_4]^-$.

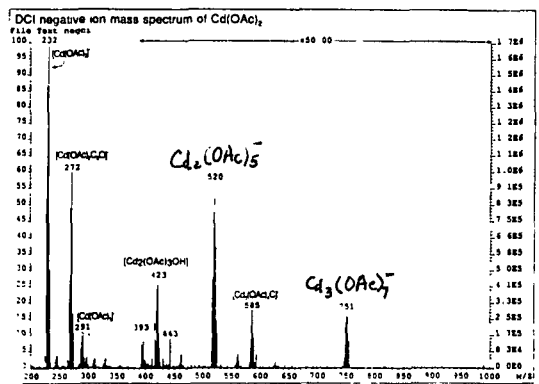

Fig. 1 NCI mass spectrum of cadmium acetate

Extensive mass spectrometric studies for alkali acetates have been reported in the literature[1,2,3], but the range of ions formed is still further extended in this research. Electron ionization, positive and negative chemical ionization mass spectra for the acetate salts of lithium,

sodium, potassium and their mixtures have been recorded. Here the variety of cluster ions have been broadened, and the mass limit to which they extend has been expanded. In positive ion mode, there are no significant differences observed between DEI and DCI spectra. Clusters $[M_n(OAc)_{n-1}]^+$ are measured up to n=8 for Li, n=14 for Na, and n=7 for K. The sizes of the clusters are highly dependent on the volatility of sample itself. Ions at low masses are relatively more intense in DEI mass spectra than they are in DCI spectra, and ion intensities decrease more rapidly as the sizes of clusters increase.

Several interesting results are obtained in the methane negative chemical ionization study for alkali acetates that we describe here in detail. Cluster ions $[M_n(OAc)_{n+1}]^-$ are observed. The value of n can be as high as 16 for lithium acetate and n=8 for sodium and potassium acetate salts. For lithium acetate (Fig.2), intensities of clusters decrease along the exponential curve as shown in the following figure (Fig.3). The ion intensities follow a regular decrease with mass, and the figure shows an excellent match with an exponential equation.

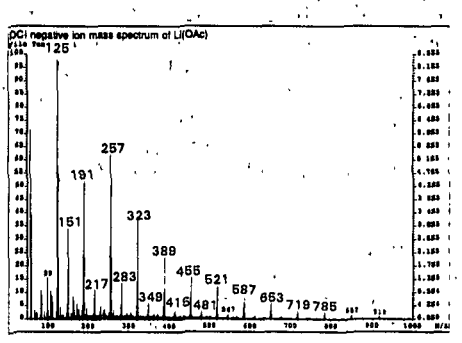

Fig. 2 NCI mass spectrum of lithium acetate

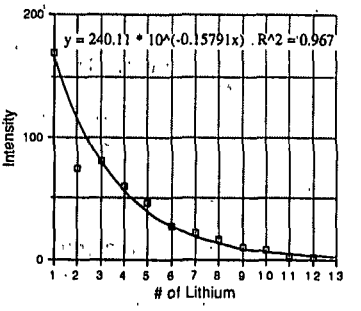

Fig. 3 Exponential fit for intensities of $[Li_n(OAc)_{n+1}]^-$

The intensity of the ion $[M_2(OAc)_3]^-$ reproducibly falls below the expected intensity. At the same time, the ion at m/z 151 (configured as loss of allene from the cluster) is above the expected intensity. The sum of the these two ions, however, regenerates the expected intensity. We suggest that there is a special form of the $[M_2(OAc)_3]^-$ ion that facilitates allene loss; the trigonal ion shown in the model is structurally unique to this composition, and we speculate that access to this structure may account for the loss of intensity below that otherwise expected. A difficulty with this speculation is that although m/z 191 is always lower in intensity than expected, the putative fragment ion at m/z 151 is not always observed.

EXTENT OF CLUSTER DISSOCIATION IN DI - RRKM CALCULATIONS

Jan Sunner
Montana State University, Bozeman, MT 59717

INTRODUCTION

It is generally recognized that desolvation (in vacuum) of analyte ions in DI results in cooling and that this may prevent fragmentation of the analyte ion. In an extension of this process, it has frequently been suggested that large clusters or microscopic droplets are ejected in DI and that these undergo successive desolvation to leave the bare analyte ion. Such a process could also explain the formation of large cluster ions such as the alkali halide cluster, $M^+(MX)_n$, since these involatile ions would be left behind. This work addresses the question of the extent of such declustering. Protonated glycerol clusters, Gl_nH^+, were chosen as the model system. Glycerol is, of course, the most common matrix used in FAB (Liquid SIMS). The behavior of glycerol clusters should, however, be characteristic also of other polar matrix molecules of roughly the same size. Here, we concentrate on the behavior of $(Gl)_{10}H^+$ clusters ejected from the surface.

RRKM CALCULATIONS

RRKM theory was used to calculate the unimolecular dissociation rates of the protonated glycerol clusters as a function of internal energy. The rotational constants were those of a spherical cluster of the same size. The intra-molecular vibrational frequencies were those of isolated glycerol. The intermolecular vibrational frequencies were selected to yield an entropy of -20 kcal/mol for successive clustering reactions. Rate constants were calculated for Gl_nH^+ clusters as a function of internal energy for n = 2 to 10. The Gorin model was used. The activation energy was 31 kcal/mol for the 2→1 reaction and gradually decreased to 17 kcal/mol for the 6→5 and higher fragmentations, i.e. close to the heat of vaporization of glycerol (18.2 kcal/mol).

Figure 1 shows the RRKM microcanonical rate constant for the 10→9 reaction as a function of the internal energy in the 10-cluster. The figure also shows the internal energy distributions of the 10-cluster at 5 different temperatures. It is seen that practically all 200K clusters will not dissociate, whereas almost all 400K clusters will dissociate prior to mass spec analysis. The same calculations were done for the smaller clusters.

SUCCESSIVE DISSOCIATIONS

The 9-cluster product in the 10→9 reaction may or may not dissociate further depending on the internal energy of the 9-cluster. The 10→9 reaction is endothermic by 17 kcal/mol. In addition, some of the internal energy is carried away by the neutral glycerol molecule. This energy was assumed to be statistically distributed between the products. The calculations were started with 10-clusters of a given temperature. The size and energy distributions of the clusters were then followed with time. Figure 2a shows the result starting with 10-clusters at 400K, rear bar graph. At 10^{-11} s, the clusters have shed 1-2 glycerol molecules, middle bar graph. At the mass spec detector (20 us) the

clusters have shed another 1-2 molecules. Figure 2b shows the same result for an initial temperature of 800K. At 10^{-11} s, the clusters can not have left the impact site; indeed they can not have been formed. The difference between the middle and the front bar graph is thus an estimate of the number of "slow" dissociations occurring after the clusters have left the surface.

CONCLUSIONS

When large glycerol clusters are ejected from a surface at a sufficiently low temperature, they will not dissociate. At high temperature, on the other hand, the first dissociation reactions are so fast, $< 10^{-11}$ s, that they would have occurred before the cluster could have formed from the matrix. The number of "slow" dissociations, $10^{-11} < t < 10^{-6}$ s, is surprisingly small; for glycerol clusters smaller than $(Gl)_{10}H^+$ *it is a maximum of ca. 2.* The calculations also demonstrate efficient cooling by desolvation; the internal temperature of glycerol product clusters is ca. 200-250 K.

With matrices that are not too widely different from glycerol, it seems that in DI "what you see is (almost) what you had" (at the time of cluster ejection). Droplet models do not seem to be valid. Cluster breakup and cluster formation at the early stages can not be conceptually separated from the matrix disintegration.

Characterization of the Extent and Relative Abundance of Excited State Transition Metal Ions Produced by Various Methods

J. V. Oriedo, T. Solouki, F. H. Strobel, S. Morgan, D. H. Russell
Department of Chemistry, Texas A&M University, College Station, TX 77843

A substantial amount of work has concentrated on the reactivity of transition metal ions in the gas phase. In these studies, the transition metal ions are formed by a variety of methods, including laser desorption, electron impact, and collision- induced dissociation. Recent studies have indicated that these ionization techniques can produce a significant amount of electronically excited states, however, the excited state metal ion populations produced by these ionization methods have not been quantitatively measured.

We have developed a method for quantifying of the state specific populations using dissociative charge transfer reactions. In this paper we have determine the excited state distribution for ions formed by a variety of methods.

The laser desorption studies were performed in a single-section ICR cell in a 7 tesla magnetic field strength. A Laser Science, Inc. pulsed N_2 (model VSL-337ND) laser was used for desorption and ionization of solid metals ,*e.g.* , Fe^+ and Cr^+, from a stainless steal sample probe surface. Ions of interest were isolated by using ejection techniques and reacted with $Fe(CO)_5$ neutral molecules. The $Fe(CO)_5$ was introduced into the cell through a leak valve. The extent of electronic excitation for M^+ ions was probed using dissociative and non-dissociative endothermic ion-molecule reactions.

Electron impact studies were performed in a differentially pumped two-section ICR cell in a 3 tesla magnetic field strength The two-section ICR cell consists of two cells that share a common trapping plate between them referred to as a conductance limit. The only opening that allows for ion transfer between the two differentially pumped cells is an aperture in the center of the common plate (2mm in diameter). M^+ was initially formed by electron impact of $M(CO)_x$ in region 1 of the two-section cell. The M^+ ions were isolated and partitioned to region 2 where the extent of electronic excitation was probed.

An examination of the effect of ionizing energies on ions produced by electron impact indicates that for some systems the higher lying excited state are preferentially produced at a lower ionizing energies,. For example, the abundance of high-lying excited states of Fe^+ is quite high at ionizing energies near-threshold whereas, the high-lying states of Co^+ disappear at threshold ionizing energies. The relative abundance of the low-lying states of Co^+ are unchanged at threshold ionizing energies.

The excited states populations of transition metal ions formed by CID and laser desorption indicate that these techniques form substantial amounts of excited states. For example, CID of $Fe(CO)^+$ yield, 65% Fe^+ ^4F (first excited state). The populations of excited states produced by collision induced dissociation are shown in Table 1.

In conclusion, all methods of ionization produce significant populations of excited transition metal ions.

Table 1: Extent and distribution of electronic states of Fe^+ formed by off-resonance CID of $Fe(CO)^+$ [produced by EI of $Fe(CO)_5$].

Reactions of M^+ and CpM^+ with 1,3,5-Trisilacyclohexane in the Gas Phase. First Observation of the Trisilabenzene Ligand.

Asgeir Bjarnason and Ingvar Arnason
Science Institute, University of Iceland, Dunhaga 3, IS-107 Reykjavik, Iceland

INTRODUCTION

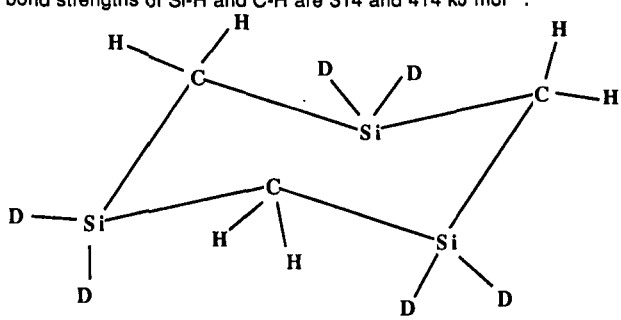
Reactions of metal ions with organic molecules in the gas phase have been extensively studied in recent years by several research groups. Dehydrogenation of **cyclohexane** by Fe^+, Co^+, Ni^+, $CpCo^+$, and $CpNi^+$ have been reported by Freiser and coworkers [1] and Beauchamp and coworkers [2], and elimination of up to three hydrogen molecules were observed in all cases, save Ni^+, to form the **benzene** ligand. The formation of the benzene ligand from cyclohexane in the reactions with metal ions and metal-containing ions prompted us to investigate reactions of such ions with trisilacyclohexane in the gas phase, as efforts to produce trisilabenzene have been unsuccessful so far.

EXPERIMENTAL PROCEDURE

The experiments were done by employing an EXTREL FTMS-2000 Fourier transform mass spectrometer with a dual-cell configuration and have been described previously [3]. Fe^+ and $CpFe^+$ were generated from $CpFe(CO)_2I$, which was incorporated into the mass spectrometer in a sample vial on the direct insertion probe. Co^+ and $CpCo^+$ were produced in the same manner from Cp_2Co, and Ni^+ and $CpNi^+$ from $[CpNiCO]_2$.

RESULTS

The product distribution in the dehydrogenation reactions of M^+ and CpM^+ is shown in **Table 1**. A question that arises in light of the results of Beauchamp and coworkers on the reactions of metal ions with methyl silanes [4] is if hydrogen is only eliminated from Si The bond strengths of Si-H and C-H are 314 and 414 kJ mol^{-1}.



1

Triple dehydrogenation in the reactions of CpM^+ with **1** was shown to involve mostly elimination of 3HD and to a lesser extent 2HD + D_2. Only traces of $3D_2$ elimination were observed and these observations support the hypothesis that the main product in the triple dehydrogenation reaction involves the formation of 3 carbon-silicon double bonds and that the 1,3,5-trisilabenzene ligand is produced.

Jacobson and Freiser successfully employed CID to study products from the reactions of $CpCo^+$ with cyclohexane. We were able to reproduce their findings, but unable to get meaningful information about the $CpMC_3H_6Si_3^+$ ions using either similar or different CID conditions. It appears that the kinetic energies sufficient for dissociation of these ions using either argon or xenon as the collison gas is greater than the maximum value for containment of the ions in the cell. This points to a stronger bond between the metal and the carbosilane ligand than the benzene ligand.

TABLE 1.

Product distribution in dehydrogenation reactions of M^+ and CpM^+ with 1,3,5-trisilacyclohexane.

Reactant Ion	Elimination of		
	H_2	$2H_2$	$3H_2$
Fe^+	1.0	0.15	0.01
Co^+	0.2	1.0	0.04
Ni^+	1.0	0.5	0.02
$CpFe^+$	0.4	1.0	0.2
$CpCo^+$	0.1	1.0	0.3
$CpNi^+$	0.2	0.7	1.0

Studies of the Gas-Phase Reactions of Protonated Methanol with Methanol Using Oxygen-18 and Deuterium Labeling.

Thuy Thanh Dang and *Veronica M. Bierbaum

Department of Chemistry and Biochemistry
University of Colorado, Boulder, CO 80309-0215

The tandem flowing afterglow-selected ion flow tube (FA-SIFT) has been employed to measure the rate coefficients and branching ratios for oxygen-18 and deuterium labeled reactions of protonated methanol with methanol under conditions where proton transfer, condensation (S_N2) and association can be observed simultaneously.

$$CH_3OH_2^{\ddagger} + {}^*CH_3OH \longrightarrow CH_3OH + {}^*CH_3OH_2^{\ddagger}$$
$$\longrightarrow (CH_3)_2OH^+ + H_2O$$
$$\xrightarrow{M} (CH_3OH)_2H^+$$

Our results are summarized in Table I.

When hidden channels are properly accounted for, we find that all collisions are reactive. At helium pressure of 0.47 torr, 85% of the ion-molecule collisions result in proton transfer, 4% lead to condensation and 11% result in association. In agreement with previous experiments which employed deuterium labeled reagents, we find complete equilibrium of the isotope label in both the proton transfer and condensation products. However, in contrast to previous results, we also find nearly complete equilibration of the oxygen-18 label in the condensation products of the reaction $CH_3{}^{18}OH_2^{\ddagger}$ + $CH_3{}^{16}OH$. Our results are consistent with the predominant (> 99%) formation of a hydrogen-bonded dimer in which there is rapid proton transfer between the two methanol molecules. Most of this complex re-dissociates, a smaller amount is collisionally stabilized while a minor fraction rearranges to the methyl-bound dimer; this latter species generates condensation products in which the isotope labels are statistically distributed. Our results demonstrate that the direct formation of the methyl-bound dimer is a minor (< 1%) pathway.

Gas-Phase Chemistry of Bis(η_5-cyclopentadienyl)methyltitanium(+1) with Dihydrogen and Unsaturated Hydrocarbons

*Matthew F. Ryan, Mohammed N. Khan, David E. Richardson, and John R. Eyler, Department of Chemistry, University of Florida, Gainesville, FL, 32611-2046.

Zieglar-Natta catalysts are an important class of homogenous olefin polymerization catalysts which have been used industrially for more than 30 years. Electron deficient early transition metal alkyl complexes have demonstrated reactivity, in the gas-phase[1] and solution[2], comparable to Zieglar-Natta systems. Because of the similarities of early transition metal complexes to Zieglar-Natta systems we have investigated the chemistry of $Cp_2TiCH_3^+$, (**1**; Cp=cyclopentadienyl), and $Cp_2TiCD_3^+$, **2**, with dihydrogen and unsaturated hydrocarbons by applying Fourier transform ion cyclotron resonance mass spectrometry.

The hydrogenation reactions of **1** and **2** (reaction 1), are observed to be ¼ as efficient as compared to the hydrogenation reactions of $Cp_2ZrCH_3^+$.[1]

$$Cp_2TiCH_3^+ + H_2 \rightarrow Cp_2TiH^+ + H_2 \qquad (1)$$

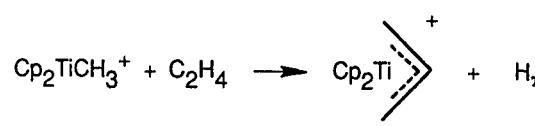
The measured second-order rate constant for the above hydrogenation reaction k_H is (3.4 ± 0.7) x 10^{-12} cm^3 $molec^{-1}$ s^{-1} [(2.0 ± 0.4) x 10^9 M^{-1} s^{-1}] and k_D = (1.5 ± 0.3) x 10^{-12} cm^3 $molec^{-1}$ s^{-1} [(1.0 ± 0.2) x 10^9 M^{-1} s^{-1}]. These two rate constants give a deuterium kinetic isotope effect, k_H/k_D, of 2.2 ± 0.6. The kinetic isotope effect for the hydrogenation reaction of $Cp_2ZrCH_3^+$ is 2.0 ± 0.5.[1] With respect to the estimated Langevin collision rate, 1 X 10^{-9} cm^3 s^{-1}, k_D/k_c is 0.002, as compared to a value of k_D/k_c of 0.007 for the zirconocene complex.

Measurement of the ion/molecule reaction rate constants was complected by formation of binuclear titanium ion complexes which form at extended reaction times (~500 ms). Additionally, the methyltitanocene cation reacts readily with H_2O (reaction 2) even when present as a slight impurity, generating the hydroxide complex, Cp_2TiOH^+.

$$Cp_2TiCH_3^+ + H_2O \rightarrow Cp_2TiOH^+ + CH_4 \qquad (2)$$

Concerning reactions of **1** and **2** with olefines, two reactions pathways are possible: insertion/dehydrogenation and σ-bond metathesis which is recognizable by sole elimination of methane. Reaction of **1** and **2** were studied with ethylene, C_2D_4, propylene, allene, and several isobutylene compounds. Isotopic labeling studies were used to distinguish between the two possible reaction pathways. Double-resonance experiments (MS/MS) were performed to determine the source of product ions and collisional induced dissociation[3] (CID) experiments were performed to gain insight concerning the structures of product ions.

The reaction of **1** with ethylene proceeds with the formation of $Cp_2TiC_3H_5^+$, **3**,(product ions reported as single ion corresponding to the species with most abundant ^{48}Ti isotope) and elimination of H_2.



(3)

Additionally, evidence of up to 3 or 4 insertions of ethylene have been observed (Figure 1). Product ions corresponding to $Cp_2TiC_4H_5^+$, **4**, $Cp_2TiC_5H_7^+$, **5**, $Cp_2TiC_6H_7^+$, **6**, and $Cp_2TiC_8H_9^+$, **7**, along with dehydrogenated complexes of **4** and **5** ($Cp_2TiC_4H_3^+$, **8**, $Cp_2TiC_5H_5^+$, **9**) have been

observed. Double resonance experiments on **3** results in loss of product ions **4-9** indicating that sequential insertions originate from reaction of C_2H_4 with **3**. CID experiments on **3** resulted in formation of the Cp_2Ti^+ fragment inferring an allyl $Cp_2Ti(\eta^3\text{-allyl})^+$ structure. The π-bonded η^3-allyl structure is more stable than the charge localized η^1 complex do to resonance stabilization but isomerization from $\eta^3\text{-}C_3H_5$ to an $\eta^1\text{-}C_3H_5$ may be necessary for additional insertion of ethylene. Since product ions **4-9** are observed, the barrier to isomerization is expected to be small.

Reaction of **2** with ethylene results in formation of $Cp_2Ti(\eta^3\text{-allyl-}d_2)^+$, and HD elimination, as major product ion. Higher m/z product ions are also observed, typically shifted 2 or 3 mass units higher with respect to reaction of **1** with C_2H_4. Nonstatistical H/D scrambling is observed for the reaction of **1** with C_2D_4 and can be accounted for by facile insertion/deinsertion mechanism.

The reaction **1** with propylene proceeds with the formation of an η^3-methylallyl complex, $Cp_2TiC_4H_7^+$ (m/z 233; **10**) shown in figure 2. Moreover, product ions **4, 6** and **9** have also been observed indicating reaction of **10** with of a second molecule of propylene (reaction 4).

$$Cp_2TiC_4H_7^+ + C_3H_6 \rightarrow Cp_2TiC_6H_7^+ + CH_4 \qquad (4)$$

The reaction of isobutylene with **1** and **2** results in formation of **10**, the η^3-methylallyl complex, which has been determined through CID experiments. Labeling studies using $CH_2C(CD_3)_2$ and $CD_2C(CH_3)_2$ show that the reaction proceeds through allylic C-H activation rather than vinylic attack. Additionally, the reaction of $Cp_2ZrCH_3^+$ with isobutylenes were investigated and an allylic C-H activation pathway has been observed. These results are consistent with the ion-molecule chemistry of $FeCH_3^+$(g) and $CoCH_3^+$(g) studied by Jacobson and Freiser.[4]

Collisionally activated dissociation has found wide application as a tool for the structural characterization of ions. There remain, however, a variety of structural problems that cannot be solved by the use of this technique. In the work presented here, we have investigated the suitability of some simple ion-molecule reactions for the structural characterization of organic radical cations.

The reactions found to be the most useful ion structural probes satisfy three criteria. First, the reaction must be thermodynamically favorable, necessitating an exothermic reaction. The reaction must also be kinetically favorable so that it is fast. This is achieved when the reaction has a very small or no activation barrier. Finally, different pathways must be possible for various isomeric ions to yield qualitatively different ionic products for different reactant ion structures. All the possible combinations of the following simple ion-molecule reactions were explored as possible ion structural probes: homolytic cleavage of a weak bond, proton transfer and electron transfer. To characterize each ion structural probe, reactions of ions of known conventional, enol and distonic structures as well as protonated molecules were studied.

Homolytic cleavage of a weak bond can be used to identify distonic ions. Most distonic radical cations abstract a thiomethyl group from dimethyl disulfide, Figure 1a. Other radical cations undergo fast electron transfer with dimethyl disulfide. *Hence, the reaction with dimethyl disulfide can be used for positive identification of distonic ions.*

Basic reagents such as triethyl amine, cyclohexanone and trialkyl phosphites may allow the distinction between certain radical cations with and without acidic protons. This is based on the fact that ions that are Bronsted acids, such as enol forms of radical cations and certain distonic ions, undergo fast proton transfer if it is exothermic, Figure 1b. Ions without acidic protons react via electron transfer when the ionization potential of the neutral reagent is lower than the recombination energy of the ion.

Suitable perdeuterated reagents may also allow the distinction between ions with and without acidic protons. Hydrogen-deuterium exchange reactions can be used to probe the presence of acidic protons: these are exchanged for deuteriums when the proton affinity of the neutral reagent is slightly less than that of the conjugate base of the ion. Radical cations of conventional structure may abstract a deuterium atom from the deuterated reagent if the reaction is exothermic. When reacted with d_8-isopropanol, the distonic ions studied here undergo hydrogen-deuterium exchange, Figure 1c, while the enol ions studied undergo abstraction of a deuterium atom in addition to hydrogen-deuterium exchange. Therefore, reaction with a suitable deuterated reagent may allow the distinction between conventional, distonic and enol structures.

Bimolecular Reactions of the Molecular Ions of Simple Organic Esters

Diane T. Leeck[1], Loreen C. Zeller[1], Krista M. Stirk[1], L. K. Marjatta Kiminkinen[1], Joseph C. Orlowski[1], Pirjo Vainiotalo[2], Hilkka I. Kenttämaa[1]
[1]Dept. of Chemistry, Purdue University, West Lafayette, IN 47907
[2]Dept. of Chemistry, Joensuu University, Finland

The structures of the molecular ion of acetates and formates have been the subject of controversy for nearly ten years. Previous mass spectrometric studies on simple ester radical cations have almost exclusively dealt with short-lived species. These studies have shown that the short-lived molecular ions of methyl acetate and methyl propionate isomerize to a distonic ion intermediate prior to fragmentation. Studies using electron spin resonance spectroscopy to investigate the ground-state radical cations of several carbon esters in frozen matrices yield similar results. In this work, the structures of low-energy, long-lived radical cations of several simple ester ions were investigated using bimolecular reactions in a dual-cell FT-ICR mass spectrometer. The ions studied include ionized methyl and ethyl acetates, methyl and ethyl formates, dimethyl carbonate, γ-butyrolactone and δ-valerolactone. Reference ions with distonic and enol structures were generated by low-energy ion-molecule reactions and dissociative ionization.

Cyclohexanone, d_8-isopropanol, dimethyl disulfide and triethylamine were used as neutral reagents in the reactions used to probe the ion structures. These reagents were chosen for their distinctive reactivity with ions of different structures. Cyclohexanone undergoes charge exchange with conventional radical cations, while ions with acidic protons (i.e. some enol and distonic ions) react by proton transfer. Reactions of the conventional ester radical cations with d_8-isopropanol result in $D^{\bullet}$ abstraction. Distonic ions react with this deuterated reagent by H/D exchange, while the enol ions exchange a hydrogen atom with a deuterium atom and abstract a $D^{\bullet}$. Triethylamine can be used to distinguish the distonic isomers from the enol and keto forms. Proton transfer is observed with the distonic ions, while charge exchange occurs for the enol ions and conventional radical cations.

The molecular ions of dimethyl carbonate and methyl and ethyl formates were found to rearrange to distonic isomers in the ICR. The presence of an acidic hydrogen in the rearranged ion was detected by reacting the molecular ions with cyclohexanone, d_8-isopropanol and triethylamine. The spectrum in figure 1 provides evidence for the isomerization of the dimethyl carbonate ion to a distonic ion. The long-lived molecular ions of methyl and ethyl acetates isomerize to their enol isomers. The reactions of the molecular ions with cyclohexanone provide evidence for the presence an acidic hydrogen (Figure 2), but cannot distinguish between the hydroxyl containing distonic and enol isomers. The results from reactions with d_8-isopropanol suggest that the molecular isomerize to the enol isomer (Figure 3). The products of the reactions of the cyclic esters γ-butyrolactone and δ-valerolactone with cyclohexanone, d_8-isopropanol and dimethyl disulfide suggest that the molecular ions do not undergo isomerization in the ICR.

We conclude that the molecular ions of methyl and ethyl acetates, methyl and ethyl formates, and dimethyl carbonate rearrange to their lowest-energy isomer: the ionized dimethyl carbonate and the methyl and ethyl formate ions isomerize to a distonic form; ionized methyl and ethyl acetates rearrange to their enol forms. Small ionized lactones are stable toward isomerization.

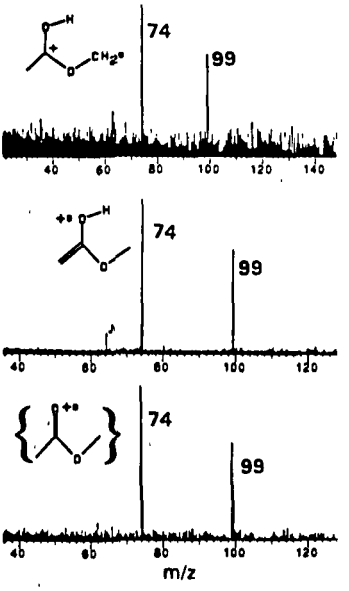

Fig. 3

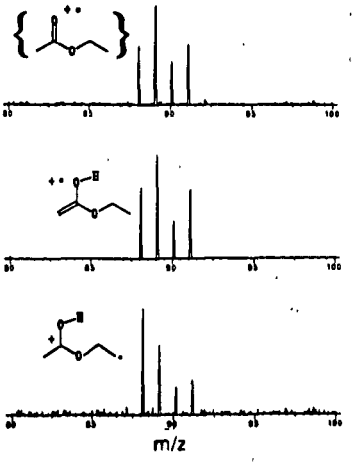

ION-MOLECULE REACTIONS OF PROTONATED PROPYLENE OXIDE AND ITS ISOMERS WITH H_2S

*Peiping Lin and Hilkka Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907

Many mass spectrometric methods have been used to distinguish protonated epoxides from their isomeric forms. One of these methods was based on an ion-molecule reaction with H_2S[1]: loss of H_2O was observed for protonated ethylene oxide, but not for its isomers. Our previous work[2] demonstrated that protonated propylene oxide is stable, and can be distinguished from protonated propanal by collision-activated dissociation carried out as a function of collision energy. The energy required for the isomerization of the epoxide ion is approximately 5-10 kcal/mol. We report here an investigation on the ion-molecule reactions involving H_2S and protonated propylene oxide as well as its isomers.

The ion-molecule reactions of H_2S with protonated propylene oxide and its isomers were studied in an FT-ICR by using multiple-stage MS experiments. The dependence of the reactivity on ion internal energy was examined by generating the ions in proton transfer reactions with different exothermicities (ΔH_{rxn}). The theoretical calculations were performed by the AM1 semi-empirical method with the MOPAC program (Version 5.0) on a VAX station 3200 computer.

Protonated propanal and protonated acetone do not react with H_2S. Protonated propylene oxide generated with a thermoneutral proton transfer reaction does not react with H_2S. When the epoxide ion is generated by a proton transfer reaction with exothermicity greater than 5 kcal/mol, it reacts with H_2S to produce $C_3H_7S^+$. However, the reaction rate appears to become slower as a function of time (Fig.). The possible reasons for this are: (a) The ion $C_3H_7O^+$ generated by exothermic proton transfer reaction is a mixture of isomers of which one is unreactive and the other one is reactive toward H_2S. (b) There is a competing isomerization reaction in the collision complex which generates protonated propanal. Protonated oxetane shows reaction pattern similar to that of protonated propylene oxide. It reacts with H_2S to produce $C_3H_7S^+$ only when the ion is generated by a proton transfer reaction with exothermicity greater than 15 kcal/mol. Earlier study[3] has indicated that protonated oxetane isomerizes to protonated propanal after ring-opening. Therefore, the slower reaction rate observed at longer reaction times may be attributed to a similar mechanism as that of protonated propylene oxide. Examination of the reaction of H_2S with ions with differing internal energies (ΔH_{rxn})

suggests that the barrier for the ring-opening of protonated propylene oxide is about 5 kcal/mol above the protonated epoxide, and the barrier for the ring-opening of protonated oxetane is between 9-15 kcal/mol above protonated oxetane.

We applied AM1 calculations to investigate the reaction mechanisms for the reaction of protonated propylene oxide and H_2S. The results suggest that the ring-opened structure of protonated propylene oxide may be a stable species in the gas phase, and that the formation of protonated propylene sulfide may be energetically more favorable than the isomerization reaction in the collision complex which generates protonated propanal.

The barrier for the isomerization of protonated propylene oxide to protonated propanal obtained from our previous energy-resolved collision-activated dissociation study might actually be the barrier for the isomerization of the ring-opened protonated propylene oxide to the protonated propanal. The energy-resolved CAD method may not allow the differentiation between protonated propylene oxide and its ring-opened isomer; however, it does distinguish them from all the other isomers. The ion-molecule reaction with H_2S can be used to distinguish between the ring-opened protonated propylene oxide (reactive) and all the other isomers (unreactive). In this respect, the ion-molecule reaction with H_2S and the energy-resolved CAD method provide complementary information.

Comparison of the Reactivity of Distonic and Conventional Radical Cations and their Even-electron Counterparts.

*L.K.Marjatta Kiminkinen, Joseph C. Orlowski, Hilkka I. Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907

The distonic ions, $^{\bullet}CH_2CH_2OCH_2^+$ and $^{\bullet}CH_2CH_2CH_2CO^+$, have well characterized structures.[1,2] However, an understanding of the behaviour of these ions in bimolecular reactions is just beginning to emerge. Distonic ions are proposed to be especially reactive, having the ability to react at both the charge and the radical sites. We report here the first comparison of the reactivity of the distonic ions to that of the corresponding even-electron ions and related conventional radical cations by using dual-cell FT-ICR (Extrel FTMS 2001).

The reactivity of the distonic ion $^{\bullet}CH_2CH_2OCH_2^+$ is distinct from that observed for ionized oxetane, , and resembles the reactivity of the ethoxy methyl cation $CH_3CH_2OCH_2^+$ (Table 1). Sesifically, the distonic ion transfers ionized ethylene to those nucleophiles which abstract an ethyl cation from the even-electron analogue. Ionized oxetane shows quite different reactivity from that observed for the other two ions. The distonic ion $^{\bullet}CH_2CH_2OCH_2^+$ undergoes occasionally reactions involving homolytic σ bond cleavege: for example, it abstracts $^{\bullet}SCH_3$ from dimethyl disulfide.

Table 1.

Reactions of the distonic ion, the even-electron counterpart and the conventional radical cation with various neutral molecules.

Neutral molecules	$^{\bullet}CH_2CH_2OCH_2^+$	$CH_3CH_2OCH_2^+$	
$(CD_3)_2=O$	$C_2H_4^{+\bullet}$-transfer	$C_2H_5^+$-transfer	H^+-transfer
CH_3COOH	$C_2H_4^{+\bullet}$-transfer	$C_2H_5^+$-transfer	$H^{\bullet}$-abstraction
$(CH_3)_2S$	e^--transfer	$C_2H_5^+$-transfer	e^--transfer
$(CH_3)_2S_2$	e^--transfer $CH_3S^{\bullet}$-abstraction	no reaction	e^--transfer
NH_3	$C_2H_4^{+\bullet}$-transfer	$CH_2=NH_2^+$	

Another distonic ion studied, $^{\bullet}CH_2CH_2CH_2CO^+$, undergoes several reactions that involve homolytic bond cleavages (Table 2). This behaviour differs considerably from that of conventional ketone radical cations and from the even-electron analog $CH_3CH_2CH_2CO^+$.

Table 2.

Reactions of the distonic ion, the even-electron counterpart and a conventional ketone radical cation with various neutral molecules.

Neutral molecules	$^{\bullet}CH_2CH_2CH_2CO^+$	$CH_3CH_2CH_2CO^+$	
$(CH_3)_2C=O$	$H^{\bullet}$-abstraction	no reaction	no reaction
$(CH_3)_2S_2$	e^--transfer $CH_3S^{\bullet}$-abstraction	no reaction	e^--transfer
CH_3CH_2I	$C_2H_5^{\bullet}$-abstraction $I^{\bullet}$-abstraction	no reaction	e^--transfer C_2H_5-abstraction $H^{\bullet}$-abstraction
$CH_2=CH_2\text{-}O\text{-}CH_2CH_3$	$CH_3^{\bullet}$-abstraction $C_2H_5^{\bullet}$-abstraction	no reaction	

We conclude that the bimolecular reactions of the distonic radical cations studied are clearly distinct from those of their conventional counterparts. However, the reactivity of individual distonic ions can be quite different. For, example, while the ion $^{\bullet}CH_2CH_2OCH_2^+$ reacts with many neutral molecules in a similar manner as it's even-electron counterpart, this is not true for the distonic ion $^{\bullet}CH_2CH_2CH_2CO^+$. The only reaction common for both distonic ions is abstraction of $^{\bullet}SCH_3$ from dimethyl disulfide.

Ion-molecule Reactions of Dicoordinated Borocations with Organic Compounds

Thilini D. Ranatunga, *James M. Kennady, and Hilkka Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47906.

Dicoordinated borocations exist as transient intermediates in solution reactions. These highly electron deficient ions are expected to react rapidly with many organic compounds. Condensed phase studies have been limited to ions with at least one nitrogen containing substituent, which strongly π back bonds to boron. The substituents of the ions studied are usually bulky, and provide steric restriction for nucleophilic addition by the solvent. Mass spectrometry allows the detailed investigation of the properties of highly reactive, coordinatively unsaturated borocations with no conjugatively stabilizing or bulky substituents. In this study, we report our initial results on the intrinsic reactivity of $CH_3OBOCH_3^+$ and $CH_3BCH_3^+$ with alcohols, ethers, aldehydes, and ketones in a dual-cell Fourier transform ion cyclotron device. The borinium ions are found to be exceedingly reactive toward oxygen lone pairs in organic substrates: most of the ion-molecule reactions studied occur at near collision rate. Formation of the very strong B-O bond is likely to be the driving force for all the observed reactions.

For the alcohols and ethers studied, abstraction of water by the ion is the predominant exit channel for the collision complex. Although proton catalyzed dehydration of alcohols in the gas phase has been reported earlier in the literature, the very facile ionic dehydration of diethyl ether and diisopropyl ether is a notable reaction with no well-known precedent. The dehydration mechanism of ethers (Scheme 1) was studied using different experimental approaches, such as using different organic ethers, deuterium labelling, collision-activated dissociation of the ionic reaction products and the proposed ionic intermediates, bimolecular reactions of the proposed intermediates, and by generating the intermediates using independent routes. On the basis of these data, dehydration of organic ethers by dicoordinated borocations is proposed to occur via consecutive 1,2- elimination of two alkene molecules from the ether. The overall reaction is estimated to be highly exothermic (by at least 40 kcal/mol). This calculation is based on the estimated proton affinity of trimethylborate to be 195.0 - 199.7 kcal/mol.

Reactions of simple ketones with dicoordinated borocations occur by very slow adduct formation. In contrast, the borocations react with long chain ketones and with some aldehydes (e.g., butanal) by abstracting an aldehyde. The major product observed for the reaction of $CH_3OBOCH_3^+$ with 2-pentanone is $(CH_3O)_2B\text{-}O{=}CHCH_3^+$ (m/z 117). This ion is formed by loss of $CH_3CH{=}CH_2$ from the adduct. Hydroxyl group abstraction is the major reaction channel observed for long chain aldehydes. For example, $CH_3OBOCH_3^+$ abstracts OH from pentanal and from hexanal, resulting in the major products $CH_3CH_2CH{=}CHCH_2^+$ (m/z 69) and $CH_3CH_2CH_2CH{=}CHCH_2^+$ (m/z 83), respectively, by loss of $(CH_3O)_2BOH$. The mechanisms of these reactions are under investigation.

REACTIONS OF Ar^+ WITH HALOCARBONS AND I^+ WITH CF_3I

Robert A. Morris, J. M. Van Doren[1], A. A. Viggiano, and John F. Paulson
Phillips Laboratory, Geophysics Directorate/GPID, Hanscom AFB, MA 01731-5000

Mixtures of argon and halocarbons are used in plasma techniques for microcircuit fabrication such as plasma etching and reactive ion etching. Ions in these plasmas may be active species in the etching process, but little is known about the gas phase ion-molecule reactions which are involved. In this abstract we report results for the gas phase reactions of Ar^+ with the halocarbons CF_3Cl, CF_3Br, CF_3I, CF_4, C_2F_6, and C_2F_4 obtained at 298 and 500 K. In addition, results are reported for the reaction of I^+ with CF_3I at 298 K. The investigation was conducted using a variable temperature-selected ion flow tube (VT-SIFT) instrument. Reaction rate constants and product branching fractions are presented. Few of these reactions have been studied previously, and none has been investigated as a function of temperature.

The Ar^+ ion reacts at the collisional rate with all of the above halocarbon neutrals at 298 and 500 K. Measured rate constants and branching fractions are presented in Table 1. The reaction of Ar^+ with CF_4 forms CF_3^+ as the only ionic product. The reactions with CF_3X (X = Cl, Br, I) yield the product ions CF_3^+ and CF_2X^+ for all X. In addition, in the reaction with CF_3I, I^+ and possibly CF_3I^+ (<1%) are formed as well (the small amount of CF_3I^+ may arise from the secondary reaction $I^+ + CF_3I$, discussed below). Product branching for the CF_3X reactions is not strongly dependent on temperature. Ar^+ reacts with C_2F_6 to form the ionic products CF_3^+ and $C_2F_5^+$. The measured product branching fractions for this reaction are consistent with results from a photoion-photoelectron coincidence (PIPECO) study[2] of C_2F_6; the appropriate comparison is made at the PIPECO photon energy corresponding to the available energy in the ion-molecule reaction.

The reaction of Ar^+ with C_2F_4 forms the following ionic products: CF^+, CF_2^+, CF_3^+, $C_2F_3^+$, and $C_2F_4^+$. The channels forming CF^+ and CF_3^+, which differ only by the location of the charge, are approximately equal in their branching. However, the ionization potentials (IP's) of CF and CF_3 differ by about 40 kJ mol^{-1}. The similar branching fractions despite quite different IP's may be a result of the high exothermicities of these channels and/or the short lifetime for dissociation and product separation. The channel forming $C_2F_3^+$ is endothermic by ~9 kJ mol^{-1} and contributes significantly more at the higher temperature at the expense of all other products. An Arrhenius plot of the rate constants for this channel yields an activation energy of ~4 kJ mol^{-1}.

The reaction of I^+ with CF_3I was studied at 298 K, and the branching fractions and rate constant are given in the Table. The $I^+ + CF_3I$ reaction forms four ionic products: CF_3^+, CF_2I^+, CF_3I^+, and I_2^+. The I_2^+ product was not observed in a low pressure (10^{-7} torr) ICR experiment[3], but the rate constants measured in the two experiments are in very good

agreement. The discrepancy in the product spectra may be the result of the different pressure regimes.

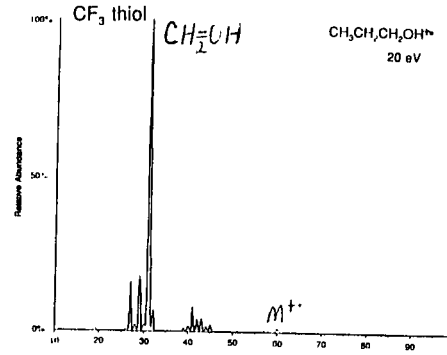
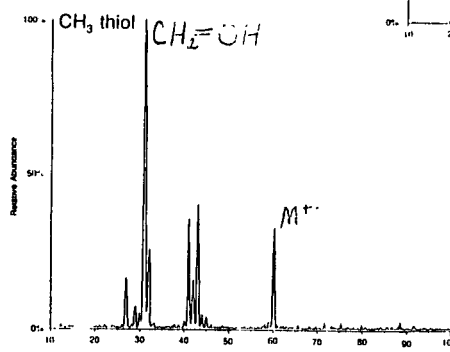
Reactivity of Distonic Radical Cations with Self-Assembled Monolayer Surfaces

*J.L. Jones and V.H. Wysocki
Department of Chemistry
Virginia Commonwealth University
Richmond, VA 23284-2006

Distonic radical cations have been investigated both experimentally and theoretically and were found to be stable species in the gas phase.[1] Previous studies[2], by low-energy gas-phase collisions, have been able to distinguish distonic radical cations from their conventional isomers. We have used surface-induced dissociation[3] as a means of distinguishing distonic radical cations from their conventional counterparts. The goals of the work presented here are (1) to compare the reactivity of distonic radical cations and their conventional counterparts at a well-characterized surface and (2) to determine whether these ions can be employed for surface characterization. The distonic ions investigated include $^{\cdot}CH_2(CH_2)_nOH_2^+$ with n = 0-2. These ions were allowed to collide with various types of chemically modified surfaces[4] and their ion/surface collision behavior was compared to that of their conventional isomers ($CH_3(CH_2)_nOH^{+\cdot}$). The types of surfaces investigated consist of self-assembled monolayer films (e.g., 1-octadecanethiol, 2-(perfluorooctyl)ethanethiol, and 1-eisocosane-d_{41} thiol) on gold.





The distonic ion and its conventional isomer can still be distinguished regardless of the nature of the surface, but extent of fragmenation and ion/surface reactions is dependent on the type of surface employed. Both isomers show a propensity for hydrogen addition for surfaces with no available hydrogen. A deuterated projectile ion, when collided into a perdeuterated surface, still shows fragment ions corresponding to hydrogen addition. These ions must react with (1) any adventitious contaminants adsorbed at defect sites on the monolayer film or (2) any projectile ion that may be adsorbed onto the surface. Methanol and its distonic isomer both show hydrogen addition on all surfaces investigated, but the distonic ion shows a small amount of D-addition on the perdeuterated surface. The fluorinated surface shows a tendency for greater energy deposition into these small, odd electron ion. This is apparent in the comparison of the 20 eV SID spectra of 1-propanol and its corresponding distonic isomer.

Hydrogen Bonding in α,ω-dialcohols.

*G.R.Nicol, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716
P. Kebarle, Department of Chemistry, University of Alberta, Edmonton, AB T6G 2G2

Protonation of polyfunctional compounds has the interesting possibility of forming an internal hydrogen bond. The resulting cyclization of a protonated polyfunctional molecule is shown in reaction 1. A larger enthalpy change will be observed for reaction 1 than for reaction 2 where no intramolecular solvation can occur. Furthermore, reaction 2 should have a small entropy change, typical for simple proton transfer reactions, while reaction 1 should have a substantial entropy loss due to the loss of internal freedom on cyclization.

$$H_2N(CH_2)_nNH_2 + BH^+ = B + \underset{H^+}{H_2N\overset{(CH_2)_n}{\diagup\!\!\diagdown}NH_2} \qquad [1]$$

$$CH_3(CH_2)_nNH_2 + BH^+ = B + CH_3(CH_2)_nNH3^+ \qquad [2]$$

In this work we looked at several α,ω-dialcohols. The proton affinities (PAs) are given in Table 1. The ΔH°_{cyc} are given in Table 2 along with the strain associated with each ring formed. The negative value for 1,10-deccanediol is due to the uncertainty in the van't Hoff plot and the asssumptions made in estimating the PA of the monoalcohol. The entropy increases linearly with chain length but it would be interesting to see if this trend continues for larger dialcohols. The ΔH° and ΔS° for the proton bound dimer of the dialcohols is given in Table 3. The ΔH° is similiar to the sum of the second and third hydration energies of H_3O^+. This lead to the proposal of a second ring being formed upon dimerization. (Structure 1)

Determination of Relative Cation Affinities of Crown Ethers and Other Ionophores Using FTMS

In-Hou Chu, Hong Zhang, Qizhu Chen, and David V. Dearden
Department of Chemistry, University of Texas at Arlington, Arlington, TX 76019

Introduction:

The binding constants of crown ethers for alkali metal cations in solution are known to be strongly solvent-dependent. To determine the intrinsic cation affinities of ligands in the absence of solvation, we have examined crown-cation complexes in the gas phase. Isolated crown-cation complexes were trapped inside an ion cyclotron resonance (ICR) cell and allowed to react with other ligand molecules. The occurrence or non-occurrence of cation transfer reactions from one ligand to another was used as a probe of relative cation affinities. These results are compared with those obtained by the kinetic method,[1] which employs MS/MS on cation-bound dimer complexes using a triple stage quadruple mass spectrometer. The effects of alkyl substitution on the macrocyclic rings and of substitution of N for O donor atoms in the ligand were also examined.

Experimental:

Transfer reactions: Complexes of alkali metal cations with organic ligands were generated and isolated using laser desorption Fourier transform ion cyclotron resonance mass spectrometry in combination with stored-waveform inverse Fourier transform (SWIFT) techniques. Reactions with neutral ligands were monitored as a function of time.

Kinetic method: Gas-phase dimer complexes were generated using two different methods:

(A). Gas-phase reactions: alkali metal cations were introduced by heating their salts (~ 600° C) on the direct exposure solid probe (DEP). The ligands were painted on the CI ion volume and thermally vaporized by heat from the DEP.

(B). Fast atom bombardment (FAB): Liquid 12C4, 15C5 and 21C7 were mixed with LiCl directly; no additional solvent was used. A small amount of H_2O was added to the 18C6 (solid) in order to aid in dissolving LiCl.

The collision energy was held between 3 and 5 eV (lab frame) and Ar was used as collision gas. The Ar pressure in the collision cell was held below 0.6 m torr and the source pressure was between 0.1 to 0.5 torr.

Results and Discussion:

A summary of the results obtained from both the transfer reaction and kinetic methods is given in Tables 1 and 2. With both methods, for alkali cations Na^+-Cs^+, the cation affinity increases with the number of ligand donor atoms. This mirrors the proton affinities measured for these ligands,[2] but is very different from the order of relative affinities reflected in binding constants measured in the presence of solvents, where there is an apparent size-match selectivity. Li^+ affinities are less clear-cut and seem to be dependent on the method used to prepare the dimer in the kinetic studies (Table 2). The different CID behavior observed for complexes generated using FAB and using gas-phase reactions indicates that the kinetic method should be used with caution. The kinetic method measures the relative binding strength of the metal to the two ligands *in the dimer.* However, there are probably large structural differences between fragments of the 2:1 complexes and true 1:1 complexes, so measurements of bond strengths in the 2:1 complexes do not necessarily reflect bond strengths in the 1:1 complexes. In particular, steric or other structural factors may prevent daughter intensities from being a true reflection of relative cation affinities of the two ligands, especially when the metal may reside in the binding cavity of one of the ligands. Cation transfer reaction studies, which

[2] Sharma, R. B., Blades, A. and Kebarle, P. *J. Am Chem.Soc.* **1984**, 106, 510.

examine the relative cation affinities of the two isolated 1:1 complexes, probably reflect the relative strengths of the 1:1 complexes more accurately.

The effects of alkyl substitution on the macrocyclic rings and of substitution of N for some of the O donor atoms in the ligand were also examined. Dicyclohexano-18C6 has higher affinity for Na^+-Cs^+ than 18C6. This observation may be the result of substitution of cyclohexane for the less polarizable H atoms. As for the cryptand, the weaker interaction between the N donor and M^+ acceptor apparently is compensated by the 3-dimensional structure of the cryptand in cases where the cation can access the interior. This may explain why [2.1.1] has a greater affinity for the smaller cations (Li^+ and Na^+) than 18C6, even though N is a weaker donor than O. Cryptand [2.2.1], which is favored by both its structure and by the larger number of donor atoms it possesses, has higher cation affinities for Na^+-Cs^+ than any of the crown ethers studied (12C4-18C6).

Observation and Characterization of Gas-Phase Complexes of Alkali Metal Cations with Natural Ionophores using Matrix-assisted Laser Desorption Fourier Transform Ion Cyclotron Resonance Mass Spectrometry

* Philip S. H. Wong and David V. Dearden
Department of Chemistry, The University of Texas at Arlington
Box 19065, Arlington, TX 76019-0065

Introduction: Valinomycin (Vm) is a natural ionophore built from a 3-fold repetition of the alternating amino acid and hydroxy acid residues L-valine, D-α-hydroxyvaleric acid, D-valine and L-lactic acid. In solution, valinomycin is selective for K^+ over Li^+, Na^+, or Ca^{2+}.[1,2] Based on studies in various solvents, the conformation adopted by the ligand is highly solvent-dependent, as are metal-complex stability constants. The presence of counterions also affects the stability constants. We have undertaken a study of valinomycin-alkali metal cation complexes in the gas phase, where neither solvents nor counterions are present, to examine the *intrinsic* Vm-cation interactions.

Experimental: Valinomycin-alkali metal cation complexes are readily generated and trapped in the gas phase using matrix-assisted laser desorption Fourier transform ion cyclotron resonance mass spectrometry. All experiments were performed on an Extrel FTMS-1000 instrument equipped with a capacitively-coupled open cell for easy optical access to the cell interior. Samples were inserted into the vacuum chamber on a stainless steel probe. We employ a sinapinic acid (Aldrich) matrix with a matrix-to-analyte ratio of about 100:1. Desorption was accomplished using a Lambda Physik LPX 205i/FL 3002 excimer-pumped dye laser (λ = 360 nm).

In experiments designed to determine whether complexes were desorbed intact or formed in gas phase ion-molecule reactions, alkali metal nitrate was laser-desorbed from the probe surface and valinomycin was introduced separately via a small capillary tube mounted in the center of the temperature-controlled probe. The valinomycin was thermally evaporated. Using the same technique, the kinetics of complexation were also investigated. In these experiments, two or more alkali metal nitrates were deposited on the same probe tip and desorbed together, ensuring that each cation is exposed to the same valinomycin pressure. Pseudo-first-order conditions are assumed. Since we were unable to measure absolute valinomycin partial pressures, only relative rate constants were obtained.

Relative complex stabilities were examined in competition experiments between valinomycin and the synthetic ionophores 18-crown-6 (18C6) (Sigma) and cryptand [2.2.2] (C_{222}) (Aldrich). Reactions (1) and (2) were each examined in both directions. Ionic reactants were isolated using standard FTICR swept-RF methods, and products were monitored as a function of time.

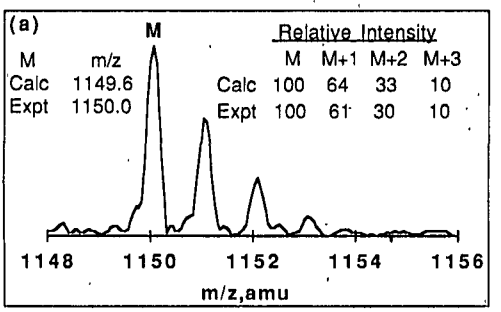
$$Vm + C_{222}M^+ \rightleftharpoons VmM^+ + C_{222} \qquad \text{Rxn(1)}$$

$$Vm + 18C6M^+ \rightleftharpoons VmM^+ + 18C6 \qquad \text{Rxn(2)}$$

Results and Discussion: Spectra of valinomycin-alkali metal complexes obtained using matrix-assisted laser desorption ionization are shown in Figure 1. Both resolution and signal-to-noise ratio were improved by operating at low trapping voltage (0.02-0.2 V). This is probably due to reduced space charge effects at low trapping potential. The relative intensities of the peaks matched well with the expected isotope distributions of the valinomycin-metal complexes. The observation of peaks at the expected m/z values, along with the expected isotopic patterns, confirms the mass spectroscopic assignments. Thermal evaporation of valinomycin, coupled with laser desorption of alkali metal salts, resulted in the formation of the metal complexes in the gas phase via ion-molecule reactions. The relative rates with respect to potassium-complex formation are shown in Table I. The relative rate constants decrease as the size of the cation increases. The relative rates correlate well with collision rates calculated using classical ion-molecule collision theories,[3] which predict an inverse dependence on the square root of the reduced mass of the collision pair. Hence the complexation rates are probably collision-limited.

The transfer of alkali metal cations (Na^+, K^+, Rb^+, Cs^+) from both synthetic ionophores (C_{222} and 18-crown-6) to valinomycin was observed. The reverse reactions were not seen, indicating that valinomycin-alkali metal complexes are more stable than the [2.2.2]-cryptate and 18-crown-6 metal

complexes in the gas phase. In solution, cryptate complexes are more stable than valinomycin complexes. This has been described as the "macrobicyclic cryptate effect."[4] The conformation of valinomycin depends on the polarity of the solvent used.[5,6] In a polar solvent such as methanol, valinomycin forms hydrogen bonds with solvent molecules. This greatly destablizes complex formation. In the gas phase, no solvent is present and the complex becomes more stable. The gas phase conformation should be similar to that exhibited in non-polar solvents, which are dominated by intramolecular hydrogen bonds. The intramolecular hydrogen bonds within the ligand may serve to pre-organize it for cation binding, strongly stabilizing the complex. This leads to the conclusion that valinomycin has a higher *intrinsic* alkali metal cation affinity than either C_{222} or 18-crown-6.



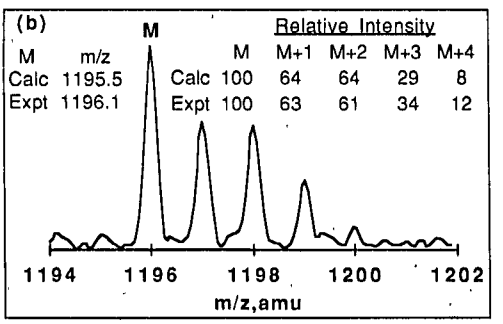


Table I: Relative rate constants for the formation of valinomycin-metal ion complexes.

Cation	Relative Rate Constant ($Vm\text{-}K^+ = 1$)
Na^+	2.0±0.4
K^+	1.0
Rb^+	0.31±0.03
Cs^+	0.12±0.01

Fig.1 (a) and (b) show high resolution mass spectra of the valinomycin-K^+ complex ($m/\Delta m$= 3937 at M peak, 0.02V trapping voltage) and the valinomycin-Rb^+ complex ($m/\Delta m$= 4216 at M peak, 0.2V trapping voltage) respectively. Both spectra are obtained from one laser shot, 64K data points and a bandwidth of 127 KHz in heterodyne mode.

How do Electric Fields Effect Proton Transfer Reactions?

Alan L. Rockwood*, Richard D. Smith,
Chemical Sciences Department,
Pacific Northwest Laboratory,
Richland, WA 99352

Very large electric fields exist in highly charged ions, such as those produced from electrospray sources. The mutual repulsion between the charges will, to some degree, influence the reactivity of these ions, particularly for reactions that involve changes in the charge distribution. Already, preliminary experimental and theoretical work has addressed the role of coulombic energy in the dissociation of highly charged ions. A second group of reactions, proton transfer reactions, will also be perturbed by large electric fields. In principle, the proton "acceptor" could be 1) an intra-ion accepting group, 2) an adduct that is non-covalently attached to the highly charged ion of interest, 3) a second body acceptor that becomes available during collisions, or 4) the vacuum. In each case, the transfer of a proton implies a substantial charge redistribution, and any large electric fields present will alter the energetics of both the over all reaction and the transition state. Consequently, both the thermodynamics and kinetics of the reaction will be effected.

We have initiated a series of ab initio potential surface calculations to investigate the effect of electric fields on the reactivity of charged systems. Most multiply protonated ions of interest are too large to study by ab initio methods, so we have concentrated our efforts on simple model systems. The first simplification is to model the mutual repulsion of the charges as a uniform electric field oriented along the reaction coordinate with a magnitude comparable to that of a single charge at 10 to 20 angstroms. The second simplification is to simplify the molecular structure: We chose the dissociation of the ammonium ion as one model system to study, and proton transfer followed by dissociation of an ammonia/ammonium complex as another. Hartree-Fock calculations showed that at the largest electric fields studies, the energy barrier was lowered by as much as 1.0 eV and 0.85 eV for the two systems respectively. These systems were dominated by fairly simple electrostatic effects involving the interaction of the system dipole moment with the electric field. Therefore, the concepts and qualitative results developed in this work should be readily transferable to more complex systems, forming a basis to interpret observed proton transfer reactions between gas-phase multiply charged protein ions and relatively weak proton acceptor molecules like ammonia and water.

Effect of Halogenation and Metal Substitution on Electron Affinities and Reactivities of Metalloporphyrins

Henglong Chen, S. E. Groh, T. E. Hagan and D. P. Ridge*
Department of Chemistry and Biochemistry and Center for Catalytic Science and Technology, University of Delaware, Newark, DE 19716

The direct catalytic air-oxidation of an alkane to selectively produce an alcohol has long been an important challenge. It has been reported that severe electron-withdrawal from the tetraphenylporphyrinato ligand of an oxidation-active first transition metal complex causes a dramatic increase in the air-oxidation activity of the complex.[1] Iron perhaloporphyrin complexes are the most active catalysts known to date for the oxidation of light alkanes using molecular oxygen without added coreductants. Electron withdrawal from the tetraphenylporphyrinato ligand of an iron complex can be accomplished by replacing the hydrogens on the periphery of the porphyrin macrocycle with a halogen group. This results in a large increase in Fe(III)/Fe(II) reduction potential which may be important in facilitating Fe(III) reduction in an oxidizing medium. A gas phase or a solvent-free environment offers an opportunity to study intrinsic properties such as the electron affinities of metalloporphyrins as well as an opportunity to characterize the reactive intermediate. The metalloporphyrins studied are listed in Fig. 1. The correspondant metalloporphyrin neutrals are introduced to the FTMS-2000 reaction chamber through a heated probe. Metalloporphyrin cations were formed by electron impact or laser desorption, and anions were formed by low energy electron attachment.

Electron Affinity vs. Reduction Potential The electron affinities of several halo-substituted iron porphyrins were determined from measurement of equilibrium constants for charge transfer reactions. The referenced compounds for the EA measurements are: naphthalene benzoquinone (EA=1.81 eV), 1, 4 - benzoquinone (EA=1.91 eV), 1, 4 - dinitrobenzene (EA=2.0 eV) and tetracyanoethylene (EA=3.17 eV).The EA values determined are respectively: EA(**3**)=1.87 eV, EA(**4**)=2.10 eV, EA(**5**)=3.21 eV, EA(**6**)=1.97 eV, EA(**7**)=2.07 eV, EA(3Cl)=2.15 $\pm$ 0.15 eV, and EA(4Cl)=3.15 eV. These results show that the electron affinities of the iron porphyrins are greatly enhanced by halogenation on both the phenyl groups and the pyrrole positions, but the effect of substitution at the pyrrole positions is greater than on the phenyl groups. The correlation of electron affinities of metalloporphyrins vs condensed phase reduction potentials obtained in a nonpolar solvent is plotted in Fig. 2. The linear relationship evident in Fig. 2 indicates that both values reflect an intrinsic electronegativity. The EA values provide an absolute scale independent of solvent effects, counter ion effects and reference electrode.

Electron Affinity vs. Reactivity with NO_2 In the catalytic cycle, the intermediate of oxo-species, MO^+(IV), is thought to activate C-H bond, but it is difficult to characterize in condensed phase. In a recently paper we describe the preparation of MO^+ for M=**3**, **4**, **7**. MO^+ reacts rapidly with NO_2 or M to form MOH^+ and MNO^+. For **5**, however, no reaction with NO_2 was observed. That suggests that the stability of MO^+ increases with the electron density on the central metal, and therefore decreases with the the increasing of electron affinities of the metalloporphyrins. This is consistent with the observation that stable MO^+ gives lower catalytic efficiency and unstable MO^+ gives higher catalytic efficiency because the catalyst must give up an O atom to the substrate. When the central metal is changed to Cr or Ru, the oxo-species $CrTPP(O)^+$ and $RuTPP(O)^+$ were observed. Both species are stable in NO_2, M, and hydrocarbons. These results are consistent with the observation that among the

first row transition metals, iron porphyrin is most effective catalyst.

Reactivities of CrTPP⁻ and RuTPP⁻ toward O_2, CO, and SO_2 We recently reported the reactions of **6**⁻ and **7**⁻ with NO_2. We report here the reactions of CrTPP⁻ with O_2 and RuTPP⁻ with CO, O_2 and SO_2. CrTPP⁻ reacts with O_2 to give $CrTPP(O_2)^-$ and $[CrTPP(O_2)\text{-}C_6H_5)^-$ where the latter is dominant product. This process may be intepreted as follows:

$$CrTPP + e \xrightarrow{} CrTPP^{\bullet-} \xrightarrow{O_2} [CrTPP(O_2) - 77]^- \xrightarrow{} CrTPP(O_2)^-$$

For RuTPP⁻, ligand attachment and ligand substitution reactions with O_2, CO and SO_2 were observed. Some interesting ligand exchange reactions were shown below:

$$RuTPP(CO)^- + O_2(SO_2) \xrightarrow{} RuTPP(CO)(O_2)^- \text{ or } RuTPP(CO)(SO_2)^-$$

$$RuTPP(SO_2)^- + O_2(CO) \xrightarrow{} RuTPP(SO_2)(O_2)^- \text{ or } [RuTPP(CO)^- + SO_2]$$

$$RuTPP(O_2)^- + CO(SO_2) \xrightarrow{} RuTPP(CO)^- \text{ or } RuTPP(SO_2)^-$$

These reactions indicate that $D(RuTPP^-\text{-}CO) > D(RuTPP^-\text{-}SO_2) > D(RuTPP^-\text{-}O_2)$. CID experiments on $RuTPP(CO)(O_2)^-$, $RuTPP(CO)(SO_2)^-$ and $RuTPP(SO_2)(O_2)^-$ gives ion products $RuTPP(CO)^-$, $RuTPP(CO)^-$ and $RuTPP(SO_2)^-$ indicating that CO, O_2 and SO_2 bind to the metal as separate axial ligands.

Reactions of MCO^+(M=Cr, Mn, Fe, Co, Ni) with O_2 and M^+ with NO_2

Henglong Chen, D. P. Ridge*.
Department of Chemistry and Biochemistry and Center for Catalytic Science and Technology, University of Delaware, Newark, DE 19716.

The title reactions were examined using FTMS techniques to determine the effect of the CO ligand on the reactivity of M^+ toward O_2. M^+ and MCO^+(M=Cr, Mn, Fe, Co, Ni) were generated by a 5 msec pulse of an electron beam of varying energy on $Cr(CO)_6$, $Mn_2(CO)_{10}$, $Fe(CO)_5$, $Co(NO)(CO)_3$ and $Ni(CO)_4$ respectively. The neutral metal carbonyl was introduced to the source cell region at pressure of $\sim 10^{-7}$ torr.

Endothermic reactions of M^+ with O_2 have been discussed by Armentrout and Beauchamp.[1] Thermal reactions of MCO^+ with O_2 have not been described. We found that reactions of MCO^+(M=Cr, Mn, Fe) with O_2 follow the pattern shown in (1) and (2), and $CoCO^+$ and $NiCO^+$ are inert toward O_2.

$$MCO^+ + O_2 \begin{cases} \text{---}> MO^+ + CO_2 & \text{Cr(20\%) Mn(10\%) Fe(85\%)} \quad (1) \\ \text{---}> MO_2^+ + CO & \text{Cr(80\%) Mn(90\%) Fe(15\%)} \quad (2) \end{cases}$$

The rate constant for disappearance of MCO^+ is 1.4×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for Cr, 1.2×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for Mn and 1.0×10^{-10} cm^3 $molecule^{-1}$ s^{-1} for Fe. As shown in Fig. 1, reaction (1) is a minor channel which is favored at high electron beam energy for M=Cr and Mn. For M=Fe, however, reaction (1) is the major channel and is independent of electron beam energy. This suggests that only for Fe reaction (1) is efficient for ground state species. We note that reaction (1) is exothermic for all the title metals.

O_2 in MO_2^+ could be a single ligand written as $M^+(O_2)$(I) or split as two O atoms bound to metal, written as $(O)M^+(O)$(II). For M=Mn and Fe, CID on MO_2^+ gives exclusively M^+ (loss of O_2) and MO_2^+ undergoes rapid ligand exchange reactions with H_2O and C_2H_4. These results suggest structure I for MnO_2^+ and FeO_2^+. For M=Cr, however, CID on CrO_2^+ gives both Cr^+ and CrO^+. In addition CrO_2^+ does not undergo ligand substitution reactions with H_2O and C_2H_4. These results tend to support structure II for CrO_2^+. The II structure of CrO_2^+ is also confirmed by the reaction (3).

$$Cr(CO)_2^+ \xrightarrow[-CO]{O_2} Cr(CO)(O_2)^+ \xrightarrow[-CO]{O_2} CrO_4^+ \quad (3)$$

Only one O_2 in CrO_4^+ could be displaced by H_2O. This suggests that one O_2 in CrO_4^+ is a dioxygen ligand and the remaining two O atoms are mono-oxo ligands bound to the metal. Since CrO_4^+ contains CrO_2^+, these results also support II for CrO_2^+. CrO^+ was not observed to oxidize CO, but CrO_2^+ does as in (4) with a rate of 4.2×10^{-13} cm^3 $molecule^{-1}$ s^{-1}.

$$CrO_2^+ + CO \text{-----}> CrO^+ + CO_2 \quad (4)$$

In the reaction (1), (3) and (4), the same intermediate of $(O)Cr(O)(CO)^+$ is formed, in reaction (1) and (3), however, the expected channel of activation of CO in the intermediate can only be proceeded with the additional internal energy in the reactant ions. The schematic potential energy surface for these three reactions was drawn in Fig. 2. This suggests a barrier to move an O atom from the metal to the CO ligand. It may be that while reactants and products ground states are on the same surface, a crucial intermediate is only accessible on some high surface. We note that addition of an O atom to CO could not go on the lowest surface since the ground state of an O atom is ^3P while CO and CO_2 have singlet ground states. Thus it may be that the surface leading to the $CrO^+ + CO_2$ products is only weakly coupled to the ground state reactant surface (spin orbital coupling, etc.). This is indicated by a dashed

line on the schematic surface. On the other hand reaction (4) begins with reactants CrO_2^+ and CO which may have only one energetically accessible reaction channel that leading to CrO^+ and CO_2. Access to $CrCO^+$ and O_2 would be cut off by the barrier between the wells in the schematic. Hence the CrO_2^+-CO pair get trapped in the electrostatically bound well long enough for the weak coupling to the $CrO^+ + CO_2$ channel to be effective.

Reactions (5) and (6) were observed for M=Cr, Mn, Fe, and Co, and only reaction (7) was observed for M=Ni.

$$M^+ + NO_2 \text{----}> MO^+ + NO \quad (5)$$

$$MO^+ + NO_2 \text{----}> NO^+ + MO_2 \quad (6)$$

$$Ni^+ + NO_2 \text{----}> NO^+ + NiO \quad (7)$$

Assuming that (5) and (7) are observed when exothermic and not observed when endothermic the following limits on $D(M^+\text{-}O)$ can be derived. In Eq. (8), M=Cr, Mn, Fe, Co and in (9), M=Ni.

$$73.4 \text{ kcal/mol} < D(M^+\text{-}O) < 73.4 + IP(NO) - IP(MO) \quad (8)$$

$$73.4 + IP(NO) - IP(MO) < D(Ni^+\text{-}O) < 73.4 \text{ kcal/mol} \quad (9)$$

The calculated values from these equations are listed in Table I and compared with some recent literature values. Except for $D(Mn^+\text{-}O)$ the present values are in very good agreement with literature values.

Reaction (1), (2) and (5) provide a method to synthesize metal oxide ions in the gas phase.

Proton Affinities of Peptides Assessed Using the Kinetic Method in a EBE Mass Spectrometer

Zhuchun Wu and Catherine Fenselau, Department of Chemistry and Biochemistry
University of Maryland Baltimore County, Baltimore, MD 21228

Gas phase basicities and proton affinities (PA) have received intensive study because of their analogy to the fundamental acid/base chemistry of solutions. With the development of ionization methods such as fast-atom-bombardment (FAB) and electrospray (ES), studies of the ion molecule chemistry of non-volatile materials in the gas phase have experienced rapid growth. Proteins, peptides and their basic building units, amino acids, are of great interest and widely studied in the gas phase. Proton affinities of all 20 common amino acids have been measured[1] with the exception of arginine, the most basic one. Here we report proton affinities of arginine and of a peptide series, assessed by kinetic method[2].

Arginine is the most basic amino acid. It contains a guanidino functional group and shows quite high proton affinity. We used 1,1,3,3-tetramethylguanidine(TMG), 1,5-diazabicyclo[4.3.0.]non-5-ene(DBN), and 1,8-diazabicyclo[5.4.0.]undec-7-ene (DBU) as standard reference bases[3]. The similarity of the basic functional groups will minimize any differences of entropy changes in the competing dissociation reactions.

All MIKE experiments were performed on a JEOL HX110/HX110 tandem mass spectrometer. The dimer proton-bound ions are simply generated by fast-atom-bombardment gun. Proton-bound dimer ions were selected by the first two sectors (EB), allowed to dissociate spontaneously in the third field free region without the use of collision gas, and detected immediately after the second electrostatic analyzer. Each MIKE experiment was repeated three times. Standard deviations of ion abundances and hence of the ratios k_1/k_2 were less than 5%. By the linear correlation of the experimental data [Figure 1], we obtain the proton affinity of arginine as 245.2 kcal/mol.

The uncertainties are estimated from the standard deviations of the ion abundance ratio and from the linear regression to be less than ± 0.2 kcal/mol. Uncertainty can also arise from uncertainties in the proton affinity values of reference base in the literature, which are reported as ± 0.3 kcal/mol[3]. Therefore we report the proton affinity of arginine as 245.2 ± 0.5 kcal/mol[4]. This is about 14 kcal/mol higher than the nearest value for His, in sharp contrast to the average of 1 kcal/mol difference between the other nineteen commonly occurring amino acids.

Peptides consist of multiple functional groups and intramolecular hydrogen bonding which make proton bonding much more complicated. We assessed the proton affinities of polyglycines ranging from one residue up to 10 residues, using amines as standard reference bases. Multiple hydrogen bonding has been reported for the complexes of peptide-like alanine derivative CH_3CO-Ala-OCH_3 with amines[5]. Our study shows that using different amines (primary, secondary or tertiary amines) as standard references gives no significant differences in the determined proton affinity values.

Figure 2 shows the proton affinities of polyglycines determined using this method. Proton affinity in the polymer increases with the increase of the number of glycine residues. This steady increase maybe explained by charge-induced dipole interaction, intramolecular hydrogen bonding, internal solvation of proton or simply statistical effect.

The kinetic method is applicable to non-volatile and small amounts of samples, and employed easily in commercial tandem mass instruments. It is a quite suitable for determining the proton affinities of amino acids and peptides.

Reaction of Propene Radical Cation with Ethylene Neutral: A Study by an Rf-only-mode Event in FTMS

D. L. Vollmer, D. L. Rempel and M. L. Gross

Midwest Center for Mass Spectrometry
University of Nebraska Lincoln, NE 68588

The goal of this study is to investigate the mechanism and adduct formation in the reaction of propene radical cation with ethylene neutral by using diagnostic bimolecular reactions. Last year we reported on this reaction and characterized the adduct by use of tandem mass spectrometry[1]. We were able to observe a covalent $C_5H_{10}^{\ddagger}$ adduct formed in a high pressure source and characterize it by charge stripping. However, the spectra were difficult to predict *a priori*.

It was proposed by our group last year that by the introduction of an rf-only-mode event along with a high pressure bath gas in the FTMS experiment, adducts of high energy reactions could be collisionally stabilized[2]. This was not possible under normal FTMS conditions because the adduct fragmented immediately upon formation due to the lack of collisional stabilization at low pressure [See Figure 1a]. By using the rf-only-mode event in the FTMS sequence, the $C_5H_{10}^{\ddagger}$ adduct could be stabilized and then selected for reaction [See Figures 1b and 1c].

Once selected, the adduct was allowed to react with various reagents in order to find a diagnostic bimolecular reaction. 1,3-Butadiene was found to be suitable in this way.

The products of the 1,3-butadiene reaction in the normal FTMS experiment were used to differentiate the $C_5H_{10}^{\ddagger}$ adduct from the other $C_5H_{10}^{\ddagger}$ reference compounds. Most of the reference compounds either charge exchanged or were unreactive with 1,3-butadiene [See Figure 2a]. 2-Methyl-2-butene gives products similar to the adduct reaction [See Figures 2b and 2c].

Based on the bimolecular reactions with 1,3-butadiene, we tentatively conclude that the structure of the adduct is that of 2-methyl-2-butene. This is consistent with our conclusion in our previous study[1].

Gas Phase Reactivities of Aromatic Hydrocarbon Cations Toward *N*-methylimidazole.

A. B. Whitehill, M. George, and M. L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska Lincoln, Lincoln, Nebraska USA 68588-0304.

Aromatic hydrocarbons such as benzo[*a*]pyrene and benz[*a*]anthracene have been known to be carcinogenic since the early 1900's. Carcinogenic activity can be determined by observing tumor formation in rats after exposure to these hydrocarbons but the mechanisms for genetic mutation are not well understood.

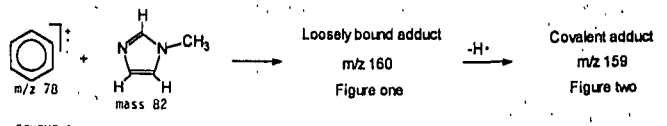
Although the mechanisms for tumor formation are not fully understood it is believed that for a compound to initiate tumor formation it must first be activated by the human body to a reactive form and second it must bind covalently to DNA (1).

There are two principal theories for activation of polyaromatic hydrocarbons (PAH's) to carcinogenic species. The first involves enzymatic oxidation of the PAH to a bay-region diol epoxide (2). This theory was developed mainly due to the fact that adducts of the diol epoxides and DNA fragments were the first hydrocarbon species isolated from carcinogenic tissue. The second theory for activation was developed by Cavalieri and coworkers in the 1970's and involves one electron oxidation of the PAH to a radical cation (3). This theory is based on two premises; many carcinogenic hydrocarbons have ionization potentials low enough (<7.35 ev) to be enzymatically oxidized; and carcinogenic activity can be correlated to a compounds ability to localize charge.

Cavalieri and coworkers have published a series of articles in which 7,12-dimethylbenz[*a*]anthracene and benzo[*a*]pyrene were oxidized to radical cations and allowed to react with DNA fragments to see if adduct formation would occur (4,5). Both radical cations formed adducts with the N-7 position of guanine and the N-7 and C-8 positions of adenine.

In order to see if radical cations would form adducts with a nitrogen and carbon atom in a similar environment in the gas phase, a series of hydrocarbons with increasing number of aromatic rings (benzene, napthalene, anthracene, benz[*a*]anthracene, and benzo[*a*]pyrene) were allowed to react with *N*-methylimidazole in the high pressure region of a CI source. In short, this study is an attempt to model biological activity with inherent gas phase reactivity.

The first two systems studied used benzene and napthalene as the radical cations. Both systems were able to form covalent adducts at the loss of a hydrogen from the hydrocarbon but the most abundant source ion was that of the loosely bound species (see scheme 1). CAD of the loosely bound adducts mainly produced the reagent ions (figure 1). CAD of the peak one mass unit lower than the loosely bound species produced higher mass fragments resulting from cleavage of the imidazole ring (figure 2). The napthlaene system was also studied using FTMS in the rf-only-mode (6). The rf-only-mode allows the study of unstable species in the gas phase through collisional stabilization with a bath gas such as helium. Without the collisional stabilization the [napthlaene + *N*-methylimidazole] cation is not detectable but through collisional stabilization the increase in abundance of the adduct and the decrease in abundance of the napthlaene radical cation can be monitored.



SCHEME 1

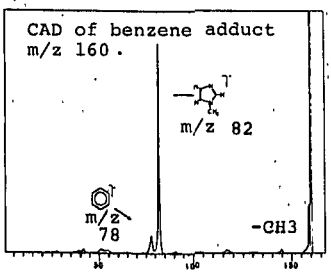


Figure 1

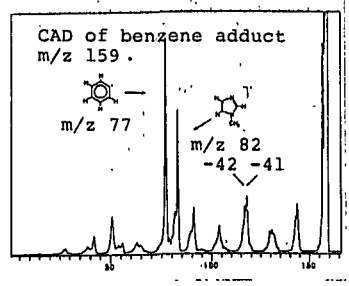

Figure 2

The third system monitored used anthracene as the radical cation. This was the first system to produce a more abundant adduct ion than a loosely bound species. This suggests the greatest propensity to form a covalent adduct thus far.

The fourth and fifth systems used the listed carcinogens benz[*a*]anthracene and benzo[*a*]pyrene as the radical cations. Both systems produced almost exclusively the M-1 peak corresponding to a true covalent adduct (figures 3 and 4). The fragmentation patterns are very similar to CAD patterns produced from DNA adducts analyzed by Gross and Cavalieri (7).

The radical cations from carcinogenic hydrocarbons produced the most abundant covalent adduct (M-1) peak relative to loosely bound species. This suggests the greatest ability to form an adduct with the nucleophile.

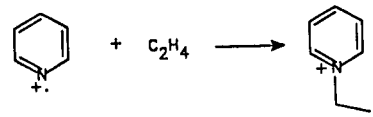
An Experimental Strategy For Studying Bimolecular Reactivity of Distonic Ions: Application of an RF-Only-Mode Event in FTMS. *C. L. Holliman, D. L. Rempel, and M. L. Gross,* Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304.

Distonic ions are odd-electron ions whose radical and charged sites are separated by one or more heavy atoms, and cannot be formed directly by the ionization of a neutral. Generation of distonic ions by ion-molecule reactions in an ICR cell was demonstrated by Gross and McLafferty in 1971 [1], but few systematic studies of the bimolecular reactivity of these ions have been reported. This is because there are two difficulties in their study. The first, is that few methods generate sufficiently large populations of distonic ions for systematic study, and the second is that, once formed, distonic ions often react with their precursors or undergo hydrogen rearrangements to non-distonic ions.

Study is further complicated by limitations in current trapping techniques. Fourier transform mass spectrometry (FTMS) is a high performance technique but does not provide a means for collisional stabilization of the ion. Quadrupole ion storage traps (QUISTORS) provide collisional stabilization but do not have the high performance of FTMS at low mass. To probe systematically the chemical properties of distonic ions, two hurdles must be overcome. The first is to develop methods that prepare reasonably large quantities of stable distonic ions that do not react with their precursors. The second is to investigate their bimolecular reactivity by using a high performance ion trapping technique.

We have observed that the reaction of pyridine radical cation with ethene in the CI source of a sector instrument generates sufficiently large populations of the ethylenepyridinium ion that does not undergo the aforementioned reactions [2].

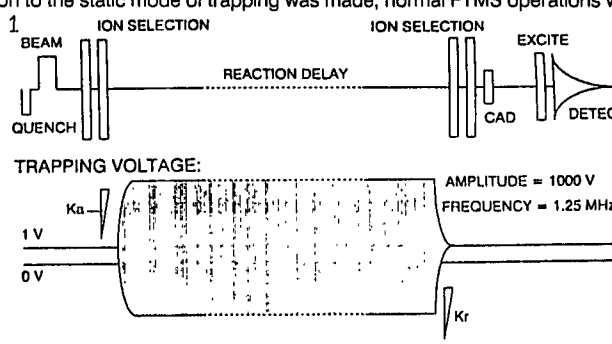


The high pressure of the CI source provides collisional stabilization for the generation of this adduct, however, the adduct is not detectable as such at the low operating pressures of FTMS.

The FTMS cell employs static (Penning) trapping fields and, as a result, there is a rapid loss of performance at pressures greater than 1×10^{-7} torr. QUISTORS, however, employ dynamic (Paul) trapping fields and are commonly operated at pressures of 10^{-2} torr. We recently showed that the incorporation of an rf-only-mode event into the FTMS sequence allows the efficient transition between the low pressure static field trapping mode and the high pressure dynamic trapping mode [3]. This should allow the β-distonic isomer to be produced in copious quantities in the FTMS cell. This represents the first use of a "high-pressure" FTMS event in the area of ion chemistry research.

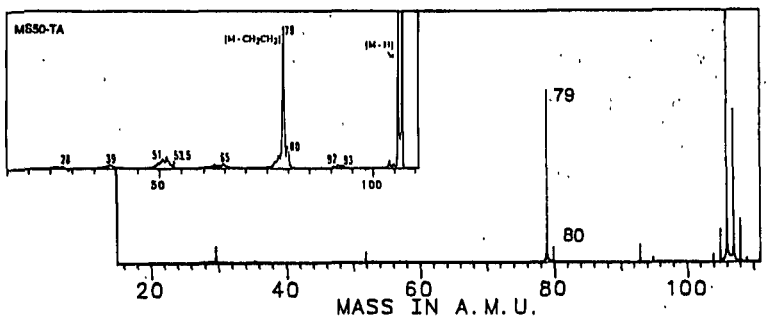
The FTMS system used for the generation and identification of the adduct consisted of a 2.54-cm molybdenum cubic trap in a Varian V-3400 electromagnet. The FTMS sequence (FIG 1) was executed with a Nicolet FTMS-1000 data system. All FTMS experiments were performed at 1.2 Tesla with a 1 V trapping potential. The cell was pressurized to approximately 5.3×10^{-7} torr with pyridine and ethylene at roughly a 3:1 ratio. Ionization was at 12 eV, employing 400 nA of emission current for 200 msec. Following double resonance to remove the ethylene radical cation, the rf-only-mode event was implemented by superimposing a 1000 V_{0-p}, 1.25 MHz potential on the trapping potential. Simultaneously the cell was pressurized to approximately 3×10^{-3} torr with He by opening a modified Varian leak valve with a solenoid for 1.3 sec. The duration of the rf-event was determined by the rate of turn on/off of the modulation, the desired reaction-/cooling period, and the time to remove the bath gas pressure to one commensurate with FTMS operation. Once the transition to the static mode of trapping was made, normal FTMS operations were resumed.

FIG 1



Formation of an adduct at *m/z* 107 was observed after an rf-event time of 3.9 sec. Confirmation that the adduct formed in the FTMS was the same as that formed in the CI source of a sector instrument was by two routes. The first was comparison of the sector-generated CAD spectrum (inset FIG 2) to the FTMS-generated CAD spectrum (FIG 2). In the CAD experiment the adduct is selected by double resonance and excited to approximately 20% of the cell radius to increase translational energy. Dissociation was further enhanced by shortening the rf-event period by 0.68 sec so that the adduct could collide with neutrals and residual helium bath gas (~1×10^{-6} torr total cell pressure). Comparison of results shows that in both instruments, the adduct readily loses ethylene to form the radical cation of the electrophile pyridine (*m/z* 79). Such a loss is characteristic of β-distonic ions [4]. The second route was reaction with *d5*-pyridine (*m/z* 84) to form the adduct at *m/z* 112 followed by CAD to observe the ability to undergo H/D exchange with the ethylene moiety. Sector experiments have demonstrated that the β-distonic ethylenepyridinium ion undergoes exchange at the ortho positions through a five-membered ring intermediate. Loss of the ethylene then gives ions of *m/z* 84, 83, and 82. A similar experiment in the FTMS reveals significantly more H/D exchange than what is observed in the sector instrument due to longer residence times.

FIG 2



Formation and isolation of the β-distonic ethylenepyridinium ion in the FT mass spectrometer presents us, for the first time, with the opportunity to study unambiguously the ion-molecule reactivity of a beta distonic ion. As a probe of structure, we reacted the isolated adduct with molecular oxygen through the use of *two* rf-events. In this experiment isolation of the adduct was followed by a second rf-event of 6 secs. During the event, oxygen was introduced through a pulse valve along with the helium bath gas. The inset in FIG 3 shows the result of opening the oxygen pulse valve without the second rf-event. A small amount of product at *m/z* 139 is observed with poor signal to noise. Figure 3 shows the dramatic increase in product when the reagent is admitted during the second rf-event. The ability to use higher reagent pressures during the rf-only-mode event significantly increases the number of ion-molecule collisions, and provides collisional stabilization. Furthermore, the dynamic trapping field focuses the ions to the center of the cell, permitting significantly longer reaction times.

Nucleophile/Electrophile Ion/Molecule Reactions in a Quadrupole Ion Trap Mass Spectrometer

Brad I Coopersmith and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611
Douglas W. Kuehl
U.S. Environmental Protection Agency, Duluth, MN 55804

Gas-phase ion/molecule reactions between potential carcinogens and mutagens (electrophiles) and model DNA bases (nucleophiles) in a tandem mass spectrometer can be analytically useful as an environmental screening technique. Previous work in our laboratory investigating gas-phase ion/molecule reactions between carcinogenic allyl halides and pyridine on a triple quadrupole mass spectrometer (TQMS) showed good correlation to the Ames Test, a bioassay used to determine mutagenicity [1]. However, the TQMS can only perform two stages of MS It therefore lacks the ability to both choose a reactant ion and obtain MS/MS structural information on product ions. The quadrupole ion trap mass spectrometer (ITMS) has these abilities and should be ideal for these gas-phase ion/molecule electrophile/nucleophile reactions.

In evaluating the ITMS for its ability to perform these ion/molecule reactions, certain advantages and disadvantages became apparent. The ITMS, being tandem-in-time, has no spatial separation between the stages of mass spectrometry. It is demonstrated that, depending upon the nucleophile and electrophile, this lack of spatial separation can allow unwanted side reactions to occur. For the reaction of the isolated pyridine N^+ ion (m/z 79) with the allyl halides (EX), the desired product is the addition of the allyl group to the pyridine, yielding a product ion (P^+) at m/z 120. In Figure 1a, allyl chloride reacts with the pyridine N^+ ion to produce the product ion at m/z 120 [P^+], while Figure 1b shows that allyl iodide reacts with the pyridine $N^{+\cdot}$ ion to form several other undesired products as well The major advantage of the ITMS is its ability to perform MS^n. This capability was used to identify the unwanted product ion at m/z 285, as shown in Figure 2. Another significant advantage of the ITMS is its ability to collect time-resolved data. These data are used to calculate the rate constants for the formation of both the desired and undesired product ions for the reaction of pyridine N^+ ions with neutral ally iodide. Product ion spectra can then be predicted, which compare favorably with the observed product ion spectra.

Two approaches, raising the electrophile pressure and using a less reactive nucleophile, have been investigated to reduce unwanted side reactions. As shown in Figure 3, raising the electrophile pressure relative to the nucleophile pressure shows only a slight reduction in side reactions. The use of piperidine, a less reactive nucleophile, eliminates all side reactions except self-protonation of the nucleophile.

Investigations into the reactions of pyridine N^+ ions with α,b unsaturated ketones were also performed. Figure 4 demonstrates that nucleophilic attack of the α,b unsaturated ketones can occur either at the vinyl bond, resulting in a substitution product, or at the carbonyl bond, resulting in both a substitution product and an addition product. Nucleophilic attack is preferred at the electron-rich vinyl bond over attack at the electron-poor carbonyl bond. Also, nucleophilic attack at the carbonyl bond will be sterically hindered when R_1 is larger than H; however, when attack can occur it will result in more substitution product (Product C) as R_2 gets bulkier.

Classical and Non-classical Forms of the Ethyl Cation and their participation in the Ions $RO^+(C_2H_5)R'$.

M. Sirois, J.R. Cao, M. George and J.L. Holmes
Chemistry Department, University of Ottawa,
Ottawa, Ontario, Canada K1N 6N5.

Since the early 1970's there has been considerable interest in the structure of the ethyl cation. High level ab initio orbital theory calculations[1,2] have established that the classical ethyl cation does not exist in a potential well and lies some 6 kcal mol^{-1} above the more stable, non-classical ground state configuration of proton-bridged ethene. Thus $C_2H_5^+$ ions with an internal energy of ≥ 6 kcal mol^{-1} should undergo loss of positional identity of the H atoms. A $C_2H_5^+$ ion generated at the minimum energy threshold should not; e.g. the $C_2D_3H_2^+$ ion from CD_3CH_2X should retain D^+ as the bridging species.

In order to probe the participation of the high energy (classical) and low energy (non-classical) forms of the ethyl cation in ethylated ROR′ species (where R and/or R′ = H, CH_3 and C_2H_5) we have performed ion-molecule reactions of the type

$$C_2H_5^+ + ROR' \rightarrow RO^+(C_2H_5)R'$$

in the ion source of a modified VG Analytical ZAB-2F double-focussing mass spectrometer of reversed geometry. The major dissociation for all metastable $RO^+(C_2H_5)R'$ ions was loss of C_2H_4. The results were independent of the origin of the $C_2H_5^+$ ions. Significant H/D mixing was observed only when a labeled ethyl cation was reacted with a non-labeled ROR′ molecule and the degree of H/D mixing depended on the size of R and R′ (see Fig. 1). When non-labeled ethyl cations were reacted with labeled ROR′ molecules, H/D mixing was not observed. The size effect was such that for small ROR′ species (e.g. CH_3OH), H/D mixing in metastable $[CH_3OH(C_2D_{5-x}H_x)]^+$ ions prior to loss of labeled ethene was very small, whereas, for example, for the corresponding species for R = R′ = C_2H_5, showed a high degree of scrambling. We propose that this result is best explained by different reactivities of the low energy (non-classical) and high energy (classical) forms of the ethyl cation. If R and R′ are relatively large, it becomes difficult for the low energy (non-classical) form to react with the ROR′ species. Energy rich (classical) ethyl cations (which by virtue of their internal energy content will have randomized H/D positions before reaction with

the substrate) can react with ROR′ with less size constraint. The low energy (non-classical) $C_2H_5^+$ ions react most readily with small ROR′ molecules giving rise to the observed marked reduction in H/D positional mixing in the ethene lost from metastable adduct ions. This trend is clearly illustrated in Figure 1.

It was also observed that for a given ROR′ species, a greater degree of H/D mixing is always observed when the latter was reacted with $C_2D_3H_2^+$ rather than with $C_2D_2H_3^+$ (see Fig. 1). This may be explained by the non-classical form of $CH_3CD_2^+$ having a hydrogen ion in the bridge whereas for $CD_3CH_2^+$ a deuterium ion serves as the bridging species. If the low energy (non-classical) form of $CH_3CD_2^+$ reacts more readily than that of $CD_3CH_2^+$ then relatively less H/D mixing will be observed for the former because a greater proportion of low energy (non-classical) ethyl cations will have reacted with ROR′.

NICI MASS SPECTRA OF DICARBOXYLIC ACID ESTERS

*Elizabeth A. Stemmler and John L. Diener
Bowdoin College, Brunswick, ME 04011

The NICI mass spectra of esters of a series of aromatic and aliphatic dicarboxylic acid esters have been studied under a range of ionization conditions using a conventional chemical ionization (CI) source and an FT-ICR mass spectrometer. Ion-molecule reactions between $O_2^{\cdot-}$, $O^{\cdot-}$, and OH^- and aromatic dicarboxylic acid esters were examined using the FT-ICR mass spectrometer, and spectra were compared with O_2/Ar, N_2O/CH_4/He, and N_2O/He NICI mass spectra measured using a conventional CI source. Reaction mechanisms were elucidated using labelled esters, labelled reagents gases, and mixed alkyl esters.

$O_2^{\cdot-}$ Reactions. Aromatic dicarboxylic acid esters show $[M-R]^-$ ions when oxygen is present in the CI source. No ^{18}O incorporation is observed when $^{18}O_2$ is added. FT-ICR ion isolation and ion ejection studies show that $O_2^{\cdot-}$ reacts to form the $[M-R]^-$ ion. The lack of ^{18}O incorporation suggests an S_N2 type mechanism (see Scheme I), as has been reported for aliphatic esters[1]. This mechanism is supported by the spectra of mixed dialkyl phthalates, where reduced $[M-R]^-$ abundance is observed for attack at the more structurally hindered alkyl group (see Figure 1). Additional support for an S_N2 type mechanism is found in the spectrum of diphenyl phthalate, which would be expected to offer an unfavorable site for S_N2 attack. New reaction pathways involving ^{18}O incorporation, similar to those previously reported for phenyl benzoate[2], are observed.

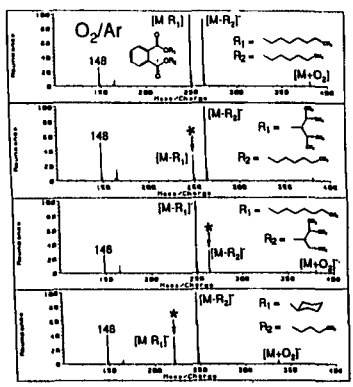

Figure 1.

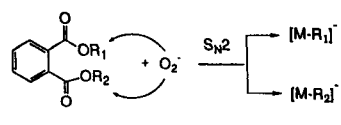
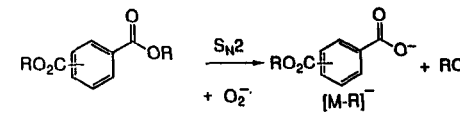
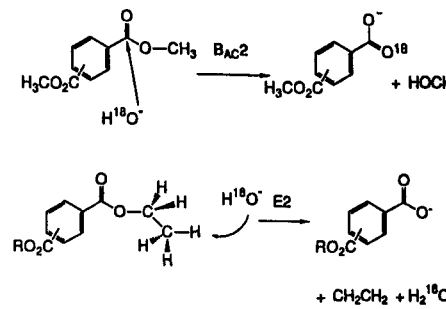




Scheme I



Scheme II

Under NICI conditions, all ortho aromatic dicarboxylic acid esters showed an m/z 148 ion in the presence of oxidizing gases like O_2. This ion is produced by an initial neutral surface-assisted reaction to produce phthalic anhydride, which is then ionized by electron-attachment. The spectra of aliphatic dicarboxylic acids were complicated by related surface-assisted reactions.

OH^- Reactions. When OH^- is used as the reagent gas, the spectra of aromatic dicarboxylic acid esters are dominated by $[M-R]^-$ ions (vs $[M-H]^-$ for aliphatic acid esters). Experiments on the FT-ICR and CI instruments show that $^{18}OH^-$ reacts to produce ions showing a high degree of ^{18}O

incorporation for methyl esters. A $B_{AC}2$ type mechanism is proposed (see Scheme II), as reported previously for esters of aliphatic and aromatic acids[3,4]. The extent of incorporation decreases for ethyl and higher esters, suggesting that an E2 mechanism is competing with the $B_{AC}2$ pathway. (see Scheme II). The E2 mechanism is supported by a decrease in ^{18}O incorporation that correlates with the number of ß hydrogens. This is demonstrated in the spectra of mixed dialkyl phthalates, where attack occurs at the alkyl chain with the most ß hydrogens. A factor that complicates the proposed $B_{AC}2$ mechanism i is the observation of one ring hydrogen/OH^- hydrogen exchange in the spectra of aromatic (not aliphatic) mono and dicarboxylic acid esters under NICI conditions. This exchange has been demonstrated using ring d_4-dimethyl phthalate, dideuteromethyl phthalate and reactions in OD^-. The extent of exchange is found to decrease with the extent of ^{18}O incorporation.

$O^{-\cdot}$ Reactions. When aromatic dicarboxylic acids react with $O^{-\cdot}$, many ionic products are observed. A number of these products may be attributed to reactions previously observed for aromatics[5], such as $[M+O-H]^-$ and $[M-H_2]^{-\cdot}$. The dominant ionic product is $[M-R]^-$. Some ^{18}O incorporation is observed, suggesting an addition-radical elimination mechanism. $[M+O-CO_2R]^-$ and $[M+O-R]^-$ ions are also observed (see Figure 3). Aliphatic dicarboxylic acids show $[M-R]^-$ and $[M-H]^-$ ions. The $O^{-\cdot}$ spectra are most structurally informative; however, overall sensitivity was poor under NICI conditions.

ION-NEUTRAL COMPLEX-MEDIATED DECOMPOSITIONS OF IONIZED DIALKOXYALKANES

Mohammed S. Ahmed[a], Charles E. Hudson[a], C.S. Giam[b] and David J. McAdoo[a]

[a] Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77550

Inctroduction

Unimolecular fragmentation of ions in the gas phase does not always lead to prompt separation of the resulting fragments. Ion-neutral complexes have often been proposed as intermediates in the unimolecular decomposition of radical cations. In recent years much experimental evidence favoring this model has appeared in the literature [1-3]. Common reactions between the partners in ion-neutral complexes are: 1) hydrogen exchange, 2) single hydrogen transfer and 3) double hydrogen transfer.

Dialkoxyalkanes have peaks corresponding to protonated dialkyl ethers in their mass spectra. Such peaks cannot be explained by direct dissociation of dialkoxyalkane radical cations. We undertook this study to rationalize the mass spectral fragmentation of dialkoxyalkane radical cations and to discover additional types of ion-neutral complex-mediated unimolecular dissociations.

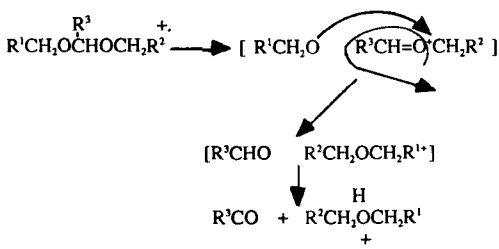
Experimental

The mass spectra were recorded on an Extrel FTMS-1000. Samples were ionized at 12 eV electron energy. Commercially available samples were used without further purification. Commercially unavailable and partially deuterated samples were synthesized in this laboratory.

Results and Discussion

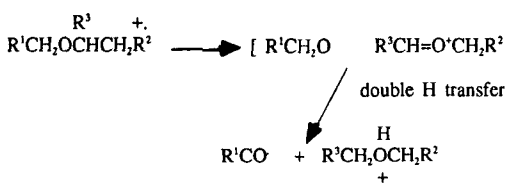
The partial electron impact mass spectra of the compounds **1-5c** are shown in Table 1. Two mechanisms might rationalize the results.

1) SN2-like attack of an alkoxy radical on carbon to form an ether, followed by hydrogen transfer.



R^1	R^2	R^3
--	--	--
H	H	H
CH_3	CH_3	H
C_2H_5	C_2H_5	H

2) Cleavage of a C-O bond followed by double hydrogen transfer from the alkoxy radical.



R^1	R^2	R^3
--	--	--
H	C_2H_5	CH_3
CH_3	C_2H_5	CH_3
C_2H_5	C_2H_5	CH_3

Mass measurement by high resolution at m/z 75 in **3** shows that neither mechanism leads to the formation of $(C_2H_5)_2OH^+$ with the expulsion of the two carbon neutral, C_2H_3O This is also true for **4a**-**5c**. The elimination of the two carbon neutral, C_2H_3O from **4a** by either mechanisms will lead to the formation of $C_2H_5O(H)C_3H_7^+$. In **5a**, double hydrogen transfer would have produced $(C_3H_7)_2OH^+$ by the expulsion of a two carbon neutral. Instead, **4a** and **5a** gave m/z 75 and 89 corresponding to $(C_2H_5)_2OH^+$ and $C_2H_5O(H)C_3H_7^+$ respectively by the elimination of the three carbon neutral, C_3H_5O. The preference for the formation of the three carbon neutral over the two carbon neutral could be due to greater stability of a three carbon neutral (e.g., CH_2=CH-$\dot{C}$H-OH). Hydrogen transfer from positions 1 and 3 of $CH_3CH_2CH_2O$ in partially deuterated **4b, 4c, 5b** and **5c** suggests that the hydrogen transfers from $CH_3CH_2CH_2O$ are nearly random. Lack of hydrogen exchange prior to other dissociations implies that randomization of propoxy radical hydrogens takes place after the cleveage of the C-O bond.

Table 1. Partial EI mass spectra of ionized dialkoxyalkanes

		m/z*								
Compounds	no.	47	75	76	77	78	89	91	92	93
$(CH_3O)_2CH_2$	**1**	5								
$(C_2H_5O)_2CH_2$	**2a**		14							
$(C_2H_5O)_2CD_2$	**2b**			14						
$C_2H_5OCH_2OCH_2CD_3$	**2c**					11				
$C_2H_5OCH_2OCD_2CH_3$	**2d**				10					
$(C_2H_5O)_2CHCH_3$	**3**		15							
$C_2H_5OCH(CH_3)OCH_2CH_2CH_3$	**4a**		26							
$C_2H_5OCH(CH_3)OCH_2CH_2CD_3$	**4b**		20	15						
$C_2H_5OCH(CH_3)OCD_2CH_2CH_3$	**4c**		15	9						
$(CH_3CH_2CH_2O)_2CHCH_3$	**5a**						18.5			
$(CH_3CH_2CD_2O)_2CHCH_3$	**5b**							15	4	
$(CD_3CH_2CH_2O)_2CHCH_3$	**5c**								13	10

*The intensities are relative to R^1OCHOR^2 (100%).

Conclusion

The two pathways to protonated ethers from ionized dialkoxyalkanes are interesting additions to ion-neutral complex-mediated dissociations. The SN2-like attack by a radical is particularly novel.

MASS SPECTROMETRIC DETECTIONS OF NEUTRAL RADICALS IN CH_4 MICROWAVE DISCHARGE BY USAGE OF Li^+ ION ATTACHMENT TECHNIQUES

Fujii Toshihiro and Ken-ichi Syouji*

National Institute for Environmental Studies, Tukuba Ibaraki 305, JAPAN

The chemical species of the neutral radicals in the methane microwave (MW) discharge plasma were studied by a quadrupole mass spectrometry in combination with a Li^+ ion attachment technique. Mainly radicals like C_nH_{2n+1} (n=2-11) and C_nH_{2n-1} (n=2-11) were detected and their relative intensities were determined; suggesting that reactions of various types such as radical/molecule lead to the polymerization. Moreover, formation of species such as C_4H_3, C_4H_5, C_5H_5 or with higher carbon numbers may also be produced in the process. We evaluate the presence of these above species by comparison with few results of optical spectroscopy or threshould ionization mass spectrometry. The effects of additional gases to the CH_4 stream such as Ar, H_2 and O_2 were also investigated.

Objectives The detection of intermediate radicals formed in the i-butane/He discharge of microwaves (MW) were previously reported using a quadrupole mass spectrometry (QMS) coupled to the Li^+ ion attachment reactor. Because the neutral radicals in the MW plasma are ionized by Li^+ in the reaction chamber and sampled by QMS, we proved in the previous study that the newly-developed method was found to be suitable to detect free radicals from the plasma and was applied to various studies on the behavior of neutral radical species. As a continuation of these and earlier studies on the detection of gaseous HC radicals, we are reporting in this paper the identification of neutral radical species in a methane MW plasma discharge flow tube. The aim of the present work is to identify the radical species in a methane MW discharge plasma, to determine the new species formed due to the additives and to assume the types of reactions leading to the formation of these radicals.

Experimental The experimental setup used for the present experiments is schematically shown in Fig. 1. The MW discharge tube forms part of a conventional flow system. The CH_4 gas or mixed gas is controlled so as to flow at a constant rate of 10ml/min through a discharge tube. The discharge tube is made of quartz glass tubing having an internal diameter of 3mm and is mounted to the reaction chamber (RC). The CH_4 gas enters the discharge tube where it is excited at 2450MHz by a magnetron oscillator (MR-301) having a nominal output power of 200W. The microwave oscillator is coupled to a resonant Beenakker -type cavity. The lens chamber was newly equipped with another QMS (066, Anelva Corp. Tokyo) which was used as a mass analysis for sample gases. The formation and involvement of free radicals in the MW plasma was confirmed directly with Li^+ ion attachment to them. The experimental setup was such that Li^+ ions attached to the chemical species (R) in the RC termolecular reactions to produce $(R+Li)^+$ ions. The Li^+ adduct ions were transferred to the QMS through the skimmer.

The experimental procedure only consisted of mixing an additional gas with CH_4. However, the total gas flow rate was constant at 10ml/min. Correspondingly, the total gas pressure of the RC was almost the same as 0.2torr through the series of the present experiments. Each gas mixture was sampled with and without MW power at 10W. This enables clearing the mass spectrum of impurities or addities. The analysis of the mass spectra was made in terms of mass identification, peak height determination and the normalized concentration of each m/z considered. The peak of Li^+ was disregarded because it remains almost unchanged with plasma activation. The analysis also substracts from each plasma spectrum its previous spectrum (no plasma); thus, the result reveals the particular radical peak due to plasma activation.

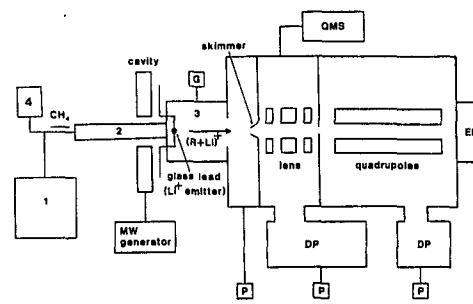

Fig.1

2) T. Fujii and K. Syouji, Phy. Rev. Lett. in press.

Mass Spectrum Fig. 2 shows the partial mass spectrum obtained in the mass range m/z 5-9, 23-27, 83-87 and 130-134 amu when CH_4 alone flowed at the flow rate of 10ml/min through the MW discharge tube and measured the Li^+ ion adducts by the quadrupole mass spectrometer. This figure also includes the results for the same CH_4 sample without the MW discharge. The analysis of the individual spectral peaks was made in terms of mass identification and classification by their formula. Table I shows all The identified species appeared. As far as the assignment of the mass spectral peaks goes, validity is principally based the mass number. From the results given in Table I, it can be concluded that: 1) The C_nH_{2n+1} and C_nH_{2n-1} radicals, where n=2 to 11, have been detected.

Radicals due to Additives (Impurities) Due to the presence of H_2O in CH_4 as impurities, there appeared OH radicals in the spectrum. The decrease in H_2O concentration in the MW plasma may be attributed partly to the formation of OH, because the decrease of H_2O is associated with the increase in OH, as shown in the Fig. 2.

When O_2 was added to the CH_4 stream, the intensities of oxygen-containing species increased. Their enhancement was found to be proportional to the increased of O_2 on the gas mixture. The increase of O_2 concentration above the O_2/CH_4 ratio of 4/6 completely depressed the hydrocarbon radicals. The use of O_2 additive gases with the mononer CH_4 leads to the production of a new type of O-containing species. Their relative intensities are shown in Fig. 3.

Table I. Analysis of radical products formed from the MW discharge plasma of pure CH_4 in terms of mass identification, classification in their formula and the relative intensities (per cent values).

ION-MOLECULE REACTIONS OF COPPER CLUSTER IONS WITH ALCOHOLS AND HYDROCARBONS

Paul Sharpe and Carolyn J. Cassady
Department of Chemistry
Miami University
Oxford, OH 45056

Gas-phase transition metal cluster studies provide fundamental information which may be of use in surface, catalytic, and organometallic chemistries. Metal cluster ions are of particular interest, but are much more difficult to produce than atomic metal ions. The present work couples a universal cluster ion production method, fast atom bombardment (FAB), with a versatile method for studying gas-phase ion chemistry, Fourier transform ion cyclotron resonance mass spectrometry (FTMS). A variety of metal cluster ions can be studied by this technique.

The present study focuses on copper cluster ions, Cu_x^+. Our recent studies of the gas-phase chemistry of silver cluster ions revealed dramatic size-related effects.(1) Thus, studies of copper were undertaken in order to determine if this unusual chemistry exists for other group 11 metals.

Copper cluster ions were produced by bombardment of copper foil, copper oxides, and copper halides with a 10 kV xenon beam in an external FAB source. Electrostatic focusing was used in transfer the ions into the cell region of a Bruker CMS-47X FTMS. The reactivity of the mass-selected cluster ions was investigated with C_1-C_4 alcohols and alkenes.

One area of interest is the production of copper cluster ions. In the present experimental configuration, FAB on copper foil yields Cu_x^+, x = 1-11. As is illustrated in Figure 1, Cu_x^+ with odd x were seen in much higher abundances than ions with even x. A similar odd x dominance also occurs in FTMS studies of Ag_x^+, while studies in a magnetic sector instrument produced abundant even x clusters.(2) Thus, on the FTMS timescale the more stable odd x clusters (which have paired electrons) dominate.

The absolute ions intensities of Cu_x^+, x = 1-5, may be greatly increased by acidifying the Cu foil. In addition, copper halides produce small Cu_x^+ in high yields. Therefore, preionization can increase the production of metal cluster ions by FAB. The halide spectra also contain copper halide ions, as is illustrated in Figure 2 for $CuBr_2$. Copper (I) and copper (II) halides give similar spectra. Copper halides proved to be the most convenient method for producing abundant small Cu_x^+ and were employed in our reactivity studies.

Cu^+ reacts readily with C_1-C_4 alcohols via four major pathways, producing: $Cu(H_2O)^+$ + Alkene, $Cu(Alkene)^+$ + H_2O, $Cu(Ketone\ or\ Aldehyde)^+$ + H_2, and $Cu(Alcohol)^+$. Our results agree with a study by Weil and Wilkins on the reactions of Cu^+ with alcohols.(3) The primary products react with addition alcohol molecules, yielding $Cu(Alcohol)_2^+$ as the terminal product. Cu^+ is more reactive than Ag^+, which yields only $Ag(Alcohol)_{1,2}^+$ adducts.

Cu_2^+ reacts readily with small alcohols and alkenes via copper atom displacement, producing CuL^+ + Cu. These facile reactions occur at near the collision rate. The Cu^+-Cu bond is weak, with a dissociation energy of 47 kcal/mol (4). Therefore, $D(Cu^+\text{-}L) > 47$ kcal/mol for small alcohols and alkenes. Ag_2^+ also has a weak metal-metal bond and reacts in a similar manner.

Cu_3^+ reacts slowly with alcohols and alkenes by the sequential addition of three reactant molecules, eventually producing $Cu_3L_3^+$. These reactions are slow, occurring at < 0.05 of the collision rate. Ag_3^+ reacts in a similar manner, but at even lower rates. Collision-induced dissociation (CID) of $Cu_3L_3^+$ results in the loss of intact ligands. Our results are consistent with a triangular Cu_3^+ which has been predicted by ab initio calculations.(5)

Rapid Cu atom displacement dominates the reactions of Cu_4^+ with alcohols and alkenes, forming Cu_3L^+. CID of Cu_4^+ also results in facile Cu elimination. These results suggest that the Cu_4^+ structure has one Cu atom loosely bound to a stable, triangular Cu_3^+. Ag_4^+ also reacts readily by Ag atom displacement.

Cu_5^+ reacts in a similar manner to Ag_5^+, producing $Cu_5L_2^+$ and $Cu_5L_3^+$ by adduct formation. The Cu_5^+ reactions occur slowly at < 0.01 times the collision rate; however, this is ten times faster than the corresponding Ag_5^+ reactions. These results suggest a stable, generally non-

reactive Cu_5^+ structure.

In conclusion, dramatic size-related reactivity effects exists in the reactions of Cu_x^+, x = 1-5, with small alcohols and alkenes. With the exception of atomic metal ion chemistry, copper's reactivity is similar to that of its group 11 neighbor silver, although Cu_x^+ reactions generally proceed at faster rates.

Design and Construction of a Simple SFC/MS Interface

Earl L. White*, William M. Coleman,III and Mary S. Uhrig

R.J. Reynolds Tobacco Company
Bowman Gray Technical Center
Winston-Salem, NC, 27102

Supercritical fluid chromatography (SFC) is a rapidly developing separation technique for compounds that lack volatility and/or thermal stability for separation by gas chromatography (GC). Direct interface of SFC to a mass spectrometer (MS) is, however, more difficult than GC/MS. Although high performance liquid chromatography (HPLC) might be amenable to non-volatile and thermally unstable compounds, it is a low resolution technique and coupling to a mass spectrometer is also difficult. Direct interface of SFC to an information-rich detector such as MS enhances the utility of this separation tool. Both electron impact (EI) and chemical ionization (CI) spectra can be obtained. Because EI spectra can be obtained, current MS databases can also be searched.

A standard VG direct insertion probe (DIP) was obtained unassembled and with slight modifications has proven to be an effective interface for SFC/MS. The only modification to the probe itself was the insertion of a piece of 1/16" stainless steel tubing to serve as a tunnel for the restrictor. A 200 μm hole was drilled in a solid ceramic probe tip and a 200 μm o.d. fused silica frit restrictor (1.7 cm/sec CO_2,) that was 50 cm in length to transverse the length of the probe was inserted (non-frit end first) into the ceramic tip and pulled through until the fritted-end was slightly inside the ceramic tip. The restrictor must fit tightly in the ceramic tip to allow efficient transfer of heat to the tip of the restrictor. A Suprex Model SFE/50 Extractor System (Suprex Corp., Pittsburgh,PA) with a 250 mL syringe pump, dual flame ionization detectors and a Valco Model IJ-57910V 4 port 100 nL injector was used. A 3 m X 100 μm SB-Methyl-100® (Lee Scientific, Salt Lake City, UT) fs capillary column with 0.25 μm film thickness was used for separation. SFC grade CO_2 (Scott Speciality Gases, San Bernardino, CA) was used as the mobile phase. SFC analyses were pressure-programmed with an initial pressure of 100 atm, then rampped to 350 atm at 10 atm/min and subsequently to 425 atm at 15 atm/min. The column oven was maintained at 100°C. Mass spectra were collected on a VG70-VSQ mass spectrometer (VG Analytical, Manchester, UK) with a VAXStation 3100 using OPUS software. The standard EI/CI source was operated at 300°C and 70 eV. Mass range scanned was from 50-1200 amu at 1 sec/decade. The interface probe was inserted through the standard vacuum lock. The standard DIP power supply was used to both monitor and control the temperature.

The utility of this interface was tested with solanesol, a known tobacco component which consists of nine isoprene units, with a molecular weight of 631. This compound cannot be readily separated by GC due to its thermal instability and low volatility. A supercritical fluid extract (SFE) of a tobacco sample submitted to SFC with flame ionization detection (FID) contained a major component which co-eluted with authentic solanesol standard. Total-ion-chromatogram and FID chromatogram profiles were essentially identical for both SFC/FID and SFC/MS. The EI mass spectrum of solanesol from SFC/MS with this interface was essentially identical to that obtained with the DIP.

Modification of a Vestec Electrospray Ion Source for Ionspray Operation

*Steven M. Musser , Kevin D. White and James A. Sphon

Division of Contaminants Chemistry, Center for Food Safety and Applied Nutrition, U.S. Food and Drug Administration, Washington, DC 20204.

Introduction

Electrospray ionization has proven to be a very effective means of introducing polar compounds into a mass spectrometer. It is generally a soft ionization method and is useful for a variety of polar, unstable, heat labile compounds. While electrospray has gained popularity for its ability to analyze very large molecules, our interest is primarily in small molecule identification, in particular sulfonated azo dyes which are used as food coloring additives. Sulfonated azo dyes are very difficult to analyze using mass spectrometric methods because of their non-volatile properties and tendency to easily undergo reduction. We have found that for some dyes electrospray has worked very well; however, as the number of sulfonic acid groups increase and the percentage of water in the mobile phase increases, it becomes impossible to obtain mass spectral information. In an effort to understand the ionization processes and to explain the decrease in sensitivity observed for some dyes, we decided to modify several features of our Vestec electrospray ion source to see what, if any, effect these modifications had on the performance of the ion source. Benzidine pyrazalone T (BPrT), a contaminant azo dye found in Yellow #5 preparations, was used to evaluate all modifications that were made to the ion source.

Experimental

All experiments were performed on a Vestec Model 201 quadrupole mass spectrometer equipped with a standard electrospray interface. Several modifications were made to the original Vestec design. The first change was to modify the probe for nebulizer assisted electrospray, also known as ionspray. The second modification was to remove the conical nozzle and replace it with a flat stainless steel (SS) plate that had a 0.4 mm aperture. Finally, the first pumping region was removed and replaced with a region that allowed for the countercurrent flow of nitrogen gas towards the needle.

In a typical experiment the needle voltage was between 2.5 and 3 kV, the current at the sampling orifice was between 0.15 and 0.25 μA and the block temperature was 150 °C. The effluent from a 2.1 mm x 25 cm HPLC column, packed with 5μ C-18 particles, was split (10:1) such that 20 μl/min of mobile phase was directed into the ion source. The mobile phase consisted of 5 mM formic acid in a 90:10 solution of H_2O:ACN. When the sodium salt of BPrT was injected onto the HPLC column using these conditions it eluted with a retention time of 16 minutes.

Discussion

Of the modifications that were made on the Vestec source and probe, the changes which produced the most dramatic effects were, the addition of a nebulizer gas and replacement of the nozzle with a flat plate. When there is a high concentration of water in the mobile phase (90%), and a nebulizing gas is used, baseline noise can be greatly reduced. The observed increase in stability can be attributed to better, more uniform droplet production and the drying effect of the gas itself. While the stability of the solvent ion signal was increased by the nebulizer, the negative ion mass spectrum of BPrT that was recorded, showed primarily pyrolysis products (figure 1A). With the replacement of the conical nozzle by a flat plate, a more representative mass spectrum of BPrT was recorded that included a prominent molecular anion (45%) at m/z 773 (figure 1B). An explanation of this effect may be that the flat plate tends to deflect the nebulizing gas back at the needle thereby increasing the drying effect of the gas; this serves to break up highly solvated dye clusters. Experiments with source designs incorporating a countercurrent flow of drying gas have yielded increased signal; however there is a loss in baseline stability. This is most likely due to inefficient pumping of the heated region between the sampling orifice and the skimmer.

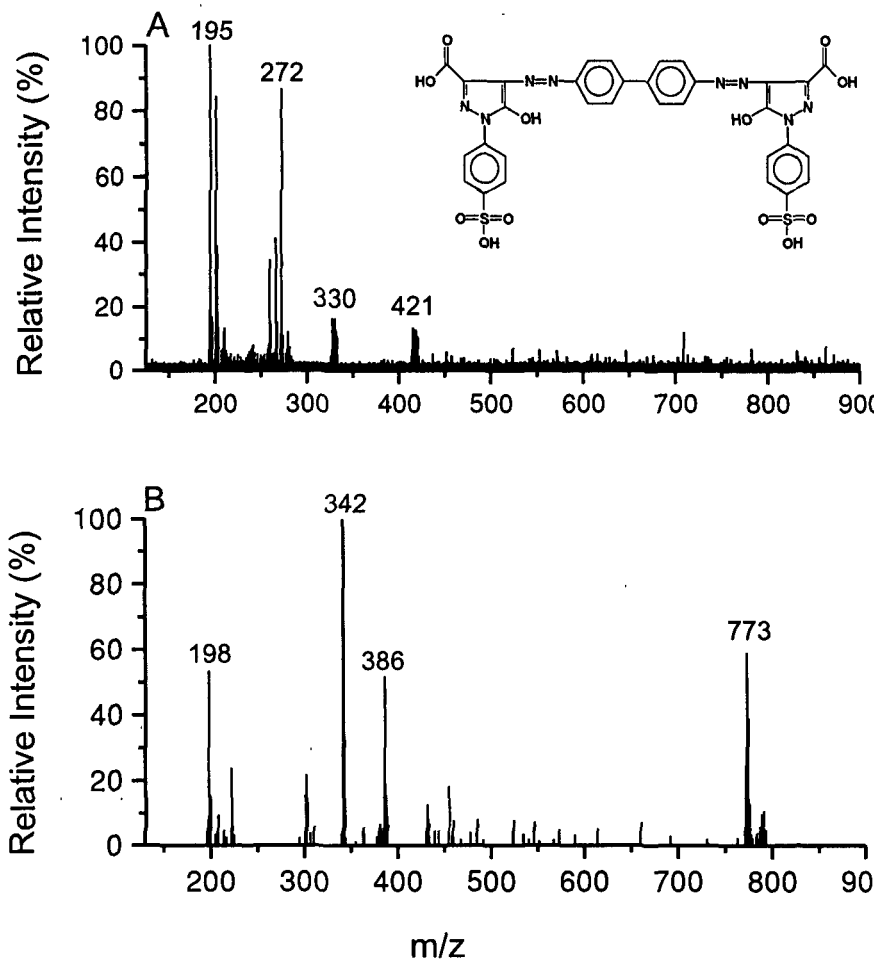

Figure 1. Negative ion mass spectra of BPrT recorded with a conical nozzle (A) and flat (B) counter electrode.

Laser Desorption and Electrospray Ionization Interfaces for Capillary Electrophoresis with Tandem Time-of-Flight Mass Spectrometry

G.C. Jones, Jr., L. Fang and R.N. Zare; Department of Chemistry, Stanford University, Stanford, CA 94305
and
E.R. Williams; Department of Chemistry, University of California, Berkeley, CA 94720

The objective of our research is to couple capillary electrophoresis (CE) with its rapid and high resolution chromatographic separations to time-of-flight mass spectrometry (TOF-MS). TOF-MS has the advantages of unlimited mass range, multichannel detection and rapid scan speed, thus serving as an ideal detector for the small volume, temporally short plugs eluting from a CE column. An interface for these two techniques must be able to vaporize and ionize large molecules present in the aqueous effluent from the separation column. For this purpose we have chosen laser desorption (LD) and electrospray ionization (ESI); both of which are powerful techniques for producing gas phase ions of large biomolecules. Tandem MS, accomplished using surface induced dissociation in the reflectron mirror adds further power to our instrument.

Matrix-assisted laser desorption, in experiments using nicotinic acid matrices, has produced the largest ions to date and generates almost exclusively molecular ions.[1] In our experiments sample introduction is accomplished by allowing the effluent of the capillary directly into the ion source of our instrument (figure 1). The water freezes via evaporative cooling, producing a continuous flow of ice which serves as a matrix for the laser desorption. We are using 1.9, 2.9 and 10.6 μm pulsed IR lasers for both the production of ions directly and to produce neutrals for subsequent photoionization. These infrared wavelengths are chosen because of their relative ease of production and the strong absorbance of water at these frequencies. The 1.9 μm radiation is produced by Raman shifting 1064 nm (Nd:YAG fundamental) in H_2, while the 2.9 and 10.6 μm light are the fundamental frequencies of an Er:YAG and CO_2 laser. The absorption coefficient of liquid water is roughly 10^2, 10^3 and 10^4 cm^{-1} for 1.9, 10.6 and 2.9 μm light respectively.

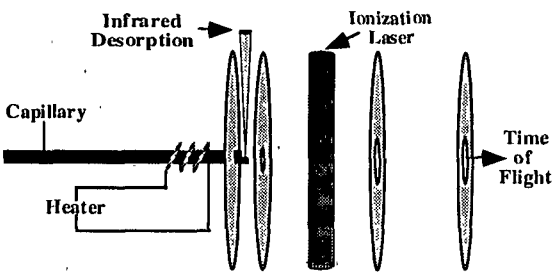

Figure 1: Laser Desorption Interface

The absorption of water at all three wavelengths, however, is sufficient to completely vaporize ~1nL of ice, the amount which exudes from the capillary in the interval between laser shots (1 to 10 Hz repetition rate). It is therefore interesting to explore the similarities and differences of the ions and neutrals formed with the various lasers. Neutrals are ionized with tunable radiation in a single or multi-photon process. The tunable VUV is produced by resonant four-wave mixing in Krypton. Both 1.9 and 2.9 μm light directly produce similar distributions of water cluster ions. The 10.6 μm radiation readily vaporizes neutral peptides. An overview of the results other than those obtained at 2.9 μm is given elsewhere.[2] Preliminary results suggest that only the 2.9 μm light is able to produce peptide ions directly and that at least two orders of magnitude more neutral peptides are produced in the desorption process. A more complete and detailed comparison of desorptions using these lasers is in progress.

Electrospray ionization[3] (ESI) is one of the most powerful and popular 'soft' ionization techniques to produce intact gas phase ions from large biomolecules in solution. One of the many advantages of ESI is that multiply charged ions are generated, thus reducing the m/z value.

The ion current from ESI is essentially a continuous current, while TOF-MS is a pulsed technique, requiring spatially and temporally well-defined ion packets for mass analysis. To make these two techniques compatible, ion packets are generated by pulsing the continuous current at a 90° angle[4]. This method for modulating ions takes the advantage of low translational energy spread along the time-of-flight axis.

Our ESI-TOF system is shown in figure 2. The electric pulse applied to the repeller was provided by a 0-400 V pulser. It has a specified rise and fall time of 10 ns. ESI-TOF spectra have been obtained for compounds as large as bovine insulin (MW 5733). A spectrum of bovine insulin is shown in figure 3. In order to obtain an improved ion signal, the repeller and extractor were initially held at a positive potential (e.g. 90 V), then a 400V pulse was applied to the repeller. A pair of deflection plates were placed right after the extractor plate to minimize the velocity component perpendicular to the time-of-flight axis.

Implementation of Ion Spray on a Benchtop Saturn II Quadrupole Ion Trap.

Alexander Mordehai* and Jack Henion, Drug Testing and Toxicology, NYS College of Veterinary Medicine, Cornell University, 925 Warren Dr., Ithaca, NY 14850

The current excitement in electrospray and ion spray combined with its potential for coupling modern separation sciences merits continued effort to develop more sensitive mass spectrometric detection devices. Although electrospray LC/MS has been demonstrated on an ion trap mass spectrometer system, we would like to implement this capability on a simple, inexpensive benchtop ion trap that could potentially become widely available if improved performance is demonstrated. The focus of the present study was to: (1) optimize the design of a novel interface for the transport of ions produced by ion spray to the ion trap and (2) develop a rugged and sensitive benchtop mass spectrometer system with an API interface for the on-line coupling of high performance liquid chromatography (HPLC) and capillary electrophoresis (CE).

We have successfully demonstrated the feasibility of modifying a commercial Saturn II GC/MS quadrupole ion trap for sampling and detecting gas-phase analyte ions produced by ion spray at atmospheric pressure. This is accomplished using the standard (60 L/s) turbomolecular vacuum pump supplied with this system, but with an attached one-stage vacuum region and ion sampling system constructed in-house. Gas-phase ions produced by ion spray are sampled through a 75 μm nozzle and focussed through a flat diaphragm (400 μm i.d. orifice) that separates the first pumping stage (960 L/min, 0.3 Torr) from high vacuum (60 L/s, 7×10^{-5} Torr residual; 2×10^{-4} with He dampening gas). The unique features of the design are "electric skimmer" ion optics geometry designed for ion focusing in the first vacuum region and a "liquid shield lens" at the atmospheric pressure region. The "liquid shield lens" facilitates using higher flows of aqueous solvents while maintaining a stable ion current and good sensitivity. Ion optics in the first vacuum region ("electric skimmer" geometry) provides ion focusing with a focal point at the Mach distance from the nozzle opening following the electrostatic drift region with ion transfer into the high vacuum region outside the Mach disk. In the high-vacuum region the ion optics consists of an Einzel lens assembly powered by a combination of four DC power supplies.

An applied DC voltage in the first vacuum region produces ion fragmentation via "up front" CID that provide structural information in addition to molecular weight information. A mass spectrum of tetrabutylammonium hydroxide (used as a calibration compound) is the same as the MS/MS spectrum obtained from our triple quadrupole mass spectrometer (potential difference across the first vacuum region was 65V).

To test the ruggedness and utility of this instrument as an on-line detector a series of experiments were conducted coupling HPLC and CE to the the API-ion trap system. The compounds chosen for these studies were small quaternary ammonium drugs: succinylcholine, neostigmine, ipratropium and tetrabutylammonium hydroxide. These charged compounds were chosen because they are not amenable to gas chromatographic analysis (GC) without pyrolysis, so the combination of liquid chromatography or capillary electrophoresis with mass spectrometry may provide a preferred tool for their identification at the low nanogram level. Good quality mass spectra (s/n>15) were obtained from a synthetic mixture containing 5 ng/each and 150 pg/each for micro HPLC and CE, respectively. The total column effluent (40 μL/min) was directed to the mass spectrometer in the HPLC experiment. The analysis of a synthetic mixture containing four quaternary ammonium compounds by CE/ITMS is shown in Figure 1. The potential drop across the first vacuum region was 70 V. It is interesting to note that compounds are identified not only in extracted ion current profiles, but they also apparent in the total ion current electropherogram. This feature allows detection of unknowns using the API/IT technique with HPLC and CE. A representative full-scan mass spectrum of the data obtained by CE/ITMS is shown in Figure 2 for 150 pg neostigmine (scan #275, Figure 1) The base peak is the molecular ion, *m/z*=223, while the mild "up-front" CID conditions used also lead to the formation of two minor structurally informative fragment ions at *m/z*=208 and 72. The system is presently amenable to on-line analyses with full-scan detection limits of 1-5 ng for LC/MS and 150 pg by CE/MS[1].

A Flow Injection Interface for Electrospray Ionization Mass Spectrometry with a Small Quadrupole Mass Spectrometer

William H. Cusworth, III,* and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

An electrospray interface is designed for coupling with a Hewlett-Packard 5971A MSD quadrupole mass spectrometer and a flow injection delivery system to be used in process analysis. The electrospray part *(1)* consists of a 20 cm long, 0.4 mm I.D. stainless-steel capillary (Figure 1. c) embedded in an alumina tube (h) which is adjustably positioned in a vacuum housing tube. In-axis movement is provided by set screws (j) leaning against the mounting QF-50 flange, while off-axis adjustments are made by moving the mounting piece (i) from outside the vacuum by set screws furnished with sapphire balls. The alumina tube can be resistively heated up to 130°C and the temperature is monitored by a thermocouple. The interface is pumped by a 16 cfm mechanical pump to 0.8-0.9 Torr at 85°C capillary temperature. The gas expansion part is separated from the intermediate vacuum region by a Beam Dynamics skimmer (d) with 0.4 mm i.d. orifice, which is mounted on the downstream end of the interface and vacuum and electrically insulated by a Teflon gasket. The interface is mounted on a QF-50 flange welded axially to the MSD vacuum housing which is further furnished with a port for a 250 L/s diffusion pump welded perpendicularly to the ion source region. The latter is maintained at ≈ 4 x 10^{-4} Torr as measured at the MSD ionization gauge. The ion source mounting of the MSD has been modified to include two pairs of ion deflectors (e) and an einzel lens (f). The analyzer and detector region is separated by a conductance limit and pumped by the MSD diffusion pump.

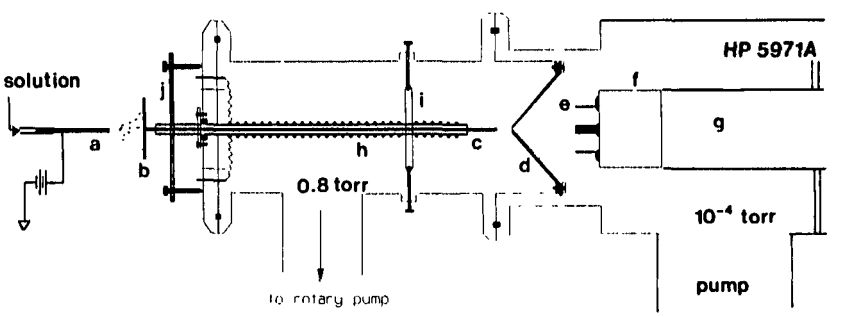

Figure 1. Electrospray interface for HP 5971A MSD.

Spraying is done from a 24 gauge syringe needle (Hamilton) maintained at +4-5 kV. The transfer capillary, skimmer and all focusing elements can be charged independently to ±300 V, although discharge between the capillary and the skimmer is observed at higher voltages. The whole system fits on a standard desk and could be mounted on a cart.

Electrospraying 2 x 10^{-4} mol/L $(n\text{-}C_4H_9)_4N^+Cl^-$ provides 0.22 μA total current at 4.5 kV of which 50 pA is transported through the capillary and detected on the skimmer. Passing through the skimmer results in about a ten-fold reduction of ion current. The further transport of ions into the ion source and the analyzer is hampered by the gas expansion in the intermediate region and small imperfections in the skimmer orifice alignment with the ion source; the latter is mounted with the analyzer on the MSD lid.

Our SIMION *(2)* ion trajectory simulations (Figure 2) suggest that the problem of ion transport could be solved by introducing a cylindrical focusing electrode that would prevent off-axis drift of ions emerging from the skimmer orifice. The electrode, which is currently being installed, is made of rolled stainless steel mesh to insure good gas conductivity and will reach into the skimmer inner cone. The simulations further suggest a variety of capillary-skimmer-electrode voltages that should allow improved ion passage into the mass analyzer.

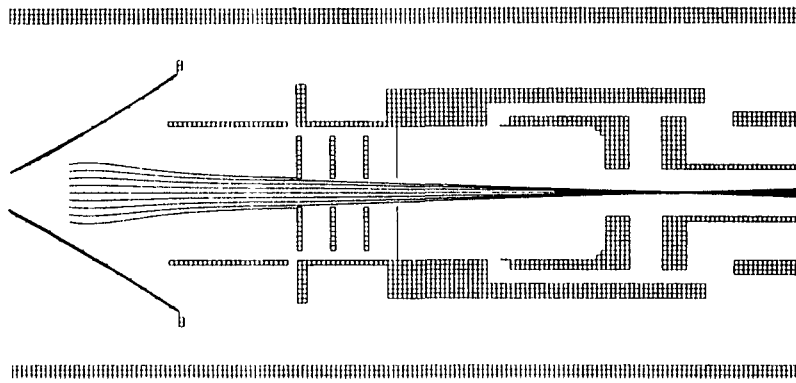

Figure 2. SIMION ion trajectory calculations in the intermediate region. Skimmer: +125 V, electrode -75 V, initial beam divergence 3°, ion kinetic energy 10 eV.

AN ATMOSPHERIC PRESSURE CHEMICAL IONISATION INTERFACE FOR LC/MS ON A MAGNETIC SECTOR MASS SPECTROMETER

Woolfitt, A.R., Bateman, R.H. and Major, H.J., VG Analytical, Fisons Plc., Floats Road, Wythenshawe, Manchester, M23 9LE, England.

An electrospray ion source for the VG AutoSpec high performance double focusing magnetic sector mass spectrometer has already been described (1). Relatively minor modifications are required to affect the conversion to the Atmospheric Pressure chemical Ionisation (APcI) mode of operation, namely the inclusion of a corona discharge needle in the atmospheric pressure region, and the design of a dedicated nebuliser probe (Figure 1). This APcI probe, operated at ground potential, produces an aerosol containing sample and solvent molecules by means of a combination of pneumatic and heat nebulisation. Solvent flows of up to 1.5ml/minute can be accommodated. Ionisation subsequently takes place as a result of the corona discharge between the needle and the counter electrode.

APcI on a magnetic sector mass spectrometer allows accurate mass measurements. Figure 2 shows the mass measurement of fenfluramine (MW 231) to within 2mDa, obtained by loop injection using PEG 200 as an internal standard and a resolution of 4000 (10% valley definition).

Figure 3 details the APcI LC/MS analysis of a mixture of three triazine herbicides. A 4.6x250mm C-18 column was used, and the herbicides (165ng each) were eluted isocratically at 0.5ml/minute using 1:3 water:acetonitrile. There was a good correlation between the UV trace and the chromatogram.

REAL-TIME MASS SPECTROMETRIC EVALUATION OF OLFACTOMETER PERFORMANCE

P.R. Nelson and R.A. Jennings
R.J. Reynolds Tobacco Company, Bowman-Gray
Technical Center, Winston-Salem, NC 27102

INTRODUCTION

An olfactometer presents odorant stimuli to the nose and then measures the psychophysical and physiological responses of either humans or animals. An important design criterion of an olfactometer is that it rapidly provide a constant, known odorant concentration to the subject. Verification of the delivery characteristics of the olfactometer at low (ppm, ppb) concentrations provides a daunting task. Detectors such as a photo-ionization detector (PID) can be used to quantify concentrations of many odorants. However, the PID is insensitive to some compounds and is not sensitive enough to determine other odorants at low ($<10^{-3}$ vapor saturation) concentrations. Due to slow response time, many PIDs are unsuitable for determining the time necessary to attain steady state odorant concentrations.

An atmospheric pressure chemical ionization (APCI) mass spectrometer is ideally suited to studying the time dependant behavior of an olfactometer. The mass spectrometer provides a real-time output on a time scale with sufficient resolution to evaluate olfactometer odorant delivery characteristics. In addition, the instrument is sensitive enough to determine concentrations of many compounds at the ppb level.

A SCIEX TAGA 6000 APCI mass spectrometer was interfaced to the outlet of an olfactometer for this investigation. The odorant 4-oxopentanoic acid was chosen as an example because it combines many of the worst properties (low volatility, hygroscopic, solid at room temperature) of odorants which would be evaluated with the olfactometer.

OLFACTOMETER

Detailed olfactometer descriptions have been published elsewhere (1,2); a brief description of the system evaluated in this investigation follows. To generate a constant, known concentration of odorant, air follows one of three paths through the olfactometer. One stream of air passes through an odorant saturator which is immersed in a constant temperature bath (A). At flows below 6 lpm, the air passing out of this path is saturated with odorant vapor. Flow through this path is regulated to control odorant concentration. Air following the second path flows through a water vapor saturator. Flow through this path is regulated to control humidity of the final effluent (B). Dilution air follows the third path through the system and is not treated in any way (C). All three flows are combined and make up the olfactometer output. Mass flow controllers are used to regulate flow through each path in the system. Different odorant concentrations are generated by varying the ratio of air passing through the odorant saturator to the total flow through the olfactometer. For example, if an odorant concentration of 10^{-3} times the saturation vapor pressure at a total flow of 30 l/min is desired, then the flow through each path (A, B, and C) would be 30 ml/min, 5.4 lpm and 24.6 lpm, respectively. For the case of 4-oxopentanoic acid, the saturation vapor pressure of the odorant was 600 ppm at 60°C, and the above flows would provide an effluent concentration of 600 ppb.

MASS SPECTROMETER

Odorant concentrations were monitored in real time using a SCIEX TAGA 6000 APCI mass spectrometer. The instrument was operated in the positive ion mode for this investigation. Because a pure component was being sampled, there were no problems with interfering ions and it was not necessary to use MS/MS to monitor the odorant.

The APCI mass spectrum of 4-oxopentanoic acid is unusual in that it contains a large number of fragment ions. The most intense ions in the APCI mass spectrum of this compound are: m/z 117-45%, m/z 99-100%, m/z 71-10%, m/z 61-25%, and m/z 43-10%. All the air exiting the olfactometer was directed into the ion source of the spectrometer. For this investigation, the concentration of the analyte

was monitored using the protonated molecular ion at m/z 117. The spectrometer was set to determine the intensity of this ion once every second. The mass spectrometer was used to detect concentrations of odorant as low as 60 ppb, and the LOD for 4-oxopentanoic acid was estimated to be 6 ppb.

RESULTS

In the original olfactometer configuration, fairly long lengths of tubing were used, water vapor was added to the dilution air upstream from the odorant, and the total flow through the spectrometer was 10 liters per minute (lpm). Initial testing was performed at odorant concentrations of ≈ 6 ppm. Figure 1 shows the relative concentration of odorant delivered as a function of time for the original olfactometer configuration. Following activation of a valve to supply odorant to the TAGA, nearly 9 minutes elapsed before a steady state odorant concentration was delivered. This long lag between valve activation and achieving a constant concentration was unacceptable.

Successive modifications were made to the olfactometer following which the performance of the apparatus was re-checked by APCI-MS. The most significant modifications were: total flow through the olfactometer was increased from 10 lpm to 30 lpm; tubing lengths following the saturator were minimized (≈ 50 cm. overall); and the water vapor was added at the last possible moment before the effluent flowed through a switching valve. Figure 2 illustrates the performance of the olfactometer following modification. In the final configuration the odorant rapidly achieved the target concentration when a valve controlling odorant delivery was activated.

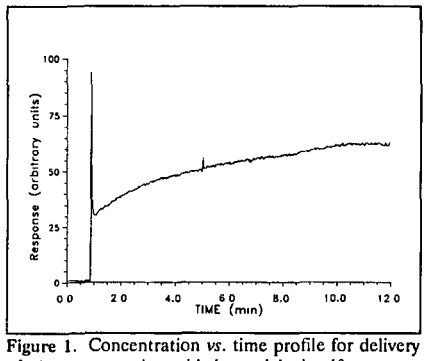

Figure 1. Concentration *vs.* time profile for delivery of 4-oxopentanoic acid by original olfactometer configuration

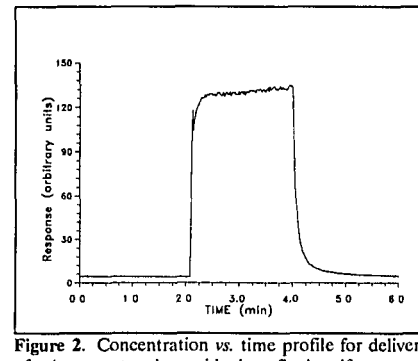

Figure 2. Concentration *vs.* time profile for delivery of 4-oxopentanoic acid by final olfactometer configuration

CONCLUSIONS

The application of real-time mass spectrometry to the olfactometer optimization process allowed rapid evolution of the olfactometer design. Within approximately four hours, the olfactometer was repeatedly modified and tested, and proper operation at all necessary flow rates was demonstrated. Were it not for the availability of the real-time mass spectrometer, optimization of the olfactometer would have been more difficult.

Direct Thermal Analysis of Chewing Gums for Terpenes, Sesquiterpenes and BHT

John J. Manura
Scientific Instrument Services, Inc.
1027 Old York Rd., Ringoes, NJ 08551

Introduction

Consumer groups have become increasingly concerned over the health and safety of various food additives and artificial flavoring compounds as well as the chemicals used in the production, packaging, storage and preservation of these food products. The antioxidant and food preservative Butylated Hydroxytoluene (BHT) is widely used throughout the food industry and is considered to have toxological significance. In the U.S. BHT is added to many brands of chewing gums.

Previous methods for the analysis and quantification of BHT in chewing gum utilized a 16 hour solvent extraction. The following method was developed using the Short Path Thermal Desorption System and the Direct Thermal Desorption Technique to accurately identify and quantify the BHT in chewing gums quickly and without the use of any chemical solvents. In addition to BHT, the various terpenes, hydroxy-terpenes and sesquiterpenes which give the gums their characteristic flavors were also identified.

Experimental

One to 10.0 milligram samples of the thinly sliced chewing gums were placed directly into the Glass-Lined Desorption Tube on top of a glass wool plug. To this the internal standard (100 nanogram of d_{20}-BHT in methanol) was added. The desorption tube with sample was then attached to the S.I.S. Short Path Thermal Desorption System and a syringe needle attached to the end of the desorption tube. The samples were purged with carrier gas for 1.0 minute to remove the methanol solvent, then injected into the GC and desorbed or extracted for 10.0 minutes into the GC injection port at a desorption temperature of 125° C. The volatiles and semi-volatiles extracted from the gum were trapped at the front of the GC column which was held at 0° C during the desorption process. After desorption was complete, the GC was temperature programmed from 0° to 300° at a rate of 4° per minute to produce the total ion chromatogram. The mass spec (H.P. MSD) detector was scanned from 45 to 300 amu at 2 scans per second. The peaks were identified via a computer match from the Wiley-NBS library from the mass spectrometer scans.

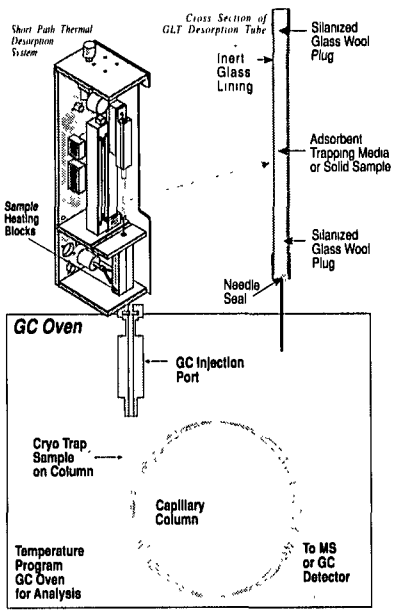

Fig. 1 Direct Thermal Desorption of Chewing Gum by Thermal Desorption Quantification of BHT

In order to quantify the BHT in the chewing gums samples, BHT stock solutions were prepared in methanol. An internal standard stock solution was prepared consisting of d_{20}-BHT at a concentration of 50 ng/ul in methanol. This solution was then utilized to prepare a stock solution of BHT at a concentration of 200 ng/ul. Successive dilutions using the internal d_{20}-BHT solution produced the required stock solutions. Two ul of each of these solutions were injected into empty GLT desorption tubes and the Direct Thermal Desorption technique was used to analyze the samples as described above. Extracted ion profiles for the major ions for the BHT and d_{20}-BHT were used to prepare the calibration curves for BHT. For the quantification of the BHT in each of the gum samples, two ul of the same internal standard solution was injected into the desorption tube with each of the gum samples. The ratios of the BHT/d_{20}-BHT selected ions was used to quantify the BHT in each of the gum samples. The various terpenes, hydroxy-terpenes and sesquiterpenes were also semi-quantitated from this same internal standard, assuming a response factor of 1.0 for each of these compounds relative to the d_{20}-BHT.

Conclusion

The Direct Thermal Desorption technique utilizing the Short Path Thermal Desorption System has proven to be a versatile and time-saving technique not only for the qualitative analysis of the various flavoring terpenoids in chewing gums but also for the quantification of these organic compounds. Utilizing this technique with deuterated internal standards has proven to be an extremely accurate technique for the quantification of BHT between 20 ppb and 400 ppm without the need for solvent extraction or other sample preparation. The accuracy of the technique has proven to be better than 5%.

The unique advantage of this technique is first that it is quick and requires no sample preparation. Secondly, no solvent extraction is required which eliminates the exposure of laboratory staff to solvents and also eliminates the disposal of the solvents. In addition the thermal extraction of the volatiles and semi-volatiles from the solid sample is thorough and complete and no trace foreign contaminants from the extraction technique or solvents contribute to the chromatograms. The Direct Thermal Desorption Technique makes it possible to identify all the volatiles and semi-volatiles present in the solid sample accurately and quantitatively By selecting the proper desorption temperature, the user can determine the complexity of the chromatogram. The same technique has been used to quantify BHT in cereals, packaging materials and plastics. This methodology could readily be applied to a rapid qualitative and quantitative quality control procedure for the food and packaging industry.

Flow Injection Thermospray Mass Spectrometry for the Automated Analysis of Potential Agricultural Chemicals

*Mark J. Hayward, Joseph T. Snodgrass and Michael L. Thomson
American Cyanamid Company
Agricultural Research Division
P.O. Box 400
Princeton, NJ 08543-0400

Flow injection Thermospray (TSP) mass spectrometry (MS) has been developed and utilized for molecular weight and structural confirmation for thousands of potential new agricultural chemicals. Initially, it was necessary to find a set of TSP conditions which provide an optimal compromise between delivering reproducible, informative mass spectra and being sufficiently universal and rugged for a wide variety of compound types. Two sets of TSP conditions which are used to obtain both positive and negative ion spectra have been found which work extremely well. As a result, flow injection TSP-MS now provides the required information in approximately 70% of the mass spectrometric structural confirmations performed at the Agricultural Research Division of American Cyanamid.

The high degree of success using flow injection TSP-MS has led to the development of instrumentation to fully automate these analyses. An IBM PC/AT compatible computer is used to control sample delivery, data acquisition and data output. The PC performs the functions of both terminal and operator for a Finnigan TSQ 46 triple quadrupole mass spectrometer and its Data General Nova 4X data system, while simultaneously controlling a Micromeritics 725 (Alcott) autosampler and its Reodyne 8126 pneumatically actuated 6 port sampling valve. Furthermore, the need to document analyses in a manner that is consistent with Good Laboratory Practices (GLP) has led to automated documentation for the instrument analysis log, as well as for the headers of the electronic data files and the printed spectra output. The new automated flow injection TSP-MS system has improved the efficiency of mass spectrometric operations at the Agricultural Research Division by reducing the instrument time required to record spectra and minimizing the required analyst intervention.

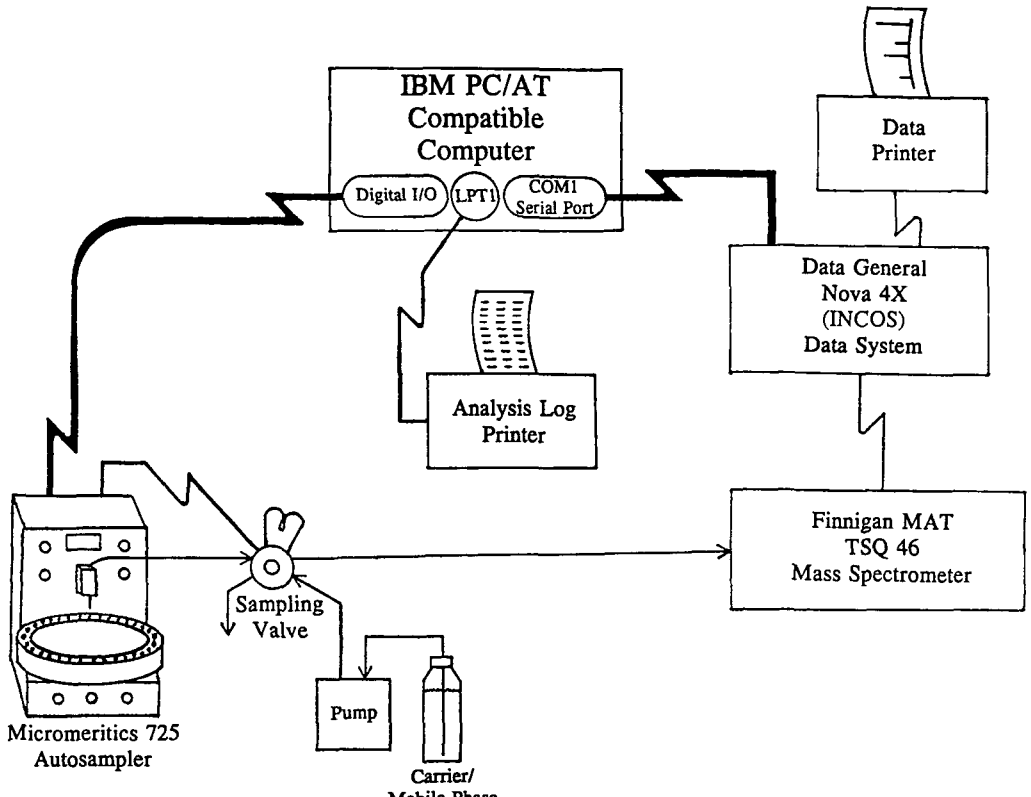

Figure 1. Schematic showing the control and data line connections linking the PC, autosampler, mass spectrometer data system, mass spectrometer, and printers. All operations are coordinated by a program running on the PC which issues the same commands to the mass spectrometer data system that would normally be entered by an operator. The program also controls and monitors the autosampler, and sends sample log information to the analysis log printer.

Fast Neutral Beam Ionization FT/ICR Mass Spectrometry of High Molecular Weight Compounds

Patrick A. Limbach, Hyun Sik Kim, and Alan G. Marshall†

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

The feasibility and analytical utility of a fast neutral SF_6 beam (FNB) ionization source coupled to an FT/ICR mass spectrometer have been demonstrated previously.[1] Several instrumental improvements have been made in order to increase the utility of this technique. Previously, the primary ion current was in the low picoampere range. In order to increase the primary ion current, two changes were implemented. The exit aperture of the SF_6 beam source was made larger. To compensate for the increased gas load to the mass spectrometer, another stage of differential pumping and a second conductance limit were added to the flight tube. These modifications make it possible to produce primary ion current up to tens of nanoamperes.

Previous results and SIMION[2] simulations led us to believe that the secondary ion current detected in the trap was, in part, limited by the trap geometry. Therefore, we have constructed an elongated cylindrical open ended ion trap[3] for use with the SF_6 beam source. Prior results were obtained by use of a continuous SF_6 beam, with the obvious disadvantage that SF_6^- ions and neutrals continue to bombard the trapped ions during the trapping and subsequent excitation/detection events. Therefore, we have implemented a pulsing circuit controlled by the 1280 computer to allow for pulsed beam operation.

These changes to the experimental configuration have increased the analytical capabilities of the FNB FT/ICR instrument. The FNB FT/ICR instrument now allows for the analysis of insulating materials, fullerenes, polymers, and biomolecules. For example, we have re-analyzed a Teflon® film in greater detail with the improved instrument. The polymer distribution is now detected to m/z ≈900 (Figure 1), and high-resolution analysis shows that the polymer contains impurities leading to two separate repeating chains. Operating the FNB source in the neutrals-only mode with pulsed-beam operation increases the sensitivity of analysis for insulating materials. The ability to produce and detect fullerene ions is due to the larger primary ion current of the source (since fullerenes were not observable with our prior lower-current source). We have detected C_{60} and C_{70} signal from extracts of the soot produced by arc-welding of graphite (Figure 2). In order to improve the negative-ion mode spectra, SWIFT excitation[4] has been used to remove the interfering residual beam signals. Detection of biomolecules with the FNB FT/ICR instrument has been demonstrated with results from lipids and small proteins. This work was supported by NSF (CHE-9021058) and The Ohio State University.

ANALYSIS OF REACTIVE GASES WITH QUADRUPOLE MASS SPECTROMETRY AND GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Jeremiah D. Hogan and Tom Talasek
Texas Instruments, Inc.
13546 N. Central Expwy.
Dallas, TX 75265

As critical dimensions in semiconductor chips continue to shrink, the requirements for reagent purity during the fabrication process also increase. One of the key reagent commodities in wafer fabrication is bottled gas. Previously, semiconductor manufactures were forced to rely on the purity claims of gas bottlers for their quality control. Though requirements for purity have increasingly become more stringent, the gas suppliers' abilities for low level detection and varied analyses have failed to grow at the requisite rate. For this reason semiconductor manufacturers have taken it upon themselves to develop the necessary technology in-house in order to maintain ultimate control of their incoming gas purity and reliability. Of the many formidable challenges facing the growth of this technology, the most difficult and important requires analyzing for trace level components in reactive or hazardous gases. Tungsten hexafluoride, boron trifluoride and trichloride, arsine, phosphine, chlorine, and silane are all gases which are used regularly in the production of modern semiconductor wafers. The need for accurate, low level contamination control in these and similar gases is a given. The ability to perform some of these analyses, however, is not yet established. Our lab is currently in the process of developing analytical capabilities toward the goal of analyzing trace level gaseous impurities in a wide variety of bottled gases. In most cases, the method of choice is mass spectrometry (MS) or gas chromatography/mass spectrometry (GC/MS).

Work to be presented here details equipment modifications and methods being developed for the analysis of several inert and hazardous gases for trace level contamination from gaseous impurities, and moisture utilizing quadrupole MS and GC/MS.

Using direct inlet quadrupole mass spectrometry as a screening method to obtain an overview of analyte characteristics has proven to aid in the methods development in this lab. A VG Pegasus gas analysis mass spectrometer with a single sector quadrupole has proven to be very effective for this purpose. Figure 1 below shows a standard 70 eV mass spectrum of NF_3 show predictable fragmentation/recombination products. Closer examination, however finds that there are at least twelve ions produced in the source from NF_3. Actual contaminants present in the sample are found only at or below the low ppm level.

GC/MS of HCl with an HP 5988A with a custom gas inlet system reveals interesting results in that two separate forms of moisture were identified in the analysis: one which elutes prior to the HCl, and another which coelutes with the HCl. It is believed that the latter is in a tightly held "water of hydration" form, and is therefore retained through the column with the HCl gas, and only comes off in the source. This leads to some novel specta, as shown in figure 2 a), wherein during the elution of HCl without the coeluting moisture, only the expected peak is seen, whereas when the water coelutes with HCl, the expected peak is replaced with three other peaks representative of several different forms of protonated and deprotonated HCl (fig. 2 b).

Aberdeen Proving Ground, MD 21005

INTRODUCTION

A good deal is yet unknown about the actual reaction mechanisms in many of the flames that comprise a large share of the power and propulsion generation systems in use today. It is becoming increasingly important that such mechanisms are known due to energy considerations and environmental concerns. Flame optimization with particular attention to product formation and thermal efficiency requires this information.

Sampling by quartz microprobe[1] has been shown to be adequate for stable species and well-suited for GC studies However, large residence times at significient pressures in the probe preclude this technique for reactive species. Most MS studies of radical intermediates have been done by molecular-beam sampling techniques; indeed, the molecular beam is essential in preserving the radicals until they can be ionized Comparison of OH radical concentration profiles determined by optical methods with those determined by molecular-beam mass spectrometry (MB/MS) has shown that minor perturbations of the preheat zone occur but that flame front zone and post-flame regions are relatively undisturbed [2,3] Previous work[3] with $C_2H_4/O_2/Ar$ flames with the present instrument showed that, while laser-based diagnostics were most appropriate for analysis close to the burner surface (0-2 mm), MB/MS was able to investigate many more species concurrently and also able to provide greater detail for some species higher in the reaction zone. It was concluded that in the current instrument MB/MS, while not immune to quartz sampler perturbation, adequately describes nascent chemistry in the flame environment The current study ($C_2H_4/N_2O/Ar$), while relatively simple, includes the more complex nitrogen flame chemistry present in propellant (where oxides of nitrogen are primary oxidizers) and air-breathing flames

EXPERIMENTAL

All of the flames in this study were operated at 20 Torr absolute pressure. The instrument has been described earlier[3] and only its salient components are mentioned. The low-pressure burner chamber was a stainless steel cylinder with an inside nominal diameter of 25 cm and a height of 40 cm Provision for temperature measurement by thermocouple was provided

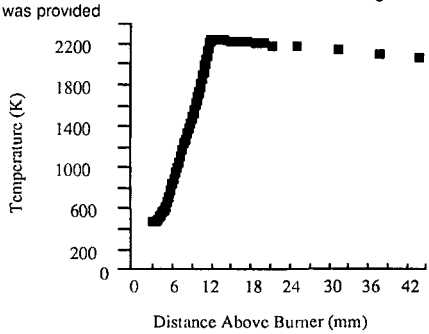

Figure 1 Temperature profile of $C_2H_4/N_2O/Ar$ flame at 20 Torr

The mass spectrometer consisted of an Extrel C50 TQMS inline triple quadrupole mass filter with a concentric-axis ionizer Sampling of the flame gases occurred through a quartz skimmer (250 micron diameter orifice). The expanding gases were collimated through a second skimmer and introduced into the ionization region. The beam was modulated at 200 Hz and ionized Signal was processed with a lock-in amplifier to discriminate background gases and to signal average.

The flame was produced upon and supported by a McKenna-type flat burner. Under proper gas flow conditions the flame was produced in a laminar flow field with the flame front parallel to the burner surface and therefore one-dimensional with respect to the burner surface. Subsequently, the distance from the burner surface to a sampling point in the flame can be used as the reaction coordinate to describe the progress of reaction in terms of species concentration profiles as well as temperature profiles

For these flames it was evident that use of only moderate mass resolution posed a problem. Molecules such as CO_2 and N_2O (nominal m/z = 44) may exhibit the same nominal mass-to-charge-ratio. Differentiation of such species was possible with the triple quadrupole mass spectrometer through the use of collision-induced dissociation (CID) of the ions in the primary ion beam to produce fragmentation patterns unique to each molecule studied. Calibration gas mixtures of each gas were prepared and the fragmentation patterns and branching ratios obtained

RESULTS AND DISCUSSION

In this paper are reported temperature and mass spectrometric measurements of many of the stable flame species in a stoichiometric, premixed $C_2H_4/N_2O/Ar$ flame at 20 Torr The uncertainty in temperature measurements was estimated to be 50 K in the region of peak temperature and 10 K in the preheat region. The temperature profile in Figure 1 clearly

demonstrates flame gas temperatures near the burner surface (about 510 K) that are in excess of that measured by the imbedded thermocouples (about 310 K). Currently, this condition is not included in present theoretical flame models. The region between 0 and approximately 6 mm above the surface is typical of the "dark" or preheat zone of the flame. From 6 to 12 mm the major flame chemistry occurs. This region of steep temperature gradient also contains the visible luminous zone (a light purple or violet color). Above 15 mm is the burnt gas region. This region is on average the hottest region of the flame and is in partial equilibrum with product concentrations near stabilization. Major flame intermediates such as H^+, O^+ and OH^+ are still in abundance[3] (due to space considerations temp versus intensity plots are not included).

Profiles of stable species where mass assignment is not ambiguous are reported in Figure 2. NO and O_2 appear to be produced by predominately high temperature reactions in the upper regions of the luminous zone. Essentially none of these two products appears below 2000 K, and both reach maximum concentration near 2300 K. Since O_2 appears just after NO and has the same profile shape, it is likely that it is produced by the high-temperature reaction, $NO + O \rightarrow N + O_2$.

Figure 3 shows total ion currents observed at nominal m/z = 28 and 44 (each profile normalized to unity). These profiles show the sum of the concentrations of all species at these masses. As shown, little information is available prior to utilizing CID to differentiate between species. The experiment was therefore repeated at m/z = 28 and 44, this time utilizing the entire triple quadrupole mass filter with collision gas present in the second quadrupole. The mole fraction of each gas was then obtained using sensitivity factors obtained during calibration. Comparison of Figure 3 with Figure 2 demonstrates the utility of using CID to obtain the identity of flame species at the same nominal mass. The species lumped into nominal m/z = 28 and 44 in Figure 3 are clearly discerned and the progress of the reaction is now easily traced by looking at the consumption of reactants and the evolution of major products

Fundamental Investigations with a New Atmospheric-Sampling Glow Discharge Ionization Source

D.M. Chambers, D.E. Goeringer, S.A. McLuckey, and G.L. Glish
Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6365

INTRODUCTION

In direct air-monitoring applications a high degree of specificity as well as sensitivity for organic compounds is often desired. Although the ability to characterize compounds with a certain degree of confidence is intrinsic to mass spectrometry, successful adaptation of currently available instrumentation has been restricted to those systems with ionization sources that provide the highest ionization efficiency.

The atmospheric-sampling glow discharge ionization (ASGDI) source has recently been developed in our laboratory specifically for direct analysis of untreated air [1]. Unlike the atmospheric pressure ionization (API) source, air is first adiabatically expanded into an intermediate pressure region before ionization is initiated. This reversed arrangement is advantageous in that ionization occurs at lower pressures and near the skimmer resulting in short residence times and reduced collisional frequencies that limit electron-ion-molecule interactions. This method appears to suppress ion-cluster formation and favor kinetically fast processes over more thermodynamically preferred reactions. Low detection limits have been reported, especially for negative ion formation (1–2 ppt for 2,4,6-trinitrotoluene). Positive ion yields are less as determined by higher detection limits in the low parts per billion range [1].

Studies presented here were undertaken to determine whether a higher level of source performance could be achieved. The approach chosen was to identify the accessible ionization mechanisms that produce intact molecular ions and to determine which parameters enhance these ion yields. These experiments have been carried out on a specially designed ASGDI source that permits the study of hydrodynamic effects and glow discharge processes on ion detection. Only negative ion processes were studied.

RESULTS AND DISCUSSION

The effect of the free-jet expansion on negative ion formation was investigated by skimming different regions of the expansion. This procedure was performed either by mechanically adjusting the skimming position or by altering the source backing pressure thereby changing the expansion dimensions. In each case the general trend that persisted was that skimming had to occur a certain distance behind the Mach disk for DNT anion detection.

Results presented in Fig. 1 show the minimum source pressure required to observe the DNT^- anion signal. Also plotted in the figure are the distances at which the skimmer is located behind the Mach disk. Although lower source pressures cause the Mach disk to form farther downstream closer to the skimmer, a linear increase in skimmer separation from the Mach disk was required to maintain a minimal level of detection. These findings indicate that anion formation is not occurring in the Mach disk and identify the need for a specific pressure requirement on the basis of anode-cathode separation. Even though these findings suggest that anion formation might be independent of gas dynamics, experiments on lateral skimming across the expansion given below show that ion yields are dependent on skimming within the reflected shock boundary. A possible explanation is that species from the reflected shock maintain a portion of their mean molecular flow from the expansion permitting them to reach the skimmer under the proper electron-ion-molecule collision conditions (e.g., residence time, collisional frequency).

In the results presented in Figs. 2 and 3, signals for the DNT anion at two skimming positions, on-axis and 1 mm off-axis, are compared at two skimming distances (sampler-skimmer axial separation), 7 and 12 mm, respectively. At skimming positions farther off axis, from 3 to 12 mm, both DNT and background ions were not detectable regardless of skimming distance, source pressure or cathode voltage. At the 7-mm skimming distance (Fig. 2) ion signals could be observed at lower pressures as skimming was moved 1 mm off-axis. The significance of this response is that ion signal, which was not initially detectable on-axis behind the Mach disk, can be observed when skimming occurs off-axis (i.e., similar source pressures and skimming distance). As the source pressure is raised the distinguishable regions of the expansion become compressed upstream and cannot be discerned as a function of lateral skimming distance. This explanation accounts for the coinciding drop in ion signal with higher source pressures observed at the 12-mm skimming distance (Fig. 3).

Ionization Mechanisms. Ion formation pathways can be discerned from the results presented in Fig. 4 where the source pressure was varied. As either skimming distance or source pressure was increased the DNT anion signal first maximized and then various background ions, O^-, O_2^-, NO_2^-, and CO_3^- began to rise in intensity. The absence of proton abstraction, dissociative, and cluster anion formation products limits the primary ionization mechanism to either electron capture or charge transfer. Because source conditions that favor optimal DNT anion signals can be achieved without the presence of background species, electron capture is believed to be a primary means of ionization. The high gas density environment near the expansion may promote associative electron capture and subsequent stabilization through third-body collision as well as a means to moderate electron energy through inelastic collision for resonant electron capture. Under those conditions that do not yield O_2^-, NO_2^-, and CO_3^-, which require third body collisions for efficient formation, DNT anion production might be restricted to resonant associative attachment where gas density is high enough to moderate electron energies.

A GLOW DISCHARGE ION SOURCE FOR THE ANALYSIS OF GASEOUS/ LIQUID ORGANIC COMPOUNDS.

Daniel Carazzato and M. J. Bertrand
Regional Center for Mass Spectrometry,
Department of Chemistry, University of Montreal, Montréal, Canada H3C 3J7.

Since the introduction of DC glow discharge ion sources in mass spectrometry, there has been very few applications[1] involving organic analysis as most of the work was done on elemental analysis. The technique, re-introduced by Harrison[2] in 1986 uses atomic bombardment (sputtering) of the cathode to eject particles and atoms which are further ionized and mass analysed. Ionization mostly takes place in the negative glow by metastable (Penning) energy transfer when excited atoms in the discharge collide with sputtered particles producing positive ions and slow moving electrons. Electron impact also occurs in the cathode fall before the atoms enter the glow but its contribution to ionic production is much less than that of the Penning transfer. Ions then diffuse through the glow as a result recombination and ion-molecule reactions such as clustering and proton exchange Formation of space charge occurs and the glow potential reaches a value higher than the anode potential. This phenomenom called "plasma overpotential" increases the ion extraction efficiency at the anode and has a value that depends on the source pressure, current density and nature of the discharge gas.It's value is usually in the range of 5-50 volts. Although the use of this technique mainly concerns elemental analysis, it is also possible to analyze gazeous organic compounds introduced into the glow. The use of a noble discharge gas such as argon makes it compatible with gas chromatographic techniques as well as with capillary liquid chromatography if the liquid effluent is vaporized and used as the discharge gas.

The glow discharge source used in this work is illustrated in Figure 1 and has been designed to fit on a Kratos MS-9 mass spectrometer It is mainly composed by a moveable cathode (3 mm dia) and a fixed extraction cone (4 mm dia, 0.4 mm aperture) placed at both ends of a 6 mm ID x 17 mm long glass cell. A roughing pump outlet and a discharge gas inlet have been added on each side of the cell. The purpose of the glass cell is to provide a linear and symmetrical discharge between the electrodes in order to sample each region of the glow by moving the cathode closer to the anode until the glow extinguishes. Additional focussing and extraction plates were used because of the small circular aperture. Two diffusion pumps (total of 225 L/sec) were also connected to the source housing in order to increase the pumping speed. Despite this addition, the pressure in the housing reached 3×10^{-4} torr and the accelerating voltage was brought down to 4 kV to prevent source arcking. The DC discharge was obtained using a homemade 1450 VDC variable power supply floating at the accelerating voltage. During the optimization experiments, the sample was introduced in the source continuously via a 150 µm quartz capillary connected to a temperature controlled vial in order to maintain a constant vapor pressure and, hence, a constant flow rate of the analyte. The pressure in the source could be controlled between 0.4-2 torrs with an argon flow rate of 0.5-4 mL/min Sensitivity studies were conducted, using a GC injector installed on the argon line by injecting different gaseous concentrations of the analyte. When a liquid effluent was used, a stainless steel tubing containing a 15 µm quartz capillary was resistively heated to provide good vaporization of the sample. In this case a 3.1 µL/min flow rate (70:30, ACN/H_2O) was used as the discharge gas

A longitudinal cut of the plasma showed that the plasma was not homogenous, since singly and doubly charged argon ions were found closer to the cathode Furthermore, molecular species were found farther and this suggests that high energy processes (electron impact) at the edge of the cathode fall might destroy them. Ionic mobility can also account for part of the plasma inhomogeneity. Ion distribution measurements have been repeated in the presence of butylbenzene (<0.1%) in the gas discharge(Fig 2). The ions observed and their intensities indicate that proton transfer, electron impact and Penning transfer, are happening in the source. As expected, the signals at m/z 134, 92, and 91 increased when the sampling was effected closer to the cathode.

The mass spectrum (Fig. 3) obtained for butylbenzene at a pressure of 2 torrs shows both low energy processes (m/z 135) and fragments which is an interesting feature. This suggests that at least two ionization processes are involved, one being of the CI type proton transfer (H_3O^+ or ArH^+) and the others consisting in a combination of higher energy processes such as electron impact or metastable energy transfer A more extensive mapping of the source parameters has shown the effects of the source pressure and current with the associated voltages on the intensity of the $(M+H)^+$ and M^+ ions. Results showed that an increase of source pressure increases the

protonation efficiency $(M+H)^+$ while M^+ is not really affected suggesting that electron impact is not the only process that produces it. The combined effect of current and voltage on ion intensities results in a decrease of signal for both $(M+H)^+$ and M^+ if the current values are outside the range of 50-90 µA. The effect was observed for most of the pressures that were studied. Higher pressures also moves the negative glow closer to the cathode reducing the optimum distance. In our experiments the use of higher pressures above 2 torrs was not desirable because of the poor pumping efficiency and arcking problems in the system. Despite of the pressure used, a fair sensitivity was obtained for propyl benzene and 2-heptanone. Detection limits of 100 pg (S/N>3) were obtained for a 25 sec peak width, a limit that can be reduced with a proper injection system such as those found in GC. For technical reasons, isobutane was used in order to evaluate the linearity of the source signal which proved to be linear over at least 6 orders of magnitude. Moreover, the prototype proved to be fairly resistant to contamination and reached a daily resolution of 4000

ADAPTATION OF A TRIPLE QUADRUPOLE MASS SPECTROMETER TO PERMIT GLOW DISCHARGE STUDIES

F.L. King, G.Chen, J.Teng, F.Fotia, L. Meadows, and C.K. Pan
Department of Chemistry, West Virginia University
Morgantown, WV 26506-6045

Introduction

Mass spectrometry is a useful tool for the characterization of glow discharge plasmas permitting the sensitive determination of trace elements in solid samples and the evaluation of thin film deposition processes. The described system permits the identification of the ionic composition of plasmas, the determination of ion kinetic energy distributions, and the evaluation of glow discharge plasma chemistry.

Experimental

A standard triple quadrupole mass spectrometer was modified to permit investigation of glow discharge plasmas, Figure 1. The instrument was equipped with differential pumping through a 1 mm orifice between the ion source and mass analyzer regions. The EI/CI ion source was removed and replaced with a Bessel box energy analyzer obtained from the mass spectrometer manufacturer. The glow discharge ion source, which could be operated with DC or RF power, was mounted in a six-way cross attached to the front flange of the mass spectrometer chamber. A 0.5 mm orifice was placed between the discharge chamber, usually operating at 0.7 torr, and the ion source region of the mass spectrometer, usually operating at 5 X 10^{-5} torr. A simple three-tube Einzel lens was constructed to guide ions from the discharge chamber into the Bessel box.

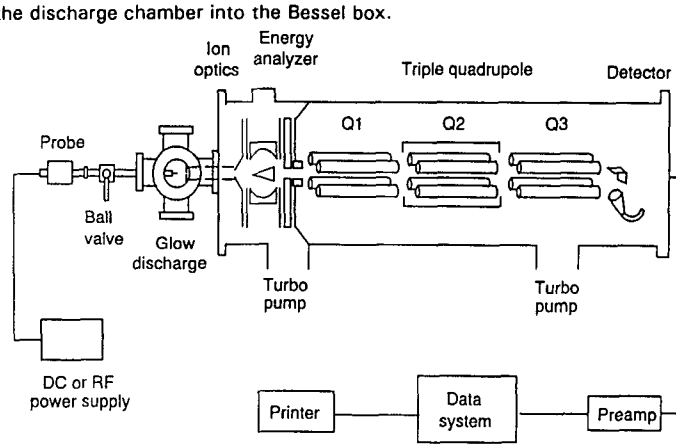

Figure 1. Glow Discharge Mass Spectrometer

Results

The performance of this glow discharge mass spectrometry system was evaluated for both RF and DC-powered glow discharges. Optimum sensitivity yielding low ppm detection limits was obtained for DC-powered glow discharges. In these experiments the neutral beam stop was removed form the Bessel box energy analyzer and the mass spectrometer was operated in a Q3 MS mode. Operation with the neutral beam stop in place or with the instrument in an MS/MS mode was found to reduce sensitivity by a factor of 100.

For the trace element determination of metal alloy samples, relative sensitivity factors were found to be stable for DC discharge powers in the range of 2 to 5 watts, irrespective of changes in discharge current or pressure, Figure 2. Under these conditions RSF values were found to vary by 5% over a three hour time period. These RSF values were observed to vary little as the alloy matrix was changed. The relative abundance of polyatomic spectral interferences, ie. MAr^+, was found to decrease as the relative argon ion temperatures increased. Argon ion temperatures were estimated from the relative abundance of doubly to singly charged argon species in the plasma.

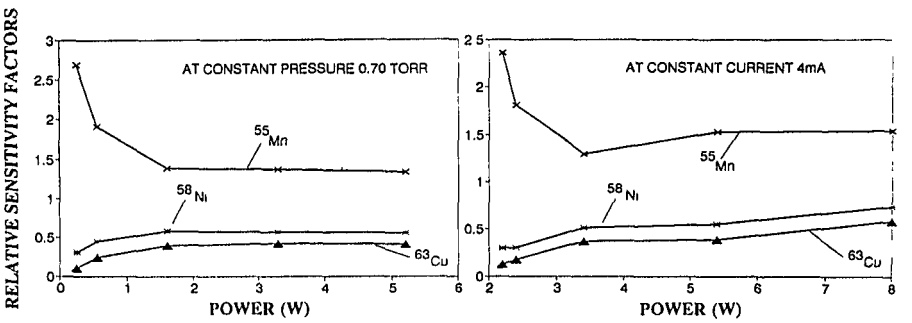

Figure 2. Power Dependence of RSF Values

Discharges supported with mixtures of argon, methane, and hydrogen were examined with this system in an effort to elucidate plasma chemistry relevant to the deposition of diamond thin films. The effect of operating parameters, particularly support gas composition, on the relative abundance of CH_x ions was investigated. In deposition plasmas the presence of C_2 and higher hydrocarbons is associated with poor film quality arising from gas phase aggregation and "powdering". The ratio of CH_x^+ to $C_2H_x^+$ was observed to track the change in estimated argon ion temperature as a function of the dilution of argon with a 5% CH_4/H_2 mixture. A maximum was observed for the 25% dilution. The relative abundance of CH_2^+/CH_3^+ was controlled by the population of metastable argon atoms present in the plasma. This observation is in agreement with reports in the literature of reactions between methane and metastable argon atoms that yield predominantly CH_2 as the product.

A Microwave Induced Plasma Source for Trace Analysis

S. Dheandhanoo[1], S.N. Ketkar[2], S.M. Penn[1] and J.G. Dulak[1]
[1]Millipore/Extrel, 575 Epsilon Drive, Pittsburgh, PA 15238 and [2]Air Products and Chemicals, 7201 Hamilton Blvd., Allentown, PA 18159.

Atmospheric Pressure Ionization (API) Mass Spectrometry has been recognized as a very sensitive analytical technique. The primary ionization is generally induced by either a DC corona discharge or a beta particle emitter such as ^{63}Ni. In the case of the DC corona discharge, the sensitivity of API depends on the proton affinities (PA) as well as the relative concentrations of the analytes According to the rate-equation analyses of Ketkar et al.[1], the sensitivity for analytes with lower proton affinities decreases as the concentration of analytes with higher proton affinity increases. This analyses was experimentally verified. The degradation in sensitivity can be attributed to the competitive reactions in a complex matrix. The analyses also suggests that this effect can be eliminated by using higher density plasma sources, such as a microwave-induced discharge. In this experiment, we investigated the effect of a high plasma density source on the instrumental sensitivity for compounds of completing PA.

The experiment was carried out using a newly developed microwave induced plasma source (MIP) and an EXTREL triple quadrupole mass spectrometer. The microwave discharge region was a glass tube of 0.5" ID. A KIVA 2450-MHz microwave generator with an Evenson microwave cavity was used in this experiment. The typical forward and reverse microwave power was 30W and 2W, respectively. Air was used as a carrier gas. The flow of the sample into the MIP was controlled by a leak valve. The operating pressure inside the MIP source was maintained at about 8 torr for discharge stability. Air samples were prepared by injecting hexane solutions of known concentrations into the carrier gas by using a syringe pump. The concentrations of the analytes in the sample gases were calculated from the injection rate of the hexane solutions, the concentrations of the analytes and the air flow rate.

Three analytes were used in this experiment; dimethyl methyl phosphonate (DMMP), diisopropyl methyl phosphonate (DIMP) and pyridine. Among these three compounds, DMMP has the lowest proton affinity (PA). The analyte ions from the MIP were analyzed by a TQMS which was operated in a single quadrupole mode. Intensities of ions of mass 124, 139 and 80 amu represent the concentrations of DMMP, DIMP and pyridine respectively.

In this experiment, the concentration of DMMP was kept at 250 ppb while the concentration of DIMP and pyridine were varied. The concentrations of DIMP and pyridine varied between 125 -1000 ppb. The results of the experiment are shown in Figs. 1 and 2. There is no significant change in the response of the instrument to DMMP as the concentrations of either DIMP or pyridine increases. This implies that the sensitivity of the instrument for DMMP is not affected by the presence of the compounds of higher PA when a high plasma density source is employed. The results of this experiment support our previous prediction that using a high plasma source eliminates the matrix effects on instrument sensitivity for compounds of differing PA.

A Dual Ion Source to Produce Cs^+ or I^- Ions For Secondary Ion Mass Spectrometry

J. Zhou, W. Ens, and K. G. Standing

Physics Department, University of Manitoba,
Winnipeg, Manitoba, Canada R3T 2N2

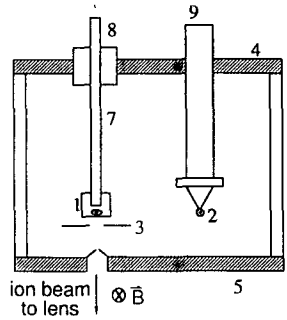
I. Introduction

Cesium ions have been widely used in secondary ion mass spectrometry as projectiles. If positive secondary ions are measured, the target is set at a positive potential, for example +15 kV. Thus cesium ions will *lose* 15 keV energy while passing through the acceleration region for secondary ions. But if I^- ions are used as projectile ions, they will *gain* 15 keV energy while passing through the acceleration field.

A dual Cs^+ / I^- source has been constructed to enable positive and negative secondary ion spectra to be examined under I^- and Cs^+ bombardment respectively. With the I^- ion source, the secondary ion mass spectra of several molecules have been measured on a reflected time-of-flight mass spectrometer. Comparison measurements with Cs^+ and I^- ion bombardment have been carried out for insulin with similar voltages on the ion gun.

II. Set-Up, Experiment and Results

Figure 1 below shows a schematic diagram of our dual ion source.



1. Furnace
2. Cesium Aluminosilicate Bead
3. Extracting Plate
4. Rotatable Top Flange
5. Bottom Flange
6. Glass Tube
7. Tantalum Tube
8. I^- Plug
9. Cs^+ Plug

The Cs^+ and I^- ion sources are mounted on two separate plugs, which can move up and down and rotate relative to the big top flange. The top flange itself can be rotated to switch the two sources . With the two rotations and the up and down motion, we can make a three-dimensional spatial adjustment to get the best ion extraction. The cesium ion source consists of a cesium aluminosilicate bead on a tungsten filament[1]. At high temperature, there will be positive cesium ion emission from the bead. The negitive iodine ion source is composed of a high temperature furnace opening plugged with sintered Lanthanum Hexaboride (LaB_6)[2]. Iodine vapor is introduced into the furnace through a tantalum tube. At high temperature LaB_6 produces large amounts of electrons. When passing through porous LaB_6, iodine molecules will dissociate into I atoms, and electrons will attach to the I atoms to form negative ions.

To compare secondary ion emissions under Cs^+ and I^- bombardment an insulin target was bombarded with I^- or Cs^+ ions for 15 kV accelerating voltage and the same beam intensity. The voltage on the ion gun was 20 kV for I^- and 25 kV for Cs^+. Thus the bombarding energy was 35 keV for I^- and 10 keV for Cs^+. Results are shown in Figure 2. Figure 3 and 4 show the reflected spectra of insulin and ACTH 18-39 under 35 keV I^- bombardment.

III. Conclusion

Positive secondary ion mass spectra taken with similar voltages on the ion gun show considerably stronger secondary ion signals for I^- bombardment than for Cs^+ bombardment, as expected. The advantage increases with mass.

Introduction

Liquid SIMS (LSIMS) including FAB has proven to be a versatile means for making gas-phase ions from wide variety of non-volatile and/or preformed ionic substances. This method, basically a soft ionization technique, yields pseudo-molecular ions with some fragmentation.

Many improvements for increasing the yields of LSIMS have been made over the years. The improvements include: employing a massive charged particle for the primary ion beam, increasing the kinetic energy of the primary ion beam, and lowering the pressure in the source region. These improvements have been incorporated into the design for LSIMS on the VG ZAB-T. Further improvement in production yields can be obtained for surface-active materials by appropriately pulsing the primary ion beam.

During LSIMS of a surface-active material, the initial burst of secondary ions upon initial sample irradiation is often > 5X greater than the steady-state yield. The initial burst of ions reflects the surface concentration of the analyte whereas the steady-state yield depends on its bulk concentration. Initial production intensities can be maintained if the primary ion beam is pulsed with frequency and duty cycle such that the surface concentration of analyte can be maintained [1,2].

Pulsed methods of signal generation are basically incompatible with the normal operation of conventional sector machines which requires a continuous source of ions. Such instruments must be scanned very slowly which results in very inefficient collection of data from the sample. Alternately, TOF and hybrid FTMS instruments, though pulsed instruments, do not have the general MS/MS advantages of a complex sector instrument.

The VG ZAB-T, a four sector instrument of BEBE design with an MCP/photodiode array as one of the final detectors can readily accommodate pulsed LSIMS and yet maintain the MS/MS advantages. The array can readily integrate the signals that would be generated by pulsed LSIMS for the efficient data collection. In addition, the array has a multichannel advantage in that a wide range of m/z's can be simultaneously collected thus alleviating problems related to scanning with pulsed signal generation.

Thus pulsed LSIMS would be compatible with an instrument of this type operating in both MS and MS/MS modes and would be expected to show advantage over the continuous mode through enhanced S/N of the detected ions. The S/N advantage is principally due to increased signal ion production relative to background chemical ion noise. Such improvement would be useful in the MS/MS analysis of large precursor ions such as those derived from biomolecules.

Objectives

Implementation of pulsed LSIMS on the ZAB-T has been constrained by several considerations. No basic structural modifications of the instrument would be made. Modifications would be transparent to the normal operation of the instrument. And the modified Cs^+ gun would conform to the normal configuration and placement of the Cs^+ gun on the instrument.

The intent is to enhance the functionality and sensitivity of the instrument without eliminating or impairing the performance of other modes of operation or compromising overall instrumental reliability. In addition, the pulsed Cs^+ gun would function adequately in the continuous mode and be interchangeable with the regular Cs^+ gun for that purpose.

The duty cycle and repetition frequency of the pulses from the Cs^+ gun need to be variable to accommodate various sample conditions related to surface repair. To function effectively, the pulsing of the Cs^+ gun must be synchronized with data readout of the array detector to insure proper timing overlap with signal generation.

Design

The Cs^+ gun was modified by insertion of a grid in front of the Cs source, a gating method of direct beam modulation. Pulsing the primary ion beam is performed by driving the grid bias from the quiescent off state to the on state for the specified time period. Normal continuous operation is accomplished by forward biasing the grid, the on state. The modifications are transparent to normal operation, which is also useful for the setup of pulsed operation.

The intensity of the incident primary ion beam can also be modulated by physically deflecting the beam relative to the sample. The gating approach was selected because it is less wasteful of the expensive Cs^+ source of the gun in that the gun is not continuously producing ions in contrast to the deflection method.

The modified Cs^+ gun differs from the standard Cs^+ gun only by a more complicated source or anode piece. The modified gun was constructed by essentially duplicating the standard gun except for anode details and the main body which was made from Teflon instead of ceramic.

Modifications to the anode piece, which is also the source carrier, involved recessing by 2.5mm the Cs source pellet within the anode piece and electrically isolating it. On the front side of the anode a grid, mounted on its own carrier, was placed in the same position originally occupied by the Cs source. The anode, which now functions as an extractor, was connected to a spare feedthrough on the gun body.

New gun control circuitry was designed, built and assembled to produce pulses of Cs^+ ions of variable repetition rate and duty cycle. The new control circuitry is inserted into the HT lines before the Cs^+ gun and acts upon the potentials provided by the Cs^+ gun power supply.

The circuitry that directly controls the grid must float at the potential of the Cs^+ source, up to 50kV. This is achieved by powering it entirely by a photocell which is in turn illuminated by a small high-intensity lamp. Control information is coupled optically by a fiber-optic cable. The circuitry is housed in an 1" thick plexiglass box for electrical isolation.

The operation of both the modified and unmodified guns was modeled by using SIMION v4.0. The operating parameters for the modified Cs^+ gun were derived on the basis of such studies.

Relative Ion Yield Measurements in Liquid Matrix Assisted Secondary Ion Mass Spectrometry

T. Y. Yen, E. Barofsky, and D. F. Barofsky
Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331-6502

Liquid Matrix assisted secondary ion mass spectrometry (LSIMS) and fast atom bombardment (FAB) are widespread, sensitive analytical techniques. The secondary ions generated from the topmost layer of the liquid matrix's surface are governed by an analyte's chemical environment and the characteristics of the impinging primary ions. For liquid matrices like glycerol, sensitivity is partly controlled by the surface activity of the analyte in the matrix.

We have constructed a pulsed time-of-flight (TOF) mass spectrometer to study the influences of incident keV primary ions on the ionization processes in liquid matrices. We have used deoxyadenosine monophosphate (dAMP) and deoxyguanosine monophosphate (dGMP) in presence of a surfactant (Hexadecylpyridinium acetate)[1] for our studies because this system affords us a degree of control over the surface activity of analyte molecules.

The relative yield of a given ion species in our measurements is defined as the number of secondary ions detected in a given experiment divided by the number of deprotonated dAMP ions produced by bombardment with monoatomic Au primary ions. The deprotonated ion yields of dAMP and dGMP have been systematically studied as functions of the velocity and the energy deposition (stopping power) of atomic and polyatomic primary ions. In our instrument, the primary ions are produced by a liquid metal ion column. The different species of ions, i.e. monoatomic and polyatomic ions of Ga, In, Au, and Bi, are selected by Wien filter.

Analyte compounds are prepared in a water solution, and mixed with 10mM surfactant-glycerol solution. Final analyte concentration used in this study were between 0.01 and 1 mM, and sample amounts ranging from 0.4 to 3 nL were introduced into the mass spectrometer. The sensitivity of our time-of-flight mass analyzer is very good. We have detected down to 4-5 fmol dAMP and dGMP (Figure 1).

Figure 2 and 3 show the deprotonated ion yield of dAMP (3pmol) and dGMP (3pmol) as a function of stopping power of primary atomic ions. The stopping power is calculated as the sum of nuclear stopping power and electronic stopping power[2]. This result indicates that the deprotonated ion yield of dAMP bombarded by Bi^+ or Au^+ are about 10 fold larger than obtained from bombardment by Ga^+. Figure 4 shows the deprotonated ion yield of dAMP as a function of the velocity of primary monoatomic and polyatomic ions. The deprotonated ion of dAMP generated by bombardment with cluster ions of Au and Bi (Au_2^+, Au_3^+, Bi_2^+, and Bi_3^{+2}) is greatly enhanced (about 20 times) over that generated by bombardment with monoatomic Au^+ and Bi^+ ions.

Our studies have shown that the deprotonated ion yields of mononucleotides, localized on the matrix surface through the action of a surfactant, are strongly dependent on the stopping power of primary ions. According to our measurements, the mechanism of ionization seems to follow the thermal spike model[3] in which the ion yield is quadratically proportional to the stopping power. The enhancement of secondary ion yield by cluster ion bombardment is clearly a nonlinear effect, that is the energy deposited (stopping power) by a single cluster ion is significantly larger than the summed energy deposited by individual monoatomic ions equal in number to the atoms contained in the cluster ion.

VAPORIZATION VS THERMAL DECOMPOSITION IN THE LASER DESORPTION PROCESS

Davinder S. Nagra, Jianyun Zhang, and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta T6G 2G2, Canada

Laser desorption is a powerful method for the generation of ions and neutrals. In particular, matrix-assisted laser desorption (MALD) has become an increasingly important technique for ion generation in mass spectrometry. With MALD in a time-of-flight mass spectrometer (TOFMS), molecular ions can be observed with little fragmentation even for proteins as large as 300,000 Da. Although a large amount of energy is implanted to the sample and substrate, these fragile biopolymers apparently survive the desorption process. The question here is why these biopolymers can be vaporized with little or no degradation? An equally important question is what roles does the matrix play in the desorption process? The understanding of these questions is important not only for the overall fundamental understanding of the MALD mechanism but also for designing mass spectrometers and searching for new matrices for performing MALD.

This work is focused on the studies of the rapid heating and the gas expansion processes in MALD. In studying MALD, it is perhaps advantageous to separate the LD process into two temporal events. One is the initial interaction between the laser beam and the sample and/or the sample substrate. The other is the gas expansion after the interaction. In the initial desorption process, sample molecules and the matrix gain some kinetic energy as well as internal energy from the laser beam. A sharp temperature rise at the sample substrate is generally observed. However, because of the short laser pulse (< 1 μs), the heating rate is very high. There is evidence suggesting that rapid heating could prevent the sample from thermal decomposition. Indeed, we have recently developed a pulsed rapid heating (PRH) probe [1] to vaporize small biochemicals based on this fact. In PRH, a heating probe that consists of an electrically heated plunger driven by a solenoid is used to make a brief contact with the sample probe to vaporize the sample. The resulting gas phase molecules are studied by laser-induced multiphoton ionization in a reflectron TOFMS.

We now extend this PRH probe work to provide information on questions such as what is the minimum heating rate needed to prevent thermal decomposition? and how does the heating temperature affect the vaporization and decomposition? The current version of the PRH probe is capable of varying the heating rate from >100 K/sec to 1×10^6 K/sec. In addition, the heating temperature can be adjusted from room temperature to >500 °C. We find that with a fixed heating time, an increase in the heating temperature generally increases the intensity of the decomposed products. However, if a high heating rate is used, decomposition is not observed across the entire working temperature range. For small biochemicals, the minimum heating rate required for the vaporization of the intact molecules is compound dependent. For tyrosine, a heating rate greater than 15,000 K/s is sufficient to prevent decomposition. A heating rate of 24,000 K/s is needed for tryptophan. In general, if the heating rate is in excess of 1×10^5 K/s, thermal decomposition is not observed for many compounds studied. Now, in MALD, if any heating is involved in the desorption process, the process is quite rapid. Even that a 1-μs laser pulse produces a temperature increase of 1 K would result in a heating rate greater than 1×10^6 K/s. In reality, the heating rate is much higher than this. Thus, this PRH probe work on the minimum heating rate study indicates that there should not be any significant amount of thermally decomposed species generated in MALD. The small fragments from the matrix molecules often observed in MALD are very likely from photodissociation of neutrals, followed by photoionization and/or from photofragmentation of the intact molecular ions of the matrix.

Next we study the gas expansion process. After the initial laser desorption, the sample and matrix molecules expand into the acceleration region of the TOFMS. During this expansion, energy can be redistributed among various species at different energy states. Thus, decomposition could take place if a molecule acquires a sufficient amount of internal energy before it exits the acceleration region. Here we use resonant two-photon ionization (R2PI) spectroscopy to study the molecules generated from MALD. In this work, a continuous flow probe is used to deliver sample and matrix through a capillary tube and onto a stainless steel frit, upon which laser desorption is carried out (see Figure 1). Glycerol is used as the matrix and LD is performed with a CO_2 laser. The sample molecules expand into the acceleration region of a reflectron TOFMS, where R2PI is performed with a tunable dye laser. For the first time, we demonstrate that sample molecules, at least for the model compounds studied herein, can be internally cooled during the MALD process. It is found that vibrational temperatures of the molecules can be significantly lower than the room temperature if an adequate expansion is provided. This preliminary work confirms that supersonic

jet expansion is indeed a dominate process after the desorption and the molecular cooling may play an important role in preventing sample decomposition in MALD.

Figure 2A shows the room temperature R2PI spectrum of benzimidazole in the vicinity of its origin 0-0 transition. This was obtained by directly inserting the sample into the vacuum chamber without performing MALD. In this case, benzimidazole produces sufficient vapor in the vacuum to allow us to obtain a wavelength spectrum. Figure 2B is the R2PI spectrum of the same sample obtained by using MALD for neutral generation, with a 7 cm distance between the probe tip and the ionizing laser beam. There are several important features shown in these two spectra. In Figure 2A the 0-0 origin band (277.57 nm) is observed along with two comparable vibrational hot bands (278.10 nm and 278.63 nm), corresponding to 1-0 and 2-0 transition, respectively, with a vibrational spacing ~ 69 cm^{-1}. Clearly, any decrease in the internal energy of this molecule will result in the intensity reduction of these hot bands in the R2PI spectrum. Thus, this molecule should serve as an excellent model to examine the molecular cooling process in MALD. Figure 2B shows the origin band along with one weak hot band at 278.10 nm. The origin band has been greatly intensified and become much sharper, which indicates that good rotational cooling is obtained for benzimidazole in MALD.

The vibrational temperature of the molecule can be estimated from population distribution among the internal states. It is found that the vibrational temperature of molecules in the case of Figure 2B is about 46K for the vibrational mode associated with the hot bands shown. The rotational temperature is, at present, unable to be derived due to the lack of spectral resolution to reveal the individual rotational states and also the lack of the data for the rotational strength. Nevertheless, from the comparison of origin band peak widths in the spectra shown in Figures 2(A) and (B), one would expect that it should be much lower than the room temperature. Indeed, the spectrum shown in Figure 2(B) is comparable with those obtained by using a nozzle source. This study indicates that significant internal molecular cooling may have occurred in the MALD process.

In summary, pulsed rapid heating during the initial interaction between the laser beam and the sample and/or the sample substrate along with the supersonic jet molecular cooling during the gas expansion process in MALD prevents sample molecules from thermal decomposition.

A Commercial Ion Trap (ITD) Modified by Monopolar Excitation for Resonant Ejection and Extended Mass Range.

Xiaomin Wang and Diethard K. Bohme, Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, ON, CANADA M3J 1P3

Raymond E. March, Department of Chemistry, Trent University, Peterborough, ON, CANADA K9J 7B8

A commercial quadrupole ion trap detector (ITD), Finnigan MAT Model 800, has been modified to allow operation in the asymmetric monopolar mode.[1] Two physical modifications were carried out on the ITD; one of the end-cap electrodes was electrically isolated so as to permit application of a supplementary oscillating potential, and a pulse controller was added to the electric system. The ITD has been modified to permit extension of the mass range of the ITD which has been achieved by resonant ion ejection using an oscillating potential of appropriate frequency applied asymmetrically on the end-cap electrode during the mass scan, in analogy with the mass range extension achieved in the dipolar mode.[2] The Figure below showns the mass spectrum for $C_{24}F_{45}N_3$ obtained by resonant ejection using a supplementary rf potential of 10 V_{0-p} oscillating at 200 kHz. Under these conditions q_z = 0.45. The three peaks at *m/z* 1166 due to $[M-F]^+$, where M represents $C_{24}F_{45}N_3$, *m/z* 866 due to $[M-C_6F_{13}]^+$, and *m/z* 771 due to $[M-C_6F_{18}]^+$ are paticularly interesting since they are not present in the normal mass scan which extends only up to *m/z* 650. The spectrum clearly shows that the mass range of the commercial ion trap detector has been extended two-fold to ca. 1300 Da/charge. The relatively simple modifications which are required, particularly the addition of a pulse controller, permit a degree of temporal latitude in the normal scan function. When the modified scan function is combined with a supplementary oscillating potential to an electrically-isolated end-cap electrode, the resulting versatility of the commercial ITD is enhanced considerably.

DESORPTION OF IONS FROM GLYCEROL FILMS BY BACKSIDE IMPACT WITH MASSIVE CLUSTER IONS

John F. Mahoney
Phrasor Scientific, Inc, Duarte, CA 91010

Terry D. Lee and Paul A. Martino
Beckman Research Institute of the City of Hope, Duarte, CA 91010

Introduction

We have recently reported on a novel sputtering method that uses a primary beam of massive, multiply charged clusters for desorbing biomolecular ions [1]. Spectra obtained by massive cluster impact (MCI) mass spectrometry are characterized by a near absence of fragment ions and greatly reduced background derived from matrix ions. This difference from spectra obtained by FAB or liquid SIMS was attributed to low impact energies (< 0.7 eV/amu) of the primary cluster beam which precludes excessive radiation damage and ionization of damaged matrix material. In our view, the desorption process results from material ejection initiated by classic macroscopic shock waves formed by hypervelocity cluster impacts [2]. It is suggested that clusters that impact matrices with energies/nucleon in the range $0.01 < E/N < 1.0$ eV/amu provide an extremely soft method for sputtering intact molecules. As a test of the shock wave unloading mechanism, we have examined ion ejection from the frontside of thin glycerol films when the backside of films were bombarded with 10 kV massive clusters and cesium ion beams (see Fig.1).

Experimental

The heavy, multiply charged clusters used in this study were formed by electrohydrodynamic atomization of a 70% water/30% glycerol solution in vacuum. Aided by electrostatic deflection, focused cluster beams were directed onto the backside of thin, concave glycerol films (≈ .009" thk) as shown in Fig.2. Glycerol films were prepared by supporting glycerol solutions inside a 2 mm circular aperture machined into a thin target plate. The plate served to block transmission of any ions formed on the backside of the film. The target plate with film was installed in the source block of a JEOL HX100HF double focusing mass spectrometer.

Results

Fig.3 shows the frontside spectra (top) for a NaI/glycerol film bombarded by a +6kV xenon FAB gun. Fig.3 also shows the backside spectra (bottom) for the same film bombarded by the massive cluster beam. Although nearly identical spectra were obtained in each case, the MCI shock-induced backside spectra were much weaker (≈20-30 times less base peak intensity) than the frontside xenon FAB spectra. The weaker MCI spectra is attributed to the relatively thick glycerol films used in the experiment.

Conclusions

Unlike MCI cluster backside bombardment, no ion emission was observed when films were back-bombarded with +10 kV cesium ion beams. We therefore attribute the phenomena of ion desorption from the frontside of films back-bombarded with massive, hypervelocity clusters to shock unloading during the expansion of compressed material at the free surface of the film. To date, no cluster-induced shock spectra has been observed without preformed ions in the film solution. Preliminary data also indicates that the relative intensity of cluster-induced shock spectra increases with decreasing film thickness. Therefore to decrease film thickness (and shock wave attenuation effects) we are planning future experiments using gold foils (< 3μ thick) with both dry and wet ultrathin sample overlayers.

OPERATING CHARACTERISTICS AND RELIABILITY OF CHANNEL ELECTRON MULTIPLIERS IN ICP-MS

W.D. Jamieson and A.R. Kean, Fenwick Laboratories, 5595 Fenwick Street, Suite 200, Halifax, Nova Scotia, B3H 4M2;
K.W. Halligan, Sciex, 55 Glencameron Road, Thornhill, Ontario, L3T 1P2;
A.D. McGreer, K and M Electronics, 11 Interstate Drive, West Springfield, Massachusetts, 01089.

The cost-effectiveness and reliability of channel electron multipliers (CEMs) for the detection of ions in mass spectrometry led some years ago to their extensive use, particularly in quantitative analytical applications. However, many laboratories have found CEMs to be less durable in ICP-MS service than in other mass spectrometry applications. It is considered this is probably due to the much higher ion currents often encountered in ICP-MS, and to occasional or accidental exposure of the CEM to exceptionally high ion currents caused by operational accidents or by ions yielded by major analytes present at levels much higher than anticipated.

The operating characteristics and reliability of two types of commercially available CEMs were compared in ICP-MS service as the instrument was in regular use in an analytical services environment. The alternate CEMs were installed in the same Perkin Elmer - Sciex ELAN 5000 ICP-MS, an instrument which uses a pulse-counting approach to detect ions. One (Galileo Model 4816B) used a conventional glass-based design, the other (K and M Model 7550M) used a monolithic ceramic cartridge body. The gains, optimization curves, dynamic ranges and noise characteristics were compared over a service interval of several months for channel electron multipliers of the two types. Differences in pre-installation treatment were also considered.

The glass CEM was in service from 24 May, 1991 until 15 January, 1992, when, though still usable, it was replaced by an alternate ceramic CEM so the performance of the latter could be assessed. This ceramic CEM had been extensively exposed to air during fabrication of custom mounting hardware and in storage before installation. Its performance, initially extremely good, deteriorated over about a month of use, requiring increasingly higher operating voltages for optimum performance. Though still usable and with higher gain than the original glass CEM, it was replaced on 14 February by a second ceramic CEM which had not been unduly exposed to air before installation.

Some results are shown in the Figures. One Figure shows the response recorded for ^{103}Rh in the course of typical daily sensitivity checks over the past year, as a standard solution containing 20 µg/L of Rh was aspirated into the plasma after all tuning parameters had been optimized in a standard way. Typical increased responses due to operating voltage increases for the glass CEM are indicated, as are those due to replacement of the RF power tube. Note the initial sensitivity was lower for the replacement ceramic CEM than for that first used. The other Figure shows voltage / response curves for the second CEM in February and in May.

Based on four months use, the ceramic CEMs seem more durable and more consistently sensitive (by 50 to 100%) in ICP-MS service, whether or not the CEM had been unduly exposed to air prior to installation, which may, indeed, temporarily enhance the sensitivity. The sensitivity of the ceramic CEMs was less variable day-to-day, and showed less temporary decrease after exposure to excessively high ion currents. Our experiments continue.

Characteristics of a High Gain Single Channel Electron Multiplier Under High Ion Dose Conditions

P. Mahaffy, K.Galuk[#], D. Harpold, and H. Benton[#]
Code 915, Goddard Space Flight Center, Greenbelt, MD 20771 and
Nyma Corp.[#], Greenbelt, MD 20770

Introduction: A systematic study of the effects of high ion doses on multiplier characteristics has been carried out on a widely used commercial pulse counting multiplier. For this very high gain multiplier, a reversible change in multiplier gain with input ion current is observed over a significant portion of the operating range of the multiplier. In addition, high input detector ion currents (for example, an average of 5×10^6/sec) extending for a period of several hours lead to significant changes in multiplier performance which persist for a time period of several hours. Extended tests on one multiplier operating under nearly current saturated conditions were carried out for several weeks and *the multiplier lifetime established.*

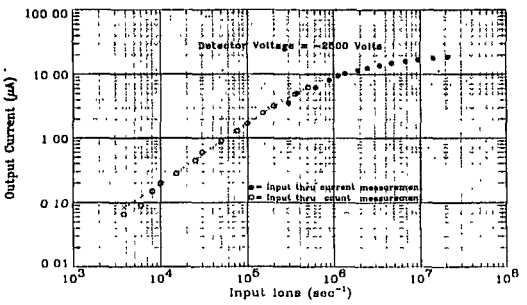

Figure 1. The output current saturation characteristics of the high gain channeltron are shown.

The ion source used in these studies, with a beam deflection/raster capability, was separated approximately 45 cm from the channeltron detector and typically operated at -2500 V. N_2^+ ion input rates into the detector in the *range* 10^3 to 10^8 *ions/sec could routinely* be achieved at the detector and measured by monitoring the input ion current on the multiplier deflector or in a separate experimental configuration on a Faraday cup mounted past the deflector on the ion beam axis. The ion energy was approximately 20 eV. Pulse characteristics such as the pulse height distributions were measured with either a 1 GHz transient recorder or with a CAMAC based pulse processing system. The multipliers studied were Galileo series 4870 pulse counting channeltrons.

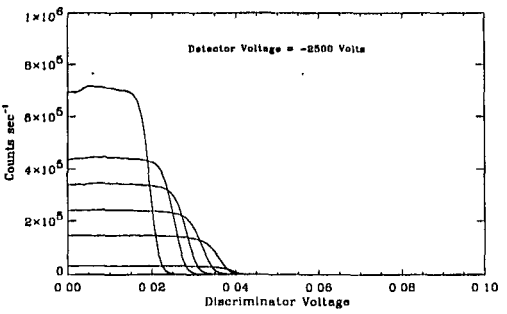

Figure 2. *The dependence of the count rate on the discriminator* level shows that the average pulse amplitude is a strong function of count rate.

Results: The multiplier resistance is approximately 120 MOhm. The multiplier output current begins to saturate for an *input of* 10^6 *to* 10^7 *ions/sec as shown in* Figure 1. The pulse height distributions for the high gain multipliers studied, however, change considerably with count rate. This *effect is illustrated in Figure 2* where a number of pulse height distributions are recorded as a function of multiplier count rate. These changes with input ion current are entirely reversible. The multiplier gain shows a substantial change as a function of count rate, from approximately 10^8 at low count rates to approximately 6.5×10^7 at the highest input currents shown in Figure 2.

The following measurement sequence was repeated for a period of many days in order to determine the lifetime of the multiplier and the multiplier characteristics prior to failure.

- the multiplier pulse height distribution and gain were measured and recorded for an input ion current of 10^6 ions/sec.
- the ion input rate was increased to 10^7 ions/sec with a 50% duty cycle (50 m-sec ON and 50 m-sec OFF) for a time period typically 15 - 45 min depending on the rate at which the multiplier characteristics were changing.
- the input ion current was reduced and the multiplier pulse height distribution and gain measured for an ion input of 10^6 ions/sec,

Over the course of the 5 to 8 hour daily time periods of ion bombardment, the multiplier underwent substantial changes. Figure 3 shows the changes in output current for a constant input current over a time period of several days. Over a time period of several minutes the multiplier does not recover. However, by the next morning the multiplier has regained its original characteristics. The time of recovery was shown to be several hours. The recovery was measured by first reducing the activity of the multiplier by operating at the high input rates for a period of several hours and then monitoring the multiplier characteristics periodically for a period of several additional hours. These effects were reproduced for three separate multipliers. The lifetime of the multiplier was long enough under these conditions, however, that only one long-term test was carried out. The end of the useful lifetime of the multiplier under the conditions of this test came at a total ion dose of approximately 2×10^{12} . The lifetime test was carried out over a period of 23 working days.

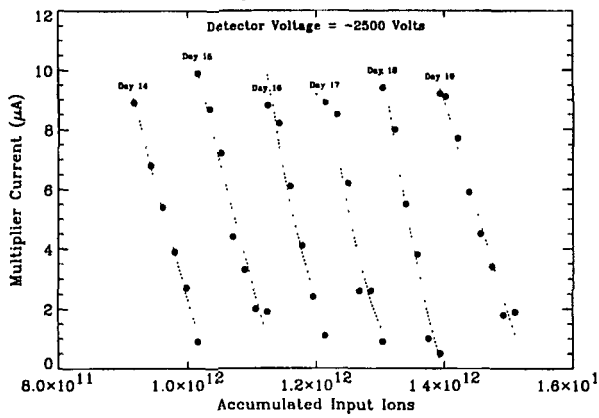

Figure 3. The daily change in multiplier current output for the high ion input rates described above are shown for several days of the extended test. The multiplier count rates show a similar pattern.

Discussion: In the course of this multiplier lifetime test, various effects were observed which could affect measurement accuracy in certain pulse counting mass spectrometer experiments. The very high gain and the sharp pulse height distribution for these detectors is expected to generally enhance the measurement accuracy. However, the large change in gain with count rate suggests that care in selection of the discriminator level should be exercised so that higher count rates do not cause the average pulse height to fall below the discriminator threshold. The changes in multiplier efficiency after extended high input ion current exposures may also be of concern in certain applications. If this degradation is due to ion sputter damage of the active thin film multiplier surface, it may not be of as great concern in secondary dynode mass spectrometer configurations where primarily electrons impact the channeltron surface.

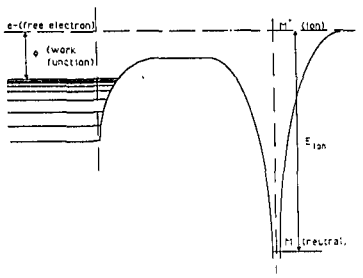
Improved Positive Ion Detection Resulting from Reduction of the Surface Work Function

Stephen A. Ruatta, John F. Mahoney, Julius Perel and Edward S. Parilis
Phrasor Scientific, Inc., Duarte CA 91010

Introduction

Detection of ions in most mass spectrometers is facilitated by some type of electron multiplier detector which provides 'built-in' amplification before electronic processing. Detection of both positive and negative ions is usually achieved by accelerating the ion into the surface of some material. The collision results in emission of negative secondary electrons and ions (for positive incident ions) or positive ions (for negative incident ions).

In this work we have concentrated on detection of positive ions by emission of secondary electrons and negative ions.



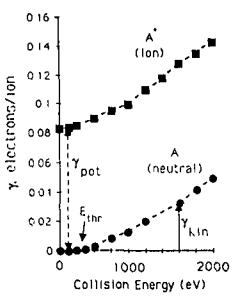
Electron Emission

Secondary electrons can be produced by either potential or kinetic emission: Potential emission of electrons results from the neutralization of the incoming ion and ejection of a surface electron due to the energy released on neutralization. This is the energy difference between the electron affinity of the incident ion and the work function of the surface as shown in the adjacent Figure[1]. If we can reduce the work function, we can increase the potential emission.

Kinetic emission results from the electronic interaction between the surface and the incoming ion above a certain velocity. For example, an ion with a single charge and a mass of 600amu must be accelerated to about 7000eV before kinetic emission becomes significant[2]. Larger masses require higher collision energies (dynode voltages). The yield of secondary electrons with ion velocity and the relative contributions from potential and kinetic emission are shown below[3].

Secondary Ions

The emission of secondary ions is also dependent on the work function of the surface. The mechanism for emission of ions is not well understood but negative ion yeilds are a function of electron availability at the surface. Negative ion yeilds should be proportional to an exponential function of (I-φ); the difference of the surface work function and the IP of the (neutralized) incoming ion. By reducing φ, we can also increase the number of negative secondary ions as well as electrons, which also results in improved detection.



For these reasons we are continuing to investigate ways of reducing the work function of mass spectrometer dynodes to increase the yield of secondary electrons and ions resulting from surface impact of positive ions.

Experimental

Much of the work done thus far has been to characterize materials in terms of both their work function and their long term stability with respect to air exposure and typical mass spectrometer pressures of 10^{-4} to 10^{-7} Torr. Since a surface at a pressure of 10^{-6} Torr will be covered with a monolayer of adsorbate in 1 second (nominally), these surfaces must be fairly robust.

Results

Listed below are selected materials that we have tested to determine their suitability for enhanced secondary emission. Clearly, some materials (eg Cesium), while having low work functions, are too reactive to use outside of a vacuum or glovebox environment and are thus not practical for use in a mass spectrometer.

Elements or "Standard Materials"

Stainless Steel, Aluminum, Sodium, Copper-Berylium, Zirconium, Tantalum, Tungsten, Titanium, Manganese, Samarium, Zinc, Copper, Gold, Indium... We have tried these and others. Most of those that we have tried either are not significantly different from stainless steel, form oxides with higher work functions or are not amenable to dynode formation.

Implanted Elements

We have tried implantation of both Cesium and Lithium on a number of substrates including Silicon, Stainless Steel and Tungsten. Cesium has a low work function but its mean implanted range (at 20keV) is low because of its mass/size. Lithium was tried because it has a range about 10 times that of Cesium however its work function is not as low.

Preliminary results indicated that annealing the implanted material might help to protect the surface - unfortunately, to achieve a useful degree of protection resulted in evaporating most of the alkali metal.

Higher projected ranges (mean range of 0.75μm) could be achieved by using 1MeV Cesium ions or 100keV Lithium ions - Instead we have pursued work with alloys.

Alloys

Barium alloys were tried because BaO tends to diffuse into the bulk. Unfortunately this effect doesn't seem to make any difference.

Other alloys are currently under study. We are currently testing an alloy with a work function of about 3.75eV in AlR and is relatively unchanged even with a thin layer of pump oil on it. Preliminary results indicate that the this alloy may increase the signal/noise (over conventional dynode materials) by at least a factor of at least 2 for masses less than 1000amu. We are now in the process of more carefully quantifying this increase, especially for very high masses (>10000 amu) where this effect should be much larger.

Coatings

Coatings of alkali metals such as Cesium are not stable in air. LaB_6 is a special case but does not have a very good work function at low temperatures. We are still working on other possible coatings. One problem is that they must be very smooth to avoid being too noisy.

Discussion

To this point we have concentrated on finding stable materials with low work functions. A few materials look very promising.

Complementary testing of materials by measurement of secondary emission is in progress.

Dynodes with reduced work functions should allow significant improvements in detection sensitivity, especially for high molecular weight ions. Recent theory[4] indicates that ions with multiple charges may exhibit a nonlinear increase of potential emission with increasing charge.

AN INNOVATIVE DETECTOR DESIGN FOR THE ION TRAP MASS ANALYZER

John Gray, Joan Cardin, and Tony Bauco - Galileo Electro-Optics Corporation, Sturbridge, Massachusetts

Recent years have witnessed a significant rise in interest in the ion trap as a mass analyzer. Instruments for use in high volume applications as well as research and development have been designed based on this technology. Historically, the trap is mounted vertically in the instrument with the exit aperture at the bottom followed by a single channel electron multiplier detector (see figure 1). This configuration may suffer from the fact that the multiplier is easily contaminated due to particulates exiting the trap and falling via gravity into the entrance aperture of the detector. In addition, the on axis geometry of the detector may result in excessive noise due to detection of otherwise unwanted neutral or charged particles or photons generated in the source or trap. Single channel detectors also tend to be rather bulky in comparison with standard ion trap mechanical dimensions as well as being difficult to mount and align properly.

The objective of our current program is to develop a detector which is more compact and more sensitive than commonly used single channel detectors as well as being simultaneously less susceptible to noise or performance degradation induced by contamination falling from the trap. To this end we have designed a microchannel plate (MCP)-based detector with an unusual rear-looking geometry which should make it uniquely suited as a detector for the ion trap. The design incorporates a center-hole geometry which allows the ion beam to pass completely through the detector whereupon it is deflected back toward the MCP (see figure 2). This geometry has the advantage of shielding the MCP from particulate contamination as well as photon noise generated in the analyzer. In addition, a conversion dynode may be substituted for the deflector electrode for enhanced sensitivity at higher mass. The detector is compact and is designed for easy installation and removal to limit instrument down time.

Preliminary design considerations will be presented along with modeling data including an investigation of various deflector geometries. We will also propose a more sophisticated device using a gradient field-type deflector fabricated as part of the detector housing. Future work will include testing the optimized configuration in both quadrupole and ion trap instruments.

STANDARD ION TRAP MULTIPLIER CONFIGURATION

Adjustable Multipole Elements in Sector Field Mass Spectrometers

M. Przewloka, A. Przewloka, H. Wollnik and H. Haas [1]
II. Physikalisches Institut der Universität Giessen, 6300 Giessen, Germany
[1] *ISOLDE Collaboration, CERN, CH-1211 Geneva, Switzerland*

Misalignments of particle spectrometers or beam guidance systems can be categorized in different orders. For deviations of zeroth order the optic axis of the particle beam does not pass through the middle of the foreseen aperture, for deviations of first order the focus point is shifted upstream or downstream from the foreseen position, etc. To compensate such misalignments of n_{th}-order, versatile magnetic or electrostatic multipole elements of n_{th}-order have been proposed [1], built and used [2,3]. One example is the ISOLDE-3 on-line mass separator in which ideally for all used multipole elements the multipolarity, the orientation and the field strengths are computer controlled.

1. **The magnetic multipoles**
   To compensate 2_{nd}- and 3_{rd}-order image aberrations inside a magnetic sector-field one can either shape the field boundaries of a homogeneous or inhomogeneous sector-field, or one can use a superposition of different multipole surface coils in the main field. While in the first case the multipole-strengths are fix and not adjustable, one can in the second case easily and independently adjust correction elements of each order to correct the corresponding image aberrations. A Magnetic octupole surface coil for example requires a linear increase of the current density with the radius of the magnetic sector.

   To produce the required field distributions by surface coils for the 90° and 60° ISOLDE-3 sector-field magnets, we have used wires of constant separation connected by a resistor network. Here each sector-field magnet was provided with separately adjustable hexapole and octupole surface coils for which the corresponding power supplies ($I_{max} \approx 25\,A$) could be adjusted and controlled from the ISOLDE-3 control room.

2. **The Electrostatic multipoles**
   To produce - under computer control - ion-optical effects of superimposed and independently adjustable electrostatic hexapoles and octupoles, we have built and tested electrostatic multipoles using a 32-wire 'squirrel cage' configuration (see Fig. 1) in which each wire requires a separate power supply [2]. Such elements were inserted in three field-free regions in the ISOLDE-3 on-line mass separator. For this purpose electrostatic potentials of up to $\pm 750\,V$ were generated, using computer controlled power supplies.

By activating the magnetic and electrostatic multipole elements at the ISOLDE-3 separator we demonstrated [3] a drastic increase of the mass resolving power. Using a tungsten-surface ionization source a mass resolving power $m/\Delta m > 10000$ (FWHM) was achieved, which allowed the isobaric separation of ^{37}Ca from ^{37}K as is shown in Fig. 2.

For the 'new' ISOLDE-3 separator at the CERN-Booster now called High Resolution Separator (HRS), we have thoretically optimized again the modified ion-optics using the same magnetic and electrostatic multipole elements. After additional tests it is planned to use the HRS in the future as standard on-line mass separator with a mass resolving power > 10000 (FWHM).

Ion Trajectories and Focusing Properties of an Electrostatic Ion Mirror and a Solenoid Coil Represented by Transfer Matrices

T. Sakurai and M. Baril
Département de Physique, Faculté des Sciences et de Génie,
Université Laval, Ste-Foy, Québec G1K 7P4, CANADA

An electrostatic ion mirror and a solenoid coil are utilized as focusing elements in particle spectrometers and beam transport systems. In order to design a high performance spectrometer, accurate estimations of ion trajectories are necessary. In this report; precise ion trajectories through an electrostatic ion mirror and through a solenoid coil are calculated. The inferences of extended fringing fields for finite apertures of the ion-optical devices are studied. The results of the calculations are represented by transfer matrices; which describe ion trajectories under the effects of an entrance fringing field; of an idealized central region; and of an exit fringing field. The focusing effects and ion-optical properties of a mass spectrometer consisting of an electrostatic ion mirror or a solenoid coil can be evaluated by using these transfer matrices.

Solenoid coil: Ion trajectories through a solenoid coil are calculated to a third-order approximation [1]. The effects of the extended fringing fields of a finite coil aperture are taken into account. Fig 1 shows the projections of real and ideal ion trajectories through a real solenoid. The effects of the fringing fields are expressed as small shifts and bends of the ideal ion trajectory on the transformation planes at the entrance and exit of the solenoid. Hence three transfer matrices are introduced to describe the real ion trajectories; the transformations are:

1. $(x_1,\alpha_1,y_1,\beta_1) \rightarrow (x_2,\alpha_2,y_2,\beta_2)$; for the effects of the entrance fringing field,
2. $(x_2,\alpha_2,y_2,\beta_2) \rightarrow (x_3,\alpha_3,y_3,\beta_3)$; for the effects of the idealized central region,
3. $(x_3,\alpha_3,y_3,\beta_3) \rightarrow (x_4,\alpha_4,y_4,\beta_4)$; for the effects of the exit fringing field.

The ion-optical properties of a solenoid can be obtained by these matrices. The coefficients of these matrices are given in Ref 1.

Electrostatic ion mirror: Ion trajectories in fringing fields of an electrostatic ion mirror with oblique incidence (Fig 2-a) are calculated to a second-order approximation [2]. The inferences of the fringing fields of the ion mirror are important, because the fringing fields have large defocusing effects on ion trajectories. We calculate the real ion trajectories under the consideration of an extended fringing field. The fringe effects are expressed by transfer matrices. The results show that the real ion trajectories deviate from those neglecting the effects of the fringing fields (Fig 2-b). In this study we take into account the effects of the fringing fields.

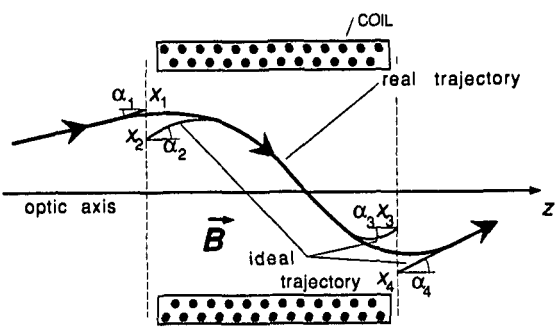

Fig. 1: Real and ideal trajectories through a real solenoid coil.

Table 1.

	a)	b)
A_δ	$0.499L_0$	$0.499L_0$
$A_{\alpha\alpha}$	$0.00L_0$	$0.00L_0$

$A_{\beta\beta}$	$-2.10L_0$	$-0.50L_0$

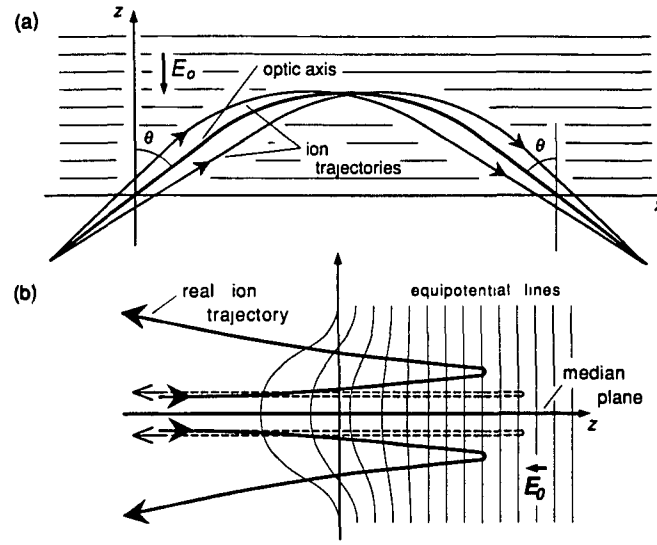

Fig. 2-a: Ion trajectories of an ion mirror with oblique incidence. b: The ion trajectories out of the median plane of the mirror. ▬ Real trajectories including fringe effects. --- Without the fringe effects.

We calculate ion trajectories through a solenoid coil and an electrostatic ion mirror with higher-order approximation. The results are given as three transfer matrices in both cases, two of which are for the extended fringing fields at the entrance and exit, whereas the third is for the idealized central region. We investigate the ion-optical properties of the following two cases by using these matrices:

1) We confirm that a solenoid can rotate the dispersing direction of an ion-optical system. When a solenoid is introduced into two-sector analyzers, the rotational misalignment between these sectors can be compensated for.

2) We estimate image aberrations of a single focusing system consisting of an ion mirror with 60° incidence. The results are listed in Table 1; (a) considering the fringe effects and (b) neglecting the effects. The energy dispersion, A_δ, and three aberration coefficients, $A_{\alpha\alpha}$, $A_{\alpha\delta}$, $A_{\delta\delta}$ are identical, since we adopt two-dimensional symmetry for the aperture shape. On the other hand, the three coefficients A_{yy}, $A_{y\beta}$ and $A_{\beta\beta}$ are different between the two cases. The difference expresses the deviation of the real ion trajectory shown in Fig 2-b. In this study, we can estimate the serious effects of the fringing fields of an electrostatic ion mirror on image aberrations.

Analysis of 1-(2,6-difluorophenyl)-1H,3H-Thiazolo[3,4-a]benzimidazole (TBI or THZO) and Its Meatbolites by Atmospheric Pressure Chemical Ionization LC/MS

L. M. Rose, C. F. Posey, D. L. Hill, R. F, Struck, Southern Research Institute, Birmingham, AL 35255

S. W. Stiller, Hitachi Instruments, Inc., San Jose, CA 95134

HPLC combined with Atmospheric Pressure Chemical Ionization (APCI) mass spectrometry provides a powerful tool for the identification of both drugs and their metabolites. APCI, which produces ions by gas-phase chemical ionization, provides sensitive detection of moderately polar molecules. APCI is an extremely soft ionization technique and produces predominately molecular ions. Molecular weight may then be obtained directly from the mass spectra. With collision induced dissociation in an intermediate pressure region, before the quadrupole mass analyzer, structural information may be obtained with a routine quadrupole mass spectrometer. Using this technology we were able to identify three metabolites of 1-(2,6-difluorophenyl)-1H,3H-Thiazolo[3,4-a]benzimidazole (which is known variously as TBI or THZO), the axial and equatorial isomers of the sulfoxide derivative and the sulfone derivative, present in plasma and urine of mice treated with this drug. Identification of metabolites was confirmed by synthesis of authentic samples of the derivatives. THZO has shown significant activity in the NCI AIDS-antiviral evaluation.

The thizolobenzimidazole, 1-(2,6-difluorophenyl)-1H,3H-Thiazolo[3,4-a]benzimidazole (THZO) is a novel agent active against the human immunodeficiency virus (HIV-1). At a concentration of 1 micromolar, the EC_{50} value, THZO protects T4 lymphocytes from the cytopathic effects of HIV-1 (Schultz, et al., *Proc. Am. Assoc. Cancer* Res., 33:517, 1992). In preclinical pharmokinetic studies THZO was administered to male CDF1 mice. Three metabolites were isolates from the plasma and urine of these animals. Using HPLC combined with Atmospheric Pressure Chemical Ionization (APCI) we were able to identify these metabolites.

METHODS

THZO was administered intravenously, subcutaneosly, or orally by gavage, or intra-peritoneally to male mice, approximately 8-9 weeks old and weighing 19-32 g. Blood, collected into heparinized tubes, was centrifuged to obtain plasma. For determination of THZO, plasma samples were diluted with equal volumes of acetonitrile, mixed, and centrifuged to obtain clear supernatants suitable for analysis. Urine samples were not diluted. All samples were analyzed by HPLC with a Hypersil BDS (4.6 x 250 mm, C-18) reverse-phase column. The mobile phase was 100mM ammonium formate : acetonitrile (55:45, v/v) with a flow rate of 1 ml/min; detection was by UV absorption at 254 nm.

For LC/MS identification, LC conditions were similar to those used for the determination of the drug in biological samples. The column used was a supelco (4.6 x 150 mm, C-18) with a particle size of 5 microns. A Hitachi L-6200A gradient HPLC pump was used with a Hitachi L-4000 UV detector set at 246 nm. The output of the UV detector was coupled with a Hitachi M-1000 LC-APCI-Mass spectrometer. The MS conditions were as follows, nebulization termperature, 250°C; vaporization temperature, 400°C; corona discharge needle current, 5μA (at 3.0 kV); drift voltage, 60V; electron multiplier, 2500V. Both UV and MS data were collected by a Hitachi HITmass data system.

Infrared spectra were determined with a Nicolet 10DX spectrophotometer with samples in a potassium bromitde disk. FAB mass spectral data were obtained with a Varian/MAT 311A double-focusing mass spectrometer with electron-impact and fast-atom-bombardment (FAB) ion sources.

RESULTS and DISCUSSION

HPLC peaks attributable to metabolites were observed upon analysis of plasma and urine from dosed mice. Three peaks, which eluted with retention times of 4.7 min (major), 5.0 (minor), and 7.8 min (minor) were not present in samples from control mice. Since it was reasonable to expect that oxides of sulfur and/or nitrogen might be present, we considered it likely that reaction of the parent compound with hydrogen peroxide might lead to synthetic products identical to one or more of the metabolites.

For THZO, mass spectral analysis by FAB revealed a molecular ion with a mass of 288. Reaction of the compound with hydrogen peroxide in methanol yielded major and minor synthetic products detectable by TLC abalysis. Isolation of the major synthetic product by preparative TLC and subsequent mass spectral analysis demonstrated a molecular weight of 304, which corresponds to a mono-oxidatation product.

To identify the urinary metabolites, a urine sample was spiked with the major synthetic product obtained from oxidation with hydrogen peroxide; this product has a retention time (5.0 min) identical to that of one of the metabolites. IR analysis of the synthetic standard and of the parent compound revealed the presence, in the spectrum of the former, of two strong peaks at 1068 and 1060 cm^{-1}, which were absent in the spectrum of the parent compound. This is the region for sulfoxide absorption, but not for amine oxide absorption. Mass spectral and IR analysis established the identity of the metabolite as a sulfoxide of THZO.

The minor synthetic product was isolated by preparative TLC for for FAB mass spectral analysis and was also identified as a mono-oxidized product of the parent drug. These data are consistent with the metabolites being the axial and equatorial sulfoxide isomers of THZO. The close similarity of their retention times (4.7 and 5.0 min) is also consistent with these structural assignments.

Samples of the metabolites from the plasma of treated mice were isolated by HPLC and identified by LC-APCI-MS methodology. The peak at T_R 4.7-5.9 min was identified as a mixture of the axial and equitorial isomers of the sulfoxide derivative,which confirmed earlier studies. The minor peak at T_R 7.8 min had a UV absorption maximum of 246 nm, a value similar to those for the parent compound (248 nm) and the sulfoxide isomers (245 nm) LC/MS analysis of the minor metabolite yielded a molecular ion of m/z 321 $(M+H)^+$. With collision-induced dissociation in the MS interface, a major fragment ion of m/z 257 was observed. These data are consistent with a di-oxidized metabolite of THZO. We tenatively assigned its structure as the sulfone. Although an N-oxide sulfoxoxide structure was also possible, the apparent reduction in polarity of this metabolite in relation to the sulfoxide as indicated by a longer T_R on reverse-phase HPLC suggested that the sulfone structure was more reasonable. Further, although the fragment at m/z 257 could correspond to loss of $(CH_3SO)H^+$ from the parent ion, it also corresponded to loss of SO_2 with the addition of a proton; the latter fragmentation seemed more reasonable This is corroborated by the lack of a loss of $(CH_3SO)H^+$ peak in the sulfoxide metabolite.

CONCLUSIONS

Using LC-APCI-MS methodology we were able to identify three metabolites of THZO: the axial and equitorial isomers of the sulfoxide, and the sulfone. Identification of the metabolites was supported by: (1) synthesis of authentic samples of the derivatives; (2) IR; (3) FAB mass spectral analysis; (4) UV; and (5) retention time data from reverse-phase HPLC.

Design of a Time-of-Flight Mass Spectrometer for a Plasma Source

D. P. Myers and G. M. Hieftje, Department of Chemistry,
Indiana University, Bloomington, IN 47405

Introduction

An inductively coupled plasma (ICP) ion source has been interfaced to a time-of-flight mass spectrometer (TOFMS) for trace elemental analysis. Potential advantages of the the TOFMS include speed, sensitivity, virtually simultaneous measurement of all masses, and improved precision for isotope-ratio measurements.

The layout of the TOFMS, outlined previously (1), employs pulsed right-angle extraction of the ions into a constant acceleration field. Similar atmospheric-pressure ionization TOFMS instruments have been reported recently (2,3). Our initial endeavors have involved designing an interface for the atmospheric-pressure plasma, largely based on an existing quadrupole ICP-MS instrument. Preliminary interface design and beam measurements will be described, and the relative merits of proposed ion optical systems will be discussed.

Instrument Design

The mass spectrometer is an angular reflectron (R.M. Jordan Co., Grass Valley, CA) which can be operated in either a linear or reflecting flight mode. Ions in the beam will be extracted at 90° to the beam by a pulsed field (0-300 V) into a second acceleration field which gives the ions their final kinetic energy. The pulsed-field duration (~2 μsec) is long enough to allow all of the elemental ions to enter the acceleration field. The pulsed field strength is chosen for proper space focusing at the detector which also depends on the two-field geometry, flight length, and acceleration potential. We are employing a three-stage differential-pumping interface which is identical to that in a quadrupole-based ICP-MS instrument in our laboratory (Figure 1). The beam shield shown in Figure 1 isolates ions from the acceleration field at the TOFMS entrance. After a pulse of ions are sent into the flight region the repeller and extraction grid are brought to ground potential to ensure that following ions can pass through the extraction region and not enter the TOFMS.

Results

Attempts at generating mass spectra with the configuration in Figure 1 were not successful. Current measured at the plate containing the third-stage orifice was -1 μA, indicating that the supersonic beam contains a high flux of electrons, which were earlier thought to be largely lost to the sampling plate and skimmer cone because of their greater mobility (4). Small negative potentials applied to the third stage orifice produced ion currents beyond the orifice in the 0.1 nA regime.

Two second-stage ion optics similar to those found in a quadrupole based ICP-MS instrument (5) were next added, the highest current seen at point A with optimized optics has been 10 nA. This value drops to 0.1 nA at point C. From ion signals measured in a similar quadrupole instrument we estimate that approximately 10^{11} ions/sec or 10^{-8} A should enter the third stage. Beam current in the second stage of the instrument was measured at the orifice plate and second optic element while the first optic element was maintained at -600 V. The resulting value of 1.0 μA suggests that most of the extracted beam does not pass through through the 1-mm orifice leading to the third stage.

Conclusions

A clear goal in further instrument development is to improve ion flux through the orfice to the third stage. Also two options to improving third-stage transmission exist: if a three-

stage interface is used, third-stage optics should be added and the distance between the third-stage orifice and extraction region needs to be shortened.

A second alternative is to construct a two-stage vacuum system which will also reduce the ion-source-to-TOFMS distance. In this interface the skimmer orifice diameter is being reduced to 0.1 mm so two turbomolecular pumps attached to the second (mass spectrometer) stage can achieve a pressure of 10^{-6} Torr. Disadvantages of the smaller orifice include decreased throughput and possible clogging.

Ion Optical Investigation of Deceleration lens System

Morio Ishihara
Analytical Instrument Division, JEOL Ltd., Akishima, Tokyo 196 Japan
Takekiyo Matsuo
Institute of Physics, College of General Education, Osaka University, Toyonaka, Osaka 560 Japan

INTRODUCTION

It is quite important to decelerate ion energy from kilo electron volt order in many fields, for example, hybrid tandem MS, ion transportation into ion trap. We investigated ion optical lens systems by theoretical simulation based on numerical ray tracing. For this purpose, a computer code named "ELECTRA"[1] was used. This code can solve Laplace's equation and can integrate Lorentz's equations of motion in the two dimensional, axially symmetric three dimensional or three dimensional spaces. The most difficult part of the ray tracing is to derive electric field by solving Laplace's equation. In ELECTRA, a charge density method[2] is used to do this, because the accuracy of calculated electric field is very high and both two and three dimensional calculations can easily be completed. The process of determining the voltage to each electrode which satisfy the optimum focusing condition for a certain lens system was studied.

RESULTS AND DISCUSSION

1. In the design of a lens system, we have to determine the lens geometry and the lens potential. Here we demonstrate an automatic determination of the lens potential by the combination of ELECTRA and an optimization code "MSPLEX"[1] based on a simplex method[3]. Figure 1a, shows the axially symmetric deceleration lens system and ion trajectories before optimizing the lens potentials; the energy of the ions is decelerated from eVa to 0.003eVa. The three lens potentials V1,V2,V3 were determined to perform the parallel to point focusing, in another words, to minimize the magnification $|(x|x)|$, which can be calculated by ELECTRA as a function of V1,V2,V3. The values of the magnification in the minimizing process by MSPLEX is shown in Fig.2. The magnification becomes substantially zero after twenty iterations. The ion trajectories after this optimization is shown in Fig. 1b, where the ions are focused at the exit of the lens. Defining proper functions to be minimized, we can also determine potentials for other types of focusing modes.

2. One of the features of ELECTRA is the capability to calculate a three dimensional lens system. A result of this type of calculation, ion trajectories through a three dimensional lens system consisting of twelve lens plates, is shown in Fig.3. In general, the three dimensional calculation is very difficult compared with the two dimensional one because it needs long computation time, whereas it as only 170S to perform the calculation shown in Fig.3 by ELECTRA and it was proved that we can also investigate three dimensional lens systems by ELECTRA within a reasonable time. The computer used in the calculation was an HP9000-730 RISC based EWS (23MFLOPS).

CONCLUSION

Here we demonstrate ion optical investigations of deceleration lens systems by the codes ELECTRA and MSPLEX. These codes are expected to be applied effectively to design and investigate any type of deceleration lens systems.

Design, Construction and Preliminary Operation Parameters of a Transportable Molecular Beam Mass Spectrometer (TMBMS), with Quadrupole and Time of Flight Detectors

D. A. Gratson, M. A. Ratcliff, T. A. Milne, S. P. Deutch
National Renewable Energy Laboratory
1617 Cole Blvd., Golden, CO 80401

A state-of-the-art Transportable Molecular Beam Mass Spectrometer (TMBMS) has been designed and constructed in order to extend our current investigations in the use of free jet molecular beam mass spectroscopy, (as applied to bench scale high temperature reactive systems) to scaled up chemical processes located off-site. Application examples include gasifiers, pyrolysis reactors, combustion systems, catalytic reactors and continuous emissions monitoring.

The TMBMS is based on a 3 stage differentially pumped vacuum system (shown in Fig. 1) for the formation (stage 1), collimation (stage 2) and detection (stage 3) of the molecular beam. The transportability requirement dictated the minimization of size, weight and utilities. These goals were accomplished principally by employing a high speed molecular drag pump for stage 1 (Osaka TS440) and turbomolecular pumps for stages 2 and 3 (Balzers TPU520 and TPU240 respectively). The vacuum chambers, pumps, mass spectrometers and associated hardware are mounted on a rolling cart that weighs approximately 400Kg and will fit through a 40in door. The remaining equipment includes a recirculating chiller for the turbo pumps, an electronics rack and computer. The total system weight is approximately 500Kg, the only utility requirement is electrical power: 60A, 208V, 3-phase.

The TMBMS was designed to use either a quadrupole mass spectrometer (Extrel C50) mounted on axis with the molecular beam, or a time-of-flight (TOF)(R. M. Jordan Co. Angular Reflectron) mass spectrometer mounted normal to the molecular beam. The quadrupole has a range of 0-720 amu with a scan rate of 1000 amu/sec. A Teknivent Vector II system performs data acquisition. The TOF employs an electron gun and a pulser (up to 3KHz) to ionize the molecular beam and gate the ions into the TOF. The data acquisition system for the TOF consists of a high speed analog to digital conversion board and an arithmatic processing board. The latter will transform the time domain spectra into its equivalent mass domain spectra. A real time mass spectrum is then stored and displayed using a modest display program. The mass spectra can also be manipulated off line by the Teknivent Vector II data system. The system control software is currently in its initial development stages, when completed, this TOF/data acquisition system will allow the continuous monitoring of reactions over periods of up to several minutes with 0 to @ 1000 amu spectra acquired every 3msec.

Using a 0.28mm orifice, a 1.2mm skimmer and room temperature air, the pressures in stages 1-3 were 19mT, 3×10^{-5}T and 5×10^{-7}T , respectively. The dynamic range of the instrument was demonstrated to be at least 10^6 by comparing the intensities of N_2 (mass 28, I = 6.3×10^6) with Kr (mass 84, I = 5.9). The natural concentrations of these

gases in air are 774,400ppm and 0.65ppm respectively. Under similar operating conditions, Figure 2 gives an indication of the quality of the free jet expansion and the molecular beam by the observation of argon clusters out to 400 amu (actually 480 amu was observed) from room temperature argon at @ 20psia.

Analysis of Complex Biological Samples by Gas Chromatography/Time-of-Flight Mass Spectrometry with Time-Array Detection

B. D. Gardner[1], **J. A. Johnson**[1], **D. A. Gage**[2], **J. Allison**[1], and **J. T. Watson**[1,2], *Departments of Chemistry*[1] *and Biochemistry*[2], *Michigan State University, East Lansing, MI 48824*
G. E. Yefchak, *Meridian Instruments, Inc., 2310 Science Parkway, Okemos, MI 48864*

We have been developing time-of-flight mass spectrometry (TOFMS) as the detection method of choice for capillary GC/MS [1]. By combining a TOF mass spectrometer with an integrating transient recorder (ITR), we have been able to generate up to 150 complete mass spectra per second. This high rate of mass spectral production, made possible through time array detection (TAD) using the ITR coupled with deconvolution, has allowed for a better than 20-fold reduction in analysis times of some mixtures using a short capillary column and minimal chromatographic separation [2].

Our current efforts are directed toward applying GC/TOFMS/TAD technology to mixtures of compounds of increasingly greater analytical challenge. We report here the analysis of an oxysterol mixture having biological and biomedical interest. Separation of this type of mixture is difficult, and even under optimal chromatographic conditions, some components nominally co-elute. Using the information obtained by collecting 30-50 mass spectra per second on our GC/TOFMS/TAD instrument and spectral deconvolution techniques, these compounds can be distinguished.

Figure 1a shows the reconstructed total ion chromatogram of an epoxy sterol mixture with mass chromatograms from two components that are nominally co-eluting. An 8-meter 0.10 mm i.d. RT_X-5 capillary column and a data acquisition rate of 30 spectra/second on the GC/TOFMS/TAD instrument were used for analysis of this mixture. Deconvoluted spectra as seen in figure 1b show the two components to be 5β,6β-epoxy cholestane-3-ol TMS and 3β,5α-cholestane-6-one TMS.

In addition to the utility of this instrument for the analysis of samples by conventional gas chromatography-mass spectrometry, this instrument also has the capability for significantly reducing analysis time of some mixtures. For this application a complex bacterial fatty acid methyl ester mixture was analyzed by conventional gas chromatography, and by high-speed chromatography using a high data collection rate. Figure 2a shows the reconstructed total ion chromatogram of this mixture separated on an 8-meter 0.10mm i.d. RT_X-5 capillary column. The GC was held at 150 C for 4 minutes and ramped to 250 C at 3 C/minute. Data were acquired at a rate of 10 spectra/second. Figure 2b is the reconstructed total ion chromatogram of the same mixture separated on a 1-meter 0.10 mm i.d. capillary column. The GC was ramped from 150-250 C at 50 C/minute, and data were collected at a rate of 150 spectra/second. This high speed analysis and fast data acquisition rate allowed us to cut our analysis time from over 16 minutes to 100 seconds; a 10-fold reduction. Further reductions in analysis time will be possible with improvements in injection techniques and in greater column heating rates.

In each of these cases, GC/TOFMS/TAD provides complete mass spectra by which to distinguish and identify compounds that were not sufficiently isolated for unequivical identification by conventional scanning GC/MS technology. The GC/TOFMS/TAD approach provides a sufficiently high number of consecutively-recorded complete spectra of unskewed relative peak intensities so that deconvolution techniques can be employed to identify compounds that nearly co-elute from a capillary GC column.

Comparative Study of Alternative GC-FTIR-MS Methods

Kevin A. Krock, Christoph Klawun, N. Ragunathan,
and Charles L. Wilkins
Department of Chemistry, University of California, Riverside
Riverside, CA 92521-0403

Introduction:

In previous years, many complex mixture analyses have been done by gas chromatography/mass spectrometry (GC/MS) because of the low detection limits and high structural specificity of the method. More recently, use of gas chromatography/Fourier transform infrared spectroscopy (GC/FT-IR) for the analysis of these has been well demonstrated. However, detection limits ranging from hundreds of nanograms to several micrograms have limited the acceptance of this approach for trace analysis. Recent improvements in infrared technology have provided detection limits less than ten nanograms for most organic compounds, and use of matrix isolation and cryogenic trapping techniques can result in detection limits less than a nanogram.

Although recent literature has compared the merits of lightpipe versus matrix isolation GC/FT-IR interfaces, there have not, to date, been any direct quantitative comparisons using the same samples. This paper presents results of a study intended to establish the practical detection limits for a variety of standard samples using a commercially available lightpipe based system and a commercially available matrix isolation system.

Instrumentation:

Two GC-FTIR systems were used in this study. The first system was the Hewlett-Packard (HP) GC-IRD-MSD system, which consisted of a 5890 Series II Gas Chromatograph, a 5965B Infrared Detector (IRD), and a 5970B Mass Selective Detector (MSD). It was set up in a serial configuration to maximize IRD sensitivity. The other system that was used was the Mattson Cryolect 4800 GC-IR system which consisted of an HP 5890 Gas Chromatograph, the Mattson Cryolect 4800 matrix isolation infrared spectrometer, and an HP 5970B MSD. This system was set up in a parallel configuration with flow split percentages of 15%, 50%, and 35% to the flame ionization detector, Cryolect 4800, and MSD respectively.

Samples:

The 35 compounds that were analyzed were broken up into three classes of compounds for which standard GC mixtures could be purchased. These three classes were chlorinated hydrocarbons, phenolic compounds, and polynuclear aromatic hydrocarbons. The standards were diluted with hexane to provide individual component concentrations from 0.5 ng/mL to 50 ng/mL.

Results:

For the purposes of the present study, the operational definition of a practical detection limit is the Minimum Identifiable Quantity (MIQ), as defined in United States Environmental Protection Agency method 8410 (1,2), which is a method for capillary lightpipe GC/FT-IR spectrometry for semivolatile organics. An MIQ is specifically defined as the minimum quantity of material that produces a library searchable spectrum that falls among the top five search hits, with the spectrum visually matching at least one of the top five library spectra. This process of library searching each component in the standards was carried out on the HP system, and the results obtained are compared to the late 1990 US-EPA proposed update of Method 8410 MIQ values. Typical MIQ values ranged from 0.5 ng to 10 ng for all compounds analyzed. Improvements over the EPA MIQ results were approximately an order of

magnitude, and in the most favorable case, the MIQ for hexachloroethane was two orders of magnitude better. At low concentrations, known retention times were required for obtaining spectra. MIQ values for the matrix isolation instrument were not determined due to instrumental optimization difficulties.

The comparison between the two systems was carried out by examining the reconstructed chromatograms from each of the classes of compounds. As was previously mentioned, the matrix isolation reconstructions were done using a phase sensitive infrared reconstruction (PSIR), and the lightpipe reconstructions were done with a second derivative selected wavelength chromatogram reconstruction (SD SWC).

Upon comparing the reconstructed chromatograms from the chlorinated and phenolic hydrocarbon standards, it was clear that the matrix isolation instrument is capable of providing better chromatographic signal to noise at low component concentrations than the lightpipe instrument. In addition to the better reconstructed chromatograms, the advantage of signal averaging with matrix isolation should provide MIQ values an order of magnitude lower than the values obtained by lightpipe GC/FT-IR.

The use of the mass spectrometers to supplement the IR MIQ values and information in this study was attempted, but the detection limits for the mass spectrometers were not comparable to those of the infrared detectors. The infrared MIQ for hexachloroethane is 0.5 ng on the HP system, but the mass spectral MIQ was determined to be approximately 10 ng injected. With this large difference in sensitivity, the MSD is not capable of providing additional information at the levels required. This lack of sensitivity was due to the maximization of IRD sensitivity in the HP instrument by having the IR and MS in a series configuration. In this configuration, only a fraction of the column effluent gets to the mass spectrometer, and this fraction depends on the column flow and lightpipe make-up gas flow. Flow splitting difficulties in the matrix isolation instrument also prevented the use of the mass spectrometer as an additional tool for sensitivity and information improvement.

Conclusions:

- GC/FT-IR instrumentation is presently capable of providing trace (low ppb) component analysis in complex mixtures, especially chlorinated hydrocarbons.

- Present lightpipe instrumentation is capable of providing an order of magnitude improvement over previously reported MIQ values. MIQ values may be further decreased by an order of magnitude by the utilization of matrix isolation, however, suitable spectral library databases will be required.

- Utilization of a combined GC/FT-IR/MS system may provide increased confidence in the and assignments of MIQ values for compounds, however, the serial interface does not allow for the collection of mass spectra at the same concentration levels as the infrared detector is capable of collecting library searchable infrared spectra.

Supercritical Fluid Extraction for GC/MS Sample Preparation

Adam J. Patkin and Gregory L. McClure
The Perkin-Elmer Corporation, 761 Main Avenue, Norwalk, CT 06059-0257

Supercritical fluid extraction (SFE) has recently been the subject of increasing interest for analytical sample preparation. SFE allows rapid extraction of analytes from complex matrices because the supercritical fluid possess gas-like diffusivity and liquid-like solvating properties. SFE extractions typically are much faster than the Soxhlet equivalent. SFE can potentially replace many conventional Soxhlet extraction sample preparations, provide enhanced sample throughput, and lower cost-per-analysis.

This paper will discuss the use of SFE for GC/MS sample preparation.

Introduction

Extraction can be static or dynamic. In static extraction the supercritical fluid sits in the extraction vessel and equilibrates with the sample. In dynamic extraction the fluid passes through the vessel leading to a non-equilibrium condition. The typical extraction combines both static and dynamic stages.

Sample collection may be either off- or on-line. Off-line collection is usually performed either by passing the effluent through a solvent, or by cold-trapping the analytes as the supercritical fluid evaporates, and then desorbing the cold trap to collect the analytes. On-line collection is often performed by passing the eluent to the split-splitless injector of a GC. The CO_2 is vented during the dynamic extraction period, while the analytes are trapped in the injector or on the head of the column. The off-line approach permits more flexibility in control over chromatographic conditions and easier addition of quantitation standards. It allows the collection of the analytes in a solvent which can be stored, transported, concentrated, diluted, or re-injected as needed. On-line coupling of SFE to a benchtop GC/MS system permits easy, automated and efficient sample transfer from the extraction to the analysis stages of the analysis. It eliminates the extra step of sample collection, but a re-analysis of the sample also requires re-extraction. In addition, severe overloading of the GC column and possible contamination of the mass spectrometer is possible. The off-line approach is probably safer unless the sample is well-characterized.

Experimental

All SFE extractions were carried out on the Perkin-Elmer PrepMaster. The GC/MS analyses were performed with the Perkin-Elmer AutoSystem gas chromatograph and the Q-Mass 910 mass spectrometer.

Figure #1. Air Filter Sample

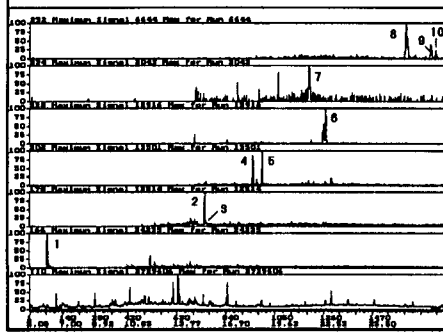

Figure #1 shows an example of SFE/GC/MS analysis. It presents a reconstructed total ion current (TIC) chromatogram for the off-line SFE analysis of an air filter sample collected during an atmospheric inversion in Salt Lake city. The SFE step was a 60 min dynamic extraction at 125 atm and 100°C. This data illustrate that target analytes, in this case PAH's, can be extracted in a relatively short period of time from complex matrices. Current work is focusing on using the Perkin-Elmer AccuTrap for cryogenic trapping of the SFE eluant. Using this approach, higher dynamic flow rates will permit faster, quantitative extraction.

Conclusions

SFE/GC/MS has been shown capable of extracting target analytes from complex matrices.

The benefits of supercritical fluid extraction are:

- Rapid extraction compared to Soxhlet
- Faster sample throughput
- Reduced cost-per-analysis
- Elimination of toxic or environmentally hazardous solvents
- Automation of extraction process

Relaxation Spectroscopy by an Especially Designed Time–of–Flight Mass Spectrometer

H. Wollnik, U. Grüner, J. Kelleter, D. Kohl
Universität Giessen, Heinrich–Buff–Ring 16, D-6300 Giessen, Germany

A special time–of–flight mass spectrometer (TOF–MS) has been adapted to an UHV environment to investigate surface reaction kinetics. As a test reaction the catalytic decomposition of gaseous acetic acid on a Palladium foil has been selected. For the relaxation spectroscopy experiments (Fig.1) the pressure has been less than 2×10^{-10} Torr. Single gas pulses were used to produce submonolayer exposures. During the gas exposure (20 ms) the desorbed reaction products were analysed by the TOF–MS with a spectra repetition rate of 2 kHz (i.e. every 0.5 ms one complete mass spectrum). The TOF–MS uses an electron impact storage ion source, a gridfree ion reflector and a MCP detector /1/. The 45 cm long system is mounted on a 8"-flange.

Exposing a clean Pd foil to single gas pulses of acetic acid ($= 1.3 \times 10^{12}$ molecules $cm^{-2} \approx$ 1/1000 ML) one finds CO_2 as the main desorption product at sample temperatures above 500 K. Transients are shown of the CO_2 response signals at 5 different temperatures between 548 K and 643 K (Fig.2). The solid curves result from a model calculation assuming:

1. first order reaction kinetics;
2. non activated adsorption;
3. instant desorption of CO_2:

$$\frac{dn}{dt} = Q_0(t) - nk_a \qquad (1)$$

with n = no. of acetate molecules at the surface, $Q_0(t)$ = flux of molecules of acetic acid and k_a = rate constant of CO_2 formation (see Eqn.2).

The rate constants k_a were obtained from the exponentially decreasing part of the transients. The temperature dependence is described by:

$$k_a = f_a \times e^{-E_a/kT} \qquad (2)$$

with k = Boltzmann constant and T = temperature [K]. The activation energy for CO_2 formation is found to be $E_a = 0.78$ eV and the preexponential factor $f_a = 3 \times 10^8\ s^{-1}$.

After a total dose of 2×10^{15} molecules $cm^{-2} \approx 2$ ML the formation of CO_2 is largely suppressed. We assume that **carbon deposition** spoils the reactive sites on the Pd surface. On this non–reactive surface molecular adsorption and desorption of acetic acid was observed. From these transients an activation energy for desorption of 0.44 eV and a preexponential factor of 9×10^8 s^{-1} was obtained /2/.

Conclusions:

The TOF-MS has proven its value for the relaxation mass spectrometry in an UHV environment. Kinetic data of single surface reaction steps were determined using **submonolayer exposure doses (1/1000 ML)**. Due to the special storage ion source a high sensitivity is obtained.

In future experiments it will be possible to investigate systems with changing reactivity during exposure of gas due to:

- poisoning of reactive sites;
- change in surface stoichiometry;
- change in surface restructuring.

Because of the high repetition rate (up to 15 kHz) very fast reactions can be analysed monitoring the different products simultaneously.

A Precise Method of Determining Sample Temperature During Vacuum Pyrolysis*

Michael A. Grayson, McDonnell Douglas Research Laboratory, St Louis MO 63166

Robert Bateman, VG Analytical Fisons Instruments, Manchester, UK

Pyrolysis mass spectrometry (Py/MS) is a versatile tool for investigating the thermal degradation mechanisms of polymeric materials. Westall and Pidduck [1] demonstrated that the kinetic parameters of apparent activation energy and frequency factor can be obtained by analyzing the peak evolution temperature of a particular reconstructed ion current profile at different heating rates. In some instruments, however, the recorded probe temperature is not an accurate measure of the sample temperature. Consequently, kinetic parameters calculated from such data are erroneous [1]. This situation arises most frequently in magnetic sector instruments in which the ion source is at high voltage and the sample must be electrically isolated from the probe temperature control circuitry.

A method for improving the accuracy of the temperature measurement during vacuum pyrolysis of polymeric materials with a VG ZAB mass spectrometer was developed. A Vanzetti infra-red pyrometer is situated outside the vacuum system and sighted onto the probe tip through a sapphire vacuum window located on the HPLC port (Figure 1). The output of the Vanzetti (10mV/C) is recorded by the data system and also used to control the power to the probe tip heater. The Source Control Unit temperature set point and temperature programming controls are used to establish operating parameters.

Prior to use, the temperature measuring system must be calibrated. This procedure requires two separate steps: 1) calibrating the infra-red pyrometer with a black body source; and 2) calibrating the probe temperature. In both cases, the calibrations are performed sighting the pyrometer sensor through the sapphire vacuum window.

After the black body calibration is completed, the pyrometer is installed on the mass spectrometer and sighted on the tip of the solids probe. A thermocouple is placed in a gold sample cup and the walls of the cup are crushed around the thermocouple to ensure good mechanical contact. With the ion source removed, the VG Source Control unit is set to a fixed temperature and the emissivity of the infra-red pyrometer is adjusted to match the pyrometer readout with the thermocouple temperature. The correspondence between the two temperature readouts is then checked across the temperature range of the pyrometer. The results of a typical calibration are shown in Figure 2.

There are a number of minor details which must be considered if accurate temperature measurement is to be achieved.

* Probe tip emissivity
* Thermal contacts in the probe tip

A high emissivity is required to improve the signal-to-noise ratio of the measurement and to 'brighten' the probe tip compared to other hot metal objects in the vicinity such as the ion source block. The probe tip is made of molybdenum, a material which has good thermal conductivity, but very low emissivity. Consequently, the surface of the probe tip was coated with nichrome using a special vacuum deposition technique. Nichrome has a very high emissivity, but poor thermal conductivity. This increases the surface emissivity from less than 0.1 for molybdenum to about 0.4. Thus, the nichrome coated molybdenum probe tip provides a surface with emissivity over four times that of the uncoated tip while maintaining high thermal conductivity.

Gold is used as the sample cup material because it has high thermal conductivity -- considerably better than glass or quartz -- and it is malleable. After the sample is placed in the gold cup, it can be crushed around the sample to ensure good thermal contact. When the sample is placed in the probe tip, the distance from the sample to the portion of the probe tip where the temperature is sensed is less than 5 mm. The method of measuring and controlling the probe temperature and the use of gold sample cups outlined here provides a means of determining the true sample temperature during a pyrolysis experiment within a degree or so at heating rates as high as 10C/min. This provides us with an excellent tool

to measure the kinetic parameters of specific compounds formed during thermal degradation of polymeric materials.

An Investigation of the Thermal Decomposition of Polyethylene Glycol, a Ceramic Binder, by Gas Chromatography Mass Spectrometry

Douglas N. Stevenson, Kent J. Voorhees, Steven F. Baugh,
Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO 80403
Gary E. Maciel, Haiou V. Pan
Department of Chemistry, Colorado State University, Ft. Collins, CO 80523

Polyethylene glycol (PEG) is a common polymeric binder used in the production of alumina ceramics. Binders are used to hold the ceramic raw materials together for forming and fabrication. As the ceramic is sintered, the organic binders are burned off which occurs with temperatures typically reaching 1200-1700°C.

A tube furnace was used to generate the products from both the PEG and the PEG mixed with alumina. Approximately 0.2 grams of the pure PEG8M (an 8,000 AMU PEG), and an approximately 0.5 grams of PEG20M (20,000 AMU PEG) on alumina, were pyrolyzed in the tube furnace. The products from the thermal degradation were transferred from the furnace through a heated line into ice cooled methanol.

Volatile product analysis was conducted using a Varian gas chromatograph interfaced to an Extrel ELQ 400 triple quadrupole mass spectrometer. The electron impact volatile product analysis conditions included: injector 260°C; split 10:1; 1:30 delay; DB5 column (0.32 mm id. x 30m, 0.25 µm film thickness; flow 35 cm/sec; initial temp 35 °C, 2 min hold; ramp a- 6 °C/min to 280 °C, 5 min hold; ramp b- 40 °C/min to 320°C, 4 min hold. Mass spectrometer conditions were: interface 280°C; filament delay 3:50 min; Mass range 29-501 amu with a 475 amu/sec scan rate, and total run time of 5 min.

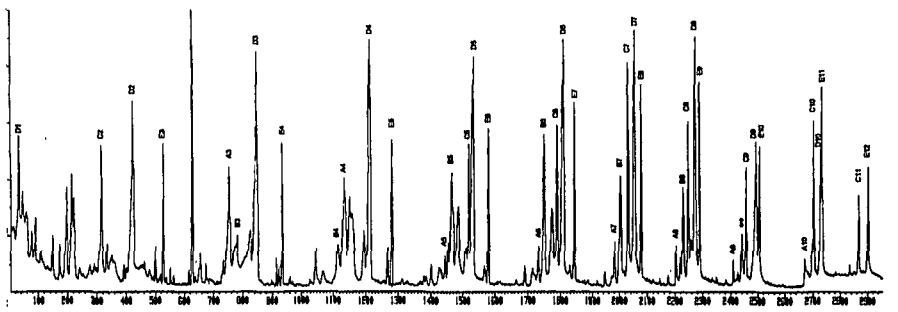

Figure 1. Polyethylene Glycol 8M Thermally Degraded in Nitrogen.

Five series of homologous compounds with identical end functional groups which increase in size and weight by one monomeric unit ($-CH_2-CH_2-O-$) of mass 44 were observed in the chromatogram. They are labeled A, B, C, D, and E, with increasing numbers for each addition of a monomer. These homologous compounds are summarized in Table 1.

In the absence of oxygen, disproportionation and intramolecular degradation reactions are more pronounced, leading to the volatile pyrolysis products described. With an abundant supply of atmospheric oxygen, combustion competes favorably with the polymer inter- and intra-molecular degradation processes.

Polyethylene glycol disassociates into radicals first at low temperatures by cleavage of the polymer chains' carbon-oxygen bond and carbon-carbon bond. The reported PEG pyrolysis products are thermally labile and continue to thermally degrade at similar temperatures. This continued degradation leads to the clean removal of polyethylene glycol from a ceramic.

Table I. Summary of Homologous Series of Compounds.

CH_3-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_2-OH	Series A
CH_3-CH_2-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_2=O	Series B
CH_3-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_3	Series C
CH_3-CH_2-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_2-OH	Series D
CH_3-CH_2-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_3	Series E

Analysis of the non-volatile products by ^{13}C magic-angle spinning-sample (MASS) NMR (Figure 2) was done to provide further evidence for the proposed degradation mechanisms. As can be seen in the ^{13}C spectra, there is formation of carbonyl or aldehyde functional groups early in the degradation process, with subsequent alkene formation. Upon further degradation, the carbonyl or aldehyde groups are degraded and the more thermally stable alkene groups dominate until complete degradation occurs. Complete burnoff is a desired binder characteristic, since it leaves no ceramic/organic interfaces to interfere with sintering

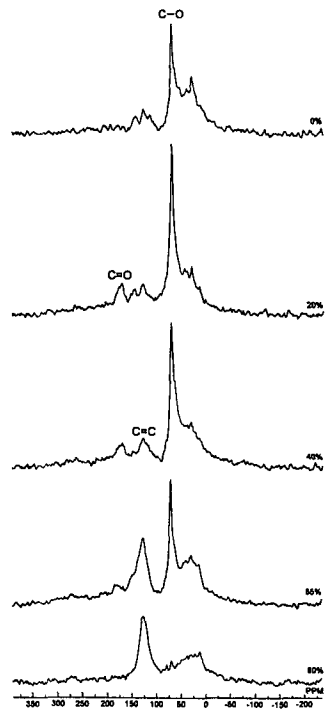

Figure 2. ^{13}C MASS NMR Spectra from the Powder of Partially Degraded Polyethylene Glycol with Alumina in Approximately 20% binder loss intervals

MASS SPECTROMETRY OF POLYMERIC HINDERED AMINE LIGHT STABILIZERS

Ted Chang, Paul Waterman and Michael Piquette
Chemical Research Division, American Cyanamid Company,
Stamford, CT 06904

Hindered amine light stabilizers (HALS) are a class of high performance stabilizers that are currently being used to extend the service life of polymeric materials such as polyolefins and different types of coatings. The mechanistic action and use of HALS have been described in numerous papers and review articles.

Primarily there are two types of HALS, monomeric and polymeric. Polymeric HALS are multi-component mixtures of closely related oligomers. Identification of their composition is a challenging analytical task. NMR and IR are usually not applicable because of the complex nature of the sample. Of all mass spectrometric techniques investigated, FABMS was found to be the most suitable technique for the analysis of these samples. The major advantage of FABMS is its capability of acquiring a spectrum without thermal alteration of the sample. Polymeric HALS readily produce FABMS spectra with steady signals. Each component produces only the protonated molecular ion with minimum fragmentation. As in most FAB analyses, the sensitivity decreases with increasing molecular weight. General information concerning the compositional profile of the sample can be easily obtained from a single experiment.

The structure of polymeric HALS is generally reported as (XY)n in most of the literature, where X is the hindered amine group and Y the bridging group. Our study found that polymeric HALS exists as a complex mixture of components. A typical commercial polymeric HALS, CYASORB UV-3346® light stabilizer (American Cyanamid Company), is employed for this study. In CYASORB UV-3346 light stabilizer, the X unit is [N,N'-bis(2,2,6,6-tetramethyl-4-piperadinyl) -1,6-hexanediamine] and the Y unit is morpholinotriazine. The X side end is terminated with a hydrogen atom and the Y side end is terminated with a morpholine group.

CYASORB UV-3346 light stabilizer produces a complex FAB spectrum consisting of intense ions up to m/z 2,000. Intensity magnification of the higher mass range shows the presence of higher oligomers at m/z greater than 4,000. It was found that the general structure of (XY)n is insufficient to express the composition of the sample. The sample actually consists of three major oligomeric series which we named as the A series, the B series and the C series. The A series is comprised of the traditional (XY)n type oligomers; the B series contains the Y-(XY)n type oligomers which incorporate an additional Y group; and the C series contains the (XY)n-X type oligomers which incorporate an additional X group. The A1, A2, A3,...etc. reflect n=1, n=2, n=3,...etc., respectively.

When CYASORB UV-3346 light stabilizer was separated by HPLC, it produced a highly complex chromatogram as expected. Without positive identification of the isolated components, the HPLC result can only be used for qualitative assessment of the product. The applicability of two LC/MS techniques for the analysis of polymeric HALS was evaluated. The thermospray technique was able to produce additional useful

information. However, the recently introduced electrospray technique did not provide useful information in the analysis of this sample.

Thermospray generates a mass spectrum very similar to the FAB spectrum for CYASORB UV-3346 light stabilizer. Since thermospray is a less sensitive technique, it usually requires a larger sample size than FAB analysis. As in FAB, thermospray also shows a lower sensitivity for higher oligomeric species. HPLC peaks corresponding to lower oligomers are easily identified. Identification of the HPLC peaks of higher oligomers are more difficult. However, it was found that the oligomers of the same series eluted sequentially. Tentative assignment of higher oligomeric peaks were made accordingly.

In summary, we found that FABMS is a quick and simple technique to provide compositional profiles for polymeric HALS samples. However, for the complete characterization of the sample, a combined use of FABMS, HPLC and thermospray LC/MS is recommended.

MASS SPECTROMETRIC STUDY OF THE DEGRADATION OF A PERFLUORINATED COPOLYMER BY NITROGEN TETROXIDE

M. P. Easton and S. L. Zacharius
The Aerospace Corporation
P. O. Box 92957, Mail Station M2-250
Los Angeles, CA 90009

Nitrogen Tetroxide (N_2O_4) is a reactive oxidizer used in launch vehicles and satellite systems. Many materials, including elastomers used for sealing valves and other devices, are attacked by N_2O_4 causing changes in their physical properties. Even the elastomers currently qualifyed for use with N_2O_4 do not possess the required compatibility for the intended applications. Their acceptance was based on time limited exposures so that the material property changes would not be significant. This restriction has resulted in costly flight delays due to the need for tear down and rebuild. Consequently, alternate materials with superior compatibility with N_2O_4 are under investigation.

The copolymer of tetrafluoroethylene (TFE) and perfluoromethyl vinyl ether (PMVE) is linear and chemically inert. A crosslinked polymer is obtained by adding perfluoro-(2-phenoxylpropyl vinyl ether) (PPPVE) as cure site monomer together with bisphenol AF as crosslink agent.[1] In this paper the cross-linked polymer will be referred to as TFE-PMVE copolymer. Figure 1 shows the chemical structures of the monomers, crosslink agent, and polymer. Physical and mechanical tests indicate that this material possess superior compatibility with N_2O_4.[2] However, chemical degradation was suspected when the physical and mechanical properties of exposed samples did not recover to their original values. A small change in the chemical structure of the polymeric material can produce a significant change in the mechanical properties, therefore identification of the chemical change becomes very difficult. The high sensitivity of the mass spectrometer and the uniqueness of the perfluorinated copolymer structure were used to identify the type of degradation reactions that occurred during the N_2O_4 exposure.

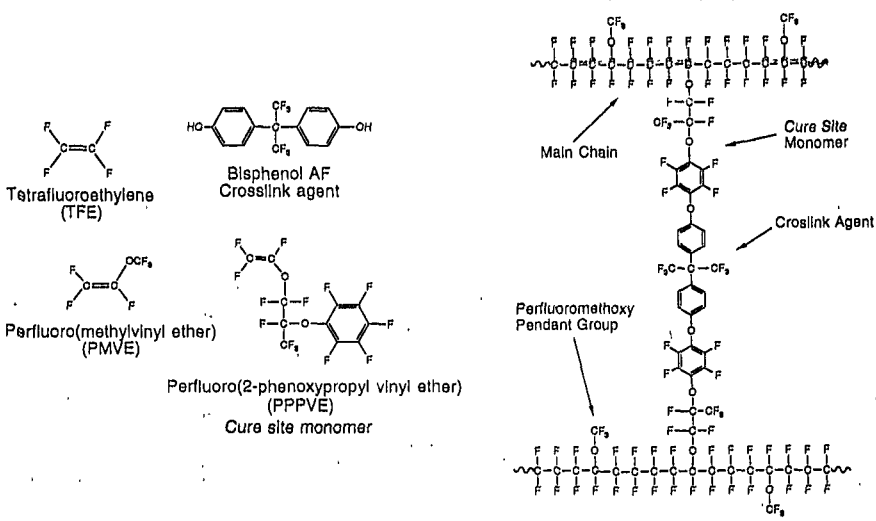

Figure 1. Chemical structures of monomers, crosslink agent, and TFE-PMVE copolymer.

Solid probe mass spectrometric (SP-MS) analysis was performed on unexposed and N_2O_4 exposed samples as a function of exposure time. A Kratos MS-25 RF magnetic mass spectrometer was used for the SP-MS analysis. The DS-90 Kratos data system was used for data acquisition and

[1]Polymer manufactured by Dupont with the trade name of Kalrez 1045.

[2]M. P. Easton, E. W. Fournier, S. Genova, T. A. Spiglanin, D. G. Sutton, and S. L. Zacharius, "Effects of N_2O_4 Exposure on Dupont Kalrez 1045", Polymer submitted for publication

processing. The samples, approximately 8 mg, were introduced into the mass spectrometer by means of the solid probe which was temperature programmed linearly from 25 to 350°C at a rate of 15°C/min. The samples, 1cm long sections of o-rings, 2.54 cm in diameter, and 0.23 cm thick, were immersed in liquid N_2O_4 for 0, 16, 24, 96, and 150 hours; and 30, 60, and 90 days. After removal from N_2O_4, the samples were exposed to flowing air, 32°C and 100% relative humidity, for 80 hours.

The sites of the TFE-PMVE copolymer most vulnerable to chemical attack by N_2O_4 are the various ether (-C-O-C-) linkages and the phenyl rings of the bisphenol AF (crosslinking agent). Damage to the TFE-PMVE polymeric structure was assigned when the SP-MS analysis of the exposed samples detected characteristic ions of the copolymer's chemical structure at analysis temperatures below the thermal decomposition temperature of 350°C (i.e., ions were observed in the limited mass plots at scans below 100). Figure 2 and 3 show the total ion currents (TIC) (the top curve of each figure) and below the selected ion plots for the masses 85,148, 146, 166, and 169 of the unexposed sample and the sample exposed for 60 days. The x-axis gives the scan number, the analysis time, and the temperature of the solid probe. The y-axis displays relative intensity. The full-scale, 100% intensity, is indicated by the number to the right of each plot.

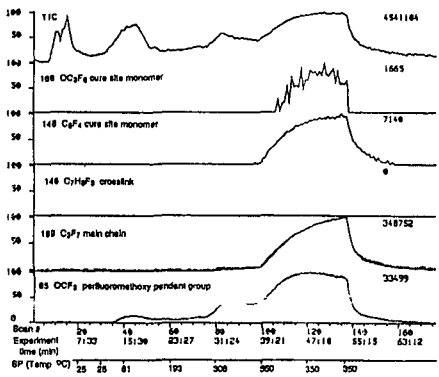

Figure 2. Plot of the solid probe-mass spectrometric analysis of unexposed TFE-PMVE copolymer.

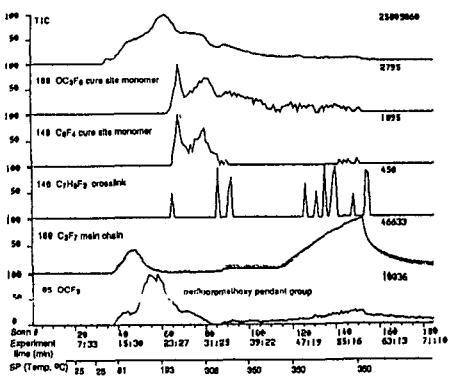

Figure 3. Plot of the solid probe-mass spectrometric analysis of TFE-PMVE copolymer exposed for 60 days.

The specific ions shown in Figure 2 and 3 were chosen because they are characteristic of a particular fragment of the polymer structure (see Figure 1), and were interpreted as representing a certain type of chemical degradation. Scission of the main chain pendant group, perfluoromethoxy, was assumed when the analysis detected the masses of 85, the ($-OCF_3$) group, and 66, the ($-OCF_2-$) group (not shown in the figures), at a lower scan number, or a lower temperature than in the unexposed sample. These ions were detected after only 16 hours of exposure. The other ether linkages that could be affected were those of the cure site monomer PPPVE. A number of ions were detected, but for simplicity, masses 148 ($-C_6F_4-$) and 166 ($-OC_3F_6-$) were selected for illustration. Although the exposure times at which the ions were initially detected varied, all the ions possible from PPPVE behaved similarly. Mass 146 is the main ion observed from the mass spectrum of Bisphenol AF and its detection was interpreted as resulting from the loss of the crosslink. Detection of mass 169 ($-C_3F_7-$) was evidence of main chain scission. Mass 169 was observed in samples exposed for 60 days.

In summary, the solid probe mass spectrometric analysis has provided evidence of structural degradation of TFE-PMVE copolymer from exposure to N_2O_4. The loss of ether pendant groups, the crosslink, and crosslink site monomer in TFE-PMVE copolymer were detected after a few hours of exposure to N_2O_4. Main chain scission was detected after 60 days of exposure. The SP-MS analysis was unable to determine if nitration of the phenyl groups of the bisphenol AF had occurred. Compared to other elastomers, TFE-PMVE copolymer is relatively compatible with N_2O_4. However, these results indicate that TFE-PMVE copolymer can not withstand indefinite exposure to N_2O_4.

The Use of Direct Insertion Probe Mass Spectrometry to Determine the Structures of Dialkyl Polysulfides

*Aris Gallon, The DOW Chemical Company, Plaquemine, Louisiana, 70765-0400.

INTRODUCTION:

The crosslinking of polymers or curing enhances the elasticity of polymers, which enables the polymer to return to its shape when deformed under stress. (1) The use of sulfur as a crosslinking agent is the most common method of curing polymers. (1) When sulfur is used as a crosslinking agent, a number of sulfide bonds linking the polymer together can be formed. To determine whether the number of sulfide linkages between polymers can be distinguished, mixtures of dioctyl polysulfides were analyzed by GC-MS and direct insertion probe mass spectrometry. Our study indicates that direct insertion probe (DIP) mass spectrometry rather than GC-MS analysis is the method of choice.

EXPERIMENTAL:

The mixtures of dioctyl polysulfides were analyzed using a HP 5985 mass spectrometer with the following GC, DIP, and mass spectrometer conditions:

Direct Insertion Probe:
initial temperature = 30 C hold = 2 min
rate = 25 C/min
final temperature = 325 C hold = 5 min
source temperature = 200 C
mass range scanned = 30-800 amu
EI voltage = 70 eV

GC-MS:
column = DB 1701 30m X 0.32 mm
initial temperature = 50 C hold = 1 min
rate = 15 C/min
final temperature = 225 C hold = 8 min
injection port temperature = 250 C
source temperature = 200 C
mass range scanned = 33-500 amu
EI voltage = 70 ev

RESULTS AND DISCUSSION:

The GC-MS analysis of the dioctyl polysulfide mixture indicated that crosslinking did not occur since only 2-octene was dectected in the GC chromatogram shown in Figure 1. The detection of 2-octene by GC-MS was believed to result from the formation of 2-octene via the decomposition of the dioctyl polysulfide compounds in the GC injection port.

The DIP-MS analysis of the mixtures of dioctyl polysulfides enabled the mass spectrum of the dioctyl disulfide (shown in Figure 2), dioctyl trisulfide, and dioctyl tetrasulfide compounds to be obtained. The mass spectra of the dioctyl polysulfides contained abundant molecular ions as well as ions resulting from S-S

and S-C bond scissions. Extracted ion chromatograms of the molecular ions of the dioctyl polysulfide compounds were used to optimize the reaction conditions for the dioctyl polysulfide formation to predominantly form the preferred dioctyl disulfide.

Applications of Desorption Chemical Ionization (DCI) Mass Spectrometry to Polymer Analysis

Robert L. Dilliplane and Lisa K. Turner
Rohm and Haas Company,
Analytical Research Laboratories
Spring House, PA 19477 and Bristol, PA 19007

INTRODUCTION

Desorption Chemical Ionization (DCI) was used to determine both the structure of additives within a polymer as well as the the composition of the polymer backbone.

While the additives remain intact during sampling, the high MW polymer chains are broken into smaller fragments, representative of the polymer composition.

ADVANTAGES

- Analysis time is under 5 minutes
- DCI probes are commonly available
- Sample preparation is minimal
- Soluble or insoluble polymers can be analyzed
- Spectra are easily interpreted (CI minimizes fragmentation)
- Tandem MS provides structural information

Description of Experiment

The experiment is straightforward. A small amount of polymer is placed on the probe filament. The probe, inserted directly into the CI source, is surrounded by a plasma of reagent gas ions. When the filament current is increased, fragments of the polymer are desorbed and immediately ionized.

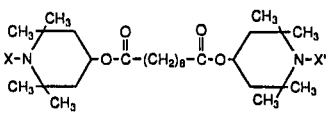
Using a variety of reagent gases, the protonated forms of the polymer fragments are differentiated from adducts. MS/MS elucidates the composition of the fragment ions, enabling the structure of the polymer backbone to be deduced.

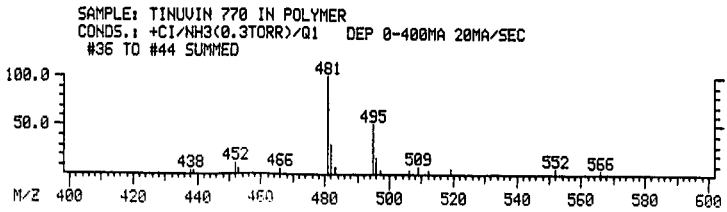
The analysis of polymer additives is performed similarly. The additive is not separated from the polymer but often desorbs prior to the polymer fragments.

RESULTS

I. Tinuvin 770

The application of DCI/MS to polymer additives in situ is demonstrated by the analysis of Tinuvin 770. Ideally, each additive will produce a single protonated molecular ion. Structural changes of the additive can be easily studied. During processing, the Tinuvin 770 undergoes successive methylation of the hindered amine. The degree of methylation depends on process conditions.

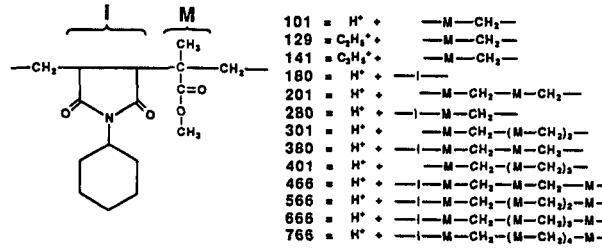


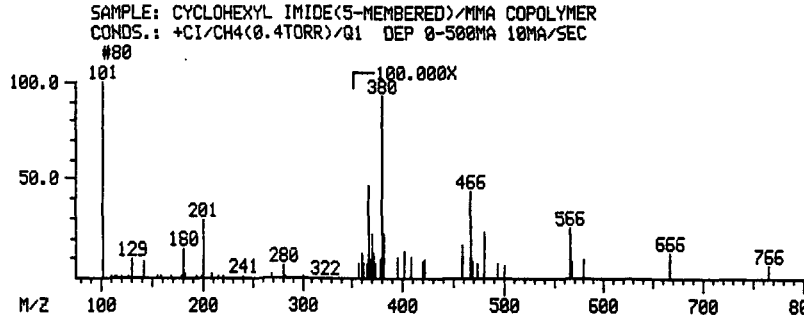


II. Imide Copolymers

Although these polymers have MW > 100,000, DCI/MS produces low molecular fragment ions. Series of repeat oligimers units account for the majority of ions in the spectrum and reflect the backbone of the polymer. The structure of the base unit can be determined using MS/MS and confirmed by analysis of individual homopolymers.

CYCLOHEXYL IMIDE(5-MEMBERED)/MMA COPOLYMER





CONCLUSIONS

DCI/MS is an easy method to detect polymer additives without separating the additive from the polymer prior to analysis. Since polymer additives may undergo reactions during processing, DCI/MS/MS can determine the reaction products of polymer additives.

High molecular weight polymers will not produce the protonated molecular ion using DCI/MS. However, we have demonstrated that polymers of molecular weights >100,000 produce ions that provide backbone structural information.

AN EVALUATION OF THE DESORPTION CHEMICAL IONIZATION MASS SPECTROMETRY OF ORGANOSILICON POLYMERS

Ron E. Tecklenburg
Dow Corning Corporation, Midland, MI 48686

Polysiloxane polymers ($R_3Si(OSiMe_2)_xOSiR_3$) are an important class of organosilicon materials having a wide range of useful physical properties. These substances have been used for a variety of commercial purposes, including lubricants, surfactants, antifoaming agents, sealants and matrices for drug delivery systems. The vast majority of organosilicon polymers exhibit low volatility and therefore are not amenable to conventional mass spectrometric analysis. In addition, organosilicon polymers are typically nonpolar and are not characterizable by secondary-ion mass spectrometry. To date, most mass spectrometric studies of nonvolatile polysiloxane materials have involved pyrolysis mass spectrometry, whereby the sample is thermally decomposed, and the thermal decomposition products are subsequently ionized and mass analyzed. This approach has met with only limited success, however, due to the fact that pyrolysis MS yields inconsistent and irreproducible mass spectra which are often difficult to interpret. With the advent of "softer" ionization/volatilization techniques, such as desorption chemical ionization (DCI), as well as advances in magnet technology, the molecular weight range of thermally labile/nonvolatile polymers which can be directly measured has been greatly extended.

A general study of the desorption chemical ionization of siloxane polymers was undertaken in our laboratory. In general, NH_3 reagent gas was found to be superior (to the more commonly used CH_4 and i-C_4H_{10} reagent gases) due to the relatively high ammonium ion affinities of siloxanes. Ammonia DCI mass spectra of polysiloxanes were found to typically produce ammonium adduct ions $[M+NH_4]^+$, $[M+NH_4-CH_4]^+$ and $[M-Me]^+$ fragment ions. The $[M+NH_4]^+$ versus $[M-Me]^+$ ion yields were not found to depend strongly upon the probe heating rate , suggesting that siloxanes have high thermal stabilities. As a result, relatively low DCI probe heating rates were used (1-15°C/sec), thereby i) increasing the time frame during which desorption/ionization occurred and ii) lowering detection limits.

Desorption chemical ionization was found to be a powerful tool for the elucidation of organosilicon polymeric structures as large as 4000 amu. For example, Figure 1 contains the NH_3 DCI mass spectrum of a silsesquioxane resin $(OSi_{3/2}H)_x$; x=10-74, sample size, 1μg, probe heating rate, 20°C/sec. $[M+NH_4]^+$ ions are formed throughout the 500-4000 amu mass range while $[M-H]^+$ are also observed at low mass (<1000 amu). Figure 2 contains the NH_3 DCI mass spectrum of trifluoropropyl-methyl macrocyclic siloxanes, $[OSi(CH_2CH_2CF_3)Me]_x$; x=11-47, sample size, 0.5 μg, probe heating rate, 12°C/sec. $[M+NH_4]^+$ ions predominate the DCI mass spectrum of $[OSi(CH_2CH_2CF_3)Me]_x$. Pseudomolecular ions as large as 7000 amu were recorded for this material. As these spectra demonstrate, DCI MS yields easily interpretable spectra. In addition, the absolute molecular weight distributions (for species as large as 5000 amu) agree well with those measured by gel permeation chromatography. DCI was found to be particularly advantageous in obtaining mass spectra for Si-H and Si-OH containing polymers which are not directly amenable to field desorption MS.

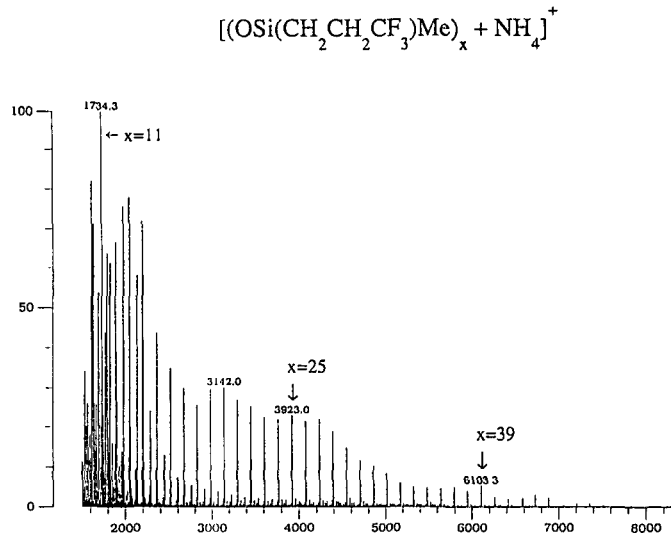

Figure 2. NH_3 DCI mass spectrum of $[OSi(CH_2CH_2CF_3)Me]_x$ macrocyclic siloxanes.

Time of Flight Secondary Ion Mass Spectrometry of Polybutadienes

Lucinda R. Hittle and David M. Hercules
Dept. of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260

TOF-SIMS has been used to characterize the mass of the repeat unit, the fragmentation within the polymer, and the molecular weight distribution of polymers. (1) In this investigation, we used TOF-SIMS to characterize the oligomer and fragment ions produced from polybutadienes, an industrially important class of polymers. Fragmentation within the polymer chain can yield valuable insight into polymer stability and degradation mechanisms. The relation of fragmentation pathways under ion bombardment to chemical structure is important for polymer identification and differentiation between structurally similar homo- and copolymers.

A series of molecular weight standards with narrow oligomer distributions were analyzed to obtain information about the fragmentation mechanisms of polybutadienes. The effect of the terminal group on fragmentation was also examined; t-butyl and benzyl terminal groups were studied. All experiments were conducted on the TOF-SIMS III, Ion-Tof GmbH, Muenster, Germany. The samples were cast as thin films on etched silver.

The molecular weight distributions of t-butyl terminated polybutadienes were examined to calculate M_n and M_w. Reasonable agreement was found with results from GPC and vapor pressure osmometry. Typical oligomer distributions are shown in Figures 1-2. The dominant peaks in the spectra are oligomers cationized with silver, but smaller peaks resulting from fragmentation were also observed. Although fragmentation between repeat units is common in polybutadienes, fragmentation may occur at other bonds. The mass region between two oligomer peaks for a typical polybutadiene is shown in Figure 3. Clusters of low intensity, approximately 14 mass units apart, can be seen for the fragments $nM + \Delta$, $nM + 2\Delta$, and $nM - \Delta$, where Δ is a CH_2 group. These clusters each contain several peaks, and may be the result of CH_2 loss as well as H_2 elimination.

The effect of increased polymer mass on fragmentation was studied. As the polymer mass increases, the formation of fragment ions from bond cleavage within the repeat unit becomes more important. In general, the intensities of the fragment clusters increased as a function of the polymer molecular weight. As the polymer chain length increases, the ability to stabilize radical ions through resonance should improve; thereby allowing fragmentation at bonds of greater energy.

Benzyl terminated polybutadienes having M_n similar to the t-butyl terminated polybutadienes were surveyed to determine the effect of the terminal group on fragmentation. The oligomer distribution was extremely broad, and the M_w was much higher than expected. All 4 samples showed nearly identical spectra; displaying a series of cationized fragment peaks rather than actual oligomer distribtions. A representative spectrum is shown in Figure 4. It was not possible to discern any radical trends in fragmentation as a function of polymer size. The primary fragmentation mechanism was cleavage between repeat units. The analogous fragment clusters $nM + \Delta$, $nM + \Delta$, and $nM - \Delta$ were observed for the benzyl terminated series. In general, the fragmentation patterns were the same regardless of the terminal group, which is not surprising since the majority of the polymer, with the exception of the terminal group, is identical for both the t-butyl and benzyl-terminated polybutadienes. For benzyl terminated polybutadienes, the intensities of the various fragment clusters tend to be much lower for fragments resulting from bond cleavage within the monomer than fragments resulting from cleavage between repeat units.

Static Secondary Ion Mass Spectrometric Analysis of Polymeric Materials Using a Magnetic Sector Mass Spectrometer

Y.P. Lin, and Y.C. Ling*

Department of Chemistry, National Tsing Hua University, Hsinchu, Taiwan 30043, R.O.C.

This study reports our results of systematic static SIMS analysis of six polymers using a magnetic sector SIMS instrument. Charging phenomena, which were generally considered to be more serious with a magnetic sector SIMS than a quadrupole or time-of-flight based SIMS, were studied first with a PTFE sample under dynamic SIMS conditions. Once the charging problem was resolved, the collected mass spectra were compared to those reported in the literature and collected using either a quadrupole[1,2] or time-of-flight[3-5] based SIMS. The aim is to evaluate the feasibility of using the vast amount of currently available mass spectra collected using either a quadrupole or time-of-flight based SIMS to aid the identification and interpretation of mass spectra collected using a magnetic sector SIMS such as the one used in this study.

All SIMS experiments were performed with a Cameca IMS-4f equipped with a O_2^+ ion source, a primary beam magnetic mass filter, and a normal incident electron gun. Instrumental control, data acquisition and processing were carried out with a IBM-AT compatible PC (SunMoonStar, Taiwan) run under Evans control software. PTFE, PE and PET films were pressed onto a small piece of silicon wafer individually to make sure that the analyzed surface was flat. A grid was then put on top of the sample to minimize charging. PMMA, PS and PC were obtained as granules. PMMA was dissolved in acetone at room temperature and then solvent-casted upon a silicon wafer with a 2,500-rpm spinner. PS and PC were dissolved in chloroform first and then prepared as the PMMA sample.

Charging effects on PTFE monitored in depth profile mode

Relative standard deviation (RSD) of at least eighty data points in the profile was calculated to evaluate the the degree of charging effects. This approach is based on the findings that charging generally leads to instability, reduction, or even complete suppression of the secondary ions intensity[6]. Positive ions of C^+, CF^+, and CF_3^+ as well as negative ions of O^-, F^-, F_2^- are selected as monitored ions due to their relative high intensities. The profiles stability in terms of RSD relative to the primary ion currents with or without electron beam on are shown in the Table 1. The results indicate that electron compensation for positive ion analysis was not necessary either under static or dynamic condition. When the negative ions were analyzed, a electron beam was needed to compensate excess positive charges on the surface of the polymer.

Table 1. Charging effects in terms of relative standard deviation of data points obtained from profiles under various operational conditions

HIGH RESOLUTION TOF-SIMS STUDIES OF SUBSTITUTED POLYSTYRENES

M. Paul Chiarelli, Andrew Proctor, Ioannis V. Bletsos and David M. Hercules
Department of Chemistry, University of Pittsburgh
Pittsburgh, PA 15260

Herbert Feld, Angelika Leute and Alfred Benninghoven
Physikalisches Institut, Universität Münster
4400 Münster, Germany

Introduction.

High resolution ($M/\Delta M$ = 7000) time-of-flight secondary-ion mass spectrometry (TOF-SIMS) was used to study the mechanism of fragment-ion formation for several polystyrenes. Ions are formed from neutral fragments resulting from chain cleavage, and are cationized with a silver ion. The results of this study support the idea that chain fragmentation proceeds through a cyclic intermediate. The present investigation represents the first high-resolution study of polystyrene fragment ions in the range m/z 600-3000. The focus is on the effect of molecular structure on the overall spectral pattern, and detailed analysis of the structures contributing to the mass spectrum of a given polymer fragment. Analysis of the spectra provides insight into the initial events of chain scission when a pulse of energy is provided to the polymer chain.

Results and Discussion

Interpreting fragment-ion spectra requires two separate considerations. First, it is necessary to explain the overall structural features of the mass spectrum. In the case of the polystyrenes, this constitutes a repeating pattern of peaks, separated by the mass of the polymer repeat unit. A typical example is shown in Figure 1(A) for poly(4-methyl styrene) (poly 4-MS). The repeating sequence will be referred to as a pattern, so noted in the figure. Second, each pattern consists of groups of peaks spaced approximately 14 amu apart. Each of these contains a number of individual lines and will be referred to as a cluster, also noted in the figure. The spacing between clusters will be noted by "Δ" (so-noted in Fig. 1) rather than by a numerical value, because species having varying degrees of unsaturation contribute to each cluster (loc. cit.). The pattern for poly 4-MS centered at m/z 1407 is derived from fragments consisting of 11 monomer units, plus or minus additional CH_n units (Δ). The detailed structure of the clusters having six repeat units is shown in Figure 2(A) for poly 4-MS.

The spectrum for poly 4-MS in Fig. 1 shows three repeat patterns, each consisting of three major clusters corresponding to R_n, $R_n+\Delta$ and $R_n-\Delta$ where R_n is some multiple (n) of the mass of the repeat unit. Two smaller peaks are observed at $R_n+2\Delta$ and $R_n+3\Delta$ for each pattern. All of the polystyrenes studied showed this general type of pattern except for poly(α-methyl styrene) (poly α-MS) which was quite different, as can be seen from Fig. 1B. None of the polystyrenes studied showed any evidence for fragmentation involving the phenyl group or functionalities on it. No polystyrene showed any ions having characteristic end groups (all had MW $\geq$ 70,000) and no uncationized radical ions were observed for species larger than one or two monomer units. All ions to be discussed here are derived from cationized neutral fragments.

We will make several assumptions for discussion of polymer fragmentation. First, each event observed is initiated by only one primary ion and the initiation process does not involve the ion

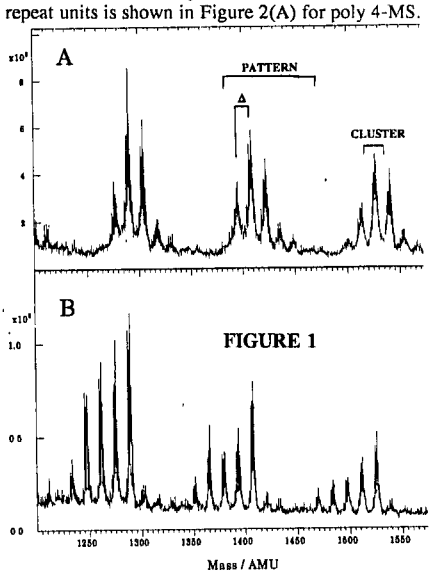

FIGURE 1

hitting the polymer chain directly. Chain fracture is initiated by the collision cascade resulting from impact of the primary ion with the silver surface. Second, each event involves an isolated polymer molecule. Third, two fragments are formed per event; the polymer chain is fractured initially, and two subsequent fractures occur, one involving each chain fragment produced by the initial fracture. Fourth, the cationization probablilties of all neutral fragments produced are equal. Fifth, the probabilities of breaking all carbon-carbon bonds involving the polymer backbone are the same; this assumption is reasonable given that the C-C bond energies vary by only a few kcal/mole.

The formalism for the interpretation is given in Scheme 1 for a generic polystyrene. We consider two possible fragmentation pathways for the polymer: initial fracture of the backbone chain (path A); and initial loss of a phenyl group with subsequent chain fracture (path B). The two pieces produced initially in Path A can subsequently fracture, giving only two possible structures each: A-1 yields only R_n-Δ or R_n; A-2 gives only R_n+Δ or R_n. Either fragment from Path A can lose styrene monomers (chain unzipping), but doing so merely generates the same type of radical having n reduced. Adding up the intensities, if this were the only fragmentation mechanism operative, the mass spectrum would consist of a series of triplets, centered about R_n, and having relative intensities of 1:2:1. Path B differs qualitatively in that one piece generated by chain fracture has a neutral end (B-1) and other is a radical (B-2). Subsequent scission of the neutral fragment (Path B-1) will produce peaks at R_n+2Δ or R_n+3Δ; B-2 is equivalent to A-1 and as such produces R_n or R_n-Δ. Thus the two pathways account qualitatively for the five peaks seen in the spectrum of poly 4-MS, and is typical of the polystyrenes.

Poly α-MS shows a distinctly different cluster pattern than the other polystyrenes, as can be seen from Fig. 1. The most striking feature is that the peak corresponding to R_n+Δ is greatly reduced in intensity and significant peaks appear at R_n-2Δ, R_n-3Δ and R_n-4Δ. The major structural difference is that poly α-MS has a methyl group replacing the benzylic hydrogen. This methyl group is labile as indicated by MIKES/CAD studies of $C_9H_{10}^+$ isomers. Pulse radiolysis studies of poly α-MS postulated that a rearrangement involving the methyl group is responsible for the chain unravelling mechanism. The radical produced by initial chain cleavage rearranges to form the more stable benzylic radical which loses a neutral to produce a radical. This type of reaction has been reported for the thermal degradation of polystyrenes.

Tandem Mass Spectrometry (MS/MS) of Poly(ethyleneglycol) Proton- and Deuteron-attachment Ions.

Robert P. Lattimer, The BFGoodrich Research and Development Center, Brecksville, Ohio 44141.

Earlier work from our laboratory [1-2] investigated the MS/MS behavior of $[M + H]^+$, $[M + Na]^+$ and $[M + Li]^+$ ions from linear poly(ethylene glycol), PEG, and poly(propylene glycol), PPG. The $[M + H]^+$ ions fragmented readily under low energy collisional activation ($\approx$50 eV) [1]. The product ions were of relatively low mass and were explained in terms of charge-site initiated decomposition (see Scheme 1).

The principal thrust of the current work was to investigate in detail the collisional dissociation of proton- and deuteron-attachment PEG ions. Both cyclic ("crown ether") and linear (hydroxyl- or methyl-terminated) oligomers were studied. Interestingly, it was found in several experiments that considerable H/D exchange occurs during the formation of hydroxyl-terminated product ions from $[M + D]^+$ precursors. This exchange indicates that more complex decomposition pathways than those described previously [1] are needed to explain the observed product ions.

MS/MS experiments were carried out with a Finnigan MAT 95Q hybrid mass spectrometer (BEoQ), with E_{lab} 50 eV and collision gas air ($\approx$0.2 Pa). Ionization was by fast atom bombardment. Three samples were linear polymers, R-O-(-CH_2-CH_2-O-)$_n$-R': PEG (R=R'=H), PEGME (R=H, R'=CH_3), and PEGDME (R=R'=CH_3). Three other samples were cyclic polymers, -(-CH_2-CH_2-O-)$_n$-: 12-crown-4 (MW 176), 15-crown-5 (MW 220), and 18-crown-6 (MW 264).

Major features in the product ion spectra may be summarized as follows:

$[M + H]^+$ or $[M + D]^+$ precursors from PEGDME (dimethyl ether) gave only one major series of product ions (designated **B**): CH_3-O-(-CH_2-CH_2-O-)$_n$-CH_2-CH_2^+ (m/z 44n + 59).

$[M + H]^+$ precursors from PEGME (methyl ether) gave two major series of product ions, designated **B** and **A**: HO-(-CH_2-CH_2-O-)$_n$-CH_2-CH_2^+ (m/z 44n + 45). For the **A**-series product ions from $[M + D]^+$ precursors from d_1-PEGME, considerable abundances of *both* the d_0 and d_1 ions were observed.

$[M + H]^+$ precursors from PEG (dihydroxyl-terminated) gave principally **A**-series product ions. For the $[M + D]^+$ precursor from d_2-PEG, the **A**-series was again split between d_0 and d_1 ions.

The product ion scan for $[M + H]^+$ from 18-crown-6 was very similar to that for the linear PEG, with only the **A** series prominent. For the $[M + D]^+$ precursor, the **A**-series ions were again split between the d_0 and d_1 species.

As a first approach, one might suppose that the **A**-series product ions from linear PEG are formed via a simple charge-site initiated cleavage. This is an inductive effect (*i*) which produces the hydroxyl-terminated carbonium ion series shown in Scheme 1. In the case of the $[M + D]^+$ d_2-PEG precursor [DO-(-CH_2-CH_2-O-)$_n$-D]·D^+, this scheme predicts that only a d_1 product ion series will be formed: DO-(-CH_2-CH_2-O-)$_x$-CH_2-CH_2^+ (m/z 44n + 46). That is, there is no provision in Scheme 1 for the abundant d_0 **A**-series ions that have been observed in the current study.

Scheme 2 is proposed as a decomposition pathway that appears to be consistent with the current data. $[M + D]^+$ precursors from linear PEGME (I) and cyclic PEG (II) are used for illustration. The first step (as in Scheme 1) is a heterolytic C-O cleavage. For PEGME this gives two product pairs. In one case, methoxy-terminated **B**-series ions are formed. In the second case, hydroxyl-terminated (-OD) carbonium ions (V) are formed. A number of fates are possible for this intermediate. Key to the formation of d_0 **A**-series product ions, however, is a reversible exchange reaction (intermediates VIII and IX). Hydroxyl-terminated ions (-OH or -OD, V and IX) can eliminate one or more ethylene oxide units (EO, C_2H_4O) via "backbiting" reactions (*cf* intermediate VI) to give lower-mass **A**-series product ions (VII and X).

At first it seems curious that *linear* PEG gives a product ion scan essentially identical to that for *cyclic* PEG. This suggests the possibility of a common intermediate, as is proposed in Scheme 2. A charge-site initiated cleavage of the cyclic $[M + D]^+$ ion (II) leads directly to intermediate V, which is the same as that formed from the linear precursor (I). Note in Scheme 2 that elimination of small cyclic EO oligomers (particularly the dimer, dioxane) seems to be a favorable decomposition pathway for the cyclic ethers.

One would expect that H/D exchange via intermediates VIII and X should be more prominent at higher collision gas pressures. Thus, one prediction is that the ratio of d_1 product ions (VII) to d_0 ions (X) should be larger with a lower collision gas pressure. Secondly, one would expect to find a higher proportion of *higher mass* **A**-series product ions at lower collision gas pressure. These two predictions were borne out by experiments in the collision gas off (CG OFF) mode.

The results of this study show that the collisionally-induced dissociation of proton-attachment ions from ethylene glycol polymers is more complex than previously supposed [1]. It was found in several experiments that considerable H/D exchange occurs during the formation of hydroxyl-terminated carbonium product ions from $[M + D]^+$ precursors. A new decomposition pathway (Scheme 2) has been proposed that attempts to explain the current MS/MS data. The first step in this scheme is the charge-site initiated, heterolytic cleavage of a C-O bond. This produces a hydroxyl-terminated carbonium ion that can be formed from either cyclic or linear PEG $[M + H]^+$ precursors. From deuterated (-OD) precursors, this scheme proposes that H/D exchange occurs internally within this key intermediate. Subsequent decomposition of this intermediate (via backbiting) leads to elimination of one or more ethylene oxide (EO) groups, with some loss of deuterium. In addition to accounting for the H/D exchange, Scheme 2 also helps to explain the high abundance of lower-mass product ions observed during CID of $[M + H]^+$ precursors.

LASER MICROPROBE MASS SPECTROMETRY OF CERTAIN SYNTHESIZED COPPER ORGANIC COMPLEXES AND THEIR ANALOGS FORMED IN THE LASER INDUCED PLUME

R.A. Fletcher and A.J. Fatiadi
National Institute of Standards and Technology
Gaithersburg, MD 20899.

The initial goal of the study was to use laser microprobe mass spectrometry to structurally characterize the poly(4-vinylpyridine) (PVP) copper complexes thought to be formed on the surface of a column packing bead material.[1] There has been considerable interest in PVP copper complex polymer bead material for use in protein immobilization.[2] Such polymer matrices have been used for affinity chromatography; protein molecules are replaced by molecules with greater affinity to the bonding site.[3] A commercial laser microprobe time-of-flight mass spectrometer, previously described, was used in the study.[4,5] The spatial resolution (1 to 4 μm) of the UV probe beam and the absence of charge accumulation on the sample were beneficial for the analysis of the bead material. For this study, the copper sulfate salts of 2,2'-dipyridyl, 2,2'-biquinoline, and 4,4'-dimethyl-2,2'-dipyridyl were synthesized at NIST and characterized by laser microprobe mass spectrometry to aid in the determination of the fragmentation pattern of the PVP bead material. Similarity in these compounds lies in the dual pyridine members present in all compounds, which serve as a coordination site for the copper.

Gas-phase addition (or vapor phase recombination) to laser ablated materials is well known.[6-12] Similar behavior has been found in secondary ion mass spectrometry.[13,14] In the present experiments, gas-phase copper addition is shown for 2,2' biquinoline and PVP by co-ablating copper metal with the compound. The copper biquinoline salt was mounted and analyzed on a nickel transmission electron microscope (TEM) grid while the gas-phase addition was achieved utilizing copper metal TEM grids as mounting substrates. In Figure 1a, a single positive ion mass spectrum of pure 2,2'-biquinoline (BQ) crystal is presented. The relevant ion is $(BQ+H)^+$ at m/z 257. Figure 1b presents the average of 10 positive ion mass spectra of the 2,2'-biquinoline copper sulfate in crystal form. In addition to $(BQ+H)^+$, there are peaks at $(BQ+Cu)^+$. The evidence for gas-phase formation of biquinoline copper complex is shown in Figure 1c which is also the average of 10 positive ion spectra formed by simultaneously ablating copper metal and pure biquinoline. The same peaks are present as in Figure 1b; the main difference in the two averaged spectra is the relative abundance of copper ions in the latter (1c). Another example of gas-phase addition is illustrated in Figure 2 for the PVP polymer bead. The monomer (M) of this polymer has molecular weight of 105. Figure 2a shows a peak at m/z 106 corresponding to $(M+H)^+$. A single positive ion mass spectrum of PVP copper complex is shown in Figure 2b indicating the presence of the monomer copper complex (m/z 168,170) and a dimer complex. Figure 2c shows the gas-phase addition to the monomer and dimer as indicated.

In summary, spectra generated from the preformed compounds and the spectra obtained from the gas-phase attachment are compared and found to be quite similar. The main difference between the spectra is the abundance of copper ions in the gas-phase case. This is an example of gas-phase attachment processes complicating structural characterization by laser mass spectrometry.

Study of Experimental Parameters for Laser Desorption FTMS Analysis of Nonpolar Polymers

Michael S. Kahr and Charles L. Wilkins

Department of Chemistry
University of California, Riverside
Riverside, CA 92521

Introduction - Laser desorption FTMS of nonpolar polymers is generally more difficult than for polar polymers. Difficulties arise during both sample preparation and in the ionization of the analyte by laser desorption. Presented here are the results of substrate assisted laser desorption/ionization of polybutadiene and matrix assisted laser desorption/ionization of polystyrene by FTMS.

Experimental - Mass spectra were obtained using a 7-Tesla Nicolet FTMS 2000 Fourier transform mass spectrometer, equipped with a solids autoprobe and a differentially pumped dual cell.

Lasers: For substrate assisted laser desorption/ionization of polybutadiene, a Tachisto 215 pulsed TEA CO_2 laser operating at 10.6 μm was employed. For matrix assisted laser desorption/ionization of polystyrene, a Lambda Physik excimer -pumped FL-2001 dye laser operating at 355 nm was employed.

Experiment Sequence: A retarding potential sequence was used to assist in trapping ions formed during the desorption process. During and after the laser desorption event, the source trap plate was grounded while the conductance limit was held at 9.0 volts for a period (optimized for each sample) of between 100 and 300 μsec. Following this event, the source trap plate and the conductance limit were set to a 1.6 volt trapping potentional before excitation and detection of the trapped ions.

Samples: All samples were obtained commercially and used without further purification. Polybutadiene Mw=2800 was obtained from Polysciences Inc., Warrington PA. Polystyrene Mw=8300 was obtained from Scientific Polymer Products Inc., Ontario NY. Gold foil, 0.1 mm thick 99.9 % Gold Label, was obtained from Aldrich Chemical Co. Inc., Milwaukee WI. 2,5 Dihydroxybenzoic acid was obtained from Fluka, Ronkonkoma NY.

Sample Preparation:. For substrate-assisted laser desorption/ionization, polybutadiene was dissolved in methylene chloride and applied to a gold foil disk. The solvent was allowed to evaporate before introducing the sample into the vacuum system. For matrix assisted laser desorption/ionization (MALDI), a 500 to 1 ratio of 2,5 dihydroxybenzoic acid to polystyrene was dissolved in acetone. Homogeneous sample deposition was obtained by spraying an aerosol of the matrix/analyte solution onto a rotating stainless steel probe tip.

Results and Discussion

Substrate Assisted Laser Desorption/Ionization:. Gold has a high ionization potential (9.22 eV) and forms reactive charge exchange reagent ions by laser desorption. Figure 1 is a LD-FTMS spectrum of polybutadiene of average molecular weight 2800. This spectrum was obtained by employing a gold foil substrate. For this sample, conventional laser desorption conditions failed to yield useful spectra. Future work will include exploring the use of a gold substrate for analysis of other nonpolar polymers.

MALDI:. An example of MALDI FTMS is shown in Figure 2 for a high mass polystyrene sample. The observed oligomer distribution is that corresponds of sodium attached oligomer ions . Alkali metal attachment is probably occurring to the electron-rich phenyl rings. If this is the case, then other nonpolar polymers that contain phenyl functionality may yield mass spectra under similar experimental conditions. Future work will involve applying MALDI to other nonpolar polymers containing phenyl functionality, to explore the generality of the technique.

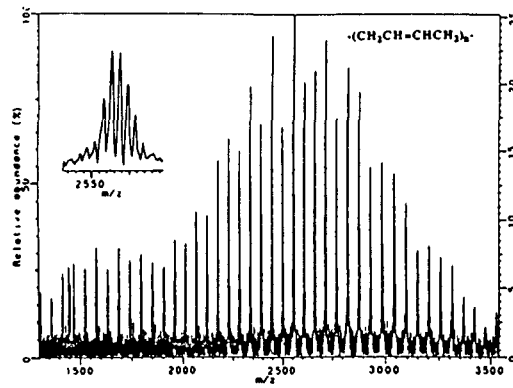

Figure 1: Polybutadiene Mw=2800 Laser desorbed from a gold foil substrate.

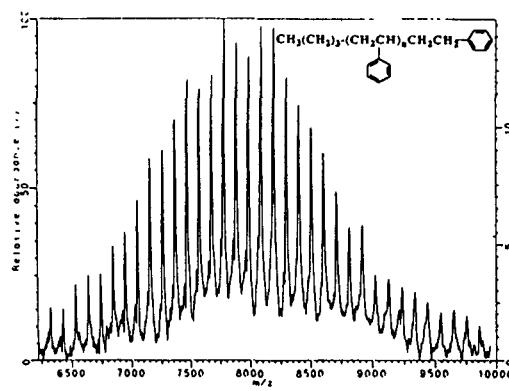

Figure 2: Polystryene Mw=8300, Matrix Assisted Laser Desorption/Ionization FTMS. This spectrum shows the distribution of sodium-attached oligomer ions.

cw-CO_2 Laser Polymer Pyrolysis in a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

Jeffrey A. Zimmerman and William R. Creasy
IBM Corporation, P.O. Box 8003, Dept. T67
Endicott, New York 13760

Polymer decomposition routes have been characterized in a Fourier transform ion cyclotron resonance mass spectrometer (FTICR-MS) using a cw-CO_2 laser to pyrolyze the samples. This method of pyrolysis offers several advantages over more conventional techniques, in addition to complementing the existing ionization sources. The ability to heat only the sample, selectivity over which portion of a sample is investigated, rapid heating (for strongly absorbing samples up to ca. 2500°Cs^{-1}), ease of interfacing, positive and negative ion formation, and the use of other techniques in tandem add to the value of this method. Disadvantages include the inability to heat some samples because of lack of a suitable chromophore and an inherent uncertainty in the heating rate.

A 40 W Synrad, sealed tube cw-CO_2 laser operating in a narrow wavelength range centered at 10.6 μm ($\pm$ 0.1 μm) was used to pyrolyze samples in an Extrel FTMS-2000 mass spectrometer previously equipped with a Nd:YAG (266 nm) laser microprobe[1] and containing only a source-side cell. The degree of sample heating was controlled by adjusting the laser pulse duration (pulse energy could not be altered). Samples could be mounted on the solids probe for analysis by either pyrolysis or laser desorption with the Nd:YAG laser. The ability to use both the techniques in tandem was accomplished by introducing the infrared light via the analyzer-side of the vacuum chamber which was devoid of obstructions barring the external electron beam. The laser beam entered the chamber off-axis to center through a ZnSe lens to bypass the electron beam, however both the laser target and the electron beam were coaxial within the cell. The analyzer-side trap plate was replaced with nickel mesh. Both positive and negative ions (via electron ionization) were subsequently detected.

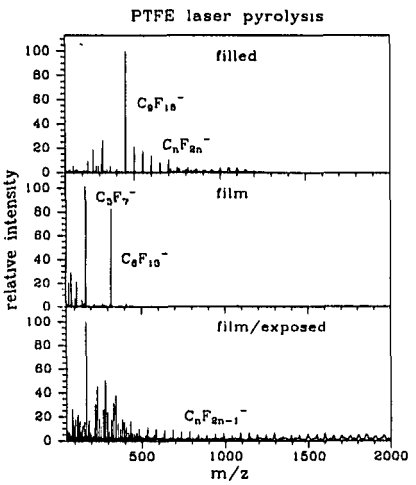

Figure 1 Laser pyrolysis of PTFE.

Figure 1 illustrates typical results obtained using laser pyrolysis for different poly(tetrafluoroethylene)s, PTFE, samples. The uppermost spectrum is a filled PTFE film at 400 ms laser exposure time and negative ion formation/detection. Under these pyrolysis conditions repeating $C_nF_{2n}^-$ monomer units replicate past 1200 amu. These ions were not the result of ion/molecule reactions. The large mass fragments were not observed for unfilled PTFE shown in the middle spectrum. The

largest mass ion in this spectrum occurred at m/z = 169 ($C_3F_7^-$) and m/z = 319 ($C_6F_{13}^-$). In contrast, the bottom spectrum was acquired from a sample treated downstream from a helium microwave plasma. Surface modification is evident from the defluorinated fragment ions observed ($C_nF_{2n-1}^-$). Laser pyrolysis was useful for this study because it was possible to only ionize those neutrals emitted from the side of the polymer that was exposed to the UV radiation. Defluorination and accompanying oxygenation of the polymer have been observed for these polymers by XPS analysis,[2] and are readily observed in the laser pyrolysis analysis.

Additional PTFE based polymers have been investigated with this technique as well. Teflon FEP® and PFA® (I.E. Dupont Nemours, Inc.), copolymers of tetrafluoroethylene and hexafluoropropylene or perfluoro(propylvinylether) respectively, produce very similar positive ion pyrolysis spectra to PTFE. In fact, the spectra were so comparable that identification based solely on the subtle differences was very ambiguous. However, the negative ion spectra were quite different, with the FEP producing $C_nF_{2n-1}^-$ fragments via the apparent loss of CF_3, and PFA predominately furnishing $OCF_2CF_2CF_3^-$. Thus, polymer identification as well as decomposition routes were facile when examined via the negative ion chemistry.

Figure 2 demonstrates another application of the laser pyrolysis technique. The laser pyrolysis mass spectra of Triton® X-100 (Rohm and Haas, Co.), $C_8H_{17}C_6H_4(OCH_2CH_2)_nOH$ with an average n = 10, are shown at differing pyrolysis exposure times for the positive ion spectra and a comparable negative ion spectrum. For this polymer the positive ion spectra produced the molecular ion, while the negative ion spectrum was characterized by rearrangement. Poly(ethylene glycol)s produced the converse. The effect of varying the laser exposure period can be observed in the positive ion spectra. As would be expected, lower molecular weight oligomers originate at the shorter exposure times. This hinders the ability to accurately determine average molecular weights and to obtain reasonable distribution assessments, however offers ease in attaining a spectrum without the constraint of having to alter the sample with an inorganic salt (to obtain a laser desorption spectrum).

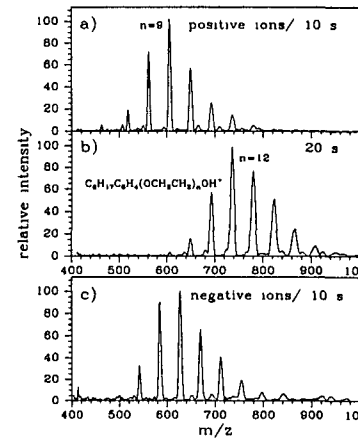

Figure 2 Triton X-100 laser pyrolysis.

The laser pyrolysis technique, coupled with the ability to obtain information by forming negative ions, has proven to be a worthwhile technique for the routine identification of polymeric materials and the characterization of new decomposition pathways via negative ion chemistry. It was also quite useful, and has been used successfully, in the detection of trace levels of residual halogenated solvents and the detection of brominated resins.

Laser FTMS of Perfluorinated Polyethers

K. Reihs, E.F. Cromwell, M.S. deVries, H.R. Wendt, and H.E. Hunziker
IBM Research Division, San Jose, CA 95120
and S. Ghaderi, IBM ADSTAR, San Jose, CA 95193

There has been a great interest in studying large bio-molecules and polymers by gas phase mass spectroscopy techniques traditionally used for much smaller molecules. Some of the methods used for this have been matrix assisted laser desorption/ionization with a time-of-flight (TOF) mass spectrometer,(1) TOF secondary ionization mass spectroscopy (SIMS),(2) and laser desorption/cationization with Fourier transform ion cyclotron resonance mass spectroscopy (FTMS).(3) We present a study of laser desorption and ionization of large perfluorinated polyethers (PFPE) on metal surfaces. An example of is shown below.

CF3-CF2-CF2-O-(CF2-CF2-CF2-O-)n-CF2-CF3 (I)

We have observed the fragmentation patterns of these polymers and have developed a new method of cationization which, by using two lasers, separates the desorption and metal ion formation processes and enables us to observe the parent mass distributions of various perfluorinated polymer samples.

The mass spectra were taken with a FTMS system using a cubic ion trap and a 4.3T superconducting magnet. FTMS is described in detail elsewhere.(4) Three different lasers were employed for desorption and ablation. A Nd:YAG laser with a KDP doubling crystal at 532nm , a KrF excimer laser at 248nm and an ArF excimer laser at 193nm. The lasers were focused by a lens, through the ion trap, and onto the sample surface held next to the ion trap in the vacuum chamber. Samples were prepared by making 5% by weight solutions of the PFPE's in n-perfluorohexane and the placing a few drops onto a metal foil piece forming an approximately micron thick film.

When a few mJ of 193nm (or 248nm) light is focused onto a PFPE film a characteristic negative ion fragmentation pattern is observed. A mass spectrum of (I) (n[avg]=25) taken under such conditions is shown in Figure 1. The negative ions are formed by a photoelectron attaching to a polymer molecule proceeded by a C-O bond cleavage. The pattern is consistent with a random breaking of a C-O bond after electron attachment and shifts towards lower mass as the laser energy is increased. No negative parent ions are observed. This is believed to be due to a fast and efficient dissociation of those ions.

When a defocused 248nm beam (3mJ, 2mm dia.) is used to desorb the PFPE film and a tightly focused 532nm beam (0.3mJ, <50um dia.) is overlapped with that desorption spot cationized parent molecules (PFPE * M+) are observed. A mass spectrum of (I) (deposited on a Cu foil) taken under these conditions is shown in Figure 2. The main progression of peaks correspond to the PFPE/Cu cation complexes for n=13 to 46 while the satellite peaks result from polymers with different end groups. From the parent mass distribution it is possible to calculate an average molecular weight of the polymer sample. The spectrum shown in Fig. 2 yields an average weight of 4610 amu which is in good agreement with NMR measurements of 4560 +/- 50 amu. Cationization had been observed with various metals (Cr, Fe, Co, Ni, Cu, Zn, Al, Mo, Ag) and polymers having different end groups and backbone structures. Row 3 metals appear to be the most efficient although direct comparison between these metals (using alloys) show similar efficiencies. By changing from a straight chain polymer, (I), to a "Y" chain

(-C(CF3)F-CF2-O- repeat unit) a factor of 5 increase in cationization cross section was observed. This is believed due to a greater "visibility" of the F-atoms and is consistent with a cationization mechanism where the metal ions attack the F-atoms before complexing.(5)

The use of two lasers allows examination of the time and spatial relations between the PFPE desorption and cationization processes. Varying the time delay between the two lasers reveals that the maximum signal is realized for PFPE desorption occurring 1-3us before metal ion formation and the signal persists out to >20us delay. However, if the metal ion laser comes first the signal disappears after 1us delay. Spatially, the two laser spots do not have to be overlapped to observe cationization although the signal intensity decreases as the beams are separated. The signal was observed to disappear for separations greater than 200um.

In another experiment, the photochemistry of a polymer with a phenyl containing end group was examined. A film of this PFPE was placed on a Cu foil and exposed to 248nm light in vacuum. The phenyl end group, which absorbs at 248nm, was observed to dissociate while the polymer backbone remained intact. When exposed to 193nm light under similar conditions the end group dissociated and the polymer chain length became shorter. The increased reactivity can be explained by the fact that the polymer product absorbs at 193nm but not at 248nm.(5)

Previous cationization has been accomplished by mixing Na and K salts in with a sample.(3) The use of a metal surface to provide the cations eliminates the need to mix in salts (which is not alway possible) and allows for observations of processes which might be inhibited or obscured by the presence of large amounts of salts.

MATRIX-ASSISTED LASER DESORPTION IONIZATION MASS SPECTROMETRY OF SYNTHETIC POLYMERS

Michael Karas, Andreas Deppe and Franz Hillenkamp
Institute for Medical Physics and Biophysics, University of Münster,
4400 Münster, FR Germany

Ulrich Gießmann, Finnigan MAT, 2800 Bremen, FR Germany

In recent years, matrix-assisted laser desorption ionization (MALDI) has become established as a powerful technique for mass spectrometry of biopolymers in the mass range up to 500 000 Dalton [1].

Synthetic polymers pose an interesting challenge for mass spectrometry once high molecular masses are accessible. Both the average molecular weight and the distribution of the oligomers can be directly taken from the mass spectra. Though in principal the matrix approach should also be applicable to this group of compounds, application of the MALDI technique to the analysis of synthetic polymers has to account for several differences. Most of the matrices used so far are soluble in aqueous solvents and used for water-soluble biopolymers. Water-soluble, e.g. polar or ionic polymers may therefore be examined using these well-known matrices, others may require new matrices to ensure a good miscibility in the condensed phase, a prerequisite for successful MALDI analysis. Moreover, ionization cannot be expected to take place via protonation as in the case of peptides and proteins. Therefore additives for an effective and uniform cationization of the molecular species have to be found.

For the results reported here, a reflectron TOF mass spectrometer (Vision 2000, Finnigan MAT, Bremen) was used, equipped with a Nd-Yag laser delivering 5 ns pulses at 355 nm. The laser beam is focused to 70 μm in diameter.

All polymers investigated were from commercial sources and used as supplied. The following samples were successfully analyzed: Polyethylene glycol (PEG), Polyethylene oxide (PEO), Methoxy polyethylene glycol with average molecular weights up to 40000 Da; polypropyleneglycol (PPG) up to 6000 Da., Polystyrene (PS) and Polystyrene sulfate up to 70 000 Da; Polymethyl methacrylate (PMMA), Polyacrylic acid and its Na-salt up to 10 000 Da. Water soluble polymers were dissolved to 1g/l and mixed 1:1 with a 10g/l 2,5-dihydroxybenzoic acid (2,5-DHB) solution as matrix. Polymers which are insoluble in water are directly dissolved in the liquid matrix nitrophenyl octylether (NPOE) [2] at a concentration of 10g/l. To induce a uniform cationization sodium or silver salts were added. 1-3 μl of the solutions were dripped onto a metal substrate.

In the positive ion spectra of all polymers investigated exclusively cation-attached molecule ions of the individual oligomers are observed, fragmentation is not apparent from the spectra. Fig. 1 shows the MALDI mass spectrum of PMMA 7100; NPOE was used as matrix. Only silver attached molecule ions appear. Beside the number average molecular weight (M_n) of 6395 as determined from the peak areas, information about the unit of repeat (100 Da), the width and symmetry of the distribution can be obtained.

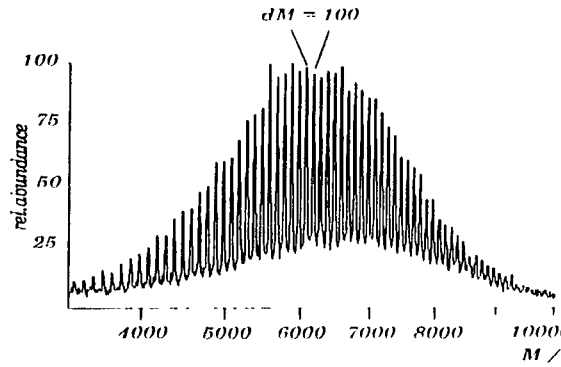

Fig. 1: PMMA 7100. Matrix:NPOE

Fig. 2 shows the spectrum of polystyrene sulfate 46000 using a DHB matrix. Although the unit of repeat is not resolved in this mass range, the maximum and the width of the distribution characterize the sample.

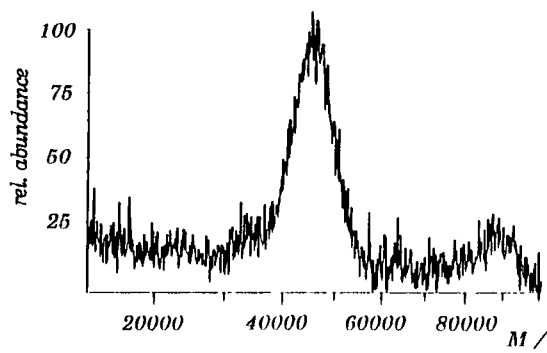

Fig. 2: PS sulfate 46000. Matrix DHB

Analysis of the non-soluble ether fraction of Baltic amber

Frédéric SALTRON, Christian ROLANDO,

Ecole Normale Supérieure. Département de Chimie,
U.R.A 1110 du CNRS, Laboratoire de l'Activation Moléculaire,
Laboratoire associé à l'Université Pierre et Marie Curie, 7
5231 Paris Cedex 05, France

Amber is a fossilised diterpenic resin, located in geological deposits aged between one and two hundred millions years. It is widely found in archaeological excavations in artistic forms: beads, pendants and carved objects of unknown use. The most important bed of amber is on Baltic coast. But it is also found in South of Europe (France, Italy, Sicily), in North Africa (Morocco), Middle East (Lebanon) and North America (Dominican republic).

Analytical characterisation of amber is an important objective in order to identify the provenance of native amber used in these archaeological objects and for ascertaining the famous "ancient Baltic trade route".

Solubilisation of Amber

Amber has a very low solubility in usual organic solvents, in opposition to fresh terpenic resins (rosin, dammar, copal) or fossilised resins like kauri which are completely soluble. The elemental composition of amber shows the presence of a few percents of sulfur. This fact prompted us to try to dissolve amber with a reagent able to cleave disulfur bonds like thioglycolic acid.

Sample treatment

For this preliminary study an authentic sample of Baltic resin was used. Amber was manually finely grounded using a mortar.

Ether solubilization

For solubilisation in diethyl ether, the powder was poured over solvent during one week with soft stirring, at room temperature. Extract was then filtered and the non-soluble part was collected.

Thioglycolic acid solubilization

Solubilisation was performed by refluxing a suspension of grounded amber in aqueous 5% thioglycolic acid during a night. The solution is then treated by a solution of 3 g of KOH in 10 ml of H_2O and 25 ml of ethanol during few hours. After neutralisation with

10 % HCl and filtration, the recovered aqueous solution was submitted to extraction with diethyl ether.
Methylation: all the organic extracts were methylated with diazomethane and concentrated under nitrogen just before GC/MS analysis.

Results of action of thioglycolic acid

In the case of ether solubilization, the non-soluble part was around 80 % by weight of the initial sample after drying This non-soluble part could not be decreased by performing the whole experiment again.

In addition to the action of thioglycolic acid, the reflux in water improves the access of reactant in the polymeric structure since the glass-transition temperature of amber is about 70-80°C.

Under these conditions, depolymerization with mercapto acetic acid resulted in a significant increase of the solubilization: after drying the residue was around 50 % by weight of the diethyl ether insoluble part.

GC/MS analysis

GC/MS analysis of ether soluble fraction is consistent with previous studies from J.S. Mills, R. White and L.J Gough (*Chemical geology*, 47, 15-39, 1984-1985).

GC/MS analysis of mercaptoacetic acid soluble fraction shows a pattern different from the previous one. In particular the GC/MS chromatogram shows several new peaks with higher retention time. Most of these new compounds are terpenic isomers. Currently it is difficult to ascertain the origin of these compounds:
- native molecule from the polymeric part of the resin.
- chemically modified products produced by the acid or basic step of the depolymerization.

As an efficient library is not available for these complex terpenes, identification of these compounds is still in progress.

Experimental

The capillary column used was a non polar WCOT CPSIL 5 CB (Chrompack, Netherlands) 50 meters length, 0.32 millimeter internal diameter and 0.42 micrometer stationary phase thickness; the carrier gas as Helium U (Air liquid) with 0.8 bar entrance pressure, the splitting ratio was 1:10.

The injector temperature was 280°C. The column temperature was programmed as follows: initial temperature 80°C during 10 mn; linear heating rate 3°C/mn; final temperature 290° during 30 mn.

The GC column was connected to a Nermag R10 10 B quadrupole mass spectrometer via a transfer line heated to 300-350 °C. Spectra were recorded in electron impact mode at 70 eV or in chemical ionization with NH_3 at 100 eV. The mass range was 33-900 in EI and 83-900 in CI/NH3.

Surface Characterization of Polymer Films and Additives Using Time-of-Flight Static Secondary Ion Mass Spectrometry

[1]M. P. Mawn, [1]A. M. Belu, [1]R. W. Linton, [2]A. Benninghoven
[1]University of North Carolina at Chapel Hill, Chemistry Dept. Chapel Hill,NC 27599
[2]Physics Institute, Univ. of Münster D-4400 Münster, Germany

This paper describes the application of static time-of-flight secondary ion mass spectrometry (TOF-SIMS) to the analysis of polymeric materials, including functionalized polymers and polymer additives. Examples include the detection of intact functionalized polystyrene oligomers, which indicates successful termination of an anionic polymerization reaction and provides molecular weight distributions, the monitoring of hydrogenation reactions of a polybutadiene polymer, and the detection of trace level polymer additives in a linear low density polyethylene (LLDPE) polymer. Polymer additives include classes of materials such as antioxidants, slip agents, UV absorbers, and thermal stabilizers. Evaporation of a 150 nm thick Ag patterned film on the LLDPE surface improves the *in-situ* detection of the additives through enhanced secondary ion yields for the polymer additives.

Experimental

The TOF-SIMS positive ion spectra were acquired using the TOF II instrument, developed at the University of Münster, Germany. Typical instrumental conditions were 0.9 pA primary ion current, 200 sec acquisition times, 250x250 μm^2 analysis area, and 10 keV postacceleration. Primary ion doses were approximately $2x10^{12}$ ions/cm^2. Pulsed electron charge compensation was used for the *in-situ* measurements of the LLDPE surfaces.

Polymer solutions in chloroform were prepared at concentrations of 1.0 mg/mL and approximately 1 μL aliquots were deposited on roughened Ag substrates. The polymers consist of a functionalized polystyrene (Mn=1489 determined by gel permeation chromatography) and an unsaturated polybutadiene polymer which underwent a hydrogenation reaction.

A standard LLDPE film was prepared which contained the following polymer additives and weight percents: a) 0.150% Erucamide (Amide Wax Slip Agent), b) 0.065% Irganox 1076 (Phenolic Antioxidant), c) 0.060% PEPQ and Irgafos 168 (Phosphonite Antioxidants) and d) 0.030% Irganox 1010 (Phenolic Antioxidant). The Irgafos 168 is a reaction product formed during PEPQ synthesis, and therefore is a minor contaminant of unknown concentration. An extract of the LLDPE bulk film containing the additive mixture also was prepared by extracting 0.5g of the film for 24 h at room temperature using 20 mL of diethyl ether and later deposited in 1 μL aliquots on roughened Ag substrates. Additionally, *in-situ* analyses were performed on both untreated and Ag patterned LLDPE surfaces. An evaporated 150 nm thick Ag film was patterned on to the LLDPE surface using a transmission electron microscope (TEM) grid as a mask. The chemical structures of the polymers and additives are given in figure 1.

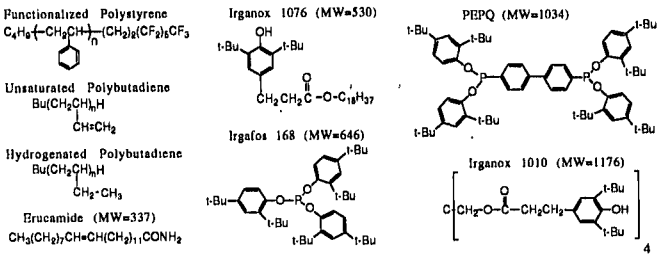

Figure 1. Chemical structures of functionalized polystyrene, hydrogenated polybutadiene, and LLDPE additives.

Results and Discussion

Figure 2 shows the distribution of the Ag cationized intact oligomers, ranging from 4 to 15 repeat units of polystyrene. The oligomers contain the perfluorinated end group used to terminate the living polymerization reaction. The calculated number average molecular weight (M_n) is 1203 for TOF-SIMS and 1489 for gel permeation chromatography (GPC). A lower TOF-SIMS result for M_n may be due to fragmentation of the oligomers, although the accuracy of GPC also is limited in this low molecular weight range.

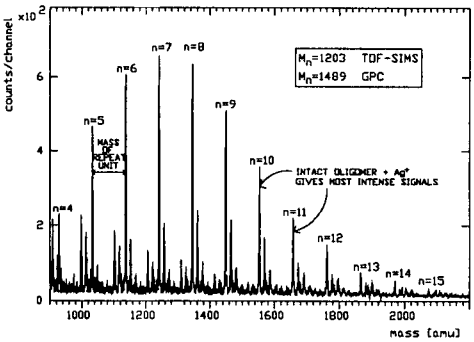

Figure 2. Spectrum of functionalized polystyrene showing intact Ag-cationized oligomers.

A comparison of the spectra for an unsaturated and hydrogenated 1,2 polybutadiene sample is shown in figure 3. A much broader distribution, which is shifted to higher masses, is indicated for the hydrogenated sample due to the additional protons. For chains of twelve repeat units, the calculated percent hydrogenation for TOF-SIMS is 62%, compared to 80% found by NMR. Further work involving deuteration and internal hydrogenated standards is being performed, as well as studies of the influence of oligomer molecular weight on hydrogenation efficiency.

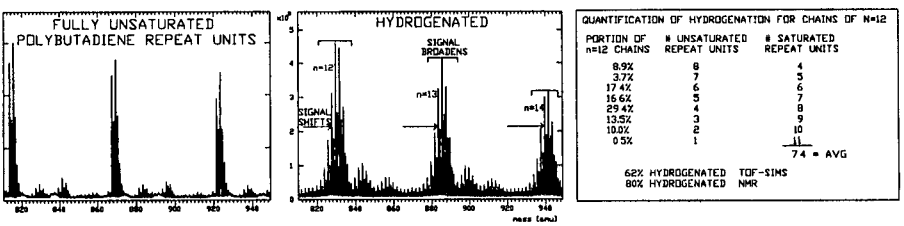

Figure 3. TOF-SIMS comparison of unsaturated polybutadiene and partially hydrogenated polybutadiene.

The high surface sensitivity of TOF-SIMS is demonstrated in figure 4, which shows the positive ion spectra of the polymer additives for the various sample preparations. The spectrum of the *in-situ* LLDPE surface (figure 4a) reveals two of the five polymer additives. These two additives are believed to surface segregate. The polymer extract spectrum (figure 4b) includes all five additives and shows evidence of expected oxidation products for the Irgafos 168 and PEPQ. The *in-situ* results using the patterned Ag overlayer (figure 4c) show dramatic improvements in polymer additive detection through Ag cationization. This analysis approach has some advantages over the polymer extract analysis due to the high surface specificity of TOF-SIMS providing information on the extent of oxidation and surface segregation of the additives at the polymer / environment interface.

ULTRAMARK 1621 AS A REFERENCE COMPOUND FOR POSITIVE- AND NEGATIVE-ION FAST-ATOM BOMBARDMENT HIGH-RESOLUTION MASS SPECTROMETRY

Longfei Jiang and **Mehdi Moini**

Department of Chemistry and Biochemistry
University of Texas at Austin, Austin, TX 78712

Ultramark 1621, a commercially available mixture of fluorinated phosphazines was found to be a useful calibration compound for negative and positive-ion fast atom bombardment high resolution mass spectrometry. Ultramark 1621 worked very well with the most widely used matrices such as glycerol, nitrobenzyl alcohol, and triethanolamine. The negative and positive-ion FAB mass spectra of the Ultramark produce a series of intense peaks extending from 700 to 1900 amu.

When Ultramark and the samples were added to a matrix, the relative intensities of the sample to the Ultramark reference peaks depended largely upon the concentration of Ultramark in the matrix. High concentrations of Ultramark suppressed the sample peaks. This effect was reduced by adjusting the Ultramark/matrix ratio or using a split target. Bringing down the Ultramark/matrix ratio to 1/100 or 1/1000 remarkably reduced this suppression effect. In practice, the appropriate amount of Ultramark was determined by trial and error through the stepwise addition of an Ultramark-dichloromethane solution until its signal was comparable to that of the sample.

The negative-ion FAB spectrum of Ultramark shows (Figure 1) two series of ions intense enough for accurate mass measurement. The major peaks of the first series of these ions have chemical compositions of $C_{15}H_{15}O_6N_3P_3F_{20}(C_2F_4)_n$, with corresponding nominal masses of $806+(100)_n$, where n=0-10.

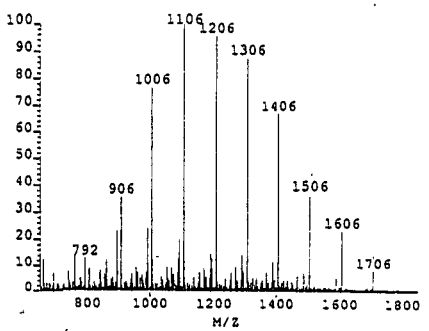

Figure 1. Negative-ion FAB mass spectrum of Ultramark in triethanolamine matrix. Experimental conditions: ratio of Ultramark to triethanolamine 1/10 - 1/100; magnetic scan; accelerating voltage -8kV; and resolution of 1500.

This series of ions arises from the loss of an R group of the phosphazines under negative-ion FAB conditions. The consecutive loss of the $CH_2(C_2F_4)_n$, where n=1, 2, etc., from the first series of ions gives rise to the second series of ions.

The positive-ion FAB spectrum of Ultramark in the NBA matrix (Figure 2) shows two series of ions intense enough to be used as references for accurate mass measurement. They are protonated phosphazines molecular ions $(M+H)^+$ and the ions arising from molecular ions minus the $(CF_2)_nH$ group.

Vitamin B_{12} (with the calculated M^- of 1354.567) and a sapphyren sugar derivative (calculated M^+ of 1032.533) were used as unknowns in the negative and positive modes, respectively to check the correctness of the listed masses. The accurate mass of the vitamin B_{12} molecular ion was measured in the negative FAB mode using a pair of Ultramark peaks from the first series of the reference ions. The result of the vitamin B_{12} experiment is shown in Figure 3. The measured mass errors for vitamin B_{12} and sapphyren sugar derivative were both 1.4 ppm. The chemical compositions for the second series of peaks in the negative ionization mode of Ultramark 1621 were confirmed, with the first series of peaks used as reference masses. The results agreed with our projected chemical compositions with an accuracy of better than 1 mmu.

Because of the similarities between the spectra obtained in the positive- and negative-ion FAB modes and positive- and negative-ion chemical ionization modes, the results presented here also apply to the CI mode.

In the mass spectrum of Ultramark under electron ionization we have identified two series of ions intense enough to be used as reference peaks in the HRMS. They are the molecular ions of phosphazines; and ions arising from these molecular ions, minus the $(CF_2)_nH$ groups, where n = 1, 2, etc.

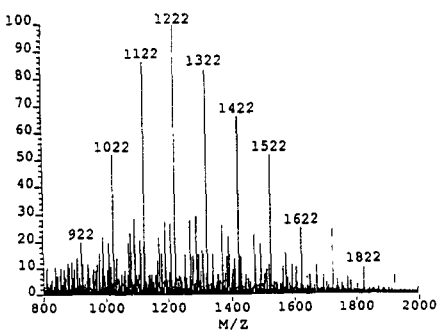

Figure 2. Positive-ion FAB mass spectrum of Ultramark in NBA matrix. Experimental conditions: ratio of Ultramark to NBA: 1/10 - 1/100; magnetic scan; accelerating voltage 8 kV; and resolution of 1500.

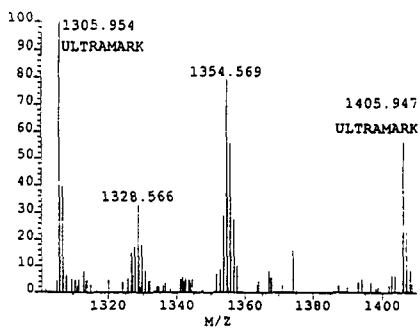

Figure 3. Accurate mass measurement of vitamin B12 molecular and fragment anions using Ultramark as the reference compound in NBA matrix. Experimental conditions: ratio of Ultramark to NBA: 1/100 - 1/1000; voltage scan, accelerating voltage -8 kV; and resolution of 10,000.

MATRIX-ASSISTED UV-LASER DESORPTION/IONIZATION MASS SPECTROMETRIC DETERMINATION OF THE LOADING VALUES FOR ANTI-CANCER DRUGS AND SUGARS CONJUGATED TO PROTEINS

Marshall M. Siegel*, Hwei-Ru Tsou

INTRODUCTION

A suggested means for delivering large numbers of drug molecules to targeted sites is to attach large numbers of drug molecules to protein or synthetic polymer carriers which would in turn be bound to a monoclonal antibody or other material which would target tumor sites. The drugs are conjugated either directly to the polymer or indirectly linked through a sugar molecule. The number of moles of drug or sugar relative to the number of moles of polymer, called the loading value, is usually determined by UV spectroscopy or by radioactivity measurements. Often the loading values cannot be determined because the materials lack UV chromophores, or the chromophores of the polymer and drug or sugar overlap or the synthesis of a radioactive label may be difficult and time consuming. Matrix-assisted UV-laser desorption/ionization mass spectrometry (LDI/MS) was evalutated as an alternative method for determination of the loading values for anti-cancer drugs and sugars conjugated to proteins. The mass spectrometric loading values are obtained from the difference in the chemically averaged mass values of the conjugated and native protein divided by the change in mass of the protein when conjugated with one mole of the drug or sugar.

EXPERIMENTAL

The polymer used in these studies was a protein, human serum albumin (HSA) [MW ~66,000]. The conjugated proteins were prepared in the following manner. Aminopterin, methotrexate and 4-desacetylvincristine hemisuccinate were prepared as N-hydroxysuccinimide derivatives which were reacted with the lysine groups of the HSA (1). HSA-Gal was provided by Professor A. Trouët (University of Leuven) and was prepared by reductive amination of HSA with lactose (2). Likewise, HSA was modified with helicin to give HSA-Hel.

The mass spectrometer used for analyzing the conjugated proteins was a reflector-type time-of-flight microprobe instrument (LAMMA 1000) equipped with a Q-switched (7 ns) frequency-quadrupled Nd-YAG laser (Quantel YG 660S) which operated at a wavelength of 266 nm with spot size diameters of 10-50 μm and irradiances between 10^{+6} and 10^{+7} W/cm^2. The matrix used was nicotinic acid.

RESULTS AND DISCUSSION

Typical LDI/MS full spectra obtained for the native HSA protein and when conjugated with relatively moderate amounts of aminopterin and large amounts of the vincristine derivative are illustrated as Figure 1A, 1B and 1C, respectively. The most prominent ions observed were the charged molecular ions M^{1+}, M^{2+} and the less abundant M^{3+}. Less abundant ions, often observed, were the dimer ions $2M^{1+}$ and $2M^{3+}$ and the trimer ion $3M^{2+}$. The averaged chemical masses for the conjugated and native proteins were computed from the M^{1+}, M^{2+} and M^{3+} ions and are listed in Table 1. The LDI/MS loading values were computed from the differences in these masses divided by the mass change upon conjugation with a mole of drug or sugar. Duplicate LDI/MS experiments were performed for the different conjugates. The LDI/MS and UV loading values are also listed in Table 1 and were found to be in agreement, within experimental error.

Figure 2 vividly illustrates the shifts in the centroids of the M^{1+} ions for a variety of HSA conjugates. The peak profiles were expected to be Gaussian, however, after background subtraction, the peak profiles were found to be Lorentzian. The fitted Lorentzian peak shapes to the observed peak profiles for the molecular ions of the native HSA protein and the HSA-aminopterin conjugate (with loading of 10.3) are illustrated in Figures 3A and 3B, respectively. Elevations of the ion abundances in the wings of the expected Gaussian profile are believed to be responsible for converting the Gaussian peak shape into a Lorentzian one. Salt and matrix adduct ions increase the ion abundances on the high mass side of the peak centroid and metastable and fragment ions increase the ion abundances on the low mass side of the peak centroid. Figure 3B also illustrates the deconvoluted Lorentzian profiles for the individual HSA-aminopterin conjugate components. The individual components range from 0 to 19 aminopterin conjugates with an average loading value of 10.3 aminopterin molecules per HSA molecule. (Note that the intensities of the deconvoluted peaks are magnified two times.)

CONCLUSIONS

Loading values for anti-cancer drugs and sugars conjugated to proteins can be obtained by LDI/MS which are consistent with similar measurements made by UV spectroscopy. In the absence of a UV chromophore, LDI/MS would be an alternative method for obtaining reliable loading values.

CAN PROTEIN-COFACTOR INTERACTIONS BE DETERMINED BY MATRIX-ASSISTED LD-MS?

William E. Seifert, Jr. and Richard M. Caprioli

The Analytical Chemistry Center and
Department of Biochemistry and Molecular Biology
The University of Texas Medical School at Houston
Houston, Texas 77030

Sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) has been shown by Beavis and Chait[1] to be an excellent matrix for the analysis of proteins by matrix-assisted laser desorption ionization mass spectrometry (MALDI-MS) when using a nitrogen laser. However, because of the low solubility of cinnamic acid analogs in water, high organic solvent concentrations are needed to achieve dissolution. Sample preparation conditions such as these usually result in the dissociation of multimeric protein complexes and non-covalent protein-cofactor associations.

Farmer and Caprioli[2] have successfully used the cross-linking agent glutaraldehyde to trap proteins in their multimeric state preventing them from dissociating in the sample preparation and desorption process. Glutaraldehyde reacts with the ϵ-amino group of lysine and the N-terminal amino group of proteins. Glutaraldehyde also has the advantage that it polymerizes in solution, thus forming cross-linking appendages of various lengths to fit the distances between reacting groups on proteins. In addition, when protein concentrations are kept low, little cross-linking occurs between molecules which are not in direct contact.

The purpose of the current study is to determine whether protein-cofactor complexes can be successfully analyzed by MALDI-MS. If not, then perhaps the cross-linking ability of glutaraldehyde could be used to trap the non-covalent protein-cofactor complexes in the bound form. By comparing the apo- with the cofactor-bound protein following reaction with glutaraldehyde, a difference in mass corresponding to the mass of the cofactor will be observed upon analysis by MALDI-MS.

MALDI-MS analyses were performed on a Vestec Model VT-2000 LD-TOF mass spectrometer using a nitrogen laser (337 nm) as the irradiation source. An acceleration voltage of 30 kV was used, and 30-100 spectra were summed to yield the final spectrum. Internal standards (bovine insulin, 5733.8, and horse heart cytochrome c, 12360) were used to calibrate the mass scale. Samples were prepared by layering the protein-containing solution (1 μL, 5 - 10 pmol/μL) over 1 μL of sinapinic acid matrix onto a stainless steel probe tip (2.2 mm diam.) followed by gentle heating under a heat lamp. Glutaraldehyde cross-linking reactions were performed by adding glutaraldehyde (25%) to aqueous protein solutions (10 pmol/μL) to give a final glutaraldehyde concentration of 1.2% (v/v). The reaction was incubated at room temperature for 30-60 min, at which time the reaction was quenched by the addition of 10M $NH_2OH{\cdot}HCl$. Control protein solutions were analyzed by first mixing with an equal volume of quenched 1.2% glutaraldehyde before layering onto the sinapinic acid matrix. Avidin and biotinylated oligosaccharide binding reactions were carried out by incubating avidin (10 pmol/μL) with the biotinylated oligosaccharide (20 pmol/μL) for 60 min at room temperature.

MALDI-MS analyses were performed on the apo- and cofactor-bound forms of horse myoglobin, *ras*-protein (a GDP-binding protein), and avidin. In the case of avidin, it was first incubated with one of the biotinylated oligosaccharides 6-biotinamidohexanoyl-Asn-$[GlcNAc]_2$-$[Mannose]_5$ ($BAHM_5$) or 6-biotinamidohexanoyl-Asn-$[GlcNAc]_2$-$[Mannose]_6$ ($BAHM_6$). In all cases, the cofactor-protein complex gave $[M+H]^+$ ions which were identical (within experimental error, $\pm$ 0.1%) to that of the apo-protein. Thus, no evidence of protein-cofactor binding could be observed by direct MALDI-MS using a sinapinic acid matrix and a nitrogen laser.

MALDI-MS analyses were then performed on the apo- and cofactor-bound forms of the same proteins after cross-linking with 1.2% glutaraldehyde. Comparison of the cross-linked apo- and cofactor-bound proteins revealed no increase in mass corresponding to the mass of the cofactor. In each of the cases studied, the apo-protein increased 100-700 Da higher in mass than did the

corresponding protein-cofactor complex. This was most dramatic for the apo-*ras* and GDP-*ras* proteins (Figure 1). An interesting observation was made when comparing samples analyzed in a sinapinic acid matrix versus a "control" matrix composed of sinapinic acid and 1.2% quenched glutaraldehyde. Proteins of higher mass, i.e., greater than 12,000 Da, gave an apparent increase in sensitivity in the modified matrix. An increase in the intensity of adduct ions was also observed.

The results of these experiments indicate that non-covalent protein-cofactor binding does not survive the sample preparation and laser desorption process when using a nitrogen laser and sinapinic acid matrix. This is true even for avidin-biotinylated oligosaccharide complex. The binding of avidin to biotin has a dissociation constant of $\sim 10^{-15}$M and is supposed to be undisturbed by extremes of pH, salt concentrations, and denaturing agents such as 3M guanidine HCl. Attempts to trap the protein-cofactor complexes in the bound form by cross-linking were not successful. The observation that the apo-protein increased in mass more than the cofactor-protein complex after reaction with glutaraldehyde can probably be best explained by more sites being available for cross-linking in the apo-protein, either because the active site has sites available when the cofactor is absent, or because of steric considerations.

Analysis of Multimeric Proteins: Comparison of MALDI MS With Other Biochemical Methods

Terry B. Farmer and Richard M. Caprioli
The Analytical Chemistry Center and the Department of Biochemistry and Molecular Biology, University of Texas Medical School, Houston, Tx 77030

Protein quaternary structure involves the noncovalent interaction of protein subunits. Chemical cross-linking with subsequent analysis by biochemical methods such as sodium dodecyl sulfate polyacrylamide gel electrophoresis as well as by matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI MS) has been used to determine protein quaternary structure.[1,2] Cross-linking preserves native conditions and allows subsequent manipulation of the stabilized multimer to determine the molecular weight of the multimeric forms and the number of monomers involved in the assembled structures.

Quantitative information can be obtained from SDS-PAGE by densitometrically scanning stained gels or by LC techniques such as size exclusion chromatography and integrating the area under eluted peaks. Quantitation of MALDI MS data, however, has not yet been established since much is yet to be learned about the high mass discrimination effects of the spectrometer.

MALDI MS data were obtained using a Vestec VT2000 laser desorption time-of-flight mass spectrometer with a nitrogen laser (337 nm) and an accelerating voltage of 30 kV. We also used a Finnigan MAT LaserMAT laser desorption time-of-flight mass spectrometer with a nitrogen laser (337 nm) and an accelerating voltage of 20 kV. Sinapinic acid (Aldrich Chemical Co.) was dissolved in either 66.5% water/33.5% acetonitrile (Vestec) or 70% acetonitrile/30% water with 0.1% TFA (Finnigan) to a concentration of 10 mg/ml.

Carbamyl phosphate synthetase (obtained from Dr. F. Rausch), and the remaining proteins analyzed (purchased from Sigma Chemical Co.) were dissolved in water or an appropriate buffer to a concentration of 10 pmol/μl (10 μM). To cross-link the proteins in solution glutaraldehyde (25% solution, Sigma Chemical Co.) was added to make a final concentration of 0.8% (by volume). After 10 to 60 minutes at room temperature the protein reaction mixture was analyzed.

SDS-PAGE analyses were performed in phosphate buffer (pH 7) under constant current conditions using the Weber-Osborn method.[3] The gels were silver stained (BioRad Inc.) and scanned using a Bio Med Scanning Laser densitometer.

One of the complications in quantitation of MALDI MS data is the appearance of laser-induced multimers and multiply-charged ions that coincide with the multimeric ions of interest. In order to estimate the contribution of these peaks to the peak area, a limited number of non-cross-linked proteins over a wide molecular weight range were examined on the Vestec VT2000 and the relative % areas of the doubly-charged and dimeric ions were calculated and plotted against the molecular weight (MW)(Figure 1). Linear regression analysis of these data gave the following equations with the corresponding confidence levels and sample sizes:

$M+2H^+$:

For MW < 14,500 da: Relative % Area = 2.47×10^{-3}(MW) + (-4.42) (r = 0.99, n = 3)

For MW > 14,500 da: Relative % Area = 1.50×10^{-4}(MW) + 23.645 (r = 1.0, n = 2)

$2M+H^+$: Relative % Area = -9.76×10^{-5}(MW) + 14.344 (r = -0.78, n = 5)

These were then used to estimate and correct for the contribution of the laser-induced and doubly-charged ions for the relative % areas of the cross-linked proteins.

The quantitative aspects of the comparison of MALDI MS and other techniques for the analysis of cross-linked multimeric proteins are complex. The majority of proteins analyzed by MALDI gave results that correspond well to those obtained by other biochemical methods (e.g. SDS-PAGE), although some results showed poor correlation with this technique (Table 1). Quantitation of SDS-PAGE depends on the amount of stain binding to the protein, often a variable process, and MALDI TOF mass spectrometers may show significant discrimination in ionization and ion detection. At this point,

it is unclear what factors give rise to the differences seen between the techniques.

Continuing work will involve the ongoing investigation of these quantitative aspects in comparing MALDI MS with LC techniques, SDS-PAGE, and analytical ultracentrifugation.

The authors would like to thank the NIH (Grant #GM43783-03) for its support and Dr. Fred Rausch for the E. coli carbamyl phosphate synthetase.

Matrix-Assisted Laser Desorption Mass Spectrometry of Proteins Isolated from Capillary Zone-Electrophoresis

T. Keough, R. Takigiku, M. P. Lacey, M. Purdon and R. E. Schneider
The Procter and Gamble Co., Miami Valley Labs, PO Box 398707, Cincinnati, OH 45239-8707

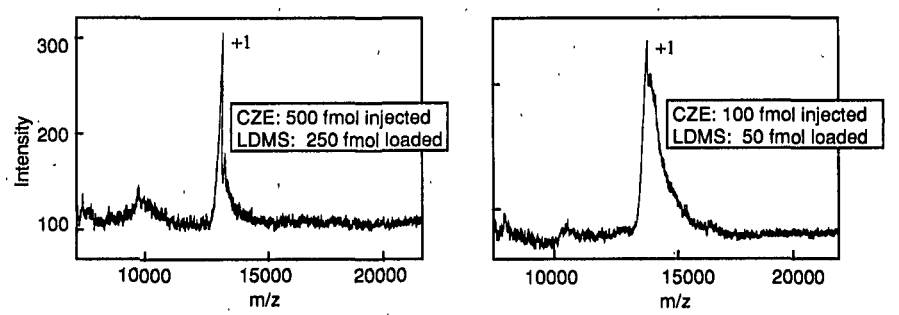
We describe a simple method for off-line coupling of matrix-assisted laser desorption mass spectrometry (LDMS) and capillary-zone electrophoresis (CZE). Fraction collection was primarily achieved by use of a "porous glass joint" (1) near the cathodic end of the CZE column. We also describe some preliminary results using a coaxial capillary system for fraction collection. Importantly, such off-line methods permit independent optimization of both the CZE and mass spectrometry parts of the experiment. Finally, an advantage of off-line techniques in general is they make protein available for analysis with complementary biochemical methods such as automated Edman sequencing.

To date, most published methods for coupling CZE and mass spectrometry (MS) have been on-line. They include coaxial continuous-flow fast atom bombardment (CF-FAB, 2), electrospray into an atmospheric pressure ion (API) source (3) and pneumatically assisted electrospray (or ionspray), also into an API source (4). Of these, the CZE/electrospray MS approach offers subpicomole sensitivity (in favorable cases) and a demonstrated mass range >75,000 Da (5).

However, CZE/electrospray MS necessitates a make-up flow to stabilize the electrospray process (4), and higher senstivities are only attained with the use of low pH buffers (5), potentially limiting the CZE portion of the experiment. Another important consideration is that electrospray ionization is not universally applicable to proteins, as these analytes must have enough charged residues so their mass-to-charge ratios (m/z) fall within the range accessible to the particular mass spectrometer. Finally, electrospray ionization produces ionized proteins containing more than a single charge state; which, for large proteins, can decrease the absolute sensitivity at any particular m/z.

In contrast, LDMS appears to be universally applicable to proteins and glycoproteins, has high mass range (> 300,000 Da, 6), low detection limit (ca. 1 fmol, 7), and offers mass measurement accuracies of ± 0.01% for proteins having molecular masses up to about 30,000 Da. And, unlike electrospray ionization, LD mass spectra typically do not exhibit broad distributions of charge states. High sensitivity has been observed even for high MW proteins (150,000 Da).

Representative spectra demonstrating the sensitivity of the CZE/LDMS method are shown for α-lactalbumin below. These data can be compared with our previous study (8) of CZE/plasma desorption mass spectrometry where the detection limit for α-lactalbumin was only 5 pmole.



The table below summarizes CZE/LDMS mass measurements and compares them to calculated values. Mass measurement accuracies for molecules having masses greater than about 30,000 Da deteriorate with current time-of-flight instruments, due in part to the unresolved contributions of matrix adducts.

Protein	Average molecular mass calculated	measured	error (%)
bovine ribonuclease A	13,682.4	13,682.0	-0.003
bovine α-lactalbumin	14,179.1	14,181.3	+0.016
equine myoglobin	16,951.5	16,955.6	+0.023
bovine lactoglobulin	18,363.1	18,371.7	+0.047
subtilisin BPN'	27,533.7	27,536.2	+0.009
porcine pepsin	34,549.9 [a]		
a	34,643.9	34,592.8	*b*
bovine serum albumin	66,432.3	66,795.0	+0.546

a. Two entries because of the known heterogeneity of this enzyme.
b. The error cannot be determined accurately because both forms of this enzyme may be present. The measurement is +0.38% greater than the lower-mass form and -0.15% lower than the high-mass form of pepsin.

The possiblity of protein identification by combined CZE/LDMS and Edman sequencing is illustrated by the following example. A 5-pmole CZE isolate of subtilisin BPN' was collected directly onto a prewetted PVDF membrane, washed with de-ionized water and inserted into a automated sequenator, where 20 cycles were carried out. The experimental results (which precisely matched the known sequence) were searched against three protein information resources data banks (PSQ, PSQ NEW and PSQ NRL_3D) with a strategy that permitted as many as 3 mismatches. A number of proteins were identified by this procedure. However, the experimentally measured mass of 27,536.2 was in close agreement only to that calculated for subtilisin BPN'.

Additional structural confirmation can be obtained by selective chemical or enzymatic degradation. For example, a CNBr digestion was performed on a portion of a CZE isolate of subtilisin BPN'. The mass spectrum of the unseparated CNBr digest of the BPN' isolate showed fragments whose average masses agreed well with the values expected for subtilisin BPN'. Hence, while Edman sequencing data alone was insufficient to identify subtilisin BPN', both the molecular masses and the masses of the CNBr digestion products provided the necessary complementary data to permit identification.

Finally, because materials to manufacture the porous glass joint for CZE fraction collection are not readily available, we have been investigating a coaxial fraction collection design. In our system, a 75 μ id CZE capillary is inserted through a zero dead-volume tee and exits through a 27 gauge SS needle (where the capillary ends just before the end of the needle). Coaxial addition of buffer is generated at the tee via a syringe pump. A sheath flow of about 5 μl/min is maintained. This coaxial arrangement permits collection of eluted compounds and maintains electrical connection to ground, permitting CZE. This design is much simpler than the porous glass joint (and more universally applicable to the various modes of capillary electrophoresis), but can result in broadened peaks as the sheath flow is maintained at a faster flow rate than eluting compounds. Preliminary results from 15% of a 20 pmole CZE isolate of bradykinin is shown at right. Significantly improved results were obtained using dihydroxybenzoic acid (b) rather than sinapinic acid (a) as the LDMS matrix.

Matrix-Assisted Laser Desorption Mass Spectrometry of Neuropeptides

James Z. Chou, Mary Jeanne Kreek and Brian T. Chait, The Rockefeller University, New York, NY 10021

The processing of opioid peptide precursors, pro-dynorphin, pro-enkephalin and pro-opiomelanocortin (POMC) has been characterized in brain and other tissues. It is suggested that the processing of these peptides may be site and tissue specific. We are primarily interested in the understanding of external factors (such as stress and drugs of abuse) on the processing of these opioid peptides in a number of systems, including human blood plasma, rat brain and other tissues and biological fluids. Traditionally, these neuropeptides have been determined and characterized by radioimmunoassay. We report here preliminary findings using laser desorption mass spectrometry (LDMS) to study the processing of dynorphin A (Dyn A) and its family of peptides in human plasma. The aim is to use the accurate mass determination to "read out" the presence and identity of the processed peptides.

Dyn A (1-17) is one of the major post-translational products from pro-dynorphin precursor. Dynorphin standards used in this study include Dyn A (1-6), Dyn A (1-7), Dyn A (1-8), Dyn A (1-9), Dyn A (1-10), Dyn A (1-13), Dyn A (2-17) and Dyn A (1-17). A typical LD mass spectrum of a mixture of these eight dynorphin standards is shown in Figure 1. 0.25 pmole of each standard (in 0.2 M of PO_4 buffer) was applied to the mass spectrometer probe tip in a solution containing 5 g/L α-cyano-4-hydroxycinnamic acid in 30% acetonitrile, 70% 0.1% trifluroacetic acid (TFA). Intense peaks are observed corresponding to each of the eight peptides present in the mixture. The LDMS technique appears to tolerate well the large excess (5 orders of magnitude) of involatile inorganic contamination over peptides. Dilution studies demonstrated that LDMS is a very sensitive method for detecting peptides. For example, a total amount of only 10 fmole of Dyn A(1-10) amide applied to the 2 mm diameter probe tip yielded a protonated molecular ion peak having a signal to noise ratio of 27 to 1. Moreover, on average, less than 1% of the material on the probe tip is consumed to generate a LDMS spectrum.

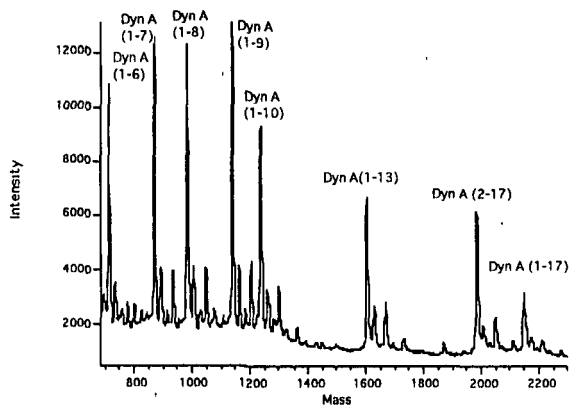

Figure 1. A spectrum of 8 dynorphin standards, 0.25 pmole each on the probe tip in 100,000 fold molar excess of PO_4 buffer.

The results obtained from the dynorphin standards encouraged us to study the LDMS response to the neuropeptides spiked in plasma, which more closely resembles a biological system. Human plasma samples spiked with dynorphin standards were processed with various extraction schemes in order to establish a method for retaining the maximum amount of the dynorphins of interest while removing as much of the interfering proteins and peptides in human plasma as possible. The separation/purification methods that we exploited include C_{18} Sep Pak reverse phase mini-extraction columns, regenerated cellulose membrane filters with 3000 or 5000 molecular weight cut off, and a micro-bore HPLC system with C2/C18 reverse phase column. Spiked plasma samples were diluted with 5-10 times (v/v) of acidic aqueous solution (typically 0.1-0.5% TFA in deionized water). Filtration using membrane filters was found to be the most successful first step for removing plasma proteins. A spectrum of seven dynorphins spiked into blank plasma is shown in Figure 2. The initial concentration of each dynorphin is about 10^{-7} M. The spectrum was recorded after the mixture was filtered through a 3000 mw cutoff membrane filter. All seven spiked dynorphin peptides are identified in Figure 2, although the signal

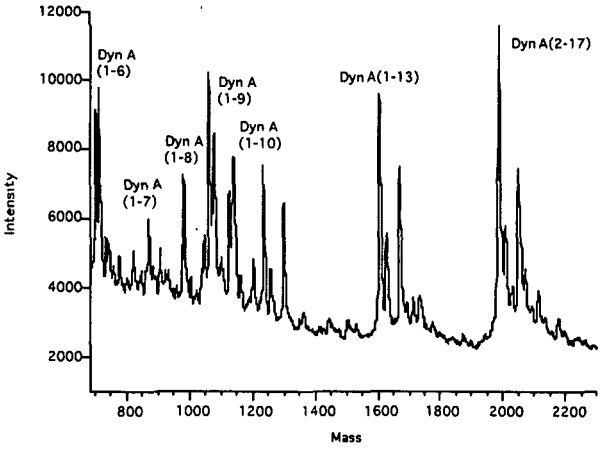

Figure 2. A spectrum of 7 dynorphin standard spiked into blank plasma. The initial concentration of each dynorphin is 10^{-7}M.

intensity is weaker compared to that of the standards (due to losses during the process of the mixture and/or interference from contaminants). A large quantity of salt also passed through the membrane filter and a quick wash of the probe tip was needed to remove these salts using cold aqueous acidic solution (in which the matrix is not very soluble). Although the C_{18} Sep-Pak column is also effective in removing the salt, the recovery of peptides from the Sep-Pak columns is reduced rapidly as their concentration is lowered close to 10^{-6} M. Improved levels of recovery were obtained with the micro-bore HPLC system, although significant losses still occur at concentration level of several times 10^{-7} M at the present time.

Finally, a dynorphin A (1-13) *in vitro* break down study in human plasma is presented as an example of what we hope to achieve in real biological systems in the future. A relatively high concentration of Dyn A (1-13) is injected into fresh blood taken from normal volunteers, and the major degradation products of that peptide are identified by LDMS. The plasma is diluted with 0.1% TFA in water and filtered through 3000 mw cutoff filters. The LDMS spectrum is shown in Figure 3, where the major products are identified as Dyn A (1-6), Dyn A (2-11) or (4-12), Dyn A(3-12), Dyn A(2-12) and Dyn A (1-12). The precursor (Dyn A(1-13)) concentration is about 10^{-5} M, while the actual concentrations of the processed dynorphin fragments are not yet determined in this study. Although considerable work is needed to bring the detection level of the peptides down to the level of endogenous dynorphin contained in human plasma, the mass spectra obtained from the spiked plasma and dynorphin break down study demonstrate that the method has potential for the specific characterization of neuropeptides and the sensitive detection of the processing of these peptides in biological systems. USE OF DIVALENT CATIONS FOR ENHANCED SENSITIVITY OF MALDI-MS ANALYSIS OF OLIGONUCLEOTIDE HOMOPOLYMERS

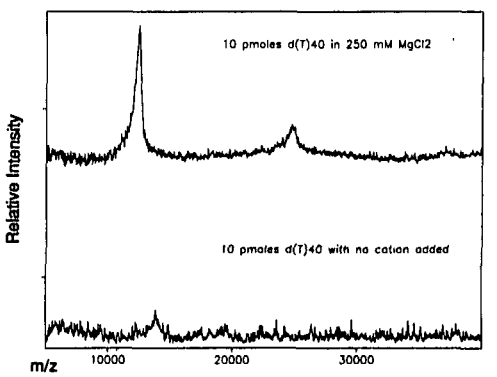
Brenda S. Whaley and Richard M. Caprioli

The Analytical Chemistry Center and the
Department of Biochemistry and Molecular Biology
The University of Texas Medical School
Houston, Texas 77030

DNA fragments are expected to have a large number of negative charges due to the anionic nature of the phosphodiester backbone. We have investigated the addition of divalent cations, known to bind to DNA, to the analyte solution for the neutralization of these negative charges in an effort to facilitate the production of singly-charged ions for MALDI-MS analysis. We have used oligonucleotide homopolymers in this study. In the presence of Mg^{+2}, Ca^{+2} or Mn^{+2}, $d(T)_{40}$ can be detected in a sinapinic acid matrix at a level of less than one picomole (see figure). In the absence of divalent cations only a minimal signal can be recorded for as much as ten picomoles of $d(T)_{40}$. The sensitivity enhancement is observed for 1 mM - 1 M $MgCl_2$ with optimum results obtained for 100 - 250 mM $MgCl_2$. Mg $(CH_3COO)_2$ yields the same sensitivity enhancement for $d(T)_{40}$ as $MgCl_2$. The phenomenon is also observed using ferullic and caffeic acids as matrices. $Co(NH_3)_6Cl_3$, also known to bind to DNA, enhances sensitivity for $d(T)_{40}$, but the peak shape observed is highly asymmetrical. Other metal cations, e.g. copper and titanium, yield no sensitivity enhancement.

Mass measurements of $d(T)_{40}$ in the presence of Mg^{+2}, Ca^{+2} and Mn^{+2} show that the mass observed for the oligonucleotide increases linearly with the mass of the cation added. This indicates the cations are interacting with the oligonucleotide to form an adduct which survives the MALDI process. Replicate mass measurements of $d(T)_{40}$ in a 250 mM $MgCl_2$ solution where $[Mg^{+2}]$ to $[PO4^-]$ is 641 yield an average mass of 12435 μ. The difference between this mass and the predicted mass for the free acid form of $d(T)_{40}$ (12067 μ) indicates that fifteen magnesium cations are optimally present in the singly-charged molecular ion.

Mass spectrometric analysis of a smaller homopolymer, $pd(T)_{20}$, in the presence of Mg^{+2}, Ca^{+2} and Mn^{+2} shows there are actually several species of oligonucleotide/cation adducts formed which contain various numbers of divalent cations. However, sensitivity enhancement is not seen for $pd(T)_{20}$ when divalent cations are present. A study of other homopolymers of similar size, including $pd(A)_{20}$ and $pd(G)_8$, also yielded no sensitivity enhancement with divalent cations even though mass shifts indicate these oligonucleotides are forming adducts with the cations. Although sensitivity enhancement for MALDI-MS of oligonucleotides is not always observed in the presence of divalent cations, the study of divalent cation interaction with $d(T)_{40}$ during the laser desorption ionization may yield information important to the improvement of MALDI-MS analysis of random sequence oligonucleotides.



PROGRESS TOWARDS DNA SEQUENCE DETERMINATION USING LASER ABLATION TIME-OF-FLIGHT MASS SPECTROMETRY

David M. Schieltz, Robert M. Thomas, Cong-Wen Luo, Chau-Wen Chou and Peter Williams
Department of Chemistry and Biochemistry, Arizona State University, Tempe, AZ 85287-1604

Our objective is to develop a capability for time-of-flight mass spectrometric characterization of mixtures of DNA fragments arising from the Sanger sequencing technique. If TOFMS can replace gel electrophoresis, which is the technique now used to order sequence fragments by size, this sequencing step can be accelerated by several orders of magnitude.

Following our earlier demonstration that massive lengths of DNA (over 400 kDa) could be volatilized by pulsed laser ablation of thin frozen solution films [1], and that a fraction of the ablated DNA was ionized so that crude TOF mass spectra were obtained at masses up to 18 kDa [2], we have now constructed a time-of-flight mass spectrometer designed to explore the ablation process and the mass spectrometry of DNA molecules up to about 100 bases in length (~ 30 kDa). The instrument is linear, with a modular flight tube currently 1.4 m in length. We chose to operate with the sample at a high potential for efficient detection, rather than risk the detector time spreads encountered in post-acceleration. A high voltage cryomanipulator was built (Fig. 1), which allows a sample frozen to liquid nitrogen temperature to be floated at ± 30 kV and moved in three dimensions. In the ablation process we developed [1,2] an ice film sublimed down to a thickness of several μm and ~ 200 x 200 μm^2 in area is ablated by each laser pulse, hence the need to move the sample. This ablated volume produces a significant amount of vapor (~ 10^{-4} torr-L), and the ion source is required to have an open architecture to facilitate pumping and minimize the possibility of gas discharges which can produce spurious signals over the time region of interest (20 - 100 μs). The source, shown in Fig 2. has large apertures (2.5 cm) to minimize the surface area that could be struck by ice fragments, and is gridless to eliminate grid wires which are a further initiating source of discharges. The acceleration gap is 3.5 cm, and focussing is achieved by a Wehnelt electrode held at the sample potential, requiring only one high-voltage lead in the sample chamber. Depending on the position of the sample relative to the Wehnelt, ions with a low angular spread can be focussed on the detector from an area up to 1 cm^2 (sample adjacent to Wehnelt), or ions with a high angular spread (up to 50 eV initial energy, at angles up to ± 80° from the sample normal) can be focussed if emitted from the center of the sample (sample retracted from Wehnelt).

We believe that the process of pulsed laser ablation of large biomolecular ions requires the following key components:

(a) a chromophore to couple the laser energy efficiently into the target (and preferably selectively into the chromophore rather than the analyte molecules,

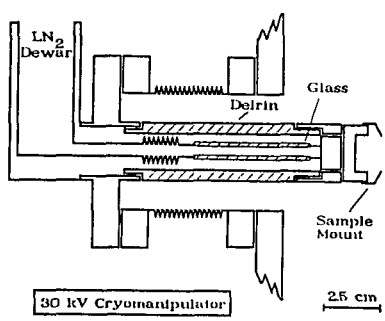


Fig. 1. 30 kV cryomanipulator

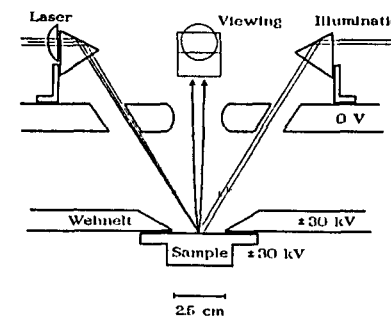

Fig. 2. Ion source design and light optics

(b) a propellant which either volatilizes or photochemically decomposes when irradiated, producing a microscopic vapor explosion to entrain the analyte molecules and expel them into the vacuum
(c) an ionization process, most probably through the production of small gas phase ions which form adducts with the analyte molecules
(d) a cooling process resulting from the free jet expansion of the ablated propellant, which can act to cool and stabilize the ablated analyte molecules

The chromophore and propellant can be the same material or two (or more) different substances; they can be intimately mixed or separate domains. In our approach, which uses a visible dye laser, the chromophore is the surface of the cooled copper substrate. The ice film is transparent to the laser light, and high energy densities can be deposited in the surface region of the substrate. High pressures generated at this interface cause rapid shock heating of the ice film, sufficient to vaporize films up to several μm thick in a few nanoseconds. Collection of the ablated material and assay for intact proteins or DNA by gel electrophoresis suggests that ablation of intact large molecules occurs readily whenever sufficiently thin ice films are present. Angular distributions of the collected material are forward-peaked, consistent with a free jet expansion of the propellant water vapor [1]. However, sample regions which produce *ions* of these intact molecule are rare and difficult to find. In the new instrument we have obtained mass spectra of a single-stranded DNA 8-mer and of a mixture of 8-mer and 20-mer. When a "good" region of the sample is found, the spectra are fairly stable from point to point as the sample is moved under the laser beam for up to 10-15 shots. However, "good" regions are extremely rare, and we have not yet identified the variable responsible for ionization. Fig. 3 shows our best result to date, obtained on a synthetic mixture containing 8, 14, 20, 26, 32 and 60 base lengths of ssDNA. When spectra are obtained, they are remarkably noise-free, with no evidence of the fragmentation seen in protein spectra with UV ablation. The resolving power at the 20-mer is ~ 80 (FWHM) and ~ 55 at the 10% peak height. At the 60-mer, resolving power is ~ 70 (FWHM) and ~ 50 (10% height). Good resolving power measured at the 10% peak height is important for complex mixture analysis because significant tailing, as seen with UV-ablated protein mass spectra, is unacceptable. Spectra of at least the quality of Fig. 3 must be obtainable routinely before this approach to DNA mass spectrometry can begin to be considered for use in DNA sequencing.

Analysis of Oligonucleotides by Matrix-Assisted Laser Desorption Mass Spectrometry

Klaus Schneider and Brian T. Chait
The Rockefeller University, 1230 York Avenue, New York, N.Y. 10021

Matrix-assisted Laser Desorption Mass Spectrometry (LDMS) has proved to be a valuable tool for the analysis of peptides and proteins. This was accomplished through the development of suitable matrix materials, which permit the analysis of complex mixtures having a large number of components (1). These results together with first spectra of oligonucleotides (2,3) suggest the possibility of developing LDMS as a very rapid and accurate method for the sequencing of DNA fragments generated by the Sanger dideoxy method. The objective of this study was to develop and improve LDMS for the analysis of oligonucleotides and evaluate its suitability as a tool for DNA sequencing purposes.

We started by testing a variety of different matrix materials ranging from well established matrices for proteins (e.g. sinapinic acid at 355 nm) to pyrimidine bases (e.g. thymine and uracil at 266 nm). We were able to obtain mass spectra of 1 pmol of deoxyribooligonucleotides consisting of 10-40 nucleotides using sinapinic acid, ferulic acid, caffeic acid and 2,5 dihydroxybenzoic acid as other matrices in both negative and positive ionization modes. As negative ion mass spectra showed higher intensities all further measurements were carried out in negative ion mode. The negative ion LD mass spectrum of a 12mer (d(TTGCGGCCGCAA)) showed an intense singly charged (mass resolution 200 (FWHM)) and a minor doubly charged molecule ion as well as a broad peak corresponding to the dimer. The negative ion mass spectra of a 29mer d(CGACGGCCAGTGCCAAGCTTTTTTTTTTT) showed intense singly, doubly and triply charged molecule ions. Although overall intensity was comparable with the 12mer the mass resolution decreased significantly to about 20 (FWHM). In an attempt to optimize sample preparation we varied the pH of the matrix/sample solution in the range pH < 1 to pH 5. Although we did not observe a very significant influence of pH on spectra intensities, we were able to monitor the apurination reaction of a 10mer d(GTCACGTGGC). Fig. 1 shows the LD mass spectrum 4 h after adding the 10mer to ferulic acid dissolved in 1 n HCl/30% AcCN (50mM). The hydrolysis of all four guanines and of the one adenine can be readily observed.

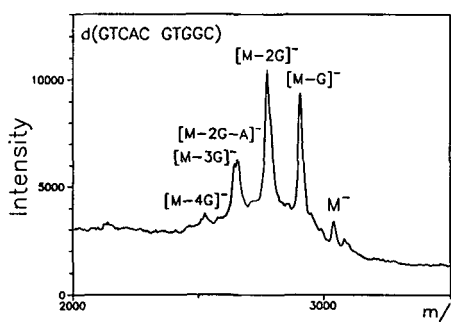

Fig. 1. Negative ion LD mass spectra of d(GTCAC GTGGC) in ferulic acid (30 % acetonitrile/1 n HCl).

In order to investigate the source of the decrease in mass spectrometric response with increasing oligonucleotides mass and the observation that base composition is a critical factor for successfull mass spectrometric analysis of oligonucleotides (4), we tested a large variety of different matrix materials with $d(T)_{18}$ and $d(G)_{18}$ as model compounds. Table 1 contains a list of compounds successfully tested as matrices for the analysis of $d(T)_{18}$.

In general, we dissolved the matrix material in 30%-50% AcCN/H_2O (20-50 mM) and added the oligonucleotide to obtain a concentration of 2 μM. We discovered some new matrix materials like 4-Amino-2,3,5,6 tetrafluoro benzoic acid, α-cyano-cinnamic acid and the coumarine derivatives psoralen and esculetin.

In the negative ion LD mass spectrum of $d(T)_{18}$ in ferulic acid strong singly and doubly charged molecule ions were observed with a mass 136 u higher than that calculated for the intact oligonucleotide. Minor peaks in the range of 2000 to 5500 u appeared with an intensity of up to 10 % of the molecule ion peak and were due to side reactions in the phosphotriester synthesis of $d(T)_{18}$. Despite the encouraging results for d(T)18 we were not able to obtain any mass spectrometric response neither from d(G)18 in any of the listed matrices, nor from d(C)18 and d(A)18 for which only a few matrices were tested. Comparison of individual base properties like basicity and self association constants between the individual bases do not yet provide an obvious explanation for the observed phenomenon. The only outstanding difference between thymine and the other bases is the missing of an exocyclic amino group in thymine.

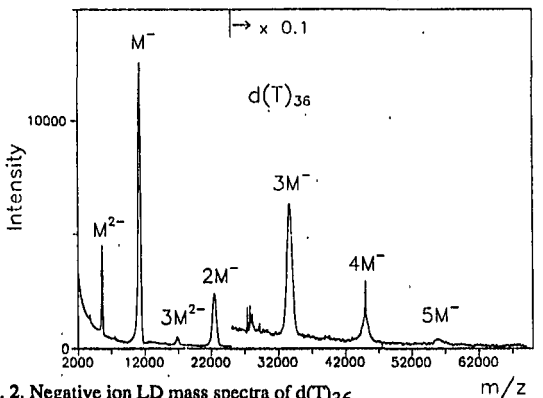

Fig. 2. Negative ion LD mass spectra of $d(T)_{36}$ in ferulic acid (30 % acetonitrile/water)

The striking dependence on the base composition, as noted earlier (4), is the major problem for the analysis of oligonucleotides with LDMS and limits its feasibility for sequencing purposes. The results for oligothymidine are nevertheless encouraging as they show the capability of LDMS for the analysis of complex mixtures and an achievable mass range of up to 180 bases as shown in fig. 2 in the negative ion LD mass spectra of $d(T)_{36}$, in which the highest mass observed corresponds to the pentamer.

To overcome limitations for oligonucleotides with random sequences the influence of base composition on the LD mass spectra has to be understood. This may lead to the development of a suitable matrix. Alternatively, alteration of base properties by modification reactions may lead to suitable improvements of the mass spectrometric response.

Matrix Assisted Laser Desorption of Oligonucleotides

Graeme J. Currie and John R. Yates
California Institute of Technology, Division of Biology,
Pasadena, CA 99125.

Matrix assisted laser desorption (MALD) developed by Karas and Hillenkamp[1] has greatly enhanced the mass range and sensitivity available in the mass spectrometry analysis of biopolymers such as proteins and polysaccharides. The application of MALD to oligonucleotide analysis however, has not proven so straight forward and relatively little progress has been made in mass spectrometry analysis of these compounds.

The use of modifiers to change the crystal structure of the matrices used in matrix assisted laser desorption (MALD) has been found to enhance the application of MALD for the analysis of oligonucleotides. Ammonium compounds such as ammonium acetate or bicarbonate in equimolar ammounts have been found to greatly enhance the performance of MALD matrices in desorbing/ionizing these compounds.

Oligonucleotides were synthesized on an ABI 394 DNA synthesizer and subsequently purified using reverse phase C18 HPLC, using a triethylammonium acetate(pH7)/ water/ acetonitrile buffer system. Matrices were an equimolar mixture of the chromophore matrix (e.g. 2,5-dihydroxybenzoic acid) and ammonium acetate adjusted to pH 7.5 with ammonium hydroxide. Spectra were acquired on a Finnigan MAT Lasermat time of flight mass spectrometer.

Illustrated in figure 1 is a negative ion mass spectrum of a mixture of three phosporothionate ester oligonucleotides dGC(s)ATGACTG, dGC(s)ATGCATGG and dGC(s)ATGCATGCATGGG (approximately 15 pmols of each) using a mixture of 3,4-dihydroxybenzaldehyde/ammonium acetate as the matrix. The spectrum has a resolution of 150 (FWHM). Typically this matrix gives a resolution of between 100-150 (FWHM) for small oligonucleotides. This is far in excess of the resolution obtainable from other matrices when used on our instrument . Although the matrix produces positive ions as well as negative, the negative ion spectra were generally more intense. Interestingly, 3-hydroxy-4-methoxybenzaldehyde does not work as a matrix without the addition of ammonium acetate. A variety of modifiers have been tried with the matrix 3-hydroxy-4-methoxybenzaldehyde to desorb a 11 mer (Table 1). Of the ammonia salts tried only the volatile salts gave positive results. Possibly, increased ionic interactions with the non-volatile salts prevented desorption. The results from alkyl amines were inconclusive, since the hydroscopic nature of these compounds prevented co-crystallization of the matrix/analyte.

Ammonium acetate can also be used to extend the workable mass range of matrices. For example, 2,-5-dihdroxybenzoic acid can successfully desorb/ionize oligonucleotides upto 15 mers. Addition of ammonium acetate extends this range to at least a 60 mer. Figure 2 shows the negative ion mass spectrum of a 60 mer oligonucleotide (approximately 100 pmols, dGCAT(GCAT)$_{13}$GCAT) using 2,5-dihydroxybenzoic acid/ammonium acetate as matrix.

Characterization of Radiation-Induced Damage to Nucleic Acid Constituents by Matrix-Assisted Laser Desorption FTMS*

Robert Hettich and Hiroko Yoshida
Analytical Chemistry Division, Health and Safety Research Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

Ionizing radiation causes DNA damage that can result in strand breaks as well as base and sugar modifications, and may lead to mutations and ultimately, cell death. It is necessary to determine both the identities and abundances of the radiation-induced products in order to probe the nature of DNA damage in these cases. Previous research in this area has focussed on the use of GC-MS techniques for the separation and identification of radiation products. However, because these biomolecules are polar, non-volatile species, it is necessary to derivatize these compounds prior to analysis. This sample preparation step may distort the sample by creating compounds that were not generated by the radiation event. In order to circumvent this problem, matrix-assisted laser desorption FTMS is being developed for the direct examination of products generated by x-ray irradiation of aqueous nucleotide solutions. No hydrolysis or derivatization is necessary in this case, and products ranging from nucleic bases to small oligonucleotides can be simultaneously examined. The ion manipulation and accurate mass measurement of FTMS should provide detailed structural information for picomole quantities of these products. In particular, collisional dissociation experiments will be used to probe compound structures in an effort to differentiate isomers.

The experimental approach for this study involves x-ray irradiation of aqueous nucleotide samples at various dose levels. Initial research involved direct examination of these irradiated samples by laser desorption FTMS. The major radiation damage observed for thymine monophosphate samples was simple fragmentation of the nucleotide to generate the free thymine base or phosphate groups. However, other minor products were also observed which result from chemical addition of functional groups, such as hydroxyl groups, to the nucleotide. In general, the amount of radiation products generated even at high dose levels (1000 Gy) is quite small. HPLC fractionation was employed to provide some sample cleanup and to eliminate that large amount of unmodified parent compound for the minor radiation products. Reverse phase HPLC with a C18 column and methanol/water mobile phase was optimized for separation and collection of various fractions for subsequent identification by laser desorption FTMS.

In order to probe the radiation-induced products of thymidine monophosphate, we have synthesized several possible standard compounds. For example, hydroxylated thymines such as thymine glycol are reported to be one of the radiation products of thymidine phosphate. We have generated these compounds by reacting thymine with potassium permanganate in aqueous solution according to the procedure given in Biochemistry (1981) 20, p 750-754. The resulting mixture was separated by reverse phase HPLC and examined by laser desorption FTMS. Three HPLC fractions were collected and identified by FTMS to be hydroxy thymine (specifically hydroxymethyluracil), thymine glycol, and trihydroxy thymine. These compounds were then used to verify HPLC retention times and mass spectral fragmentation for actual irradiated samples.

In order to extend these studies to larger biomolecules, a dinucleotide, TpT, was irradiated with 5,000 Gy (^{60}Co gamma rays) and examined with the HPLC and FTMS techniques. The HPLC profile of this irradiated sample, shown in Figure 1, revealed that the major radiation damage was simple bond fragmentation such as glycosidic bond cleavage to generate thymine. HPLC fraction collection and examination by laser desorption FTMS verified that peak #2 was thymine and that peak #5 was primarily TpT, with a small amount of hydrogenated TpT. Fraction #3 was a collection of many minor components, as shown in the negative ion mass spectrum, Figure 2. Several compounds resulting from simple phosphate ester bond cleavage as well as hydroxylation were observed, including phosphate (m/z 79 and 97), dihydrothymine (m/z 127), hydroxymethyluracil (m/z 141), hydroxydihydrothymine (m/z 143), thymine glycol (m/z 159), ribose-phosphate (m/z 195), thymidine (m/z 241), thymidine phosphate (m/z 321), and dihydrothymidine phosphate (m/z 323).

The combination of HPLC and laser desorption FTMS provides a powerful method for the structural investigation of radiation damage to nucleotides and oligonucleotides. Laser desorption FTMS can be used for the direct examination of radiation products and can provide detailed structural information for unknown compounds. HPLC provides sample purification as well as verification of compound identity and should be quite useful for investigation of the dose dependence of product formation.

The Analysis of Polymers by Matrix-Assisted Laser Desorption/Time-of-Flight Mass Spectrometry

Paul O. Danis and Dane E. Karr
Rohm and Haas Company, Spring House, PA, 19477 USA

Armin Holle and Franz Mayer
Bruker-Franzen Analytik GmbH, 2800 Bremen 33, Germany

Clifford H. Watson
Bruker Instruments, Inc., Billerica, MA, 01821 USA

The technique of matrix-assisted laser desorption/time-of-flight mass spectrometry (MALD/TOF) has proven to be very powerful for the analysis of peptides and other biopolymers into the 10^5 dalton range.[1] For another class of large molecules, synthetic polymers, some polyglycols[2,3] have been analyzed. However the potential for the technique has not been clearly demonstrated. We have investigated the application of MALD/TOF to synthetic polymer analysis and shown that it has distinct advatages over the conventional methods of polymer characterization. Primarily MALD/TOF provides absolute molecular weight distributions into the 10^5 dalton range without the use of polymer standards. Both the number- and weight-average molecular weights are determined as well as the complete distribution of species. Also the MALD/TOF is faster (minutes vs. hours) and more accurate for non-linear species. We have obtained spectra showing the distribution of species for polymers of acrylic acid, vinyl alcohol, and styrenesulfonic acid ranging from 3,000 to 170,000 daltons. For molecules above ~10,000 daltons the resolution is insufficient to identify individual oligomers. However, below this information is obtained on the composition and end group of the polymers.

Measurements were performed using a Bruker REFLEX™ MALD/TOF mass spectrometer. Measurements were made in both linear and reflector modes. Samples were prepared in sinapinic acid, 2,5 dihydroxybenzoic acid, or 3-amino-4-hydroxybenzoic acid matrix at a mole ratio of 10^{-3} to 10^{-4} with a total loading of polymer around 20 to 100 picomoles. Ions were formed by laser desorption at 337nm (N_2 laser, 3ns pulse width, 10^7 to 10^8 watts/cm^2, 0.2mm^2 spot) and accelerated with 10-33 kV. The negative ions were detected in all cases, and ions less than m/z 1000 were removed with a pulsed deflector.

The MALD/TOF mass spectrum of poly(styrenesulfonic acid) is shown in the figure below. The peak at m/z 170,000 is due to the singly charged molecules/oligomers. Several additional maxima observed in the spectrum are due to the higher charge states of $[M]^{-2}$ through $[M]^{-5}$. The other figure shown is the low molecular weight poly(acrylic acid) sample and was detected in the

reflectron mode with an ion acceleration energy of 10kV. The separate oligomers are clearly resolved and the distribution extends from about 1000 to 7000 dalton. In addition to the molecular weight distribution, the composition of the polymer can be proposed because the molecular ions are resolved. The difference between the peaks is 72 Da which corresponds to the monomer mass of acrylic acid. To determine the endgroup composition, if any peak mass (without neutral losses) is divided by 72, the result is nonintegral, and the residual is due to the mass of the polymer end group. In the case here the residual is 82 Da which corresponds to H on one end of the molecule and an SO_3H on the other.

The analysis of synthetic organic polymers by MALD/TOF mass spectrometry provides values for the absolute molecular weight as well as showing the entire distribution of polymer species. For low molecular weight polymers the individual molecular species can be resolved showing the mass of the monomer and revealing the mass of the end group. Also the determination of end group or groups will aid in the elucidation of polymerization mechanisms.

Matrix-assisted laser desorption mass spectrometry of complex oligosaccharides

D. J. Harvey

Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, OX1 3QU, UK.

Introduction.

Matrix-assisted laser desorption mass spectrometry has been shown to be a viable technique for determining the molecular weight of complex oligosaccharides without the need for derivatization (1-3). This paper presents an improved method for sample preparation, allowing detection in the fmol range and discusses quantitative aspects of the technique.

Materials and Methods

Reference oligosaccharides were obtained from Oxford GlycoSystems (Abingdon, Oxfordshire, UK). Matrix compounds were obtained from Aldrich Chemical Co. (Gillingham, Dorset, UK). Most Experiments were conducted with 2,5-dihydroxybenzoic acid as the matrix, but other dihydroxybenzoic acids, mono- and trihydroxybenzoic acids, and related compounds were also investigated. Spectra were acquired with a Finnigan LaserMat mass spectrometer (337 nM nitrogen laser, 0.5 M flight tube, 20 KV extraction voltage). The targets, which consisted of flat, stainless-steel plates, were loaded with 0.5 µl of the matrix solution [7.0 mg of matrix in 1 ml of acetonitrile:water (4:1)] and 0.1 - 0.5 µl of the aqueous sample solution and allowed to dry. Ethanol (0.2 µl) was then added to spread and crystallise the sample. Quantitative data were obtained by averaging signals from 80 laser shots aimed at 16 areas of the target.

Results and Discussion.

The method described above for preparation of the target usually gave more intense signals than were obtained simply by allowing the sample and matrix, dissolved in aqueous acetonitrile, to dry on the target. This is probably related to the form of crystallisation induced by the ethanol; crystals appeared much more uniform than those obtained from the aqueous acetonitrile used to dissolve the matrix. Hillenkamp (2) used ethanol containing a small amount of water as the solvent in his work with oligosaccharides, but this method was found to be inappropriate with the LaserMat targets as the sample spread over a wide area. By allowing the sample to dry from an aqueous solvent, a much smaller spot was obtained. This sample spot was then recrystallised with a very small amount of ethanol in a more controlled manner.

All oligosaccharides gave single peaks consisting of the $[M + Na]^+$ ion with most matrices; only with 3-hydroxy- and 3,4,5-trihydroxybenzoic acids did the sugars fail to produce signals. 2,5-dihydroxybenzoic (2,5-DHBA) acid gave the most intense signals (Fig. 1) with complex bi- and tetraantennary oligosaccharides containing up to thirteen monosaccharide residues and with high mannose oligosaccharides. 2,6-Dihydroxybenzoic acid gave reasonably strong signals but the matrix was too volatile to permit results to be obtained for more than about 1 min. The most intense signals were observed with matrix/sample ratios in the range 1000:1 to 2500:1. With 2,5-DHBA as the matrix, and oligosaccharides with molecular weights in the 1.5 - 2 KDa range, good correlation was found between peak height and sample concentration (Fig. 2). Peak height/concentration plots were linear from 100 pmol to the detection limit at 100 fmol. This linearity considerably surpasses the earlier results obtained with 3-amino-4-hydroxy-benzoic acid (3) were saturation was observed at about 30 pmol with a detection of only 1 pmol. Signal intensity was found to fall as the molecular weight of the oligosaccharide increased; this decline appeared to be linear for related sugars as shown for the series $(GlcNAc)_2$-$(Man)_{5-9}$ in Fig. 3.

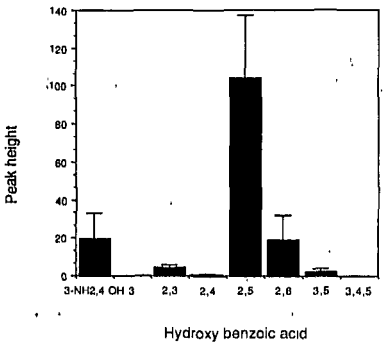

Fig. 1. Relative response of 10 pmol of $(GlcNAc)_4(Man)_3(Gal)_2$ in different matrices

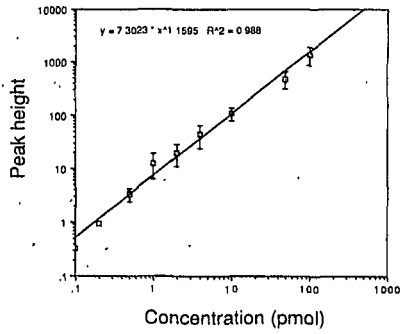

Fig. 2. Plot of peak height/concentration for $(GlcNAc)_4(Man)_3(Gal)_2$ in the 2,5-dihydroxybenzoic acid matrix.

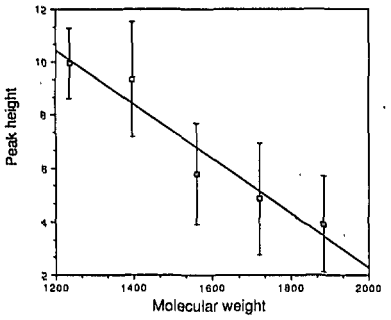

Fig. 3. Plot of peak height/molecular weight for a series of high-mannose sugars $(GlcNAc)_2(Man)_{5-9}$.

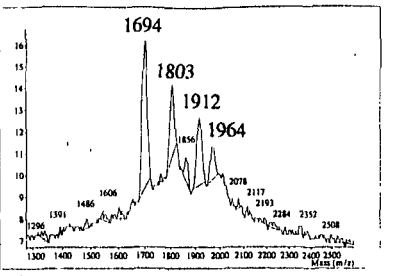

Fig. 4. Profile of *N*-linked oligosaccharides obtained from mouse brain. Peak 1, $(Hex)_3(HexNAc)_5(DeoxyHex)_1$ (Measured *m/z* = 1694, calc. = 1689.6); peak 2, $(Hex)_4(HexNAc)_4(DeoxyHex)_2$ (1803, 1794.7); peak 3, $(Hex)_4(HexNAc)_5(DeoxyHex)_1$ (1856, 1851.7); peak 4, $(Hex)_9(HexNAc)_2$ (1912, 1906.7); Peak 5, $(Hex)_5(HexNAc)_4(DeoxyHex)_2$ (1964, 1956.8).

Mass accuracy for pure oligosaccharides was within 1 mass unit of the calculated values for oligosaccharides having molecular weights in the 1 - 2 KDa range. When oligosaccharides were extracted from biological media, the peaks were usually somewhat less intense and mass accuracy was within 1 - 3 units of the calculated mass; the lower accuracy was attributed to a greater tendency for adduct formation. For neutral *N*-linked oligosaccharides containing hexose, deoxyhexose and *N*-acetylaminohexose units, this was sufficient to enable a composition to be calculated in most cases. Fig. 4 shows a typical profile of released *N*-linked oligosaccharides; compositions are given in the Figure legend.

ANALYSIS OF PORPHYRIN MIXTURES USING LIQUID MATRIX-ASSISTED LASER DESORPTION MASS SPECTROMETRY

*Yeonhee Kim, Shankai Zhao, Andrew G. Sharkey, and David M. Hercules
Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260

Porphyrins are of major interest in the areas of biological, biochemical, geological and petrochemical sciences. The use of mass spectrometry for porphyrin analysis has been the subject of recent papers. Mass spectormetry has become a powerful tool for studies of porphyrins, especially with the recent development of soft ionization techniques. Recent studies using matrix-assisted laser desorption coupled with a time-of-flight mass spectrometer demonstrate the soft ionization feature and very high mass capability of this technique (1,2). Use of a liquid matrix with soft laser ionization enhances molecular ion formation and provides a valuable technique for obtaining mass spectra of thermally sensitive compounds (3).

This work presents the results of use of a liquid matrix with fibrous material as substrate for assisting laser desorption of porphyrins and metalloporphyrins such as meso-tetraphenylporphine (TPP), Iron(III) octaethylporphine chloride (Fe-OEP), Zinc(II) protoporphyrin (Zn-PP), Magnesium (II) meso-tetra phenylporphine (Mg-TPP), Nickel(II) meso-tetraphenylporphine (Ni-TPP), Cobalt(II) meso-tetraphenylporphine (Co-TPP), Copper(II) meso-tetraphenyl porphine (Cu-TPP), and Vanadyl (IV) meso-tetraphenylporphine (VO-TPP). The liquid matrices used for porphyrin studies were o-nitrophenyl octyl ether (NPOE) and 15-crown-5. The use of a liquid matrix with soft laser ionization enhances molecular ion formation.

Figure 1A and 1B show single shot LD spectra of Zn-TPP using the two liquid matrices. As can be seen in the figures, the $(M+H)^+$ ion at m/z 677 dominates the positive ion spectra of both NPOE and 15-crown-5 matrices.

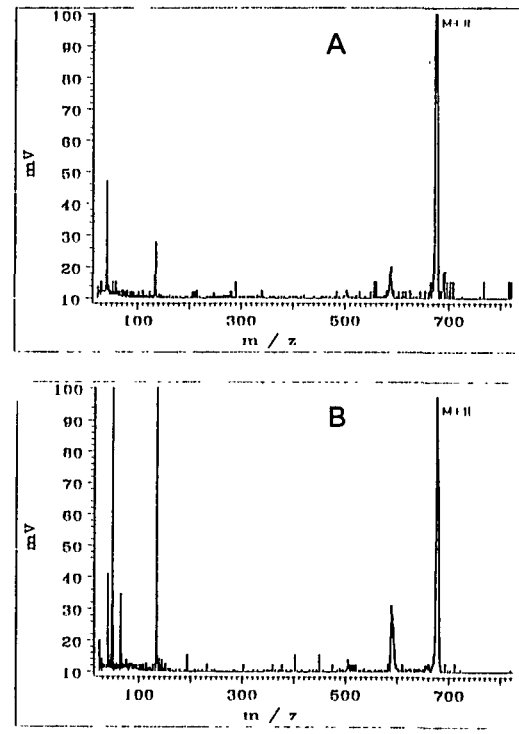

Fig.1 Single shot laser desorption mass spectra for Zn-TPP of (A) NPOE (B) 15-crown-5.

The laser desorption (LD) spectra of the porphyrins and metalloporphyrins show that the $(M+H)^+$ peak is generally the most abundant peak in the spectrum, except for Fe-OEP chloride where the most abundant peak is $(M-Cl)^+$. Comparing the LD spectra obtained with the two liquid matrices, the spectrum by 15-crown-5 always shows a greater degree of fragmentation.

Using NPOE as the liquid matrix, 0.5 μl of sample solution was dripped onto a 1 mm^2 area of fibrous paper providing 0.5 ng of sample. Single shot LD spectrum of Zn-TPP is shown in Figure 2. The molecular ion of Zn-TPP can be identified from the LD spectra. This result clearly shows that low detection limits for porphyrins are possible using the NPOE fibrous matrix. Compared with the LD spectra shown in the previous figure, much more fragmentation is seen in this spectrum. It should be noted that the amount of liquid matrix added is the same, but the concentration of sample is a thousand times lower.

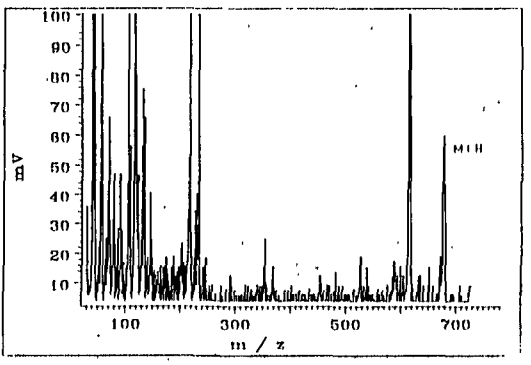

Fig.2 Laser desorption mass spectrum of 0.5 ng Zn-TPP using NPOE matrix.

The unique character of NPOE liquid matrix assisted LD spectra provides the possibility of analyzing porphyrin mixtures from a single shot spectrum without previous separation. Three sets of porphyrin mixtures were analyzed to illustrate this point: mixture 1 contained Fe-OEP, TPP and Zn-PP; the components in mixture 2 were Mg-TPP, Co-TPP and VO-TPP; and the components in mixture 3 were Fe-OEP, TPP, Zn-PP, Mg-TPP, Co-TPP and VO-TPP. The NPOE liquid matrix LD spectrum of mixture 3 are shown in Figure 3. The $(M+H)^+$ ions of TPP, Zn-PP, Mg-TPP, Co-TPP and VO-TPP with m/z 615, 625, 637, 672 and 680, respectively, and the $(M-Cl)^+$ ion of Fe-OEP at 588 are all shown in the figure. All the molecular ion peaks of each component in the mixture are clearly seen in the spectrum and no obvious interference effects are observed.

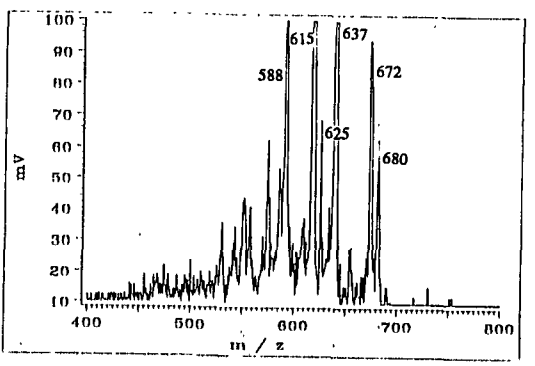

Fig.3 Laser desorption mass spectrum of mixture including Fe-OEP, TPP, Zn-PP, Mg-TPP, Co-TPP, and VO-TPP

Development of a UV-laser microprobe with coaxial optics for laser desorption, sample observation and ion extraction

*M. Hubert, D. Kirsch, R. Kaufmann, B. Spengler

Institute of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

For laser desorption mass spectrometry with high lateral resolution, a coaxial desorption optics, using a centrally drilled objective with high aperture, has been constructed to be fitted into a laser microprobe. As a result the angle of laser-beam incidence is rectangular to the sample-surface (in reflection-geometry). Desorbed ions are accelerated and focussed by ion optics, transmitted through the central hole of the objecitve into the first field free drift tube of the reflectron mass spectrometer (see Figure 1).
The focus diameter of the desorption beam has been measured by means of a UV-sensitive diode array as less than 2 μm. (266 nm). The specimen can be imaged, coaxially with the laser and ion beam, through the focussing optics by means of a video camera. Optical images of microscopical samples show a resolution in the range of 1-2 μm.
Rectangular to the axis of ion extraction, a postionization laser beam is positioned.

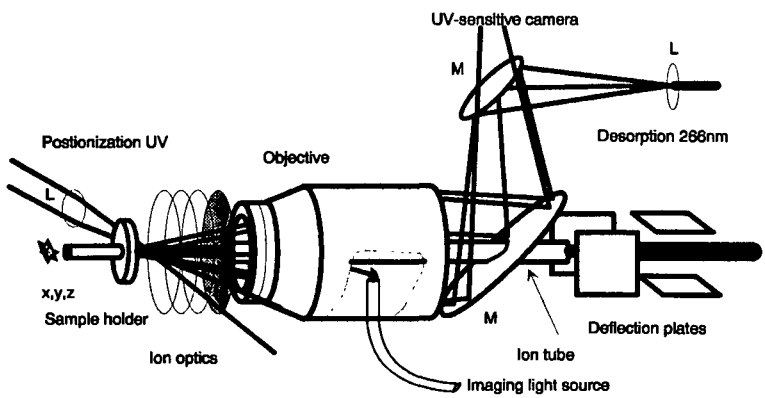

Fig.1 Coaxial optics for laser desorption, sample observation and ion extraction

As a first result, good signal stability and a mass resolution M/ΔM of about 6500 (FWHM-definition) for substance p at high ion transmission has been obtained.
In the postionization mode, zinc has been selektively ionized by tuning the postionization dye laser to a resonant wavelength of 213.8 nm. Figure 2 shows postionization spectra of zinc at 210.4 nm and 215 nm (both off resonance) and at 213.8 nm (resonant).
Positioning of the desorption focus allows μm-resolved mass analysis of biological, technical or chemical specimen for both, elemental and molecular analysis. The coaxial geometry is able to overcome the limitations of spatial resolution and sample imaging of the LAMMA 1000 instrument.

A Compact Time-of-Flight Mass Spectrometer for the Structural Analysis of Biological Molecules Using Laser Desorption

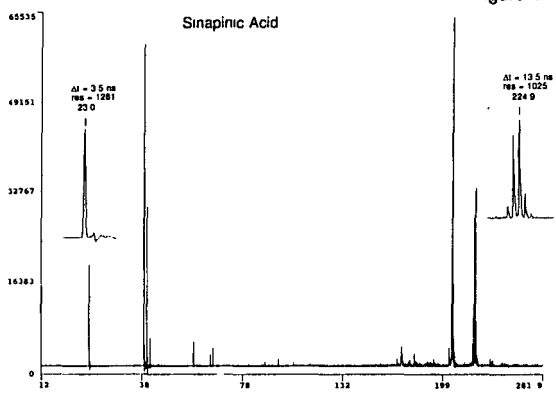
Timothy Cornish and Robert Cotter
The Johns Hopkins Medical School, Baltimore, MD

A laser desorption, double reflectron time-of-flight mass spectrometer is currently under development in order to study small proteins and nucleotides (1000-4000 daltons) with unit resolution. The completed instrument will incorporate a collision cell after the first reflectron so that mass selection and subsequent collisional or reactive dissociation can be implemented. The second reflectron will then facilitate the observation of fragmentation products with moderate to high resolution.

An emphasis has been placed on building this instrument with small physical dimensions in order to accurately characterize the trade-offs between overall size and performance. Due to the reduced flight times in the compact design, high resolution can only be accomplished if TOF peak widths are quite narrow and the detection system is capable of precisely measuring the sharp peaks. We are also interested in collecting the mass spectra in the analog mode because of substantial advantages over pulse counting techniques in total analysis time. A number of efforts have been made to accomplish these goals.

Figure 1 is the mass spectrum of sinapinic acid with several regions enlarged to show the peak widths. The Na+ peak in this spectrum is only 3.5 ns wide which is approaching the lower limit in measurable peak widths for this instrumental design. The factors prohibiting the observation of narrower peaks include the detector response time (about 2 ns width), vacuum feedthroughs (1 GHz), and the oscilloscope bandwidth (500 MHz).

Figure 1



Figures 2 and 3 are the single reflectron mass spectra of two polypeptides (proenkephalin: 904 amu and dermenkephalin: 956 amu). Both of these spectra show parent ions and salt adducts with sufficient resolution to measure isotope distributions. The peak widths of the parent ions are about 16 ns and have flight times on the order of 55 µs producing resolutions in excess of 1500. Figure 4 is the enlarged spectrum of the major fragment peak of caffeic acid collected in the dual reflectron mode. Mass resolutions over 4000 have been observed in this configuration.

Thus far, the prospects for producing a high performance, double reflectron TOF in a compact package are quite encouraging. The small size does restrict, however, the possible incorporation of some desirable components, such as gridless or long, single stage reflectrons. Both of these designs would enhance performance with metastable compounds resulting in improved high mass transmission. The goal of this work, though, is to limit the size and determine the highest possible performance given these constraints. The collision cell hardware has recently been installed and is currently being tested in the tandem TOF mode.

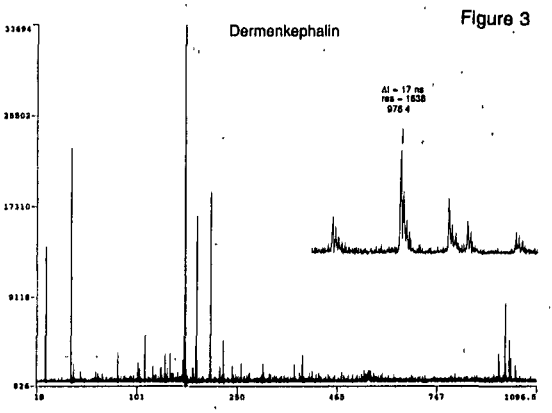

Figure 4

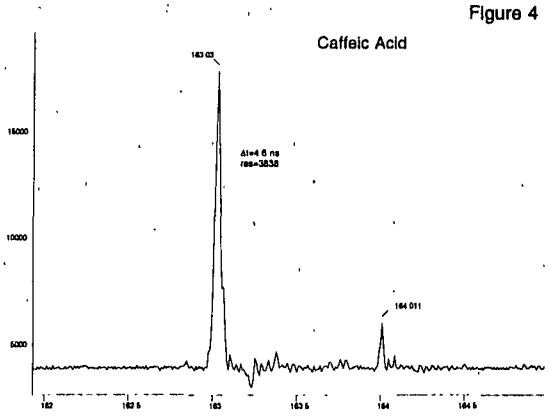

Construction and performance of a Laser Desorption/Ionization TOF Mass Spectrometer System: Applications to Problems in Peptide, Protein, and DNA Structural Analysis.

David Arnott, Jeffrey Shabanowitz, and Donald F. Hunt,
Department of Chemistry, Univ. of Virginia, Charlottesville, VA 22901

Matrix assisted laser desorption/ionization mass spectrometry has shown great promise as a technique for the analysis of biopolymers. The construction and performance of a MALD/I time-of-flight mass spectrometer built in our laboratory is described here. Results of some experiments on proteins and peptides, including on-probe proteolytic digests are presented. Preliminary work on a DNA sequencing strategy exploiting the chemistry of 5'-O-(1-thiotriphosphates) is also described.

The instrument is illustrated in figure 1, and employs a 159 cm flight tube with a grid extractor, an ion guide wire, and a dual microchannel plate detector. Samples in the appropriate matrices are desorbed with a 3 ns pulse from a 337 nm nitrogen laser. Data are collected on a 350 MHz digital oscilloscope and transferred to an IBM compatible computer via a General Purpose Interface Bus. Spectra are processed and stored using a combination of software written in our lab and obtained from the Finnigan-MAT Corporation.

A cryopump system maintains a pressure in the high 10-8 torr range during operation. The voltages applied to the sample plate (V1) and extractor grid (V2) are normally set to +20 kV and +10 kV respectively for positive ions, and -20 kV and -10 kV for negative ions. The detector is operated at -2 kV. The voltage applied to the ion guide wire may be varied to maximize signal and resolution but is typically set to -75 V for positive ions and +100 V for negative ions. A permanent magnet placed outside the flight tube deflects electrons when the instrument is in the negative ion mode.

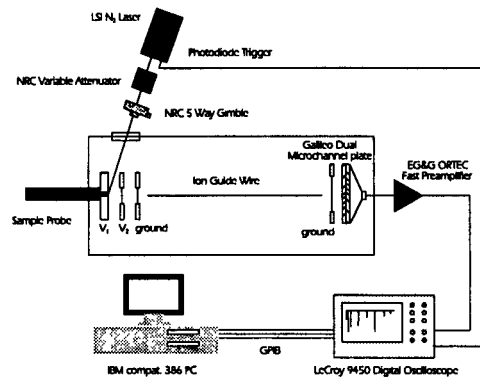

Figure 1 The MALD/I TOF Mass Spectrometer

MALD/I TOF mass spectrometry for protein and peptide molecular weight determination is described extensively in the literature, and has been successfully applied to this purpose in our laboratory. 2,5-Dihydroxybenzoic acid and sinapinic acid matrices were used routinely. Sample quantities of <= 1 pmol for small proteins and peptides, and 1-5 pmol for larger proteins generally yield useful spectra. Resolutions (m/fwhm) of between 200 and 500 were obtained for most protein samples; under favorable conditions a resolution of greater than 900 has been achieved. Singly charged ions are typically produced, but higher charge states are observed for some proteins.

The utility of MALD/I TOF mass spectrometry for the direct analysis of enzyme digests has been demonstrated. There are frequently occasions, however, when it is desirable to do such a digest on a very small quantity of sample. Sample handling considerations, however, make it difficult to work at the low picomole level. Experiments have therefore been carried out to do digests directly on the instrument's sample probe tip. One to five pmol of sample is added to the probe in water, with an appropriate amount of enzyme. The mixture is allowed to sit at room temperature for 15 minutes, with the periodic addition of water to maintain a volume of 0.5 - 2 uL. Matrix is then added in a small volume of buffer, mixed, and allowed to dry. A spectrum is then acquired. Figure 2 shows the results of a 5 pmol digest of Beta Lactoglobulin A with Asp-N. Even after 15 minutes virtually all the starting material has been cleaved. Although digestion is not complete, many of the low mass limit peptides are present, and the incompletely digested intermediates are may be used to find overlaps and assign an order to the peptides.

Because laser desorption only consumes a small portion of the total sample, the experiment may be taken one step further. A sample may be run to determine its molecular weight, and removed from the instrument. It may then be redissolved in water while still on the probe. Enzyme is added and and incubated as described above. The sample is allowed to dry and another spectrum acquired. Even under acidic conditions, and in a virtually saturated solution of organic matrix, partial digestion occurs, allowing two experiments to be performed on a single sample.

In order to extend either of the these experiments to achieve more complete digestion the probe tip may be covered with a small length of teflon shrink-tube sealed at the top. With evaporation thus retarded digests may proceed overnight.

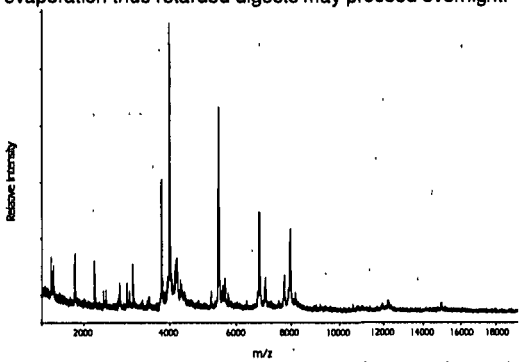

Figure 2
A 15 minute on-probe digest on 5 pmol. of the 18.3 kDa protein BLG. The matrix is sinapinic acid: 10 g/L in 30% MeCN, 0.1% TFA.

Large scale DNA sequencing projects such as the Human Genome Initiative require the development of new sequencing technologies. It has been proposed that mass spectrometry could replace the time consuming electrophoretic stage in conventional Sanger methodology. An entire ladder of enzymatically synthesized chains terminating in the same nucleotide base might be analyzed directly by a mass spectrometer; peaks appearing in 300 dalton windows would indicate the presence of the chosen base at those positions. Such a strategy could be implemented with MALD/I or electrospray ionization.

This sequencing method may be enhanced by exploiting the chemistry of phosphorothioate analogs of nucleotide triphosphates. DNA chains incorporating these analogs are identical to normal DNA except that a sulfur replaces a nobridging oxygen in the phosphodiester linkages. This sulfur can be derivatized by a variety of alkylating agents. The number of charge states which appear in electrospray spectra could be reduced by blocking a fraction of the phosphorothioates with ethyl iodide. Sodium and potassium adducts found in both MALD/I and electrospray spectra would likewise be reduced. Other effects might be achieved with different functional groups.

Samples of synthetic oligonucleotides - normal and phosphorothioates - have been studied with MALD/I TOF mass spectrometry. Oligonucleotides up to 21 bases long were successfully desorbed, but as the length increased so did the necessary laser power, with a deterioration of both resolution and signal to noise ratio. Spectra of normal oligonucleotides showed Na and K adducts as expected, but the phosphorothioate analogs showed a series of peaks 63 Da apart. It is not clear whether they are adducts or an altered form of the phosphorothioate. Figure 3 shows the spectrum of a phosphorothioate nucleotide 10-mer. The reactivity of the phosphorothioate was demonstrated by alkylation with ethyl iodide and the resultant mass shift in the spectrum. These results suggest that phosphorothioate analogs may be useful in mass spectrometric methods to rapidly sequence DNA.

Resonance Enhanced Two-laser Infrared Multiple Photon Dissociation of Gaseous Ions

Dilrukshi M. Peiris, Mitchell A. Cheeseman, and John R. Eyler
Department of Chemistry, University of Florida,
Gainesville, FL 32611-2046.

An indirect method, such as ion photodissociation, must be used in mass spectrometry to obtain spectra of gaseous ions. We have utilized the technique of infrared multiple photon dissociation (IRMPD) in a Fourier transform ion cyclotron resonance (FTICR) mass spectrometer to obtain infrared spectra of gaseous ions (1,2). When an ion has a high density of vibrational and rotational levels, it can resonantly absorb only a few photons and then enters the "quasicontinuum". In this quasicontinuum, the ion can readily absorb additional photons regardless of their energy, until it gains sufficient internal energy to dissociate. A low power tunable pulsed CO_2 laser was used for probing the resonant absorption spectrum and a more powerful nonresonant continuous wave (cw) CO_2 laser was used to complete the dissociation. This two laser approach, effectively a "probe-pump" experiment, has permitted us to obtain the photodissociation spectra of bis(methoxy diethyl) ether cation, 3-bromopropene cation, and gallium hexafluoroacetylacetonate anion.

All experiments were performed on a home-built FTICR mass spectrometer, utilizing a Nicolet FTMS 1000 data station, and equipped with a 2T superconductimg magnet. Background pressure was maintained around 2×10^{-9} Torr. A modified White-type FTICR cell was used (1) to enhance the photodissociation effect in all the experiments performed. Three spherical concave brass mirrors were incorporated as the receive plates. A turning mirror was attached to one of the receive plates. The cell dimensions were 2.5 x 2.5 x 6.5cm. The laser beams entered the vacuum chamber through two ZnSe windows mounted on a flange. The pulsed CO_2 (probe) laser beam was reflected by the turning mirror into the cell and reflected from the spherical mirrors to create multipasses. The cw CO_2 (pump) laser entered the vacuum chamber through a second laser window, passed into the cell through one of the trapping plates, and was reflected from the other trapping plate, thus giving a double pass inside the cell.

Ions were produced by electron ionization. The molecular ion of interest was isolated by a series of ion ejections, and then underwent thermalizing collisions for 1s. Subsequent to thermalization the probe laser was fired and another series of ion ejections removed any unwanted adducts and fragments formed by the probe laser. Then the pump laser was gated for 30ms. The fragments and the molecular ions present were then excited and detected by standard FTICR methods.

The first series of experiments was done by using <u>one</u> high power laser (1J $pulse^{-1}$) and the modified White-type cell. The photodissociation spectra are shown in Figure I. In a second series of experiments, useful <u>two-laser</u> photodissociation spectra was obtained by using a resonant low power tunable laser (100mJ $pulse^{-1}$) in conjunction with a more powerful (1J $pulse^{-1}$) nonresonant pump laser. Figure II illustrates the results of the <u>two-laser</u> "probe-pump" technique.

The a newly installed ir extension package, which generates wavelengths from 1.54μm to 4.5μm by difference frequency mixing of the dye laser fundamental and the residual 1.06μm Nd:YAG laser beam, we will be able to obtain infrared spectra of gaseous ions which contain O-H, C-H, and N-H stretching modes. The proposed system will use the Nd:YAG laser as the probe and the gated cw CO_2 as the pump in the modified White-type cell.

Comparison of Multiphoton, Single Photon and Electron Impact Ionization mass spectra of laser desorbed neutrals.

M. Dey, W. Böhm, S. Prinke, J. Grotemeyer
Institut für Physikalische Chemie, Technische Universität München,
Lichtenbergstr. 4, D-8046 Garching, Germany

Postionization methods, such as multiphoton ionization (EI), single photon ionization (SPI) or electron ionization fail in the formation of large cation radicals. Although strong differences in the highest observed mass are obtained by these three methods, masses exceeding a couple of thousand Daltons have not been measured, contrary to methods, which form adduct ions, such as matrix assisted laser desorption/ionization (MALDI). To investigate these differences and propose a mechanism for the lack of ionization of larger molecules leading to cation-radicals, we have investigated a large number of smaller and medium-sized peptides up th mass 2000 with respect to all three ionization methods.

The mass spectrometer used in these investigation is a Bruker TOF 1 equiped with a multiphoton ionization source. Single photon ionization is induced by generating VUV-photons from laser radiation as previously described [1]. Electron ionization mass spectra are produced by irridiating a tantalum wire in the multiphoton ion source by light below 290 nm [2]. Neutral molecules are produced by laser desorption into a supersonic beam. The advantage of this setup is the direct measurement of laser desorbed neutrals by all three methods without changing the experimental setup.

A comparison of mass spectra from the peptide Leu-Trp-Met-Arg-Phe taken by these three ionization methods is shown in figure 1. Beside differences in the observation of fragment ions, the most notable difference is the intensity of the molecular ion formed by the three methods. Cleary the EI mass spectrum shows strong fragment ions in the lower mass range and only little intensity on the molecular ion while in SPI ions are also detectable in the upper mass range with notable intensity. But again the molecular ion is formed with little intensity. Contray to this behaviour is the multiphoton ionization mass spectrum. Even if a "hard ionization" is applied, the molecular ion shows clearly a strong intense signal. Differences in the fragmentation behaviour can be explained through the different excess energy applied to the molecular ions during the ionization process. Since the same experimental setup in all three ionization methods is used, difference in the yield of the molecular ion can not counted to difference in the desorption process or the ionization method. By using an internal standard, tryptophan, all three ionization method were calibrated to give almost the same yield of ions.

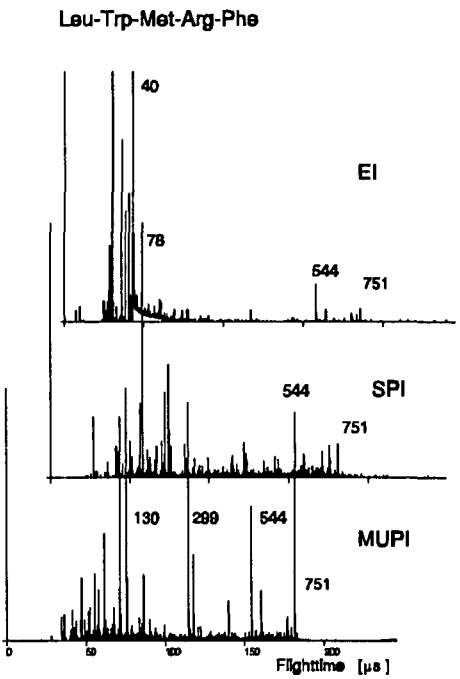

Fig. 1 Comparison of the mass spectra from Leu-Trp-Met-Srg-Phe.

The diagram shown in figure 2 gives the measured intensities from molecular ions of different tryptophan containing peptides with MUPI, SPI and EI. Clearly a mass dependent ionization yield is observable. EI gives a cutoff in the appearance of ions around mass 1000 while SPI yields in ions up to mass 1500. It should be

noted that with this two methods the yield of the molecular ion is fairly lower than with the MUPI method. Here the formation of cation-radicals can be observed exceeding mass 2000.

There could be some reasons for this behaviour. First, large molecules can not be desorbed as neutral. To check th argument we have investigated the neutral desorption of large systems such as cytochrom c or myglobin in according to work done by P. Williams [3]. As a result one can clearly state that the desorption of these molecules is as efficient as the laser desorption of smaller peptides.

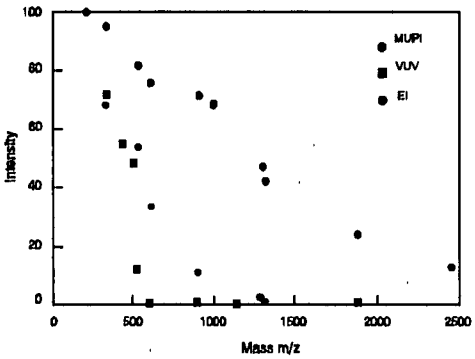

Fig. 2 Diagram of measured intensities of some Trp-containing peptides versus their mass.

Second, the ionization process must be responsible for the decreasing yield in the formation of larger ions by impact methods. From the presented data it can be excluded that either different Frank-Condon factors or differences in the activation energy for fragmentation reactions are accountable for this behaviour. It has been proposed, that the formation of a geminate charge pair from the molecule in the ionization step can be explain the decreasing ionization efficiency with growing mass of the molecule. The formation of geminate charge pairs is known from the photoionization in solution. The formed geminate charge pair can either recombine to give highly excited neutrals, or fragment as neutral or form unspecified ions. The formation of these species can be theoretrical treated by a modified Debye-Hückel theory, which leads to a scaling of the gas phase ionization efficiency [4] :

$$\phi \propto \exp\left(-\lambda\,(M/M_o)^{3/2}\right)$$

with M the molecular weight of the molecule, M_o the molecular weight pre vibration and λ a factor depending on the ion strength of the charge pair, the excess energy etc.

By fitting the formula to the experimental data, one finds for the power term : MUPI : power = 1.6 ± 0.2, SPI: power = 1.5 ± 0.4. As seen from the formula the theoretical value should be 1.5.

The results presented here indicate that the formation of a geminate charge pair is responsible for the non-obserbance of large cation-radicals. It should be noted, that the direct proof of these species in the gas phase has not been succeeded.

Matrix-assisted Laser Desorption of Neutral Molecules Followed by Multiphoton Ionization and TOF Mass Analysis

* R.Frey, A.Holle, F.J.Mayer, R.Schäfer
Bruker-Franzen Analytik GmbH,
Fahrenheitstr. 4, D-2800 Bremen 33, Germany

Introduction

The desorption/ionization method consisting of

- laser desorption of neutral molecules,
- supersonicjet cooling,
- resonance enhanced multiphoton ionization

in combination with time-of-flight mass analysis has become a valuable technique to examine non-volatile, labile molecules [1]. Particular features are the selective ionization and the controllable fragmentation.

As yet the mass range was about 3,000. In order to extent the mass range of this method, the use of matrices for neutral desorption was investigated.

Method

The measurements were performed with a Bruker REFLEX TOF mass spectrometer equipped with the TOF-1 ion source (Fig.1), (2).

Neutral molecules are vaporized by pulsed CO_2-laser radiation (10.6 μm, 10 μs, 10^5 W/cm^2 typ., Pulse Systems, LP 30) or N_2-laser radiation (337 nm, 4 ns, 10^6 W/cm^2, LSI). The desorbed molecules penetrate a pulsed supersonic jet (backing pressure 4 bar, 500 μs), which cools them and carries them into the ionization region. The molecules are postionized by UV-laser pulses (250 - 270 nm, 8 ns, 10^7 W/cm^2 typ., Lambda Physik, excimer laser LPX110, dye laser FL3001, BBO frequency doubler) or by EI ionization. The mass resolution is 5,000 for MPI, and 2,000 for EI ionzation.

Results

A number of peptides in the mass range up to 2,000 u mixed with a series of matrices was examined.

The matrices investigated for matrix-assisted neutral desorption are:

Caffeic acid, Sinapinic acid, DHB, Nicotinic acid, Urea, Uric acid, Glycerol, Trioxan, Sucrose, Ribose, Raffinose, Glucose, Polyethylene, PE/metal powder, $NaPO_4$, frozen H_2O

Compared to the signal intensities for pure substances at low sample amounts, signal enhancements up to a factor 3 for IR-desorption of molecules with masses around 2,000 in caffeic acid matrix were observed. A gain of factor 15 for gramicidine S in an ice matrix was achieved. Some matrices, e. g. succrose, yield no higher signal but a steady signal for a lot more (ca. 100) desorption laser pulses than without matrix. Other matrices show no signal improvement. A matrix which is generally applicable for a substance class or for many substances either for IR- or UV neutral desorption has not been found.

Analysis of Polycyclic Aromatic Hydrocarbons in Extraterrestrial Samples

C.R. Maechling, S.J. Clemett, and R.N. Zare

The trace organic analysis of particulates and samples that are heterogeneous on a microscopic scale presents a major challenge to the fields of geochemistry and cosmochemistry. In order to apply the ultra-sensitive detection method of mass spectrometry, the sample must be both introduced into the gas phase and ionized. The nonvolatility of large organic species combined with their thermal fragility and tendency to fragment upon ionization have, however, severely limited this approach. We have developed a microprobe two-step laser mass spectrometer (μ-L^2MS) with a spatial resolution of 40 μm, mass resolution of over 3000 for toluene (92 amu), and sensitivity of 6 attomoles for coronene (300 amu) to meet this challenge.

Our technique utilizes the advantages of laser desorption, to volatilize intact neutral molecules from a solid sample, with the molecular selectivity and sensitivity of resonance-enhanced multiphoton ionization (REMPI), and the high ion transmission, unlimited mass range, and multichannel detection of a reflectron time-of-flight (TOF) mass spectrometer. In our μ-L^2MS, the output of a pulsed CO_2 laser (10.6 μm) is focused through a Cassegrainian microscope objective onto a 40-μm spot of the sample from which efficient desorption of neutral species occurs. After a 20-μs time delay, the fourth harmonic of a pulsed Nd:YAG laser (266 nm) selectively ionizes any polycyclic aromatic hydrocarbons (PAHs) in the mixture of desorbing species by 1+1 REMPI. We have found that it is often useful to alternatively photoionize with either the third (355 nm) or fifth (212 nm) harmonic. The ions thus formed are mass analyzed in a TOF mass spectrometer, equipped with a two-stage reflectron. The ability to completely resolve the individual isotopomers of a molecular species offers the potential to determine the carbon isotope ratio for that molecule.

We have already demonstrated the use of this technique on a wide range of cosmochemical samples finding organics below the detection limits of other techniques, and have applied our technique to the spatial mapping of organics in freshly-cleaved meteorite samples. We aim not only to confirm whether organics are present within our detection limits, but to identify trends, if such exist, on PAH distribution and degree of alkylation. We have already shown this to be important in the analysis of meteoritic acid residues [1].

Expanding upon previous studies [1], we have analyzed a series of acid (HF-HCl) insoluble residues prepared from the interiors of seventeen ordinary and carbonaceous chondrite meteorites. Very distinct trends have been observed within series of both the ordinary and carbonaceous chondrites with respect to the PAH distributions and degrees of alkylation of the PAH skeletons. For instance, we observe that ordinary chondrites which have interacted with greater amounts of water (as determined by previous mineralogical studies [2]) show a marked loss of pyrene (202 amu) with respect to methyl-phenanthrene (192 amu). We also find that ordinary chondrites which have experienced greater heating (also determined by mineralogical studies [3]) have a more pronounced, albeit less in absolute terms, phenanthrene alkylation series. In a model study, samples of grains smaller than 150

μm in diameter from the interiors of both the Allende (CV3) and Murchison (CM2) meteorite were prepared and half of each sample was baked for 24 hr in an argon environment. Trends similar to those found in the ordinary chondrites were observed. This indicates that it is possible to observe the effects of secondary processing (aqueous alteration and thermal metamorphism) by monitoring the PAH contents of the meteorite.

We have also applied our technique to a variety of small particles including freshly-cleaved, interior chips of meteorites and crushed samples of interplanetary dust and micrometeorites collected from the blue ice of Antarctica. A 50-shot average spectrum of the Antarctica particle WU3-29 is displayed in Figure 1. The spectrum is rich in PAH skeletons and their associated homologs. The size of this crushed particle is roughly 100 μm x 100 μm; however, we have observed complete, single-shot mass spectra of meteorite chips as small as 10 μm x 15 μm.

For clarity, the alkylation series, with incremental spacings of 14 amu, of phenanthrene (178 amu) is pictured. The spectrum is a 50-shot average.

The Degrees of Freedom Effect Revisited: A Comparison of Multiphoton and Electron Impact Mass Spectra

McKeown, P.J., Nicol, G.R., Johnston, M.V.
Department of Chemistry and Biochemistry
University of Delaware
Newark, De 19716

Introduction A homologous series of β-Naphthyl Esters, ranging from the acetate (MW 186) through the stearate (MW=410), has been studied by electron impact (EI) and multiphoton (MPI) ionization. The spectra are dominated by a parent ion, a prominent fragment ion (m/z 144), and smaller fragment ions at m/z 116 and m/z 115. The fragmentation sequence is shown in figure 1.

Upon ionization, the internal energy is randomized throughout the parent ion. The neutral produced in the primary fragmentation step increases with increasing molecular size. Thus, a greater portion of the parent ion internal energy is carried away upon decomposition. The m/z 144 ion is left with less internal energy for the secondary fragmentation process (forming m/z 116) and therefore the rate decreases. This rate decrease is reflected by a decrease in the ratio of the metastably formed secondary ion (m/z 116 *) to the primary ion (m/z 144) with increasing number of internal degrees of freedom (DOF).

Experimental The MPI data were obtained using the fourth harmonic of a Nd:YAG laser (266 nm). A representative MPI spectrum for β-Naphthyl Myristate is shown in figure 2. The tail on the high mass side of the m/z 116 peak is due to metastable decomposition. Both prompt m/z 144 and metastable m/z 116 are produced by the absorption of one photon by the parent ion. The ratio of [m/z 116*]/[m/z 144] was obtained by integrating under the tail of the metastable peak from m/z 117 to m/z 125.

The EI data were obtained on a VG 7070F (EB) mass spectrometer. 70 eV electron impact was used for ionization. Two methods of sample volatilization were used. First, the source pressure was held constant by varying the probe temperature and second, the probe temperature was held constant. Metastable ion spectra were obtained by scanning the acceleration potential. [m/z116*] and [m/z 144] were determined by peak height measurements.

Results Figure 3 shows plots of log [m/z 116*]/[m/z 144] versus 100/DOF for the MPI and EI experiments. The EI data obtained for both volatilization methods show the expected behavior: the ion current ratio decreases with increasing DOF. However, the ratio hardly changes with MPI.

There are several possible explanations for the difference between the MPI and EI data. First, MPI produces parent ions with a narrower range of internal energies. However this effect can be "averaged" out in the secondary fragmentation step due to partitioning of energy between the neutral and fragment ion. Still, it is unlikely that the two experiments are sampling exactly the same internal energy distribution. Second, the internal energy may not be completely randomized throughout the entire molecule before fragmentation during MPI. Although this situation is unlikely, population of a long lived, metastable electronic state may occur. Finally, the time domains are different for metastable observation. The MPI experiment detects metastable decomposition occurring 0.2 to 0.5 microseconds after ionization while the EI experiment detects metastable decomposition between 2.2 and 2.5 microseconds. Although the range of decay rates probed is different for the two experiments, the regions do overlap. However, the EI experiment does favor the slower rates thus a larger DOF effect might be expected.

Characterization of the Desorption and Ionization Behavior of Polyethylene Glycol by Matrix-Assisted Laser Desorption/Ionization

R. King, D. Stewart, R. Goldschmidt, *K.G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104

Matrix-assisted laser desorption/ionization has been used to analyze biopolymers with masses well over 200,000 amu. Extension of the MALD/I technique to the analysis of large synthetic polymers has lead to investigations concerning the mechanisms by which the organic matrix compounds work to desorb and ionize large intact molecules. The work presented here is an attempt to determine what limits our laboratory's ability to analyze polyethylene glycol polymer samples above 1500 amu.

Polyethelyene glycol has been studied by UV laser matrix assisted methods using colloidal cobalt metal as a matrix.[1] We have found that a solution of graphite[2] in isopropanol mixed with an aqueous solution of PEG also works well for molecules up to mass 1500. Attempts to analyze larger PEG samples produced no ions charateristic of the polymer. There are two possible explainations for these observations:

- the larger polymer molecules are not being desorbed from the surface.
- the larger polymer molecules are being desorbed as neutrals but then are not being ionized.

The experimental results presented here attempt to address these two possibilities. Determination of which process is limiting will naturally suggest methods to improve the technique for the analysis of higher mass polymers.

Sample Preparation

Graphite matrix:

The PEG samples were dissolved in a 30% /70% (v/v) acetonitrile / water mixture to a concentration of approximately 1 mM for the molecular weight at the specified peak of the distribution. The graphite is a commercial mixture of colloidal graphite in isopropyl alcohol (Aerodag G, Acheson Colloids, Port Huron, MI). The samples for analysis were prepared by mixing 5 microliters of each solution on a stainless steel probe tip and drying under a gentle stream of nitrogen.

Sinapinic acid, 7-Hydroxycoumarin matrices:

The PEG samples used were prepared as described above for the graphite matrix, except the final PEG concentration was approximately 0.1 mM. 10 microliters of each PEG solution was mixed with 50 microliters of 50 mM sinapinic acid or 50 mM 7-hydroxycoumarin dissolved in acetonitrile / water (30 / 70). 10 microliters of this mixture was then applied to a stainless steel probe tip and dryed under a gentle stream of nitrogen.

Diethylene glycol addition:

The PEG samples used were prepared as described above for the graphite matrix. 10 microliters of each PEG solution was mixed with the appropriate matrix as described above for each matrix. 5 microliters of 0.1M diethylene glycol (30/70 acetonitrile / water) was then added to the matrix - PEG mixture on a stainless steel probe tip. The sample was partially dried under a gentle stream of nitrogen. Excess diethylene glycol is removed in the vacuum chamber through evaporation prior to analysis.

Summary of Observations:

- Both sodium and potassium cationized molecular ions are observed for the lower molecular weight PEG samples (mw<=1500) using the graphitic carbon as well as the organic matrix 7-hydroxycoumarin.
- The mass resolution ($m/\Delta m$) for the cationized PEG peaks is approximately 1000. This is much higher than that observed for the matrix-assisted laser desorption/ionization of peptide samples. Detailed study of the ion time-of-flight distributions (not shown) indicate cationization is occuring in a very narrow region above the sample surface.
- In the two-color neutral desorption/gas-phase laser ionization experiments, characteristic PEG fragments are only observed for low molecular weight samples. For the graphite matrix, as the

molecular weight of the PEG increases, the polymer tends to suppress the desorption of matrix neutrals. For the organic matrices, little desorption of neutral PEG is observed.
- The addition of a small amount of diethylene glycol increases the sample ion intensity for both the graphitic carbon and organic matrices. This is likely due to improved dispersion of the matrix material through the longer polymer chains.
- 7-hydroxycoumarin is a new matrix material useful for the study of both biological and synthetic polymers.

LASER DESORPTION - LASER PHOTOIONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY: APPLICATION TO THE DIRECT ANALYSIS OF POLYCYCLIC AROMATIC HYDROCARBONS IN SOOTS

Catherine H. Smith, Mary K. Young, and Peter B. Kelly, Department of Chemistry, and
A. Daniel Jones, Facility for Advanced Instrumentation,

Introduction

Current methods for the screening and identification of polycyclic aromatic hydrocarbons (PAHs) in soot and fly-ash samples are labor-intensive, time-consuming and expensive. Typically, samples must undergo extraction and separation steps prior to actual analysis by a technique such as mass spectrometry. We have developed a laser desorption - laser photoionization mass spectrometry (LDLPMS) technique which provides a means for rapidly screening particulate matter samples for PAHs, with no extraction or separation steps. LDLPMS has been demonstrated to be a powerful technique for the analysis of semi- and non-volatile compounds present on a solid substrate (1). We have been able to extend the technique to the direct analysis of particulate matter collected on air-sampling filter substrates.

Experimental

At the core of the LDLPMS instrumentation is a custom-built TOF mass spectrometer operating in the linear mode. A metal probe was designed with a flat face which is 90° to the flight tube axis. The sample filter is attached to this face using sticky tape. Pulsed IR radiation at 10.6 μ generated by a CO_2 laser impinges the probe face at 30° and is focussed to a 1 mm^2 spot size. Pulsed UV radiation at 266 nm produced by a Q-switched Nd:YAG laser is focussed into the plume of desorbed neutral species to effect multiphoton ionization. The exact position of the UV beam with respect to the probe face, as well as the relative arrival times of the IR and UV beams, significantly affect the ion intensities and flight times in the recorded spectra. These experimental parameters were optimized prior to routine data collection. Aliquots of PAH standard solutions were delivered by syringe onto glass fiber filters and allowed to air-dry prior to attachment to the probe.

Results

The LDLPMS spectra of a series of PAH standards in both "soft" and "hard" ionization modes were investigated at 266 nm. At this wavelength, ionization occurs via resonant two photon absorption and ionization in a [1+1] process (2). In the "soft" ionization mode, the parent molecular ion peak, M^+, was the dominant feature in the LDLPMS spectra for all the PAHs tested, as shown in **Figure 1**. This allows compound identification via molecular weight determination. When the UV power was increased to induce "hard" ionization, the resulting fragmentation patterns were dominated by the low mass carbon fragments corresponding to C through C_6H_x.

Rice soot samples collected above burning rice fields on Gelman glass fiber air sampling filters were analyzed by LDLPMS as received. **Figure 2** illustrates a LDLPMS spectrum obtained with photoionization at 266 nm. The major feature is an intense peak at m/z 202, which corresponds to a condensed four-ring PAH such as pyrene or fluoranthene. GC/MS analysis of the CH_2Cl_2 extract of this sample indicated that the PAH content was less than 100 ng/sample.

[f] Mass Spectrometry Facility, University of California, San Francisco, CA 94143-0446

The goal for the application of the Laser Desorption Laser Photoionization TOF mass spectrometer (LDLPMS) constructed in our lab was to screen airborne particulate from rice field burning or incinerator ash from chlorinated solvent disposal for polycyclic aromatic hydrocarbon (PAH) and polychlorinated dibenzodioxin (PCDD) content by direct analysis. The speed and sensitivity of the technique (ppm levels achieved in direct soot analysis requiring only 40-100 seconds) coupled with the wavelength selectivity of the ionization process [1,2,3] made LDLPMS the method of choice. The first step in bringing the instrument on line was to evaluate UV induced single step desorption /ionization for direct soot analysis. The wavelength selectivity observed for PAHs in a trichloroethylene soot was promising[4], however, on applying the single step process to PAH standards , molecular ions were not observed and phenomena suggestive of competing photochemical processes were evident.

Figures 1, 2, and 3 show the UV absorption spectrum for perylene, the LDLPMS spectra obtained using three different UV wavelengths, and the cluster ion formation observed using 2.12 x 10^6 W/cm^2 of 266 nm radiation with numbers of shots averaged varied. The absence of molecular ions for the single step UV desorbed/ionized PAHs even at threshold power densities coupled with the evidence of competing excited state photochemistry determined that single step UV desorption/ionization was inappropriate for the direct analysis of soots. The application of a two step IR desorption/UV ionization process to soots produced PAH molecular ion dominated spectra[4]. PAH standards ionized by UV in the two step process follow the expected multiphoton ionization (MPI) trends for the power dependence of ion yield[1,5]. (For example,.using 266 nm radiation, the observed pyrene molecular ion current shows a two photon dependence with increasing laser power.)

Intrigued by the perylene ion clusters, we decided to extract the PAHs from the probe after the LDLPMS single step UV desorption/ionization experiments. The extracted phenanthrene sample showed the production of several photoisomers. The major photoisomer was 9-methylene-fluorene (or another dibenzofulvene isomer possessing the same column retention characteristics). Pyrene showed one weak photoisomer peak in the GC/MS which remains unidentified. The EI spectra of the photoisomer and pyrene peaks are virtually identical. The PAH standard solutions which had not been irradiated were analyzed by GC/MS as controls. Only single peaks were observed in ion chromatograms of the non-irradiated standards. A separate experiment using a nitrogen purged windowed stainless steel cell was used to examine the UV induced photochemistry further.

A final experiment in UV desorption/ionization involved matrix desorption using 3-nitrobenzyl alcohol (3-NBA) as the matrix. Pyrene and perylene in 3-NBA (3-NBA was present in 100 fold excess to pyrene and 1000 fold excess to perylene) were irradiated with 266 nm light at varying laser powers. Only molecular ions were observed for the PAHs. There was no molecular ion observed for the 3-NBA. The PAH signal intensity did not

follow any trend with the variation in laser power, however the PAH flight times became longer with increased laser power. The observed shift to longer flight time may be the result of shielding of the newly formed PAH ions by the bath of ejected matrix neutrals. Variation in the point of PAH ion origin with respect to the extractor grid cannot be neglected as a contribution to the flight time shift. We are currently examining this question experimentally.

Matrix-Assisted Laser Desorption Using a Magnetic Sector Mass Spectrometer

Lydia M. Nuwaysir and John T. Stults
Genentech, Inc., Protein Chemistry Department
460 Pt. San Bruno Blvd., South San Francisco, CA 94080

Introduction: Matrix-assisted laser desorption/ionization (MALDI) mass spectrometry has rapidly become one of the premier techniques for analyzing large thermally labile biological molecules. To date, most MALDI experiments have been performed using time-of-flight (TOF) mass spectrometers, however, just recently there have been a few cases in which MALDI has been accomplished using sector and Fourier transform mass spectrometers[1-3]. The objective for the following research was to modify a magnetic sector mass spectrometer equipped with both an array detector and a point detector to permit MALDI for routine applications of protein analysis; to assess the resolution, sensitivity, upper mass limit, and mass accuracy obtainable using the MALDI source; and to apply MALDI to the C-terminal sequencing of proteins enzymatically digested with carboxypeptidases.[4]

Experimental: The instrument modifications consist of using an LSI N_2 laser directed into the MS2 FAB source of a JEOL HX110HF/ HX110HF four-sector mass spectrometer. A fused silica window replaces the FAB gun and the laser beam follows what is normally the path of the FAB primary beam. The laser is attenuated with a color glass filter followed by a variable attenuator and is focussed with a 150 mm fused silica lens onto a conventional FAB probe tip. A timing synchronization circuit permits the ion current from multiple laser shots to be integrated on the detector to increase signal-to-noise ratio. Ions with m/z 14,000 may be analyzed at full accelerating voltage and are detected with a 3-inch array detector with a 9.5% acceptance. For higher resolution studies, the magnet is slowly scanned across a mass range spanning ±0.25% of the molecular ion mass and ions are detected using a point detector (conventional exit slit with discrete dynode electron multiplier).

Dihydroxybenzoic acid was used as the matrix in all cases. Samples were dissolved in 0.1% TFA and mixed with DHB in 50% ethanol. The final concentration of analyte and matrix, when mixed, was ≤0.15 g/l and 5 g/l, respectively. For spectra acquired using the array detector, between 0.1 and 3 µl of solution was deposited onto a conventional FAB stainless steel probe tip and the solvent allowed to evaporate (however, because of the design of the probe tip, it is estimated that the laser irradiated less than 10% of the sample loaded). Spectra were acquired from single laser shots or several (<3) laser shots, and between 20 and 200 spectra were selectively co-added to improve signal-to-noise ratio. For higher resolution studies (using the point detector), between 20 and 50 µl of solution was deposited onto the probe tip. For these studies, the laser was fired at 20 Hz and typically between 2 to 20 spectra were selectively co-added to improve signal to noise ratio. Accurate mass measurements were obtained via mass correction with CsI FAB spectra generated using the MS1 ion source.

Discussion: The high resolution spectrum for bovine insulin chain b, oxidized, (MW 3494), obtained using the point detector, is shown in Figure 1, in which a resolution of 7000 is obtained for $[M+H]^+$ ^{13}C isotope ions. For this experiment, the magnet was slowly scanned from m/z 3490 to 3510 and 11 scans were co-added to improve signal-to-noise ratio. Because it was necessary to scan the magnet, about 500 pmol of protein was loaded onto the probe tip, however, it is estimated that this amount could be reduced by at least a factor of 10 with optimization of the probe tip design. The raw data (prior to smoothing) are shown in the inset region.

The β-lactoglobulin (M_r 18,400) mass spectrum obtained from 15.6 pmol of protein loaded onto the probe tip was obtained using an accelerating voltage of 6 kV (Figure 2). Ions appearing at higher masses than $[M+H]^+$ ions are due to impurities and matrix adduct ions. Ions corresponding to loss of NH_3 and ($2NH_3$) are also observed and can be partially resolved. It is certain that by using even lower accelerating voltages that the upper mass limit can be extended beyond that demonstrated for b-lactoglobulin, although the signal strength will decrease as a result of the requirement for lower accelerating voltages.

The mass spectrum of the 58 amino acid protein, aprotinin (M_r 6,500), after carboxypeptidase Y digestion was obtained from 10.0 pmol of sample loaded onto the probe tip. A resolution of 1000 is obtained for $[M+H]^+$ ions. The composition of the sample after digestion for 120 minutes shows abundant ions corresponding to loss of alanine and glycine C-terminal residues.

Conclusion: A relatively simple and inexpensive modification of a magnetic sector FAB ion source permits MALDI spectra to be obtained. Using the array detector, sensitivity (pmol) and mass accuracy (0.01%) are comparable to MALDI-TOF instruments, while resolution (4300 FWHM) exceeds TOF instruments. The use of a point detector allows even higher resolution (7000 FWHM) to be obtained, however at the expense of sensitivity (loss of the multiplex advantage). Improvements in probe tip design will allow an increase in sensitivity by at least a factor of 10. Application of MALDI to a protein enzymatically digested with carboxypeptidase Y provided partial C-terminal sequence data. Presently, work is aimed at exploring MALDI for the generation of parent ions for MS/MS daughter ion spectra.

Matrix Assisted Laser Desorption Ionization in a Magnetic Deflection Mass Spectrometer

R.S. Annan, H.J. Köchling, J.E. Biller, J.A. Hill, and K. Biemann
Department of Chemistry, MIT, Cambridge, MA, 02139 USA

Recently, we have demonstrated the feasibility of carrying out matrix-assisted laser desorption ionization (MALDI) using the fast atom (ion) bombardment (FAB) ion source of MS-2 of our 4-sector magnetic tandem mass spectrometer (1). Because of the pulsed nature of the ionizing laser beam, an integrating focal plane detector (2) had to be used.

We have further continued these investigations to improve resolution, to scan the full mass range for "survey spectra", to cover a wider mass range by reducing the accelerating voltage, and to investigate the peak shape at high mass.

We have also explored the feasibility of MALDI-MS/MS by guiding the laser beam all the way to the FAB ion source of MS-1 and producing fragments of a selected precursor ion by colliding it with xenon in the collision cell located between MS-1 and MS-2

EXPERIMENTAL

A conventional fast atom bombardment ion source was installed between MS-1 and MS-2 of a JEOL HX110/HX110 tandem instrument of the $E_1B_1E_2B_2$ configuration for the 2-sector or standard MS experiments, and the standard ion source of MS-1 was used for the MS/MS or 4-sector experiments. The only modification to the sources for MALDI was that the FAB guns were removed and replaced with a laser desorption optical assembly. We used an excimer laser generating 12 nsec pulses at 353 nm (XeF). The laser was operated at a repetition rate of 10-30 Hz with an irradiance of 10^7-10^8 W/cm^2 at the sample. Samples were dissolved in a saturated aqueous solution of 2,5-dihydroxybenzoic acid (DHB) or a saturated solution of sinapinic acid in 50/50 (vol.%) CH_3CN/H_2O. 1 μL of the resulting solution was applied to the gold tip of a FAB probe and allowed to dry in air. An array detector was used to collect the data as described previously (1).

RESULTS AND DISCUSSION

2-Sector Performance.

A resolution of 1:5,800 (FWHM) has been achieved for substance P, $(M + H)^+ = m/z$ 1347.7 and of 1:4,600 for ACTH (18-39), $(M + H)^+ = m/z$ 2465.2. This increase over previous results (1) is mainly accomplished by using the maximum dispersion setting of our variable dispersion array detector. The number of pixels of the detector covered by the monoisotopic ion beam seems to be one of the resolution limitations. The resolution in the region of $m/z \sim 10{,}000$ is still 1:2,800. However, resolving monoisotopic beams is only important for MS/MS experiments, which, for other reasons, are limited to a mass range below 3000 u.

For determining the molecular weight of an unknown substance, one must survey the entire mass range and then home in on the appropriate signal. The first is accomplished using the smallest dispersion (widest mass range per detector segment), as shown in Fig. 1, and then recording the region of interest with the highest dispersion for best resolution and mass assignment (Fig. 2).

The MALDI spectra of small proteins exhibit a low mass tail, which seems to become wider when lowering the acceleration potential. Most or all of this tailing is, therefore, most likely due to metastable decomposition of the $(M + H)^+$ ion in the region after the electric sector.

Lowering the accelerating potential to 5kV doubles the mass range of the spectrometer and allows the detection of ions up to m/z 26,000, as demonstrated in Fig. 3, which shows the signal obtained with trypsinogen, $(M + H)^+ = m/z$ 23,982.0 Avg.

4-Sector Experiments

The feasibility of MALDI-MS/MS by collision-induced dissociation (CID) was demonstrated by ionizing the peptide substance P in the ion source of MS-1, and passing the monoisotopic $(M + H)^+$ ion of m/z 1348.7 through the collision cell (Xe) into MS-2. The latter was stepped through the appropriate E_2 and B_2 settings to record the CID spectrum shown in Fig. 4, which compares well with that obtained by conventional FAB-MS/MS under similar CID conditions.

CONCLUSIONS

Matrix-assisted laser desorption ionization of peptides and proteins of molecular weights up to ~ 25,000 has been demonstrated. It is also shown that MALDI can be used in a magnetic tandem mass spectrometer to generate precursor ions and record complete CID spectra thereof. Particularly for the latter experiments, it is necessary to develop sample preparation techniques that generate a relatively steady ion signal.

PROBLEMS WITH MASS RESOLUTION IN MATRIX ASSISTED LASER DESORPTION TOF-MS AND PRACTICAL SOLUTIONS.

Marvin L. Vestal, and Randall W. Nelson
Vestec Corporation, 9299 Kirby Drive
Houston, TX 77054.

The matrix assisted laser desorption technique pioneered by Hillenkamp and Karas[1] presently provides a very sensitive technique for producing intact molecular ions from large molecules such as proteins. The mass resolution obtained with simple linear TOF analyzers is disappointingly low, particularly at high masses, and attempts to improve the resolution using conventional "reflectron" type analyzers have been only moderately successful.

In this paper a new TOF mass spectrometer is described. This instrument employs a novel reflector geometry which allows exact correction of the time dispersion in the ion source due to a spread in initial kinetic energy, and either first or second order correction for time dispersion in the drift tube. A differentially pumped ultra-high (10^{-9} torr) vacuum system is employed to minimize collisional effects. Up to 24 samples are loaded at one time, and sample selection, position of the laser beam on the sample, and laser intensity are controlled by the data system and monitored by a video camera.

Recent measurements by Beavis and Chait[2] and by Ens and Standing[3] show that the major limitation of resolution at high mass for MALDI-TOF is imposed by the fact that the initial velocity distribution for ions desorbed from the sample surface is nearly independent of mass. For the purpose of designing the new TOF analyzer the ion energy distributions were approximated by assuming that ions are produced from a surface of constant potential (which may be lower than the potential applied to the sample holder) with initial velocities (independent of mass) between 0 and 1000 m/s in a forward cone with half-angle 15 degrees. Since this model implies that the energy spread is proportional to the mass of the ion, at high masses the resolution is determined by the energy spread. Calculated resolving powers for some linear TOF analyzers are summarized in Figure 1. The middle curve (standard) corresponding to time error of 15 ns, total effective flight distance of 1.5 m, source length 2.5 cm, and accelerating potential of 30 kV approximately represents the linear analyzer used in the present work. Reducing the time error to 5 ns and increasing the drift length to 5 m substantially improves the resolving power at low mass but has little effect on high mass performance. Resolution at higher masses can be improved by shortening the ion source and increasing the acceleration as shown by the "super" curve in Figure 1, but the parameters used in this calculation are near the practical limit for a linear analyzer and represent approximately the best resolution that can be obtained by a linear analyzer unless the initial energy spread can be reduced.

It is well established that loss of resolution due to energy spread can be corrected by use of a properly designed ion mirror. A single stage mirror, such as shown schematically in Figure 2, corrects the flight time to first order in energy, but does not correct for the effect that initial energy has on the ion source transit time. A similar mirror with a source correcting stage at the end, shown in Figure 3, was developed in this work to provide this correction. Calculated resolving powers for TOF analyzers employing single stage mirrors, with and without source correction, are shown in Figure 4. The lower curve with source correction corresponds approximately to the geometry used in the present work, and the upper curve with source correction corresponds to a new analyzer which has been designed following these results.

Samples of results obtained with the linear obtained with the linear and reflecting analyzers are shown in Figure 5 where in each case the upper trace is from the linear analyzer and the lower from the reflector. These results were obtained at an analyzer pressure of ca. 5×10^{-9} torr. Even at this pressure it appears that performance at high mass (ca. 10,000 da and beyond) is severely limited by collisions which cause ion fragmentation and loss of ion intensity. Crude calculations suggest that it may be necessary to further reduce the drift tube pressure, perhaps to less than 10^{-10} torr if high performance is to be achieved up to 100,000 da.

DESIGN AND APPLICATION OF A SIMPLE MALD-TOF INSTRUMENT

Jeffrey W. Finch and Kevin L. Schey
Department of Pharmacology, Medical University of South Carolina
Charleston, SC 29425

Since its introduction the mass range and mass accuracy of matrix-assisted laser desorption ionization (MALDI) [1,2] have made this technique increasingly important for biomedical applications. We have designed and constructed a simple low-cost MALDI time-of-flight instrument using a sealed-tube nitrogen laser and a linear time-of-flight instrument. Here we present the design, characterization, and application of this instrument.

A sealed-tube nitrogen laser is used as the source of UV photons which bombard a stainless steel probe tip onto which the matrix and sample have been deposited. The TOF mass spectrometer consists of a 1.4 m drift tube which houses a custom built two-field ion source and a chevron microchannel plate detector. A LeCroy 9400A digital oscilloscope is used as the data system with storage and calibration capabilities provided by a Zenith 386SX computer. Typical source potentials are 25 kV, 22 kV, and 0 V for the repeller, drawout grid, and ground grid, respectively. A 450 V pulse is applied to one of a pair of deflector plates to suppress low mass ions.

A variable wheel attenuator allows attenuation of the laser power to just above the threshold for producing MALDI signals. Power densities of 10 MW/cm^2 are typically employed for the MALDI spectra presented here. Calibration is accomplished by the use of a two point calibration procedure written in BASIC. A custom program from Genetics Institute was used to calibrate and display some of the data presented here. Typically 20 to 100 laser shots are summed while the probe is rotated to produce a spectrum.

Protein solutions of 1 mg/ml were prepared in water while 50 mM sinapinic acid (SA) solutions were prepared in 70/30 acetonitrile/water, 0.1% TFA. Improved ion signals were obtained when both the protein and SA were dissolved in a 50/50 isopropanol/water. Typically 1 µl of the protein solution and 1 µl of the SA solution were co-deposited on the probe tip and allowed to dry in air. Hydrophobic proteins present in biological membranes were dissolved in 99% formic acid and hexafluoroisopropanol (1:7:2) and mixed with SA (70% formic acid) before being deposited on the probe tip.

Detection limits of 200 amol for glucagon and 80 fmol for cytochrome c were obtained. Mass accuracies for a series of peptides and proteins were determined to be less than 0.01% for species below 10,000 daltons and increased from 0.07 to 0.3% from 20,000 to 100,000 daltons The usable mass range extends to at least 150,000 daltons.

A mixture of guanosine triphosphate binding protein (G-protein) subunits, including α, β, and γ, was isolated from bovine brain in a preparation containing 1mM EDTA, 1 mM DTT, 0.2% lubrol-PX, 20 mM HEPES buffer, and 100 mM NaCl. This mixture was placed directly on the MALDI probe with SA. Interestingly, only the γ subunits

were observed as is seen in the upper spectrum of Figure 1. The three isoforms observed at m/z 7432.6, 7777.9, 8348.5 have different molecular weights from those predicted by the cDNA sequence and hence, posttranslational modifications may be present.

Intact disk membranes isolated from bovine retinae were solubilized as described above and the MALDI spectrum is shown in Figure 2. The molecular weight measured for bovine rhodopsin is 42,034 which corresponds to the value calculated for bovine rhodopsin with the major posttranslational modifications identified to date (calc. 42,002). Bleached rhodopsin gave a measured molecular weight of 41,748 indicating loss of the retinal chromophore (calc. 41,718). Similar results were obtained for bacteriorhodopsin (MW 27,068).

A simple MALDI-TOF instrument has been constructed and successfully applied to a variety of protein structure problems. The instrument performance is similar to that reported for commercially available instruments. The MALDI technique was found to be applicable to hydrophobic proteins and proteins in the presence of complex matrices. Further improvements in sample preparation and detector technology should make this instrument more applicable in the future.

Laser Desorption VS Fast Atom Bombardment which is Better?

Timothy MacMahon, IBM, Hopewell Junction, New York, 12533.

There have been few direct comparisons between laser desorption and Fast Atom Bombardment ionization techniques. Both these techniques are used to desorb positive and negative ions from large involatile molecules that are not usually amenable to traditional electron impact or chemical ionization techniques. This paper will present a side by side comparison of the two techniques on the same molecules and contrast the different type of information that the can be obtained from each one.

These series of experiments were carried out on two different instruments . All laser desorption experiments were carried out using an Extrel FTMS–2000 equipped with a Tachisto CO_2 pulsed laser at 10.6 microns. The Fast Atom Bombardment experiments were performed on a Kratos MS25RFA sector mass spectrometer equipped with an Ion Tech. Fast Atom Bombardment ion gun. Xenon was used as the FAB gas for all FAB experiments.

The species studied were CsI, glycerol / CsI, ethylenediaminetetraacetic acid (EDTA), and cyclodextrin. Laser desorption of CsI showed only mass 133 Cs^+ in the positive ion mode and mass 127 $[I]^-$ in the negative mode. FAB, on the other hand, showed many more peaks due to clustering reactions. Positive ion FAB showed ions at mass 133 Cs^+, 266 Cs_2^+, 393 $[CsI{\cdot}Cs]^+$, 653 $[(CsI)_2{\cdot}Cs]^+$, and finally 912 $[(CsI)_3{\cdot}Cs]^+$. In the negative ion mode the clusters formed were at mass 127 $[I]^-$, 254 $[I_2]^-$, 387 $[CsI{\cdot}I]^-$, 647 $[(CsI)_2{\cdot}I]^-$ and 906 $[(CsI)_3{\cdot}I]^-$. This is consistent with the fact that CsI is routinely used as a calibration compound in FAB due to the large number of cluster species formed allowing calibration past mass 1000. The lack of these same clustering ions in laser desorption is probably due to the lower pressure burst of the laser plasma and time available for clustering reaction to occur when compared to a static sputtering experiment like FAB.

Both FAB and laser desorption of the glycerol / CsI mixture showed ions in the positive and negative spectra out to around 1000 amu. Negative ion FAB showed the base peak at 127 amu corresponding to $[I]^-$ while in laser desorption the base peak occurred at 387 amu corresponding to $[(CsI){\cdot}I]^-$. The ions that were formed in both laser desorption and FAB tended to be $[(CsI)_x{\cdot}Cs]^+$ and $[(CsI)_x{\cdot}glycerol]^+$ in the positive mode and $[(CsI)_x{\cdot}I]^-$ and $[(CsI)_x{\cdot}glycerol]^-$ in the negative mode.

Laser desorption of EDTA proved far more informative than FAB. In FAB little information could be obtained due to the relatively high number of intense background ions formed from the glycerol matrix necessary for desorption. Laser desorption, on the other hand, does not require any special matrix for desorption and, thus, the background is

considerably lower. The base peak in the positive ion mode was 315 amu which corresponds to $[C_{10}H_{16}O_8N_2Na]^+$ or $[EDTA{\cdot}H_4{\cdot}Na]^+$ where EDTA is the fully deprotonated terra acid form of ethylenediaminetetraacetic acid. The other major ions seen in the spectra were 337, 359, 381, 403 which correspons to $[EDTA{\cdot}H_3{\cdot}Na_2]^+$, $[EDTA{\cdot}H_2{\cdot}Na_3]^+$, $[EDTA{\cdot}H{\cdot}Na_4]^+$, and $[EDTA{\cdot}Na_5]^+$ respectively. Negative ion also shows some interesting ions in that the base peak is 357 amu corresponding to $[EDTA{\cdot}Na_4]^-$ with other ions at 255 $[EDTA{\cdot}H_3 - 2H_2O]^-$, 291 $[EDTA{\cdot}H_3]^-$, 313 $[EDTA{\cdot}H_2{\cdot}Na]^-$, 335 $[EDTA{\cdot}H{\cdot}Na_2]^-$, 672 $[(EDTA)_2{\cdot}H_4{\cdot}Na_4]^-$, 694 $[(EDTA)_2{\cdot}H_3{\cdot}Na_5]^-$, 716 $[(EDTA)_2{\cdot}H_2{\cdot}Na_6]^-$, and 738 $[(EDTA)_2{\cdot}H{\cdot}Na_7]^-$. In this case, the laser desorption experiments were able to give molecular weight information and show interesting mass spectral information by the plethora of gas phase ions produced.

The last compound studied was cyclodextrin, it has a cyclic structure with 7 repeating sugar units ($C_6H_{10}O_5$) to give a molecular weight of 1134 amu. Neither FAB nor laser desorption was able to detect a molecular ion or pseudo molecular ion. Again, FAB had trouble detecting any fragments in either glycerol or thioglycerol. Laser desorption was able to detect residual sugar units from cyclodextrin. The highest molecular weight peak at mass 545 $[(C_6H_{10}O_5)_3{\cdot}C_2H_3O_2]^-$ has 3 of the 7 original sugar units intact. The other mass fragments correspond to additional losses of the complete sugar unit and eventually there are fragments even smaller than one complete sugar unit.

In conclusion, laser desorption tents to give less clustering than FAB, and there is less interference from background materials in laser desorption. This lack of background is an advantage in that low level peaks are more easily seen in laser desorption than in FAB. In this limited study, laser desorption seems to be more applicable over a wider range of compounds than FAB probably because dissolution in a desorption matrices is not required. Where both FAB and laser desorption were able to obtain useful information, the information seemed about the same in both techniques. More work needs to be done on direct comparisons between these two techniques in order to better determine the strengths and weaknesses of the two.

DIRECT MEASUREMENT OF THE KINETIC ENERGY DISTRIBUTION OF PARTICLES GENERATED BY MATRIX ASSISTED LASER DESORPTION

Eric L. Kerley

Comstock, Inc.
1005 Alvin Weinberg Drive
Oak Ridge, TN 37830

An Electrostatic Energy Analyzer/linear Time-of-Flight mass spectrometer is being constructed at Comstock, Inc. for the purpose of in-house studies into fundamentals of the Matrix-Assisted Laser Desorption (Ionization) [MALD(I)] process under conditions of high kinetic energy resolution (approximately 0.14%). Ultimate resolution of <10 meV should be possible in this configuration.

The nascent energy of ions (and post-ionized neutrals) can be obtained in this experiment due to the field-free conditions normally employed in the desorption region. Several experiments are planned for this device: i) accurate measurement of the absolute energy of MALD generated ions with respect to mass, ii) assessment of the effect of analyte structure on the mean absolute ion energy, and iii) determination of the energy distribution under different conditions. The prospect of using the Energy/TOF spectrum to enhance analytical utility will also be evaluated.

The instrument described here is nearly complete. This poster presents the fundamental features of this device and describes theoretical aspects of its proposed operation.

The instrument under construction is depicted to below. Samples are mounted on a rotatable turret direct insertion probe. For most studies, 337.1 nm light from a N_2 laser is focussed onto the probe tip. The 5-element lens images the laser spot onto the apertures of the 36.5 mm mean radius 160° hemispherical sector electrostatic energy analyzer. The 5-element lens allows control of at least one lens parameter (magnification or aberration coefficient, for example) independent of the focus condition. Ion energies are adjusted in the lens to allow energy analysis under constant resolution conditions. Energy scans at constant resolution from 0 up to 140 eV are under computer control via a control card mounted in a pc-type computer.

Energy selected ions are accelerated to approximately 2 keV on exiting the energy analyzer. The ions travel through a 1 meter flight tube and are detected using a 50 ohm impedance-matched chevron mounted dual microchannel plate assembly.

The ESA/TOF will allow straightforward measurement of the kinetic energies of MALD particles in the absence (or presence, if desired) of extraction fields. Such measurements will aid in rectifying the disparity in previous velocity measurements[1,2]. High resolution velocity determination will allow detection of fine

[1] Beavis, R. C.; Chait, B. T. The 38th ASMS Conference on Mass Spectroscopy and Allied Topics, Nashville, 1991, 1444.

structure (if any exists) in the desorption energy deposition due to unimolecular decay or molecular structure effects. Accurate measurement of the energy distribution will allow correlation of MALD processes and the associated plume expansion in terms of slippage and cooling. Further studies on angular distributions will be possible on this instrument allowing direct correlation to models of MALD processes[3].

HIGH ENERGY RESOLUTION MALD(I)-TOF SPECTROMETER

Determination of Post-Source Ion Kinetic Energies in Time-of-Flight Mass Spectrometry

*Bernhard Spengler, Raimund Kaufmann

Institute of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

A simple and reliable method of measuring ion kinetic energies in time-of-flight mass spectrometry (TOF-MS) is described. It is based on a special mode of operation of a two-stage reflectron. In contrast to common methods, measuring the ion signal intensity as a function of a retarding potential, the method described here can be used to determine the mean ion kinetic energy directly, by detecting the point-of-return of the ions in a two-stage grid-reflectron. This way the ion kinetic energy can be determined with high precision, independently of the usually varying absolute ion signal intensity.

In TOF-MS, two-stage grid-reflectrons are commonly employed to compensate ion flight time distributions which are due to the initial ion energy spread. They usually consist of a short decelerating field followed by a weaker and longer retarding field, separated from each other by a grid held at a potential U_1. Under the usual working conditions, ion kinetic energy variations are compensated with respect to flight time, by an appropriate shift of the "plane of turn-around" within the second stage of the reflectron. Thus, the total flight time becomes independent of the acceleration voltage (the kinetic energy).

If, however, U_1 is set close to the acceleration voltage U_{acc}, flight times become very critically depending on U_{acc} (thus on the ion kinetic energy), in a way that a sharp minimum is reached exactly when the plane of turn-around falls into the plane of the separating grid (see Fig. 1). In this situation, ions have precisely the kinetic energy which corresponds to the grid potential U_1. In monitoring the potential differences ($U_{acc} - U_1$) where this minimum in flight time is reached, energy deficits or excesses can be determined to a precision of about 0.1% of U_{acc}. By systematically scanning U_{acc}, not only the mean ion kinetic energy but also the kinetic energy distribution can be derived.

The sensitivity of the method can be further increased by lowering the electric field strength in the second stage of the reflectron, since the slope of the curve of total flight times will become steeper in this mode of operation.

For exact measurements, several considerations have to be taken into account:
- The deflection angle (angle of ion flight path with respect to the sample surface normal) lowers the effective kinetic energy of the ions:

$$U_{eff}=U_{acc} \cdot \cos^2\alpha$$

- Field penetrations at the separating grid have to be calculated, lowering the effective potential of U_1. This effect is dependent on the mesh size of the grid.

- The influence of the complete resistor network on the voltage measurement has to be taken into account.

Fig. 2 shows, as an example, the appearance of a molecular ion signal from bombesin at the transition of the plane of turn-around from the first stage into the second stage of the reflectron. Splitting and "hole-burning" of the signal is observed, due to the complete loss of the ions when the plane of turn-around and the plane of the separating grid exactly meet. In addition to the mean kinetic energy, the width of its distribution can be derived.

Since this method is independent of the common fluctuations of signal intensities, its precision is much higher than known from other methods.

Experimental Study of Ion Ejection Processes in Matrix Assisted Laser Desorption

A. Verentchikov, W. Ens, J. Martens and K. G. Standing; Physics Dept; University of Manitoba, Winnipeg, Canada R3T-2N2

Introduction: Early in the development of Matrix Assisted Laser Desorption(MALD) [1] models of the ion ejection mechanism included the formation of a gas jet of matrix molecules (volcano model). Later the model of a supersonic gas jet was used to explain ejection of heavy peptides from the solid , their mild ionisation and the reduction of resolution with increasing ion mass [2]. The model was supported by the experiments of Beavis and Chait [3] who showed that all the ions in wide mass range (1 to 15kD) are ejected with the same initial velocity, but -to contradict the model -the matrix ions achieved a higher velocity than the analyte ions. We have repeated these measurements for a wider range of ion mass (up to 100 kD), and for a wide range of laser irradiance, and also checked the influence of the acceleration field.

Experimental: A linear Time of Flight (TOF) apparatus with MALD as a source of ions was constructed (Fig.1).Multiple grids in the acceleration region enabled us to use various methods (including the 'field free 'method of ref.[3]) to measure the initial ion velocity. A Faraday cup provided measurement of the total beam current.

Results: **1)** In the field free MALD process all heavy peptide ions up to 100kD mass have the same initial velocity ~500 m/s and narrow velocity distributions(Fig.2 and 3).

2) The initial velocity of peptide ions coincides with the velocity of matrix ions at the threshold laser irradiance (I~2.10 W/cm).Peptide velocity is independent of irradiance (up to 50 I), but velocity of the matrix ions *does* increase with irradiance (Fig.4),so at high irradiance the matrix ions have a higher velocity than the peptide ions [3].

3) The total ion beam current increases strongly with the laser irradiance and at I~ 100 I it corresponds to ~ 10 ions per shot. The presence of space charge (as well as heating by the laser after ejection) may explain why the light matrix ions are accelerated to a higher velocity as the irradiance increases.

4) In the normal TOF spectra when the accelerating electric field is applied an increase of the laser irradiance causes a reduction of the resolution and a shift of the ion peak centroid to a longer time of flight (both for the matrix and for heavy peptides). This effect can't be explained as a prolonged ejection process because the time width of the peak is reduced at higher accelerating voltage. Hence here the irradiance increase causes a shift to a lower average energy when acceleration electric field is present. Note that the ion initial kinetic energy in the abscence of a field has the opposite behaviour (it increases for the matrix and stays the same for peptide ions as the irradiance increases).

Conclusions: **1)** The present results support the statement that in the MALD process ejected matrix molecules *do* form a supersonic jet, narrowing the velocity distribution of neutrals and driving ions (at least up to 100 kD mass) with the same velocity (~500m/s).

2) The average kinetic energy of matrix molecules in the jet is ~.25eV, a value much smaller than its internal energy (even at a room temperature equal to 1eV). Hence the gasdynamic' cooling assumed to be present in the jet in fact is very inefficient.

3) The initial kinetic energy spread does not correctly explain the broadening of ion peaks in Time of Flight MALD. The observations do not contradict the gas jet model , because collisions with the neutrals are able to reduce the final energy of ions accelerated by the electric field [2]. Self space charge of the ion beam was found as a possible reason affecting TOF resolution.

Comparison of Arrival Time Distributions of Mass-Selected Ions Produced Using Matrix-Assisted Laser Desorption Ionization.

*M.A. White; F.H. Strobel, and D.H. Russell
Department of Chemistry
Texas A&M University
College Station, Texas 77843

Matrix-assisted laser desorption ionization (MALDI) has developed as an ionization method for biomolecules with molecular weights of several thousand daltons. We have examined the arrival time distributions (ATDs) of mass-selected $[M+H]^+$ ions using a tandem magnetic sector (EB)/reflectron time-of-flight instrument. Comparison of the ATDs of the mass-selected $[M+H]^+$ ions of both the matrix and analyte show that variations in the temporal profiles are dependent upon the source accelerating potential and the absolute amount of matrix applied to the sample probe.

A striking feature of the ATDs is the bimodal peak shape that consists of prompt ions (ions that have the appropriate flight time relative to the laser shot) and slow ions (ions that have a longer flight time than the prompt arrival time for the mass-selected ion). The kinetic energies of the prompt and slow ions have been measured in an effort to gain a better understanding of the mechanism for ion formation in the MALDI experiment. A series of ATDs were collected for the $[M+H]^+$ ion of sinapic acid at several source potentials. Figure 1 is a plot of the ion counts for prompt and slow ions as a function of the source potential (see graph). The appearance of a bimodal shape occurs at higher source potentials and the abundance of the slow ions increases with the source potential up to the limits of the ESA bandpass for transmission of the ions. The slow ion component of the ATD is increased at higher source potentials because the slow ions are deficient in kinetic energy and require a higher accelerating potential in order to be transmitted through the ESA. The prompt ions are of higher kinetic energy than the slow ions and are formed at the probe tip surface simultaneously with the laser shot as observed in conventional TOF/MS experiments. However, the slow ions observed in the ATDs of mass-selected ions are formed at some distance from the probe tip surface in the gas phase. The slow ion component is also observed in the ATDs of mass-selected $[M+H]^+$ ions of small peptides (500-3500amu).

In addition, the temporal profile of the ATDs is also sensitive to absolute amount of the sample on the probe and the type of solvent used. Preliminary studies show that increasing the absolute amount of matrix applied to the sample probe results in an increase in the slow ion abundance. The formation of ions in the gas phase are thought to be due to the ejection of clusters from the probe tip surface.[1]

Internal Energy of Matrix-Assisted Laser Desorbed Neutrals Probed by Single Photon Ionization

C.D. Mowry and M.V. Johnston, University of Delaware,
Department of Chemistry and Biochemistry, Newark, DE 19716

Introduction: Matrix-Assisted Laser Desorption (MALD) followed by single photon ionization of the desorbed neutral molecules is performed using a linear Time-of-Flight mass spectrometer. Coherent vacuum ultraviolet radiation achieves soft and universal ionization of analyte neutrals. Both laser desorption (LD) and photoionization (PI) occur in the source region of the mass spectrometer. The LD/PI spectra of neutrally desorbed alkyl amines using various matrix materials and different desorption laser irradiances are compared. The fragmentation observed in LD/PI provides information on the internal energy of desorbed neutrals while the total ion current in LD/PI provides information on the yield of neutrals relative to ions.

Experimental: An excimer laser (248nm) focused to 300μm x 70μm is used for desorption. Coherent vacuum ultraviolet radiation from 9.67 eV to 10.5 eV is generated by frequency tripling UV radiation produced by a Nd:YAG / dye laser system. For LD/PI, a voltage pulse in the source region rejects MALDI ions. The voltage pulse can be shifted in time to record either MALDI or LD/PI spectra under identical voltage conditions. Spectra are averaged for ten laser pulses per sample spot. Static voltage conditions are used to record MALDI and LD/PI spectra simultaneously and for vapor phase photoionization spectra.

Results: Figure 1 shows both MALDI and LD/PI spectra for n-heptylamine in Ferulic acid. Spectra are labeled with the excimer laser irradiance relative to the MALDI threshold. The amount of fragmentation, and therefore the internal energy of the desorbed neutral amine molecules, increases with increasing desorption irradiance. The MALDI and LD/PI total ion currents (TIC) also increase with increasing desorption irradiance, although the MALDI TIC increases faster. Greater fragmentation and greater TIC with increasing desorption irradiance are also observed when other matrix materials and other alkyl amines are used. Gas phase dissociation of $M^{+\cdot}$ is confirmed by the observation of metastable broadening in the LD/PI fragment ion peaks. No LD/PI signal is observed without excimer irradiation of the probe.

Recording MALDI and LD/PI spectra simultaneously allows direct comparison of the TIC produced by each technique. Using dipentylamine as an analyte, the analyte ion current ratio of LD/PI to MALDI is observed to scale for different matrices in the following way:
Ferulic acid $\approx$ Sinapinic acid > Vanillic acid > Isonicotinic acid > Cinchomeronic acid > Nicotinic Acid > p-Toluenesulfonic acid. In other words, Ferulic acid produces the highest number of neutrals relative to ions under these experimental conditions.

Figure 2 shows vapor phase spectra of n-heptylamine at various photoionization energies and temperatures. The difference in fragmentation observed in LD/PI compared with vapor phase 9.67eV PI indicates that the internal energy distribution of desorbed neutrals is non-thermal. The fragmentation is similar, however, at 1.2X threshold in LD/PI and at 10.2eV PI. This suggests that neutrals produced near threshold are desorbed with about 0.5 eV more internal energy than 298 K vapor phase molecules. Similarly, fragmentation at 2X threshold in LD/PI and 10.5 eV PI is alike; suggesting that neutrals desorbed at 2X threshold have about 0.83 eV greater internal energy than 298 K vapor phase molecules. Those desorbed at 3X threshold have even greater internal energy.

COMPARISON OF LASER DESORPTION KINETIC ENERGY EFFECTS ON DETECTION BY TOF AND FTICR MASS SPECTROMETRY

*J. S. Anderson, E.G. Schmidt, V. H. Vartanian, D. A. Laude, Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Ausitn, TX, 78712

Laser desorption/ionization (LDI) generates analytically useful ions from non-volatile, large molecular-weight materials that are readily detected by mass spectrometry. Of specific interest here is the LDI technique in which a short, high energy pulse of infrared radiation from a CO_2 or Nd:YAG laser initiates a rapid thermal desorption process. The technique is characterized by formation of abundant $(M+C)^+$ species from the gas phase attachment of a proton or metal cation, C^+, to an intact molecule, M. Much is now known from TOF studies about the mechanism for formation of the cation-attached product. The desorption event must initiate rapid thermal heating of the sample and substrate at laser irradiances exceeding 10^6 W/cm^2 to generate high surface temperatures that vaporize and ionize the salt with coincident desorption of neutral analyte. Within the complex ensemble of gas phase charged and neutral particles, reactive gas phase collisions yield $(M+C)^+$ products with average kinetic energies of less than one eV [1]. It is uncertain whether the mechanism for generating the cation-attachment product detected by TOF can be extended to LDI/FTICR because even under identical sample preparation and laser desorption conditions, many differences exist between the two mass analyzers that potentially discriminate in both formation and detection of the ions. Gross and coworkers verified that cation-attached products detected by FTICR were formed in the gas phase [2]. More recently we used variable trapping potential and double resonance experiments to demonstrate that the precursor ion for the experiment could be an adduct of the salt rather than the bare cation [3]. In work to be presented, a more thorough comparison is made between the TOF and FTICR to explain the discrepancies that exist in the two IR LDI .experiments.

The conditions which favor FTICR detection of K^+ and its adducts formed by LDI was evaluated. In general, adducts are observed at lower trap potential, at high laser power irradiance and on the initial laser firing on a sample spot. K^+ detection is favored at lower laser power irradiance, higher trapping potential, and after multiple firings of the laser on the same sample spot. Thus on the first laser firing at high laser irradiance, equal amounts of K^+ and adduct are observed at 2V while K^+ is preferentially observed at 7V. The second laser firing exhibits reduced adduct signal at low trap potentials and no signal at higher trap potentials.

The observation that trap potential plays such a strong role in the type of ions formed by LDI that are detected suggests that kinetic energy effects are important in the trapping oricess. To evaluate this, variable trapping potential studies were performed in which K^+ and K_2X^+ abundances were measured. Variable trapping profiles for KF and KI salts acquired at laser power densities of 3×10^8 W/cm^2 and 7×10^7 W/cm^2 exhibit features common to K^+ and K_2X^+ profiles for each salt and are of consequence in the formation and detection of $(M+K)^+$. In general, at a power irradiance of 3×10^8 W/cm^2, efficient trapping of K_2X^+ adducts occurs at much lower potentials than for the bare cation and there is also less of a less dependence on X.

The IR LDI experiments performed with the FTICR were repeated with the TOF instrument. Again, initial experiments were conducted in which conditions which favored formation of K^+ versus the adduct were evaluated. Comparison LDI/TOF spectra are shown in Figure 1. Results are analogous to those for the FTICR experiment. At lower laser irradiance (3×10^7 W/cm^2), for thin sample films, and on the fresh sample, exclusive formation of K^+ is favored as shown in Figure 1a. In Figure 1b for the same sample, as laser irradiance increases beyond the threshold for plasma

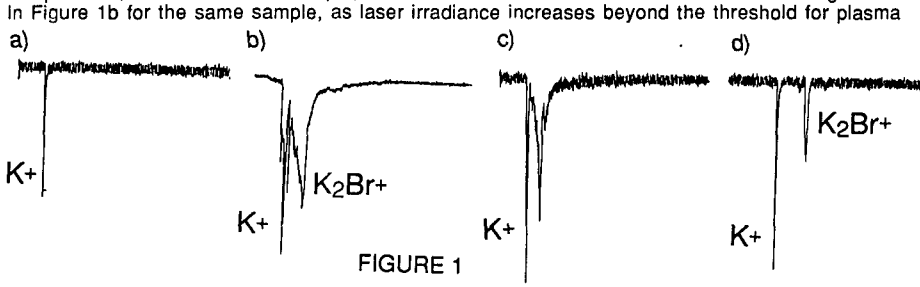

FIGURE 1

ignition, K_2Br^+ is observed in high yield on the first laser firing, but the dense plasma contributes to gross spectral distortion. As shown in Figure 1c, by the second laser firing on the same sample spot, the K_2Br^+ is not observed and the K^+ is present in larger yield. The only conditions under which both K^+ and adduct could be observed in the absence of a plasma was for heavy coatings of the sample. Shown in Figure 1d is a spectrum acquired at high laser irradiance on a much thicker coating than for Figures 1a-c.

From the TOF spectra in Figure 1 it is evident that laser irradiance and sample preparation play a critical role in the competitive formation and detection of K^+ and K_2Br^+. The data suggest that conditions for obtaining higher quality TOF spectra would be favored at lower laser irradiance in the absence of plasma ignition. Figure 2 presents comparison LDI/TOF spectra of a KBr/grmaicidin-S mixture at increasing laser irradiance. In Figure 2a, at the lowest laser irradiance, K^+ is observed along with the $(M+K)^+$. In Figure 2b at higher laser irradiance under plasma ignition conditions, K^+ and K_2Br^+ are observed along with stainless steel ions from the plasma. The intensity is reduced and resolution deteriorates. Presented in Figure 2c is a spectrum acquired from laser firings on fresh spots of a thick sample at high laser irradiance. Under these conditions, plasma ignition is minimized and simultaneous formation of both K^+ and K_2Br^+ is favored as shown in Figure 1d. Under these conditions, $(M+K)^+$ was detected with highest sensitivity. Because both K^+ and K_2Br^+ are formed in similar yield, it is not possible to designate which species is involved in the cation attachment process.

The comparison TOF and FTICR data collected indicate that both K^+ and its adducts may be involved in the cation attachment process. Double resonance and variable trapping data verify that the adduct is the dominant precursor for the LDI/FTICR experiment at high laser power densities. Under these conditions, laser plasma ignition often occurs which in the FTICR experiment is not necessarily deleterious because the plasma metal ions possess a sufficiently high kinetic energy that they are not trapped for detection. However, in the TOF experiment it was observed that for the high laser irradiance conditions that favor adduct formation, the associated plasma formation is deleterious to the TOF spectrum which is generated. Consequently, laser operation at lower laser irradiances which favor K^+ formation will necessarily favor K^+ as the gas phase precursor ion. One exception to this is for the case that thick samples are used which initially minimize plasma ignition effects even at high laser irradiance. Under these conditions $(M+K)^+$ formation in the presence of both K^+ and adduct suggests that each may participate in the reaction.

MATRIX-MIXTURES FOR A SUPERIOR PERFORMANCE OF MATRIX-ASSISTED LASER DESORPTION IONIZATION MASS SPECTROMETRY

Michael Karas, Eckhard Nordhoff, Bernd Stahl, Kerstin Strupat and Franz Hillenkamp

Institute for Medical Physics and Biophysics, University of Münster, 4400 Münster, FR Germany

It has been shown in a previous investigation [1] that by controlled crystallization of matrix (2,5 dihydroxybenzoic acid (2,5-DHB)) and protein mm-size crystals are formed showing excellent performance in matrix-assisted laser desorption ionization mass spectrometry (MALDI). Homogeneous distribution of protein molecules inside the crystals has been documented by MALDI. Embedding is highly effective yielding the same molar ratio of matrix and protein in the crystals as used in the starting solution for the concentration range typically used in MALDI. An extended crystalline rim formed out of matrix-analyte droplets in standard preparation usually allows for a comparable quality of MALDI mass spectra.

2,5-DHB is an excellent matrix at wavelengths of 337 or 355 nm exhibiting high sensitivity, high tolerance towards contaminants and low intensity adduct ion signals. It may be used for (glyco)proteins as well as for oligosaccharides. On the other hand, molecule ion signals above 50 kDa tend to be broadened and of low intensity and signal-to-noise ratio. Peak tailing to the low mass side indicates that (metastable) fragmentation may be resonsible for the observed degradation of matrix quality. In order to find out whether the performance in the high mass range can be improved, a series of experiments has been preformed applying the admixture of additives or the use of a mixture of matrix compounds. This approach was based on the consideration that a (too) high energy deposition is required to overcome the energy of the rigid DHB-lattice made of the polyfunctional matrix molecules and that a reduction of solid state cohesive energy by disturbing the lattice or by inserting compounds which lack some of the polar groups may result in an improved performance of 2,5-DHB.

For the investigation a number of either benzoic acid derivatives or hydroxyl-substituted benzenes were selected which because of their close relation to the 2,5-DHB molecules should allow for an effective insertion into the crystals. In several cases, improvements of the performance in the high-mass range have been obtained which were most prominent for admixture of 2-Hydroxy-5-methoxy benzoic acid (2H5MB) (see Figure 1), 3-nitrobenzoic acid and 1,4-hydroquinone when added in the 5 to 10% range to the 2,5-DHB matrix solution.

In order to elucidate the effects responsible for the desirable behaviour of some matrix mixtures, the system 2,5-DHB/2H5MB was further inspected. The formation of mixed crystals was controlled by quantitative determination of both constituents using HPLC for redissolved crystals. The results proved that up to a 5% concentration in the starting solution, the additive is quantitatively embedded. Electron micrographic inspection revealed that, even though the

both accumulated from 25 laser shots

crystals formed from standard preparation are of comparable size for pure 2,5-DHB and for 2,5-DHB containing 2H5MB, the crystals of the mixture showed a considerably rougher surface structure under high magnification. Determination of the threshold irradiance required for pure and mixed matrices yielded a slightly decreased value. Deterioration of matrix performance e.g. in the case of 2-aminobenzoic acid could be attributed to the fact that the additive molecules compete for charge with the analyte molecules. This effect is indicated by a strong relative increase of the additive signals and decrease of the 2,5-DHB (quasi)molecular ion signals.
The results indicate that the idea to admix certain well-chosen and chemically related compounds to the host matrix forms an attractive tool to improve its MALDI performance. Both a reduction of deposited energy required to overcome the solid state cohesion and thus lower volume excitation and an increase in ionization yield may explain the observed improvements. Inspection of the matrix-mixture LDI mass spectra is useful because additives may be discarded due of their the abilility to compete for the charge with the analyte molecules.

SUBSTRATE ASSISTED LASER DESORPTION OF NEUTRAL PEPTIDE MOLECULES†

J. Paul Speir and I. J. Amster
Department of Chemistry, University of Georgia, Athens, Georgia 30602

INTRODUCTION

A new method for the laser desorption of neutral peptide molecules has been developed in this laboratory. This technique, called substrate-assisted laser desorption of neutrals, utilizes a uv-absorbing compound, sinapinic acid, as a substrate upon which a peptide sample is applied. The analyte material is desorbed using either 248 nm or 337 nm radiation from an excimer laser and is postionized by chemical ionization. The desorption of neutrals by this method is sensitive to the thickness of the substrate film and the analyte film, and to the wavelength of the laser radiation used for desorption. In contrast to matrix-assisted laser desorption, substrate-assisted laser desorption allows peptide neutrals to be desorbed without the generation of gas phase ions directly by the laser. The desorption energy, which is strongly absorbed by the substrate layer, appears to be transferred to the sample layer, causing peptide molecules to be ejected into the gas phase, without the desorption of substrate material.

EXPERIMENTAL

The experiments are performed in a Fourier transform mass spectrometer designed and constructed specifically for laser desorption/chemical ionization (LD/CI) studies (1). Samples are prepared by applying an amount of sinapinic acid corresponding to 500 monolayers (100 ng/mm^2) to a gold/palladium coated Macor stub by electrospraying a methanol solution of the organic substrate. The electrospray method allows small quantities of a sample to be evenly dispersed over the entire surface of the sample stub (2). The equivalent of 500 monolayers of a peptide sample (100-500 ng/mm^2) is applied on top of the sinapinic acid film, also by electrospray techniques. An excimer laser provides the pulsed ultraviolet radiation for desorption of the peptide samples. The 248 nm (KrF) and 337 nm (N_2) output of the excimer laser is used to desorb peptide samples from the organic substrate. The irradiance of the desorption laser incident upon the sample is in the range of 1-10 MW/cm^2. All mass spectra are recorded from a single laser shot, corresponding to 100 pmol of sample desorbed per mass spectrum.

RESULTS

The effect of the sinapinic acid substrate on the laser desorption of neutral peptide molecules can be seen in Figure 1. The mass spectra result from the LD/CI ($(CH_3)_3NH^+$ reagent ion) of a pentapeptide, phe-phe-gly-leu-met-NH_2. For this experiment, a film of sinapinic acid was applied to half the surface of a sample stub. A film of the peptide was then applied over the entire surface of the stub. The mass spectra shown in the figure were recorded with identical experimental conditions, including laser irradiance, and are scaled so that peaks of identical absolute abundances are plotted with the same intensity. The mass spectra show that molecular neutrals are desorbed only when the peptide sample was coated directly onto the sample stub, even when the laser irradiance was increased, although ions could be formed by laser ionization with higher irradiances of the desorption laser.

The technique of substrate-assisted laser desorption has been used to desorb molecules as large as the cyclic decapeptide, gramicidin S. Figure 2 shows the LD/CI mass spectrum of gramicidin S. With NH_4^+ as the reagent ion, the only ion observed in the mass spectrum is that of the protonated molecule. Clearly, intact neutral molecules are desorbed by this method, and upon ionization, are stable for the length of the trapping and detection event, in this experiment, 100 ms. Another feature of the substrate-assisted laser desorption method is that the desorbed neutral peptide molecules appear to have less internal energy than those in our earlier LD/CI experiments, in which peptides were applied directly metal coated sample stub, and desorbed with 193 nm light from an excimer laser. A comparison of LD/CI data for the tripeptide val-pro-leu obtained using both desorption techniques, suggest that the substrate enhanced desorption produces neutrals having 1 eV less internal energy than those produced with 193 nm desorption of the neat sample. The experimental results show that a substantial improvement in the laser desorption of neutral peptide molecules can be obtained by using an organic substrate

that absorbs strongly at the wavelength of the laser. The substrate-assisted laser desorption of neutral molecules also allows much larger peptides to be examined by LD/CI than have been previously reported.

EXPERIMENTAL STUDIES ON THE MECHANISM OF THE MATRIX-ASSISTED LASER DESORPTION

P. Juhasz, B. H. Wang, and K. Biemann
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

Several efforts have been directed toward the understanding of the processes taking place during matrix-assisted laser desorption (MALD) ionization, recently. Some of these studies focused on the desorption problem, and attempted to explain the "softness" of MALD ionization: the emergence of internally cool intact ions of macromolecules from a process characterized by harsh conditions of energy deposition [1,2]. Other mechanistic studies tried to explain the ion formation process itself, by means of reaction schemes where a pair of positive and negative radical ion plays the role of the precursors [3]. This study was intended to accumulate experimental background for a model which describes UV and IR MALD in a unified framework. The experiments focused on the matrix suppression effect first observed by Chan et al. [4]. Three wavelengths were used for the experiments: a N_2-laser (337 nm), a frequency quadrupled Nd:YAG laser (266 nm), and an Er:YAG laser (2.94 μm). The instrument was a VT2000 time-of-flight mass spectrometer (VESTEC Corp.)

Under favorable experimental conditions, which include the proper matrix-analyte combination, matrix/analyte ratio, low irradiance, *etc.*, the matrix peaks can be completely suppressed in the spectrum. The test analytes, for which the suppression effect could be demonstrated were tBoc-Val-Asn-(Ac_3GlcNHAc)-NHMe (687.7 Da), angiotensinogen (1-13) (1645.9 Da), β-endorphin (3445.0 Da), and ubiquitin (8564.9 Da). However, not all the investigated matrices exhibited the matrix suppression effect. The best results were obtained with 2,5-dihydroxybenzoic acid (DHB) and α-cyano-4-hydroxycinnamic acid (αCCA). Sinapinic acid represented a notable exemption for which no matrix suppression effects could be observed with any of the test peptides. Matrix suppression is known to depend on the matrix/analyte ratio. A study of this dependence indicated that the lower the molecular weight of the analyte is, the wider is the relative concentration range where the matrix apparently is not ionized in the MALD process. For the angiotensinogen+DHB system complete matrix suppression was found from the matrix/analyte (molar) ratio 100:1 up to 3500:1.

The matrix suppression effect could be studied at three wavelengths with caffeic acid and 6-aza-2-thio-thymine (aTT) matrices since these compounds are good matrices at all of the three wavelengths. The MALD mass spectrum of angiotensinogen (1-13) with caffeic acid matrix is shown in Fig. 1. The 266 nm mass spectrum exhibits the most intense matrix background; strong $M^{+\cdot}$ peak can be observed. At 337 nm the protonated peptide is the most abundant ion still strong $(M\text{-}H_2O+H)^+$ peak is found. In the IR MALD mass spectrum there are no matrix peaks at all. Similar series of mass spectra was recorded with aTT matrix with the protein ubiquitin. These experiments suggest that in many cases IR MALD is the best choice for reducing the matrix background. We could not observe matrix suppression effect in the negative ion mode with any of the matrix-analyte combinations having been tested. The experiments made on the matrix suppression effect indicate that under favorable conditions peptides are ionized more readily than the matrices themselves. Since this effect could be observed in a wide range of the matrix/analyte ratio, there is a possibility that nonionic precursors ionize the analyte molecules exclusively. The proposed scheme for these processes is:

$$M(\upsilon \neq 0) + P \longrightarrow PH^+ + \text{other products}^{\cdot}$$
$$M^{\cdot} + P \longrightarrow PH^+ + \text{other products}^{\cdot}$$

where *M* symbolizes the matrix and *P* the peptide (protein). It is important that the interactions of these excited species with other matrix species does not lead to ion formation. The participation of the vibrationally hot precursor in the ionization process explains the very effective matrix suppression in IR MALD. This scheme could be corroborated experimentally by carefully monitoring the total (integrated) ion intensity with and without the analyte under the same experimental conditions. Statistically significant results could be obtained on the αCCA - angiotensinogen (1-13) system, on which complete matrix suppression can be demonstrated easily. The ion current monitoring experiments revealed that the admixture of the peptide to the matrix brought about a fivefold increase of the total ion current. This finding suggested that in this case the majority of the PH^+ ions was a product of charge disproportionation between a neutral matrix precursor and a neutral peptide molecule.

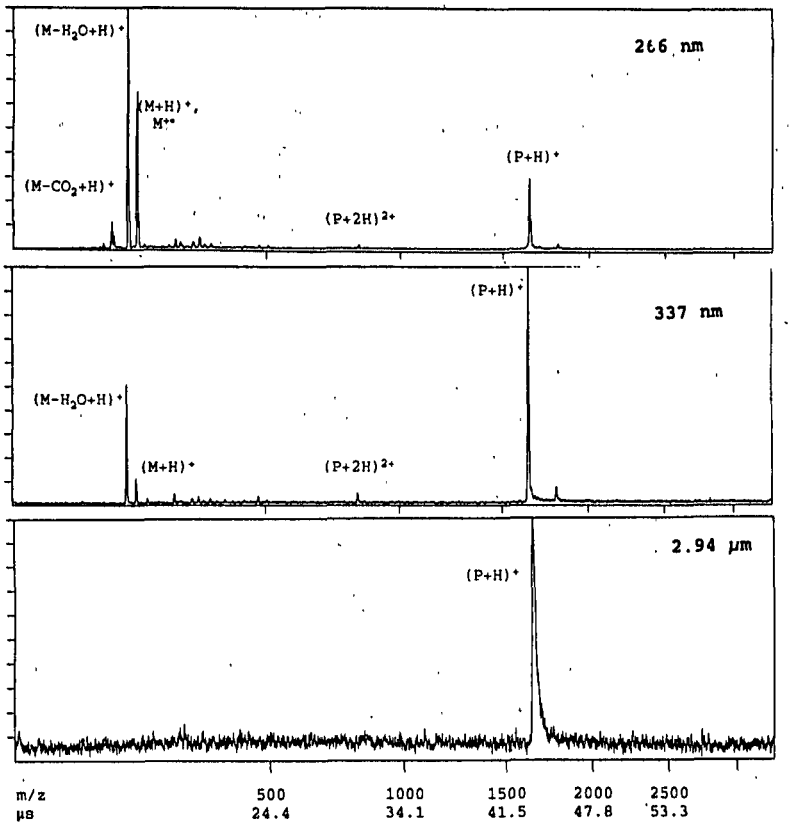

Fig. 1 MALD ionization mass spectrum of the peptide angiotensinogen (1-13). Matrix: caffeic acid. The mass spectra were recorded from the same sample load.

Evidence for Matrix Photochemistry Occuring during the Matrix-Assisted Laser Desorption Experiment

R. Goldschmidt, R. King, K. Balasanmugam, J. Schnable, *K.G. Owens, Department of Chemistry, Drexel University, Philadelphia, PA 19104

A study aimed at elucidating the mechanism of the matrix-assisted laser desorption process has shown evidence of photochemistry occuring for the cinnamic acid derivatives ferulic and sinapinic acid. While monitoring the neutrals desorbed by a pulsed nitrogen laser from an unheated solids probe on a modified Varian MAT311A double focussing mass spectrometer, copious amounts of CO_2 are initially observed to desorb from the surface. However, neutral/ion signals from the cinnamic acid matrix remain constant over 30 minutes of irradiation. Analysis of the residue remaining on the probe after irradiation using heated probe techniques on a Finnigan 4500 quadrupole mass spectrometer showed strong evidence of dimer and trimer formation (with a loss of CO_2), especially when compared to results obtained with unexposed sinapinic acid crystals. Similar photoproducts are observed in small quantities in the time-of-flight mass spectra of the matrices ferulic and sinapinic acids alone and with analyte.

In MALD/I experiments on a time-of-flight (TOF) instrument using the cinnamic acid derivatives sinapinic and ferulic acids, we consistently see peaks assignable to the matrix dimer and trimer. We have also observed that matrix and analyte signals decrease and eventually are lost after a sufficient number of laser shots at the same sample spot. We propose that laser exposure of these cinnamic acid derivatives causes their photo-dimerization. The solid state photodimerization by sunlight of many cinnamic acid derivatives has been well-documented in the literature.[1,2,3,4] As shown in figure 1, this dimerization has the effect of "cross-linking" the various layers in the cinnamic acid crystal. This "cross-linking", in addition to the strong hydrogen bonding interactions within each layer, may result in the observed signal reduction. Further evidence of this possibility is the fact that the signal can be restored after exposure of the surface to a few high intensity laser pulses, which presumably results in desorption of the dimer layer(s). Although the dimers initially formed should have a mass twice that of the monomer, continued absorption of photons is believed to account for the photoinduced loss of CO_2 as well as the other dimer and trimer peaks observed.

Solid State Photochemistry:

The "topochemical postulate" states that a reaction in the solid state occurs with a minimum amount of atomic or molecular movement.[1] Thus, certain solid state reactions may be controlled by the restrictions which the crystal structure imposes on the relative positions of potentially reactive centers. It has been well-documented that topochemical factors control the photodimerization behavior of many cinnamic acid derivatives.[1,2,3,4]

The crystal structures of substituted cinnamic acids are of three types: α, β, and γ.[3] The α- and β-types consist of stacks of parallel, nearly planar, hydrogen bonded acid pairs. In the α-type the acid pairs are stacked head-to-tail (see the illustration for ferulic in figure 1), while in the β-type they are head-to-head. In both of these cases, adjacent ethene units are separated by approximately 4 Å, and photodimerization results in cyclobutane derivatives of symmetries which reflect the packing arrangements. Thus the α-form gives exclusively derivatives of α-truxillic acid , while the β-form gives exclusively derivatives of β-truxinic acid, a structural isomer of α-truxillic acid in which there is no center of symmetry. In the γ-form the closest ethene unit separation is approximately 5 Å, and this crystal form is found to be photostable.[3]

Though we have only illustrated ferulic acid in the α-form, we propose that the cinnamic acid derivatives ferulic and sinapinic acids, both in "pure" form and in the matrix-assisted experiment, crystallize in structures which readily give photodimers upon irradiation with the ultraviolet desorption laser.

INVESTIGATION OF ISSUES RELATED TO THE PREPARATION OF RECOMBINANT PROTEINS FOR ANALYSIS BY MALD-TOF MS.

J.E. Vath, S.A. Martin, W. Yu and H.A. Scoble
Genetics Institute, Inc., One Burtt Road, Andover, MA 01810

Molecular mass is an important characteristic of proteins. Traditionally, the mass of a protein has been established by comparison of the chromatographic or electrophoretic mobility, or the sedimentation behavior of the protein, with known protein standards analyzed under identical conditions. With each of these techniques, the physical or hydrodynamic properties of the protein can greatly influence the apparent molecular mass, most often in an unpredictable manner. Measurement of the chemical mass of the protein simplifies molecular mass interpretation, since the analysis is based upon a predictable property of the protein, i.e., the actual chemical composition. The direct measurement of the chemical mass of intact proteins can now be successfully achieved by using matrix assisted laser desorption time-of-flight mass spectrometry (MALD-TOF MS).

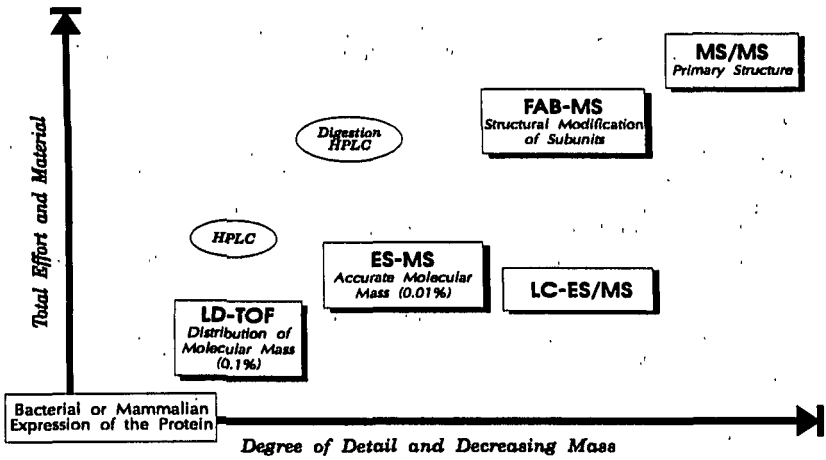
As a mass spectrometric technique, MALD-TOF MS provides high sensitivity, low resolution mass measurements. The degree of structural detail provided by MALD-TOF MS is less than that provided by strategies involving degradation of the protein and structural characterization of the individual peptides. Nonetheless, depending on the questions being asked and on the information desired, MALD-TOF MS can provide a level of structural detail which is not available using other techniques. Based on our experience with the structural characterization of recombinant proteins and the unique capabilities of MALD-TOF MS, an MS-based characterization strategy has been developed in which MALD-TOF plays an integral role (**Scheme I**). The placement of MALD-TOF early in the strategy results from the sensitivity, speed of analysis and insensitivity to a wide range of buffers. With a molecular mass measurement early on, one can quickly assess whether a protein has been correctly processed or modified, potentially obviating the need for proteolytic or glycolytic digestion, separation and subsequent analysis.

Many factors can influence the quality of a MALD-TOF mass spectrum. The interaction of the protein with other sample components and the matrix may alter the way the sample is deposited, the extent of adduct formation and potentially modify the protein covalently. These issues are compounded when dealing with proteins of different isoelectric points, hydrophobicity and solubility characteristics. Through our investigation of MALD-TOF MS we have noted many variables which influence the quality of the data. One such affect is the cleavage of Asp-Pro bonds in rhM-CSF in the presence of certain buffers and matrices.

rhM-CSF is a disulfide bonded dimer of two similar subunits that is expressed in a Chinese hamster ovary cells and contains N- and O-linked glycosylation. This protein is relatively hydrophilic and acidic in nature, with a pI of about 4. By SDS-PAGE rhM-CSF exhibits a single band with an apparent molecular mass of 90 kDa. The MALD-TOF mass spectrum of 2 pmol of rhM-CSF in 0.1 M ammonium acetate and 50mM sinapinic acid is shown in **Figure 1A**. The MALD-TOF mass spectrum exhibits a complex distribution of masses averaging about 65 kDa which are characteristic of intact rhM-CSF as well as two very abundant peaks at low mass. These peaks correspond to the cleavage of an Asp-Pro bond at position 169-170 in rhM-CSF. Based on the response of these isolated products measured with mixtures of known ratio the peaks at low mass correspond to approximately 2% of a cleavage product. Another example of protein modification is the illustrated by the effect of dihydroxybenzoic acid on the molecular ion region of rhM-CSF (**Figure 1B**). Both Asp-Pro cleavages and carbohydrate loss have been detected to increase with increasing number of laser shots when using DHB. The early peak represents the profile after a few shots while the late peak represents protein degradation after 50 to 100 shots. These degradations may be due to the acidic nature of the solution or matrix, sample handling and/or the interaction of the prepared sample with the laser.

These data were obtained on a Bruker REFLEX MALD-TOF MS. We acknowledge the technical expertise contributed by Cliff Watson and John Wronka.

Scheme 1. Mass spectrometric based strategy for the characterization of recombinant proteins.



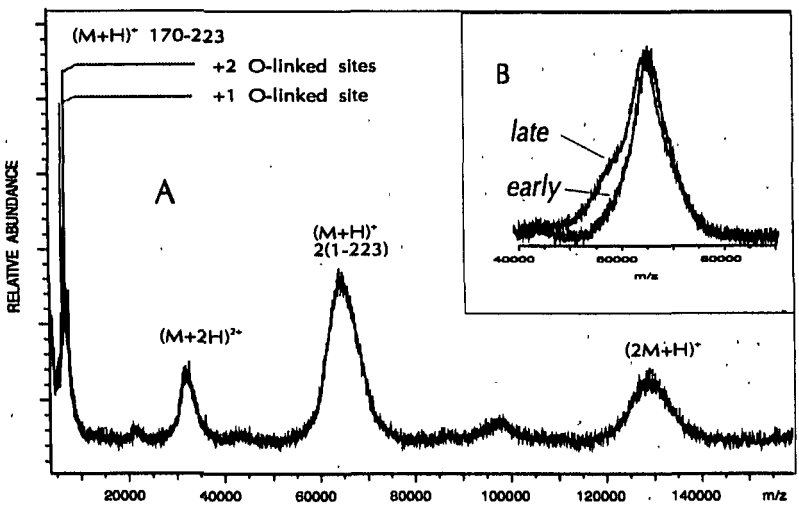


Figure 1. Effect of buffers and matrices on the MALD-TOF mass spectra of rhM-CSF. A) 2 pmol of rhM-CSF in 0.1 M ammonium acetate and 50mM sinapinic acid. The peaks at low mass are a result of an Asp-Pro cleavage within the protein. B) The effect of dihydroxybenzoic acid on the molecular ion of rhM-CSF. The early peak is the normal profile obtained during the first few laser shots. The late peak results after 50 to 100 laser shots and indicates that the protein is being degraded.

High Resolution Matrix-Assisted Laser Desorption of High Molecular Weight Ions Using a Time-of-Flight Mass Spectrometer

F.J. Mayer, A. Holle, R. Schäfer and R. Frey
Bruker-Franzen AnalytiK GmbH, Fahrenheitstr. 4, D-2800 Bremen 33, Germany

Introduction

Matrix-assisted laser desorption (MALD) of ions is a method of rising interest. It allows to determine the molecular weight of large organic molecules up to several 100,000 u.

The mass resolution, defined as m/dm, is an important specification. It determines the capability of analyzing mixtures and influences the accuracy of the mass determination.

As pointed out by R. C. Beavis and B. T. Chait (1) and others, the laser power density is a dominant factor in determining the mass resolution.

With increasing laser irradiance, the comparison of measurements with the linear and the reflecting TOF instrument shows a remarkable difference in the deterioration of the mass resolution. Additionally, a mass shift towards higher masses takes place. Both effects lead to a faulty mass determination.

Experimental

Measurements of several biological compounds in the mass range 10,000 u to 30,000 u were executed using the Bruker Reflex MALD TOF (Fig. 1).

The samples were prepared as described elsewhere (2). As a matrix, trans-3,5-Dimethoxy-4-hydroxy-cinnamic acid was used. The molar ratio matrix-to-analyte was 10,000. 2 pmol total loading of sample were deposited onto the probetip.

Ions were produced by means of a pulsed Nitrogen laser (337 nm, 5 ns, 250 uJ). In order to increase the detection efficiency and to minimize the effect of the initial energy distribution of the ions at the same time, 35 kV acceleration voltage was applied.

The linear TOF and the reflecting TOF were utilized alternatively. When using the linear detector with the reflector voltage switched on, only neutral species were recorded.

The measurements were performed with stepwise increasing laser irradiance.

Results

Measurements near the threshold irradiance S (some 10^6 W/cm^2) yield to highest mass resolution both in the linear and the reflecting TOF. Typical resolution using the reflector is 400 - 1,800 in the range of interest, whereas the resolution in the linear TOF is limited to 300 - 900, .

At this laser power density, negligible neutral yield was recorded by using the linear TOF with high voltage applied at the reflector.

With increasing laser irradiance, the mass resolution of the molecular ion signal in both recording modes deteriorate.

Figures 2-4 show the molecular mass signal of Cytochrome C (m = 12360 u), Myoglobin (m = 16950 u), and Trypsin (m = 23290 u) comparing on one side the linear with the reflecting TOF, and low laser power (S) with high laser power (5 S) on the other side. As listed in Table 1, the mass resolution in the reflecting TOF usually is up to a factor 2 better than in the linear TOF. The deterioration of the mass resolution in the linear TOF is up to a factor 17, in the reflectron up to a factor 8, at 5 times threshold irradiance.

The mass shift by using the reflectron is within 0.15 %, whereas in the linear TOF the shift is up to 0.56 %.

In order to investigate into this phenomena, the degree of metastable decay of the desorbed ions after the acceleration was estimated. This was achieved by comparing the yield of the neutral species with reflector switched on, with the yield of the total particles recorded in the linear TOF with the reflector switched off.

In the mass range investigated, the neutral signal amounts up to 80 % of the total particle yield .

The spectra of the neutrals exhibit an even stronger shift than the ion signal, in respect to the molecular ion yield at low laser irradiance (Fig. 5 and Fig. 6). This result suggests that the shift of the molecular ion signal at high laser power emerges due to a superposition with the delayed neutral signal. When using the reflectron, the shift is smaller because less neutrals contribute to the molecular ion signal. On the other hand, superposition of charged fragments partially compensate for the shift, or even cause a negative mass shift as seen in the case of Trypsin (Fig. 4).

Discussion

Obviously, a process within the ion source during or right after the desorption is the origin of this phenomena. The recording of negative ions shows similar results. This excludes an explanation based on shielding effects of the electrical field.

Neutrals emerging out of larger ions (photo adduct ions) are unlikely because there no significant ion yield is obtained in the reflector TOF.

As described in (3,4), desorbed ions travel with high axial velocity. This suggests, that slow neutrals might be produced by late ionization of desorbed neutrals and subsequent decay in the field-free region. Measurements concerning the desorption process at high laser power are beeing in process.

Strategies for HPLC-Accurate Mass FAB Measurements

*D.J.Bell, A.West and J.E.Wilde,
SmithKline Beecham Pharmaceuticals, Epsom, Surrey KT18 5XQ,

INTRODUCTION

With the advent of usable HPLC-FABMS interfaces, it has become possible to routinely use the technique in attempts to characterise components in mixtures. An indication of molecular mass is often of great use and can even lead to the tentative suggestion of structures, however in many cases it would be of great help in structure elucidation if the molecular mass of the material can be determined accurately to allow the generation of possible molecular formulae. It was with this objective that systems for HPLC-accurate mass FAB- and EI-MS were developed.

EXPERIMENTAL

Various HPLC conditions were used in an attempt to develop relatively universal systems for the accurate measurements of masses, from the use of 3.9x150mm C_{18} columns operating at flow rates of 1ml/min with gradient buffer elution to the use of 1x100mm columns using flow rates of 50ul/min. A major problem in accurate mass FAB is the lack of reference ions. One possible source of reference ions is the FAB matrix which is added to either the eluent or mixed post column. Typically 2% glycerol is used, generating usable reference ions up to 461 daltons. For high mass measurements it was found that reference materials such as polypropylene glycol (PEG) were required. Such materials were added to the HPLC eluent post-column as a 5% solution in a solvent system compatible with the mobile phase. For accurate mass EI measurements, PFK was introduced into the ion source via a heated septum.

In order to accurately measure masses, a stable signal must be generated. The combination of a pneumatic splitter to stabilise and limit the flow to the ion source with a Frit-FAB or Frit-EI interface has resulted in extremely stable signals. The instrument used, namely a JEOL SX-102, was set to 10 000 resolving power and operated under data system control with accelerating voltage scans through the ion of interest and reference ions to both higher and lower mass. Spectra were calibrated post-acquisition by the assignment of the reference ions.

RESULTS AND DISCUSSION

Using glycerol ions as reference masses, it was found that the pseudo-molecular ion of Cimetidine could be measured with an average error of less than 1 p.p.m. (calculated molecular mass 253.1235, measured mass 253.1237, average error 0.79 p.p.m.). The

measurements were made following on column injections of 20ul of 0.028mg/ml solutions, thus the molecular mass of the equivalent of a 2.8% impurity in a 1mg/ml solution can be readily measured to less than 1p.p.m. accuracy with no modification to the original low resolution HPLC-FABMS conditions. When using standard bore columns, the amount of sample required is relatively high because of the need to split the flow from typically 1ml/min to ca. 13ul/min. Microbore HPLC-FABMS was investigated as the lower flow rates, and hence lower split ratios, require less sample injected on-column to result in the equivalent amount being introduced into the ion source. Again results acquired show that the mass measurements of the equivalent of materials in low percentage concentrations were routinely possible.

Accurate mass measurement following the reverse phase HPLC-FABMS analysis of a macrocyclic antibiotic of molecular mass 600 daltons with a solution of 5% 1:1 PEG300:PEG600 added post-column resulted in errors of ca. 4p.p.m. for the $(M+H)^+$ ion.

Using the FritEIMS with on-line HPLC, it was found that amenable samples could be measured to within an error of 7p.p.m. at mass 169. In the example cited the references used were PFK ions at 169 and 181, and although the former reference ion is of the same mass as the ion of interest the high resolution selected avoided any possible interference between the two ions of the same nominal mass.

CONCLUSION

It has been found that it is feasible to accurately mass measure components at the low percentage concentration level with little or no modification to the original HPLC conditions. Although sensitivity is highly sample dependant simple yet effective systems for mass measurements have been developed which generate useful data for the identification of unknown components without the need for isolation of such materials.

STUDY OF THE PERFORMANCE OF CAPILLARY LIQUID CHROMATOGRAPHY-FAST ATOM BOMBARDMENT MASS SPECTROMETRY SYSTEMS USING PRE-COLUMN ADDITION OF VISCOUS MATRICES.

Alain Carrier, Jean-Pierre Gagné and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7

The use of fast atom bombardment (FAB) as an ionization technique to obtain the mass spectra of polar, thermally labile or involatile compounds such as peptides, has become a powerful tool in mass spectral analysis. The advent of CF-FAB has not only increased the power of the technique but it has also allowed its interfacing with liquid chromatography (LC-FABMS). In systems using continuous flow fast atom bombardment to interface liquid chromatography to mass spectrometry, the addition of a viscous matrix to the mobile phase is essential for optimization of ionization and the obtention of quality data Our recent work (1,2) on the effect of pre-column addition of glycerol and thioglycerol to the mobile phase in conventional LC-FABMS systems has confirmed the possible deleterious effects of viscous matrix on the chromatographic performance for several classes of compounds when the concentration of glycerol in the mobile phase exceeds 3% and when non-optimal linear velocities are used In seeking to broaden the scope of our previous studies and to evaluate the chromatographic boundaries within which pre-column addition of viscous matrices can be systematically used in LC-FABMS systems, the effect and the limitations of pre-column addition of glycerol in packed capillary LC-FABMS systems was examined. The changes in chromatographic parameters such as retention times, capacity ratios, number of theoretical plates, peak widths and resolution were monitored as a function of glycerol content in the mobile phase The results obtained indicate that for concentrations of glycerol in the mobile phase below 3% most chromatographic indicators are only slightly affected. However, for concentrations of viscous matrix above that value the retention times, the capacity ratios and the resolution, as shown in Figure 1, are significantly decreased. Increasing concentrations of glycerol also reduce the number of theoretical plates in the chromatographic system as indicated by the data in Figure 2 and generally have a detrimental effect on peak widths. The overall effect of the presence of glycerol on the chromatographic system can be rationalized in terms of the modification of the analyte distribution between the mobile and stationnary phases and changes in the kinetics of the system created by an increase in the viscosity of the mobile phase. Comparison of the results generated in this study to those obtained in our previous work indicates that the effect of pre-column addition of glycerol results in alterations to the chromatographic process for both conventional and capillary LC-FABMS systems. In order to identify the factors responsible for chromatographic band broadening, it is necessary to examine the variances associated with the system. The total variance is one of the best indicators to identify the presence of broadening. In multi-component systems such as LC-FABMS systems, induced broadening of the input signal can be described by the sum of individual variances associated with each component. Thus, the total variance (σ^2_t) of the LC-FABMS system is the sum of all the variances associated with the chromatographic system (σ^2_{chr}), with the interface (σ^2_{int}) and with the mass spectrometer (σ^2_{ms}) as indicated by equation [1].

$$\sigma^2_t = \sigma^2_{chr} + \sigma^2_{int} + \sigma^2_{ms} \qquad [1]$$

The total variance of the chromatographic system (σ^2_{chr}) can be expressed as the sum of the broadening occuring in the column (σ^2_c) and the broadening induced by components external to the column (σ^2_{ex}). Broadening occuring within the column results from kinetics effects and it is possible to describe these effects by Van Deemter's equation [2].

$$H = A + \frac{B}{\bar{u}} + C\bar{u} = 2\lambda dp + \frac{2\gamma Dm}{\bar{u}} + \frac{(1+6k'+11k')\,dp^2}{24\,(1+k')^2\,Dm}\,\bar{u} \qquad [2]$$

Since σ^2_{chr} is related to H it is possible to identify the factors responsible for the loss in efficiency observed in the chromatographic system when the concentration of the matrix is increased. As had been observed in our previous work, higher concentrations of glycerol increase the C term in the Van Deemter equation as withnessed by the increment in the slopes of the plots. The variations observed are mainly due to the changes in Dm induced by an increase in the viscosity of the mobile phase. Thus, the most important factor influencing broadening in systems using pre-column addition is the change in viscosity of the mobile phase that produces detrimental effects on the mass transfer kinetics Other components in the system are also likely to act as

dispersion operators The total variance associated with the interface (σ^2_{int}) will be the sum of the variance of the transfer tube (σ^2_{tu}) and the variance associated with the droplet formed at the probe tip (σ^2_d). The variance associated with the transfer capillary tubing and calculated from experimental measurements is given in Table 1, where σ^2_{tu} is shown as a function of diameter of the transfer tube, flow rates and glycerol content. The data presented indicate that σ^2_{tu} increases with increasing glycerol content, flow rates and radius of the tube and that σ^2_{tu} is less than 0,045 μL^2. Hence the dispersion produced by the transfer capillary appear to be relatively small and its contribution should not significantly affect the total variance of the system. The other contribution to the variance associated with the interface is the variance associated with the droplet formed at the probe tip (σ^2_d). Table 1 clearly indicates that the contribution of the interface to the total broadening of the chromatographic band is mainly due to the formation of the liquid droplet. Finally, the signal can also be broadened by the mass spetrometer (σ^2_{ms}). The broadening that will be induced by the mass spectrometer is essentially related to the scanning speed of the instrument, which must be sufficiently rapid to reduce broadening of the signal.

In conclusion, the broadening that is observed in capillary LC-FABMS systems originates partly from the addition of the viscuous matrix that increases the viscosity of the mobile phase and causes changes in the mass transfer kinetics and partly from the formation of the liquid droplet at the probe tip.

EVALUATION OF THE CHROMATOGRAPHIC BOUNDARIES WITHIN WHICH PRE-COLUMN ADDITION OF VISCOUS MATRICES CAN BE USED IN LC-FABMS

Jean-Pierre Gagné, Alain Carrier and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7.

Continuous-flow fast atom bombardment mass spectrometry requires an involatile solvent present with the sample in order to optimize ionization and generate high quality mass spectra. Pre-mixing of involatile matrices with the mobile phase is the easiest and most common way to satisfy this important requirement in LC-FABMS systems[1-3]. The objectives of this work was to determine the general chromatographic boundaries within which pre-column addition can be used and formulate guidelines that would help to retain chromatographic performance in the presence of viscous matrices

The effect of the presence of matrices on the chromatographic separation has been evaluated using a conventionnal column filled with 5 µm Spherisorb ODS-2 particules size and UV detection The peptides met-enkephalin, leu-enkephalin and bradykinin have been used as chromatographic markers for high mass compounds (~1100 Da) while phenolic compounds such as phloroglucinol, p-hydroxybenzoic, 3,5-dihydroxybenzoic and vanillic acids have been used as low mass markers (~130 Da). These indicators studied in different chromatographic systems have allowed:

1) The monitoring of the capacity ratio (k'), of the number of theoretical plates (N), of the peak width at half height ($W_{1/2}$), of the separation impedance (E) and the resolution (R_S) at various matrix contents.
2) The generation of Van Deemter plots at various matrix concentrations and temperatures
3) The study of three mobile phases which are mobile phase A = ACN/H_2O/GLY/CH_3COOH in 10/90-x/x/1, mobile phase B = ACN/H_2O/GLY/TFA in 30/70-x/x/0.1 and mobile phase C = ACN/H_2O/THIO/TFA in 30/70-x/x/0.05 where x represent the percent of glycerol or thioglycerol added to the mobile phase.

The behaviour of the parameters k', N, $W_{1/2}$, E and Rs with the increase of the matrix content in mobile phase leads to the following observations The pre-column addition of viscous matrices to the chromatographic eluent perturbs the performances of all the systems independently of the mass of the substances analysed and the composition of the mobile phases in acetonitrile/water mixtures. The perturbations induced by the presence of glycerol or thioglycerol are minor at matrix contents below 3%. Modifications in the chromatographic process begin to be important for all parameters monitored at matrix content in liquid vector over 5% This study has also indicated that thioglycerol shows a high eluotropic strength that results in a more significant decreases in the capacity factor than that produced by glycerol.

To broaden the boundaries of the precolumn addition of matrices Van Deemter plots at various FAB matrix content in the mobile phase have been generated. Figure 1 show typical Van Deemter plots obtained for met-enkepkalin when the content of thioglycerol added to the mobile phase is increased from 0 to 15%. The Van Deemter plots show three distinct sections. At low linear velocities (<0.1mm/sec;<0.2 mL/min) all chromatographic systems studied are under diffusion control. In the range of optimum linear velocities (0 2-1.0 mm/sec, 0.2-0 5 mL/min) the convergence of all curves indicates that the performance of the chromatographic system is independant of matrix content in the mobile phase. At high linear velocities usually used in LC analysis (>1mm/sec,>0.5 mL/min), broadening in chromatographic system is under mass transfert control and the matrix content significantly impairs the performance of the column. Figure 1 also indicate that for the concentrations of matrix of 0, 1 and 3% similar plots are generated. The effect of the change in temperature has also been monitored by Van Deemter plots. Figure 2 indicates that the use of higher temperatures can reduce the negative effects caused by the presence of matrices and can restore the performance of chromatographic system. In fact, the medium performance obtained at 10% thioglycerol in the mobile phase and 25°C can be increased to be similar to that of the column at 0% glycerol and 25°C by increasing the temperature to 38.5°C

With the perspective to optimize the chromatographic components in LC-FABMS systems, the previous observations lead us to propose four strategies that limit and control the loss of performance in the chromatographic system.

1) In order to limit the general disturbance of the chromatographic process it is proposed to limit the contents of viscous matrix in LC-FABMS systems at a maximum of 3%.

2) Since thioglycerol produces more drastic changes in the chromatographic mechanism, which is reflected in the capacity ratio and selectivity of the column, the use of glycerol must be favored over that of thioglycerol.
3) If it is necessary to conduct the analysis at contents over 3%, it would be better to use flow rates in the range of the optimum linear velocity in order to limit the loss of performance of the column. The use of low flow rates allows longer retention times which are partially compensated by faster elution at high matrix content.
4) The use of high temperature with high matrix contents can limit the losses in performance.

The previous observations and the following guidelines also applied to LC-FABMS system using packed capillary column[4].

CHANGES IN SELECTIVITY INDUCED BY PRECOLUMN ADDITION OF VISCOUS MATRICES IN LC-FABMS SYSTEMS USING ION-PAIRING CHROMATOGRAPHY

Jean-Pierre Gagné, Alain Carrier and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7

CF-FAB is a powerful technique that allows repetitive and rapid analysis of polar and labile compounds in aqueous type media. In complex mixture analysis this technique, however, suffers from ionization suppression and insufficient resolution capabilities. In order to solve these limitations LC-FABMS which possesses the needed temporal and mass resolution can be used. As the presence of a viscous matrix is necessary to optimize ionization in FAB, premixing of the matrix with the chromatographic eluent is an easy method to admit the involatile solvent into the system. The inclusion of a viscous matrix in the mobile phase will, to some extent, affect the performance of the chromatographic system[1-3]. The primary objective of this study was to investigate the changes in chromatographic resolution that result from the precolumn addition of glycerol or thioglycerol to the chromatographic eluent.

In this exploratory work, the effect of glycerol was initially studied in partition chromatography. 3,5-dihydroxybenzoic acid and vanillic acid were eluted with ACN/H_2O/GLY/CH_3COOH (10/90-x/x/1 where x expresses the percent of glycerol added). The second chromatographic system used examined the effect of glycerol in ion-pairing chromatography. Met-enkephalin and bradykinin were used as reference compounds and were separated in ACN/H_2O/GLY/TFA (30/70-x/x/0.1). The third system used monitored the effect produced by increasing contents of thioglycerol in ion-pairing chromatography. The resolution was monitored for met-enkephalin and leu-enkephalin in the mobile phase ACN/H_2O/THIO/TFA (30/70-x/x/0.05). The chromatographic studies have been conducted using conventionnal columns with UV detection.

Figure 1 shows the changes in resolution induced by the pre-column addition of glycerol or thioglycerol for the three chromatographic systems used in this study. The addition of increasing amounts of matrix to the liquid vector induces a steady reduction in resolution in all chromatographic systems. The addition of a matrix has a deleterious effect on separation irrespective of the nature and concentration of the matrix added and the chemical class of the analyte. This observation has been confirmed with conventional and capillary columns. The reduction in resolution caused by the presence of the matrix in mobile phase can be minimized by using low matrix contents.

In order to obtain insight on the causes of the decrease in resolution the specific changes induced in the efficiency (N), in the capacito ratio (k') and in the selectivity (α) terms were monitored. These parameters control the resolution as demonstrated in the equation 1.

$$R_s = f(N,k',\alpha) = \frac{\sqrt{N}}{4}\left[\frac{k'}{k'+1}\right]\left[\frac{\alpha-1}{\alpha}\right] \qquad [1]$$

In order to compare the relative importance of the contributions of N, k' and α affecting resolution all the data need to be normalized to a reference state. In this study, the 0% matrix content was chosen as the reference state. The subsequent normalization of the parameters has been done by dividing the measurements acquire at specifix matrix content by the data obtained at 0% matrix content. In this work, the efficency, the capacity ratio and the selectivity terms contributing to the resolution will be respectively designated by $\sqrt{N}x/\sqrt{N}o$, $f(k')_x/f(k')_o$ and $f(\alpha)_x/f(\alpha)_o$. This nomenclature will be used in further discussing the data.

Figure 2 shows the variations in the ratios $\sqrt{N}x/\sqrt{N}o$, $f(k')_x/f(k')_o$ and $f(\alpha)_x/f(\alpha)_o$ with matrix content in the mobile phase for the only partition chromatographic system used in this study. The data in Figure 2 indicate a reduction in the three normalized parameters with the increase content in matrix. However the chief factor that controls the observed loss in resolution is the efficiency term that decreases more than the other factors measured. As a matter of fact, at 20% glycerol content in the eluent the decrease in the normalized capacity ratio and normalized selectivity terms are limited at less than 4% and 8% of the initial values obtained in the absence of a matrix. By contrast, the normalized efficiency term shows a reduction of 15% under the same boundary conditions. The large reduction in the normalized efficiency term for partition chromatography suggests that physical processes occuring in this system are more affected than chemical processes.

Figure 3 shows the dependence of the three normalized parameters on the concentration of glycerol present in the mobile phase for the first ion-pairing chromatographic system tested which used bradykinin and met-enkephalin reference compounds It can be seen from the figure that the

presence of glycerol affects the normalized efficiency, the capacity ratio and selectivity terms. The variations in the latter parameter suggest that ion-pairing chromatography is more sensitive to the presence of the matrice contrary to what had previously been observed for partition chromatography. The similar decrease observed in the ratios $\sqrt{N_x}/\sqrt{N_o}$, $f(k')_x/f(k')_o$ and $f(\alpha)_x/f(\alpha)_o$ with increasing content of matrix indicates that each parameter contributes in an equivalent manner to the reduction in resolution.

In order to confirm the sensitivity of ion-pairing systems to the presence of a matrix in the mobile phase as previously observed, a second ion-pairing chromatographic system comprising leu- and met-enkephalin in the presence of thioglycerol was studied. Figure 4 shows, for this system, the changes induced in $\sqrt{N_x}/\sqrt{N_o}$, $f(k')_x/f(k')_o$ and $f(\alpha)_x/f(\alpha)_o$ with increasing content of thioglycerol in the mobile phase. The observed variations in the data confirm the sensitivity of ion-pairing chromatography to the presence of FAB matrix in chromatographic eluent In the presence of thioglycerol the changes observed in $\sqrt{N_x}/\sqrt{N_o}$, $f(k')_x/f(k')_o$ and $f(\alpha)_x/f(\alpha)_o$ are different than those previously observed in ion-pairing chromatographic system using glycerol as matrix. The decrease in the normalized efficiency term is similar in the two ion-pairing systems tested but in presence of thioglycerol the second system shows a sharper decrease in the normalized capacity ration terms and a dramatic increase in the normalized selectivity term.

The monitoring of chromatographic resolution for three pairs of analytes in three mobile phases containing different proportions of viscous matrix shows a steady reduction with the increase matrix content in mobile phase The chromatographic system based on partition chromatography shows a loss in resolution that is chiefly related to the reduction in efficiency induced by the presence of the matrice The results of this study also show that the decrease in resolution observed for ion-pairing systems is due simultaneously to the reduction of the capacity ratio and efficiency terms in the presence of the matrix. Furthermore, specific changes possibly related to the nature of the analyte may be encountered in the presence of thioglycerol.

Capillary Liquid Chromatography / Continuous Flow Fast Atom Bombardment Mass Spectrometric Analysis of DNA Adducts from *In Vitro* Reaction Mixtures

*[1]Susan Wolf, [2]Curt Norwood, [2]Eugene Jackim and [1]Paul Vouros; [1]Department of Chemistry, Northeastern University, Boston, MA 02115 [2]US Environmental Protection Agency ERLN, Narragansett, RI, 02882

Introduction. DNA adducts are formed by the covalent attachment of carcinogenic species to DNA and have long been considered to play a major role in the process of carcinogenesis. When DNA has been exposed to carcinogens (whether in an *in vitro* or *in vivo* situation), a mixture of adduct types typically results. In order to elucidate the biochemistry of the carcinogen-DNA interaction and to assess exposure, it is necessary to characterize as many adducts in a given mixture as possible.

The following research entails the application of LC-CFFAB MS to the detection of deoxynucleoside adducts formed by the *in vitro* reaction of calf thymus DNA with N-acetoxy-2-acetylaminofluorene (AAAF). It has previously been established (1) that the *in vitro* reaction products include primarily N-(deoxyguanosin-8-yl)-2-acetylaminofluorene and 3-(deoxyguanosin-N^2-yl)-2-acetylaminofluorene. In addition, the formation of several minor adducts which have not yet been structurally characterized has been noted (2). It was felt that an on-line separation / structural characterization approach to analyzing the products of this reaction would be capable of detecting the trace adducts which might be difficult to collect and characterize off-line.

Experimental. 1 mg DNA and 1.25 mg N-acetoxy-2-acetylaminofluorene were reacted at pH 6 in a 10 mM citrate buffer. The DNA was enzymatically degraded to deoxynucleosides and the adducts extracted according to previously published procedures (3,4). LC separations were conducted using a Carlo Erba Phoenix 20 syringe pump and MicroUVIS 20 ultraviolet detector with on-line detection by CFFAB mass spectrometry. The capillary column was a 5 um C18 packed 320 um X 30 cm column (LC Packings, San Francisco). Mobile phases contained 1 % glycerol and the flow rate = 4 uL/min. CFFAB mass spectrometry was conducted using a VG Quattro triple quadrupole mass spectrometer. Argon gas and a collision energy = 70 eV were used for the collision induced dissociation work. AAF-C8-dG, generated by the reaction of dG with AAAF, was used as a standard in this work.

Discussion. The adduct mixture which was generated and isolated as described above was dissolved in 50% MeOH for LC-CFFAB MS analysis. From the appearance of HPLC-UV chromatogram, it was clear that the n-butanol extracted materials constituted a complex mixture which would be difficult to resolve chromatographically. In order to selectively detect any adducts in the mixture, constant neutral loss scanning of the loss of deoxyribose (116D) was employed. As shown below, the precursors which were found to lose 116D were m/z 447,473, and 489. Several peaks showing the loss of 116D from m/z 489 indicated the presence of deoxyguanosine adducts. Based upon past reaction results (1) and LC data (5,6), the major adduct at 25.5 min. seemed likely to be AAF-C8-dG and the adduct at 14.2 min. to possibly be AAF-N^2-dG. In addition, three other minor deoxyguanosine adducts are indicated in the 10-13 min. range. It is conceivable that these adducts result from addition to the O^6 of deoxyguanosine or involve a different reactive site on the AAF. An m/z 473 precursor indicated adduction to deoxyadenosine. Finally, the loss from m/z 447 which occurred at the same t_r as the major loss from m/z 489 indicated the formation of a deoxyguanosine adduct which could fragment to lose the acetyl group in the ion source and subsequently lose 116D in the collision cell (or possibly a coeluting deacetylated deoxyguanosine adduct).

An MRM analysis in which the 489-->373 and 473-->357 transitions were selectively monitored gave an enhancement of these signals and was useful in highlighting the relatively weak losses from m/z 473 at t = 8.5 and 18.5 min. The utility of MRM analysis in detecting picogram amounts of the AAF-C8-dG standard is illustrated below. In order to confirm the identity of the adduct eluting at 25.5 min. as AAF-C8-dG, the CID spectrum obtained from the AH_2-C=OCH_2+ ion of the standard was compared to that of the adduct in the mixture.

To date, CID spectra have not been obtainable for the presumed deoxyadenosine adducts due to the limited amounts of these species present in the mixture. However, given the relative elution order of the adducts and the established propensity of amino- and acetylamino-PAH metabolites to react at the N^6 and C8 positions of deoxyadenosine (2), it seemed possible that the early eluting compound was an N^6 adduct while the later eluting species could be the C8. In an effort to explore this possibility, deoxyadenosine was reacted with N-acetoxy-2-acetylaminofluorene to give a major adduct with the same t_r as the early eluting "deoxyadenosine adduct" (appearing at 8.5 min. in m/z 473 CNL trace). The CID spectrum of the AH_2+

ion of this compound was not inconsistent with what might be expected for an N^6 adduct. It should be emphasized that these assumptions are quite tentative and will be explored more fully in future work. It is worth noting, however, that the formation of AAF-dA adducts has been postulated in past research (7,8), although these species have yet to be structurally characterized.

Future plans include the characterization of the minor adducts detected by neutral loss scanning, with possible scale-up of the reaction and the application of this methodology to other DNA adduct mixtures.

We are grateful to Carlo Erba for providing the Phoenix 20 LC System used in this work. We would also like to thank Dr. Frederick Beland of the National Center for Toxicological Research for the generous donation of the N-acetoxy-2-acetylaminofluorene and for advice regarding the DNA reaction.
In addition, we are grateful to Mohamed Itani for providing the AAF-C8-dG adduct.

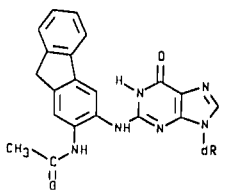
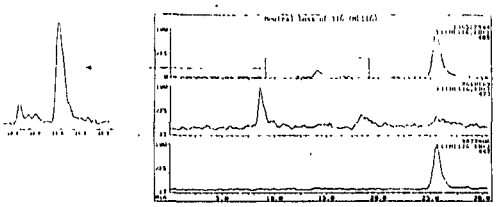
AAF-C8-dG



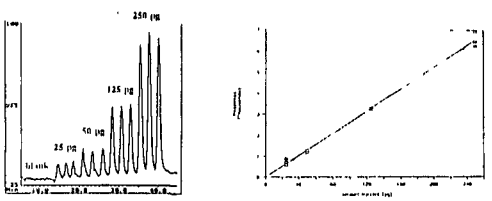
AAF-N^2-dG

Constant Neutral Loss Scanning of 116D



Constant neutral loss scanning was employed to monitor the loss of 116 mass units, which would correspond to a deoxyribose loss for a normal deoxynucleoside or a deoxynucleoside adduct. After the separation was complete, groups of scans spanning the entire data file were summed to find precursors which lost 116D. The three traces shown at the left represent those ions which exhibited this behavior (upper trace - m/z 489, middle trace - m/z 473, lower trace - m/z 447). The trace on the left is a magnification of the 9.00-19.00 region in the m/z 489 trace.

Selective Scanning of the Deoxyribose Loss for the Detection of Target Adducts



The figure on the far left shows replicate injections of standard solutions of the AAF-C8-dG adduct through the LC/ESI-MS system. Detection was accomplished by selectively monitoring the 489 -> 373 transition for this adduct. The graph on the left shows the plot of the peak area vs. the amount of adduct injected for this data.

Development of a Condensation Technique for TLC/FABMS

Ken-ichi Harada, Katsuyoshi Masuda and Makoto Suzuki
(Faculty of Pharmacy, Meijo University, Tempaku, Nagoya 468, Japan)
Hisao Oka, Yoshitomo Ikai, Fumio Kondo and Junko Hayakawa
(Aichi Prefectural Institute of Public Health, Tsuji-machi, Kita-ku, Nagoya 462, Japan)

Although thin-layer chromatography (TLC) is a simple and effective technique for the separation of components in a mixture, the identification of the separated components is difficult unless an appropriate spectrometric method such as mass spectrometry (MS) is used. However, a stepwise operation including individual separation by TLC and measurement of the mass spectrum is laborious and time-consuming, because it needs extra steps such as extraction of the desired compound from the TLC plate and elimination of adsorbents. Recently, the direct analysis of TLC spots in a mass spectrometer has been reported, and TLC/fast-atom bombardment (FAB) and TLC/liquid secondary ion (LSI) MS have been applied successfully to identification of drugs, their metabolites, and dyes.

When a sample is applied on a TLC plate and then is developed, the spot is usually diffused . Additionally, an addition of a matrix on the sample spot causes a serious diffusion with spreading the matrix . No satisfactory spectrum is obtained with good sensitivity in such a case, unless a large amount of the sample is applied on the TLC plate. In our previous reports, to prevent the diffusion of the sample component and to obtain high sensitivity for MS, we developed a sample-condensation technique using thioglycerol, and applied it successfully to the identification of food dyes.[1] This technique is highly effective for the condensation of samples on precoated silica gel TLC plates, although the samples could not be condensed on precoated reversed phase (C18) TLC plates. In addition, an evaluation of this condensation technique for a colorless sample spot had not been achieved.

Therefore, we wished to develop a universal condensation technique, effective for both colored and colorless samples on both precoated silica gel and C18 TLC plates. In this paper, such a technique for TLC/FABMS is described and the resulting mass spectra are illustrated.[2]

Our previously established sample condensation technique for TLC/LSIMS and TLC/FABMS could not condense the samples on precoated reversed-phase (C18) TLC plates, because thioglycerol used as a condensation solvent is only weakly mobile in reversed-phase chromatography although it is strongly mobile in normal-phase chromatography due to its high polarity. Since methanol, acetonitrile and acetone operate as strong mobile phases in both reversed- and normal-phase chromatography, they were tried as condensation solvents for both normal- and reversed-phase TLC/FABMS. A condensation solvent must have the following characteristics; 1) excellent solubility for sample, and 2) high volatility, because the use of a highly volatile solvent can easily correct the shape of condensed spot in a short time period. In view of these two points, we examined all three solvents and selected methanol as being the best condensation solvent. The following different types of compounds were selected: colored sample, acid red; colorless sample having chromophore, mycinamicin IV and microcystin LR; colorless having no chromophore, viridopentaose B.

We have devised the two techniques for condensation of diffused spots as shown in Fig. 1. *Normal condensation technique:* For acid red, mycinamicin IV, and microcystin LR, a small volume of methanol was applied around the sample spot on the developed TLC plate. After several tens of seconds, the sample was condensed towards the center of the spot in a line with penetration of methanol. *Trapezoid condensation technique:* For viridopentaose B, the following trapezoid condensation technique was used. 1) An area including the desired spot on the developed TLC plate was rectangularly cut and a line was trapezoidally drawn around the sample spot. 2) The outside stationary phase of the trapezoid was scratched off along the line and a small volume of methanol was deposited on the lower base of the trapezoid. 3) After several tens of seconds, the sample had become condensed along the upper base of the trapezoid in a line (0.5x2mm) by

penetration of methanol. The TLC plates were finally set onto the TLC holder, a matrix was applied on the sample spot, and the TLC/FAB mass spectrum was measured.

The mass specra obtained using the techniques showed clearly the molecular ion species at lower concentrations than were possible without the present techniques, as listed in Table 1, and it can improve the detection limits of the molecular ion species in TLC/FABMS by 3-100 times with good reproducibility. The techniques are now being applied to a mixture sample containing many components.

NANOSCALE SEPARATIONS OF BIOMOLECULES IN COMBINATION WITH COAXIAL CONTINUOUS FLOW-FAB MASS SPECTROMETRY

L. J. Deterding, J.R. Perkins, and K.B. Tomer

Laboratory of Molecular Biophysics
National Institute of Environmental Health Sciences
Research Triangle Park, NC 27709

Coaxial continuous flow FAB (CF-FAB) has proven to be a useful technique for interfacing nanoscale capillary LC (nCLC) and capillary zone electrophoresis (CZE) with mass spectrometry (1,2). Both separation techniques offer the advantages of high separation efficiencies from minimal sample volumes as well as low mobile phase flow rates. Since most biological samples are sample limited, these advantages are particularly attractive. We have demonstrated the detection of low femtomoles from CZE and low picomoles from nCLC using the coaxial CF-FAB design to interface these separation techniques with mass spectrometry. This design is particularly advantageous since the chromatography is not affected by the matrix and one gains independent optimization of the composition and flow rates of the analytes and the FAB matrix.

In this paper, we demonstrate the ability to obtain on-line separations of biological compounds using both nanoscale packed capillary LC columns and CZE. The nanoscale LC columns are typically 75 μ id, 1.5 m in length, and packed with 5 or 10 μ C18 particles to a depth of 25 cm. The CZE columns are typically 13 μ id and 1.2 m in length. CZE separations are based on different molecular parameters than are LC separations. The two are, therefore, complementary separation techniques. The separations of a mixture of five luteinizing hormone releasing hormones, [D-Lys^6]-LH-RH, LH-RH, [Gly-OH^{10}]-LH-RH, [D-Ala^6]-LH-RH, and [D-Phe^2, D-Ala^6]-LH-RH, show that LC and CZE are complementary. LH-RH and [Gly-OH^{10}]-LH-RH coelute using nLC but can be easily separated by CZE. Conversely, [Gly-OH^{10}]-LH-RH, [D-Ala^6]-LH-RH, and [D-Phe^2,D-Ala^6]-LH-RH coelute via CZE but can be separated by nCLC (data not shown).

The nanoscale LC columns can be used for the pre-concentration of low-level complex mixtures, such as biological abstracts. These columns typically have a 2 cm packing bed of 5 or 10 μ C18 particles. As an example, the extracts from approximately 10^9 influenza-infected cells were analyzed by coaxial continuous flow FAB/MS. The sample solutions containing the naturally-processed flu peptides are introduced onto the column using a pressure injection. After loading the flu peptides, the column is flushed with 0.1% TFA to remove any salts, detergents, etc. that may be present in the extracts. The flu peptides are then eluted using an isocratic elution of 80% acetonitrile in water. A broad band was observed from both the cells containing the entire flu matrix protein (MITE) as well as cells containing the minigene matrix peptide M1 (57-68) which corresponds to the amino acid sequence of LGILGFVFTLTV. In the full scan mass spectrum from the M1 extract an abundant ion at m/z 853 was observed which corresponds to the 58-65 amino acid residues. The most abundant ion was observed at m/z 835, which possibly corresponds to the loss of water from the m/z 853 ion. The total ion chromatogram and the mass chromatograms for the m/z 853 and m/z 835 ions are shown in Figure 1 along with the full scan mass spectrum. The full scan mass spectrum of the MITE extract resulted mainly in the observance of the m/z 853 ion (data not shown). The flu peptide yield from these cells is estimated to be in the low to sub-femtomole range. We are currently growing additional infected cells in order to obtain the MS/MS spectra of these peptides to confirm their identity.

TWO-DIMENSIONAL ELECTROSEPARATION METHODS COUPLED WITH MASS SPECTROMETRY

J. van der Greef, A.P. Tinke, N.J. Reinhoud, W.M.A. Niessen, U.R. Tjaden.

Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, Leiden University, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

The minimum detectable concentrations in Capillary Electrophoresis (CE) are relatively high, because narrow bore capillaries are used for the separation, providing a small optical pathlength (important in UV and fluorescence detection) and a low loadability.The absolute amount of analyte that can be injected on to the CE capillary, limits the detection especially in CE-MS. Therefore, techniques that provide analyte preconcentration during sample pretreatment are required to make CE-MS suitable for trace analysis.

Preliminary results are reported for the on-line coupling of isotachophoresis (ITP), CE and MS (ITP-CE-MS) in the analysis of a mixture of anthracyclines.

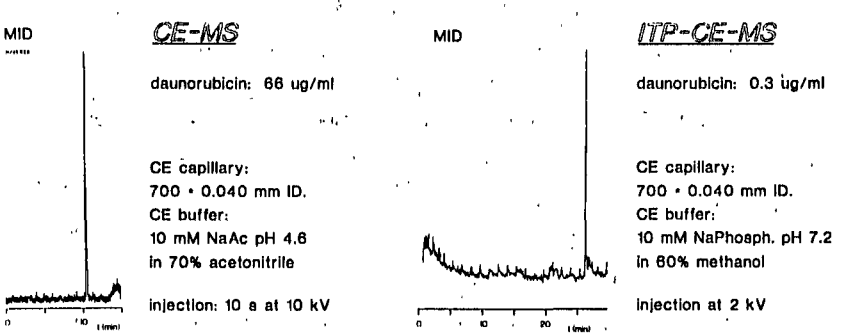
tubelens potential:	200 V
nozzle-skimmer potential:	50 V



An improvement in detectability in capillary electrophoresis - mass spectrometry (CE-MS) has been realized using isotachophoresis analyte focussing during the sample pretreatment. The practical approach has been described for the on-line coupling of capillary isotachophoresis - capillary electrophoresis - mass spectrometry (ITP-CE-MS) using an electrospray (ESP) interface. The applicability was demonstrated for the analysis of a mixture of anthracyclines. Initial experiments showed an at leat 100-fold improvement in detectability for ITP-CE-MS compared to CE-MS.

The Detection of Abscisic Acid Sugar Conjugates in Plant Material Using Continuous Flow Packed Fused Silica Capillary Liquid Secondary Ion LC/MS/MS with Reaction Monitoring

L R. Hogge, J J Balsevich, D.J.H. Olson, G.D. Abrams*, S. R. Abrams and S.L. Jacques, National Research Council of Canada, Plant Biotechnology Institute, Saskatoon, Sask. Canada S7N 0W9

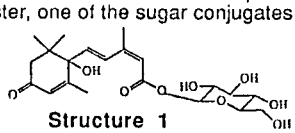
Introduction:

The plant hormone abscisic acid (ABA) is implicated in regulating many stages of plant growth and development including maturation and germination of seeds, maintenance of dormancy and resistance to environmental stresses such as cold, heat and drought. The role of ABA and its metabolites in these physiological processes is being studied by many plant chemists and biologists. Sugar conjugates of ABA are some of the more important metabolites being studied. Structure 1 shows the ABA glucose ester, one of the sugar conjugates known to exist in plants.



Structure 1

We have utilized packed fused silica capillary column LC in conjunction with continuous flow SIMS for the separation and detection of ABA and metabolites. This report shows that femtomole quantities of ABA glucose ester can be detected in plant cell tissue culture extracts using continuous flow LC/SIMS coupled with reaction monitoring MS/MS.

Experimental:

All LC analyses were done using an Applied Biosystems Model 140A solvent delivery syringe pump. Samples (1 microliter, made up in 20% MeOH, 2% glycerol in water) were injected through a Rheodyne Model 7520 injector onto a reverse phase spherisorb 3 micron C18 ODS2 packed fused silica capillary column (0.32mm x 250 mm) prepared in this laboratory. The mobile phase was as follows: Solvent A: 0.1% TFA, 2% glycerol in 80% acetonitrile; Solvent B: 0.1% TFA in 2% glycerol. Elution was achieved by using either isocratic (50% B) or gradient conditions at a flow rate of 3 microliters/min. This flow rate was obtained by delivering 150 microliters/min to a splitter system situated between the pump and the injector. The splitter consists of a low dead volume Valco tee with a 2mm x 250 mm ODS LC column attached to one side of the tee as a restricter.

The LC system was interfaced to a VG Analytical 70-250 SEQ hybrid mass spectrometer equipped for continuous flow SIMS analysis. The continuous flow SIMS stainless steel frit probe tip was designed in this laboratory. The probe tip was maintained at 50 degrees C. Spectra were obtained by scanning from m/z 650 to 65 (resolution of 1000) at a rate of 3 sec./decade. Multiple reaction monitoring experiments were performed by monitoring the transition of m/z 427.2 fragmenting to m/z 265.1 using a dwell time of 80 milisec. at a mass resolution of 1000. Zenon was the collision gas used at a pressure of 8 $X10^{-5}$ Torr. The collision energy was 16 volts (laboratory frame).

Results and Discussion:

Figure 1 shows the background subtracted magnetic scan continuous flow (CF) SIMS LC/MS spectrum obtained from the analysis of 100 ng of synthetic ABA glucose ester. This spectrum shows the major fragment, m/z 265, which is the result of the the loss of the glycone moiety from the protonated molecular ion. The CID daughter spectrum of the protonated molecular ion m/z 427 shows a similar major fragment making this transition ideal for reaction monitoring (RM) experiments. Reaction monitoring, carried out in conjunction with CF SIMS, overcomes the problem of dealing with the high levels of matrix ions while taking advantage of the low detection limits of the technique. The use of packed fused silica capillary LC columns provides a further degree of specificity.

Figure2 shows the RM ion chromatograms obtained from the injection of 100 pg of the ABA glucose ester using the transition of m/z 427.2 forming m/z 265.1.

Quantitation of ABA glucose ester is being addressed at this institute by the use of a deuterated internal standard. Response ratios for this deuterated standard relative to the natural ABA glucose ester have been determined by analyzing mixtures of known amounts of the ABA glucose ester and the D_6 ABA glucose ester. Figure 3, the plot of the D_6/D_0 ABA glucose ester ratio (MRM chromatogram area) vs amount of ABA glucose ester injected, shows a linear response ranging from 500 pg to 10 ng. Figure 4 compares the analysis for ABA glucose ester using selected ion monitoring (SIM) and RM. Although the SIM chromatogram for m/z 427.19 (Figure 4b) gives an indication of the presence of the glucose ester, the evidence is not nearly as conclusive as is shown in 4a the RM ion chromatogram for the transition of m/z 427 fragmenting to m/z 265.
Future experiments using the deuterated internal standard will allow for the direct quantitative analysis of femtomole amounts this polar plant hormone extracted from plant tissue cultures.

MONITORING OF DRUG URINARY EXCRETION BY ON LINE IMMUNOAFFINITY EXTRACTION - HPLC - CONTINUOUS FLOW FAST ATOM BOMBARDMENT

*E. Davoli, R. Bagnati and R. Fanelli
Istituto di Ricerche Farmacologiche "Mario Negri",
via Eritrea 62, 20157 Milano, Italy

INTRODUCTION

Combining immunoaffinity chromatography (IAC), which allows a simple and highly selective extraction of specific molecules, and continuous flow FAB (cf-FAB), which is a relatively high sensitive technique, we have developed a system which allows automatic on-line immunoaffinity extraction / HPLC separation / mass spectrometric analysis of drugs in urine down to the low ppb levels.

PREPARATION OF IMMUNOAFFINITY GELS AND IMMUNOAFFINITY COLUMNS

Immunoaffinity gels were prepared by coupling CNBr-Sepharose to immunoglobulins obtained from rabbits immunized with protein conjugates of diethylstilbestrol (DES) and were obtained from Genego S.p.A (Gorizia, Italy).

The gels were introduced into empty HPLC columns (2 mm I.D. x 50 mm length) and initially packed under vacuum.

DESCRIPTION OF THE SYSTEM

The scheme of the "on line" IAC-HPLC system is shown in fig. 1.

The HPLC is a computer controlled Beckman System Gold, with UV detector; the injector is a Beckman 210 A valve; the V1 and V2 valves are part of an electrical valve actuator (MUST; Chrompack, Middelburg, The Netherlands) which is controlled by the HPLC computer; P1 and P2 are low pressure pumps (Model B-100-S-2, Eldex Lab., San Carlos, CA, USA); the analytical column is a 5 µm Chromspher C_{18}, 3 mm I.D. x 200 mm length (Chrompack) and the pre-column is a 40 µm C_{18}, 2 x 10 mm; the detection with cf-FAB is performed on a VG 70-250 mass spectrometer, equipped with FAB gun and Teknivent 1050 data system (St. Louis, MO, USA).

SYSTEM OPERATIONS

The sequence of operations for the analysis of samples was the following:

- preparation of urine samples (centrifugation, eventual enzymatic digestion);
- loading of sample (urine diluted 1:1 with phosphate buffer pH 7.4) into the loop;
- injection of sample into the IAC and washing by pumping water with P1 pump at 0.8 ml/min, (V1 white position, V2 black position);
- elution of immunoabsorbed substances by pumping methanol/water 65/35 with P2 pump at 0 2 ml/min; at the same time the solvent was diluted after the IAC with water (P1 pump) to allow trapping of anabolics into the pre-column (V1 black position, V2 white position);
- HPLC - cf-FAB analysis of trapped substances and simultaneous reconditioning of IAC (V1 white position, V2 black position).

All the operations (excluding the preparation of urines) were completed within 28 min.

The use of an internal deuterated standard (octadeutero-diethylstilbestrol, $DESD_8$) allowed an accurate quantitation of samples with the cf-FAB technique.

HPLC CONDITIONS, UV AND cf-FAB DETECTION

For UV and subsequent cf-FAB detection, the HPLC conditions were the following: eluent, acetonitrile / water 75/25, with 0.8% of glycerol; flow rate, 0.2 ml/min. UV detection was at 276 nm.

The interface between the HPLC and the MS was an open split between two silica capillaries (150 µm I.D., from UV and 50 µm I.D.,120 cm length, to cf-FAB source). The flow rate through the cf-FAB capillary was 2-3 µl/min, thus leading to a split ratio of the HPLC effluent of about 1:100.

ANIMAL TREATMENT AND URINE ANALYSIS

Three Sprague-Dowley male rats weighing 280 ± 20 g were treated SC with DES in oil with 0, 0.25 and 2 mg / animal respectively. Urines were collected every 24 hours for 4 days and frozen until analysis.

Urines were centrifuged, spiked with 20 ng/ml of $DESD_8$, added with an equal volume of phosphate buffer (0.05 M, pH 7.4) and injected directly into the HPLC loop. Total DES determination (free + glucuronic acid conjugated) was performed in the same way on samples digested with β-glucuronidase/arylsulphatase enzymes overnight at 37°C.

RESULTS AND DISCUSSION

The chromatograms of a digested rat urine sample, is shown in fig. 2.

Rat urine disposition is shown on fig. 3.

The results obtained show that the system here described eliminates the greatest part of the manual procedures for the preparation and purification of samples.

The sensitivity of the method is sufficiently high for disposition studies of drugs, but can still be greatly improved by using larger injection volumes and with miniaturization of the HPLC system, in order to reduce the eluent flow and thus the split ratio in the cf-FAB interface.

CONCLUSIONS

Three important considerations need to be done on the potential evolution of this system:

- the first is that, being the HPLC chromatographic peak 30 seconds wide, detection in full scan mode should have the same sensitivity as in SIM mode as evidenced from preliminary data.
- the second is that with the use of relatively low specific policlonal antibodies, should be possible to selectively extract and identify, from biological fluids, cross-reacting compounds like metabolites of the administered drug.
- the third is that a system like this can lead to the development of hyphenated techniques which give simultaneous information on biomolecules interactions and chemical structure.

ACKNOWLEDGMENTS

This work was done with the support of Chrompack International and Chrompack Italia, which kindly supplied HPLC materials.

Identification of Isoflavonoid Conjugates in Alfalfa (*Medicago Sativa L.*) by Tandem LC-CF-LSIMS

Lloyd W. Sumner[1], Paul Geno[2], Nancy Paiva[3] and Richard Dixon[3]

[1]Department of Chemistry, Oklahoma State University, Stillwater, OK 74078

[2]Department of Environmental Chemistry, Southwest Research Institute, San Antonio, TX 74078-0047

[3]Plant Biology Division, The Samuel Roberts Noble Foundation, Ardmore, OK 73402

Flavonoids are found in a large variety of plants and serve a multitude of functions. Isoflavonoids have recently been identified as phytoalexins which are low molecular weight antimicrobial compounds that accumulate in plant tissues after exposure to microorganisms. It has been suggested that these compounds are stored as glycosides or even more complex conjugates in the cell vacuoles. Isoflavonoids are typically isolated as conjugates which rapidly decomposes to their aglycone form after extraction. In addition, a low energy mass spectral ionization method must be used, such as liquid secondary ion mass spectrometry (LSIMS) due to the labile nature of the glycoside linkage.

Our objective was to establish an on-line analysis method that would surmount the above mentioned obstacles. This was accomplished through interfacing a reverse-phase HPLC and a VG ZAB2-SE double focusing mass spectrometer by continuous-flow LSIMS. Instrumental parameters were optimized in the flow-injection mode for rutin. These parameters were then used for negative ion LC-CF-LSIMS analysis of elicited alfalfa cell suspension cultures and alfalfa roots.

The alfalfa samples were extracted with acetone and fractionated on a gravity-flow polyamide column with a step gradient of CH_3OH, 50/50 $CH_3OH/H2O$, and 2mL NH_4OH in 500mL CH_3OH. The basic fraction was taken to dryness, redissolved in methanol and analyzed by negative ion LC-CF-LSIMS. The reconstructed ion chromatogram (RIC) for the basic fraction of an alfalfa cell suspension extract is given in Figure 1. The mass spectrum of scan #107 is shown in Figure 2. This spectrum is consistent with the isoflavone formononetin-7-O-glucoside-6"-O-malonate (FGM) and has been tentatively identified as such. The mass spectrum of scan #129 is given in Figure 3 and has been identified as medicarpin-3-O-glucoside-6"-O-malonate (MGM). Identification was also supported by U.V. spectroscopy and chromatographic retention times. Positive ion LC-CF-LSIMS was performed (data not shown) and produced results that were consistent with our identifications.

An intense matrix peak was observed at m/z=113 in the mass spectra of alfalfa extracts. Additionally, an ion corresponding to [M+113]- was observed. Tandem LC-Cf-LSIMS was used to confirm that the observed [M+113]- was an adduct ion formed with the isoflavonoid conjugate of interest and the m/z=113 matrix ion. Tandem LC-CF-LSIMS was also performed on MGM (Figure 4) to further confirm its structural identity.

Negative ion LC-CF-LSIMS was found to be a very sensitive analysis method and a key tool in the identification of isoflavonoid conjugates. This is illustrated by Figure 5 which represents a mass spectrum corresponding to approximately 5ng of FGM delivered to the continuous-flow probe tip.

SYSTEMATIC CHARACTERIZATION OF ELECTROSPRAY FOR LIQUID CHROMATOGRAPHY MASS SPECTROMETRY INTERFACING

A.P. Tinke, R.A.M. van der Hoeven, W.M.A. Niessen, U.R. Tjaden, and J. van der Greef.

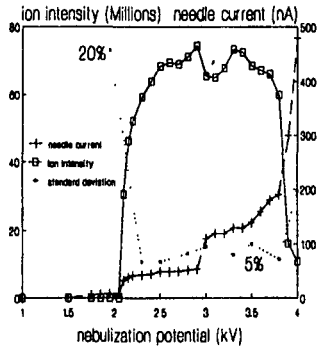
Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

One of the most recent developments in coupling Liquid Chromatography (LC) and Mass Spectrometry (MS) is the introduction of the Electrospray (ES) interface by Fenn and co-workers. Field induced disintegration of liquids at atmospheric pressure was reported to give very small and highly charged monodisperse droplets, which give rise to a high ionization efficiency and a low detection limit for various classes of compounds.

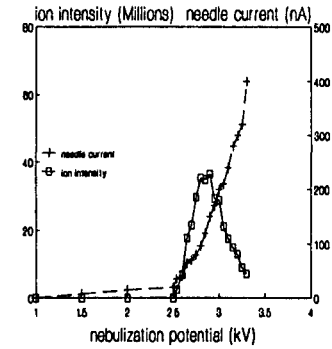
Many applications of ES are concerned with the analysis of high molecular weight compounds. Additionally, ES appears to have a great potential in the analysis of low molecular weight compounds, although relatively few systematic studies have been reported.

We investigated some characteristics of ES for the analysis of low molecular weight compounds by monitoring the ion intensity and ion current stability of ionic and non-ionic compounds as a function of various parameters.

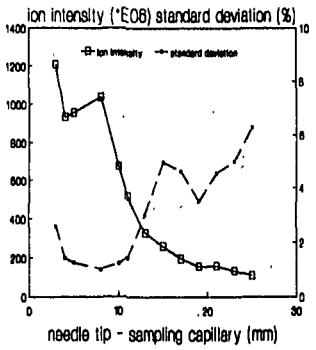
In positive ion mode mobile phases containing only 20% of modifier can be easily nebulized, without the assistance of a sheath liquid. For the ES analysis of low molecular weight compounds best ion intensity and ion current stability is obtained at a low mobile phase flow rate of ca. 0.5-1 µl/min.



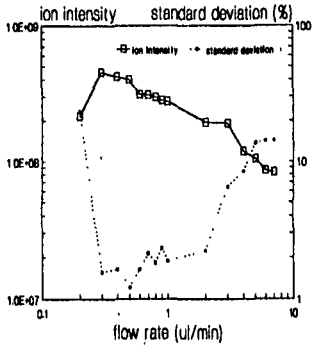
Tetraheptylammonium (THA) in 50/50 (v/v) methanol/water



THA in 3/97 (v/v) methanol/water



THA in 50/50 (v/v) methanol/water

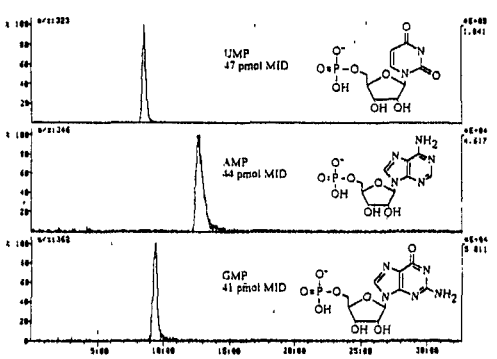


THA in 50/50 (v/v) methanol/water

In negative ion mode the assistance of a sheath liquid is often obligatory. High ion current stability can be obtained with ethanol or isopropanol instead of methanol or acetonitrile as a sheath liquid additive. For example, the analysis of nucleotides in a 10/90 (v/v) methanol/water mobile phase containing 5mM NH_4Ac and 1 mM tributylammonium could easily be done, using a 0.1% ammonia in isopropanol sheath liquid. It is important to notice, that the singly and doubly charged ions for di- and tri-phosphate nucleotides show different optima for the nozzle-skimmer (COLL) and the tubelens (L41) potential.

The nebulization potential is not critical for mobile phases of medium polarity and conductivity. Additionally, the drying gas temperature for water/methanol or water/acetonitrile mobile phases is of minor importance. The ion intensity and ion current stability decrease at a higher drying gas pressure.

The addition of a buffer to the mobile phase can increase the S/N-ratio for various non-ionic compounds. Using acetic acid as a mobile phase additive for cortisol a minimal detectable amount in FIA mode of 10 fmol was reached, using a 1mM HAc in 70/30 (v/v) methanol/water mobile phase.



Combined Liquid Chromatography/ Electron Paramagnetic Resonance Spectrometry/ Electrospray Ionization Mass Spectrometry for Radical Identification

*C. E. Parker[1], H. Iwahashi[1,2], R.P. Mason[1], and K. B. Tomer[1]

1. Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709
2. Department of Chemistry, Wakayama Medical College, 640, Wakayama, Japan

The role of free radicals in cancer, inflammation, and tissue injury continues to attract considerable interest. In order to detect short-lived radicals, the spin-trapping technique was introduced and has allowed the detection of many free radicals in biological systems. With EPR spin trapping techniques, determination of the structures of the radical adducts has been based mainly on the hyperfine splitting patterns of the EPR spectra. Hyperfine coupling constants can give detailed information about the radical center, but no molecular weight information. Direct probe MS and GC/MS have been used to identify the molecular structures of some radical adducts, usually after derivatization, but in many cases the radical adducts are only stable in solution and cannot be isolated.

For the past several years, we have been developing techniques for the identification of radical adducts in which high performance liquid chromatography (HPLC)/EPR and LC/Thermospray (TSP)/MS or LC/Electrospray Ionization (ESI)/MS are performed under identical HPLC conditions. The HPLC/EPR system uses an EPR spectrometer as a detector, and has allowed us to detect EPR active peaks in the HPLC elution profile, and LC/TSP/MS or LC/ESI/MS has allowed us to obtain parent ions for these radical species. A major difficulty in these experiments is the necessity of identical HPLC conditions for both the LC/EPR and the LC/MS experiment. We have recently developed a coupled HPLC, EPR, and MS instrument in which separation, radical adduct detection, and mass spectrometric determination occur on line. A diagram of this system is shown in Figure 1.

For on-line LC/EPR operation, the outlet of the UV detector was connected to the EPR flowcell with 75 cm 0.010" i.d. stainless steel HPLC tubing. The magnetic field of the EPR spectrometer was fixed at the signal detected from 4-POBN radical adducts, PBN radical adduct, MNP radical adduct, or DMPO radical adduct, depending on the spin-trap used in the experiment.

For coupling the EPR to the MS, the outlet from the EPR cell was connected to ~3 m of 327 μ i.d. x 432 μ o.d. fused silica capillary tubing. The volume of this tubing was approximately 0.1 mL, and led to a delay of about 10 seconds between the EPR and the splitting "tee". The ESI:waste flow ratio was set by adjusting the length of 150 i.d. fused silica capillary tubing on the "waste" side of a Swagelok 1/16" "tee". Approximately 10 μL/min of the sample stream was split off the 1 mL/min HPLC column effluent after the EPR spectrometer, and directed into the souce via a 1.1 m length of 75 μ i.d. x 150 μ o.d. fused silica capillary which terminated at the tip of the ESI needle.

Due to the additional time required for the sample to pass through the ESI interface, the total delay time between the appearance of a peak on the ESR spectrometer and its detection on the MS was 1.7 minutes.

The combined UV/EPR/ESI/MS technique has been applied to the determination of spin-trapped radical adducts, including phenyl, 2-, 3-, and 4-chlorophenyl, and 2-bromophenyl radicals trapped with a-(4-pyridyl-1-oxide)-N-t-butylnitrone (4-POBN), and phenyl radicals trapped with 2-methyl-2-nitrosopropane (MNP), a-phenyl-N-t-butylnitrone (PBN), and 5,5-dimethyl-1-pyrroline-N-oxide (DMPO). In addition to the radical forms, oxidized and reduced forms of the radical adducts were were also detected by the on-line LC/EPR/MS system. On-line coupling of these three detectors allows the correlation of the UV , LC/EPR, and LC/MS chromatograms, and slight shifts in elution profiles of selected ions have allowed the differentiation of overlapping species. A separation of phenyl radical trapped with 4-POBN is shown in Figure 2a. The on-line mass spectra obtained from this analysis are shown in Figure 2b.

Design and performance characteristics of a particle beam interface and an electrospray interface.

Mike Tomany, Doug Wittmer, Steve Gabeler, and Andy Jarrell*, Millipore Instrument Core Technology, 34 Maple Street, Milford, MA 01757

Particle beam interfaces of a variety of flavors (MAGIC, Thermabeam, Linc etc.) have proven themselves as useful means of coupling liquid chromatographs and mass spectrometers. They can be used by separation scientists to solve real problems. They operate at flow rates that are close to those used conventionally by chromatographers and they produce electron impact spectra.

We have designed a compact particle beam interface based on an ultrasonic nebulizer. Figure 1 illustrates the design. Features of this design are that it can operate at flow rates lower than 50 µl/min and that good performance is obtainable during a gradient run without the need for readjustment of interface parameters. Figure 2 shows data we obtained in an interlaboratory method validations study for EPA method 553 for the determination of benzidenes and nitrogen-containing pesticides by LC/MS.

Figure 1

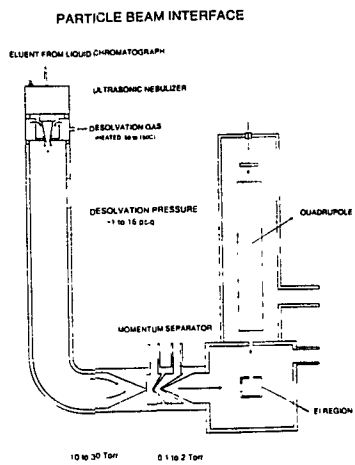

Figure 2

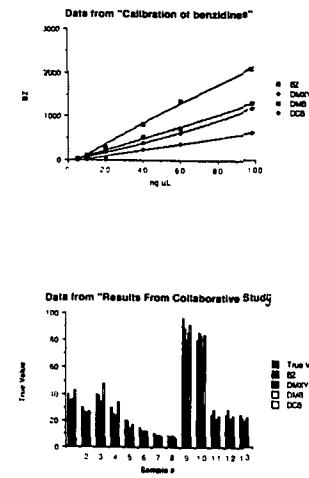

Electrospray interfaces have proven to be particularly useful for the analysis of large biomolecules. We have experimented with several different permutations of electrospray interface geometries. We have obtained data from a variety of different samples including proteins, peptides and acetylated carbohydrates. Collision-induced dissociation provides useful structural information for small peptides and other small molecules.

The different interface geometries we have used all exhibit comparable sensitivity. This raises interesting questions about where the various steps thought to be involved in ion generation actually occur.

By using an electrospray capillary made of electrically insulating material, we can cover a wide range of operating parameters because the threshold field at which electrical breakdown occurs is much higher with insulating tips than with metal tips :

Thus, on the one hand, when the material used is glass we can readily manufacture capillaries with tips fine enough so that usable electrosprays can be generated with an applied electrical potential difference of as little as 775 V with flow rates of about 1 µl/min.

On the other hand, with somewhat larger tips made with insulating materials, or with metal tips covered with an insulating layer, we find that we can apply tip voltages as high as 20 KV. This permits us to successfully electrospray at flow rates as high as 20 µl/min without the need for pneumatic or thermal assist. In addition, it is possible to electrospray high water content solutions (97% water, 3% acetic acid).

Finally we have developed a technique that allows one to do LC/electrospray/MS while keeping both the LC and the MS at or close to electrical ground. We do this by interposing a grid between the electrospray capillary and the entrance orifice to the interface. By applying a time modulated electrical potential to this grid it is possible to produce bursts of spray which travel towards the grid.When the burst of spray is in the vicinity of the grid the electrical potential on the grid is reversed such that the charged spray burst now find itself driven on towards the entrance orifice. One version of this scheme is illustrated in Figure 3 along with a spectrum of cytochrome C obtained in this manner.

This same technique can usefully be applied to other nebulization techniques in which a charging voltage is needed. In addition, the ability to rapidly modulate the generation of an electrospray has clear utility in minimizing the effects of duty cycle in mass analysis techniques such as time-of-flight or ion trap MS/MS.

Capillary Electrophoresis - Electrospray Ionization Mass Spectrometry in Small Diameter Capillaries

Jon H. Wahl, David R. Goodlett, Harold R. Udseth, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P.O. Box 999, Richland, WA 99352

Currently, a major effort in our laboratory involves exploring methods to increase analyte sensitivity in capillary electrophoresis - electrospray ionization / mass spectrometry (CE-ESI/MS). The goal of this research involves the examination of small inner diameter capillaries for increased sensitivity in CE-ESI/MS.

Commonly in ESI/MS two detection regimes exist. First, at high analyte mass flow rates into the electrospray source an ESI limited detection regime exists; where, the electrospray source is saturated. Second, at low analyte mass flow rates an analyte limited regime is present. One effective means of reducing the mass flow rate and consequently work in the analyte limited regime incorporates the use of small inner diameter (i.d.) capillaries.

The experimental system used for these studies incorporates a modified triple-quadrupole mass spectrometer (Sciex TAGA 6000E), and an in-house built capillary electrophoresis system. In all studies, aminopropylsilane coated fused-silica capillaries of various i.d.'s are used. The buffer system used is a 10 m$\underline{M}$ acetic acid solution, pH = 3.4. All samples are electrokinetically injected

The solute mixture chosen for the initial study contains tryptophan (204 Da), leucine-enkephalin (555 Da) and melittin (2845 Da) with serial dilutions at ratios between 1:2 and 1:50. The separation for this mixture is performed with capillary i.d.'s of **100**, **50**, **20**, and **10** μm. The mass spectrometer is used in the selected ion monitoring mode. The results for melittin are summarized in Figure 1 where the solute peak area is shown as a function of amount injected. In general as the capillary i.d. is reduced from 100 to 10 μm, an increase in solute sensitivity occurs; where, for the 10 μm i.d. capillary, ~**150 attomoles** of melittin is detected. Moreover, a four component protein mixture, which contains the solutes aprotinin (6.5 kDa), cytochrome c (12 kDa), myoglobin (17 kDa), and carbonic anhydrase (29 kDa) each at 30 μM, is separated using capillary i.d.'s of **50**, **20**, **10**, and **5** μm. The separations obtained for 50 and 5 μm i.d. capillaries and the extracted **full scan** mass spectra obtained from the **5** μm i.d. case are illustrated in Figure 2. In general from Figure 2, the relative signal intensity decreases only by approximately **half** in comparing the **50** and **5** μm i.d.'s; however, the relative amounts injected differ from **60 femtomoles** to **600 attomoles**.

Consequently, we have demonstrated that an increase in the solute sensitivity occurs when small i.d. capillaries (<**20** μm) are utilized in CE-ESI/MS for both a peptide and a protein mixture. Small i.d. capillaries provide an effective means of reducing mass flow rate to the ESI source without degradation of separation resolution or analysis time.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830

COMPARISON OF THERMOSPRAY AND ELECTROSPRAY LC-MS TECHNIQUES FOR ANALYSES OF GLYCOSIDES AND RELATED COMPOUNDS

*C.H. Vestal and Y.P. Wang,
Vestec Corporation, 9299 Kirby Drive, Houston, TX. 77054

[INTRODUCTION]

Applications of LC-MS, particularly in the pharmaceutical industry, often involve mixtures of compounds with a wide range of volatilities, polarities, and molecular weights. No single mass spectrometric technique has been found which is universally applicable to all such analyses, and in practice several different techniques may be required, depending on the type of sample and the results needed. In the present work thermospray with reversed phase separation using conventional 4.6 mm columns is reported for the analysis of a series of aminoglycosides (AMIKACIN, KANAMYCIN A, TOBRAMYCIN, NOVOBIOCIN, SPECTINOMYCIN, GENTAMYCIN COMPLEX, and NEOMYCIN B) and cardiac glycosides (DIGITOXIGENIN and DIGITOXIN). Aminoglycopeptide such as VANCOMYCIN is very difficult to analyze by thermospray technique, therefore the features of the electrospray interface make it worth investigating for this class of compounds.

[EXPERIMENTAL]

Thermospray (TS) LC-MS work was done using a Vestec Model 201 Dedicated MS System coupled to a Waters 600MS Multisolvent Delivery System on a DuPont Zobax-ODS, 4.6 mm I.D. x 250 mm L. column with 5 micron particle size at a flow rate of 1.0 and 1.2 mL/min. Mobile phase for the analysis of a mixture of NEOMYCIN B and GENTAMYCIN COMPLEX is a 20 minute linear gradient from 100% deionized water containing 0.1M ammonium acetate and 1% acetic acid to 30/70 water/methanol with the same buffer present. An isocratic separation was employed for a mixture of DIGITOXIGENIN and DIGITOXIN by using 45% of acetonitrile in 0.1M ammonium acetate and 0.1% acetic acid aqueous solution as mobile phase. The LC separation of a mixture of AMIKACIN, KANAMYCIN A, TOBRAMYCIN, SPECTINOMYCIN, and NOVOBIOCIN was accomplished by using 100% deionized water with 0.1M ammonium acetate and 0.05% acetic acid held for 2 minutes, then a 7 minute linear gradient to 100% acetonitrile. The mass spectrometer was used both in the positive ion and negative ion modes with filment-off or discharge ionization.

For electrospray (ES) analysis, the samples were dissolved in 50/47/3 water/acetonitrile/acetic acid and infused at 1.6 and 3.8 microliter/min with a Sage syringe pump into the mass spectrometer, operated in the positive ion mode.

[RESULTS and DISCUSSION]

The quality of TS and ES spectra of the samples analyzed is summarized in Table I. Under the TS conditions described protonated molecular ions predominated for all analytes except AMIKACIN, DIGITOXIN, and VANCOMYCIN which strong fragment ions were observed. The ES spectrum consisted of a base peak at triply-charged molecular ions for AMIKACIN, KANAMYCIN A and TOBRAMYCIN, doubly charged ions for NEOMYCIN and VANCOMYCIN, and singly charged ions for NOVOBIOCIN and SPECTINOMYCIN. Figure 1 shows a example of the TS and ES spectra of TOBRAMYCIN which indicates the consecutive losses of aminosugars from the both sides of the molecule.

The peak broading and tailing of GENTAMYCIN A & C components and TOBRAMYCIN is shown in Figures 2 and 3, however improvement of the peak resolution are needed to achieve better sensitivities on column for the analysis of these compounds.

It is very difficult to obtain molecular ions for the thermally labile compounds by thermospray with conventional 125 micron diameter vaporizer. Figure 4 shows the comparison of TS spectra using 125 and 75 micron vaporizers for DIGITOXIN.

The effect of repeller voltage on the ES spectrum of VANCOMYCIN generated from infusion at 3.8 uL/min is shown in Figure 5. There are more doubly charged ions (at m/z 725.5) obtained with repeller at 10 V than at 20 V and with equal amount of the protonated molecular ions (m/z 1450.25).

[CONCLUSIONS]

In general, the results show that electrospray is more sensitive in that smaller absolute amounts of sample are required, particularly for the more polar samples of higher molecular weight such as VANCOMYCIN, but that thermospray often gives a wider dynamic range which allows trace components

to be detected at lower concentrations than with electrospray.

The initial studies of these compounds will allow us to do further work on direct, on-line identification and quantitation of these drugs in complex biological matrices.

Ion Spray Liquid Chromatography/Mass Spectrometry from the Viewpoint of the Liquid Chromatographer.

Gérard Hopfgartner, Jack D. Henion ,
Drug Testing and Toxicology, NYS College of Veterinary Medicine, Cornell University, 925 Warren Dr., NY 14850

INTRODUCTION

Ion Spray (IS) is particularly suitable for the combination of liquid chromatography and mass spectrometry. It is generally accepted that IS works best with a high content of organic solvents and low concentrations of volatile buffer. However, in some cases these solvent systems are not satisfactory for the chromatographic separations of basic compounds such as lysergic acid diethyl amine (LSD). One alternative would be to use triethylamine or alkali phosphate buffers to improve chromatographic peak shape. In this paper we have studied the sensitivity of the MS response using phosphate buffers.

EXPERIMENTAL

The mass spectrometers used in this work were a Hewlett-Packard Model 5985B and MSD-5970 modified in-house for atmospheric pressure ionization (see for example ref. 1).The HP-5985B is differentially pumped and is equipped with a high energy dynode (HED) detector which significantly increases its sensitivity. HPLC was performed on a 5 µm Zorbax SB-CN or a Zorbax RX C_{18} (4.6 x 150 mm)

The solvent systems investigated :

a) Acetonitrile/Water (50:50) 5 mM Ammonium Acetate, Formic Acid pH = 4.5
b) Acetonitrile/Water (40:60) 5 mM Ammonium Acetate, 5 mM triethylamine
c) Acetonitrile/Water (50:50) 10 mM K_2HPO_4/H_3PO_4, pH = 3.2
d) MeOH/Water (50:50) 10 mM K_2HPO_4/H_3PO_4, pH = 3.2

RESULTS

The addition of 5 mM triethylamine in the mobile phase can dramatically improve chromatographic peak shape. However, it suppresses (about 10 times) the ion current response of the analyte and is not appropriate for Ion Spray LC/MS applications.

One of the powerful features of atmospheric pressure interfaces is the ability to perform "Up-Front" collision-induced dissociation (CID) experiments. In our case CID is achieved by increasing the potential difference between the ion sampling capillary and the skimmer (Δ CID voltage). The CID mass spectra are similar to those obtained by MS/MS and are very useful for the specific detection of an analyte. For LSD four ions were selected : m/z=324,281,223,208.

Using acetonitrile/water 5 mM ammonium acetate/formic acid we observed the pseudo-molecular ion of LSD (MH^+=324) at low Δ CID voltage as well as two intense cluster ions (m/z = 59, 100 $(CH_3CN)_nNH_4^+$ n=1,2). When this potential was increased the intensity of these ions decreased prior to fragmentation of MH^+. For the acetonitrile/phosphate buffer system we observed a similar pattern (m/z = 80,121 $(CH_3CN)_nK^+$ n=1,2). However, when a methanol/phosphate buffer was used we did not observe the predominance of some specific solvent clusters.

We recorded, for the three mobile phases, the full-scan mass spectrum versus Δ CID voltage . In all three cases we obtained the same spectra without any LSD solvent adducts. A plot of the CID ion current profiles for 4 ions (m/z= 324,282,223,208) of LSD did not show any

major changes in the signal intensities. Therefore, there is no difference qualitatively or quantitatively in the MS response for the volatile buffer or for the phosphate buffer which allows more flexibility to the chromatographist to achieve the desired separations.

High-flow IS can handle flow rates up to 1 ml/min without post-column splitting, but at these higher flows the excess HPLC effluent can condense and adversely affect sensitivity and ion current stability. To avoid this problem we have placed a grounded lens orifice (liquid shield lens) at approximately 5 mm from the ion sampling capillary (ref. 2). Using this system we were able to analyze LSD by LC/CID-MS with a standard HPLC column at a flow rate of 1 ml/min with acetontrile/water 50:50 10 mM phosphate buffer as eluant without splitting.

CONCLUSIONS

The heated capillary and the liquid shield lens is a very rugged combination for LC/CID-MS applications with all types of HPLC columns and both volatile and non-volatile LC buffers. This capability should be of considerable interest to the practicing chromatographer since less effort will be required to match HPLC conditions to the requirements of the mass spectrometer.

High Flow Electrospray Interface for Liquid Chromatography/Mass Spectrometry

Minoru Sakairi and Hideki Kambara,
Central Research Laboratory, Hitachi Ltd.,
Kokubunji, Tokyo 185, Japan.

Recently, much attention has been paid to electrospray ionization method, because of highly sensitive detection of multiply charged ions of peptides, proteins and so on. However, in this method, only low flow rate of mobile phase can be used except for the ion spray technique which is pneumatically assisted electrospray. This feature of electrospray is not so convenient for combining electrospray mass spectrometry with semi-micro or conventional liquid chromatography which is widely used, because peak broadening becomes serious problem.

From this point of view, we have tried to modify an electrospray ion source to the ion source which can accommodate a wide flow rate range of mobile phase. For this purpose, we have prepared three electrospray modes, which are a low flow mode(~0.001mL/min), a middle flow mode(~0.05mL/min) and a high flow mode(~0.2mL/min). The high flow electrospray interface is shown in Figure 1. We could not find deterioration of multiply charging condition, ion intensity and stability in a wide flow rate range of 0.001-0.3 mL/min, as shown in Figure 2. By using this new electrospray interface, we can easily combine electrospray mass spectrometry with semi-micro or conventional liquid chromatography.

In addition, we have designed the atmospheric pressure ionization (API) interface with atmospheric pressure spray with electron impact (APEI), atmospheric pressure chemical ionization (APCI), atmospheric pressure spray ionization (APSI) and electrospray ionization (ESI) mode. The LC/MS system equipped with these four API modes has several great advantages. Firstly, by using these API modes, we can measure a great variety of organic compounds from hydrocarbons with low polarity to proteins with high polarity in one LC/MS system. Secondly, these API ion source resemble each other, which results in easy exchange from one mode to other mode. Thirdly, these API interfaces can be easily combined with conventional LC.

Confirmation of Danofloxacin Residues in Poultry and Cattle Liver by Microbore HPLC-Tandem Atmospheric Pressure Ionization Mass Spectrometry

R.P. Schneider, J.F. Ericson, M.J. Lynch, and H.G. Fouda. Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340.

A specific assay is described for the confirmation of danofloxacin residues in edible tissues of cattle and chicken. The assay utilizes on-line microbore HPLC and pneumatically assisted electrospray tandem mass spectrometry. Collision induced dissociation (CID) of the danofloxacin protonated molecule results in two significant daughter ions. Monitoring both ions provides the specificity required for a confirmatory assay.

Optimization of the electrospray and MS/MS operating conditions permitted the specific monitoring of danofloxacin and the confirmation of its residues in poultry and cattle liver extracts down to 50 ppb. The analysis of control liver or of other commercially available antibacterial quinolones (enrofloxacin and ciprofloxacin) gave no response under the assay conditions. The ratios of the two daughter ions were similar for danofloxacin standard solutions, fortified tissues, and incurred tissues.

Danofloxacin is a novel fluoroquinolone antibacterial agent for the treatment of respiratory diseases in food producing animals. To satisfy regulatory requirements, a specific assay was developed for the confirmation of its residue in edible tissue of cattle and chicken. The assay utilized on-line microbore HPLC and pneumatically assisted electrospray mass spectrometry. Danofloxacin produces a single protonated molecule (M+1; m/z 358) under positive ion electrospray conditions. Preliminary results indicated that the addition of 0.1% trifluoroacetic acid to the mobile phase produced a 4 fold increase in danofloxacin response under selected ion monitoring conditions. Collision induced dissociation (CID) of danofloxacin provided additional structural information and enhanced specificity. The CID of the protonated molecule results in the production of two significant daughter ions, one representing intramolecular dehydration (m/z 340). The other daughter ion represents an intramolecular dehydration, decarboxylation and the additional loss of the cyclopropane ring system (m/z 255). The CID spectra of danofloxacin is shown in Figure 1. Monitoring these dissociation products provided the added measure of specificity required for a confirmatory assay.

The present method allows the confirmation of ≥ 50 ppb danofloxacin in poultry and cattle liver extracts. Representative chromatography and mass spectral results of fortified cattle liver are shown in Figure 2. Five replicates of fortified, blank, and incurred tissue samples were analyzed. The analysis of control liver or of other commercially available antibacterial quinolones (enrofloxacin, ciprofloxacin) gave no response under the assay conditions. The ratios of the two monitored daughter ions were similar for danofloxacin standard solutions, for fortified tissues, and for incurred tissues. The likelihood of a compound other than danofloxacin giving rise to two significant daughter ions following CID is improbable. The specificity of the assay is further enhanced by on-line HPLC analysis.

FIGURE 1. CID Daughter Spectrum of Danofloxacin

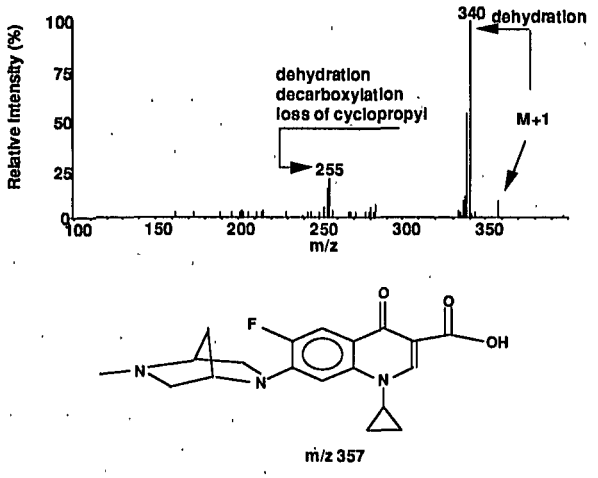

FIGURE 2. Microbore HPLC/MS/MS Selected Reaction Monitoring Chromatogram of a Fortified (50 ppb) Cattle Liver Sample. Signal for the Two Daughter Ions at m/z 340 and m/z 255.

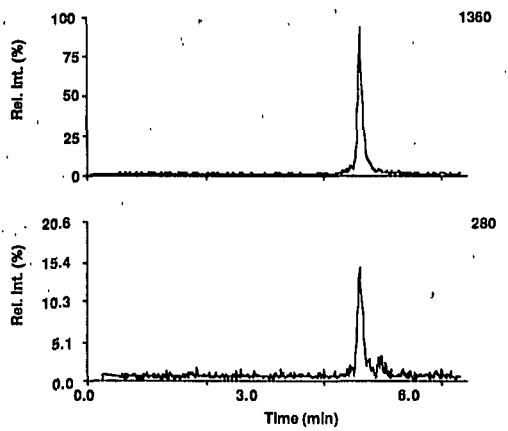

Analysis of Normal and Abnormal Hemoglobins by Liquid Chromatography/High Flow Electrospray Mass Spectrometry

Minoru Sakairi and Hideki Kambara,
Central Research Laboratory, Hitachi Ltd.,
Kokubunji, Tokyo 185, Japan.

Peptide mapping is widely used for the structural or mutation analysis of proteins. Recently, peptide mapping combined with electrospray mass spectrometry has become an established and powerful tool for this analysis. The peptide mapping method using electrospray mass spectrometry is divided into two types:(a) direct peptide mapping method1) and (b) LC/MS peptide mapping method2). In the former method, the procedure involves complete or near complete digestion of the protein with TPCK-treated trypsin or other protease and determination of the molecular weights of the tryptic digests using electrospray mass spectrometry without any chromatographic separation. In the last one, the resultant tryptic digests are analyzed by LC/MS. In both methods, disagreement between the tryptic digests of normal and abnormal proteins provides information concerning the location of variation.

As one example, we have investigated the utilization of the two peptide mapping methods for clearly showing the point mutation of sickle cell hemoglobin (Hb-S) by using the modified electrospray mass spectrometer which can accommodate a wide flow rate range (0.001-0.3 mL/min). In this mass spectrometer, both direct peptide mapping combined with low flow mode and LC/MS peptide mapping with high flow mode are carried out. In both peptide mapping methods, the presence of all amino acids residues was confirmed in normal hemoglobin (Hb A) and Hb S spectra by completely and incompletely tryptic digests. The disagreement of the tryptic digests between Hb A and Hb S was only one fragment (B1), which consists of residues 1 to 8 of the beta chain, with the sequence Val-His-Leu-Thr-Pro-Glu-Glu-Lys in Hb-A, but Val-His-Leu-Thr-Pro-Val-Glu-Lys in Hb S. The observed molecular weight difference between the B1 fragments of Hb A and Hb S was 30. This difference clearly corresponds to the variation from glutamic acid to valine in Hb S. Therefore, we could confirm the point mutation of Hb S, taking into consideration that all the other fragments were perfectly identical in the two proteins, Hb and Hb S. Finally, we have found that the direct and LC/MS peptide mapping method using electrospray mass spectrometry are very powerful as a peptide mapping method.

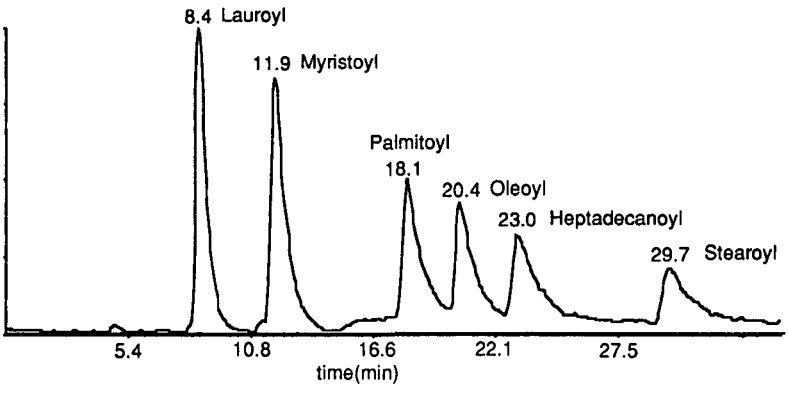
LC-MS AND LC-MS-MS CHARACTERIZATION OF LYSOPHOSPHATIDYLCHOLINES AND ACYLCARNITINES PRESENT IN THE ISCHEMIC REGION OF DOG HEARTS

Bethanne M. Warrack, S.C. Taylor, O. Vesterqvist, M.L. Ogletree, and G.C. DiDonato
Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, NJ

INTRODUCTION Accumulation of amphipathic compounds, such as lysophosphatidylcholines (LPC) and acylcarnitines (AC), during myocardial ischemia may contribute to dysfunction and electrophysiological derangements. These compounds contain no UV chromophore and are not easily detected by conventional HPLC; however, a quantitative method for measurements of LPC molecular species in rat cardiac tissue using an HPLC equipped with an evaporative laser light scattering detector has been developed(1). LC-MS and LC-MS-MS were used to identify AC as interfering peaks observed during HPLC measurements of LPC in the ischemic region of canine hearts. This method can also be used for analysis of lysophosphatidyl ethanolamines (LPE) and plasmenyl-LPEs.

EXPERIMENTAL Hearts were excised from mongrel dogs and a portion (about 5 g wet weight) of the non-ischemic and ischemic region was immediately frozen in liquid nitrogen. The tissue was then freeze-dried and pulverized. Lipids were extracted from canine myocardial tissue with methanol and chloroform (1,2). The lipids were then applied to a Bond-Elut cartridge and the LPC fraction was eluted. The total mass of the LPC fraction was less than 50 µg. A Waters 600E HPLC system was used. Separation of eleven long-chain AC and seven LPC was achieved in under 30 minutes using a YMC Basic column, 250 x 4.6 mm. The mobile phase consisted of 55:25:20 methanol: acetonitrile: water (0.1% TFA), at a flow rate of 0.7 ml/min. Flow splitting was employed to deliver 35 µl/min to the mass spectrometer. Ion spray spectra were obtained on a Sciex API III mass spectrometer. Zero grade air was used as the nebulization gas. For MS/MS experiments, collisions were 80 eV with argon.



RESULTS Ion spray spectra showed intense pseudomolecular ions, providing molecular weight information for AC, LPC, LPE, and plasmenyl-LPE. LC-MS-MS spectra exhibited the characteristic product ions for AC at m/z 85 and 144. Product ion spectra for LPC showed characteristic ions at m/z 86, 104, 125, and 184. Comparisons of LC retention time and product ion spectra for components in the extract with those of standards confirmed the identifications. Flow injection analysis combined with precursor ion scans, monitoring m/z 85 for AC and m/z 184 for LPC, provides rapid screening for the presence of AC and LPC in extracts. Product ion spectra for LPE and plasmenyl-LPE contain a common product ion at m/z 44. Flow injection analysis using precursor ion scans for m/z 44 can be used to screen for the presence of LPE and plasmenyl LPEs.

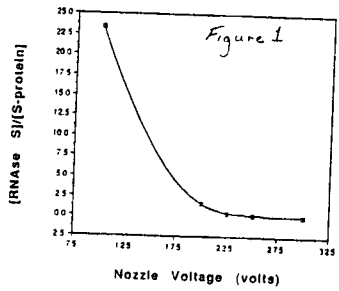
Use of Capillary Electrophoresis/Electrospray Ionization-Mass Spectrometry to Investigate Liquid and Gas Phase Protein Conformation

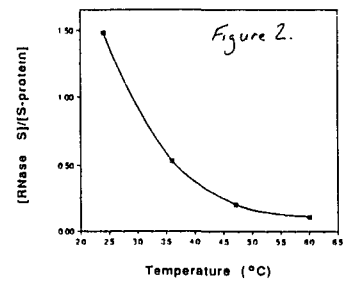
David R. Goodlett, Jon H. Wahl, Harold R. Udseth,
Rachel R. Ogorzalek Loo,Joseph A. Loo, and Richard D. Smith,
Chemical Sciences Department
Pacific Northwest Laboratory
P. O Box 999, Richland, WA 99352

Early ESI-MS studies of proteins suggested that secondary, teriary, and quaternary structures were lost during ESI. However, these studies focused on conditions designed to enhance signal at the expense of such structural features. Recent ESI mass spectra of proteins dissolved in solutions of varying pH indicated that the charge state distribution of gas phase protein ions could be affected by controlling liquid-phase parameters. This suggests, but does not prove, the possibility of transfer of solution protein conformation into the gas phase.

Noncovalent interactions between biological molecules are of general interest due to the ubiquitous nature of such reactions where molecular recognition is critical for survival and reproduction. Examples where noncovalent molecular recognition is important for biological function include: double stranded nucleic acids, transfer RNA folding, antigen-antibody complexes, lipid bilayers, enzyme-substrate complexes, and protein folding. If the specificity of binding that exists in solution can be transferred into the mass spectrometer, then the sensitivity of mass spectrometry can be used to investigate a wide range of biological processes.

The model compound for these studies was bovine pancreatic ribonuclease S (RNase S) an enzyme produced by cleavage of one amide bond (either 20-21 or 21-22) in RNase A. Ribonuclease S (M_r = 13,682) is a noncovalent complex, which under certain conditions dissociates into S-peptide (M_r = 2,166; RNase A amino acids 1-20) and S-protein (M_r = 11,534; RNase A amino acids 21-124). Both RNase A and RNase S are capable of hydrolytic cleavage of ribonucleic acids. Enzymatic activity is lost when the noncovalent interaction between S-peptide and S-protein is disrupted. Dissociation occurs readily at acidic pH and at temperatures above 30 °C.





We report the use of collisionally activated dissociation, thermal denaturation in solution, and capillary electrophoresis to affect the ratio of [ribonuclease S]/[S-protein] ions measured by ESI-MS. By Varying the voltage difference between the nozzle-skimmer interface on our in-house built mass spectrometer, the ratio of RNase S/S-protein ions measured by ESI-MS can be affected (Figure 1). Thermal denaturation of RNase S incubated in a fused-silica capillary on-line with ESI-MS allows control of the degree of dissociation in solution prior to analysis by ESI-MS (Figure 2). Ribonuclease S can be dissociated into S-protein and S-peptide during acidic CE/ESI-MS (Figure 3). Figure 4 is a mass spectrum of RNase S in distilled-deionized water obtained with a 100 volt nozzle-skimmer bias.

Finally, ion intensity values from thermal denaturation studies (liquid phase) for all observed charge states of RNase S and S-protein (gas phase) can be used to determine an enthalpy of dissociation. It was found that the enthalpy has a dpependence upon the nozzle-skimmer bias; an observation that is being investigated further. Values for enthalpy of dissociation were $\Delta H_{diss.} = +20$ kcal/mol when $V_{nozzle} = 200V$ and $\Delta H_{diss.} = +48$ kcal/mol when $V_{nozzle} = 150V$.

Thus the noncovalent interaction of S-peptide with S-protein in solution can be transferred to the gas phase under conditions where 1) the solution chemistry is favorable for tight binding i.e neutral pH and 2) the ESI-MS interface conditions do not induce further dissociation over what is present in solution.

Improved Methods for the Determination of Veterinary Drugs using Nanoscale Separation Techniques in Combination with Electrospray Mass Spectrometry.

John R. Perkins, Carol E. Parker and Kenneth B. Tomer,
Laboratory of Molecular Biophysics, NIEHS, Research Triangle Park, NC 27709.

Introduction

In animal husbandry and fish farming veterinary antibiotics may be administered to livestock for therapeutic purposes or to promote growth. Absorption of the drugs in tissues may occur such that when the half life of the drug is sufficiently long then there is a risk of the presence of residues in tissues prepared for human consumption. The low levels at which these drugs may be present in tissues mean that sensitive analytical methods are required for their screening.

We have previously demonstrated the application of nanoscale capillary liquid chromatography (nCLC) using 2 m x 75 μ i.d. packed capillary columns packed to a depth of 25cm with 10 μ AQ C-18 and capillary zone electrophoresis (CZE) using 75 μ i.d. fused silica capillaries in conjunction with electrospray (ESI) mass spectrometry for the determination of sulfonamides, quinolone carboxylic acids and tetracyclines. These techniques utilize sub-microliter flow rates so sample consumption is limited. The make up flow (50:50 methanol : 3% acetic acid) required for stable operation of the electrospray source is provided through the electrospray probe via a co-axial arrangement. Water containing 0.1% TFA was solvent A throughout the nCLC work and solvent B was acetonitrile containing 0.1% TFA. The buffer employed for CZE of sulfonamides and quinolone carboxylic acids was ammonium acetate at various pH's. CZE of the tetracyclines was performed on a 3-aminopropyltrimethoxysilane derivatized column with acetic acid (pH 3.5) as the buffer. The mass spectrometer used throughout the experimental work was a VG 12-250 quadrupole with a Vestec electrospray source and controller.

Results and Discussion

Skimmer induced dissociation of compounds to produce CAD type spectra during the electrospray process has been well documented[1]. We were interested in whether it could be used to impart additional information for sample characterization during on line experiments. The fragmentation of the sulfonamides all follow the same pathways. This can be used to differentiate between sulfonamides and other compounds within a mixture. Sulfamethoxazole and trimethoprim are frequently coadministered and during their determination sulfamethoxazole shows typical ions at m/z=92, 108, 156 whereas trimethoprim does not. Additionally the sulfonamides (with the exception of sulfadimethoxine) each show unique ions due to the $(R+NH_3)^+$ ion (corresponding to loss of 155) from the $(M+H)^+$ species. The tetracyclines only show simple losses of H_2O and/or OH from the protonated molecular ion at low voltages but this can provide sufficient discrimination between species. Doxycycline and tetracycline both show a $(M+H)^+$ ion of m/z=445. At a skimmer voltage of +11 V doxycycline shows loss of an OH group whereas tetracycline shows loss of H_2O and subsequent loss of OH to yield an ion of m/z=410. During separations monitoring m/z=410 readily identifies the presence of tetracycline rather than doxycycline.

A problem observed during ESI/MS of low molecular weight compounds is the presence of interfering cluster ions. For example sulfamerazine yields a large signal but during nCLC and CZE/ESI/MS experiments it was obscured by a cluster ion of m/z=264 thus worsening detection limits. Skimmer induced dissociation can help surmount this problem as indicated by nCLC experiments with fish extracts spiked with the quinolone carboxylic acids. The $(M+H)^+$ ion of nalidixic acid of m/z=233 was obscured but monitoring the ion resulting from loss of H_2O allowed easy detection.

One potential drawback is the decreased sensitivity at higher skimmer voltages. However, in our laboratory, all our nCLC injections are performed by timed pressure injections with subsequent preconcentration of the sample at the head of the column. For increased sample loading the time of injection is increased to yield sufficient signal from the mass spectrometer. This also simplifies analysis of dilute samples and we have utilized this approach for the analysis of fish extracts[2] spiked with different concentrations of quinolone carboxylic acids. For a sample corresponding to 1 ppm of each acid (0.05 mg/ml in solution) our injection time was four minutes on column (~35 pmole of each acid). Good signal:noise was obtained (Figure 1). The same experiment was performed for a sample corresponding to 100 ppb of each. Following an injection of 40 minutes the

chromatographic run was commenced. Sensitivity was poorer but the compounds of interest were demonstrably present. The broader peak shapes may have resulted from deterioration of the analytical column.

Of further interest is the refinement of CZE methodologies in the laboratory. Previously we have shown full scan CZE/ESI/MS experiments using 75 μ i.d., 150 μ o.d. columns. We found that this approach suffered due to column fragility combined with insensitivity. Modification of the CZE probe to accomodate 75 μ i.d., 360 μ o.d. columns and optimization of the column position has rendered CZE/ESI/MS mechanically more sound and consequently easier to perform. Additionally full scan data provided little more than molecular weight information for the compounds of interest so subsequent experiments have employed single ion monitoring and femtomolar amounts of antibiotics can be readily observed.

NCLC and CZE are complementary techniques as particularly demonstrated by the sulfonamides. The isomeric pair of sulfamethoxypyridazine and sulfameter could not be separated using nCLC but were readily resolved by CZE. The isomeric pair of sulfamethazine and sulfisomidine could be separated by nCLC but not CZE. Additionally during numerous nCLC/ESI/MS experiments we have never observed sulfanilamide but CZE/ESI/MS provides a means of on line detection.

2. Department of Chemical Analysis and 3. Department of Microbiology, Tokyo College of Pharmacy, Tokyo 192-03, Japan

Penicillins, and the structurally-similar cephems, are important antibiotics for both human and animal use. Seventeen penicillins and cephems (cephalosporins and cephamycins) were examined by positive ion ESI/MS. FIA spectra of each compound at +11 and +40 skimmer voltages were collected. Separations by nanoscale packed capillary liquid chromatography (nCLC), using 75 μ id columns packed with 10 μ C18 packing material and sub-microliter flow rates, were performed using methanol:water and acetonitrile:water (0.1% TFA) gradients. The mass spectrometer/data system used was a VG 12-250 quadrupole MS and data system (VG/Fisons, Altrincham, UK). The probe used was of coaxial flow design, and has been described elsewhere.

While penicillins and cephems show extensive fragmentation, even at low skimmer voltages, protonated (or sodiated) molecular ions are present at significant relative abundance. Fragmentation pathways for the penicillins and cephems are similar to those reported in EI, CI, FAB, TSP, and FD. Penicillin fragmentation occurs across the B-lactam ring, to give $[b+H]^+$ ions, and along the B-lactam ring sidechain (d^+, e^+, and f^+). Also present in the penicillins are fragments $\underline{h}^+$, and ions resulting from the loss of the $\underline{h}$ group from the molecular ion and from the $(a+H)^+$ ion. These fragment ions, containing useful structural information, increase in relative abundance with increasing skimmer voltage.

Significant fragmentation occurs across the B-lactam ring to give a fragment corresponding to $[c\text{-}H]^+$. This fragmentation pathway has also been observed in FAB and EI. A fragmentation occurring across both rings, which was reported as a major fragmentation pathway in EI, and has been observed in FAB, is only a minor pathway in the electrospray mass spectra of penicillins and cephems. Cephems show more extensive formation of the $[a+H]^+$ ion than do the penicillins, but show less fragmentation to give $[c\text{-}H]^+$. Cephalosporins and cephamycins, of course, have no R_4 group, so pathways involving this group cannot occur. Spectra and fragmentation pathways for Cephalothin (CET) are shown in Figures 1.

The nCLC columns used are reversed-phase columns, and both H_2O/CH_3CN and $H_2O/MeOH$ gradients were used for the separations. At the column flow rate used (~0.8 μL/min), a sheath flow consisting of 50:50 methanol:3% aqueous acetic acid was used at a flow rate of 10 μL/min. Separations were performed in $CH_3OH:H_2O$ and $CH_3CN:H_2O$ (both containing 0.1% TFA). Since these compounds are not particularly sensitive by ESI (or by any other mass spectral technique), long injection times (to concentrate the samples on the front end of the column) were used, with a gradient to elute the compounds. Figure 2 shows the separation of a mixture of cephems.

Identification of these compounds from on-line LC/ESI/MS spectra is much more difficult than from the FIA analyses. On-line spectra, which are obtained on a much more dilute sample and in the presence of varying concentrations of mobile-phase components often show significant levels of adduct formation, leading to ions above the molecular weight. Depending on the mobile phase, additions of sodium, methanol, and other mobile-phase components may occur, and the protonated molecular ion may be absent from the spectrum. Extensive formation of an adduct ion 82 daltons above the protonated molecular weight was observed in the CH_3CN/H_2O (0.1% TFA) LC/MS analyses. At first this adduct was thought to result from the addition of 2 molecules of CH_3CN, but this adduct ion was also observed for several compounds in the CH_3OH/H_2O separations. Studies on the $(M+H+82)^+$ ion from brevetoxin and tetrodotoxin, which also formed with no CH_3CN in the mobile phase, indicate that this adduct may be $(M+H+NaOAc)^+$. Similar adduct formation has been noted in the ESI spectra of bile acids. Awareness of this process is important to avoid incorrect identification. The presence of the fragment ions, especially the $[M+H\text{-}(\underline{h}+H)]^+$ ion from cephems, is also very useful for compound identification.

Assessing Structural Alterations in Natural and Recombinant Proteins by RP-LC/ESI MS

Francis Bitsch[1], H. Ewa Witkowska[1], Kerry Nugent[2], David King[3] and Cedric H.L. Shackleton[1]
1 Children's Hospital Oakland Research Institute, Oakland, CA USA
2 Michrom BioResources Inc., Pleasanton, CA USA
3 Howard Hughes Medical Institute, University of California, CA USA

ESI MS is an extremely valuable technique applied to component analysis of simple mixtures of biologically-derived proteins as well as recombinant proteins. We find that ESI MS is the method of choice for ascertaining protein purity and post-translational modifications, verifying structure, determining degree of processing (*i e.* removal) of the initial methionine of recombinant proteins, and monitoring Met oxidation to Met sulfoxide, a frequently-encountered problem with recombinant proteins. On-line separation/mass analysis considerably extends the versatility of ESI MS of protein mixtures.

HPLC/ESMS of proteins has to meet stringent criteria of resolution and sensitivity. In particular it is important to preserve chromatographic resolution between the UV and mass spectrometric detectors and to ensure accurate MW determination of proteins at low picomole level. We found that a combination of a Michrom BioResources HPLC system (Michrom BioResources Inc., Pleasanton, CA USA) and a VG BioQ quadrupole mass spectrometer (VG BioTech, Altrincham, UK) equipped with a modified interface, comes very close to meeting those criteria. Michrom HPLC system is interfaced with the VG BioQ mass spectrometer through a modified VG probe which allows for mixing a column eluate (flow rate 4 µl/min) with a sheath liquid (0.2% TFA in MeOH, flow rate 2 µl/min) prior to nebulization. HPLC separations are typically run at the flow rate 40 µl/min and splitting 10:1 of the flow is achieved directly in the UV cell. Proteins are separated on a 1mmx150mm Vydac C-4 column (300 Å particle size) using linear gradients of acetonitrile in 0.1% TFA. The electrostatic source of a VG BioQ is operated at 3.2 kV, the nozzle to skimmer bias is typically 55 V, and the resolution is adjusted to achieve a 1.5-2 Da width of the myoglobin m/z 998 peak on the base .

The system is particularly useful for: 1) Monitoring peptide/protein purification, 2) Assessment of protein purity 3) Detection of mutations/modifictions difficult to distinguish in mixture; 4) Localization of low abundant and/or badly resolved components. We report a successful application of

HPLC/ESMS to a component analysis of partially purified recombinant rat thioesterase II enzyme TE2 (MW 29,476 Da, protein courtesy of Drs. A. Witkowski and S. Smith, Children's Hospital Oakland) and very pure preparation of a truncated form of the S-alkylated recombinant human macrophage colony stimulating factor rM-CSF (MW 17,893 Da, protein courtesy of Dr. Z. Randhawa, Otsuka America Pharmaceutical, Inc.). In the latter case, the MWs of impurities present at minute quantities (<2%) were determined from the 75 pmol total protein introduced to a HPLC column. On- line LC/ESMS was also applied to examination of crude synthetic peptide (MW 1946.3 Da) to demonstrate presence of Met oxidation and Gly deletion products and was used to localize putative products of hemoglobin oxidation *in vitro* (protein courtesy of Dr. R. Mehlhorn, Lawrence Berkeley Laboratory). Application of this technology to a clinical identification of hemoglobin variants (MW 15-16 kDa) results in extension of the ESMS screening potential to all hemoglobin mutants regardless their mass differentials, provided they are separable by reversed phase HPLC from other components of hemolysate.

In conclusion, we established that 1) HPLC/ESMS allows for separation and simultaneous accurate MW measurement of proteins up to 30 kDa , 2) No loss of chromatographic resolution occurs between the UV and mass spectrometric detectors, and 2) Molecular mass measurements can be obtained at low picomole level of consumed by MS analysis protein.

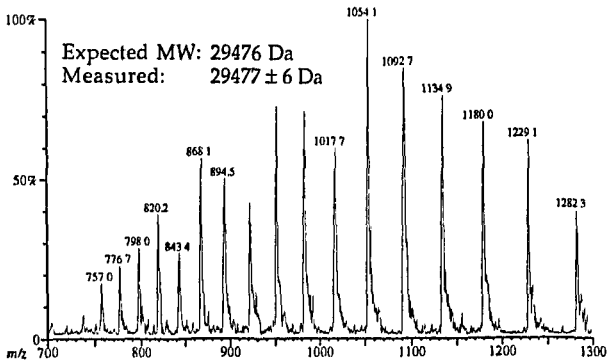

Figure 1 HPLC/ES mass spectrum of a fraction containing recombinant TE2. The spectrum was obtained from ~ 10 pmol Te2 introduced to the mass spectrometer.

DNA-CARCINOGEN ADDUCT ANALYSIS BY ION-SPRAY LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY*

Michael A. Quilliam
Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, Nova Scotia, Canada, B3H 3Z1

A critical event in expression of the genotoxicity of carcinogens and mutagens is the formation of covalent chemical adducts between these agents and DNA. In order to understand how these compounds induce mutations and cancer, it is important to characterize DNA adducts and to determine the rates of adduct formation and excision. This is a challenging trace analysis problem; typically, only 1 in 10^5 to 10^9 bases in the DNA may be modified *in vitro*, even after severe exposure to a mutagen. This paper reports on a preliminary investigation of the suitability of ion-spray LC-MS for this problem.

A wide range of normal and modified bases, nucleosides and nucleotides were examined by ion-spray MS. The spectra were very simple, showing a strong $[M+H]^+$ for all compounds, as well as abundant $[B+2H]^+$ ions for the nucleosides and nucleotides. Adducts of the mutagen N-acetoxy-N-acetylaminofluorene (NA-AAF) with 2'-deoxyguanosine-3'-monophosphate, 2'-deoxyguanosine and guanine (see Figure 1) were prepared on a microscale (<100 µg) (1,2). Analysis of dG-C8-AAF and dGp-C8-AAF by ion-spray LC-MS gave the spectra shown in Figures 2a and 2b. Only 1 to 10 ng was required for full scan spectra. Tandem mass spectrometry (triple quadrupole) produced spectra with some additional structural information. Trace level analyses could be achieved with selected ion monitoring LC-MS (Figures 2c and 2d), using a mobile phase of aqueous 60% methanol with 0.1% trifluoroacetic acid (TFA) and a Zorbax Rx-C8 column. Most of the experiments were performed on a high efficiency 250 x 4.6 mm i.d. column with a 20:1 post-column split (50 µL/min to MS), although some experiments used 0.32, 1 and 2 mm i.d. columns connected directly. Excellent concentration detection limits of 50, 170 and 80 nM were achieved with Gua-C8-AAF, dG-C8-AAF and dGp-C8-AAF, respectively. Mass detection limits (amount to MS) were 20, 80 and 50 pg, respectively. Use of microcolumns allowed the analysis of smaller volumes of sample extract, but the wider bore column provided the greatest ease of use, highest efficiency, and the opportunity to acquire UV spectra with a diode array detector simultaneous with the LC-MS experiment.

DNA reacted with NA-AAF *in vitro* was hydrolyzed to the nucleobases with anhydrous TFA and extracted into a small volume of 50% aqueous methanol (2). Figure 3 shows the analysis of a sample containing a high level of adducts (about 1 in 200 bases). In addition to the Gua-C8-AAF adduct, it was possible to see other adducts such as Gua-N^2-AAF (inset in Fig. 3a) and several AAF adducts of adenine (Fig. 3b). Full scan and MS/MS spectra acquired from this sample are shown in Figure 3c to 3d.

Tests with trace levels of adducts in nearly saturated solutions of normal bases, nucleosides or nucleotides (0.04 to 0.2 M) showed that it was possible to detect approximately 1 adduct in 10^6 bases. Preliminary separation and pre-concentration of adducts from normal components, as well as gradient elution techniques (larger injection volume) should allow the measurement of 1 in 10^8 to 10^9 base modifications in DNA. This would make ion-spray LC-MS competitive with radiolabelling techniques.

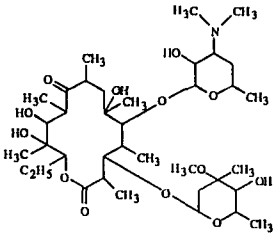
Determination of the Macrolide Antibiotic Erythromycin A in Biological Matrices by LC-MS and CE-MS with Atmospheric Pressure Ionization.*

John Kelly, Stephen Pleasance and Pierre Thibault
Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford St., Halifax, Nova Scotia, Canada B3H 3Z1

Macrolide antibiotics, such as Erythromycin A (EA), are widely used in medical and veterinary practice to treat gram-positive bacterial infections. There is a real need to develop routine quantitative assay methods for both pharmacological and toxicological use and for trace analysis in the edible tissue of farmed animals. However, many macrolides have proven difficult to assay by conventional instrumental means due to their polarity, high molecular weight, acid lability and lack of a significant chromophore. Previously published LC-FLD and GC-MS methods, though often adequately sensitive, frequently require laborious clean-up and derivatization steps, making them unattractive for routine use[1,2].

Recently, a number of LC-MS interfaces were compared as to their suitability for the analysis of a variety of polar and thermally labile compounds including antibiotics[3,4]. Under the mild ionization conditions of ionspray (ISP) the antibiotics, including EA, gave abundant protonated molecules (MH^+), well suited for selected ion monitoring (Figure 1). Structurally informative fragment ions can be generated by the collisionally induced dissociation of EA. These ions are due to dehydration or scission of either glycosidic linkage with hydrogen rearrangement. Collisional activation can be achieved either in the high pressure expansion region immediately after the sampling orifice or by the more conventional approach of tandem mass spectrometry (Figure 1).



Erythromycin A

Therefore, it was decided to develop an assay method based on LC-ISP-MS for the determination of EA in biological matrices, such as salmon tissue and human urine. A calibration curve (Figure 2) obtained for standard solutions of EA (0.01 - 50 μg/ml) using SIR conditions showed excellent linearity over the entire range (R2 = 0.998). Using either full scan or SIR conditions it was possible to confirm the presence of EA in salmon tissue at 0.1 ppm which is expected to be the Canadian maximum residue limit for EA in fish tissue (Figure 3). However, EA could be detected to a level of 1ppb using selected ion monitoring conditions. EA was measured in the urine at 2.4 μg/ml and could be detected by both full scan and SIR. It is significant to note that the only preparation involved in this analysis was a filtration to remove particulates and large molecular weight biomolecules, confirming the analytical ruggedness of this method.

Several compounds related to EA were detected in both matrices by precursor ion MS-MS. The m/z 158 ion was chosen as the target daughter ion as this was expected to be a common ion in the daughter ion spectra of many erythromycin-like compounds. Still more peaks were observed by selected ion monitoring of the MH^+ values of known erythromycins, degradation products and metabolites. Some have been identified by tandem MS-MS. Many, such as anhydroerythromycin A (AEA), are metabolites and degradation products of EA produced after administration of the medication. Others, such as erythromycin C (EC), were detected in the original formulation. It is quite likely that any future method used for residue analysis or for pharmacological research would also be required to assay for these compounds. This can certainly be achieved by LC-ISP-MS.

Finally, in this laboratory capillary electrophoresis has been coupled with ISP-MS via a co-axial interface[5]. This instrument was used to analyze the salmon tissue extract for EA and related compounds. While, the sensitivity of the technique was almost as good as for the LC-ISP-MS method, problems were encountered when attempting to resolve the complex mixture of erythromycins. To date, best results have been achieved using an electrolyte buffer with a pH just below the pKa of EA (pH 8.5). Acetonitrile was added to the buffer to aid the resolution of these closely related compounds.

Electrospray Mass Spectral Analysis of the (N)-Arylazido-β-Alanyl NAD+ Modified Bovine Heart Mitochondrial NADH Dehydrogenase

Kristine M. Swiderek[1], Terry, D. Lee[1], John E. Shively[1], Youssef Hatefi[2] & Shiuan Chen[1]
[1]Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010, [2]Department of Basic and Clinical Research, Research Institute of Scripps Clinic, La Jolla, CA 92030

INTRODUCTION

Electrospray mass spectrometry is one of the most recent developments in protein mass spectrometry. It provides new possibilities of analyzing high molecular weight components giving mass accuracies up to 0.01 %. On line connection to a micro HPLC has also made it possible to analyze protein mixtures and samples with critical solubility properties.
In this communication we demonstrate the usefulness of this technique for determining the molecular weight of the membrane protein NADH dehydrogenase from mitochondria. In addition this technique is shown to be very powerful in enzyme photoaffinity labeling studies, which are applied in the identification of active sites of enzymes.

METHODS

Mass spectra were recorded in the positive ion mode using a TSQ-700 triple quadrupole instrument (Finnigan-MAT, San Jose, CA) with an electrospray ion source operating at atmospheric pressure as described before (1). The electrospray needle was operated at a voltage differential of 3-4 kV and a sheath flow of 2 µl/min of methoxyethanol was used. Scans were continually acquired every three seconds. Chromatographies were performed with a micro capillary HPLC system build in our laboratory (2). Different gradients between solvent A (0.1 % TFA) and solvent B (90 % acetonitrile 0.07 % TFA) were used as indicated in the figure legends with a flow rate of 2 µl/min. Sample elution was monitored by UV detection at 200 nm.
NADH dehydrogenase was purified from bovine heart mitochondria as described before (3, 4).
Synthesis of N-arylazido-β-alanyl NAD+ and photolysis was carried out according to Deng et al. (5).
Tryptic digests of-NADH dehydrogenase were prepared by digesting 1 nmole unlabeled or labeled NADH dehydrogenase (0.26 mg/ml) in 50 mM KH_2OP_4, pH 7.4 with trypsin in a ratio of 20:1 (w/w) overnight. Trypsin was purified by reversed phase HPLC prior use.
The comparison between labeled and unlabeled enzyme digest was carried out with a computer program using the Finnigan instrument controlled language. The unlabeled enzyme digest was analysed several times and all computed masses were stored into a list (ulist). After acquiring as many masses as possible labeled enzyme digest was analysed and only masses not abundant in the list were computed and stored.

RESULTS and DISCUSSION

Mitochondrial NADH dehydrogenase was separated by reversed phase HPLC into its three subunits and on-line analysed by electrospray mass spectrometry. The determined masses agree with the expected masses. Subunit III has a lower mass than the calculated mass based on cDNA data. After photoirradiation of the enzyme with the photoaffinity label (N)-arylazido-β-alanyl NAD+ we can see incorporation only into subunit III, whereby the length of time of irradiation as well as the amount of label influences the efficiency of labeling. The results show that a time of 1 minute irradiation in the presence of 80 µM photoprobe is sufficient for labeling 50 % of the enzyme(figure 1).
After tryptic digestion we have found, by mass spectrometry, a few peptides derived from the labeled enzyme which are not present in the unlabeled enzyme digest. The mass of one of these peptides corresponds to the mass of a peptide with the sequence TSGLR having the aryl-β-alanyl part of the photoprobe attached (figure 2). A derivative with similar structure was found when glyceraldehyde-3-phosphate dehydrogenase was labeled with the same photoprobe (6). This sequence is located next

to a region of a conserved amino acid sequence known to be involved in the interaction with the pyrophosphate group of the nucleotides. Further MS/MS studies will allow us to identify the modified peptide and to locate the NADH binding site within the enzyme.

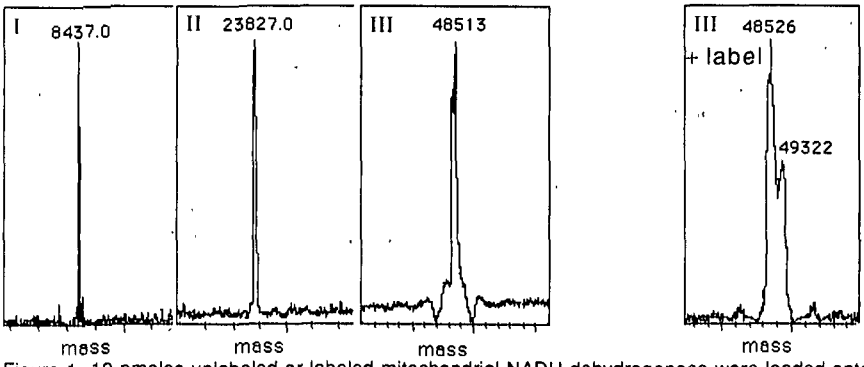

Figure 1 12 pmoles unlabeled or labeled mitochondrial NADH dehydrogenase were loaded onto a micro column and eluted with an increasing gradient from 2% to 82% solvent B in 40 min. The masses for subunit I, II and III of the unlabeled enzyme are shown. After photoirradiation the masses of subunit I and II were unchanged. Incorporation of photoaffinity label occured only into subunit III.

List of ions collected from several LC-MS runs

unlabeled enzyme						"new" ions
549.1	851.2	663.4	818.2	641.3	723.0	560.4

LC/MS Analysis of Complex Synthetic Organic Molecules Utilizing Electrospray Ionization

*Ken Johnson, Ian Jardine, Finnigan MAT, San Jose, CA 95135 and James Little, Tennessee Eastman Co., Kingsport, TN 37662

The compound in this study is one example of a group of synthetic industrial chemicals that are produced by similar multi-step syntheses. For this particular compound, an eleven step process and six chemical building blocks are utilized as shown in the structure of the molecule. Each of these steps can potentially introduce minor components from side reactions with impurities present in the starting materials.

For consistent performance in the final end use of this compound, it is important to monitor the minor impurities normally present in the final reaction product and understand their origin. This study used electrospray LC/MS and MS/MS to provide some of this information for these compounds which in previous work had proven intractable by other ionization modes such as particle beam, thermospray, and FAB.

A Finnigan MAT TSQ®700 with an electrospray source was used for this work. Solutions of the compound was infused into the ESI source at a constant flow rate of 2 μl/min for investigating solution chemistry effects and for performing the MS/MS experiments. For all of this work a sheath liquid, either isopropanol or isopropanol with 10 mM ammonium acetate, was used at a flow rate of 2 μl/min.

This compound readily forms a sodiated ion which is generally not desirable for providing informative MS/MS spectra. In solutions of acetonitrile, water, and acetic acid (ratio of 90/10/1) the sodiated species varied between 30 and 200% of the $[M+H]^+$ ion. Ammonium acetate was added to the sample for an overall concentration of 10 mM. This succeeded in shifting most of the ion current into the $[M+NH_4]^+$. However subsequent daughter experiments of the ammoniated species yielded mainly loss of neutral ammonia to leave the $[M+H]^+$ with little other structural information.

By increasing the voltage difference in the capillary-skimmer region of the ion source it was possible to induce this initial fragmentation step in the ion source so that the protonated species was the base peak with the ammoniated and sodiated species typically 20-50% of the $[M+H]^+$. The daughter spectrum of the protonated molecule also provided much more structural information than the ammoniated parent. These conditions were used for all subsequent analyses.

LC/MS work was done with a micro LC from Michrom BioResources of Pleasanton, CA using a 1mm by 15 cm C18 column and a mobile phase of 1% acetic acid in water and 1% acetic acid in acetonitrile. Ammonium acetate was added through the isopropanol sheath liquid. The column flow was 50 μl/min with 2 μl/min being split to the mass spectrometer after the UV cell by placing a restricting length of fused silica in the waste line from the UV cell. The fused silica restrictor on the waste line was connected to a Rheodyne 7000 switching valve. In addition a length of non-restrictive stainless steel tubing was connected into the alternate flow path of the switching valve. By switching the valve, back pressure in the UV waste line could be reduced thereby stopping flow through the transfer line to the mass spectrometer. This technique proved quite effective in diverting the bulk of the main component from the ion source.

Many of the impurities found differed by increments of 14 mass units and were thought to be homologs of the alkyl side chains in the molecule. A number of masses were selected for further MS/MS studies. The daughter analyses were done by infusing a 20 ng/μl solution of the mixture into the mass spectrometer at 2 μl/min. Spectra for the minor components were acquired to disk in the profile mode after two to three minutes of signal averaging.

The daughter spectrum of the main component at m/z 1002.6 indicates that much of the fragmentation provides structural information. The protonated parent ion loses sequential fragments of 70 mass units from the two t-amyl groups. The peaks in the daughter spectrum have been labelled in relation to the subunits used in the synthesis. The peak at m/z 565.3 was assigned as $[ABC+2H]^+$ and not $[CDEF+H]^+$, from the spectrum of one of the impurities which contained only one t-amyl group but whose spectrum still contained a strong signal at m/z 565.3. For a number of the minor components, the MS/MS data allowed us to propose which starting material contributed the impurities.

An Atmospheric Pressure Chemical Ionization (APcI) Interface for LC Analysis of Drugs and Environmental Compounds.

S. Bajic and S.W. Preece, Fisons Instruments, VG BioTech, Tudor Road, Altrincham, WA14 5RZ, UK.
D.R. Doerge, National Center for Toxicological Research, Jefferson, AR 72079, USA.

Introduction

Atmospheric pressure ionization (API) in the form of electrospray (ESI) and pneumatically assisted ESI has proved invaluable in the analysis of large biomolecules. More recently, there is a growing interest in the application of API techniques for the LC analysis of small molecules of environmental and pharmaceutical interest. From a chromatographic viewpoint, the relatively low LC flow rates tolerated by the above methods (≤ 200µl/min) are incompatible with conventional bore HPLC. There is however an alternative API technique, namely corona discharge APcI which can ionize low molecular weight compounds (≤ 1.5kDa) at analytical HPLC flow rates of up to 2ml/min.

In this technique, the sample and mobile phase from the LC column is converted into the gas phase via a heated, pneumatic nebuliser. Sample molecules are ionized by atmospheric pressure gas-phase ion-molecule reactions with solvent-based reagent ions derived from a corona discharge. Prior to mass analysis, the ions are expanded into an intermediate pressure region (~ 1 mbar) where high sampling cone voltages (30-100V) can be used to decluster solvated molecular ions or collisionally induce fragment ions for structural information.

Here we present data from the analysis of samples from a range of pharmaceutical and pesticide compound classes using a Fisons corona discharge APcI interface.

Experimental

All data were obtained on a Fisons TRIO-2000 single quadrupole mass spectrometer equipped with an APcI interface. Samples were tested with an APcI source temperature of 120°C and a nitrogen bath gas flow rate of 300l/hr. Nitrogen and oxygen nebulizer gases were used for positive and negative ion operation, respectively. The sampling cone voltage was chosen to optimize the $(M+H)^+$ ion for each sample and was typically in the range 25-35 volts. All samples were screened for full scan (400amu/sec) and SIR detection limits with a 50/50 acetonitrile/water mobile phase at a flow rate of 1ml/min. Chromatography was performed isocratically using a mobile phase of 60/40 acetonitrile/water at a flow rate of 0.5ml/min on a reversed phase 3µm, C18, 30x4.1mm LC column.

Sample	Classification	$(M+H)^+$	Full Scan LOD (ng)	SIR LOD (ng)
Diazinon	Organophosphate Pesticide	305	1.0	0.015
Linuron	Phenylurea Pesticide	249	4.0	0.1
Ametryn	Triazine Pesticide	228	1.0	0.2
Carbofuran	Carbamate Pesticide	222	2.5	0.15
p-Nitrophenol		138*	10.0	0.2
Fenfluramine	Anorexic Drug	232	1.0	0.02
Reserpine	Antihypertensive Drug	609	10.0	0.1
Clenbuterol	Anti-Asthmatic Drug	277	2.0	0.02

* Negative $(M-H)^-$ ion

Table 1. *Collated limit of detection (LOD) data for five pesticide and three drug samples tested by APcI.*

Results

All the pesticide and drug samples tested in this study gave rise to $(M+H)^+$ base peaks in the positive ion mode. Table 1 summarises the limits of detection (LOD) for full scanning and SIR analysis of 8 test samples. To demonstrate the "soft ionization" obtained in APcI with low sampling cone voltages, Figure 1 (top row) shows the mass spectra for 50ng of the carbamate pesticide Aldicarb Sulphoxide (MW = 222). Figure 1 also shows the progressive reduction of the $(M+H)^+$ ion and the corresponding increase in the protonated oxime (m/z = 166) and protonated nitrile (m/z = 148) diagnostic fragment ions, induced by increasing the sampling cone voltage from 24 to 44V. Finally, Figure 2 shows an isocratic, reverse phase LC separation of four triazine herbicides using full scanning APcI detection (50ng each component). On-column limits of detection of 1-2ng were determined in SIR analysis.

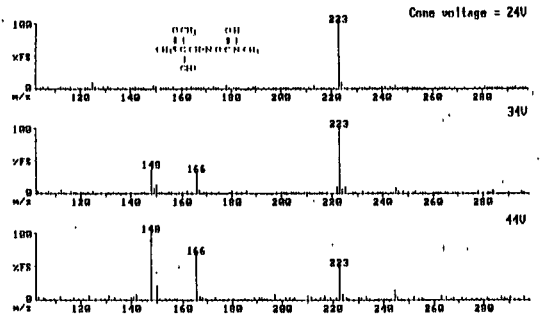

Figure 1. *An example of the structural information obtained in APcI by increasing the sampling cone voltage (50ng Aldicarb Sulphoxide).*

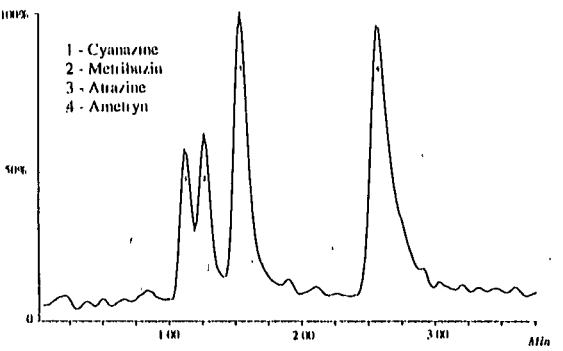

Figure 2. *Isocratic HPLC separation of four triazine herbicides using full scan APcI detection.*

Conclusions

APcI is a sensitive, versatile technique for small polar molecules that is compatible with normal and reverse phase conventional bore HPLC at flow rates of 1ml/min. Linear sensitivity responses were obtained for all pesticide and drug test samples (correlation coefficients of ≥ 0.99) with low nanogram limits of detection for full scanning and picogram range detection limits in SIR analysis. Molecular weight information ($[M+H]^+$ base peak) was obtained on all samples with no significant fragment ions for low cone voltages (≤ 30v). Moreover, high cone voltages (≥ 40v) can be effectively employed in APcI to produce fragment ions for structural confirmation.

HYPERTHERMAL SURFACE IONIZATION OF ORGANIC MOLECULES

INTRODUCTION

The molecule/gas surface interaction experiments have been performed with the use of seeded, supersonic free jet and quadrupole mass spectrometric technique for determining positive ions. Sample molecules are piperidine and toluene.

The objectives of this report are : (1) to identify the major ions in piperidine and toluene systems, (2) to derive relationships between kinetic energy (Ek) of the sample molecule and ionic intensity, and (3) to demonstrate that surface temperature is pertinent in determining the magnitude of ionization probability.

EXPERIMENTAL

Apparatus : The experiments were performed with the apparatus shown in Fig.1. It consists of a large main chamber with a supersonic nozzle, surface and quadrupole mass spectrometer (QMS) with sampling interface. The main chamber is circular with QMS chamber in it. The latter chamber is separated from the former chamber by the skimmer and the two chambers are evacuated differentially by relatively large pumping systems. The main chamber is pumped by a 2500 L/s diffusion pump plus a 1000 L/min rotary pump. Typical base pressure of 5×10^{-8} torr is obtained. The QMS chamber is a cyrindrical tube with the QMS centered within the chamber. This chamber is evacuated by a 500 L/s diffusion pump around 5×10^{-7} torr as an ultimate pressure. The pressure under beam-on condition was $\sim5\times10^{-5}$ torr.

Seeded Jet : The seeded supersonic free jet can provide neutral molecules with kinetic energies of $\sim$10 eV over a wide range, permitting to explore the effect of translational energy on a variety of chemical and physical processes. The Fk could be controlled by varying the nozzle temperature.

Surface : The surface could be heated electrically, but most studies were performed with the Ni-foil or Re-ribbon at room temperature.

RESULTS AND DISCUUSION

Effect of Kinetic Energy (Ek) : The ion yield was studied as a function of incident energy for piperidine and toluene. The results are shown in Fig. 2 for piperidine/ReO_2 system and in Fig. 3 for toluene/Ni system in semilogarithmic plot. These figures clearly show that in both cases ionization due to impact was observed and the SI ions are enhanced exponentially by the increase in kinetic energy (Ek) with deviation from this exponential behavior at higher energies. The threshold energy and energy dependence suggest a mechanism of energy transfer upon ionization. The energy required may be associated with energy due to the difference in IE of the incident molecule and the work function, ϕ, of the surface, since IE - ϕ is always the factor as the surface ionization should be efficient.

Effect of Surface Temperature : An Arrhenius plot of the logarithm of ionization probability of piperidine versus reciprocal temperature falls on a straight line. It should be noted that hyperthermal piperidine molecules also take the dissociation energy directly from the kinetic energy.

CONCLUSIONS

The experimental observation should be accounted for in any mechanism for surface ionization of molecules with kinetic energy ; a) the process is kinetic energy assisted and ion intensity increases monotonically with increasing kinetic energy of the seeded molecules, b) the ionization efficiency depends somehow on the nature of molecules and surface, c) the mechanism seems to involve conversion of kinetic energy to chemical processes and ionization by a collision with surface, d) the surface temperature is sensitive to molecules with kinetic energy, in terms of ionization efficiency.

From these results, it is possible to conclude that incident kinetic energy seems to be converted to the surface collision-induced ionization of organics.

MOLECULAR CHARACTERISATION AND SPATIAL ANALYSIS OF ORGANIC SURFACES USING TIME-OF-FLIGHT SIMS

A Brown, A Bowdler & P Humphrey

Kratos Analytical, Barton Dock Road, Manchester, M31 2LD, UK

Introduction

Time-of-flight secondary ion mass spectrometry (TOF-SIMS) offers enormous potential for the characterisation of organic surfaces such as biomedical polymers, treated fibres, composites and drug delivery systems. TOF-SIMS instruments combine the benefits of high transmission, parallel mass detection and unlimited mass range to enable optimum use of the often relatively low yields of molecularly specific ions produced in a static SIMS analysis. In addition, the ability to analyse non-conducting samples routinely and obtain mass resolutions > 10,000 has provided the capability for accurate mass determination on organic surfaces. The development of finely focused liquid metal ion sources that can operate in a low dose, pulsed regime allows high spatial resolution imaging of not only elemental but also molecular fragment ions to below 200 nm.

All analyses presented in this paper were performed on a Kratos PRISM TOF-SIMS instrument. At the heart of this is an energy-focusing reflectron mass analyser of proven design fitted with a dual channel plate detection system. The primary beam is provided by a 25 kV liquid metal ion source of monoisotopic $^{69}Ga^+$ with a beam diameter of 500 Å. The pulse width for spectral acquisition was typically 3-80 ns and all spectra were acquired with total integrated doses of less than 10^{11} ions/cm^2 which is well within the static SIMS limit. Charge neutralisation was accomplished by a controlled injection of 30 eV electrons pulsed anti-phase to the extraction field pulsing

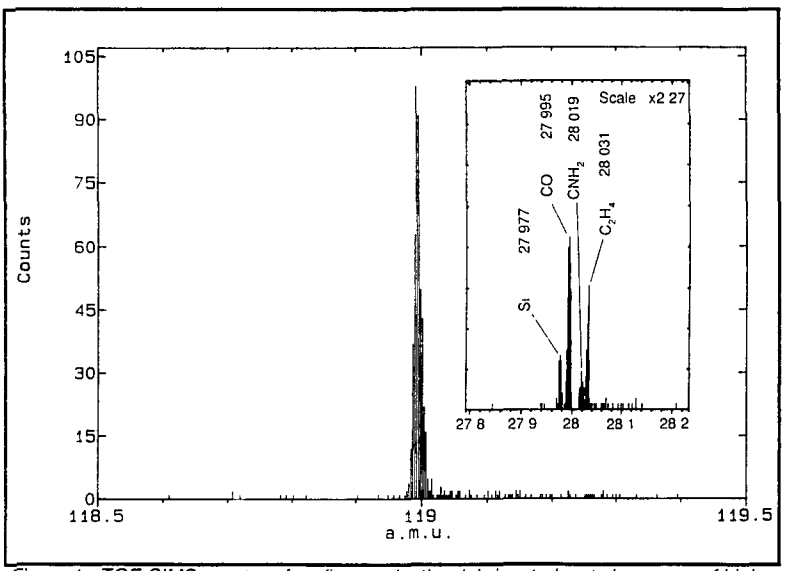

Figure 1: TOF-SIMS spectra of perfluoropolyether lubricant. Inset shows use of high mass resolution to separate peaks at m/z 28

Results

The instrument allows the straightforward acquisition of high mass resolution SIMS spectra. The example shown in Figure 1 is of a positive ion spectrum from a perfluoropoly-ether lubricant on a computer disc. The main spectrum shows a mass resolution in excess of 13 000 is achievable at m/z 119 ($C_2F_5^+$). The inset shows the practical application of high resolution to separate the m/z 28 peak into four distinct components (Si^+, CO^+, CNH_2^+ & $C_2H_4^+$) giving greatly enhanced analytical information.

Further examples have shown the power of this resolution in elucidating the structure of a polymer blend of two similar oxygen-containing hydrocarbon polymers.

In addition to mass spectra, the instrument is configured for SIMS imaging and examples have shown elemental and molecular ion imaging from a range of materials including organic coatings on biomaterials.

Conclusions

The ability of the TOF-SIMS instrument in molecular characterisation of organic surfaces has been amply demonstrated. In particular, the following features of the time-of-flight system are of immense benefit in these investigations -

- High mass resolution enables additional information to be obtained in comparison with conventional quadrupole instruments by allowing the separation of peaks at the same nominal mass.
- Accurate mass measurement in conjunction with mass spectral reference libraries greatly facilitates the interpretation of complex organic spectra.
- The combination of high transmission TOF analysers with micro-focused ion probes allows the potential for molecularly specific imaging even on complicated samples such as biomedical systems or treated fibres.
- Straight-forward applicability to an extensive range of applications

Correlating Analyte Concentration with Fragmentation Behavior in Liquid SIMS

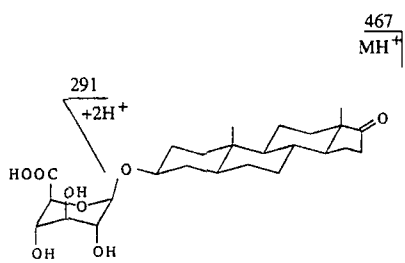
Zhaoxia Huang and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148

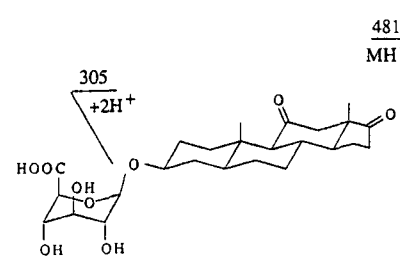
Liquid Secondary Ion Mass Spectrometry (L-SIMS, also referred to as fast atom bombardment (FAB)) is a powerful analytical tool for the investigation of fragile, polar, and heat-sensitive compounds. Although the technique has demonstrated tremendous success for qualitative analyses, the same level of success has not yet been achieved for quantitative analyses. Analyte surface activity effects are known to complicate quantitation in L-SIMS.

This study has used androsterone glucuronide and 11-ketoandrosterone glucuronide (shown below) as model 'surfactant-like' compounds to investigate the relationship between analyte concentration and fragmentation behavior in L-SIMS. Surfactant compounds such as those used in this study are known to aggregate in the form of micelles when the concentration of analyte in solution exceeds a certain minimum value known as the critical micelle concentration (CMC). The CMC for the two compounds in glycerol was determined by difference UV-absorbance spectrophotometry; results appear in Figure 1.

For each of the compounds under investigation, the absolute abundance of protonated analyte molecules (MH^+) is clearly concentration dependent. At concentrations above or below an optimum value close to the CMC, the absolute abundances of the respective MH^+ ions are shown to decrease (Fig. 2). Relative abundances of fragment ions in L-SIMS also vary significantly depending upon initial analyte concentration. As the concentration is raised above the CMC, ions formed via consecutive decompositions (requiring higher energies) are increasingly favored.



Androsterone Glucuronide



11-Ketoandrosterone Glucuronide

These results can be rationalized by considering that below the CMC, availability of the analyte near the sample-vacuum interface is the major factor influencing the abundance of desorbed MH^+. For these relatively dilute solutions, the absolute abundance of protonated molecules increases with concentration. Above the CMC, however, the liquid matrix plays a much less important role in replenishing the sample surface with fresh analyte. As the concentration of each analyte is raised beyond the CMC, the absolute abundance of MH^+ is observed to decrease (Fig. 2). The elevated level of fragmentation observed above the CMC indicates that the internal energy of desorbed analytes is significantly higher in this concentration region.

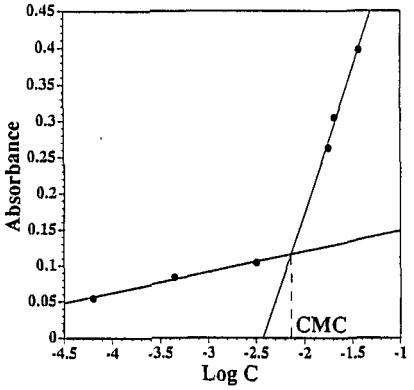


Figure 1. Plot of absorbance vs. log concentration for androsterone glucuronide in glycerol.

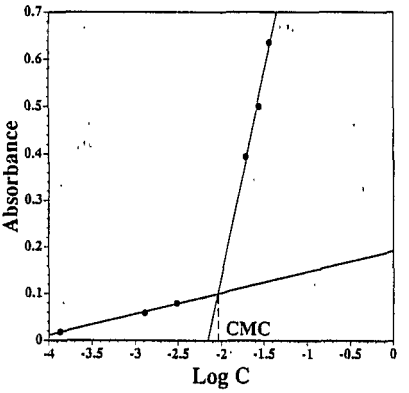

Plot of absorbance vs. log concentration for 11-ketoandrosterone glucuronide in glycerol.

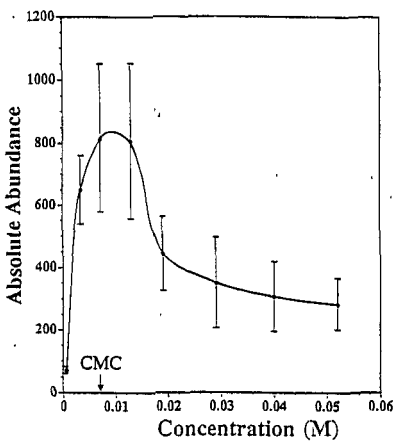

Figure 2. Plot of absolute abundance of MH^+ vs. concentration for androsterone glucuronide in glycerol.

Time Dependence and Surface Phenomena Affecting Secondary Ion Emission from Solution

M. Scott Kriger and Kelsey D. Cook, Dept. of Chem., Univ. of Tennessee, Knoxville, TN, 37996-1600.
R. T. Short and Peter J Todd, Analytical Chem. Div., Oak Ridge National Lab, Oak Ridge, TN, 37831-6365

Time dependence is a well-known complicating factor in FAB and liquid SIMS spectra. Consistent with the correlation between ion intensity and relative surface activity,[1] observed decreases in the relative intensity of more surface active analytes[2] with increasing sample exposure have been attributed to depletion of such analytes from the sample surface. Fig. 1 shows an example of such behavior for a solution of tetradecyltrimethylammonium bromide (TTAB; $C_{14}H_{29}N^+(CH_3)_3Br^-$) in glycerol. Although this interpretation seems intuitively reasonable, it is difficult to reconcile with facts that 1) establishment of surface excess concentration by diffusion is a process requiring hours of equilibration in aqueous systems;[3] 2) diffusion coefficients in glycerol are orders of magnitude lower than in water, so that equilibration may take even longer in this medium;[4] and 3) sputtering rates in FAB are relatively fast, so that surface layers would be removed on a time-scale of seconds. As a result, there is no opportunity during the course of a FAB experiment for the surface to be replenished by diffusion of solute to the surface.[5,6,7] Mixing and convection have been offered as alternative mechanisms of mass transport.[6,7] However, there is a further complication that sampling depths in FAB ordinarily exceed the surface monolayers.[8,9] Consistent with this fact, correlation between relative ion intensities and analyte surface activity is not observed when volatile surfactants are introduced via the gas phase.[10]

In an effort to reconcile these observations, the time dependence of FAB spectra from TTAB was compared with corresponding data (Fig. 2) obtained from a glycerol solution of an analyte chemically similar, but not surface active: tetraethylammonium iodide (TEAI; $(C_2H_5)_4N^+I^-$). The striking differences can be explained using information from spatially resolved secondary ion images obtained from both samples using a wide-angle secondary ion microprobe. The image obtained by monitoring the intensity at m/z 256 (TTA^+) from TTAB as the primary Cs^+ beam is rastered over the sample droplet is shown in Fig. 3. As expected, material is uniformly distributed across the sample surface. This is confirmed by the intensity profile shown A similar but much weaker image could be obtained by monitoring m/z 93, or any other ion associated with the glycerol matrix. In marked contrast, the image obtained by monitoring m/z 130 (TEA^+) from TEAI showed highly heterogeneous secondary emission, with highest intensities occurring near the rim of the sample droplet (Fig. 4a). Ions associated with the glycerol matrix formed a complementary image, with greatest brightness in the center (Fig. 4b). In sequential images of this sample, the "hot ring" of TEA^+ emission was observed to gradually fill as the area of emission of secondary ions characteristic of glycerol shrank (Fig. 4). The images of Fig. 4 are clearly inconsistent with a major contribution to mass transport from stirring or convection; such processes would disrupt the stark heterogeneities observed. To confirm that these mechanisms were not enhanced by the surface activity of TTAB, images were obtained from an equimolar mixture of TTAB and TEAI; results for m/z 256 and 130 were essentially identical to those shown in Figs. 3 and 4, respectively.

These observations can be explained in a manner consistent with the observed FAB time dependencies. As the solvent evaporates (a process accelerated by sputtering), slow-diffusing non-volatile analytes will tend to be enriched at the surface. "Marangoni effects" will promote very rapid spreading of analyte on the droplet surface so as to minimize surface tension. In the case of the surfactant TTAB, this will cause uniform distribution of analyte across the surface and gradual sample depletion by sputtering of the hydrophobic analyte. Conversely, the non-surface active TEA^+ ion actually may increase surface tension slightly, relative to pure glycerol. In this case, the Marangoni effect will tend to promote spreading of the pure solvent, pushing the TEA^+ to the periphery in much the same way chalk dust can be forced to the edge of a pool of water by the spreading of added surfactant. The resulting concentration gradient is maintained as the droplet evaporates. The relatively hydrophilic TEA^+ is sampled relatively poorly, and is left behind as dry salt (as evidenced by the recovery of the TEAI spectrum, but not the TTAB spectrum, when a sample is re-wetted with pure glycerol after being sputtered to dryness). The data of Fig. 2 can be explained by accounting for the relatively small ion optical acceptance aperture of most quadrupole and sector instruments; the peak in TEA^+ intensity occurs when the "hot ring" of TEA^+ secondary ion emission coincides with the instrument entrance aperture. Under the high flux conditions of FAB, emission of solute-characteristic secondary ions ceases once the sample is dried.

ALKALI HALIDE CLUSTER FORMATION IN LIQUID SIMS

Jan Sunner
Montana State University, Bozeman, MT 59717

The formation of charged clusters is a ubiquitous phenomenon in all Desorption Ionization (DI) techniques. Their mode of formation has been the subject of much research. Recombination in the selvedge is possibly the preferred model, but the detailed nature of the process remains unclear. Alternatively, "droplets" may be ejected from the desorption site. As the solvent evaporates from a droplet, a cluster of involatile ions, such as alkali halides, would remain.

The objective of the present study was 1) to study the alkali halide cluster distributions in Liquid SIMS spectra of alkali halide solutions in glycerol as a function of salt concentration. CsCl results are presented here because of the high solubility of this salt; 2) to investigate whether the experimental cluster distributions can be explained and reproduced with some simple model; and 3) to examine whether such a model is or is not compatible with the different ideas regarding cluster formation.

Figure 1 shows that the intensities of the glycerol ions, Gl_nH^+, decrease exponentially with salt concentration. Decay constants increase with n. Also, the intensity decrease for glycerol fragment ions is much smaller. Figure 2a shows that the intensities of the $Cs^+(CsCl)_n$ cluster ions increase with salt concentration in a characteristic manner. A simple model was found to reproduce this behavior quite well. It was assumed that 1) the Cs^+ ions are randomly distributed in the surface-near region (during dynamic bombardment conditions); 2) shortly after impact, most of the Cl^- or $(Gl\text{-}H)^-$ ions are "paired up" with a positive ion, leaving only the occasional, surviving "free" ion. If ejected, this ion will result in a gas-phase ion; and 3) during the ejection process, all ion pairs within a given "cluster formation radius", r_c, from the "free" ion will combine to form a cluster. The probability that n other "paired" Cs^+ ions will be found within a radius, r_c, of a "free" ion is simply, $p_n = x_{Cs}^{\,n} * (1 - x_{Cs})^{d-n} * (\ )$, where ( ) is a binomial coefficient, d is the number of glycerol ions within radius r_c, and x_{Cs} the mole fraction of the salt. Due to the higher volatility of glycerol, the salt will be somewhat enriched in the surface.

A GlH^+, formed in the collision cascade, will survive as a glycerol ion only if there are no Cs^+ ions within the radius r_c. The different decay rates for the Gl-ions thus imply that there is a distribution of r_c values; fragments have smaller and clusters have larger r_c's. This distribution is centered around d = 25 or r_c = ca. 9 Å. With this simple model, the calculated intensities in Figure 2b were obtained. Good results for the salt clusters are obtained also with r_c = 9Å, which then is the <u>single adjustable parameter</u> in the model.

GlH^+ and $(Gl\text{-}H)^-$ are formed in the collision cascade. A likely route to $(Gl\text{-}H)^-$ is dissociative electron capture of secondary electrons, a reaction well known in the radiation chemistry of alcohols. Cluster ions such as $Cs^+(CsCl)_n(Cs^+(Gl\text{-}H)^-)(Gl)_m$ are formed if a $(Gl\text{-}H)^-$, but not a GlH^+ is found within the local cluster formation volume. By fitting with our simple model, we find that the initial concentration of $(Gl\text{-}H)^-$ is close to 1 mol%. This is a "ballpark" figure of the extent

of ionization in the collision cascade. It does not include geminate recombination.

We make the following reasonable conclusions from the results: 1) The alkali halide clusters are not formed after ejection. The droplet model is consistent with our results. However, RRKM calculations presented in a separate poster show that the evaporation from a droplet, in order to go to near completion, must be faster than the desorption process. Also, recombination in a gaseous state seems doubtful because of the very short time available for a sequence of association reactions; 2) It is unlikely that the clusters are formed prior to impact because there is no evidence of thermodynamic control, i.e. preferred cluster sizes or cluster compositions are not observed. Also, the observed gradual decrease in clustering of $M^+(M^+X^-)_n$ with glycerol with increasing salt concentration (at low x_c) would be hard to explain. We thus conclude that cluster formation is competitive with matrix disintegration. This is in agreement with a bulk desorption process where some intermolecular interactions weaken and others simultaneously strengthen and where most of the clustering occurs between molecules that are close neighbors. At a distance of 9Å, two ions would be separated by just one glycerol molecule! The extent of proton transfer in FAB can be explained in a very similar fashion except that the r_c value is slightly larger. We believe that the simple model used here is not only successful in predicting the spectra as a function of salt concentration but is also a reasonable approximation to the actual cluster formation process in Liquid SIMS and in related DI techniques.

The characterization of micron-sized, environmental soil particles by shape, size, spatial position, and semiquantitative elemental analysis requires a technique which not only achieves a lateral spatial resolution of less than a micron, but also provides sensitive elemental analysis. Ion [1], electron [2] and photon [3] induced X-ray microprobe techniques have been used or proposed for the study of micron-sized structures. The strengths of these techniques are their ability to perform multi-element qualitative analysis of the bulk particle (sample volume of ~ μm^3) and quantitative analysis if standards are available and interferences accounted for. Secondary-ion imaging techniques have also been used to study micron-sized structures. In addition to spatial imaging, secondary ion mass spectrometry (SIMS) is more sensitive than X-ray probe techniques. It can also provide mass analysis of all the elements, surface and depth profile characterization, isotopic analysis and with the careful use of standards, semiquantitative elemental analysis.

Using a digital-imaging interface and software upgrade from Charles Evans and Associates for our Cameca ims 4f ion microscope/microprobe, we are attempting to characterize chromium-rich environmental soil particles by size, position and semiquantitative analysis. Two routines are being used. The first routine employs an automated two-dimensional step-scan (2DSS). In this routine a selected raster scan is stepped back and forth across the sample in a two dimensional pattern by moving the sample stage a preselected step size. The total counts of up to 14 elements or isotopes in each field (defined by the scan size) can be collected and displayed as a line graph of counts versus field or cycle or as an element map. Variables include the collection time for each isotope, the scan size (< 500 μm), the step size (usually chosen to match the scan size) and the number of steps (maximum of 10 x 10). By examining the element maps of the X x Y fields or the plot of counts versus cycles, the operator may step the sample stage to any of the (X,Y) fields to collect digital images of selected elements and analyze selected particles by line scans or area sums. For example, using a mass resolution of ~5000, we collected the total counts of Al and Fe (60 s) and Cr and Ni (120 s) in a 4 x 4 array using a 250 micron scan and step size (1 mm^2 area) from soil particles self-cemented on a carbon planchet. Examination of the digital images of the (1,3) field of those four elements reveal two intense Cr-rich particles. Element area sums indicate that one particle contains primarily Cr, while the other particle appears to be a Cr-rich clay. The major advantage of the 2DSS approach is that it provides a means of pre-screening fields for a particular element or combination of elements without collecting images for 14 different elements. The major disadvantage is that it is difficult to distinguish between a field which may contain a few particles rich in an element of interest and another field which may contain many particles poor in the element of interest if their total count rates are similar.

The second routine, Particle Search (PS), also collects data from a selected raster scan which is stepped in a two-dimensional pattern across the sample with the same options for step size, raster size, collection time and array size as the step scan routine. In PS, however, ion images of only two elements are collected in each field of the array. Particles composed of either or both of those two components are identified by exceeding an operator selected value for the minimum number of counts from a set of contiguous valid pixels. Valid pixels are set by the operator above the noise. All valid pixels from the two image fields are represented in registration on a third field. Comparison with the two image fields allows the operator to adjust the particle and pixel thresholds to mirror the actual shape and size of the particle. Particles are also tabulated by their physical location on the sample, counts of each element, a count ratio and the number of valid pixels in the particle. A maximum of 254 particles can be identified in each field. For

example, using the same conditions and scanning the same area as the 2DSS routine, 10 Cr-rich particles were identified in the (1,3) field and 211 particles with radii ranging in size from 3 to 15 microns in the 1 mm^2, 4 x 4 field array. Radii were calculated by assuming that each particle was spherical. A plot of Cr intensity per pixel vs radius revealed at least three groupings of particles based on the strength of their Cr intensity. The advantages of this routine are clear. If operator controlled parameters can be adjusted to mirror the actual particle shape and size, a complete list of particles in an array can be rapidly identified by counts, number of pixels and physical location on the sample. The disadvantages are that it requires prior knowledge of the particles to determine which two elements to image and it generates a large amount of data by collecting two images per each field in the array.

Although it may be time consuming, additional analysis of the individual particles found using either routine is readily accomplished by reducing the beam size or raster size and beam intensity. For example, the mass spectra of the two larger particles identified in the (1,3) field reveal that one particle is nearly pure Cr and the other is Cr-rich clay (Mg, Al, Si, Fe, etc.). Future work will be required, however, to improve the classification of the particles. It will also be necessary to develop standards for semiquantitative analysis.

Localization of Labeled Compounds in Human Hair Using SIMS

*Greg Gillen and Cindy Zeissler
Surface and Microanalysis Science Division,
National Institute of Standards and Technology,
Gaithersburg, MD 20899

There is much current interest in the development of analytical techniques for the identification of drugs of abuse in human hair (1,2). The analysis of hair is attractive because the method is non-invasive and compounds are stable in hair for extended periods of time, thus giving a clearer indication of habitual drug use. However, there are still a number of fundamental questions that must be resolved. The precision and accuracy of new methods for hair analysis are characterized by the use of reference materials that are often prepared by soaking blank hair samples in solutions containing the compounds of interest. There is some evidence that differences in hair type (e.g. racial, color, chemical treatments) may result in variations in drug incorporation and therefore may not reflect "standard" behavior for hair. There is also a question about the effect of various treatments which could potentially be used by drug users in an effort to avoid detection. It has also been suggested that environmental contamination of hair samples could lead to false positive results. In this preliminary study, we have evaluated the feasibility of using secondary ion mass spectrometry (SIMS) for imaging the distribution of labeled compounds in human hair. SIMS imaging of the cross-sectional distribution of compounds in soaked hair appears to be a useful method for assessing the homogeneity of potential hair standards. Also, the influence of various hair treatments on the distribution of compounds in hair can be determined. Finally, we have demonstrated that it is possible to image intact molecular species on the surface of hair, which may allow us to address issues of surface contamination.

Our initial experiments involved soaking various hair samples for several days in a saturated solution of a model compound (tetrabromomercurochrome, courtesy of D. Kidwell, Naval Research Laboratory). Two sample mounting procedures were used. Short sections of hair (~ 0.5 cm in length) were dropped onto conductive silver paint smears on metal substrates. Similar lengths from the same samples were also mounted in epoxy and microtomed to produce cross-sections ~1-4 μm in thickness. The samples were then analyzed in a secondary ion microscope/microprobe under Cs^+ bombardment while monitoring negative secondary ions. Images were acquired either with a TV-rate CCD camera or in microprobe imaging mode. In all cases, the Br^- secondary ion signal was used as a marker to localize the position of the molecule. Figure 1 shows a camera-acquired CN^- microscope image (indicative of the hair matrix) and a Br^- image from a hair soaked in the model compound. In this example, the Br^- image is not particularly uniform. This probably results from crystallization of the saturated compound onto the surface of the hair. Good quality images of the whole hair samples were only obtained when using the normal-incidence electron gun of the ion microscope (3). In this configuration, an electron beam is directed perpendicular to the sample, colinear with the secondary ion optics. When analyzing negative secondary ions, the electron energy is adjusted so that the electrons reach the sample with virtually no energy, producing a cloud of low energy electrons near the surface that self-regulate any charge build-up.

Cross-sectional imaging of hair could be particularly useful for characterizing mechanisms of drug incorporation and may also help in determining the effect of various chemical treatments on the distribution of the drugs in the hair matrix. Figure 2 shows cross-sectional CN^- and Br^- images from one of the doped hairs. In this example, the compound is localized mainly in the periphery of the hair, penetrating 10-20 micrometers below the surface. This type of non-uniform distribution would not be desirable in a standard hair material. Several types of hair were examined (different natural colors, dyed and permed) and very similar distributions were found. However, it should be noted that mercurochrome may not be the best model compound for drugs of abuse because it forms strong covalent bonds with the hair matrix (compounds such as PCP and cocaine do not) (2). An attempt was also made to localize brominated PCP in soaked hair (again courtesy of D. Kidwell, NRL). The Br^- was clearly localized in both the full hair strand and in cross-section. However, identification of its distribution was somewhat ambiguous due to the presence of mass interferences.

High mass resolution and energy filtering are now being used in an attempt to overcome this limitation. We are also preparing fluorinated cocaine samples which should be less susceptible to mass interference problems.

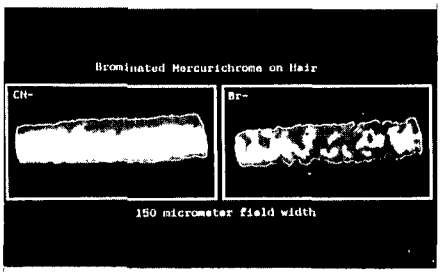

Figure 1. Secondary ion images of CN^- and Br^- from doped hair sample (150 μm field of view).

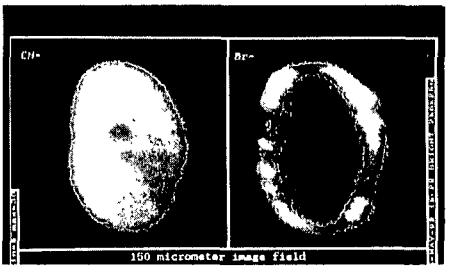

Figure 2 Secondary ion images of CN^- and Br^- from a cross-section of doped human hair (150 μm field of view).

We have also looked at the intact molecular ions from model compounds on the hair surface. As test samples, hairs were soaked briefly in saturated ethanolic solutions of tetrabutyl ammonium bromide or a 1 mg/mL ethanolic solution of cocaine. Microbeam imaging was used to examine full hair sections of these samples. Figure 3 shows the silver ion image (from the silver paint in which the hair was embedded) and the parent cation (m/z 242) from tetrabutyl ammonium bromide. Similarly, Figure 4 shows a comparison of the silver ion image and the protonated molecular ion (m/z 304) for cocaine.

In conclusion, it appears that SIMS could be a valuable tool for studying both the mechanism of drug incorporation in human hair and the influence of various external treatments on the re-distribution of drugs in the hair matrix. The ability to image intact molecular ions on the surface of hair suggests that SIMS may be useful for evaluating surface contamination effects and raises the possibility of localization studies without the need for using labeled compounds.

Methods for Increasing Parent Ion Signal Intensity from Bulk Organic Materials Analyzed with an Imaging Time-of-Flight Secondary Ion Mass Spectrometer

*Joe Bennett and Greg Gillen, Surface and Microanalysis Science Division, National Institute of Standards & Technology, Gaithersburg, MD 20899

One difficulty associated with collecting secondary ion images under static SIMS conditions (dose less than 10^{13} ions/cm^2) is the need to use the sputtered material as efficiently as possible. The necessary sensitivity can be obtained using high transmission time-of-flight mass spectrometers (TOF-MS) but the ion production process ultimately limits the ability to collect meaningful secondary ion images. We report here on our attempts to increase positive secondary ion parent signals from bulk organics sputtered with Ga^+ from a liquid metal ion source (LMIS). We emphasize the influence of primary beam energy and dose on signal intensities as related to molecular ion imaging with microprobe TOF-SIMS. Also, the use of cationization to increase the parent ion signal will be presented.

Primary Ion Energy and Dose

The smallest beam diameters (~50 nm) are obtainable from a LMIS only at high beam energies (>25 keV). While these beam diameters will provide the best lateral resolution the high beam energy may result in excess damage in the sample and, therefore, lower secondary ion signals. We monitored parent and fragment ion signals from a thick deposit of tetrapentylammonium bromide (TPB) on Al and from a leucine film vapor deposited on Si as a function of primary ion dose (i.e., decay curves) for two beam energies. The decay curves for the parent ions are shown in Figures 1 and 2. Damage cross-sections, σ, for the compounds can be calculated from the decay curves using $N(t)/N(0) = e^{-\sigma v t}$ where N is the secondary ion intensities at time t and t=zero and v is the primary beam current density[1]. A low damage cross-section indicates a longer lifetime of the species in the sample. The damage cross-sections and total intensities under the curves are shown in Table 1.

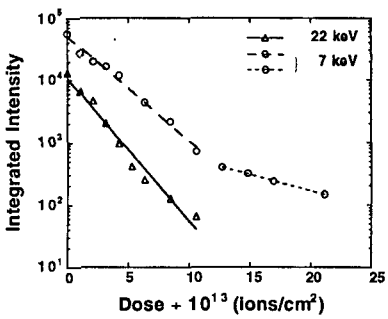

Figure 1. Decay curve for the TPB cation (m/z 302).

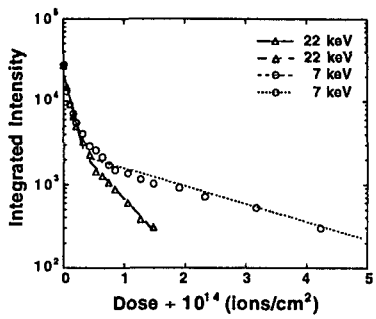

Figure 2. Decay curve for leucine $(M+H)^+$ (m/z 132).

For the quaternary ammonium compound TPB, lowering the beam energy from 22 to 7 keV lowers the damage cross-section as well as increases the total secondary ion signal. The increase in initial secondary ion signal for the lower energy beam is contrary to data presented in a prior study on intensity versus beam energy that predicted increasing signal with increasing energy[2]. However, that study used a maximum beam energy of 5 keV. There may be a maximum in the intensity versus energy plot peaking somewhere after 7 keV. The parent ion signal falls to background at around 10^{14} ions/cm^2 for the 22 keV beam while remaining above background out to 2×10^{14} ions/cm^2 for the 7 keV beam. A break in the 7 keV decay curve is seen at a dose of about

10^{14} ions/cm^2. This is similar to results observed under dynamic SIMS conditions[3]. This further decrease in the damage cross-section after the break combined with the higher signal intensity associated with the 7 keV beam results in an overall increase in integrated counts of almost a factor of 6 over the 22 keV beam.

For leucine the increase in intensity is not as great as for the salts but is on the order of 2 times higher for lower energies. Most of the intensity increase gained with the lower beam energy results from the change in decay curve slope after about 4 x 10^{13} ions/cm^2. The 7 keV damage cross-section is much lower after the break and parent ions can be detected at doses past the static SIMS level.

Table 1. Damage cross-sections and total integrated counts for parent secondary ions from bulk organics as a function of primary ion beam impact energy.

Compounds	Beam Energy (keV)	σ (10^{-14} cm^2)	Integ. Area (counts)
TPB	7	3.9[a], 1.2[b]	1.0 x10^6
	22	5.3	1.7 x 10^5
Leucine	7	5.7[c], 0.5[d]	4.5 x 10^5
	22	6.5[c], 1.8[d]	2.8 x 10^5
Leucine +LiCl			
M+H	22	5.2	3.5 x 10^3
M+Li	22	2.1	4.3 x 10^4
M+2Li-H	22	2.2	1.2 x 10^5

[a]Dose <10^{14} ions/cm^2 [c]Dose <4 x 10^{13} ions/cm^2
[b]Dose >10^{14} ions/cm^2 [d]Dose >4 x 10^{13} ions/cm^2

Cationization

The addition of alkali salts to organic compounds promotes the formation of cation adducts which can be used for structural and molecular weight assignments[4]. While the cationization of molecules may, in some instances, enhance secondary ion yields it may also lower the damage cross-section thereby increasing the lifetime of the parent ion[1]. Figure 3 shows the decay curves for $(M+H)^+$, $(M+Li)^+$ and $(M+2Li-H)^+$ from a 1:1 mixture of LiCl and leucine deposited on Ag. The damage cross-sections and total integrated intensities for the three curves are listed in Table 1. Note that while σ for $(M+H)^+$ is slightly lower for the mixture vs the bulk, σ for the $(M+Li)^+$ and $(M+2Li-H)^+$ are significantly lower.

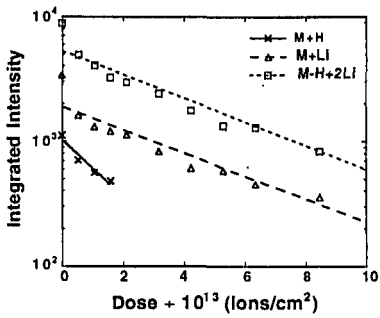

Figure 3. Decay curves for 1:1 mixture of leucine and LiCl on Ag.

Conclusions

Lowering the primary ion beam impact energy from 22 keV to 7 keV increases the instantaneous count rate for quaternary ammonium salts but not for amino acids. The damage cross-section for all compounds is lowered by lowering the beam energy. The lower damage cross-sections allows parent ions to be collected at doses past the static SIMS limit provided the compound is present in bulk form. The increased intensity and longer lifetime of the molecules associated with lower beam energies combine to give higher integrated secondary ion intensities over the range of doses studied for both quaternary ammonium salts and amino acids. The addition of alkali salts to promote cationization may further increase signal intensity by further reducing the damage cross-section. One drawback to lowering the beam energy is that the beam diameter increases with decreasing beam energy (~ 2X larger at 7 keV *vs* 22 keV). Therefore, the gain in secondary ion signal must be weighed against loss of spatial resolution.

Unimolecular Decay of Secondary Ions from Langmuir-Blodgett Multilayers

N. Poppe-Schriemer [1,2], W. Ens[1], K.G. Standing[1], J.B.Westmore[2] and J. Zhou[1],
[1] Physics Department and [2] Chemistry Department, University of Manitoba, Winnipeg, Canada, R3T 2N2.

Introduction

Since Langmuir-Blodgett multilayers have precisely defined thicknesses, they are valuable in fundamental secondary ion mass spectrometry (SIMS) studies. Galera[1] has suggested that keV incident ions may cause desorption of ions from depths as large as 150 angstroms, instead of from the surface as is usually assumed. Thus the incident ion's energy is distributed throughout a volume. Unimolecular decay of a desorbed secondary ion indicates that energy was deposited in that ion. *Unimolecular decay of ions from an ordered multilayer film of precisely defined* thickness is thus expected to give some information on how the primary ion energy is deposited in the sample.

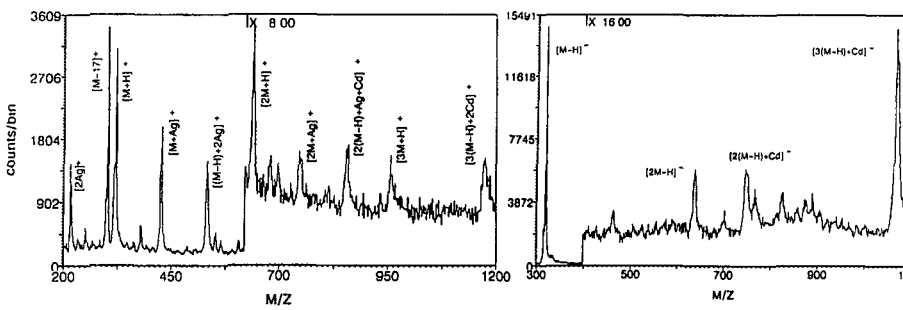
Method

Langmuir-Blodgett films up to 13 monolayers thick were prepared on hydrophilic silver surfaces. Both positive and negative ion spectra were taken with time-of-flight SIMS, using correlation techniques to observe the decays of various parent ions[2]. Iodine ions (I^-) were used as primary particles and their number was kept low to minimize disruption of the sample due to radiation damage.

Langmuir-Blodgett multilayers [3] are composed of layers of vertically aligned amphiphilic molecules. We transferred cadmium stearate and cadmium stearate (98%deuterated) monolayers from a pure water subphase to hydrophilic silver substrates at a constant surface pressure. The transfer ratio (the ratio of the area of molecules on the water to the area of the slide) averaged to 0.94+0.1, indicating that well-defined monolayers were transferred.

Results

Positive and negative spectra obtained from 5 monolayer samples are shown below.



1) Ion Yield *vs* Thickness

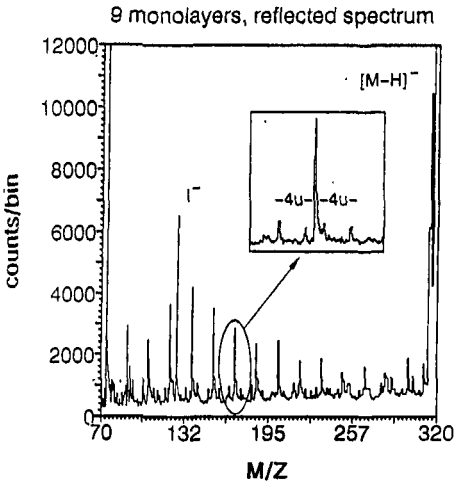
The $[M-H]^-$, $[Ag]^-$, and $[Ag]^+$ yield vs thickness curves are in agreement with earlier data[4]. Two distinct behaviors are visible in the plots:

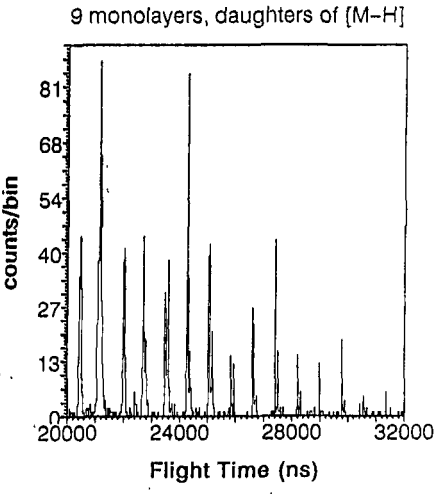
a) The yield peaks at ~1 monolayer for $[Ag]^-$, $[M-H]^-$, $[2(M-H)+Cd]^-$, $[3(M-H]+Cd]^-$, $[Ag]^+$, $[M+Ag]^+$, $[M-H+2Ag]^+$, $[2(M-H)+Ag+Cd]^+$, and $[3(M-H)+2Cd]^+$.

b) The yield is very small at 1 monolayer and increases to a peak at 5 to 7 monolayers for $[2M-H]^-$, $[M-17]^+$, $[M+H]^+$, $[M+D]^+$, and $[2M+H]^+$.

2]Fragmentation

Unimolecular decay of many ions was observed. Several of the ions gave series of daughter ions separated by 16u, corresponding to CD_2. The series for $[M-H]^-$ is given below; it is different from the series oberved in the reflected spectrum. The series for $[M+H]^+$ and $[M-17]^+$ are different and no corresponding series are observed in the positive reflected spectrum.





Conclusions

1) yield *vs* thickness
   - some ion yields peak at one monolayer (perhaps because the stopping power in the substrate is larger than the stopping power in the sample material.[4])
   - some ion yields peak at 5 to 7 monolayers (perhaps due to interactions among fatty acid polar groups)
2) positive and negative ion fragmentation
   - various unimolecular decay patterns have been observed
3) future goals
   - to analyse unimolecular decay as a function of the number of monolayers deposited on the target
   - to prepare multilayer structures composed of alternating layers of various fatty acids, and to study yields and unimolecular decay as a function of depth

Secondary Ion Desorption by Bombardment with Large Molecular Ions

J. C. Martens, W. Ens, K. G Standing and A. Verentchikov; Physics Dept.; University of Manitoba, Winnipeg, Canada. R3T-2N2

Introduction: Over the past few years there has been considerable interest in the ability of clusters to desorb molecular ions from specially prepared targets. There have been indications [1,2,3] that increasing the number of atoms in the projectile may give a strong enhancement in the secondary ion yield. By utilizing a high intensity beam of molecular ions produced by Matrix Assisted Laser Desorption (MALD) we have produced secondary ions by bombardment with massive organics at ~1eV/u or less.

Sputtering experiment		"Particle"	Mass (u)	Energy (keV)	eV/u
SIMS/FAB		Cs^+; Ar^+,Ar^0	130	~10	~100
Mahoney *et al*	[3]	clusters	100-10^6		~100-1
Knabe & Krueger	[4]	"dust"	10^{11}	10^6	0.01
Present data		benzoperylene	276	.3-40	1-100
		gramicidin-S	1140	.5-10	.4-9
		insulin	5733	.5-15	.1-3
		trypsin	23450	15	.6
		albumin	66000	15	.22

Experimental: A tandem TOF/TOF mass spectrometer was constructed as shown in Figure 1. Primary ions of organics produced by MALD, or inorganics (Cs^+, $(CsI)_nCs$) produced by laser ionization were separated in time in the first stage and desorbed secondary ions at the target. A detector - mounted behind a small hole in the target - provided knowledge of the intensity of the primary beam.

These experiments helped answer the following questions: (**1.**) Can heavy (> 5,000 u) and slowly moving (< 1 eV/u) organic projectiles desorb samples from a target? (**2.**) Is there a (non-linear) change in the sputtering properties as the number of atoms in the organic projectile increases? (**3.**) How do the spectra produced by such organic projectiles differ from those produced by particles usually used in SIMS (e.g. Cs^+)?

1. Desorption. Cs^+ and Gramicidin-S (Figure 2) ions were desorbed with organic projectiles at <.5 eV/u. (Gramicidin-S secondaries were observed even for albumin projectiles at ~0 2 eV/u.)

2. Enhancement. The ratios of both the atomic Cs^+ and the molecular gramicidin-S ions to the hydrocarbon background were found to increase with an increase in the number of atoms in the projectile (but with no change in the velocity). (See Figure 3.)

3. Comparison with SIMS. (a) The positive hydrocarbon background ions produced by organic projectiles (at all velocities) were found to be similar to those obtained from higher velocity Cs^+ projectiles. (b) The *absolute yield* of hydrocarbon background ions was 10x, and 2x greater for a benzoperylene than for similar energy (.3-10keV) Cs^+ or $(CsI)Cs^+$ projectiles. (c) The quality (molecular ion to hydrocarbon ratio) of spectra was decidedly better for Cs+ than for similar energy benzoperylene projectiles.

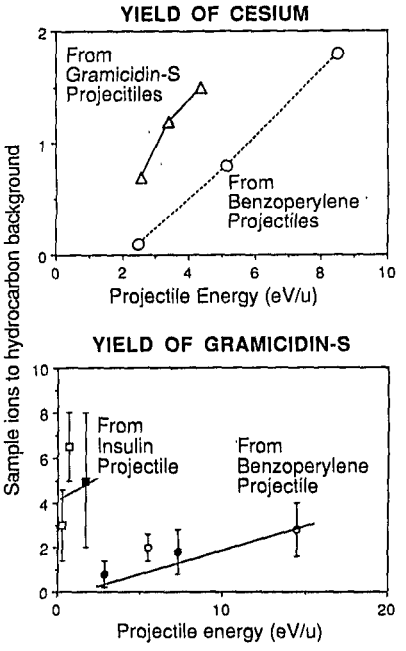

Figure 3. Relative positive-ion yield of (a) Cs^+ and (b) gramicidin-S for two different projectiles as listed. In each case, the heavier projectile produced an increase in ratio of sample-ion to hydrocarbon background ions.

ASPECTS OF LARGE ION DETECTION IN MATRIX ASSISTED LASER DESORPTION MASS SPECTROMETRY

R.S. Brown and N.L. Gilfrich
Department of Chemistry, Colorado State University
Fort Collins, Colorado 80523

Several studies have been performed with a modified discrete dynode based electron multiplier (17 stage, Thorn EMI) to try to determine the effect of secondary ion production from large m/z primary ion impact on the resulting detector signal observed. Other workers have determined[1,2] the nature of both the positive and negative secondary ion species typically observed from large m/z particle impact. While the exact m/z distribution of the secondary ion species generated varies somewhat between positive and negative secondary ion species, this difference is at most a factor of 2 in the observed m/z of the sputtered secondary ion species. If a detector were modified so that it would detect only positive secondary ion species, as opposed to the normal configuration in which both negative secondary ions and electrons are propagated through the detector, than a good estimate of the effect on the detector's response due to the more massive secondary ion species being sputtered by larger m/z ions can be determined directly. This is done by comparison of the detector's response when detecting positively and negatively charged secondary particles sputtered by a primary ion impact. If the potentials normally applied to the first and second dynode of a discrete multiplier are reversed (all other dynode potential are kept the same) positive secondary ions will be accelerated towards the second dynode and so the resulting ion signal will be due to positive secondary ions produced from the primary ion impact.

When these signals are compared for a variety of primary ion projectiles (27.7 KeV) ranging from insulin (mw=5777.58 Da) to a bacterial protease (mw=27288.4 Da), the signal profile generated by detecting the positive secondary ions produced is typically broader and shifted in time relative to the signal observed when detecting the negative secondary ions produced. Even for the relatively low mass porcine insulin primary ions, where ion-to-electron conversion processes are thought to still dominate, a small amount of positive secondary ion production is observed, offset from the normal detector signal by approximately 100 nanoseconds. This observed flight time, coupled with the dynode spacing and the applied electric field would correspond to a m/z of approximately 20. This suggests the possible sputtering of Na^+ surface contaminants. While for 27.7 keV porcine insulin ions, the yield of secondary ion is low and thus the effect on the observed detector signal small, the same is not the case for larger m/z ion projectiles with the same kinetic energy. For equine myoglobin (mw=16951.5 DA), the secondary ion yield at the detector has increased substantially as is evidenced by figure 1. By numerically subtracting the positive secondary ion signal produced from the modified detector from the ion signal observed in the normal detector configuration, a much better resolved signal is observed and a ion peak, due to adducting of trifluoroacetic acid (used in sample preparation), can be distinguished.

Another area where secondary ions sputtered from surfaces by primary ion impact becomes important is in the area of postacceleration. Postacceleration of ions is desirable to improve the detectability of slow moving ions and is typically accomplished by adding a conversion dynode after the flight tube of a TOF mass spectrometer. It was anticipated that by increasing the impacting ion's velocity by postacceleration (up to -20 kV), both increased sensitivity and a decrease in the detrimental time spreads induced by secondary ion conversion processes at the detector would be realized. While a factor of 5 improvement in S/N was obtained for rabbit γ-globulin (mw=150,000 DA) with a CuBe venetian blind style postacceleration dynode biased to -20 kV (net impacting ion energy of 45 keV) and placed in front of the conventional discrete dynode detector, the observed peak width also increased by 15%. This is believed to be due to increased detection efficiencies of secondary ion species sputtered from the conversion dynode, given the increased potential difference between the added conversion dynode and the first detector dynode (17.3 kV) when compared to the normal 150-200 volts typically present between dynodes in the discrete dynode detector. This phenomenon is demonstrated (figure 2) by the observed signal with the postacceleration modified detector from porcine insulin primary ions. As the potential applied to the conversion dynode is increased to -20 kV, a large secondary signal component is observed which is not significant when low extraction fields (i.e. several hundred volts) are present. This problem can be eliminated by utilizing a dual conversion dynode scheme in which two dynodes are added to the detector. The first is floated at the desired postacceleration voltage, while the second is held at a 100-200 volt more positive potential, identical to the normal detector configuration. The resulting peaks have the same mass resolution as the spectra produced from the unmodified detector.

The extent of signal distortion due to the generation of secondary ion species is often obscured in MALD spectra by the large amounts of matrix adduct ion species which occur for larger mass analytes. The recent development of several matrix materials which exhibit little or no adduct ion formation allows the detector tailing due to secondary ion species to be observed directly. Figure 3 shows a comparison between the ion signals produced (discrete dynode detector) for sinapinic acid and α-phenyl-4-hydroxy-cinnamic acid. The latter produces very little matrix adduct ion formation and the ion signal tail is believed to be due primarily to secondary ion processes. Figure 4 shows a mass spectrum with the α-phenyl-4-hydroxy-cinnamic acid as the matrix and a dual microchannel plate (MCP) based detector which does not suffer (apparently) from the same secondary ion signal distortions observed with the discrete dynode detector. This spectrum demonstrates the very low level of adduct formation with this matrix. While the MCP detector appears to be less sensitive to signal distortion due to secondary ion conversion processes, this insensitivity to sputtered secondary ions probably also accounts for why the MCP detector is less sensitive for large m/z ions where secondary ion conversion processes are the primary source of ion signal.

Improved Source Ion Optic Design for Quadrupole Mass Spectrometers

T.O.Merren and S. Lowes, V.G. Biotech, Tudor Road, Broadheath, Altrincham, Cheshire, WA14 5RZ United Kingdom

SUMMARY

The spectra observed in negative FAB mode were observed to have a continuum of noise superimposed on the peaks. A chicane introduced into the source lenses removed all the background without loss of sensitivity.

DEVELOPMENT METHOD

As with many development projects, the type of sample is not important. It is convenient to choose a sample which gives a very stable spectrum over a wide mass range. Caesium Iodide is a suitable candidate, although final tests have to be made on samples in a glycerol matrix.

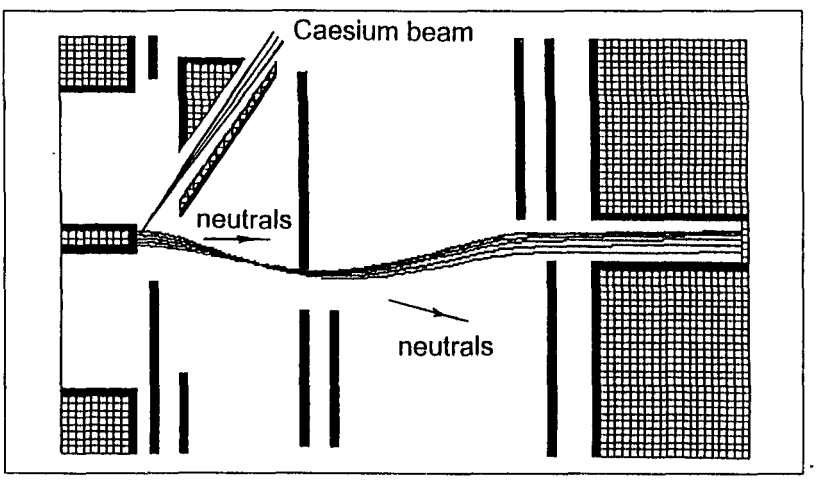
EXPERIMENTAL

The source of the noise had to be determined first. It was established that electronic and detector noise could be ignored, and that the continuum observed came entirely from the sample on the target, either directly or indirectly and further it is created by neutral particles.

METHOD OF IMPROVEMENT

Once the source of the noise has been established, the solution required becomes immediately apparent. There should be no line-of-sight between the target and the entrance to the analyser.

The ion optic program Simion* was used to find an arrangement of electrodes which would transmit all the ions, and reject neutrals (see figure below). The assembly was constructed so that it is a direct replacement for the line-of-sight version.



EVALUATION OF THE TECHNICAL IMPROVEMENT

In use, the improvement given by the chicane lens source was immediately apparent. Simple tests confirmed that the background had indeed been removed. For example, when the Caesium primary beam was removed, there was no change in the zero level recorded.

EVALUATION BY APPLICATIONS

The real test of the chicane lens is in its use. A detergent sample which is comprised of a mixture of over fifty compounds was analysed on a solids probe. The sample has two series of the form:-

$R - O - [CH_2 - CH_2 - O]_n - S - O_3$ where $R = [C_{12} - H_{25}]$ or $[C_{13} - H_{27}]$

The first spectrum of the mixture was different to that expected, but on examination was seen to be singly charged dimers of the two series, with a sodium adducted. When the sample was diluted, the masses of the two series were observed. The peaks which are observed over many minutes are being produced from tens of nanograms of sample.

CONCLUSIONS

The limitation to the application of negative FAB lies in the suitability of the sample for the technique, and the loading procedure.

Particle Beam LC/MS and MS/MS of Natural Products.

Iain Mylchreest, Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

The family of dimeric indole alkaloids that are found in leaves of the plant *Catharanthus roseus* are extremely potent anti-cancer drugs. Their detection and extraction by traditional methods is long and expensive due to their presence at low levels, and also a tendency to degrade during extraction. These methods also tend to be relatively non specific.

The combination of a Particle Beam Interface (PBI) with MS/MS techniques has allowed the rapid screening of small amounts of plant extract prior to analytical LC/MS runs and subsequent fractionation, confirming the presence of target compounds or indicating the degradation of a possible useful plant extract.

Under PBI methane CI MS/MS conditions , daughter ion spectra of the dimeric alkaloid protonated molecular ions are easily obtained. The Vinblastine family of dimeric alkaloids of which anhydrovinblastine (m=792) and vinblastine (m=810) are members, give very characteristic neutral losses in their daughter ion spectra, namely losses of m/z 456, 269 and 60. The loss of 456 being the loss of a vindoline moiety which is a characteristic unit of the dimeric alkaloids.

By introduction of a small amount of a plant extract via a loop injection through the PBI, it is possible to screen in the neutral loss MS/MS mode for the characteristic losses. The resultant neutral loss spectra show the protonated molecular ions of the dimeric alkaloid family, or in a degraded sample, the lack of ions in the expected molecular ion region.

Demonstrated here is the pre-sample screening of a fresh plant extract followed by reverse phase LC/MS analysis using the PBI in the EI mode, confirming the screening experiment and also providing characteristic EI fragmentation for structural confirmation. The MS/MS screening of a degraded sample followed by LC/MS analysis is also demonstrated showing how samples lacking in the target compounds can be rapidly dismissed.

The phytoecdysteroids are poly-hydroxylated steroid hormones which play a vital role in the moulting of insects, and are used as insecticidal agents against such pests as locust. Typical compounds of this class are the family of ecdysones . They are widely found, not only in insects, but from plant sources such as *Silene nutans and Silene otites.* These are not the type of compounds that are typically run by PBI due to their lability and lack of volatility. The combination of the PBI with EI and methane CI is demonstrated for the analysis of plant samples containing these compounds, providing LC/MS separations and both molecular weight and characteristic structural information.

High-Flow Ion Spray Liquid Chromatography/Mass Spectrometry.

Gérard Hopfgartner, Alex Mordehai, Tim Wachs, Karen Bean and Jack Henion
Drug Testing and Toxicology, NYS College of Veterinary Medicine, Cornell University, 925 Warren Dr., NY 14850

INTRODUCTION

The classical flow rates used with electrospray/ion spray interfaces are less then 50 microliters per minute. Therefore, for standard LC applications it is necessary to split effluent before the mass spectrometer which hampers qualitative and quantitative analysis.

An alternative would be to use microbore packed columns which are compatible with such flows and yield lower detection limits than standard columns for the same amount of compound injected. However, these smaller columns do not provide an increase in resolution and the injection volume is limited to only a few microliters.

In this study we have incorporated a "liquid shield lens" between the ion spray nebulizer (sprayer) and the heated capillary interface which allows conventional HPLC flows up to 2 milliliters per minute without splitting and low nanogram detection limits in the full-scan mode for quaternary ammonium drugs.

EXPERIMENTAL

The mass spectrometer used in this work was a Hewlett-Packard Model 5985B modified in-house for atmospheric pressure ionization (see ref. 1) using a heated capillary interface. The HP-5985B is differentially pumped and is equipped with a high energy dynode (HED) detector which significantly increases its sensitivity. HPLC was performed on a Zorbax SB-CN 5 µm 4.6x150 mm column. The eluant was delivered by a Hitachi L-6200A pump at 1.2 ml/min. The eluant was a mixture Acetonitrile/Water 80:20 5 mM ammonium acetate.

RESULTS

The principal limitation of electrostatic spraying to produce charged droplets is the liquid flow rate. In pneumatically assisted electropsray (Ion Spray) nebulization is primarily due to high velocity coaxial nitrogen gas. We have observed that high-flows (up to 1 ml/min) Ion Spray is still able to produce a charged spray with reasonable analyte ion current response. However, at these higher flow without post-column splitting the excess HPLC effluent can condense and adversely affect sensitivity and ion current stability. To avoid this problem we have placed a grounded lens orifice "liquid shield lens" approximately 5 mm from the ion sampling capillary. The liquid shield lens ("sombrero" type) acts as a spray splitter and an aerofocusing device. This device is absolutely necessary for high-flow Ion Spray experiments because it inhibits collapsing droplets to be drawn to the heated capillary interface which generate unstable ion current. Figure 1 shows the SIM LC/MS chromatogram of a synthetic mixture of quaternary ammonium drugs (250 pg each compound). The linearity range is two orders of magnitude and low nanogram sensitivity is obtained under full-scan "Up-Front " CID conditions (scan range m/z = 50-400).

Classical Ion Spray/Mass spectrometry behaves like a concentration sensitive device. At high-flow Ion Spray we observe an enhancement in signal versus low flow Ion Spray and electrospray (figure 2). The higher sensitivity is due to the increased rate at which sample is reaching the mass spectrometer per unit time (mass flow response). We have also successfully applied this system for the characterization of pesticides (gradient elution) as well for the analysis of LSD samples (ref. 2) using an acetonitrile/phosphate buffer.

CONCLUSIONS

The liquid shield lens/heated capillary interface is a very rugged system for conventional LC/MS applications. One of the main advantages of this setup is the avoidance of having to split the LC eluant (<= 50 µl/min). This simplifies operation and increases the sensitivity of this analytical combination.

New Applications of Liquid Chromatography - Electrospray Mass Spectrometry

T. Hutton, S. Lowes, Fisons Instruments, VG BioTech, Tudor Road, Altrincham, WA14 5RZ, UK.

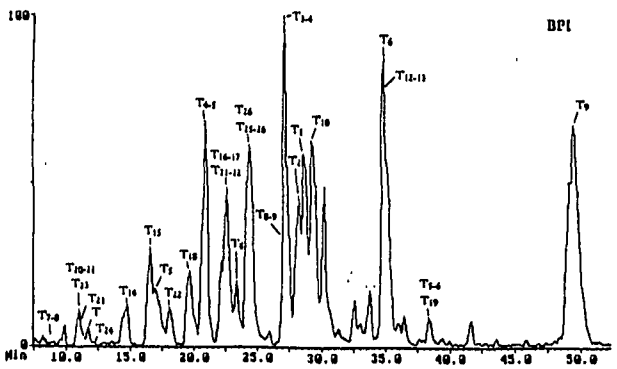
Electrospray Mass Spectrometry (ESMS) is a powerful technique for the on-line characterisation of complex mixtures separated by liquid chromatography (HPLC). Many large, thermally labile, polar or involatile molecules which were previously unnameable to mass spectrometry can now be routinely analysed in this way. Here we report three applications of LC systems interfaced to an electrospray ionisation source of a quadrupole mass spectrometer. The first and second examples highlight modifications to proteins. The third is an environmental application.

Recombinant porcine somatotropin (rPST)

Recombinant porcine somatotropin had been modified by deliberate alteration of the primary sequence by genetic engineering in order to manipulate the properties of the resulting protein - a growth hormone. Confirmation of successful amino acid substitution can be made by simple mass measurement of the intact protein. However, digestion of the protein (in this case with trypsin) and subsequent on-line HPLC MS analysis, allows the location of the amino acid substitutions to be determined.

The identification of the tryptic peptides by electrospray mass spectrometry confirms that the expected modifications to the protein have occurred. Those peptides identified from the digest are labelled on a Base Peak Intensity (BPI) plot (Figure 1) with their tryptic fragments number.

Figure 1.
rPST digest



Mass spectra, which are typical of those produced for each peptide in the chromatogram, are shown in Figures 2 and 3 for peptides T9 and T10.

Figure 2.
Peptide T9

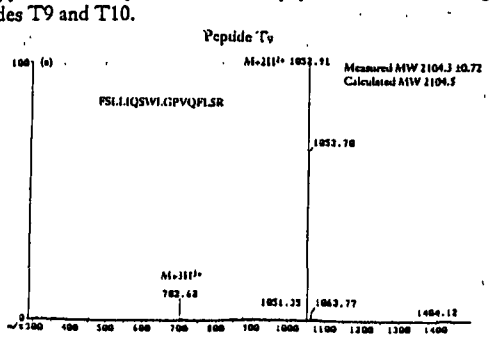


Figure 3.
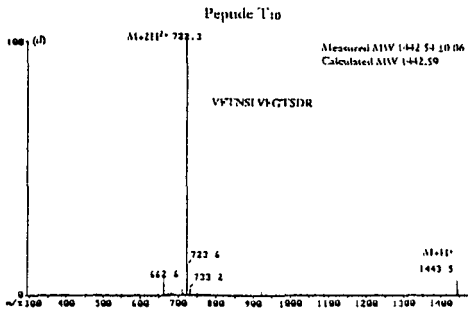
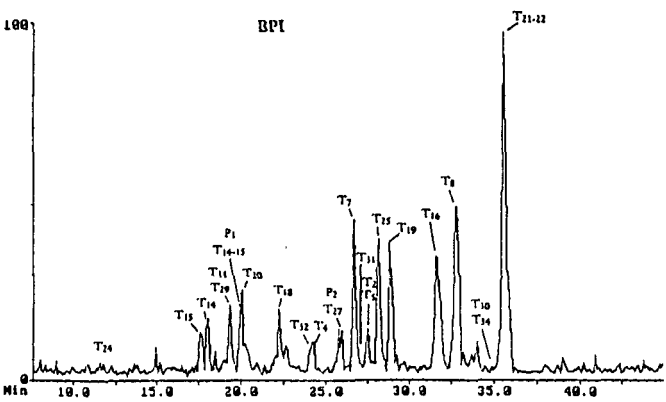
Peptide T10



Insertin

Insertin occurs as an actin binding domain in tensin, a larger protein. There are two known phosphorylation sites on the insertin molecule located at amino acid residues 154 and 310. In both cases the phospho groups are attached to serine. These phosphorylation sites on insertin have previously been located by conversion of the phosphoserine to S-ethylcysteine (Meyer H.E. et.al. 1991) and subsequent sequence analysis. Data shows the on-line detection of these phosphopeptides, P1 and P2 in Figure 4 by electrospray mass spectrometry without prior chemical modification. Thus demonstrating a much more rapid method of identifying the phosphorylation sites than with conventional methods.

Figure 4.
Insertin digest



The final example demonstrates the analysis of a waste water sample for Bentazon, 2 naphthalene sulphonic acid, metoxuran, ethylenediaminetetraacetic acid (EDTA), nitrilotriacetic acid (NTA) and polyethylene glycol (PEG). Both positive and negative ion LCMS data is presented demonstrating the ability to combine the resolving power of reversed phase liquid chromatography with the high specificity of mass spectrometry.

RADICAL CATION FORMATION IN ELECTROSPRAY IONIZATION

Gary J. Van Berkel, Scott A. McLuckey, and Gary L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365.

Recently, we reported the observation of molecular radical cations in the ES mass spectra of various alkyl-substituted metalloporphyrins (1). This observation was significant because molecular radical cations or radical anions are generally not observed in ES mass spectra. Tentatively, we interpreted our observations as an indication of either chemical oxidation of the porphyrins involving some species in the ES solvent system, prior to or during the spraying process, or electrochemical oxidation in the ES needle. These preliminary explanations for radical cation formation suggested that chemical reactions might be exploited to form ions in solution and successfully detect compounds not normally amenable to ES/MS. This reasoning led, for example, to our use of charge-transfer complexation to form chemically radical cations in solution from compounds such as *N,N,N',N'*-tetramethyl-1,4-phenylenediamine for analysis by ES/MS (2). More recently, we have used "magic acid" (fluorosulfuric acid/$SbCl_5$ (4:1) in methylene chloride) to form chemically the radical cations of PAH's and "bucky ball" in solution for analysis by ES/MS. The data presented in this paper demonstrate that the radical cations we observed from metalloporphyrins were formed via an ionization phenomenon inherent to the ES process, viz. electrochemical oxidation at the metal/solution interface in the ES needle. Moreover, we have found that this electrochemical oxidation phenomenon, in addition to chemical methods, can be exploited to form radical cations from a variety of analytes for analysis by ES/MS (3).

To confirm that a chemical reaction was not involved in formation of the porphyrin radical cations, an experiment using the ES spray system illustrated in Figure 1 was carried out. Attached to the end of the normal ES needle was a 30 cm length of 100 μm-i.d. (350 μm-o.d.) fused silica capillary. A solution of the analyte of interest was pumped through the system at a rate of 2 μL min^{-1}, for several minutes, with the high voltage turned off. The high voltage was then turned on and data acquisition started. For compounds that exist as ions in solution, like tetrabutylammonium iodide, signal due to the molecular species is observed essentially immediately upon turning on the high voltage. In the case of Ni(OEP), dissolved in methylene chloride/methanol/TFA (10/90/0.05% v/v/v), the porphyrin radical cation (*m/z* 590) was not observed in the early stages of data acquisition. The time delay before the appearance of M^+ was approximately equal to the time to elute the void-volume from the fused silica/needle butt connection to the spray end of the silica, which calculated to be about 72 s. A steady total ion current is noted until 85 s, the approximate time calculated for elution of the void-volume, at which point a significant increase to a new steady state ion current occurs. The extracted ion current for the radical cation of Ni(OEP) shows that this increase in ion current coincides with the appearance of the radical cation. Before elution of the void-volume a low abundance peak corresponding to protonated Ni(OEP) is observed along with its diagnostic fragment ion at *m/z* 562. These data clearly indicate that the metalloporphyrin radical cations are *not* preformed ions in solution and the metal/solution interface in the ES setup is involved in their formation.

Electrochemical formation of radical cations is consistent with the electrophoretic charge separation description of the ES process recently put forward by Kebarle and co-workers (4). For the electrophoretic charge separation mechanism to be operational in the positive ion mode, charge balance requires that an oxidation reaction, ultimately resulting in electron flow to ground, must occur at the metal/solution interface within the ES needle (or at the metal high voltage connection to the solution) to balance the positive ion charge leaving the needle in the spray. The types of analytes that can be ionized in this way are characterized as easy to oxidize, being comprised of highly conjugated systems and/or containing heteroatoms with lone pair electrons. These structural characteristics aid in delocalization of the unpaired electron and positive charge thereby stabilizing the radical cation. Substitution on these molecules with electron-donating groups, e.g., -OH, $-OCH_3$, $-N(CH_3)_2$, and $-CH_3$, can also aid in ion stabilization. Table I presents a representative list of compounds for which we have investigated the production of radical cations by way of this electrochemical phenomenon. Excluding free-base OEP, which formed $(M+H)^+$, only one compound listed, viz. naphthalene, could not be detected as the radical cation. The IE's and $E_{1/2ox}$ values for this compound, may therefore, represent upper limits for formation of M^+ in ES under the current experimental conditions. If this is so, the potential gradient at the metal/solution interface that drives the electron transfer process must range up to only about 1.5 V. Compounds with $E_{1/2ox}$ values above 1.5 V and IE's greater than about 8.0 eV would probably not, therefore, form radical cations. These conclusions are supported by the fact that the relative ionization efficiencies for these compounds (based on the figures of merit in Table 1) also decrease as the IE's and $E_{1/2ox}$ values increase.

Observation of radical cations in ES/MS must involve a careful selection of solvents because radical cations can be consumed by several types of rapid reactions in solution. These reactions can be minimized, thereby "stabilizing" and extending the lifetime of radical cations in solution, through the judicious choice of solvents and solvent additives. Protic solvents as well as nucleophilic solvents (e.g., water and methanol) and nucleophilic solvent additives (e.g., acetate anion) are to be avoided. Aprotic, non-nucleophilic solvents such as dried acetonitrile or methylene chloride, which are commonly employed in electrochemical generation of radical cations, give best results. The use of TFA as a solvent additive (e.g., TFA in methylene chloride) helps to "stabilize" the radical cations.

Comparison of Electrospray/MS and Continuous-flow FAB/MS for Agrochemicals and Their Metabolites

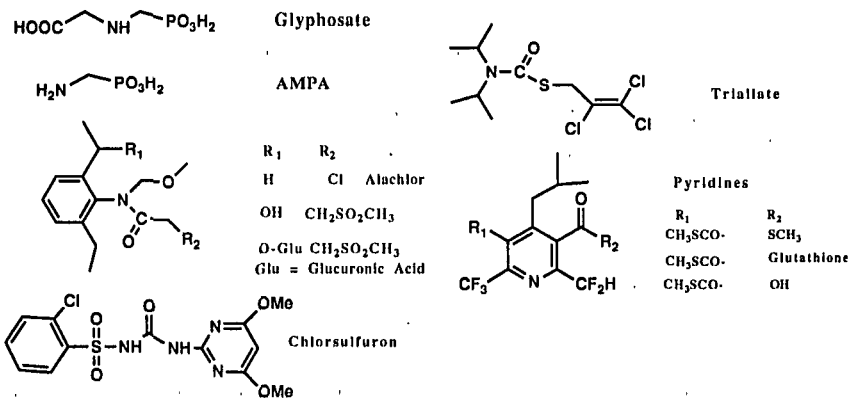
H. Fujiwara, R. T. Solsten, and R. G. Nadeau
Monsanto Co., Life Sciences Research Center,
St. Louis, Missouri 63198

J. Tamura and R. B. Cody
JEOL USA, INC.
11 Dearborn Rd.
Peabody, MA 01960

We have analyzed several classes of herbicides and their metabolites (MW: 100 -1000; Figure 1) by LC/FAB/MS on a high resolution sector mass spectrometer (VG ZAB-HF) during the last few years . On the other hand, we are currently analyzing these compounds by LC/ESI/MS using two types of quadrupole instruments (Sciex API *III* and a Vestec ESI source on a Finnigan 4535) and a high resolution sector instrument (JEOL SX-102A).

The results of LC/FAB/MS and LC/ESI/MS of these compounds are summarized in Table 1. Glyphosate (Roundup® by Monsanto) and AMPA were extremely sensitive to LC/ESI, while they were not sensitive to LC/FAB. This is probably due to poor solubility of these compounds in the glycerol matrix used for LC/FAB.

Figure 1
Agrochemicals and Their Metabolites



In the case of chloroacetanilides, polar metabolites are always sensitive to LC/FAB, while relatively less polar metabolites are not sensitive to LC/FAB at all. Electrospray ionization is better suited for metabolite identification of chloroacetanilides since both polar and non-polar metabolites are expected from plant and animal metabolism. Both pyridine and sulfonylurea families are sensitive to LC/FAB and LC/ESI. We have not analyzed triallate by LC/ESI although it is not sensitive to LC/FAB.

Table 1
Summary of LC/FAB/MS and LC/ESI/MS Data for Agrochemicals and Their Metabolites

Agrochemicals & Metabolites	LC/FAB (pos or neg)	LC/ESI (pos or neg)
•Glyphosate	Not Too Sensitive (500 ng - 1 µg)	Extremely Sensitive (1 ng - 10 ng)
•Chloroacetanilides (alachlor, acetochlor, propachlor)	Very Selective Polar - Very Sensitive Non-polar - Not Sensitive	Sensitive (10 ng - 50 ng)
•Pyridines	Extremely Sensitive (300 pg - 10 ng)	Sensitive (10 ng - 50 ng)
•Chlorsulfuron (sulfonylurea)	Sensitive (10 ng - 50 ng)	Extremely Sensitive (1 ng - 50 ng)
•Triallate	Not Too Sensitive (1µg - 3 µg)	Not Tested Yet

Note: *The value in parenthesis denotes the detection limit.*
LC/FAB (VG ZAB-HF), LC/ESI (Sciex API III, Vestec (Finnigan 4535), JEOL SX-102A)

The results of accurate mass determination of glutathione conjugates of chloroacetanilide herbicides at 5,000 resolution by electrospray ionization using magnet and voltage scan methods were somewhat better than those obtained by the LC/FAB method (Table 2). It is difficult to compare high resolution data since accurate mass determination involves many factors such as scan speed, scan mode, positive ion and negative ion modes, resolution, sample-reference ratio, and instrument. However, in general, we frequently obtain acceptable accurate mass measurements of agrochemicals using ESI/MS.

ION SPRAY LC/ MS ANALYSIS OF BILE ACIDS AND CONJUGATED BILE SALTS

Gerald C. DiDonato and Bethanne M. Warrack, Analytical Research and Development, The Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton, New Jersey 08543-4000

The analysis of bile acids and bile acid conjugates has proceeded along several pathways, including HPLC separation with UV detection, GC/MS, LC/MS, and mass spectrometric techniques employing probe FAB analysis. Though perhaps the easiest and most readily accessible analysis, HPLC with UV detection suffers from poor sensitivity and selectivity due to lack of a suitably strong chromophore. GC/MS techniques, which provide greater sensitivity and specificity, require extensive derivatization in which the information regarding the conjugation is lost due to the need for hydrolysis and derivatization. Direct analysis by FAB/MS and FAB/MS/MS has provided rapid information on the types of free and conjugated bile acids present in biological matrices. In some instances, use of high-energy CAD experiments has been able to distinguish positional isomers. However, the presence of isobaric compounds without distinguishing characteristic fragment ions makes the unequivocal identification of isobaric bile salts impossible without prior chromatographic separation.

LC/MS techniques provide both chromatographic separation of bile components as well as molecular specificity via molecular weight and MS/MS data. LC/MS techniques which have been applied to the analysis of bile salts include thermospray, plasmaspray, and frit-FAB. Analysis in the negative ion mode provided intense $(M-H)^-$ ions as well as ions due to losses of water. Low picomole detection limits via SIM were reported.

As part of our on-going application of API LC/MS techniques to drug metabolism studies, we have developed LC/MS methodology for the analysis of bile acids and conjugates utilizing the SCIEX API III triple stage quadrupole equipped with an ion spray interface. Our interest lay in the identification of components found in control bile during the course of drug metabolism studies. We have developed two LC/MS methods, one using a short (3 cm) cartridge column and a flow of 1.0 ml/min, where sample size is not limited. A second method was developed using a 1 mm microbore column, which is more amenable to small sample sizes.

The ion spray spectra of selected bile acid standards are in themselves intriguing. When analysed via ion spray using a mobile phase consisting of water/acetonitrile/TFA, the bile acids form strong $(M+CH_3CN+H)^+$ and $(M+2(CH_3CN)+H)^+$ ions. The ratio of the $(M+H)^+$, $(M+CH3CN+H)^+$, and $(M+2(CH_3CN)+H)^+$ ions are unique for each of the bile salts studied, and have been reproducible within 10% over a two year period. The table (opposite) lists the relative abundance of adduct ions for four sets of isobaric bile acids.

The acetonitrile adducts are so intense that in some cases examination of the ion spray mass spectra would yield erroneous molecular weight information. For example, examination of an ion spray spectrum of ursodeoxycholic acid (UDC) yields a weak $(M+H)^+$ ion, and intense mono- and di-acetonitrile adducts. Without prior knowledge of the compound, or MS/MS, or the use of an extremely high orifice potential during analysis, the molecular weight might be assigned as 433, and not 392. The four dihydroxylated cholanic acids listed in the table have unique ratios of $(M+H)^+$, $(M+CH3CN+H)^+$, and $(M+2(CH_3CN)+H)^+$ ions, thus enabling differentiation of the four isobaric compounds. The difference in the intensity of these ions may be related to the relative stabilities of proton-bound acetonitrile-cholanic acid complex, but might also be due to stereochemical effects occurring in solution.

Use of ion spray affords excellent LC/MS sensitivity. Figure 1 contains the LC/MS ion spray total io current from the analysis of 15 bile acid standards using a 3 cm cartridge column and a water/acetonitrile gradient containing 0.1% TFA (70/30 to 30/70 10 minutes). The eight conjugated bile salts containing glycine and taurine are completely separated and elute in less than 7.5 minutes. SIM detection limits are on the order of a few nanograms.

Figure 2 is the LC/MS chromatogram from the analysis of monkey bile following a 40 nL injection using a 1 mm microbore column. The major components are easily identified from this small injection, indicating the sensitivity of ion spray LC/MS for the analysis of these compounds. On-column detection limits of 60 pg are achieved in an SIM mode. Greater sensitivity would be obtained through the use of capillary LC.

Probing Helical Content of Peptides by Deuterium Exchange Electrospray Mass Spectrometry

Robert J. Anderegg, Cynthia L. Stevenson, and Ronald T. Borchardt
Glaxo, Inc., Research Triangle Park, NC 27709 and Kansas University, Lawrence, KS 66045

Katta and Chait have shown that the extent of hydrogen/deuterium exchange for proteins as monitored by electrospray mass spectrometry can be an indicator of protein conformation (1). We have used a similar approach to study a series of peptides related to growth hormone releasing factor (GRF). Their use as a therapy for growth hormone deficiency has been proposed as an alternative to treatment with growth hormone itself. The peptides have been characterized by NMR and CD, so the helical content is known under various solution conditions.

The peptides under investigation are related to glucagon and contain 32 amino acids, differing from each other by single amino acid substitutions. Electrospray ionization MS results suggested that the exchange was quite rapid, with the side chain protons exchanging almost instantaneously, and the backbone (amide) protons exchanging more slowly. Usually the exchange had reached a plateau in the first 3-5 min. Consequently, experiments were set up to scan only a limited mass range (m/z 900-970), encompassing the abundant +4 charge state. Solutions (ca. 2 pmol/ul) were prepared in deuterated solvents, and were infused into the Sciex API-III mass spectrometer at a rate of 2 ul/min. Spectra were scanned continuously at 2.5 sec/scan.

Bovine GRF analogs with the sequence below were studied:

Y-A-D-A-I-F-T-N-S-Y-R-K-V-L-X-Q-L-S-A-R-K-L-L-Q-D-I-L-N-R-Q-Q-G-NH2

where X in position 15 is either Ala or Pro, to promote or inhibit helix formation, respectively.

In D_2O or D_2O/40 % MeOD, deuterium exchange of the Pro-analog was virtually complete by the time the first measurement was made (ca. 45 sec.). However, in D_2O/80 % MeOD, the exchange proceeded with a half-life of about 45 sec, so the progress could be monitored by MS. Plotting the results as "% protium remaining" vs. time, and assuming first-order kinetics, one can curve-fit the exponential decay to obtain rate constants for the exchange. The results are consistent with information from CD that predicts the peptide will be randomly coiled in water (very fast exchange), and helical in 80 % methanol (slower exchange).

When the analogs containing Pro and Ala were compared, the exchange of the Pro peptide was considerably faster (half-life = 45 sec) than that of the Ala peptide (half-life = 55 sec) (see Fig. 1). This is also consistent with the CD data, which show the Pro-analog to be only 47 % helical in 80 % methanol, while the Ala-analog is 81 % helical under the same conditions. Interestingly, the MS results indicate that the exchange is going further than might be predicted based solely on helical content. This suggests that amide bonds involved in the helix are exchanging, and that MS could perhaps provide information about the stability of the helix formed. If helix is formed, unwound, and re-formed, it would exchange its protons during periods of randomness, leading to a higher degree of exchange than expected. CD measures a time-averaged helical content, with no regard for helix stability.

The fact that the mass of the peptide appears to plateau after the first five min. of the exchange experiment may allow one to perform MS-MS analysis on the multiply charged parent ions, localizing where the

deuterium atoms are incorporated. Fig. 2 shows an MS-MS spectrum of a GRF-analog obtained after 5 min of exchange. The parent ion at this point is about 75 % exchanged. Analysis of the MS-MS data is continuing, but is complicated by the fact that various multiply charged daughters (+1, +2, and +3) are present.

ACKNOWLEDGEMENTS

The authors wish to acknowledge Alan Friedman and Teresa Kubiak of Upjohn for generously providing GRF analogs, and Dan Kassel, Larry Shampine, and Jian-Mei Ding of Glaxo for useful discussions.

Conformations of Gaseous Multiply-Charged Protein Ions by H/D Exchange in ESI/FTMS

Detlev Suckau, Yuer Shi, John P. Quinn, Michael W. Senko, Mei-Yi Zhang & Fred W. McLafferty

Cornell University, Dept. of Chemistry, Ithaca, NY 14853-1301

The charge distribution of multiply-charged protein ions formed by electrospray ionization (ESI) is indicative of the solution conformation of the protein, but the structure of the corresponding gaseous ions remains unclear. In this study, the gas phase reactivity of multiply-charged protein ions towards D_2O was characterized by recently developed ESI/FTMS instrumentation (1) providing unit resolution and <1 Da mass accuracy.

Multiply-charged protein ions were trapped in the ICR-cell with pulsed nitrogen gas and the increase in mass measured as a function of time. The pressure was kept constant with D_2O at 1.1×10^{-7} torr. Numbers of exchanged hydrogen atoms were determined for each charged species by shifted molecular weights, generally obtaining pseudo-first-order kinetics.

H/D exchange analysis of cytochrome *c* in the gas phase revealed two distinct conformational states (Fig. 1): the H-state exchanging a high number of 113 and the L-state exchanging a low number of 74 hydrogens (Fig. 2). The 8+ to 14+ ions were found in the H-state and the 12+ to 16+ ions in the L-state. Both distinct states were simultaneously found for the 12+ to 14+ ions by peak splitting in the course of the reaction. Assuming, that the exposure of a higher number of reactive sites is due to a larger surface, it is obvious that the highly charged ions have a tighter conformation than the lower charged ions. Interestingly, also in solution highly charged cytochrome *c* has a tighter structure, as indicated by a higher Å-helix content at pH 1 compared to the completely unfolded state at pH 2 (2), which correlates well with the gas phase data.

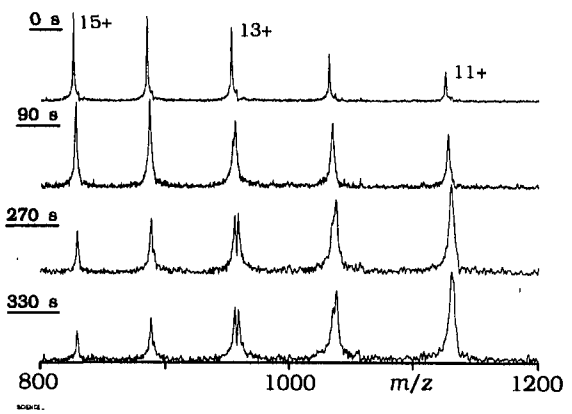

Fig. 1 ESI/FT mass spectra of cytochrome *c* after different times of H/D exchange in the analyzer.

The finding of 32 reactive sites on ribonuclease A, which is crosslinked by 4 disulfide bonds and therefore in a compact conformation, in contrast to 135 sites on the same protein with cleaved S-S bonds (VP-RNase), clearly demonstrated that a protein in a less compact conformation exposes a higher number of reactive sites.

The rate constants generally increased with charge. Ribonuclease, the only crosslinked protein in our study, showed a far higher charge dependence of reactivity than ubiquitin, myoglobin, cytochrome *c* or VP-RNase, which indicates the possible importance of charge density on H/D exchange in the gas phase.

The results of this study provide evidence that proteins adopt well defined conformations in the gas phase which are a function of the solution conformation. The observed conformational stability of gaseous protein ions can be explained by multiple attractive forces, like hydrogen and van der Vaals bonds. The importance of an aqueous environment for stabilizing protein conformations, therefore, may have been overestimated in the past.

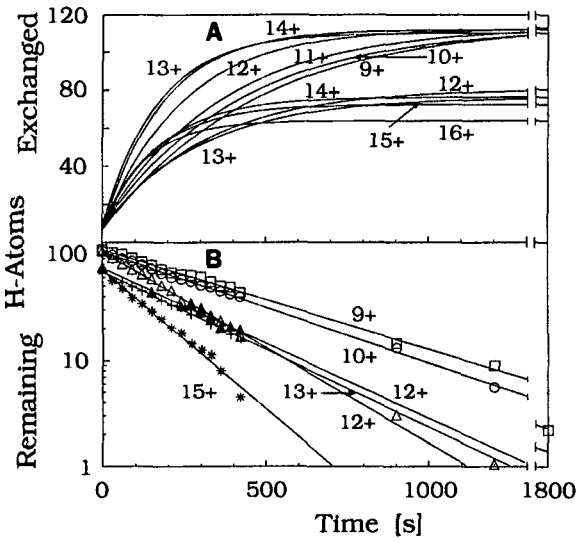

Fig. 2 H/D exchange kinetics of different cytochrome *c* charge states. The intersection with the ordinate of the logarithmic plot and the slopes determine the number of reactive sites and the rate constants, respectively.

DETECTION OF THE NONCOVALENT GDP-BOUND CONFORMATIONAL STATE OF THE HUMAN H-RAS PROTEIN BY ION-SPRAY MASS SPECTROMETRY.

B. Pramanik, A. Tsarbopoulos, E. Huang, T. Covey[1], S. Fuhrman[2] and A.K. Ganguly.

Schering-Plough Research Institute, 60 Orange Street, Bloomfield, NJ 07003, [1]Sciex, Thornhill, Ontario L3T 1P2, Canada and [2]Agouron Pharmaceuticals, San Diego, CA 92121.

In recent years, significant advances in the field of biological mass spectrometry have allowed the direct analysis of biomolecules previously not amenable to mass spectrometry. This is primarily due to the development of new ionization methods (particle-induced desorption methods and electrospray) which made possible to analyze intact biomolecules without any prior derivatization. Proteins up to 250 kDa and 130 kDa can be now successfully analyzed at the low picomole-to-femtomole range by matrix-assisted UV-laser desorption and electrospray/ion-spray ionization, respectively. Nevertheless, all these methods have failed to provide MW information on noncovalent complexes, such as those of enzyme-substrate, protein-ligand and protein-receptor. It is only recently, that noncovalent receptor-ligand complexes and enzyme-product complexes of hen egg white lysozyme have been detected via direct infusion ion-spray MS (1,2). In this report, we describe the use of ion-spray MS to the study of the noncovalent complex of human *ras* protein with GDP, as well as the effect of the pH and cosolvent (methanol) on the stability of the *ras*:GDP complex system.

The *ras* proteins are regulatory guanine nucleotide binding proteins which can exist in two interconvertible conformational states, one inactive (GDP-bound) and one active (GTP-bound); in the latter form they serve as signal transducers controlling cell proliferation or differentiation. Malignacies derived from many different tissue types are in part brought on by mutations in an oncogene that encodes the *ras* proteins. For our studies C-terminally truncated normal human H-*ras* (1-166) was expressed in *E. coli* (Fig. 1) and GDP-ras (1-166) was purified from fermentor-grown, IPTG-induced cells. The purity of the H-ras protein was checked by ion-spray analysis. An aqueous *ras*:GDP solution was infused (2 mg/mL in 2 mM NH_4OAc buffer, pH 5.8) at 5 mL/min through the ion-spray interface of a Sciex API III triple quadrupole mass spectrometer. Several scans (10-20) from m/z 300 to 2400 at a scan rate of 2 s/scan were summed to yield the final profile spectrum.

The ion-spray spectrum of the *ras*:GDP sample solution at pH 5.8 (2mM NH_4OAc) showed an envelope of multiply protonated ions (Fig. 2), corresponding to the noncovalent *ras*:GDP complex with an average mass of 19,295 Da (Fig. 2 inset). This mass value confirms the 1:1 stoichiometry of the *ras*:GDP complex, as the average mass derived from the multiply charged peak envelope present in the ion-spray mass spectrum of the apo-*ras* protein (no bound GTP) was 18,852 Da (Fig. 3). The stability of the *ras*:GDP signal was highly dependent on the solvent system employed in the ion-spray analysis. Dissociation of the *ras*:GDP complex was brought about by either adding methanol or lowering the pH of the *ras*:GDP aqueous solution. Upon lowering the pH of the infused solution from 5.8 to 4.0, a shift in the multiply charged peak envelope of the *ras*:GDP complex towards higher charged states is observed, as the partially denatured *ras*:GDP complex has exposed more basic sites for protonation, along with a concomitant minor release of the *ras* protein. A more extended release of the nucleotide was not brought on until lowering the pH of the infused solution to ca. 3.5, with a complete denaturation occurring at pH 2.8 (a weak or no *ras*:GDP signal observed). It should be noted that the degree of denaturation of the *ras*:GDP complex observed at a certain pH value was further enhanced upon addition of 10% methanol. On the other hand, addition of 10% methanol in the infused aqueous solution induced only a minor denaturation of the *ras*:GDP complex; an almost complete denaturation as evidenced by the dissapearance of the *ras*:GDP signals was not observed until addition of 50% methanol. The combined effects of the pH and methanol on the stability of the *ras*:GDP complex were clearly observed in the analysis of an 1:1 methanol:water solution containing 2mM NH_4OAc and 5% AcOH (pH 2.7) as shown in Figure 4. It is apparent that complete denaturation of the *ras*:GDP complex gave rise to the multiply charged peak envelope of the free *ras* protein, with two possible conformational states of the *ras* being present (Fig. 4).

These results suggest that this method could be extended for the study of the GTP-bound *ras* protein, as well as complexes of the *ras* protein with other compounds of pharmaceutical interest which could occupy the place of the nucleotide. Moreover, the ability of ion-spray to observe such noncovalently-bound complexes highlights, as well reinforces, its potential to measure dissociation constants, screen enzymes and receptors for inhibitors and substrates, and provide another means for probing conformational changes in proteins.

Probing Conformational Differences of Multiply Protonated Gas-Phase Protein Ions using Thermal Energy Hydrogen/Deuterium Exchange Reactions

*B.E. Winger, K.J. Light-Wahl and R.D. Smith, Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352.

With the recent advent of soft ionization methods based upon electrospray ionization (ESI), in which the formation of multiply charged ions from large polypeptides and proteins occurs, the opportunity for probing structural characteristics and reactivity of multiply protonated gas-phase proteins has arisen. In some instances, collision induced dissociation of mass-selected multiply protonated ions have yielded sequence information as well as qualitative structural information. In addition, reactions involving multiply charged ions with amines in a quadrupole ion trap have yielded information on the reactivity of various charge states of a molecule. We have recently investigated the reactivity of multiply protonated gas-phase ions towards thermal-energy hydrogen/deuterium exchange reactions as a way of inferring qualitative differences in the gas-phase structure. If remnants of higher order structure of proteins in solution exist in the gas phase, differences in reactivity to H/D exchange should be observed. To test this hypothesis, both the native and reduced forms, i.e. disulfide-bridge intact and disulfide-bridge reduced, of bovine proinsulin and α–lactalbumin were allowed to react with D_2O in the gas phase and the % H/D exchange was measured using a Sciex TAGA 6000 E triple quadrupole mass spectrometer. In addition, the native and denatured forms of equine cytochrome *c* and bovine ubiquitin were studied to determine if differences in reactivity occurs for proteins whose higher order structure is not confined by covalent bonds

The method involves the use of a dual capillary inlet/reactor system as illustrated in Figure 1, which allows for desolvation of the electrosprayed ions prior to the addition of gas-phase D_2O. The ion-gas mixture traverses a second resistively-heated "reaction" capillary for approximately 3 milliseconds prior to expanding into the mass spectrometer.

Table 1 is a summary of the % H/D exchange for the aforementioned proteins. For the disulfide-containing proteins, the amount of gas-phase H/D exchange is greater for the native solution conformation, contrary to what is observed for H/D exchange in solution. The increase in reactivity for the native species could be attributed to Coulombic contributions arising from the more compact gas-phase structure.

Contrary to that observed for the disulfide-containing species, results for the native and denatured forms of cytochrome *c* and ubiquitin show relatively little difference in the amount of H/D exchange. The results suggest that without the constraints of the disulfide bridge, the gas-phase molecular ion may isomerize to a similar structure. In addition, proton transfer reactions of cytochrome c and ubiquitin with triethylamine result in similar product mass spectra, indicating that their reactivities are similar. This combination of results is strong evidence for gas-phase isomerization.

One interesting feature of the H/D exchange reaction with ubiquitin that was not observed for the other species is a dependency of charge state upon the amount of exchange. Figure 2 illustrates this for both the native and denatured species and compares this dependency to cytochrome *c*, in which the amount of exchange is essentially independent of charge state. These results suggest possible charge state dependent differences in gas-phase structure, however more studies are needed to support this finding.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy
by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830.

SEQUENCING OF UNKNOWN CONUS *betulinus* PEPTIDES BY MICROCAPILLARY-HPLC/ELECTROSPRAY-MS/MS TECHNIQUES

T. Krishnamurthy, James G. Freedy, Alan J. Kubis, M. Prabhakaran, Tracey D. Biggs, Janet H. Brzezinski, Teressa Connell, Research Directorate, U.S. Army Chemical RD&E Center, Aberdeen Proving Ground, MD 21010-5423

Conus snail venom are known to contain a variety of small peptides, 10-30 amino acids in length and cysteine rich, with various types of toxic and biological activities. We have investigated the venom from a worm eating species, Conus *betulinus*, found in the Bay of Bengal area. Microcapillary-LC/ESI-MS technique in combination with size exclusion chromatography, amino acid analysis, automated Edman degradation methods was applied for the investigation of the complex mixture of peptides isolated from the venom glands.

Standard mixtures containing conotoxins G1, M1, GVI1 and a synthetic product containing γ-carboxyglutamate residue in picomole quantities were prepared. The mixture(1 μl) was loaded on a fused silica microcapillary LC column (C_{18}, 320 μm, 15cm, 5μ) and eluted (2.5 μl/min) using a gradient of 15-80% solvent B (0.1% TFA in acetonitrile) in solvent A (0.1% aqueous TFA) over 58 minutes. The eluted components were introduced on-line into the electrospray ionization source. The mass spectra of the ionized (nitrogen as drying and sheath gas, 22 psi, 25ml/min., 250°C; 2-methoxyethanol as sheath solvent, 2μl/min; ESI voltage at 3800-3900 v) peptides were recorded. Under these conditions, the detection limits were determined for all components present in the mixture to be 2 picomoles (Figure 1).

*Size Exclusion Fractions. Individual peptides originated during C_{18} fractionation.
X, cysteine?; P, hydroxyproline.

Crude extract from ground and lyophilized venom glands was separated over a size exclusion HPLC column (G2000SW, 4.1mm x 25cm 7μ, 0.1% aqueous TFA, 0.75 ml/min). Each peak was analyzed under the LC/MS conditions described above. Recorded ESI-MS spectra indicated poor ionization due to impurities. Clean-up over a C_{18} Sep-pak catridge did not improve the ionization significantly. Hence, each fraction was further separated over C_{18} analytical column. The LC/MS data of each of the C_{18} fractions indicated them to be complex mixture (Figure 2) and hence they were subjected to another separation on C_8 column. The

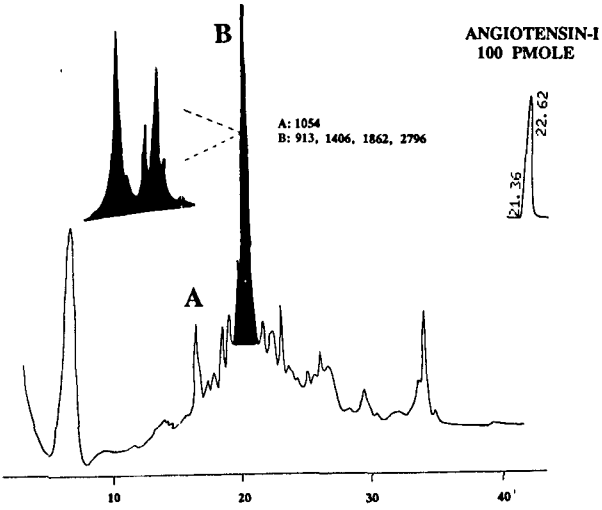

Figure 2. LC Separation of Conus *betulinus* mixture.
C_{18} Separation of Size Exclusion Fraction #3.

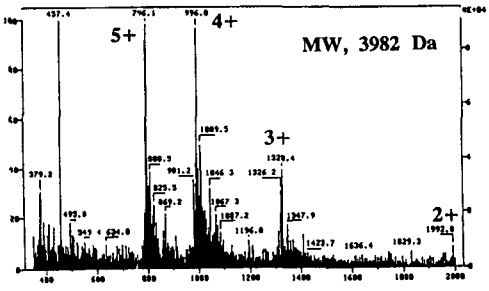

Figure 3. LC/ESI-Mass Spectrum of a Conus betulinus Peptide

amount of the conus peptides present in these mixtures to be 10-150 pmoles, based on the observed uv absorbance under the identical LC conditions for 100 pmoles of angiotensin-I (Figure 2). The LC/ESI-MS data of the C_8 fractions indicated them to be less complex containing 1-3 components. Molecular weights of few of the most abundant components were derived from the multiply charged ions observed in the corresponding ESI-MS spectra, as shown in Figure 3. The observed molecular weights ranged from 1,040 to 3,988 Daltons. Amino acid analysis of some of the fractions indicated them to be peptides. The observed Edman degradation data indicated the presence of hydroxyproline in some of the fractions (Table 1). Elution time for the standard hydroxyproline-PTH derivative was utilized for the confirmation of hydroxyproline in the Conus betulinus peptides. Reduction and carboxymethylation of one of the peptides (2+ at m/z 1398) indicated the intact peptide (2+ at m/z 1578) to have 3 disulfide bridges originating from 6 cysteins.

Conotoxin M1 (MW, 1495) was reduced and carboxymethylated. The ESI-MS spectrum of the product (MW, 1728) was in agreement with the expected presence of 4 cysteins. Most of the sequences of the amino acids present in conotoxin M1 could be derived from the LC-MS/MS spectrum of its carboxymethylated derivative. Under optimum conditions this approach could also be applied for sequencing the Conus *betulinus peptides.*

Is Droplet Evaporation Crucial in the Electrospray Mass Spectrometry of Proteins?

J.C.Y. Le Blanc, K.W.M. Siu, R. Guevremont and S.S. Berman
Institute for Environmental Chemistry, National Research Council of Canada
Montreal Road, Ottawa, Ontario, Canada K1A 0R6.

In electrospray mass spectrometry, droplet evaporation has been regarded to play a key role in effecting ion desorption from the solution to the gas phase though proof of this importance is lacking. In a study in which spraying of 0.2% acetic acid solutions of various relatively well-characterized proteins was conducted from room temperature to about 91°C, the only significant effect of temperature that we observed was one due to thermal-induced denaturation of some proteins. For protein solutions in which conformational change is insignificant, raising the temperature has little effect on the mass spectrum. This is very odd because if solvent evaporation played an important role in ion formation, one would expect changing the temperature would have a very significant impact on the electrospray response.

We have established that the distribution of multiply charged protein ions in an electrospray mass spectrum is related to the distribution of these ions in solution. A major criticism of our work was that the excellent match between (bulk) solution concentration profiles and electrospray response profiles could simply be coincidental in view of the fact that evaporation of water, organic solvent and acid from electrospray-generated droplets should occur, and the general belief that ions are desorbed from droplets that have undergone much evaporation and division; in other words, from droplets whose composition may be drastically different from that of the bulk solution.

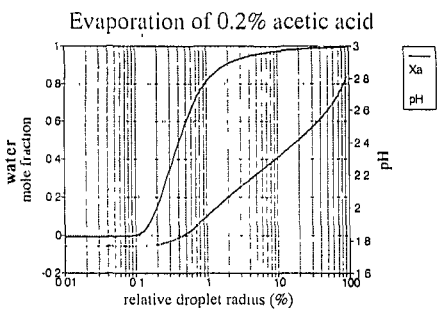

Figure 1a

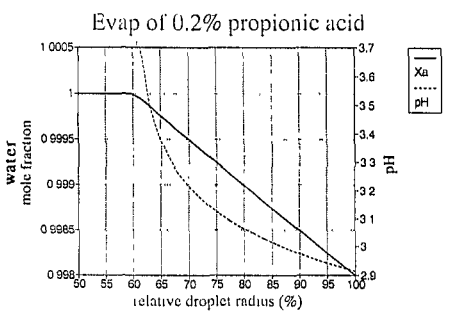

Figure 1b

Much information exists in the literature on vapour-liquid equilibria of water-simple organic acid binary mixtures. We have chosen to examine binary mixtures of water and simple organic acids because these mixtures are frequently encountered in electrospray experiments and some of these solutions display drastically different vapour-liquid equilibrium properties. Starting from a 0.2% acid solution, solvent evaporation from water-acetic acid causes the pH of this solution to decrease from 2.9 (Fig. 1a, Xa = mole fraction of water in the solution), whereas from water-propionic acid, this causes the pH to increase from 2.9 (Fig. 1b). It is, therefore, expected that if solvent evaporation played a pivotal role in effecting ion desorption, the electrospray mass spectra of a particular protein in these two different water-acid systems would be different as ions would desorb from solutions whose pH would be considerably different. As it turns out, the electrospray mass spectra of protein solutions in 0.2% acetic and propionic acid are very similar. This is illustrated in Fig. 2a which shows the electrospray profiles of 5 μM cytochrome c in 0.2% acetic and propionic acid run at 70°C, and in Fig. 2b which shows the profiles of 3.5 μM myoglobin in the same acid solutions at 25°C. From these results, we can conclude that solvent evaporation is not a prerequisite to ion desorption, and that desorption takes place early rather than late during the electrospray process.

TANDEM KINETIC ENERGY/FTICR MASS SPECTROMETRY FOR POST-ELECTROSPRAY IONIZATION SEPARATION OF PROTEIN MIXTURES

S. A. Hofstadler and D. A. Laude, Jr., Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin, TX 78712

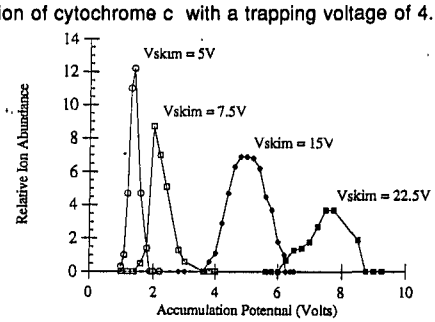
Recently Feng and coworkers [1] observed that in contaminated solutions, electrosprayed proteins typically have significantly higher kinetic energies than the non-protein components. Due to this difference it was feasible to bias the quadrupoles at an appropriate potential to serve as a retarding grid allowing only the higher kinetic energy papain ions to enter the quadrupole for mass analysis. Thus, one way in which this post-ionization separation might be described is as a high-pass kinetic energy filter in which the undesirable contaminants possess a relatively low kinetic energy filtered from the mass analyzer. To be presented here is a post-electrospray ionization separation technique used in conjunction with a high magnetic field electrospray ionization Fourier transform ion cyclotron resonance mass spectrometer (FTICR) that, as a consequence of FTICR selectivity in trapping ions for detection, is a band-pass kinetic energy filter analog to Feng's high-pass filter. The potential advantage of this FTICR bandpass filter is that individual components in electrosprayed protein mixtures can be preferentially selected and isolated for detection.

All experiments were performed on a spectrometer assembled with components that constitute the Extrel FTMS-2000 including a 3.0 Tesla superconducting magnet, Nicolet 1280 computer, cell controller, high power excite amplifier and differentially pumped dual cell assembly [2]. The electrospray ion source is modeled after that introduced by Chait [3] in which a heated stainless steel capillary is used to desolvate the charged droplets formed by electrospray. A pressure differential is maintained across this positively biased desolvating capillary which is sampled by a biased skimmer cone. After multiple stages of differential pumping through a concentric tube vacuum chamber [2] the ion beam is mass analyzed at pressures in the 10^{-8} torr to 10^{-7} torr range. Protein solutions were prepared with analyte concentrations of 3 to 10 pmol/µl in a 68:30:2 MeOH:H_2O:HoAc matrix. Solutions were pumped to the electrospray chamber at 4 µl/min and ionization by applying a potential of 3.7 kV to a 100 µm I.D. blunt ended syringe needle. The syringe needle was positioned 6 mm from the desolvating capillary which was biased to 330 V and resistively heated to ~150 °C . The other end of the desolvating capillary was positioned 4.5 mm from the 330 µm I.D. copper skimmer cone which was biased at +5 to +30 V to control the kinetic energy of the ion beam.

Key to the successful discrimination between protein mixture components is recognition of the strong correlation between the kinetic energy of the electrospray ion beam and the trapping potential at which ions are most efficiently trapped for subsequent detection [2]. A static ion accumulation period (typically of 100 ms to 2 s) at the appropriate potential will allow the selected ion population to be injected. Figure 1 demonstrates ion accumulation profiles for the charge envelope of cytochrome c obtained at increasing skimmer cone potentials.

It was found that a first order dependence of optimum trapping potential on the m/z value of the electrosprayed ions allows proteins with dissimilar m/z profiles to be easily separated. This is shown in Figure 2 for the separation of cytochrome c with a trapping voltage of 4.0 V for ions in the range

Figure 1



m/z 1000 and a trapping voltage of 5.5V for bovine albumin ions in the range of m/z 1500. However, an important extension of the general utility of the technique arises from second order effects, specifically slip velocity in the expansion and effective accelerating potential, which facilitate the separation of proteins with overlapping charge states. Thus in Figure 2, chicken egg white lysozyme is trapped at 7.0 V and isolated from the bovine albumin despite identical m/z ranges.

Recognizing that V_{skim}, and pressures effects determined by capillary-skimmer distance and orifice size are the most significant contributors to kinetic energy, a simple model was constructed which estimates V_{trap} and explains the order of separation. The two factors which define the kinetic energy of the ion beam are the velocity component achieved in the supersonic expansion and the electric field component derived from the potential drop between the V_{skim} and the grounded conductance limit. These are expressed as the first and second terms, respectively, in Equation 1.

$$K\ E_{Joules} = K_{slip} m v^2/2 + K_{eff}\ q\ V_{skim} \qquad (1)$$

where m is the mass in kg, v is the velocity in m/s, K_{slip} is a correction factor for velocity slip in the expansion, q is the ion charge in Coulombs, V_{skim} is the skimmer potential in Volts, and K_{eff} is a correction factor for the effective field experienced by the ions. Because ez = q and converting into Daltons, A, Equation 1 simplifies to equation 2 with K_{slip} and K_{eff} serving as compound dependent

$$V_{trap} = K_{slip}(v2/2Ae)(m/z) + K_{eff}\ V_{skim} \qquad (2)$$

correction factors for velocity slip in the expansion and the effective potential. The expression correctly predicts that within the electrospray ion packet for a single protein, V_{trap} increases with m/z. Presented in Figure 3 are illustrated examples of this effect. According to the model, the turkey conalbumin exhibits a velocity of 598 m/s and an effective V_{skim} of 3.2V. The cytochrome c has an estimated velocity of 901 m/s and an effective skimmer potential of 0.85 V.

Liquid Chromatography-Electrospray Mass Spectrometry Characterization of Human Hemoglobin covalently modified with a Tobacco-Specific Nitrosamine.

Mary K. Young, Hongshan Fang, David A. Maltby and Surinder Kaur.
Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446.

Reactive metabolites of carcinogenic compounds are believed to bind at nucleophilic sites in DNA *in vivo*, thereby initiating a complex process which may eventually result in cancer. Binding also occurs with other macromolecules such as proteins. Therefore, structural studies of chemically modified DNA or proteins may give valuable insight into specific compounds important in carcinogenesis. Tobacco smoke contains various compounds that cause cancer in animal models. Of these, nitrosamines, derived from the nicotine in tobacco, are potent carcinogens and have been detected in tobacco smoke and saliva from smokers (1). Unlike many other carcinogens in tobacco which are also common environmental pollutants, the nitrosamine 4-(N-nitrosmethylamino)-1-(3-pyridyl)-1-butanone (NNK) is derived only from nicotine. Therefore it may be possible to link the effects of this nitrosamine in smokers specifically to tobacco smoking. Binding of radio-labelled NNK and 4-(N-carbethoxynitrosmethyl-amino)-1-(3-pyridyl)-1-butanone (carbethoxy NNK, **1**) metabolites to hemoglobin *in vivo* has been demonstrated previously for F344 rats (2). Carbethoxy NNK (**1**) also binds to rat hemoglobin *in vitro* in the presence of esterase (2). In each case, less than 30% of the modification was identified (structure **3**) by acid or base treatment of the protein (2). Structure **2** was proposed as a reactive intermediate. In this work we have investigated intact human hemoglobin covalently modified with carbethoxy NNK (**1**) in the presence of esterase. Electrospray mass spectrometry was used to establish binding of NNK metabolites in the intact hemoglobin. The protein was digested with trypsin and the modified peptides were characterized by high performance liquid chromatography-electrospray mass spectrometry (LC-ES MS).

Carbethoxy NNK (**1**) was synthesized as previously reported (3). Hemoglobin was isolated from human whole blood (4) and was incubated with carbethoxy NNK (**1**) and porcine esterase in 0.01 M borate buffer at 37°C for 18 hours in the dark. Globins were isolated from the incubation mixture using 10 volumes of acetone/0.7% HCl (0°C). The globin mixture was fractionated by C-4 reversed phase HPLC (4.6mm x 25cm, Vydac). ES MS identified one fraction containing native α-globin (molecular weight 15,130±2 Da, expected molecular weight 15,126 Da) and a modified α-globin 147±2 Da larger (molecular weight 15,277±2 Da, expected molecular weight 15,274 Da) (Fig 1a). Similarly, β-globin and modified β-globin were identified (data not shown). These results represent the first direct evidence for the covalent binding of carbethoxy NNK-generated intermediates with human hemoglobin. The molecular weight shift of 148 Da is consistent with binding of a predicted metabolite of NNK (**2**).

The fraction containing modified α-globin was digested with trypsin (pH 8.5) and the peptide molecular weights were obtained using a C-18 reversed phase micro-bore column (1.0mm x 25cm, Brownlee) incorporated into a Carlo Erba Pheonix 20 HPLC which was interfaced to a BioQ (VG/Fisons) electrospray triple quadrupole mass spectrometer (Fig. 1b). A number of peptides with molecular weights 148 Da greater than those expected for native peptides were identified by LC-ES MS, for example, peptide 8-16 from the α-globin (Thr-Asn-Val-Lys-Ala-Ala-Trp-Gly-Lys) with molecular weight 1122.2 Da (Fig 1c). Four sector tandem MS will be used to establish the nature of the covalent moieties and identify the specific sites of binding in the modified peptides. The studies *in vitro* will be used as a basis to study blood samples from heavy smokers.

A Study of Heat Denaturation of Proteins by Electrospray Ionization Mass Spectrometry

*Urooj A. Mirza, Steven L. Cohen, Brian T. Chait
The Rockefeller University, 1230 York Avenue, NY, NY 10021

The present paper describes a study of heat-induced denaturation of proteins by electrospray ionization mass spectrometry (ESIMS).

A simple and effective device was constructed for heating the protein solution and is shown in figure 1. It consists of a two-hole ceramic barrel, one hole for the stainless steel syringe needle and the other for an iron-constantan thermocouple. A chromel wire was wound around the ceramic barrel, through which an appropriate current was passed to heat the syringe needle. This arrangement allowed the temperature of the spray solution to be finely controlled ($\pm$ 1 C) in the range of 25 - 98 C. Flow rates through the needle (dead volume = 1 µl) ranged between 0.4 - 0.7 µl/min so that protein solutions were heated to the controlled temperature for approximately 2 minutes prior to electrospray.

The initial studies were done on bovine ubiquitin (MM 8565). Ubiquitin is an especially stable protein that is highly resistant to denaturation. Electrospray ionization mass spectra (fig. 2) of aqueous solutions of bovine ubiquitin were obtained at various temperatures: Acetic acid was used in each case to adjust the solution pH to 2.8. Figure 2a is the spectrum of ubiquitin acquired at 25 C. At this temperature, the spectrum shows a single distribution of three peaks dominated by the 7+ ion. As the temperature was increased to 75 C a second distribution of charge states, centered at 11+, became apparent (fig. 2b). The half-denaturation temperature between the two distributions was found to be 70 $\pm$ 5 C. We have assigned the first distribution of peaks (centered at 7+) to a folded conformation and the second distribution (centered at 11+) to an unfolded conformation of ubiquitin. Further heating of the protein solution to 93 C (fig. 2c) shifts the spectrum almost completely to the higher charge state distribution.

We have also demonstrated the use of ESIMS to probe the reversibility of thermal denaturation of proteins. For example, we found that cytochrome c undergoes irreversible thermal denaturation when heated to 90 C. Figure 3a represents the ESIMS spectrum of bovine cytochrome c obtained when an aqueous solution of protein at pH 6.6 was sprayed at 25 C. This spectrum consists of mainly two peaks (7+ and 8+) which corresponds to a folded state of cytochrome c. When the solution was electrosprayed at 88 C (fig. 3b) a second distribution of charges appeared centered at 12+. This second distribution represents an unfolded form of the protein. Figure 3c shows the spectrum obtained after the protein solution was heated to 90 C separately in a test tube for four minutes and allowed to cool for 25 minutes to room temperature prior to ESIMS analysis. This spectrum has the same features as the one obtained at 88 C (fig. 3b), demonstrating that cytochrome c has not returned to the folded state. We performed a similar experiment with ubiquitin and found that in contrast to cytochrome c, ubiquitin, when heated to 92 C and cooled, undergoes reversible thermal denaturation.

Cooperative effects of acidity and heat on denaturation have also been studied by ESIMS. In figure 4 we show these cooperative effects by plotting the fraction of folded state, obtained from the electrospray spectra vs. temperature of bovine ubiquitin at three pH values.

We have also demonstrated the use of cooperative effects in successfully obtaining electrospray ionization mass spectra of several proteins which previously yielded no useful electrospray spectra. One example is wheat germ agglutinin (MM 17,000). Wheat germ agglutinin contains 16 disulfide bonds, is tightly folded and contains only twelve basic groups. From a protein solution of 50 % methanol:water and at pH 2.4, the electrospray at 25 C yielded no discernable protonated molecular ions. However, electrospraying this solution at 70 C resulted in intense peaks corresponding to molecular ions of the wheat germ agglutinin.

Solution Phase and Gas Phase Contribution to Electrospray Spectra

Robert D. Voyksner and Terry Pack, Analytical and Chemical Sciences,
Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709

Introduction

Ion evaporation ionization mechanisms in electrospray (ES) allow examination of solution phase chemistry through mass spectrometry. The analysis of peptides and proteins by ES-MS shows a definite dependence on parameters such as solution pH, solvent choice, hydration energy, and pK_a of the sample [1-5]. Also, it has been observed that gas phase reactions with ions formed by ES can occur in both the source and transport regions. This study will focus on determining the extent solution and gas phase chemistry has on the ES signal intensity for 85 tripeptides.

Experimental

Equal molar levels (250 pmoles/μL) of each tripeptide were analyzed in a solution of 80/20 H_2O/methanol at pH of 7 and pH 4 (1% acetic acid). Each solution was flow injected (1 μL) into an Analytica Inc. ES interface at a flow rate of 2 μL/min. The ES was operated with a needle potential of ~3.5 kV, capillary end voltage of 80 V, skimmer 35 V, lens 1-4 17 V, -23 V, 3 V and -60 V respectively. A capillary voltage of 80 V did not produce product ions from collisional activation of the $[M+H]^+$ ion from any tripeptide. The ES interface was mounted on a Finnigan MAT 4500 quadrupole MS. All data was recorded from a scan of 50-650 in two seconds.

Results and Discussion

In order to estimate ion intensities generated from ES-MS, parameters that effect each step of the ionization process must be elaborated upon. These parameters include:

1) ionization in solution
2) nebulization of the solution
3) desolvation of each nebulized droplet
4) desorption of solvated ions in the droplet into the gas phase

The complexity of the ionization process can be reduced since nebulization and desolvation parameters can be eliminated because all experiments were performed using the same solvent, flow rate, and range of sample molarity. Now, ion intensity can be related to ions in solution (net charge at a given pH) and desorption of solvated ions into the gas phase (hydration energy).

Gas phase reactions play an important role in the sensitivity and appearance of ES-MS spectra. The role of gas phase chemistry was demonstrated by the analysis of a pair of compounds that exhibit a reversal of gas phase and solution phase basicity. In the solution phase, NH_3 is a stronger base than pyridine while in the gas phase, pyridine is a stronger base than NH_3. The analysis of an equal molar mixture of NH_4^+ from ammonium acetate and pyridine reveals that only $[pyridine + H]^+$ is detected. It appears that NH_4^+, desorbed from solution, reacts in the gas phase via an exothermic proton transfer (pyridine proton affinity (PA) ~213 Kcal/mole while NH_3 proton affinity is 206 Kcal/mole) to form $[pyridine + H]^+$ in the high pressure (~1 torr) capillary - skimmer region in the ES interface. Likewise, the $[M+H]^+$ ion for Ile-Ile-Ile (PA ~218 Kcal/mole) disappears in the presence of triethylamine (PA ~232 Kcal/mole). The $[M+H]^+$ ion for triethylamine (m/z 102) is dominant. Even though Ile-Ile-Ile is nonvolatile, it is believed that the $[M+H]^+$ is formed during desorption but is lost through an exothermic proton transfer reaction with triethylamine. Based on these observations the ion current observed for a compound by ES-MS will depend on proton affinity.

The estimated contribution of each parameter on signal intensity of the tripeptide was explored. Signal intensity for the tripeptides were related to functions (f) of net charge, hydration energy and PA, as follows

$$\text{Intensity} \propto M\,k\,[f(\text{net charge}) + f(\text{hydration}) + f(\text{PA})] + b$$

where M = molarity (constant in these experiments)
k and b = constant

Linear regression analysis of intensity versus net charge, hydration and proton affinity, provided numerical values for each function. Finally, a linear regression analysis of the sum of the functions for net charge, hydration and proton affinity provided the values for k and b, as shown below for intensity in millions of counts:

Intensity = 0.54[1.7(net charge) + 2.5) + (0.24 (PA) - 51) + (-0.068 (hydration energy) + 1.2)] - 1 6

A plot of calculated versus observed intensity (Figure 1) shows considerable scatter in the data points (std. dev. 30%). Upon closer examination, the data shows a number of points that had a high calculated intensity but very low observed intensity. These outliers were, in every case, from symmetric peptides of the general nature X-Y-X (eg. Gly-Arg-Gly). The ion current from the symmetric tripeptides was four to ten times lower than the unsymmetric tripeptides of the general nature XXY (eg. Gly-Gly-Arg). It is possible the unsymmetrical tripeptides have an increased surface concentration (lower hydration energy) than the symmetric tripeptides resulting in higher ion currents. Incorporation of the symetry factor into the equation changes the calculated versus actual intensity measurement (Figure 1, line b), reducing the std. dev to 17%.

Conclusions

This study has demonstrated that gas phase and solution phase chemistry influences the sensitivity obtained by ES. The maximum signal is obtained at a high net charge, high proton affinity and low hydration for unsymmetric tripeptides. The electrospray response for these tripeptides can be estimated based on these parameters at constant molarity and solvent compositions.

The tendency of electrosprayed droplets to ionize non-covalently bound dimers and higher clusters of organic solutes such as amino acids and nucleosides has long been observed.[1,2] Unlike the aggregates studied in traditional molecular beam experiments, these clusters do not nucleate in the free-jet expansion, but rather precipitate in the droplet and emerge as charge complexes. Interest in the subject has been rapidly growing with the realization that, under the right conditions , non-covalently bound complexes of larger biomolecules may be detected as well.[3] Such complexes formed by site specific binding interactions, for example that of an enzyme with its substrate or a protein with its inhibitor, are of particular interest to molecular biologists.

We report here on the formation of mixed clusters of the amino acids Arginine with Histidine and the cyclic peptides Gramicidin S complexed with Cyclosporin A . While the mixed clusters of Arginine and Histidine shown in figure 1 may reflect different propensities of the two acids for escaping the droplet solution, we believe that the affinity of these two different amino acids for each other is reflected in some way by these measurements. It is non-covalent interaction of amino acids that in part governs the folding of proteins. If one can readily generate heterogeneous clusters of biological molecules, experiments may be performed on the gas phase 'bio-cluster' ions to determine, for example, the energy of the non-covalent bond. Figure 2 illustrates the collisionally induced dissociation of the Gram.-CsA complex in the region between the nozzle and the first skimmer of the vacuum interface. As the applied voltage is increased the complex is observed to disappear while the signals of the of the individual constituants continue to rise. It should be noted that while the monomers of amino acids fragment at moderate voltages, the spectra corresponding to figure 2 revealed no evidence for the fragmention of either cyclic peptide.

The formation of charged non-covalently bound complexes of bio-molecules with known site specific binding acitvity poses a challenging problem for ESMS. It is reasonable to assume that binding activity will require that the molecules be in a solution favorable to their natural conformation. These solutions, often high in salts and organic buffers, can be problematic for electrospray. We have had some limited success with detecting complexes with known binding affinities. Figure 3 illustrates the mixed cluster (m/z = 1539) of Guanosine with Actinomycin D, a compound known to intercolate Guanosine rich DNA. The complex of two Guanosines with one Actinomycin has been reportedly studied by X-ray crystalography.

Membrane Introduction Mass Spectrometry (MIMS) in Environmental Analysis

R. G. Cooks, F. Lauritsen, T. Kotiaho, S. J. Bauer, T. K. Choudhury and L. E. Dejarme, Department of Chemistry, Purdue University, West Lafayette, IN 47907

Semi-permeable membranes provide a convenient means of sampling aqueous solutions for small organic compounds and, in direct insertion probes, they allow continuous on-line monitoring by flow injection analysis procedures (1). The method has high chemical specificity, fast response times, excellent detection limits, linear dynamic ranges of several orders of magnitude and reliable, long-term operation, and it can be used with mass spectrometers of various types. Quantitation is achieved using external standards and matrix effects are typically negligible. Figure 1 places this application in context with others. Results are given for the monitoring the water-soluble compounds acrolein and acrylonitrile, for small aldehydes and for small halogenated semi-volatile halogenated compounds.

A major limitation of the MIMS method is its restriction to smaller and less polar compounds dissolved in aqueous solutions. In an effort to overcome this, microporous polypropylene membranes have been used instead of the conventional amorphous silicone membranes. The result is improved detection limits for more polar compounds. In addition, it is found that response times are extremely short, typical values being less than 10 second for 10 - 90% response for a 250 μL sample plug. Relatively large amounts of water enter the mass spectrometer through microporous membranes but glow discharge ionization gives long-lasting, stable performance in the CI mode. Water acts as the CI reagent (solvent CI) and the major forms of the analyte ions are as illustrated in Figure 2 which shows quantification of ethanol as the protonated hydrate. The quantitative accuracy is ± 5% at the 10 ppb level and linear dynamic range available is illustrated in Figure 3.

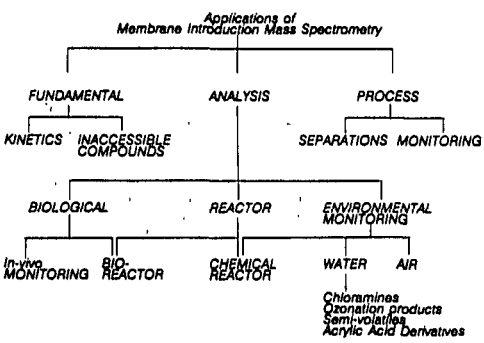

Figure 1. Various applications of membrane introduction mass spectrometry.

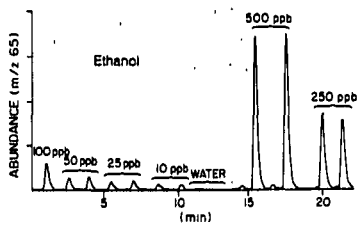

Figure 2. Single ion monitoring data on ethanol recorded for a microporous membrane.

Implementation of waste minimimization as a pollution control strategy calls for continuous monitoring of process streams. Such streams often employ non-aqueous solvents, hence the desirability of adapting the on-line monitoring capabilities of MIMS to analytes in organic solvents. This has been done using microporous membranes as illustrated for the case of an n-hexane solution in Figure 4. The solvent is again used as the CI reagent. Limitations of the method include some matrix effects, especially in the analysis of analytes of low proton affinity, and the fact that solvent ions can obscure certain regions of the spectrum. However, response times are again very rapid and detection limits are low (Figure 5).

Future work with membrane introduction will need to address the limitations of the method for larger and less volatile samples. Some procedures for doing this include laser and ultrasonic assisted desorption from the membrane surface and modifications to the chemical structure of the membrane to facilitate transport of polar compounds.

ION SPRAY LC/MS AND CE/MS: PROSPECTIVE POTENTIAL FOR ENVIRONMENTAL ANALYSES

Jack Henion, James Conboy, Alex Mordehal, Gerard Hopfgartner, Thomas Huggins, Geoffrey Rule and Timothy Wachs, Drug Testing and Toxicology, New York College of Veterinary Medicine, Cornell University, 925 Warren Dr., Ithaca, NY 14850

INTRODUCTION

The rapid, multi-residue analysis of environmental samples remains a challenging analytical problem. GC/MS techniques using electron ionization (EI) are currently the best tool for sensitive and unequivocal identification of target compounds of environmental concern. However, the GC sample handling limitations (low polarity, volatility, thermal stability, etc.) preclude our ability to characterize many environmentally important compounds. In addition, alternative ionization techniques that are amenable to on-line condensed phase separation sciences are needed to produce abundant ion current from these same classes of compounds. The implementation of HPLC and capillary electrophoresis (CE) separation on-line with mass spectrometry (LC/MS and CE/MS) would, in principle, significantly increase the range of compounds amenable to environmental regulation and control.

Thermospray and particle beam LC/MS techniques have already received considerable attention for their analytical potential for environmental applications (1,2). Although both of these approaches have shown promise, neither appears entirely suitable for more challenging trace analyses of very polar, thermally labile compounds. We have performed preliminary investigations to evaluate the analytical potential for pneumatically assisted electrospray (Ion Spray) LC/MS analysis of environmentally important compounds (3). This technique is particularly amenable to very polar compounds and shows very good sensitivity without need for elevated temperatures or other conditions that degrade analytes during their characterization. In addition, recent developments have increased our ability to carry out on-line LC/MS analysis at HPLC flow rates in excess of one mL/min. We have also modified a benchtop ion trap mass spectrometer for ion spray applications to evaluate this approach to improve our ability to analyze intractable environmental samples. This paper outlines some representative examples on how ion spray LC/MS and CE/MS may offer new opportunities to meet the challenges of modern environmental trace analyses.

EXPERIMENTAL

Four different mass spectrometers have been used in our laboratory for the results described here. System one is a Sciex TAGA 6000E upgraded to an API III. The ion spray interfaces used in this work are all constructed in-house as described elsewhere (3). The Sciex system may be operated in either the positive or negative ion mode of detection depending upon the type of analyte being investigated. System Two is a Hewlett-Packard Model 5970 MSD modified for atmospheric pressure ionization (API), (4). This system is routinely used for ion spray experiments and displays a practical full-scan LC/MS detection limit of 10-25 ng of injected compound. System Three is a Hewlett-Packard Model 5985B modified in-house in a manner similar to that of System Two. This system is differentially pumped and is equipped with a high energy dynode (HED) detector which significantly increases its sensitivity. System Four is a modified Varian Saturn II benchtop ion trap mass spectrometer which is equipped with a novel atmospheric pressure ion sampling interface (5). This system currently offers only positive ion detection and has a mass range of 650. A variety of commercial HPLC systems with column dimensions ranging from 1 mm i.d. to 4.6 mm i.d. have been used for the LC/MS experiments. The CE/MS experiments were carried out using a Beckman Model P/ACE 2050 capillary electrophoresis system coupled to the ion spray interface either via a liquid junction or sheath-flow coupling.

RESULTS AND DISCUSSION

The ion spray LC/MS interface was developed from EPA-EMSL Cincinnati-funded research in support of method development for the LC/MS determination of sulfonated azo dyes isolated from environmental waters (3). This research demonstrated that ion spray LC/MS/MS analyses of wastewater extracts using the Sciex instrument could identify and quantify these compounds at trace levels. Subsequently these same compounds were characterized by CE/MS and CE/MS/MS using the same ion spray interface coupled to CE via a liquid junction coupling.

More recently we have explored the analytical potential of our modified MSD (system Two, ref 4) benchtop mass spectrometer for the determination of low molecular weight pesticides. These

compounds are of interest due to their thermal instability which causes analytical problems when characterized by GC/MS or thermospray LC/MS techniques. When these compounds are analyzed by ion spray micro LC/MS using 1 mm i.d. x 100 mm HPLC columns operated at 40 µL/min full-scan "up front" collision-induced dissociation (CID) mass spectra may be obtained on low nanogram levels of these compounds. Recent developments with our "liquid shield lens" on both systems Two and Three have shown that standard 4.6 mm i.d. x 100 mm HPLC columns operated at one mL/min can also provide ion spray LC/MS results on comparable levels of sample without any splitting of the HPLC flow.

In addition to the analysis of samples containing organic analytes we have recently explored the analytical utility of CE/MS for the determination of inorganic cations and anions. Thus synthetic mixtures containing low ppm levels of many common cations such as K, Mn, Cd, Cr, Ag, Co, Cu, Zn, Ba, Ca, and Pb, or anions including the halides, nitrate, nitrite, thiosulfate, etc. may be separated by CE with high separation efficiency and short analysis times in contrast to ion chromatography techniques. Detection is accomplished by indirect UV or MS and CE/MS/MS techniques provide additional unique structural information for polyatomic ions such as nitrates, selenates and selenites, for example. The CE/MS analysis of an acid extract of used aircraft engine oil showed the presence of high lead levels in addition to trace amounts of chromium and nickel which are expected from normal engine wear.

As a final example, we have studied the analytical potential of CE/MS for the rapid (less than five minutes per analysis) assay of sulfonyl urea herbicides. These labile, thermally sensitive compounds and their metabolites are not well suited for GC/MS characterization, and HPLC analysis often requires 20-30 min analysis times. Using a homemade CE device and short (25-35 cm) capillaries directly coupled to the liquid junction-ion spray interface we have reported the CE/MS and CE/MS/MS analysis of eight sulfonyl urea compounds within five minutes.

SUMMARY AND CONCLUSIONS

The ion spray interface is a practical device for coupling both HPLC or CE to an API mass spectrometer. The ion evaporation ionization that results from this pneumatically assisted electrospray interface is very mild and thus provides intact molecule ions that may then be fragmented by CID techniques to provide structural information. LC/MS or CE/MS techniques using the ion spray interface have been evaluated to show that this approach is amenable to significantly broaden the areas of application to studies of polar and thermally labile compounds of environmental importance that are difficult or impossible to characterize by GC, thermospray or particle beam interfaces.

ENVIRONMENTAL FIELD MEASUREMENTS WITH AN ION TRAP MASS SPECTROMETER

M.B. Wise, M.V. Buchanan, C.V. Thompson, and M.R. Guerin, Analytical Chemistry Division
Oak Ridge National Laboratory, P.O. Box 2008, MS-120, Oak Ridge, Tennessee, 37831-6120.

Introduction

The high cost of laboratory analysis, very large sample loads, and the need for rapid results have led to an increased interest in the development of versatile and reliable instrumentation for field analytical applications. During the last several years, investigators in our laboratory have been working on the development of instrumentation and analytical methods which are based primarily on the technique of direct sampling ion trap mass spectrometry. This technology generally does not involve extensive sample preparation or chromatographic separation of the analytes prior to introduction into the mass spectrometer; instead, the unique features of ion trap mass spectrometry are utilized to achieve high sample throughput, low analytical costs, and high reliability sample screening for the presence of target analytes at very low part-per-billion concentrations. Although initial methods were developed primarily for laboratory-based applications, we have recently extended the technology to on-site field applications and have successfully demonstrated the ability to perform real-time or near real-time measurements of target volatile organics (VOCs) in a variety of real-world samples under extremes in operating conditions.

Experimental

The basic field instrument consists of a Finnigan MAT ITS-40 ion trap mass spectrometer (with CI option) which has been modified and hardened for easy transportation and operation at hazardous waste sites. Specifically, the mass spectrometer has been mounted on a specially designed base support which is equipped with carrying handles and strategically located shock absorbing pads which minimize the potential for damage to the unit when it transported over rough terrain. In order to better perform direct sampling experiments, the standard rotary vacuum pump (used as the forepump on the turbo-pump) was replaced with a Drytel-Micro molecular drag pump. This not only increases the effective pumping speed of the turbo-pump under heavy gas loads, but also significantly reduces hydrocarbon background in the spectrometer which is important for the analysis of trace levels of target compounds. One of the most important modifications to the laboratory ITS-40 was the replacement of the standard gas chromatograph interface with a specially designed open/split capillary restrictor interface. This interface enables a variety of small sampling modules (Figure 1) to be quickly coupled with the mass spectrometer without having to break vacuum. Great sample handling versatility is accommodated by having modules for direct air monitoring, purging of liquids, or thermal desorption of sorbent tubes or injected liquids. Basic operation of the instrument is performed through a Compaq 486-33MHz portable color computer using the ITS-40 software provided by Finnigan MAT as well as programs written in-house by the authors. The footprint of the instrument is approximately 30 inches wide x 24 inches deep and the total weight is less than 150 pounds, making it easily transportable in most types of vehicles. Electrical power consumption ranges from 400 to 600 watts depending on the sample module being used and may be provided by a portable generator or by a storage battery/dc inverter power source as well as standard 110 volt line power.

Results

During the last year, we have performed several field trials of the transportable instrument both at Oak Ridge National Laboratory as well as the Savannah River Integrated Demonstration Site. These tests were used to evaluate the reliability of the instrument, ease of operation, sample throughput, versatility, as well as qualitative and quantitative performance for the analysis of target VOCs. Overall, the results of the initial field tests have been very good. Instrument reliability has been exceptional with 100% up-time even under temperature extremes of near freezing to above 100 degrees F and total transportation distance of greater than 2,000 miles in a passenger van. In terms of versatility, sampling modules can be interchanged typically in less than 2 minutes enabling one to perform on-site measurements of VOCs in most types of samples usually encountered, including surface and ground water, drilling mud, soil slurries, well headspace, vadose zone sampling implants, ambient air, process streams, and preconcentrated air or soil gas samples collected on sorbent tubes. Real-time detection limits in air (including ambient air, soil gas, etc) are typically in the low ppbv range for most volatile organics. For most water samples, routine detection limits are in the range of 1 ppb and can be optimized to less than 1 ppb if necessary. Using direct purge into

the ion trap, water samples can be quantitatively analyzed in approximately 2 to 3 minutes for the presence of target VOCs. Under actual field conditions a sample throughput of 20 ground water samples per hour has been demonstrated with quantitative analysis of tri- and tetrachloroethylene. Comparison of laboratory and field results have been relatively good thus far (Table 1) although the quantitative accuracy decreases with increasing complexity of the sample as would be expected without the use of chromatography. Fortunately, the ion trap offers ways to recover a significant amount of qualitative and quantitative accuracy even for complex samples through the use of alternative EI/CI scans and through the potential use of MS/MS as demonstrated on the laboratory-based ITMS instruments. Although it is not yet possible to fully quantify all components in a complex sample by direct sampling ion trap mass spectrometry, the ability to quickly screen environmental samples for the presence of target VOCs is very close.

Conclusion

The modified Finnigan ITS-40 ion trap mass spectrometer performs exceptionally well as an on-site field analytical instrument. A specially designed sample interface and sample introduction modules provide a high degree of versatility in terms of the types of samples that can be investigated in the field. Primary limitation at this time are related to the instrument operating software which was intended primarily for GC/MS applications and not for real-time direct sampling applications. Efforts are also underway to improve the ability to more fully analyze complex samples without sacrificing the high sample throughput which is one of the most significant assets of the direct sampling mass spectrometry technique. Further, methods are also under development at this time for the rapid analysis of target semivolatile organic compounds in a variety of sample matrices.

Transportable Gas Chromatograph - Ion Trap Systems for the Analysis of Volatile Organic Compounds

M.E. Cisper, J.E. Alarid, and P.H. Hemberger
Los Alamos National Laboratory, Los Alamos, NM 87545

We report on the analysis of field samples using two GC/MS instruments designed for field applications. The technology and components selected were driven by the need for simple and inexpensive equipment which could be easily maintained in the field. Two ion trap detectors were interfaced with small commercial capillary column gas chromatographs for the separation and unambiguous identification of contaminants. We developed menu-driven software which could be easily used by field technicians without extensive training.

The ion trap detectors we used have been modified to incorporate resonant ejection during the RF ramp which has resulted in a 2 to 3-fold increase in sensitivity[1]. Extraneous hardware was removed from the GCs, but no other extensive modification of the GCs or the ITDs was required.

GC/ITD#1

An SRI 8610 GC was interfaced with a Finnigan Ion Trap Detector for GC/ITD#1 and has been reported on extensively elsewhere[2,3]. Designed for the conventional purge-and-trap analysis of VOCs in water and soils, this instrument is also suitable for other sampling schemes. For the field demonstration reported on here, the instrument and all peripherals were placed in the back of a 4-wheel drive vehicle and transported to an industrial plant site several hundred miles from our laboratory.

We were invited to analyze water samples using GC/ITD#1 at a pilot water purification system configured to remove volatiles from surface water. The instrument was set up and operating from field-generated power within an hour. At the site, surface water held in a holding tank is pumped through a bag filter for particulate removal, then through two activated charcoal stages, then returned to the creek. Samples are collected at various stages in purification and sent to a CLP lab for analysis. Routinely, CLP analysis of samples takes sixty days. The plant had been in operation for several weeks without feedback on effectiveness of their filtration process. We analyzed 5 mL aliquots from samples collected from four locations: Influent -- after bag filtration; Intermediate -- between the two charcoal stages; Effluent -- after both charcoal filters; and directly from the surface source. In a little over two days, twenty-six analyses were made including standards, blanks, and samples from the purification plant. Maintenance personnel at the purification plant were readily trained in the use of the instrument's acquisition software.

Our results immediately indicated the effectiveness of the plant's purification process (Figure 1). The largest unknown in the influent samples provoked most of our interest since its retention time did not match any of our initial VOC standards, although its mass spectrum indicated the likelihood of its being a dichloroethylene isomer. We obtained a standard mixture containing the three dichloroethylene isomers and were able to confirm the identification of the largest contaminant as cis-1,2-dichloroethylene. It should be noted that the CLP lab did not make an isomeric identification. Analysis of samples shipped for later analysis in our lab agreed well with field results (Figure 2).

GC/ITD#2

The need for rapid analytical screening propelled development of the second GC/MS described here. A short column (6 m) CMS Research Field MiniCams GC developed for the detection of chemical agents in support of demilitarization efforts was interfaced with an ITD. A brief analytical cycle with nearly instantaneous column heating allows for determination of targeted compounds within three minutes. Sampling modes include direct injection, direct air sampling, and tube desorption. Samples from the field test described below were introduced via tube desorption.

To test a Chemical Weapons Treaty Verification model, thirty-eight samples from ten locations were collected at a chemical plant that uses di-isopropylaminoethanol (DIPAE), M.W. 145.15, a Schedule 2 material. A Heat Induced Surface Sampler (HISS)[4] which uses an ir source was used to heat possibly-contaminated surfaces, including a concrete loading pad, and gravel and soil road surfaces. Evolved organic vapors and local air samples were simultaneously collected on solid sorbent tubes.

DIPAE, the targeted compound, was found in several field samples taken from various locations and is a component in the chromatogram displayed in Figure 3. The experimentally-obtained mass spectrum of DIPAE and a library spectrum are shown in Figure 4; flow inconsistencies at the interface between the GC and the ion trap may be responsible for the space charging seen in spectra obtained with GC/ITD#2. Duplicate samples were analyzed with GC/ITD#1; predictably, richer chromatographic information was acquired with a lengthier analysis. GC/ITD#2 proved most effective in fulfilling its design goal -- rapid detection of a specific organic compound.

CONCLUSION

Two transportable GC/MS instruments provided rapid analytical results and demonstrated their utility for field use. Sample screening at waste sites, process management, point source identification, and compliance verification are possible applications. The ion trap detector's simplicity, ruggedness, and high sensitivity have provided for reliable operation in field instruments developed in our lab since 1987.

SPATIALLY RESOLVED ORGANIC SURFACE ANALYSIS OF FLYASH PARTICLES WITH TIME-OF-FLIGHT SECONDARY ION MASS SPECTROMETRY

*J.A. Chakel[1], T. Fister[2], R.W. Linton[2], R.W. Odom[1]
[1]Charles Evans & Associates, 301 Chesapeake Drive, Redwood City, CA 94063, [2]Department of Chemistry, University of North Carolina at Chapel Hill, Chapel Hill, NC 27599.

Combustion-generated flyash is one of the most common forms of environmental pollution. With particles ranging in size from sub-micron to several microns in diameter, flyash particles have been extensively studied to assess their potential impact on the eco-system as well as aid in the development of control systems. Bulk solvent extraction methods have typically been utilized on a large sample of flyash particles to perform conventional organic analysis, however, this indirect approach relies on the efficacy of the extraction chemistry. Direct measurements on individual particles have previously been limited to morphological or elemental characterization. The focus of this current research is the development of methods for *in situ* spatial and chemical surface characterization of individual airborne particles emitted from combustion sources such as coal fired power plants.

This feasibility of direct analysis of organic species on individual flyash particles coated with monolayer amounts of polycyclic organic matter (POM) with time-of-flight secondary ion mass spectrometry[1] (TOF-SIMS) and laser microprobe mass spectrometry (LAMMS) has been demonstrated. In the TOF-SIMS technique, a sample consisting of particles on a substrate is bombarded by a finely focused (ca. 2000 Å) pulsed beam of primary ions which is rastered across the analyzed area. The very low flux primary beam ejects secondary ions from the sample's outer monolayers and preserves the chemical integrity of the sample surface. The high mass analysis range of the spectrometer coupled with the sputtering of intact molecular ions or structurally significant fragment ions, provides a method of determining the chemical structure of the surface. Individual particles can be analyzed through use of custom beam raster patterns. Additionally, mass selected ion images revealing the organic and inorganic constituents of flyash particle surfaces may be generated. In the LAMMS technique, a tightly focused, pulsed laser beam (266nm) with TOF mass analysis produces a mass spectrum of ions produced in the laser/solid interaction of the chosen sample spot. Spot sizes can be varied between 1 to 10 μm.

The flyash particles were NIST standards consisting of a mixture of mineral, magnetic and carbonaceous material. The POM was solution deposited at surface coverages varying from 80 monolayer thickness down to sub-monolayer thickness. The particles deposited on the substrates were inspected optically and then placed into either the TOF-SIMS or the LAMMS instrument for analysis. Organic microanalyses of nine POMs were attempted and included anthracene, 9-nitroanthracene, anthraquinone, 2-aminoanthraquinone, perylene, fluorene, fluoranthene, 9-fluorenone, decacyclene and anthrone. Positive ion TOF-SIMS and LAMMS mass spectra provided the most useful structural characterization of the POMs. TOF-SIMS exhibited the highest detection sensitivity for 2-aminoanthraquinone while the LAMMS analysis was most sensitive for perylene. Many of these model compounds have high vapor pressures and were rapidly sublimed in the instrument vacuum systems. Results showing the utility of TOF-SIMS flyash characterization with a model system (particles coated with three monolayers of 2-aminoanthraquinone) are presented. Figures 1 to 3 were acquired for 10 minutes from a 50 μm raster field. Figure 1 is a total positive ion image. Figure 2 is a mass selected ion image for the $M^+/(M+H)^+$ ions of 2-aminoanthraquinone. This image has fewer ions comprising the image and was thus convolved to render it easier to visualize. In addition to its organic microanalysis capability, ion microprobe TOF-SIMS is capable of determining the elemental surface composition of individual flyash particles. An example of this is shown in Figure 3 for Fe^+. Results from the LAMMS studies showed that a single flyash particle coated with a few monolayers of perylene produces the M^+ of perylene as the base peak. It was observed that primary ion bombardment/secondary ion formation with TOF-SIMS appears to be more sensitive for substituted POMs while laser desorption/ionization in the LAMMS displays higher sensitivity for unsubstituted POMs.

Current work is underway to investigate the capabilities of these two *in situ* microanalysis techniques for the analysis and localization of a large class of POMs on flyash particles. Instrumental improvements, such as a cold sample stage to reduce the sublimation rates of POMs, cluster ion primary ion source and laser postionization, will be implemented. Ultimate POM detection limits achievable in TOF-SIMS and LAMMS analysis of POM coated flyash will be determined. In addition, future research will also evaluate the capabilities of *in situ* microanalysis techniques in determining identity and location of POM reaction products formed on the surface of coal flyash particles. This research will also attempt to develop qualitative and quantitative analytical methods for organic microanalysis of coal flyash surfaces to extend the understanding of air-borne particulate surface chemistry.

This research was supported in part under grant No. DE-FG03-91ER81107 from the U.S. Department of Energy.

ELECTRON AND ION EMISSION BY A CSI SURFACE UNDER THE IMPACT OF HEAVY MOLECULAR IONS

A.BRUNELLE, P.CHAURAND, S.DELLA-NEGRA, J.DEPAUW, Y.LE BEYEC
Institut de Physique Nucléaire, 91406 - Orsay Cedex, France

G.B.BAPTISTA
Departamento de Fisica, P.U.C. Rio, CX Postal 38071 RJ22453, Brasil

In the present paper are reported the results of a systematic study of secondary electron and ion emission by impact of 18 keV molecular ions on a CsI surface. The mass range of these molecular ions varies from 1000 up to 70000 Da. Electron and ion emission rates were measured simultaneously with two sets of microchannel plates detectors. Molecular ions were produced by desorption induced either by a N_2 laser or by fission fragments from ^{252}Cf source. All measurements were realized with the SUPERDEPIL Mass Spectrometer TOF23 [1] equipped with an electrostatic mirror. Selection of stable molecular ions was made. The time of flight (TOF) measurements were performed in the single counting mode, using alternatively a Time to Digital Converter (TDC) or a TDC coupled to Charge to Digital Converter (CDC) [2]. The experiments performed in the event by event mode allow the study of the electron and ion emission phenomena for single molecular ion impact. Electronic coincidence windows set on TOF spectra were used to measure the correlated electron and ion emission. Grids of different transmission and a gridless aperture were used as extractors placed in front the CsI surface. This procedure allowed the study of grid effects on the secondary electron and ion emission rates.

Molecular ions (Primary Ions, PI) used a projectile were produced from standard samples of LHRH (MW 1182 Da), bovine insulin (MW 5733 Da), trypsin (MW 23295 Da), chicken egg albumin (MW 44650) and bovine albumin (MW 66430 Da).

The matrix assisted sample were prepared according to the Beavis and Chait [3] procedure.

Results and discussions

The primary ion TOF spectra were recorded by simultaneous detection of secondary electrons and secondary ions emitted from the CsI surface as a result of the molecular ion impact. In figure 1 we show a comparison between matrix assisted UV-laser desorption mass spectra for positive ions of a mixture of bovine insulin and trypsin using a gridless extractor. The upper spectrum was obtained by detecting the secondary electrons and the lower spectrum by detecting the secondary ions emitted from the converter surface after impact of 18 kV molecular ions. While one may observe a similar detection efficiency for insulin ions in both cases, the efficiency for the detection of trypsin ion is larger when secondary ions are used. This effect is more evident in the case ofbovine albumin ions.

The experiment was repeated after replacing the annular aperture extractor by a 90 and 80 % transmission grid extractor, the other conditions beeing unchanged. A large increase of secondary

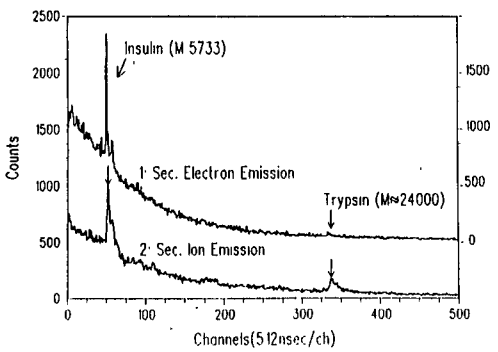

Figure 1

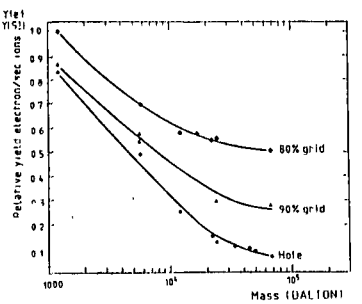

Figure 2

electron emission is then observed with respect to secondary ion emission. This enhancement, due to the presence of post-acceleration grids, was already suggested by Spengler et al [4].

The ratio secondary electron to secondary ion was systematically studied for molecular ions of 18 keV energy and in the mass range of 1000 Da to 70000 Da. Figure 2 show the variation of the ratio : yield of electrons/yield of secondary ions as a function of molecular projectile masses. One may observe that, for all the mass range, the relative yield for secondary electron emission is larger for the grid extractor with a lower transmission and both results are larger than the values obtained for the gridless extractor. To summarize, the electron emission yield increases when a grid is used. This effect is more important for heavy masses (an enhancement factor of ∝ 15 at m/z ∝ 66000).

Measurements were made to identify the negative ions desorbed under impact of molecular ions onto the CsI surface converter. Hydrogen, light organic ions 25^--44^-, iodine and CsI negative cluster ions are identified. Figure 3 shows the results from a systematic measurement of the ratio between secondary ions and electrons emitted under impact of 18 keV moleclar ions with m varying from 50 to 70000 Da. The results are shown for H^-, I^- and CsI_2^- secondary ions that were obtained with a gridless extractor. For each SI we observe an increase of SI yield between m/z = 50 and 1000 followed by a plateau for higher masses. The total SI yield is larger than 100 % in the plateau region.

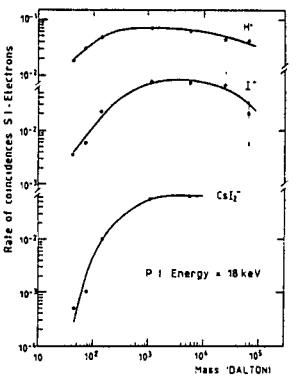

Figure 3

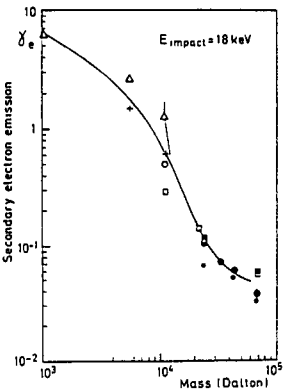

Figure 4

Conclusions

The emission of secondary electrons from CsI surfaces induced by collisions of massive molecular ions was observed for velocities lower than a "velocity thresold" suggested in previous works (see Fig. 4).

The emission of I^-, CsI_2^- was observed under molecular ion impact. This result confirms the earlier suggestion of a non linear effect for secondary emission under cluster and molecular ions impact.

The accelerating grid placed in front of the surface converter enhances considerably the emission of secondary electrons.

NOVEL INTERFACES FOR COMBINING LC WITH TIME-OF-FLIGHT MASS SPECTROMETRY

Liang Li
Department of Chemistry, University of Alberta
Edmonton, Alberta T6G 2G2, Canada

Liquid chromatography combined with mass spectrometry (LC/MS) can be a very powerful analytical tool for the analysis of thermally labile and nonvolatile molecules in complex matrices. Our research is directed towards the development of interfacing techniques for combining LC with time-of-flight mass spectrometry (TOFMS). With modern electronics and advanced computer technology, TOFMS has the potential to become a very important tool for LC detection with several unique features including versatility and higher detection sensitivity with no mass limit. In this presentation, two interfacing techniques are described. Depending on the flow rate used in LC, a continuous-flow probe interface and a pulsed sample introduction (PSI) interface are being developed to combine micro-LC (flow rates: 1-10 μL/min) and conventional LC (flow rates: 0.5-1.5 mL/min), respectively, with TOFMS.

(1). Pulsed sample introduction interface. In PSI [1], sample molecules carried by a liquid carrier are vaporized by passing through a heated capillary tube and then through a sample vaporizer of a high temperature pulsed nozzle. The resulting sample vapors are introduced into the TOF mass spectrometer in a pulsed form and ionized by a UV laser beam. More recently, we have used this PSI interface for combining LC with TOFMS. The TOFMS system has been described previously [1]. The LC solvent delivery system consists of a Shimadzu LC-600 programmable liquid pump. A Rheodyne Model 7125 syringe loading sample injector with a 20 μL sample loop is used for sample injection. In between the column and the PSI interface, a Shimadzu SPD-M6A photodiode array detector is used for obtaining a UV chromatogram.

Figure 1 shows the chromatograms of two polyaromatic hydrocarbons (PAHs), namely, benzo[a]pyrene and triphenylene. The mobile phase is 100% methanol with a flow rate of 1 mL/min. Figure 1(A) is the UV chromatogram at 266 nm from the diode array detector. Peak a is from the solvent (benzene). Peaks b and c are from triphenylene and benzo[a]pyrene, respectively. The ion chromatogram obtained by using the LC/TOFMS technique is shown in Figure 1(B). To establish the ion chromatogram, a boxcar integrator is used for monitoring the ion intensity and the output is recorded by a chart recorder. For Figure 1(B), the gate width of the integrator is set to monitor the molecular ion peaks of triphenylene and benzo[a]pyrene. The molecular ion peak of the solvent is not monitored. Note that a peak with opposite direction appears in Figure 1(B) at the same retention time as benzene. This is due to the electric noise in the boxcar integrator caused by a large ion signal from the ionization of benzene with the 266 nm laser beam. As Figures 1(A) and (B) illustrate, the ion chromatogram is almost the same as the UV chromatogram in terms of peak shapes and retention times. No peak broadening and other chromatographic distortions are found.

(2). Continuous-flow matrix assisted laser desorption (CF-MALD). We found that LC/TOFMS with the PSI interface has the potential to become a powerful means for the analysis of small nonvolatile molecules. However, it has a limited use for high molecular weight compounds. For these molecules, MALD is known to be a powerful method for ion generation. Thus, we are interested in developing a LC/TOFMS system based on MALD for the analysis of biopolymers, particularly, peptides. In this presentation, we report our first attempt to combine continuous-flow sample injection with MALD. The TOFMS system used for CF-MALD is the same as the one used for the PSI-LC/TOFMS work [1]. Unlike most reported MALD-TOFMS experimental configurations in which the sample probe is placed on the center of the repeller plate and the probe tip is floated at a high voltage, we place the probe in between the repeller and the extraction grid and it is grounded. With this configuration and the use of liquid matrix, we are able to detect ions with mass in excess of 100 kDa. Figure 2 shows the spectra of cytochrome C and bovine albumin obtained with a solid probe by using 3-nitrobenzyl alcohol (3-NBA) as a matrix. A 266-nm laser beam from a Nd:YAG laser is used for desorption.

We have also developed a continuous-flow probe for performing CF-MALD. In the CF probe, sample molecules are carried by a solvent (a mixture of water, methanol, ethylene glycol, and 3-NBA) through a capillary tube to a steel frit. Samples on the surface of the frit are then desorbed by using the 266-nm laser beam. A Rheodyne Model 7520 syringe loading sample injector with a 0.5 μL rotor is placed in between the syringe solvent pump and the CF probe. Figure 3(A) shows the mass spectrum of bacitracin (MW=1421) obtained with CF-MALD by mixing the sample with the solvent. The flow rate used here is 5 μL/min. It is found that the molecular ion signal of bacitracin can last for hours with a desorption rate of 10 Hz. Figure 3(B) shows the spectrum of bradykinin

(MW=1059) obtained by injecting ~200 pmole of sample into the continuous flow. We can observe the rise and fall of the molecular ion peak of bradykinin on the LeCroy digital oscilloscope. Currently, we are working on a data system to record the flowgram. This preliminary results indicate that CF-MALD is feasible with the experimental configuration described here and with the use of liquid matrix such as 3-NBA.

Liquid Aerosol Nozzles for Analytical Applications

L. R. Beeler, K. K. Murray, and D. H. Russell
Department of Chemistry
Texas A&M University
College, Station Texas 77843

We are currently developing an apparatus for the production and analysis of liquid aerosols. The goals of this project are twofold: first we are developing a method of introduction of liquid samples for mass spectrometric analysis. The second aspect of this work is to use aerosols to probe the mechanism of Matrix Assisted Laser Desorption Ionization (MALDI).[1] Much of the chemistry of MALDI ion formation is thought to occur in clusters ablated from solid surfaces.[2] With the liquid aerosol apparatus we will form clusters directly in the gas phase.

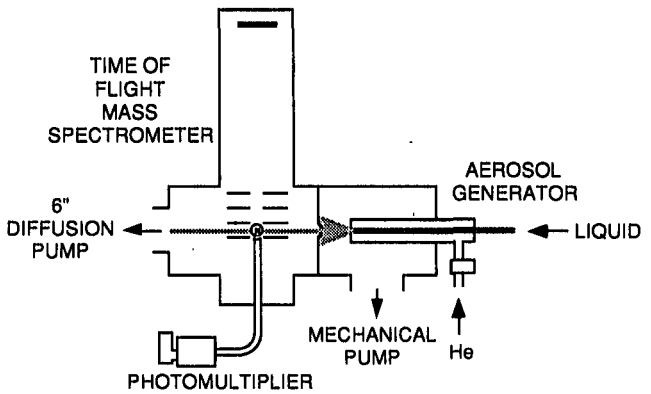

Figure 1. Liquid Aerosol Apparatus.

The liquid aerosol apparatus is shown in figure 1. Aerosols are produced by a pneumatic aerosol generator with helium as the carrier gas. The aerosol beam is skimmed in order to remove excess carrier gas and collimate the aerosol beam. Ions are produced by irradiating the beam with the output of a pulsed laser. Fluorescence and scattered light are brought out to a photomultiplier tube using a 6 mm diameter fiber optic bundle. Several pulsed laser systems have been used: an excimer laser using the rare gas fluoride lines at 353, 248, and 193 nm, YAG laser fundamental and overtones at 1064, 532, 355, and 266 nm, and an N_2 laser operating at 337 nm. Ions are formed and accelerated into a linear time of flight mass spectrometer and detected with a microchannel plate particle multiplier. Data is acquired either in analog mode with a transient recorder or in pulse counting mode using a time to digital converter.

A mass spectrum of aerosols containing fluorene in a methanol solution using focused 248 nm excimer laser radiation is shown in figure 2. The upper trace is a mass spectrum of the background gas in the ionization chamber obtained by firing the laser before the pulsed valve has fired. The peaks at high mass are due to ionization and fragmentation of polyphenyl ether diffusion pump oil. The lower trace is the mass spectrum obtained with a time delay of approximately 10 ms between the pulsed valve and the excimer laser in order to overlap with the aerosol pulse. Low mass peaks correspond to multi-photon ionization of methanol solvent molecules to form CH_3OH^+,

CH_3^+ and other fragments. At low mass there is also a strong signal corresponding to the He^+ ion formed when electrons produced by metal surface photoemission are accelerated into the ion formation region. This problem has been reduced by sending the laser beam through a positively biased iris before it enters the ion formation region. The radical cation of fluorene occurs at a time of approximately 18.5 µs. Although the fluorene peak is slightly taller in the lower spectrum, it also is quite prominent in the background spectrum due to gas phase fluorene.

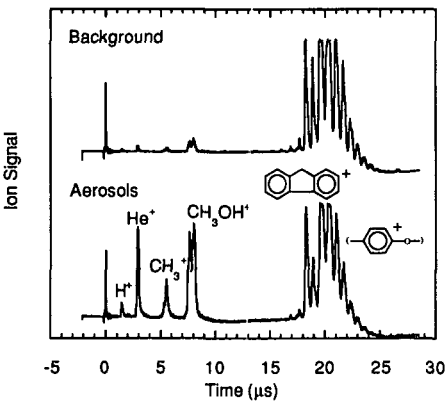

Figure 2. Ionization at 248 nm of aerosols containing fluorene in a methanol solution.

We believe that the photon fluxes necessary to produce ions from liquid aerosol particles exceeds that necessary to produce them from solid surfaces by several orders of magnitude. Working with high laser powers with our instrument produces new problems that must be overcome. First, background gasses must be reduced. We have already installed a high speed pump on the aerosol production chamber that has increased our pumping speed by a factor of 30. We further plan to install a cryobaffle over the ion source chamber diffusion pump to reduce backstreaming and install a differentially pumped region on the ion flight tube. Second, electrons produced by surface ionization in the ion source region must be further reduced. We have recently begun using a pulsed YAG laser whose superior beam quality allows precise positioning of the beam. With these changes we are confident that we can perfect this method of liquid sample introduction.

BACKSCATTERING OF LIGHT IONS IN THE BOMBARDMENT OF SOLID ORGANIC AND INORGANIC SURFACES WITH keV DEUTERATED VALINE CLUSTER

BRUNELLE, A., CHAURAND, P., DELLA-NEGRA, S., DEPAUW, J., LE BEYEC, Y.
Institut de Physique Nucléaire, 91406 Orsay Cedex, France.

BAPTISTA, G.B.
Departamento de Fisica, P.U.C. Rio, CX Postal 38071 RJ22453, Brasil.

Molecular and cluster ions of deuterated valine molecules $C_5O_2NH_3D_8$ (MW 125 Da), have been used as projectiles to bombard CsI and gold targets. The yields of H^- and D^- ions have been measured as a function of mass and velocity of the projectiles in order to estimate the rate of light mass ions emitted backwards.

Positive molecular and cluster ions $\{nM+H\}^+$ n=1,2,3 of the deuterated valine M are produced by ^{252}Cf fission fragments desorption. Those primary ions are accelerated and used as projectiles to bombard a cesium iodide or a gold surface with energies ranging from 3.5 to 20 keV. Secondary electrons and negative ions are produced under impact and their time of flight (TOF) are measured. By a correlation method, several secondary ion TOF spectra are recorded in the same experiment, corresponding to the impact of primary ions $\{M+H\}^+$, $\{2M+H\}^+$, $\{3M+H\}^+$. The secondary ion yield of mass m is given by $Y(m) = N_m/N_{PI}$, where N_m is the number of counts in the peak of the mass m in the TOF spectrum in correlation with the primary ions PI, and N_{PI} the number of primary ions. The rate of in flight decays for the valine cluster ions has been measured with the TOF mass spectrometer Super-Depil [1] which is equipped with a two stages electrostatic mirror. It is less than 15 % in our experimental conditions so that the correction of yields is negligible.

Figures 1 and 2 show the yield variations of respectively H^- and D^- ions as a function of $E/A = V^2/2$. The H^- ions come predominantly from the water covering the target surface at 10^{-7} hPa. H^- yields increase with the square of velocity and linearly with the mass of projectiles. On the contrary, D^- ions come only from the projectile and Fig. 2 shows that the D^- yields increase linearly with the square of the projectile velocity. The cross section for Rutherford backscattering beeing proportional to 1/E, another mecanism is therefore involved in the backward emission. The slopes of the yield curves change at about 20 eV per mass unit. Above this 20 eV threshold it becomes non linear with the mass of the projectiles and the yield for the backward emission of light ions follows:

$$Y = k(N_D)^{\alpha}V^2, \ \alpha \geq 2,$$

N_D beeing the number of deuterium atoms contained in the projectile. The ratio Y_D/Y_H beeing always around 0.1 means that about 10 % of the H^- ions emitted on the impact of keV small organic clusters originate from the projectile itself. This value does not depend on the nature of the material (CsI or Au surface), since most of hydrogen ions are coming from contaminant layer (mainly water). As suggested by E.Parilis, the non-linear increase of the backward emission of light ions can be explained by a shuttle collision effect [2]. During the impact of the organic cluster, light atoms

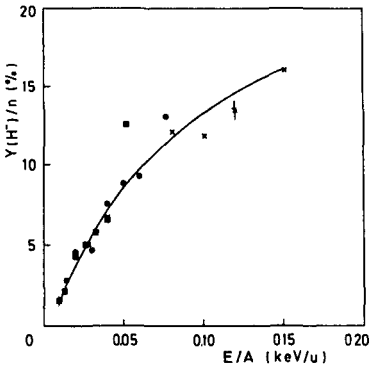

Figure 1

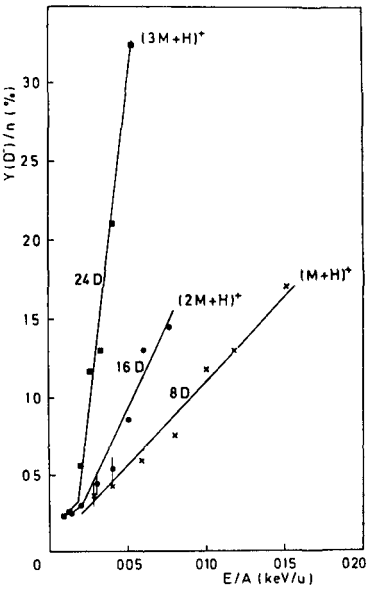

Figure 2

Normalized yields Y/n of H^- (Fig.1) and D^- (Fig 2) ions versus E/A of projectiles in keV/u. Target was CsI and projectiles were deuterated valine clusters $\{nM+H\}^+$ (crosses n=1, circles n=2, squares n=3) containing respectively 8, 16 and 24 D atoms.

like H or D could "shuttle" between heavier ones (C,O,N) and by this way acquire enough kinetic energy in the backward direction to be ejected.

We thank Professor E.Parilis for the very interesting discussions and Y.Hoppilliard from the laboratory DCMR of the Polytechnique School (Palaiseau France) for providing us with the deuterated valine samples.

LIQUID IONIZATION MASS SPECTROMETRY SUITABLE FOR ANALYSIS OF REACTION PRODUCTS

T. Kobayashi, T. Kaneko, M. Kohara, K. Kobayashi and M. Tsuchiya
Dept. Physical Chemistry, Yokohama National University
Tokiwadai, Hodogaya-ku, Yokohama 240 Japan

Analysis of reaction products containing less volatile or thermolabile compounds, is not an easy job for chemists in a laboratory for synthetic chemistry. Liquid ionization (LI) mass spectrometry (1) is a soft ionization method, providing MH^+ or a few intense peaks characteristic of each compound and separates to some extent by increasing the temperature of a sample. If an analyte was separated from others, CAD spectrum of the analyte can be obtained. Since the ion source is open to the air, sample handling is very easy and any kinds of reagents such as ethanolamine can be examined easily to improve mass spectra of analytes (2).

Recently a narrower glass envelope (diameter: 16mm, previous one: 30mm) of LI ion source (Fig.1), was found to provide easy focusing, resulting in better sensitivity (about 5 times).

An example is a product from the reactions between 1,10-diazo-18-crown-6 (azacrown) and 2-chloroethanol, which was produced as a sort of intermediates of catalysts for polymer synthesis. Since the NMR and IR spectra for this product were similar to those for the raw material (azacrown, R in Fig.2) and column selection for GC or LC was not easy, no information had been obtained for the product. LI mass spectra of 1 ul aqueous solution of the product were measured. Mass spectra between m/z 10-500 were recorded, each in 2 s, repeatedly, while the temperature of the sample was increased (3). Figure 2 shows an average mass spectrum for scan numbers between 25 and 60 and selected ion profiles (we call this "thermal desorption profile" shown upper in Fig.2) for protonated molecules, MH^+, of main compounds. The LI mass spectrum indicates clearly that the main product is N-hydroxyethyl-azacrown (A in Fig.2) with the yield of about 50 % and the raw material still remained. The spectrum shows two other products (B and C), in which more hydroxyethyl groups were connected. Their selected ion profiles also show that each compound desorbed at slightly different temperature, the larger molecule the higher temperature, indicating that these are not adduct ions. LI mass spectra for another product obtained under a different experimental condition, indicated that the compound A was a main product with the yield of about 70 %, but B and C were not produced. When the voltage applied to the skimmer 1 (V_{s1}) is increased, a kind of CAD spectra are obtained, because ions are accelerated to decompose between skimmer 1 and skimmer 2 (Fig.1), where the pressure of argon is around 0.1 Torr. LI mass spectrum of the same sample as shown in Fig.2 measured under a CAD condition (V_{s1}: 30V higher than normal) is shown in Fig. 3. Although fragment ions were produced from all compounds, the CAD spectrum is corresponding well to the structure of the compound A, much better than EI mass spectrum of the same sample. EI and CI mass spectra were measured using a conventional mass spectrometer with a direct probe. CI (CH_4) mass spectra of these reaction products showed similar mass spectra, but they gave more fragment ions and less abundances for the products with larger molecular weights. It was not easy to control the temperature of a direct probe for this kind of samples. In the LI, the temperature of a sample is generally increased from room temperature to about 250 C in 4-5 min. In this paper, the same increasing rate was used up to 120 C, and resulted in good spectra, in which the peak intensities of MH^+ ions of LI mass spectrum indicate the relative abundances of compounds in the sample, because these compounds have similar thermal properties. There are a variety of samples which can be analyzed easily by the LI mehtod. MS/MS with the LI ion source must be a powerful tool for a mixture like reaction products.

Extending the Limits for Linear Ion Counting: An Electron Multiplier for High Count Rate Mass Spectrometry

Dick Stresau and *Kevin L. Hunter - ETP Pty. Ltd.
Ermington, N.S.W. 2115, Australia

Dietmar A. Fichter - Surface Science Western,
University of Western Ontario, London, Ontario N6A 5B7, Canada

INTRODUCTION

A high speed ion-counting electron multiplier has been developed to meet the increasing demands on detector performance by mass spectrometer users and manufacturers. Four characteristics that typically limit the performance of an ion counting multiplier have been investigated and tailored to achieve optimal effectiveness: output pulse width; multiplier dead-time; maximum average linear output current; and pulse height distribution and the associated counting plateau.

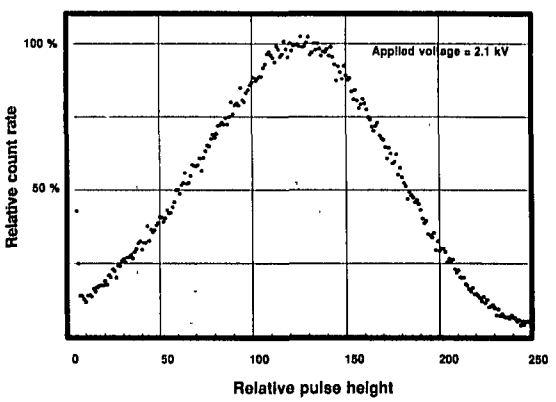
RESULTS

A fast focussing dynode structure is used to produce output pulses with typical widths of 8 nanoseconds. Active Film Multipliers have no dead time other than the time required for a pulse to fall below the system's discriminator level.

Incorporating an electron saturation stage in the multiplier has lead to a typical pulse height distribution of 100% full width at half maximum. The narrow distribution leads to a well defined counting plateau enabling stable operation of the counting system and optimal detection efficiency from the multiplier.

The most obvious difference between the high current Active Film Multiplier and all other multipliers is its linear response at exceptionally high output currents (see High Current Response curve). Notice that it is very linear with up to 60 μAmps of output current and has only 3% variation from linearity at 100 μAmps: considerably more than ten times higher than the maximum linear current from a conventional pulse counting multiplier. The second horizontal scale at the bottom of the graph shows the equivalent output count rate for a multiplier operated at a gain of 5×10^7.

Pulse height distribution of the AF150H Active Film Multiplier



For some applications it is advantageous to operate below the "knee" of the plateau curve. The reduced multiplier gain will result in less output current for an equivalent count rate. This will, in effect, shift to the left the lower horizontal scale of the High Current Response graph and will enable a higher count rate before the multiplier becomes non-linear. In this way, lower detection efficiency can be traded for higher count rate capability.

The conventional isotope ratio method has been used to demonstrate the multiplier's very linear performance with a count rate to about 20 Mhz and an ultimate count rate of 50 MHz (see High Count Rate Response curve).

CONCLUSION

The high current Active Film Multiplier provides a major advance for fast ion counting systems. Linear response to 20 MHz demonstrates an order of magnitude increase in counting performance over conventional pulse counting multipliers. The unique combination of high count rate capability and narrow pulse height distribution offers exceptional performance for high count rate applications.

A Parallel Detection System providing Femtomole Detection Limits in LC-Electrospray-MS

A.D.Hoffman, P.A.Ryan and C.Moore
Kratos Analytical, Manchester, UK

Parallel detection systems for high resolution magnetic sector instruments (array detectors) have been available for sometime, and have conventionally been fitted to 4-sector instruments for MS-MS work. Parallel detection offers significant sensitivity advantages over point detection and is therefore of great benefit in the analysis of very small amounts of material. Similarly, parallel detection is highly beneficial with ionisation techniques which generally produce relatively low ion currents.

A 2-sector magnetic sector instrument with an array detector used with techniques such as electrospray or field desorption is a powerful instrument from the point of view of both resolution and sensitivity. In an array detector ions strike a microchannel plate which produces electrons. The electron signal causes emission of photons upon striking a phosphor screen and these are integrated using a photosensitive device (Figure 1). The mass spectrum is obtained by stepping the magnet position to expose successive 'snapshots' of the array. On the Kratos CONCEPT mass spectrometer, these snapshots encompass 4% of the mass range. On the Kratos PROFILE mass spectrometer, these snapshots encompass 6% of the mass range.

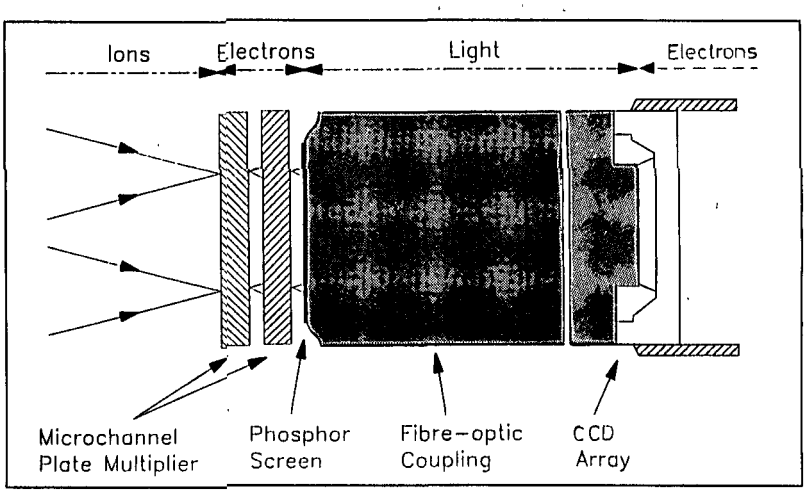

Figure 1: Schematic of array detection system

On 2-sector instruments with arrays femtomole levels of detection are routinely obtainable. Figure 2 shows a snapshot of the m/z 1592 ion (corresponding to a 4+ ion) from β-Casein tryptic digest from 20 femtomoles injected into the mass spectrometer.

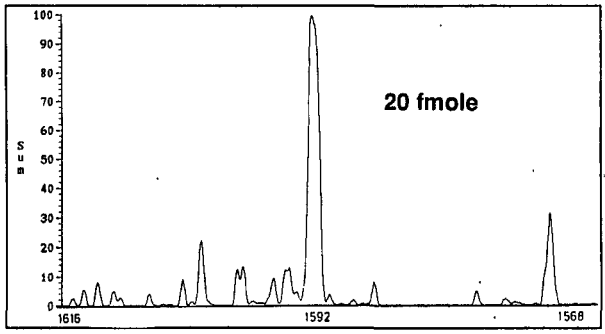

Figure 2: 20 fmole array electrospray spectrum of β-casein digest fragment

The previous array system available from Kratos has been updated to incorporate a CCD array and completely new detection electronics. This has resulted in both cost reduction and increased performance. Significant portions of the mass range can be acquired at speeds compatible with LC requirements. This enables the system to be used for on-line chromatography, and subsequently enhancing the areas applicable to this technique. Figure 3 shows the chromatographic separation from a tryptic digest of β-Caesium illustrating the benefits of identifying low levels of components by this method .

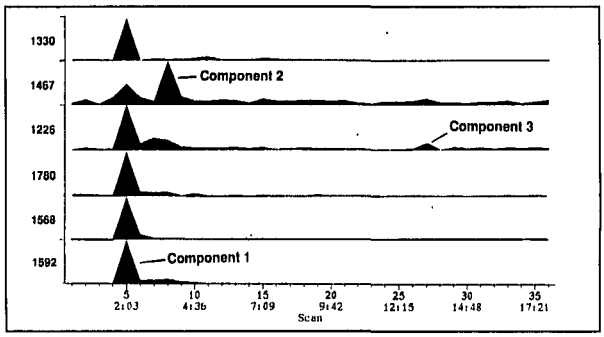

Figure 3: Chromatographic separation of tryptic digest of β-casein

The CCD array can be fitted to all 2,3 and 4-sector CONCEPT configurations for applications where ultimate sensitivity is important. The comparative low cost of the new device also enables a second intermediate array to be fitted after MS1 on tandem instruments. By utilising the capabilities of CCD technology and the high performance of modern graphics workstation computers, two orders of magnitude less sample are consumed to produce similar or better quality data as with a conventional detector.

ION TOMOGRAPHY STUDIES OF MULTI-COMPONENT SYSTEMS WITHIN AN ION TRAP MASS SPECTROMETER.

*J.D. Williams and R.G. Cooks, Department of Chemistry, Purdue University, W. Lafayette, IN 47907.
J.E.P. Syka, Finnigan MAT, San Jose, CA 95134.

We use spatially-resolved photodissociation of ions to map ion trajectories in a Finnigan ion trap mass spectrometer. Distributions measured in the present fashion are both radially-averaged and averaged with respect to the phase angle of the drive RF. Previous studies have been based on the photodissociation of benzoyl ion (from electron impact of acetophenone) at 308 nm.[1] We have extended these measurements to a number of other ions to demonstrate the validity and generality of this technique and to investigate the effects of mass and chemical parameters on the distributions. These ions include protonated benzene, protonated fluorobenzene, chlorobenzene molecular ion, and 4-methyl benzoyl ion. Their distributions measured at $q_z = 0.6$ are shown in Figure 1. In these experiments, the ion being probed was mass-selected through an AC/DC isolation step. In all cases, the FWHM of the distribution is 1.0 mm, which agrees very well with the previously reported FWHM for benzoyl ion at $q_z = 0.6$. The apparent difference in the profile of the distribution for 4-methyl benzoyl ion may be due our inability to measure all photodissociation fragments at this value of q_z. The profile of the excimer laser beam at the center of the ion trap is 1.2 mm (FWHM) as measured by scanning the laser beam across a diode array detector located on a beam line equivalent to that of the ion trap. Although the laser beam width limits our ability to fully resolve the beam profile, changes in the distribution of 0.1mm are discernible and reproducible.

Ion distributions are perturbed by applying a "tickle" voltage on the end caps of the ion trap to resonately excite ions in the z-direction. A supplemental AC voltage (164 kHz, 60 mV p-p) was applied to the end caps for 10 ms to excite benzoyl ions (m/z 105) stored at $q_z = 0.4$. At this tickle voltage, no CID products were observed. The distribution of benzoyl ion was measured at 1 ms intervals before, during, and after the resonant excitation pulse. As shown in Figure 2, the distribution gradually broadens to over 8 mm FWHM after the onset of resonant excitation and apparently begins to collapse before the tickle is turned off.

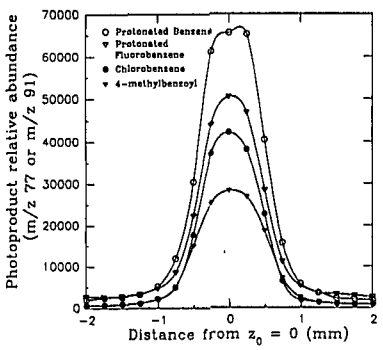

Figure 1.

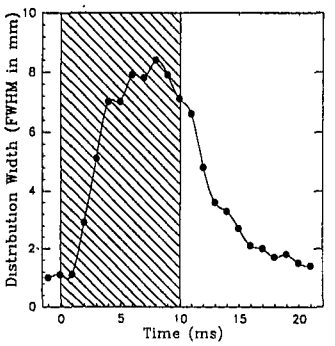

Figure 2. The shaded portion represents "tickle on."

This initial rise and collapse while the resonant AC voltage is on was also observed in other experiments. In these cases, power absorption of the resonant RF is being offset by collisional cooling of the ions by the buffer gases. This decrease in distribution width is directly equivalent to the observation of steady-state conditions in ion production during CID in the ion trap.[2] The distribution decays in a near exponential fashion after excitation as would be expected by collisional cooling of the ions.

The effects of other buffer gases on ion distributions were investigated. As the extreme example, Xenon is shown to be a very poor buffer gas for trajectory stabilization in Figure 3. At the indicated partial pressures of Xe trajectory widths were 1.4 mm at p_{Xe} = 3.3 E-8 Torr, 1.1 mm at 5.0 E-8 Torr, and 1.4 mm at 6.6 E-8 Torr, In general for rare gases other than He, ion distributions were observed to broaden with increasing pressure and with increasing atomic mass. At Xe pressures greater than 6.6 E-8 Torr, extensive collision-induced dissociation and ion scattering prevented any meaningful measurement of the distribution.

Ion-ion interactions may also perturb the distribution of ions within the trap. For example, mass spectral peak-broadening and mass shifts are observed under space-charge conditions. Peak-broadening can be ascribed to broadening of the ion cloud within the ion trap. Figure 4 shows the effect of Xe^+ on the distribution of $C_6H_5CO^+$ at q_z = 0.4. In these experiments, the partial pressure of Xe was 3.3 E-8 Torr. The broader distributions and greater peak heights shown in Figure 4 as compared to Figure 3 are due to an increase in ionization time from 1 ms to 9 ms. At the longer ionization time, the effects of space-charging on the mass spectrum were just evident. To measure the distribution with Xe^+ present, an RF ramp was used to eject all ions with masses less than m/z 105 (benzoyl ion) and resonant ejection of m/z 120 (acetophenone molecular ion) before photodissociation. For measurements with Xe^+ absent, AC/DC isolation was used to select only m/z 105. Xe^+ ions broaden the ion cloud in this experiment as would be expected from space-charge interactions, although it is conceivable that Xe^+ is shielding the benzoyl ions from the fundamental RF. Further work is in progress to increase the resolution of these experiments so that experimental variables can be more easily related to observed changes in distribution than is presently possible.

Fundamental Aspects of Collision-Induced Dissociation of Polyatomic Ions

*Jean Futrell, Kuangnan Qian, YiBai Chen, and Anil K. Shukla, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

We have now completed a suite of experiments providing accurate measurements of energy deposition, angular scattering, fragmentation patterns, and the translational energy dependance of these parameters for a set of small molecules These experiments have demonstrated dramatic changes in mechanism as a function of collision energy and have identified the "collision time" in which the activation step occurs as a singularly important variable in collisional activation. We have also drawn attention to the importance of analyzing these experiments in the center-of-mass or collisional coordinates frame in order to separate out mass effects on the interpretation of data which necessarily must be taken in the laboratory coordinate frame. These studies have shown, for individual molecules, interesting correlations with photoelectron spectroscopy (PIPECO), breakdown graphs, RRKM/QET theories. and simple scattering theories. These correlations have been used by us, and others, to discuss such important issues as energy deposition, internal energy randomization, scattering dynamics and activation/dissociation lifetimes.

In this paper we review briefly some of the general features of collisional activation mass spectrometry as revealed in our experiments and discuss the extent to which simple models can be used to interpret these features in general. In particular, we shall show that the Massey Criterion for dependence of energy transfer efficiency on relative velocity provides quantitatively correct results for hydrocarbon ions, such as the propane molecular ion Our conclusion is that CID is accounted for quantitatively, both with regard to energy deposition and fragmentation processes, over a very broad range of collision energies (1 eV to 6 Kev) and a broad selection of scattering gases, by combining a modified Massey distribution with the breakdown graph of propane obtained using PIPECO measurements.

The propane molecular ion was chosen for our study because it is the archetypical example of molecular ions whose unimolecular decay is well-described by the quasi-equilibrium theory of mass spectra. The decomposition mechanisms and energetics of the principal reaction steps are well known Regardless of how energy is deposited in the ion, it rapidly inter-converts into vibrational excitation of the ground electronic state. Dissociation of the molecular ion appears to be nearly entirely statistical, and we may infer that its CID fragmentation would be accurately described by these well-established concepts. Thus the principal new information which is obtained by our dynamics study is establishing details of energy deposition and angular scattering.

We have carried out such a detailed beam dynamics study of the principal primary fragmentation processes

$$C_3H_8^+ \xrightarrow{(He,\ Ar)} C_3H_7^+ + H \qquad (1)$$

$$C_2H_4^+ + CH_4 \qquad (2)$$

$$C_2H_5^+ + CH_3 \qquad (3)$$

We have also conducted an extensive baseline CID study using a conventional tandem mass spectrometer at the University of Nebraska (MS 50 TA, courtesy of Prof. Gross) varying collision energy, collision gas, and primary beam attenuation over broad ranges These experiments have been analyzed using our coursed beam scattering data to resolve energy shift and angular deflection information.

One of the detailed tests of the theoretical model is a comparison of calculated and experimental energy depositions as a function of collision energy. The accompanying table illustrates the essentially quantitative agreement which is achieved. Since our experimental precision in the measured energy deposition (measured as a function of scattering angle and integrated over all angles) is ±0.1 eV, this agreement is a fairly stringent test. Further, the neglible shift for the propyl ion over the energy range 1.7-5360 eV, for which the Massey function shape is dramatically changed, clearly demonstrates the breakdown graph is the controlling factor for energy shift for this ion. For ethylene ion it is the dominant factor, and for ethyl ion the energy deposition function is of about equal importance.

Comparison of the two sets of data allows a complete analysis of the influence of angular scattering and of multiple collisions on CID parameters. Somewhat surprisingly, the effect of scattering on observed fragmentation patterns is profound, but the effect on kinetic energy shift and energy release measurements is modest. Further, using measured scattering factors the simple modelling of energy deposition using the Massey criterion quantitatively accounts for CID fragmentation patterns. Both fragmentation patterns and energy deposition were fitted with a single value of the adiabaticity parameter, a, which is smaller by about 80% than the value of this parameter deduced from non-resonant charge transfer experiments This further reinforces our previous conclusions that CID primarily proceeds via small impact parameter, impulsive collisions.

The gratifying agreement of experiments with this model for the propane cation and the stark disagreement with data for acetone, nitromethane and benzene molecular ions further supports the hypothesis that CID proceeds mainly from isolated electronic states for ions which have large gaps in their photoelectron spectra Our data for the ensemble of results support the hypothesis that decomposition from the ground state manifold is adequately described by the Massey function/QET model but electronically excited state decay is not.

CHIRAL RECOGNITION OF COBALT-COORDINATED DIOLS

Julie A. Leary*, Geoffroy Bott,# and Mark Riley^
*Chemistry Dept., University of Calif., Berkeley, CA 04720
#G.B. Scientific, Novato, CA 94947
Berkshire Analytical, Kinderhook, N.Y. 12106

Metals containing chiral auxiliaries (either pre-attached or added directly to the sample) can be coordinated by a chiral organic compound of interest to form diastereomeric adducts which appear to show mass spectral differences. In the research described here, we show that we can distinguish between complexed enantiomeric diols.

A racemic mixture of $Co(AcAc)_3$ is added to equimolar concentrations (mM) of either D- or L-Diisopropyl tartrate (DIPT) and either RR- or SS- Threohydrobenzoin (THB). The mixture is ionized using 20 kV Cs ions in the presence of nitrobenzyl alcohol matrix compound and the various complexes formed are studied using kinetic energy release (KER) measurements from metastable decomposition in the MIKES cell (Figure 1). One complex, $[Co(AcAc)_2/DIPT]+$, m/z 491, forms at least two diastereomeric complexes with each of the D- and L-DIPT enantiomers. In the presence of THB, a chemical kinetic resolution (1) effect takes place, such that one enantiomer of $Co(AcAc)_2$ is preferentially coordinated to the tartrate. If this selectivity and recognition is in fact taking place, one should see KER values of the metastable product ions which are the same for the complexed enantiomeric pair, and different values for opposing pairs. Table 1 shows the KER values measured for the product ion m/z 393 when the diastereomers [Co(AcAc)/L-DIPT]+ and [Co(AcAc)/D-DIPT]+ are formed in the presence of RR- and SS-THB. In the presence of RR-THB, the m/z 393 ion formed from D-DIPT is an enantiomer of the m/z 393 ion incorporating L-DIPT in the presence of SS-THB. The KER values are in fact the same for these two enantiomers (1 and 4 in Table 1) as are the ones for the remaining two enantiomers (2 and 3 in Table 1), but they show approximately a 15 meV difference between the two pairs.

Since the ion m/z 491 represents Cobalt in its +3 oxidation state, we believe that the ion at m/z 393 is also Co+3 and that reduction of the ligand has occurred by hydrogenation via the Meerwein-Pondorf-Varley reaction (2).

Photodissociation of Proton Bond Clusters on a Magnetic Sector/Reflectron Time-of-Flight Instrument

Fred Strobel and D.H. Russell
Department of Chemistry, Texas A&M University, College Station, Texas 77843.

Proton transfer reactions are one of the most fundamental reactions in chemistry; therefore, an understanding of the factors that can influence H^+ transfer is immensely important to our understanding of chemistry. In addition, H^+ transfer reactions can be important in the methods used for ionization of large molecules, e.g., matrix-assisted laser desorption, FAB, and electrospray ionization. We have used photodissociation of protonated clusters to examine H^+ transfer reactions of excited species.

The protonated clusters were formed by 15keV SIMS on a mixture of nitroaniline, glycerol, and HCl. Ionization of this mixture formed complexes of the type [nitroaniline-H^+-$(glycerol)_n$], where n = 1-2. Two isomers of nitroaniline were used (3-nitroaniline and 4-nitroaniline). In our preliminary studies, after the complexes are mass selected, they are photoexcited with either 337 nm or 266 nm. The dissociation of the photoexcited cluster is dominated by the loss of a neutral molecule. The neutral loss may reveal information on the effect of electronic excitation of the H^+ transfer reactions. The choice of 3-nitroaniline and 4-nitroaniline was based on previous solution phase studies which indicate that the acidity of aniline compounds increase (relative to ground state) in the excited state by 2-10pk_a units. The increase in the acidity is attributed to the increase contribution of ionic resonance structures. MOPAC calculations using PM3 basis set for the ground and first excited singlet states of 3-nitroaniline and 4-nitroaniline were performed. Plots of the partial charges of 3-nitroaniline and 4-nitroaniline shows large changes between the ground and excited states.

Table 1 shows results of the photodissociation of the [nitroaniline-H^+-$(glycerol)_n$] clusters. The photodissociation of the (3-nitroaniline-H^+-glycerol) causes loss of nitroaniline with the glycerol retaining the H^+, while the photodissociation of (4-nitroaniline-H^+-glycerol) causes the loss of glycerol with the nitroaniline retaining the charge; however, loss of glycerol and nitroaniline are competitive in the photodissociation of [4-nitroaniline-H^+-$(glycerol)_2$] cluster.

The results show that excited state H^+ transfer reactions can be study using photodissociation and the H^+ transfer reactions can be influence by the enviroment. Future studies will focus on cluster size dependence of H^+. In addition, other systems will be investigated. The choice of the other absorbing species will be influenced by the solution phase studies and the MOPAC calculations.

The experiments were performed on a magnetic sector/reflectron time-of-flight mass spectrometer, which consist of a Kratos MS-50 and a homebuilt reflectron. The first step in the photodissociation experiment is to pulse the Cs^+ ion gun, and mass selecting the ion with the MS-50. Firing of the photodissociation laser is synchronized to the ionization pulse and the flight time of the mass selected ion from the source to the photodissociation region. In addition, the collection of product ions is synchronized with the laser. To obtain a true photodissociation spectrum, the spectrum must be corrected for the presence of background product ions caused by metastable ions and CID. To correct for background, a CID/metal ion spectrum is taken alternatively with the photodissociation spectrum. The photodissociation spectrum shown in Fig. 1 is a background subtracted spectrum for [4-nitroaniline-H^+-(glycerol)] at 266 nm.

Ligand Effects and Bond Energies of ML^{2+} Ions Determined by Charge Stripping Mass Spectrometry

*Sési McCullough-Catalano and Carlito B. Lebrilla
Department of Chemistry, University of California, Davis, CA 95616

Charge stripping (CS) of simple metal ion complexes produced by secondary ionization has been previously used to obtain information about the effects of ligation on the electronic energy levels of metal ions. Charge stripping of these complexes allows the determination of second ionization energies through measurement of the translational energy loss, Q_{min}, in the charge stripping process.[1,2] We have used the combination of SIMS/CS in a VG-ZAB 2F mass spectrometer to produce doubly charged metal and metal-ligand complexes from aqueous solutions of metal salts. In this manner, MO^+, MOH^+ and MX^+ (X=Cl, Br) ions have been formed. Experimental details have been published previously.[2] A full scale MIKES spectrum of the selected ion contains peaks due to the singly charged metal ion, M^+, as well as MO^+ and OH^+, confirming the identity of the charge stripped species. Q_{min} values for the bare metal ions are within ± 0.5 ev of the literature values, and therefore within the accepted uncertainty in the method.

The Q_{min} values obtained for the ligated metal ions are listed in Table 1. Although for most of these complexes the second ionization energies have not previously been determined, some have been obtained by charge stripping of FAB produced ($MgOH^+$, $MgCl^+$, $MgBr^+$) and electron impact produced ions ($TiCl^+$). In each case, our values are generally within ± 0.5 ev of the reported values. In all cases, the effect of the ligand in increasing Q_{min} increases follows the order OH<Cl<O, although the magnitude of the effect varies depending upon the metal.

We have also used the Q_{min} values of ligated metal ions to obtain metal-ligand dication bond dissociation energies. Through the energy diagram shown (Figure 1) it is possible to obtain the dissociation energy of a doubly charged ion if the dissociation energy for the corresponding monocation is known. The bond energies of several ligated metal monocations that we have produced and charge stripped have recently been obtained,[3-5] allowing us to calculate bond dissociation energies of several metal hydroxide and metal oxide dications.

From Figure 1, it is seen that the dissociation of these complexes can produce either the metal dication with its corresponding neutral ligand, or two singly charged ions. The energies for both processes have been determined for Mg, Sc, V, Mn, Fe and Co hydroxide dications, and Sc, Ti and V oxide dications (see Table 2). For the metal hydroxides, dissociation to form a doubly charged metal ion and neutral ligand corresponds to an endothermic process, and these bond energies do not vary significantly with the metal. In contrast, dissociation to form the singly charged metal ion and the singly charged hydroxyl ligand may be either an endothermic or an exothermic process, depending upon the metal involved.The bond energies in this latter dissociation are observed to decrease linearly with increasing metal second ionization energy. In contrast, the dissociation of the metal oxides is observed to be endothermic for both pathways.

Structure Elucidation of Isomeric 2-Acetylaminofluorene-Deoxyguanosine Adducts by FAB MS/MS

M. Paul Chiarelli, Matthew S. Bryant, and Jackson O. Lay, Jr., University of Arkansas-Little Rock, Little Rock, AR. 72204. and the National Center for Toxicological Research, Jefferson, AR 72079.

Introduction

The structure elucidation of carcinogen-modified nucleosides by mass spectrometry is motivated by the belief that DNA adducts may play a critical role in the initiation of cancer. In this study we demonstrate the utility of FAB combined with low energy tandem quadrupole MS/MS for identifying characteristic fragmentation pathways of isomeric 2-acetylaminofluorene adducts of deoxyguanosine. Of particular interest is the influence of the acetyl group on the fragmentation behavior on the arylamide-guanine adducts. The tandem mass spectrometry of C8-substituted arylamine guanine adducts has been studied in some detail (1); however, only one study of an N^2-substituted arylamine has been carried out (2).

Experimental

FAB MS/MS spectra were acquired using a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer equipped with an Ion Tech Fast Atom gun. Xenon was employed in the primary atom beam at energies of 8-10 KeV and Ar as the collision gas for CAD. Thioglycerol was used as a matrix. CAD spectra of the BH_2^+ and other source-produced fragment ions were acquired at 50 eV collision energy. Typically 100 ng of adduct was silylated with N-methyl-N-trimetylsilyltrifluoroacetamide (MSTFA) and then deposited on the FAB probe.

Results and Discussion

The strategy employed throughout this investigation was to activate the protonated carcinogen-modified base (i.e., the BH_2^+ ion) and other relevant source-produced fragment ions so that fragmentation characteristic of these isomeric adducts could be fully elucidated. A MS/MS spectrum of protonated N-(guan-8-yl)-2-acetylaminofluorene is presented in Figure 1. This spectrum is dominated by the ion produced by loss of ketene at m/z 331. CAD of the source-produced m/z 331 indicates that the structure of this ion is entirely consistent with N-(guan-8-yl)-2-aminofluorene studied previously (3). In contrast, the MS/MS spectra of m/z 373 (Figure 2) derived from dG-N^2-AAF exhibit several significant fragment ions. As depicted in Schemes 1 and 2, the cleavages observed in the CAD of the third generation fragment ions that have been formed by a loss of NH_3 or H_2O can be most easily explained based on the assumption of the formation of an additional carcinogen-base bond. The CAD spectrum of m/z 331 derived from dG-N^2-AAF (Figure 3), protonated G-N^2-AF, shows more extensive fragmentation than observed previously in the only other CAD study of a N^2-substituted guanine adduct done under high energy conditions (2). Most of the ions possess m/z values that suggest they are formed after ammonia loss and bond formation between the C2 of the PAH and the N1 of the guanine. Scheme 1 describes the formation of two of the prominent fragment ions. A shift in electron density in the six-membered guanine ring and the subsequent cleavage of the three bonds in the path designated A yields the ion at m/z 232. This ion may then lose HCN to give m/z 205. Alternatively, the ion at m/z 205 may be formed by the cleavage of two bonds directly as illustrated in path B. The ion at m/z 355 derived from dG-N^2-AAF was activated to obtain evidence for its structure and mechanism of formation (Figure 4). The CAD spectrum of m/z 355 yields two major ions, m/z 221 and m/z 135, that can be explained in terms of the 7-membered cyclic structure of m/z 355. These fragment ions are formed by the same bond cleavages, the two C-N bonds bridging the PAH and the guanine, and should have similar proton affinities (thereby explaining their similar relative abundances).

Conclusion

The CAD spectra of the C8-substituted AAF isomer are dominated by loss of ketene. Since the preponderance of fragmentation occurs via this single pathway other sample-specific fragmentation is suppressed. CAD of the N^2-substituted adduct produces fragment ions whose formation is preceded by cyclization reactions attributed to the interactions of the acetyl group and the fluorene NH_2 group with the N1 position on the guanine base.

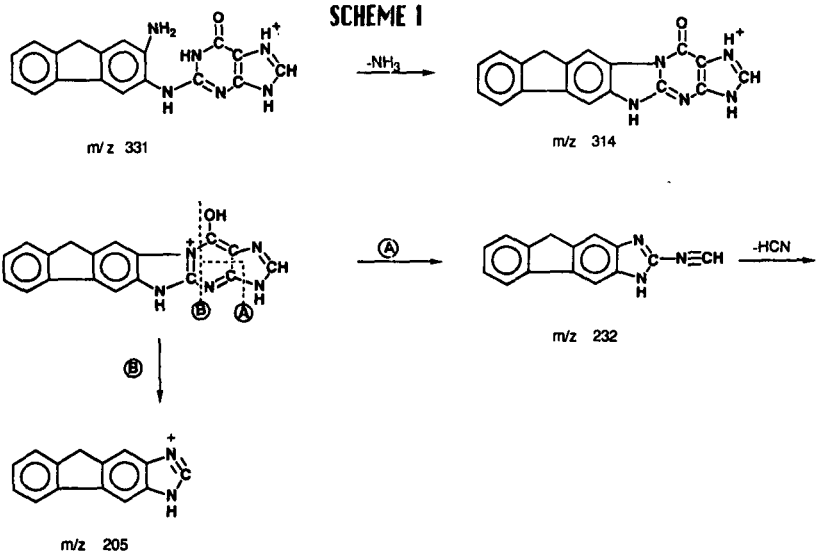

Photodissociation and Photoinduced Electron Detachment in Dinuclear Metal Carbonyl Anions

*Brian T. Cooper and Steven W. Buckner
Department of Chemistry, University of Arizona, Tucson, AZ 85721.

Several aspects of the visible and near-infrared photochemistry of the dinuclear metal carbonyl anions $M_2(CO)_n^-$, (where M = Cr, Mn, Fe, and Co; and $4 \leq n \leq 9$, depending on the metal) have been investigated with Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR). Nearly every species generated absorbs in the spectral regions studied, and the dependence of the observed photoproduct signal on the laser power is used to establish whether said process requires the absorption of a single photon or the sequential absorption of two photons. The majority of these species photodissociate, losing one carbonyl ligand per photon absorbed; however, the number of carbonyls lost from $Fe_2(CO)_7^-$ is found to vary from one (at 1064 nm) to one or two (depending noticeably on the visible wavelength -- see Figure 1), implying the existence of a vibrationally excited, predissociative $Fe_2(CO)_8^-$ * intermediate. Two-photon behavior was observed across the spectrum (mixed with a one-photon channel in the visible) for $Mn_2(CO)_8^-$ dissociation to $Mn_2(CO)_7^-$, and at 1064 nm only for $Mn_2(CO)_7^-$ dissociation to $Mn(CO)_5^-$. Sequential carbonyl loss, often producing isolable quantities of increasingly coordinatively unsaturated species, continues with irradiation (for all but the dimanganese system) until either the product ion no longer absorbs (in the case of $Co_2(CO)_5^-$ at 1064 nm) or until apparent loss of a neutral metal atom (and formation of a more saturated, 17- or 18-electron mononuclear anion) occurs. Apparent neutral metal atom loss has been observed previously[1,2] upon collisional activation of $Cr_2(CO)_5^-$ and $Fe_2(CO)_4^-$. This is an intriguing observation, since it suggests the existence of a highly asymmetrically coordinated species in which one metal atom behaves more like a ligand.

Presented here is evidence that the observed "neutral metal loss" caused by photoactivation of the "terminal dinuclear anions" $Cr_2(CO)_5^-$, $Fe_2(CO)_4^-$, and also $Co_2(CO)_4^-$ is the result of electron photodetachment, followed by subsequent attachment of the trapped electron to the background neutral. This occurs even for the chromium system, in which the neutral $Cr(CO)_6$ is admitted to the cell through a pulsed valve but is not completely pumped away on the time scale of the experiment. Double-resonance experiments were used in each case to verify the identity of the species leading to apparent metal atom loss. (The high cross section for terminal ion depletion relative to that of the prior photodissociation step forming each terminal ion made it nearly impossible to isolate these species.) The evidence for electron detachment consists of the following:

1. Electron ejection (by short-duration suspended trapping using a home-built circuit[3]) immediately *after* the shuttered laser photoactivation event caused a substantial and significant decrease in the amount of mononuclear species formed. (The amount of mononuclear species was never reduced to zero since attachment of the trapped electrons can occur *during* the laser event.)

2. For iron, the formation of two more highly saturated *dinuclear* species is observed after the laser event. Electron attachment to $Fe_2(CO)_9$ (the neutral used in these experiments) yields mononuclear and dinuclear species competitively.

3. In at least the iron and cobalt systems, a carbonyl loss channel competes slightly with mononuclear ion formation. While this is not evidence for detachment, it is evidence for the involvement of a vibrationally predissociative intermediate, which allows an analogy to be drawn between the photo- and collisional activation results. "Vibrational predissociation of an electron" (which invokes a familiar curve-crossing model) is known for activated molecular anions.

The following iron data illustrate rich photochemistry of these dinuclear species:

COLLISIONS OF BENZENE AND BUCKMINSTERFULLERENE AT FLUORINATED AND NON-FLUORINATED SELF-ASSEMBLED MONOLAYER FILMS.

* V.H. Wysocki, J.M. Ding, T.E. Kane, and A. Somogyi, Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284. J.H. Callahan, Naval Research Laboratory, Washington, DC 20375.

It has been illustrated that a variety of analytically-useful processes occur upon low-energy (eV) collisions of mass-selected polyatomic ions with a surface. These include *surface-induced dissociation*, *reactive collisions* of projectile ions with surface adsorbates, and *chemical sputtering*.[1] The goal of the research described here is to investigate the ion-surface chemistry that is detected when $C_6H_6^{+\cdot}$, $C_6D_6^{+\cdot}$, $C_6H_5F^{+\cdot}$, $C_{60}^{+\cdot}$, and C_{60}^{++} collide with a well-characterized surface at collision energies of 10-100 eV. The surfaces were prepared by the spontaneous assembly of C_2, C_3, C_4, C_{10} and C_{18} n-alkanethiols, perdeuteroeicosanethiol, and 2-(perfluorooctyl)-ethanethiol on both gold foil and vapor-deposited gold. Chemical reactions between the benzene molecular ion and the monolayer films are detected (e.g., H and CH_3 additions, F and CF_3 additions) and are sensitive to the chain length of the alkanethiolate. For benzene, the ratio of CH_3 addition to C_2H_5 addition varies with chain length, with a larger ratio obtained for the long-chain alkane thiolates. Scheme I and Figure 1 illustrate the major products detected when benzene and deutero benzene collide with an alkyl- or perdeuteroalkyl-terminated self-assembled monolayer. The isotope shifts clearly indicate that reaction is occured with the film, and not with adventitious hydrocarbons. When benzene or C_{60}^{++} collide with the fluorinated alkanethiolate films, surface-induced dissociation is much more extensive than on the hydrocarbon films (see Figure 2).

TANDEM MASS SPECTROMETRY OF IONS DERIVED FROM NUCLEIC ACIDS

Scott A. McLuckey, Gary J. Van Berkel, Rose S. Ramsey and Gary L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Electrospray (ES) provides a means for efficiently generating gas-phase ions from solutions containing nucleic acid constituents [1]. We have been studying the behavior of both singly [2] and multiply charged [3] ions derived from nucleic acids, formed by electrospray, under quadrupole ion trap MS/MS conditions. The goals of this study are to categorize and understand the fragmentation behavior of these ions in order to maximize structural information. Ideally, we would like to be able to determine the complete sequence of an oligonucleotide and the identity and location of any modified bases from as little material as possible. We are currently investigating mainly the anions of oligonucleotides varying both in length and sequence.

We label the products ions observed in MS/MS spectra according to the scheme of Figure 1. At last year's meeting we noted a very strong tendency for multiply charged anions containing adenosine to lose A^- (m/z 134) and follow with cleavage at the 3' C-O bond from which the adenine was lost. In all of the species studied to date, this tendency continues to be observed. The consistency with which this rule is obeyed facilitates determining the location of the adenosines in the chain. We have also investigated a number of oligonucleotides that contain no adenosines. When adenosine is absent, we see losses of the other bases followed by cleavage of the adjacent 3' C-O bond. Whether or not the base is lost as a neutral or as an anion depends upon the charge state of the parent ion and the identity of the base. To date, cytosine has not been observed as an anion. In every case, it has been observed to be lost as CH. Figure 2 illustrates this point with the MS/MS/MS spectrum of the triply charged 5-mer 5'-pd(CCCCC)-3'. The MS/MS spectrum showed exclusive loss of PO_3^- from the 5' end, a common observation when there is a dangling phosphate group. Note that when relatively violent ion trap collisional activation conditions are employed, as in this case, sequential fragmentation occurs allowing the complete sequence of the oligonucleotide to be determined.

Figure 3 illustrates a case with a mixed oligonucleotide without an adenosine in the sequence, 5'-d(CGTTC)-3'. Given the mass of the parent ion, as derived from the mass spectrum, the complete sequence can be determined from the MS/MS spectrum of either the doubly or triply charged parent ion (triply charged ion data shown here). Note that thymine and guanosine are both observed as anions while cytosine is lost as a neutral. Under appropriate collisional activation conditions, all of the diagnostic cleavages along the chain are observed.

One of mass spectrometry's strengths in the area of nucleic acid research is in the identification of modified bases. Figure 4 shows the MS/MS spectrum of the quadruply-charged modified oligonucleotide 5'-d(MeATGCAT)-3'. This spectrum implies the presence of a methylated adenosine from the appearance of the abundant anion at m/z 148. Note also the appearance of the unmodified adenosine and a signal for T^-. Sequential cleavages indicate the positions of the modified and unmodified adenines as well as that of thymine. The only sequence information absent in the spectrum is the order of C and G.

A variety of other unmodified and modified deoxy oligonucleotide anions up to 12-mers have been studied. In all cases, loss of base followed by cleavage at the adjacent 3' C-O bond occurs. Loss of an adenine anion is strongly preferred. Once all adenines are lost, other bases are lost without a strong preference. Guanine and thymine may be lost either as anions or as neutrals, depending upon parent ion charge state, whereas cytosine has been observed to be lost as a neutral only. The relatively high MS/MS efficiencies (>50%) and MS^n capability of the ion trap make it particularly useful for acquiring structural information from these species. Furthermore, fragile nature of these ions and high sensitivity to collisional activation conditions near the dissociation threshold makes the ion trap particularly valuable for manipulating these ions.

STRUCTURE DETERMINATION OF MODIFIED GUANOSINES BY PERMETHYLATION FAB MS/MS

John M. Gregson and James A. McCloskey
Departments of Medicinal Chemistry and Biochemistry
University of Utah, Salt Lake City, UT 84112

One of the principal difficulties encountered in the interpretation of mass spectra of nucleosides is the lack of sufficient structurally significant fragmentation from which sites of substitution in the heterocyclic base can be determined. Various approaches to this problem are in principle available, such as chemical derivatization or use of collision-induced dissociation (CID), but which generally fail to simultaneously offer high sensitivity and suitable fragmentation.

We have investigated microscale permethylation as a useful way to improve both the sensitivity and the amount of structure information available for polar or charged nucleosides such as deoxyguanosine and its derivatives. This approach offers one modest disadvantage in that an approximate 1:1 mixture of O^6-methyl and 1-methyl tautomers are formed (1), which is easily counterbalanced by three principal advantages: (*1*) the resulting derivatives are highly hydrophobic, resulting in high surface activity and thus high sensitivity for FAB; (*2*) the derivatives are chemically stable, in contrast to the corresponding TMS derivatives; (*3*) a number of fragmentation channels are generated by CID which are useful for placement of side chain substituents on the purine ring. Initial recognition of the protonated base ion in the case of subnanogram quantities can be made by constant neutral loss scans corresponding to loss of the sugar.

The chemistry used to produce permethyl derivatives is an adaptation of standard procedures (1): application of sodium methylsulfinyl carbanion to 50 pg or more of nucleoside, followed by a DMSO solution of methyl iodide, with an important variation in the original method which permits the reaction to be routinely applied to subnanogram sample quantities, for example, the use of 3 mm ID fire-sealed glass tubing for running the reactions, and microfine drawn lambda pipettes for nanoliter liquid transfer. The use of small quantities of DMSO allows for rapid direct drying of the reaction solvent after aqueous quench, which eliminates the need for a subsequent extraction step.

Collision-induced dissociation of the perdeuteromethylated guanosine base at *m/z* 203 leads to the formation of a series of relatively abundant high mass ions which arise from rupture of the aromatic ring. The resulting spectrum contains a plenitude of structure information even at low collision energies (in these experiments, 60 eV at 50% beam reduction in krypton, VG 70-SEQ). Six of the more important structurally significant fragment ions and their structural possibilities are shown on the next page, bottom right.

By extension of this methodology, the analogous ring fragmentation pathways of several other methylated guanosines (derivatized with CD_3I, to distinguish the origin of methyl groups) and deoxyguanosine-carcinogen adducts have been studied. The method has also proven useful in distinguishing N-7 versus C-8 substitution, and was important in the mass spectrometry-based structure determination of a new and novel [2,3-*d*]pyrrolopyrimidine nucleoside from tRNA (data not shown).

CONFIRMATION AND QUANTIFICATION OF DNA ADDUCTS AT THE FEMTOMOLE LEVEL BY MASS SPECTROMETRY

J.O. Lay Jr., M.P. Chiarelli, D.-X. Lin and F.F. Kadlubar
National Center for Toxicological Research , Jefferson, AR 72079 and
Department of Chemistry, University of Arkansas, Little Rock, AR 72205.

Abstract

We have investigated three strategies for the analysis of carcinogen-DNA adducts by mass spectrometry (MS). The aim of this research is the development of methods having adequate sensitivity for use in human biomonitoring. The first two methods are for the analysis of modified nucleosides. Because of the low levels of *in vivo* DNA modification and the small sample sizes available, these methods were only used for the analysis of model compounds or when unusually high levels of DNA modification were observed in dosed animals. Confirmation of targeted modified-nucleosides was demonstrated, using trimethylsilyl (TMS) derivatives, based on selected reaction monitoring (SRM), fast atom bombardment (FAB) and tandem MS. The feasibility of analyzing unknown adducts was shown using underivatized arylamine-nucleoside adducts, based on matrix assisted laser desorption and time-of-flight (LD/TOF) MS. The analysis of arylamine-adducts in human DNA required hydrolysis to the free carcinogen, isolation from the DNA matrix and derivatization to increase sensitivity. Then quantitation using isotope dilution, selected ion monitoring (SIM) and NICI/GC/MS of the electrophore-labeled derivative was performed. In initial experiments the levels of 4-ABP bound to human lung and bladder mucosa DNA were measured, with detection limits in the range of one modification per 100 million nucleotides.

INTRODUCTION

The analysis of carcinogen-DNA adducts has been proposed as a means of evaluating the extent of human exposure to specific carcinogens (*Environ. Health Perspect. 76*:141-145 1987). Unfortunately, most analytical methods having sufficient sensitivity to detect carcinogen-DNA adducts at the levels expected in humans require authentic samples for use as standards. Human dosimetry based on the MS analysis of modified nucleosides (or nucleotides) will likely require significant improvements in the sensitivity of the appropriate MS methods. Alternative approaches to dosimetry have been developed based on the analysis of carcinogen-protein adducts using NICI/GC/MS (Bryant, *et al. Cancer Res. 47*:602-608 1987). The analysis of the human DNA-adducts described herein is based on a modification of this procedure.

EXPERIMENTAL

The following modified nucleosides were used in the study: N-(deoxyguanosin-8-yl)-4-aminobiphenyl (dG-C8-ABP), N-(deoxyguanosin-8-yl)-2-aminofluorene (dG-C8-AAF) and 3-(deoxyguanosin-N^2-yl)-2-acetylaminofluorene (dG-N^2-AAF).

SRM FAB/MS: Samples of dG-C8-AAF, dG-C8-ABP, and dG-N^2-AAF were silylated by adding N-methyl-N-trimethylsilyl-trifluoroacetamide (MSTFA) directly to the dry sample and heating at 60° C for 1-2 hours. About 0.5-1.0 μl was applied to a copper target via a syringe after application of 1-2 μl of thioglycerol. Spectra were obtained using a Finnigan MAT TSQ-70 with an Ion Tech gun. FAB ionization was effected using xenon atoms accelerated to 8-10 kV. Q1 and Q3 were set to pass only the TMS derivatized protonated molecule and BH_2^+ fragment ions, respectively.

TOF/MS: LD/TOF mass spectra of dG-N^2-AAF and dG-C8-AAF were acquired with a Vestec model 2000, using a large excess of a sinapinic acid matrix, a wavelength of 355 nm, and a power density of 1 X 10^6 W/cm^2 irradiating an area of approximately 0.126 mm^2.

GC/MS Analysis: Aliquots of DNA were brought to 0.5N NaOH and extracted 3 times with hexane before addition of d_9-4-ABP. The solution was heated overnight (130°C) in a sealed vessel. The hydrolyzed 4-ABP was extracted into hexane and derivatized using pentafluoropropionic anhydride (PFPA) in the presence of trimethylamine for 30 min at room temperature. Samples were dried and reconstituted in hexane prior to GC/MS analysis. Analyses were performed using a Finnigan 4000 with a Varian 3400 GC and a SPI injector (225°C) and a DB5 capillary column (30M X 0.25mm) heated from 60°C to 180°C at 20°C/min and then at 10°C/min to 250°C. NICI was accomplished using methane (0.25 torr uncorrected) and a source temperature of 220°C. Quantification was achieved based on SIM of the $(M-HF)^-$ ions of the 4-ABP and the deuterated standard.

RESULTS AND DISCUSSION

SRM Analysis: Detection of targeted adducts was achieved at the 5-50 pg level using FAB ionization and tandem MS in the SRM mode. With Q1 set to pass only the *tris*- or *tetrakis*-TMS derivatized protonated molecule and Q3 set for the BH_2^+ ion, significant signals were observed from 5-50 pg of adduct, but not the thioglycerol matrix. Incomplete reaction with MSTFA did not appear to be a problem. Although derivatization resulted in formation of *bis*- through *tetrakis*-TMS derivatives, the first two TMS groups primarily reacted with the two hydroxyl groups of the deoxyribose moiety. The detection limits for SRM did not appear to depend on which TMS derivative was employed. More variation in the detection limit was observed when the arylamine rather than the number of TMS groups was changed. While SRM is inherently limited in application to targeted or selected masses, it is a suitable methodology for quantitative analysis using isotope dilution MS, an application that we are currently investigating.

LD/TOF Analysis: Full scan spectra of 20 pg levels of adducts were obtained using matrix assisted LD/TOF MS. The spectrum for dG-N^2-AAF, obtained by summing the signals obtained using 100 of 500 laser shots from a single probe loading of 20 femtomole, showed signals for the protonated molecule, $[M+Na]^+$ and $[M+K]^+$ at m/z 489, 511, and 527 respectively. Although the LD/TOF methodology, at present, offers little promise for structure characterization, the LD ionization step coupled with Fourier transform mass spectrometry (FT/MS) may allow more complete characterization of nucleoside-carcinogen adducts.

GC/MS Analysis: Eleven human smokers' lung and eight human urinary bladder mucosa DNA samples were analyzed for 4-ABP adducts based on isotope dilution NICI/GC/MS analysis of pentafluoropropionyl derivatives after isolation of the hydrolyzed arylamine from the tissue DNA. The adduct levels were found to be <0.33 to 3.9 adducts per 10^8 nucleotides in bladder mucosa and <0.33 to 49.5 adducts per 10^8 nucleotides in lung DNA.

Table: Detection limits for the analysis of carcinogen nucleoside adducts by MS.

Ionization Method	Derivative	Scan Type	Detection Limit
FAB	none	+MS	100 ng
FAB	TMS	+Prod	20 ng
FAB	TMS	+MS	1 ng
FAB	TMS	+CNL	0.5 ng
FAB	TMS	+SRM	0.01 ng
LD (TOF)	none	+MS	0.01 ng
GC/MS	PFP	-SIM	<0.001 ng

Notes: +/- = positive or negative ion mode; PFP = pentafluoropropionyl
MS = full scan mass spectrum; SIM = selected ion monitoring
SRM = selected reaction monitoring; TMS = trimethylsilyl
CNL = constant neutral loss mass spectrum

Levels of carcinogen modified constituents of DNA in environmentally exposed individuals indicate that a detection limit in the subfemtomole range is required for routine dosimetric analysis. In order to achieve the desired detection limit with mass spectrometric techniques, we are investigating the effect of cationic surfactants on ion yield and the production of quality spectra of nucleotides from a glycerol matrix.

Hexadecylpyridinium acetate (HDPA) has been shown to dramatically enhance sensitivity in fast atom bombardment analysis of adenosine triphosphate (ATP) with negative ion detection (1). We have performed similar experiments in ^{252}Cf plasma desorption (PD) and liquid matrix assisted secondary ion mass spectrometry (LMASIMS) as well as FAB. In addition to ATP, nucleoside monophosphates were studied. All nucleotide spectra were acquired in the negative ion mode. All samples were dissolved in glycerol containing surfactant in the range of 0.001 to 0.05 M concentration.

Direct comparison of ATP $(M-H)^-$ ion signal from samples run by FAB on a Kratos MS-50 with and without surfactant showed an enhancement in sensitivity (where sensitivity is taken as signal per unit concentration) of approximately 10X (fig. 1a & b). Additionally, matrix background was significantly depressed in the presence of surfactant. More, dramatically, spectra with comparable ion signal and signal-to-background ratios could be obtained in the presence of surfactant at analyte concentrations 2 to 3 orders of magnitude below those required for minimum detection without the use of surfactant (fig. 1c). Similar results were obtained with ^{252}Cf-PD analysis of ATP.

The ion signal was nearly independent of the ATP bulk concentration in the presence of surfactant (fig. 2). This suggests that the surface concentration of ATP is governed by the concentration of HDPA. This dependance is illustrated in figure 3. That the HDPA concentration which gives maximum ATP signal changes

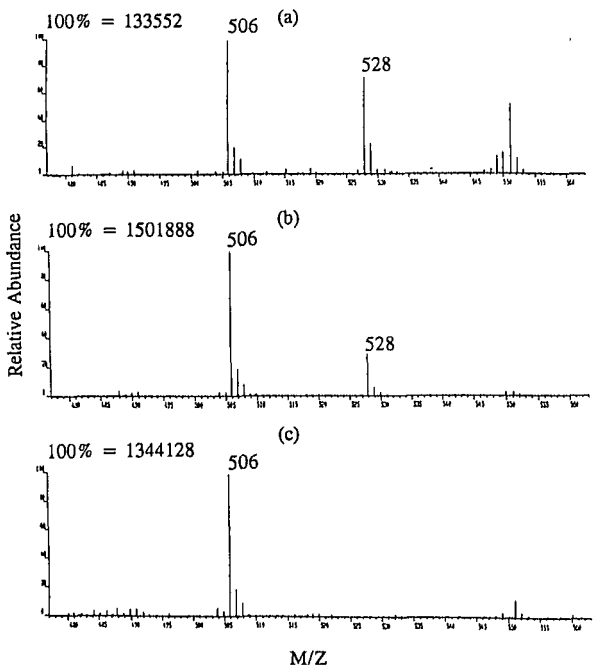

Figure 1: FAB mass spectra of glycerol solutions of (a) 10 mM ATP, (b) 10 mM ATP and 1 mM HDPA and (c) 10 μM ATP and 1 mM HDPA.

with ATP concentration indicates that the surface activity of the HDP^+ cation is not independent of its counterion. The decline in ATP signal at higher concentrations of surfactant is consistent with the formation of a micellar phase in the bulk solution which would compete with the surface sites for ATP ion.

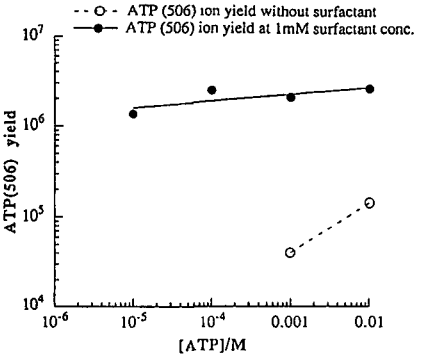

Figure 2: ATP (m/z 506) ion yield in FAB as a function of ATP concentration.

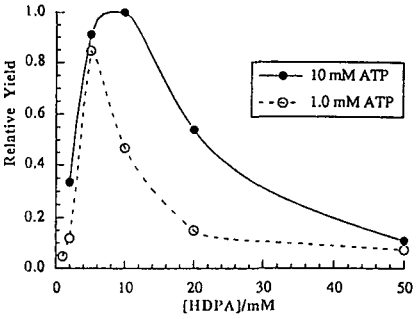

Figure 3: ATP (m/z 506) ion yield in FAB as a function of HDPA concentration.

The nucleotides deoxyadenosine monophosphate (dAMP) and deoxyguanosine monophosphate (dGMP) were shown to exhibit similar behavior in the presence of HDPA. Combining the surfactant's sensitivity gain with the instrumental advantage of our LMASI/TOF mass spectrometer (2), we have achieved detection limits for nucleoside monophosphates in the low femtomole range (fig. 4).

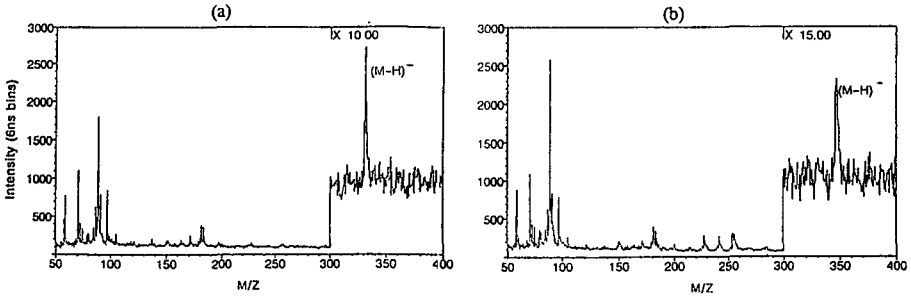

Figure 4: LMASI/TOF mass spectra of (a) 4 fmoles dAMP and (b) 5 fmoles dGMP in 10 mM HDPA in glycerol.

Quantification of Opioid Neuropeptides by Tandem Mass Spectrometry

*Dominic M. Desiderio[1,2], and Chhabil Dass[1], [1]Department of Neurology and the Charles B. Stout Neuroscience Mass Spectrometry Laboratory, [2]Department of Biochemistry, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN 38163

Mass Spectrometry has been used in this laboratory to analyze several different neuropeptides in human anterior pituitary tumor tissue (Kusmierz et al, 1991; Dass et al., 1991). The hallmark of that novel method of peptide quantification is the use of FAB-MS to produce the protonated molecule $(M+H)^+$ of a peptide and the *B/E* linked-field scan mode on a two sector E,B instrument to link the $(M+H)^+$ ion with a unique amino acid sequence-determining fragment ion. Appropriate stable isotope-incorporated peptide internal standards are used. The use of MS methods has led to the finding of a novel hypometabolism of the POMC precursor in human tumors (Kusmierz et al, 1991).

The purpose of this study is to extend the MS method for peptide quantification by using a tandem hybrid mass spectrometer. A VG AutoSpec Q hybrid instrument was used with LSIMS (Cs^+) ionization (35 kV) to determine the limits of detection for methionine enkephalin (ME) and substance P (SP) using $(M+H)^+$ and MRM detection methods. MS1 (E,B,E) collects the $(M+H)^+$ ion, and MS2 (qQ) collects a selected unique product ion. For SP, $(M+H)^+$ data were determined, and for ME several different transitions were used: $(M+H)^+ \rightarrow 425$, $\rightarrow 397$, and $\rightarrow 354$.

A mixture of dithiothreitol:dithioerythritol (DTT: DTE) was used (for SP 5:1; for ME 3:1). Ion bombardment was one min for SP and four min for ME.

Figure 1 contains the MH^+ data for SP (MW=1348); a straight line can be fitted through the data points down to 371 fmol of SP. The three transitions for ME are illustrated in Figure 2 and demonstrate a detection sensitivity down to 175 fmol.

The use of tandem mass spectrometry increases significantly the molecular specificity and detection sensitivity of these neuropeptide measurements. This research is supported by NIH 26666.

PHARMACOKINETIC STUDIES USING *IN VIVO* MICRODIALYSIS IN COMBINATION WITH TANDEM MASS SPECTROMETRY

L.J. Deterding[1], K. Dix-Washburn[2], L.T. Burka[2], and K.B. Tomer[1]

[1]Laboratory of Molecular Biophysics

P.O. Box 12233, Research Triangle Park, NC 27709

In recent years, microdialysis has become an important technique for the *in vivo* sampling of the extracellular fluid in discrete compartments of living systems. This technique is being widely used in physiological, pharmacological, toxicological, and behavioral studies for the recovery of endogenous substances or exogenous substances, such as drugs and toxicants. Microdialysis is preferred to conventional sampling techniques because there is minimal damage to the sampling site. In addition, little alteration of the fluid balance results because no fluid is removed from or introduced into the system during the sampling process. Microdialysis sampling is accomplished by implanting a small microdialysis probe into the tissue of interest. Molecules with a molecular weight cut-off of the dialysis membrane diffuse through the membrane due to concentration differences and are collected in the dialysate.

Recently, Justice and coworkers (1) reported the thermospray mass spectrometry (TSP/MS) analysis of samples collected by off-line microdialysis, and Caprioli et al. first coupled microdialysis with CF-FAB for the analysis of drug levels in blood (2). We have recently coupled *in vivo* microdialysis with tandem mass spectrometry using a coaxial continuous flow FAB interface (3). Briefly, the perfusion liquid is pumped at a flow rate of 0.8 uL/min through the dialysis probe. The perfusion liquid is contained in a stainless steel reservoir under helium pressure. The flow rate through the dialysis probe can be varied by varying the helium pressure. A sample loop of 1.1 uL is used to collect the perfusate. Injections are then made using a Valco injection valve and by using a static-split injection as previously described. Using this injection system, injections can be made at 2 minute intervals. The microdialysis probe was inserted inside a cannula surgically placed in the jugular vein of a 200-g male rat. To remove background interferences, we integrated selected reation monitoring (SRM) into the protocol.

The model compound used in the development of this technique was tris (2-chloroethyl) phosphate (TRCP). Several of these tris organophosphates have been widely used in plastics and synthetic fibers as flame retardants and are suspected carcinogens. Although the metabolism of TRCP in rats has been studied, no literature is available on the pharmacokinetics of TRCP. The present investigation uses the free concentration versus time data obtained by microdialysis/MS/MS for the pharmacokinetic analysis of TRCP. Figure 1 shows the free TRCP concentration vs time profiles following intravenous administration of TRCP (20 mg/kg) to three animals and real-time analysis by mass spectrometry. The average slope from the three animals was -0.086/min. A comparison of these results are made with the pharmacokinetic values obtained for TRCP from conventional pharmacokinetic studies. Traditionally, pharmacokinetic studies have been performed by collecting serial blood samples after chemical administration, with subsequent extraction and analysis by chromatographic methods. For chemicals with short plasma half-lives multiple blood samples should be withdrawn over sufficiently short time intervals to define the plasma concentraiton vs time curve. Figure 2 shows the free TRCP concentration in plasma vs time data following intravenous administration of 20 mg/kg of TRCP to three animals. The slopes obtained for each animal were averaged and the result was found to be -0.035/min. Figure 3 shows the data obtained from the two techniques. The data from one animal in the MD/MS/MS studies (solid squares) is plotted on the same graph as data from one animal in the conventional studies (open circles).

FILTER PAPER SAMPLING FOR THE QUANTITATION OF TEN POLYOLS IN URINE AND WHOLE BLOOD BY NEGATIVE CHEMICAL IONIZATION GC/MS.

John Roboz, Qi-tao Yu, Long-Hua Ma and James F. Holland, The T. J. Martell Laboratory of the Derald Ruttenberg Cancer Center, Mount Sinai School of Medicine, New York, NY 10029.

BACKGROUND AND OBJECTIVE. Although polyols are present in almost every living organism, little is known about their metabolism. Recent studies revealed that while normal polyol concentrations are reasonably constant, significant changes in the profiles do occur in several disease states, e.g., in hepatic (1) and renal (2) dysfunctions. Our objective was to develop a new method for the simultaneous quantification of ten polyols in a drop of urine or whole blood placed as a spot on filter paper, based on our previous GC/MS method for D- and L-arabinitol ratio measurement for the diagnosis and monitoring of disseminated candidiasis (3).

METHODOLOGY. Sample Taking: Place 10 uL aliquots of urine or whole blood on filter paper (the type used for phenylketonuria screening), dry at room temperature, and store in refrigerator or mail at room temperature. Sample Preparation: Add to the spot 10 uL int. std. ($^2H_7$-labelled D-arabinitol, 9.7 ng/uL), cut out spot, extract with 1 mL methanol, evaporate to dryness with nitrogen in a waterbath (40 °C), derivatize with 100 uL trifluoroacetic anhydride + 200 uL methylene chloride, at 38 °C for 45 min, cool to room temperature, evaporate to about 5 uL with nitrogen, reconstruct with 50 uL toluene, and inject 1 uL or 0.2 uL aliquots of blood or urine, respectively. GC: Cyclodextrin fused silica capillary column (β-Dex 120, 30 m long, 0.28 mm i.d., Supelco, Supelco Park, PA), 106 °C, isothermal. MS: (Finnigan Co., Single quadrupole, Model 3300): negative chemical ionization (isobutane), selected ion monitoring mode for the M^- ions of tetritols, at m/z 506, the $(M-CF_3COOH)^-$ ions of the pentitols, hexitols, and the int. std. at m/z 518, 644 and 525, respectively. Quantification: determine peak areas (Vector One software, Teknivent Co., Maryland Heights, MO), use peak/int.std. ratios, determine conc. from conventional or calibration curves or standard addition curves obtained for each polyol separately, and express results for both urine and blood in units of mg/L or mg/g creatinine.

RESULTS AND DISCUSSION. Profiles from normal urine (Fig. 1) and normal whole blood (Fig. 2) reveal complete chromatographic resolution of all polyols, including the D- and L- optical isomers of threitol and arabinitol in less than 10 min. Recoveries (mean values, n=6) from filter papers were within 85-103 % of those using direct analysis for all polyols. Reproducibilities, expressed as std. dev/mean (n=6) were in the 4.6-14.8% and 2.5-19.3% range for urine and blood respectively despite the large differences in individual polyol concentrations, ranging from 0.05 mg/L L-threonine to 3.6 mg/L erythritol in whole blood. Quantification was accomplished using both conventional calibration and standard addition curves, individually obtained for each polyol. Extrapolating the standard addition lines yields endogenous concentrations, as illustrated in Fig. 3 for four components. Endogenous urinary polyol concentrations were comparable to those obtained by GC, although GC did not resolve the enantiomers (on Fig. 4, for each polyol the first column is data by GC-MS, the second column is data from Ref 1). Endogenous mannitol was found highly variable in both urine and whole blood, in agreement with previous observation for serum (2). The transportation stability (round trip to Michigan by air) of the filter paper spots was established by expressing polyol conc. as percentages of those obtained for aliquots not transported. Averages (n=6) were 99.4% (range 94.5-111.8%) for urine and 103.7% (range:94.4-116.8%) for whole blood.

CONCLUSIONS. A GC-MS method was developed for the quantification of 10 polyols in both urine and whole blood. Only 10 uL sample is needed as a spot on a filter paper which can be transported safely by air. This method will help to assess the diagnostic importance of polyols by permitting prospective studies inter-institutionally.

AUTOMATED EXTRACTION AND ANALYSIS OF METABOLITES FROM DRIED SPOTS ON FILTER PAPER USING DYNAMIC LSIMS

Donald H. Chace, Steven L. Hillman, Charles R. Roe and David S. Millington, Department of Pediatrics, Division of Genetics & Metabolism, Duke University Medical Center, Durham, NC 27710

The qualitative and quantitative analysis (by stable isotope-dilution) of amino acids and acylcarnitines in small volumes of blood or plasma has been successfully accomplished using LSIMS/MS[1]. In addition to its sensitivity and specificity, the method is very fast, requiring less than 2 min of instrument time per analysis. To take advantage of these features, a fully automated method for sample preparation and analysis is under development. Blood or plasma samples are applied dropwise to a special type of filter paper made from cotton fiber (Schleicher & Schuell # 903) and allowed to dry out. Metabolites are stable on this medium for months when stored at 4 °C. Discs are punched out of these spots into glass vials using a standard 3/16" paper puncher. Two discs of dried blood (equivalent to 12.6 μL) or 4 discs of plasma (14 μL) are used. Up to 60 vials are placed in a plastic rack (Gilson code 29) placed in a programmed Gilson model 222 sample changer. The following sequence, shown schematically in Fig 1, is carried out:

(1) Methanol (400 μL) containing the internal standards is pipetted into the vials and the samples left to extract for 30 min.

(2) The extracts are transferred to clean vials in a parallel aluminum rack, which is placed in a custom-built warm air evaporator (Grey Line Eng. model 2700). Samples are evaporated to dryness under a gentle stream of dry N_2 from a generator while incubating at 50 °C (20 min).

(3) The rack is returned to the sample changer for addition of the derivatizing reagent (50 μL methanolic-HCl in this case), then loosely covered by a teflon block and incubated at 50 °C (15 min). The cover is then removed and the reagent evaporated under N_2.

(4) After placing the rack back on the sample changer, the final matrix for LSIMS (50 μL) is added to each tube.

(5) The open tube rack is now placed in the autoinjector (Gilson model 231) for the programmed injection of each sample into the dynamic LSIMS/MS system via a Rheodyne injector.

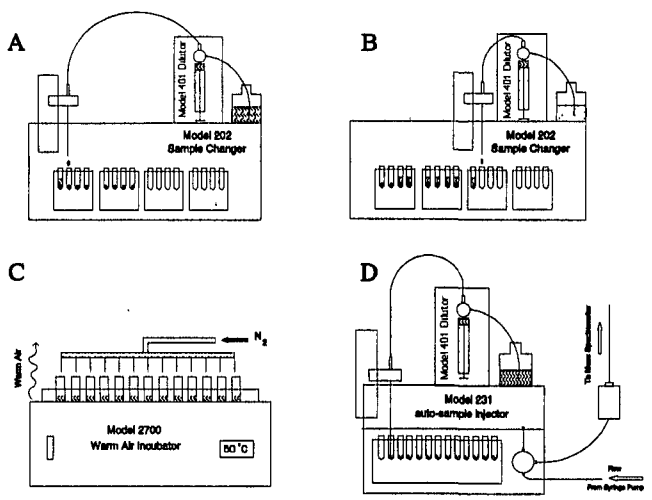

Figure 1: **A:** Addition of methanol containing internal standards to tubes containing dried blood spots using the sample changer. **B:** Transfer of solvent extracts to duplicate tubes. **C:** Incubation of blood spot extracts using a custom-made warm-air incubator. **D:** Autoinjection of prepared samples into the mass spectrometer via the dynamic LSIMS probe.

Tandem MS was performed on a VG QUATTRO triple quadrupole, preprogrammed to acquire continuum scans (3 s/scan) using the appropriate scan function and mass range; i.e. for acylcarnitines, precursors of m/z 99 (m/z 200-500) and for amino acids, neutral loss of 102 daltons (m/z 125-300). From the TIC profile, up to 20 scans over the peak maximum are combined and the resulting spectrum processed automatically by 5-pt smoothing, baseline subtraction, centroid calculation and conversion to line spectrum as shown in Fig 1.

These results are the first applications of automated preparation and analysis of acylcarnitines from neonatal blood spots using robotic equipment and dynamic LSIMS/MS. They demonstrate the concept of rapid screening for metabolic disease using a tandem mass spectrometer. At least 15 diseases can be detected in an analysis. The versatility of the technique facilitates the analysis of other metabolite groups, including amino acids[1]. The goal of this research is to analyze approximately 400 samples/day representing the live birth rate in North Carolina. This principle is also applicable to other components in blood, including drugs and their metabolites.

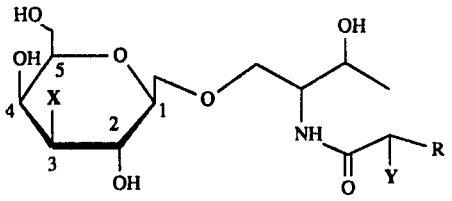
FRAGMENTATIONS OF SODIATED CEREBROSIDES, α-HYDROXY CEREBROSIDES, AND CEREBROSIDE SULFATES

Qinghong Ann and Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322.

We recently presented the collision-induced decomposition (CID) spectra of FAB-desorbed $(M + Li)^+$ ions of some types of sphingolipids (1-2). CID of the ions provide immediate information on the lengths of the sphingoid base and fatty acyl chains, and the locations of substituents on the fatty acyl chain. Here, we demonstrate some results from applying CID of $(M + Na)^+$ ions to structural differentiation of cerebrosides, α-hydroxy cerebrosides, and cerebroside sulfates.

The structures of cerebrosides, α-hydroxy cerebrosides, and cerebroside sulfates are shown in Figure 1. The differences among these compounds are the substituent groups on the C3 of the carbohydrate



X = OH	Y = H	R = fatty acyl chain	cerebrosides
X = OH	Y = OH	R = fatty acyl chain	α-hydroxy cerebrosides
X = OSO_3H	Y = H	R = fatty acyl chain	cerebroside sulfates

Figure 1. Structures of cerebrosides, α-hydroxy cerebrosides, and cerebroside sulfates.

residue and on the α-C of the fatty acyl chain.

Figure 2 shows CID spectra of $(M + Na)^+$ ions of cerebrosides (Figure 2a), α-hydroxy cerebrosides (Figure 2b), and cerebroside sulfates (Figure 2c). All the spectra show distinct charge-remote fragmentations that arise from the fatty acyl chain. The location of the double bond on the fatty acyl chain is indicated by the 54 u "gap" between peaks labelled **L** and **M**. Other charge-induced product ions, such as **T** and **K** ions, provide immediate information about the masses of the fatty acyl, sphingoid base, and carbohydrate residues. In addition, a highly abundant unique peak labelled **O** appears for α-hydroxy cerebrosides (Figure 2b). The **O** ion arises from cleavage of the amide bond and is specific for α-hydroxy cerebrosides. The formation of this special ion provides for easy differentiation of α-hydroxy cerebrosides from other cerebrosides.

CID spectra of cerebroside sulfates (Figure 2c), on the other hand, show two diagnostic peaks: One arises from loss of NaO_3SOH, and another is the $NaOSO_3Na^+$ ion. These two peaks are characteristic for cerebroside sulfates and clearly indicate the presence of the sulfate group. A previous problem with studying cerebroside sulfates is that the sulfate group is easily hydrolyzed in the 3-nitrobenzyl alcohol (3-NBA) matrix (3). We overcome this problem by using 3-NBA saturated with NaOH.

The structural determination of individual components of complex mixtures was also performed by using this approach. FAB spectra provide information about the molecular weights of each component, whereas the diagnostic fragmentation pattern that appears in the CID spectra of each component can be used to elucidate directly their structures without prior derivatization or GC separation.

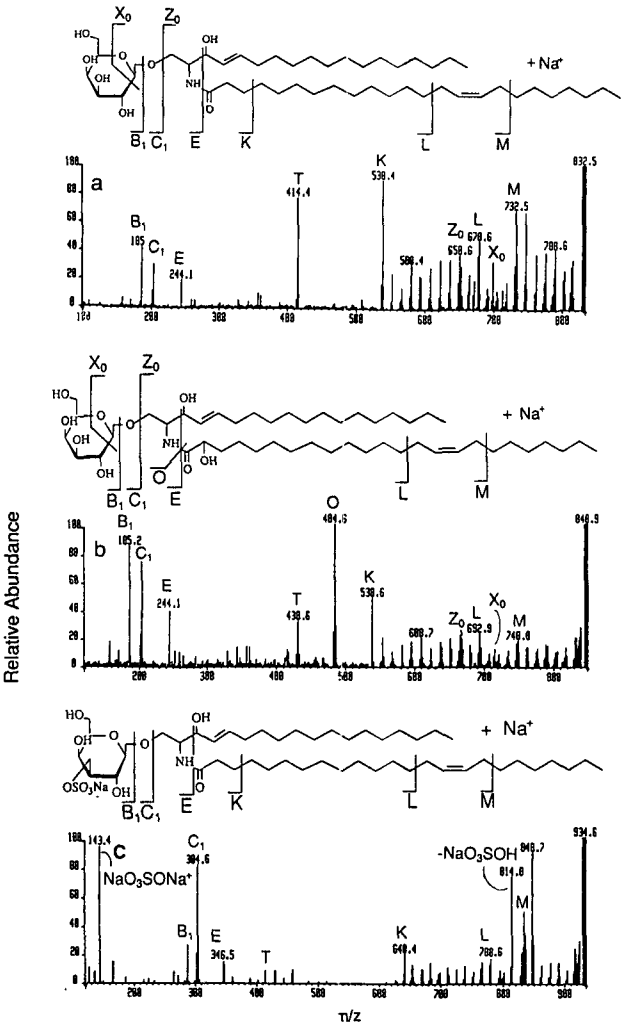


Figure 2. CID spectra of (M + Na)$^+$ ions of (a) *N*-nervonoyl cerebroside, (b) α-hydroxy-*N*-nervonoyl cerebroside, (c) *N*-nervonoyl cerebroside sulfate.

The Conversion of the Essential Fatty Acid, 18:3n3 to 22:6n3 in Neonatal Rats and Felines.

Robert J. Pawlosky and Norman Salem Jr. Laboratory of Membrane Biochemistry and Biophysics, DICBR, NIAAA, Bethesda, MD. 20892

The essential fatty acid, linolenic (18:3n3) acid, is converted to docosahexaenoic acid (22:6n3) via a series of elongation and desaturation steps. The smooth endoplasmic reticulum within the liver and brain are sites of these transformations. 22:6n3 is the most abundant polyunsaturated fatty acid in nerve cells and the reason for this enrichment is not understood. This study focused on the uptake and conversion of 18:3n3 to 22:6n3 in the liver and brain of neonatal animals during the brain growth period. Using the deuterated fatty acid, $^{2}H_{5}$-17,17,18,18,18-18:3n3, we investigated the *in vivo* biosynthesis of 22:6n3 from 18:3n3 in the brain and liver using negative ion GC-MS.

The labeled fatty acid ethyl esters were delivered to the animals by gavage and the products were detected in the various compartments after derivatization to the pentafluorobenzyl esters (PFB) using gas chromatography-negative ion mass spectrometry. The lipids were extracted using the Bligh and Dyer method. The extracts were derivatized to their PFB esters and analyzed on 30 meter FFAP capillary columns. The fate of 18:3n3 was followed in the various compartments. Accretion of the 18, 20, 22, and 24 carbon n-3 fatty acids into the brain and liver of newborn animals were compared.

Labeled 18:3n3 was found in the perfused brain 18 hours after one day old rats had been given an oral dose of the ethyl ester. Sub-cellular fractionation revealed that the $^{2}H_{5}$-18:3n3 was in the P1 pellet (3000X G spin, whole cells and capillaries) and in the P2 fraction (100,000X G spin, microsome membranes). $^{2}H_{5}$-18:3n3 was 3 times more enriched in the P2 fraction in the P2 fraction compared to the P1.

$^{2}H_{5}$-18:3n3 was 5 to 7 times more enriched in the cerebellum of neonatal rats as compared to the frontal cortex during the first eight days of life.

Conversion of $^{2}H_{5}$-18:3n3 to $^{2}H_{5}$-22:5n3, $^{2}H_{5}$-22:6n3 and the 24 carbon $^{2}H_{5}$-24:5n3 and $^{2}H_{5}$-24:6n3 fatty acids occurred in both the liver and brain of the neonatal rat. The importance of the labeled 24 carbon fatty acids is in demonstrating their involvement as intermediates in 22:6n3 production.

Accretion of $^{2}H_{5}$-22:6n3 and accretion and loss of $^{2}H_{5}$-22:5n3 in the brain of young rats after a single feeding of $^{2}H_{5}$-18:3n3 suggests that 22:5n3 is converted to 22:6n3 in the brain.

All labeled intermediates of the n-3 pathway were found in the rat brain at various times.

In the neonatal feline we detected production of labeled n-3 fatty acids up to $^{2}H_{5}$-22:5n3 in the liver and blood during the first 18 days of life. The liver did not produce 22:6n3. However brain accretion of $^{2}H_{5}$-22:6n3 was readily observed. Labeled 24 carbon n-3 fatty acids was also observed.

These studies show that 22:6n3 is made in the brain and liver of neonatal rats and that the feline is capable of making 22:6n3 only in the brain. The 24 carbon n-3 fatty acids where found in the liver and brain where 22:6n3 was produced.

Structural Determination of Porcine Cerebroside Sulfate Activator (CS-Act) by Mass Spectrometry and Edman Chemistry

INTRODUCTION

Cerebroside sulfate activator(CS-Activator) is a small (9-10 kD) heat-stable glycoprotein which binds the lipid cerebroside sulfate making it available for de-sulfation by arylsulfatase A. CS-Activator is also known as saposin B and sphingolipid activator protein 1 (SAP-1). This protein, which also binds other specific sphingolipids, is part of a family of activators which are derived from a precursor called prosaposin. All of these activators have similar structures, in particular 6 cysteine residues which are homologously aligned in each molecule. The cysteine residues are believed to be in the oxidized form but the disulfide linkage patterns are unknown. The pig kidney CS-Activator was previously sequenced by us to the 66th residue from the N-terminus. The C-terminal sequence, and thus the exact length, and the precise carbohydrate content was unknown. By sequence analysis and mass analysis of the native protein and isolated CNBr fragments of CS-Activator, we have determined the C-terminal sequence, the disulfide pair arrangement, and the length of the molecule including the number of carbohydrate residues.

RESULTS AND DISCUSSION

A purified preparation of CS-Act isolated from pig kidney(1) was subjected to FAB and ESI mass analysis. The FAB spectrum depicted in the Figure shows several signals, the mass measurements of 4 of which are given in Table I. The results are consistent with the molecule having 79 residues with either 5, 4, 2, or 1 sugar residues attached. The justification for assigning N-acetylglucosamine, mannose and fucose as the sugar residues is based on multiple criteria. Firstly, the differences in measured molecular weights between the 4 most intense signals from n2tive CS-Act (161.6, 528.0 and 672.7 D, for the difference between the 5 and the 4, 2 and 1 carbohydrate unit-containing molecules, respectively) was recognised as most likely being due to a one hexose (residue mass of 162.1 D), one N-acetylhexosamine + two hexoses (combined residue mass 527.5 D) and one N-acetylhexosamine + two hexoses + one deoxyhexose (combined residue mass 673.6 D), respectively (B.N. Green, unpublished observations). Secondly, the presence of glucosamine, mannose and fucose had been previously observed in the chemical analysis of CS-Act (Fluharty). The glycosyl component is presumed to be linked to Asn 21 in the sequence GlcNAc(Fuc)-GlcNAc-Mann-Mann, which is in agreement with the typical core structure of N-linked carbohydrate chains. Peak intensity showed that the 79 res + 5 CHO isomer to be maximally present. The mass values obtained by FAB and 3 different ESI measurements gave nearly identical results as is shown in Table I. Reduction of CS-Act by dithiothreitol increased the mass values of all 4 components by approximately 6 mass units. This is consistent with the protein having 3 disulfide bonds (Table I).

The native CS-Act protein was reacted with CNBr in 70% formic acid and were separated by RP-HPLC on a C-4 column. Two of the largest peaks, Fragment 2 and Fragment 4, were rechromatographed on a C-18 column and analyzed by ESI and Edman degradation. Sequence analysis showed Fragment 2 was a composed of the N-term and C-term ends connected by by 2 disulfide bridges, Cys4 linked to Cys77 and Cys7 linked to Cys71. Fragment 4 was a composed of two interior peptides connected by Cys36 linked to Cys47. Mass analysis confirmed the identity of the peptides and their disulfide linkages (Table II). Analysis of the remainder of the 8 chromatographic peaks by both FAB and ESI showed all of them to be isomers of either Fragments 2 or 4 by having either different amounts of sugar residues or C-terminal lactones. Sequence analysis of the C-terminal peptide completed the full sequence of pig kidney CS-Act , which is:

GDVCQDCIQMVTDLQNAVRTNSTFVEALVNHAKE ECDRLGPGMADMCKNYISQYSEIAI QMMMHMQPKDICGLVGFCEE.

The current disulfide pairing arrangement is different from models previously proposed (2) but is consistent with that recently reported for the lung surfactant protein B, a protein with certain structural similarities to CS-Act. Based on the above data, the secondary structure predictions for CS-Act, and its properties showing high resistance to heat and protease treatment(3), we propose a structural model which contains a bundle of 4 amphipathic alpha-helices forming a hydrophobic core, which could be a key site for its lipid binding properties.

Molecular Ion Imaging of Human Hair Cross Sections by TOF-SIMS

D. F. Reich, P. M. Lindley and R. W. Odom
CHARLES EVANS & ASSOCIATES
Redwood City, CA 94063

Time-of-Flight Secondary Ion Mass Spectrometry (TOF-SIMS) combines inherently high transmission and parallel detection of secondary ions, permitting surface analysis at extremely low total primary beam doses ($<10^{13}$ primary ions/cm^2). Organic molecular ions and characteristic fragment ions can be produced from a sample surface in this static SIMS regime of primary ion dose. The recent advent of imaging TOF-SIMS instrumentation allows SIMS imaging to be carried out at micrometer 1(μm) lateral resolutions. Lateral information is obtained either by synchronizing the secondary ion detector signal to the raster generator of a pulsed, focused primary ion probe[1], or via broad beam illumination with a pulsed primary beam using stigmatic ion optics and a position sensitive secondary ion detector[2]. The instrument used for these studies has both capabilities.

We have had some success in preparing hair cross-sections for TOF-SIMS imaging using microtomed thin sections of epoxy-embedded hair. However, this process is time-consuming and contamination by the embedding medium cannot be eliminated. Accordingly, we have sought a more direct, contamination free method for cross-sectioning of hair. In the present study, we have evaluated a technique in which sample hairs are introduced into the core of a packing yard of nylon or cellulose acetate fibers. This fiber bundle is compressed by passing it through a suitably small aperture (0-5 mm) in a rigid steel plate. A cross-section of the sample hairs are produced with a single sweep of a virgin, rigid razor blade.[3]

In this study we used three compounds, prepared as 10^{-4} molar solutions including: (1) Didodecyl Dimethyl Ammonium Bromide - a typical quaternary ammonium salts (QAS) used as a hair conditioner; (2) Sodium Dodecyl Sulphate (SDS) with a similar action to many surfactants used in commercial shampoos; and (3) Polyethylene Glycor 400 - used to evaluate imaging of low ion yield compounds in TOF-SIMS in this type of application. Sample hairs from a single donor were cleaned three times for fifteen minutes in deionized water, followed by a twenty-four hour soak in deionized water. The hairs were then given one of the following treatments (1) 2.5 hour soak in SDS-based solution (2) 2.5 hour soak in PEG-based solution or (3) 15 minutes, 2.5 hours or 25 hours in QAS-based solution.

Ion images were taken using a 25 keV gallium liquid metal ion probe, focused to 0.5 μm spot size with a secondary ion accelerating potential of 3 keV. Results from one of the 2.5 hour QAS-treated hairs are shown in Figures 1-3. Figure 3 shows an ion image of silicone ions. Silicone peaks are produced from the silicone constituents in the shampoo used by the donor prior to aqueous cleansing. The QAS compound was observed to penetrate to varying depths into the hair, apparently displacing the silicones. The depth of penetration of the QAS compound did not vary linearly with treatment time. An ion image of QAS specific ions is shown in Figure 2, and is the scan of three separate ion images (see text in figure). The total primary beam dose for these images was 3.7×10^{12}/cm^2. SDS-treated hair ion images indicate that sodium from the SDS penetrates only as far as the cuticle (outer) region of the hair, while the $(M\text{-}Na)^-$ ion is observed in the negative SIMS images to penetrate deeper into the dense α-keratin interior of the hair similar to the QAS compound. No ion images of PEG-specific molecules were obtained from PEG treated hair cross-sections, in either positive or negative SIMS.

We conclude from these preliminary studies that: (1) The current cross-sectioning method often equals results obtained by thin section microtoming and (2) It is possible to obtain molecular ion images at μm lateral resolution from compounds having relatively high secondary ion yields such as QAS and SDS in organic substrates.

Elucidation of The structure of a Platelet Activating Factor Analogue

Keith L. Clay and Chris A. Johnson
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street
Denver, CO 80206

Assay of Platelet Activating Factor (PAF, 1-O-hexadecyl-2-O-acetyl-sn-glycero-3-phosphocholine) by GC/MS is commonly carried out by measurement of the derivatized diglyceride derived from PAF by hydrolysis with Phospholipase C or by cleavage of the phosphate ester by hydrofluoric acid. When the acetyl-D_3 stable isotopically labelled variant of PAF is used as internal standard in an isotope dilution assay and the derivative prepared is the pentafluorobenzoyl ester, negative ion chemical ionization produces ion currents from the molecular anions at m/z 552 and m/z 555 for hexadecyl-PAF and its D_3 analog, respectively. When this procedure is applied to human blood, a very large peak in the m/z 552 channel elutes just after the peak corresponding to PAF. As illustrated in Figure 1, PAF elutes in this assay at scan number 208, while the very large peak in the ion current chromatogram for m/z 552 elutes at scan number 218. In human whole blood, the PAF concentration is in the low picogram per ml range and the large contaminant peak is present at 15-50 ng/ml. Its elution so close to PAF makes it difficult to measure PAF.

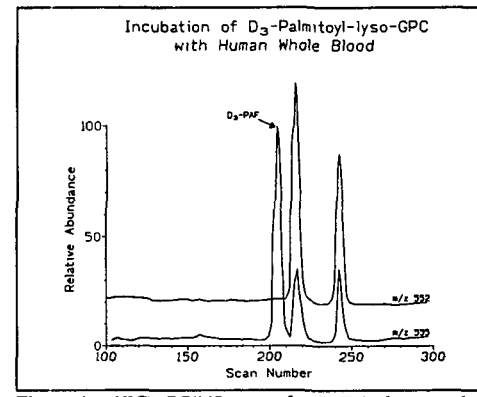

Figure 1: *NICI GC/MS assay for PAF in human whole blood. 50 ng D_3-PAF added just prior to isolation. Whole blood incubated with one microgram Palmitoyl-D_3-lyso-PC.*

We have applied chromatographic, mass spectrometric and biochemical methods to the problem of the elucidation of the structure of this contaminating material and have identified it as a structural analogue of PAF. The data obtained are all consistent with the structure of this material being 1-O-hexadecanoyl-2-O-formyl-sn-glycero-3-phosphocholine (Palmitoyl-Formyl-PhosphoCholine, PFPC). Figure 1 illustrates the biosynthesis of a compound with a molecular anion at m/z 555 by human whole blood which was incubated with one microgram of D_3-palmitoyl-lyso-PC. The peak in the ion current chromatogram for m/z 555 which elutes just after D_3-PAF is not present in normal blood extracts, but arises only from the added D_3-palmitoyl-lyso-PC. This result demonstrates the presence of palmitic acid in the contaminating material, but it also demonstrates that this material is very similar to PAF since it has the same behavior in the isolation and preparation scheme, which included a reversed phase chromatographic separation, followed by a normal phase separation, degradation to diglyceride by Phospholipase C, derivatization to the pentafluorobenzoyl ester and then gas chromatography on a high resolution capillary column.

Since whole blood contains rather high concentrations of many lyso-PC species, the corresponding formyl esters of each of those lyso-PC species were searched for by limited mass scanning procedures. Mass chromatograms for the selected mass of myristoyl-, palmitoyl-, oleoyl-, stearoyl-, and arachidoyl-formyl-PC indicated the presence of each of these formyl esters at the GC retention times expected for those molecules. It appears, therefore, that formation of formyl esters is a quite general reaction in blood.

To gain evidence for the presence of a formyl ester, a whole blood extract was derivatized to the t-butyl-dimethylsilyl derivative and ions measured in standard PFPC diglyceride-TBDMS were monitored by selected ion monitoring. Ions indicative of the presence of PFPC in blood were found at the appropriate retention time, but the signal level was insufficient to unequivocally demonstrate identity. Ions at m/z 103 (a rearrangement of the derivatizing group to the formyl ester), 313 (palmitic acid), and 415 (M-15) were detected, but the lack of sufficient signal strength prevented unequivocal assignment as arising from PFPC.

When the NICIGC/MS assay procedure was applied to whole blood and the contaminant peak subjected to argon collision induced dissociation in the RF-only quadrupole of a Finnigan TSQ70, the products of the molecular anion, m/z 552, gave evidence for the presence of palmitic acid in the molecule, as indicated by the presence of m/z 255 in the product ion spectrum (Figure 2). Since the molecule behaved like a PC in the chromatographic separations and was a substrate for phospholipase C, the assignment of partial structure as a palmitoyl-PC was made. After subtracting the pentafluorobenzoyl group from the molecular anion mass (m/z 552), only 28 amu remained to be assigned. The most likely composition of that mass increment was deemed to be a formate ester. PFPC was then synthesized from both ^{14}C-palmitoyl-lyso-PC and D_3-palmitoyl-lyso-PC and added to whole blood which was then subjected to the PAF isolation and analysis conditions. Radiolabeled PFPC co-chromatographed in a large number of TLC and HPLC procedures with the contaminating material at m/z 552 in the GC/MS assay. The deuterium atoms from D_3-PFPC were retained in a molecule which co-eluted with the contaminating peak at m/z 552.

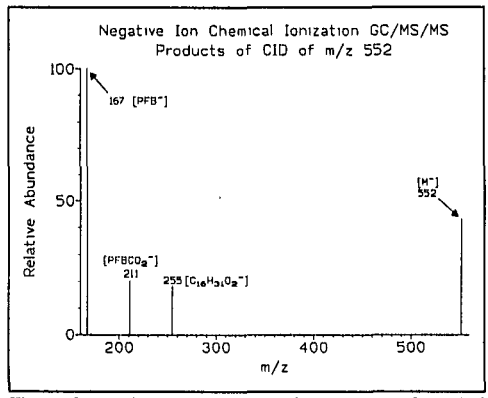

Figure 2: *Product ion spectrum of argon CID of m/z 552 which eluted just after PAF in NICI GC/MS.*

With the radiolabeled PFPC, accurate HPLC retention times were obtained for normal phase and reversed phase HPLC and a whole blood extract was fractionated first on normal phase and then on reversed phase HPLC. The reversed phase HPLC fraction which corresponded to the retention time of radiolabelled PFPC was subjected to FABMS and FABMS/MS and gave an ion at m/z 255 (Figure 3) which indicated the presence of palmitic acid in the molecule. The ion at m/z 283 indicates the presence of stearoyl-lyso-PC in the same reversed phase fraction. In the single sector FABMS analysis of this HPLC fraction, the only phospholipids detectable were lyso phospholipids and the ion at m/z 508 was not significantly above background. When subjected to MS/MS analysis, however, the reduction in noise was sufficient to allow an informative mass spectrum to be obtained.

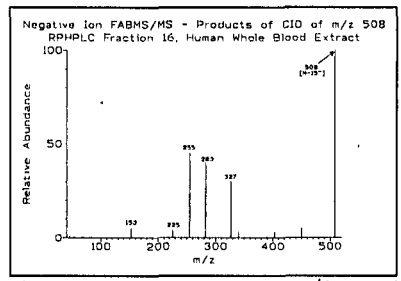

Figure 3: *FAB product ion spectrum of reversed phase fraction at retention time of radiolabelled PFPC.*

The demonstration that an anlogue of PAF is in normal blood at relatively high concentrations is significant in attempting to understand roles PAF may play in biology. This material makes it very difficult to measure PAF in blood and necessitates extensive clean-up procedures to eliminate these interferences prior to GC/MS analysis. The possible interaction of this material with antibody-based assay procedures as well as with bioloigcal assays requires assessment. Changes in the concentration of this material in blood may materially alter PAF activities, since the close structural similarity make it possible these formyl esters will interact with the enzymes which are responsible for degradation of PAF. The close structural similarity also implies that these formyl ester analogues of PAF may act on the PAF receptor, either as agonists, or as antagonists of PAF.

Cardiac Capacity to Metabolize Aldehydes; Products of Free Radical Induced Lipid Peroxidation.

Jane Montgomery, Manon Jetté, Sylvain Huot and Christine Des Rosiers
Department of Nutrition, Université de Montréal, Montréal, Québec, Canada.

Increased production of free radicals has been associated with the reperfusion injury observed following myocardial infarct (1,2). Paradoxically, introduction of oxygen to a previously ischemic tissue results in a burst of free radicals which can produce deleterious effects such as lipid peroxidation. Polyunsaturated fatty acids in lipid membranes are susceptible to peroxidative damage resulting in disruption of the membranes themselves and in the formation of numerous products from the peroxidized fatty acids (3).

Aldehydes represent a major class of degradation products (3). Among the quantitatively important aldehydes are malondialdehyde and hexanal. 4-Hydroxynonenal, although a minor product, is cytotoxic and can react with glutathione in the perfused heart (4). However, aside from conjugation to glutathione, very little is known on the heart's capacity to metabolize reactive aldehydic products of lipid peroxidation. We have recently demonstrated in vitro that pig heart pyruvate dehydrogenase (PDH) catalyses the condensation of various saturated aldehydes with pyruvate to form the corresponding acyloins (5). While this reaction is well known, it has not been considered as a mechanism to detoxify aldehydes in vivo (6).

We chose to examine the metabolism of hexanal, a known product of lipid peroxidation, in the perfused rat heart to determine i) the influence of the two substrates (hexanal and pyruvate) on the acyloin reaction and ii) the effect of ischemia-reperfusion on the production of acyloins.

Methods

Rat hearts were perfused in a non-recirculating mode under constant pressure (60-80 mm Hg) with a Krebs-Ringer buffer (11 mM glucose, 1.3 mM Ca^{++}) gassed with 5% CO_2-95% O_2. Hexanal was infused directly into the perfusion line. Global ischemia was induced by clamping the aorta. Samples of influent and effluent perfusate were collected on ice and were immediately treated with $NaBD_4$. This treatment stabilizes the samples by reducing keto groups to ^{2}H-hydroxy groups.

In the first series of perfusions, the concentration of hexanal was varied between 10-100 μM, while the concentration of pyruvate was constant (2 mM). In the second set of perfusions, both the effect of pyruvate concentration and of ischemia-reperfusion on acyloin production were investigated. While maintaining a constant concentration of hexanal (50 μM), pyruvate was added at either 0.2 or 2 mM prior to ischemia. Following a 15 min period of global ischemia, perfusion was re-established and its effect on acyloin formation was investigated.

Isotope dilution assays were developed using two internal standards of [1,2-$^{13}C_2$-2-^{2}H]-2,3-octanediol or [$^2H_{13}$]-hexanol. 2,3-octanediol was extracted and analyzed as the *bis*-TMS derivative as previously described (5). Hexanol was analyzed as described by Des Rosiers et al (Abs. #609).

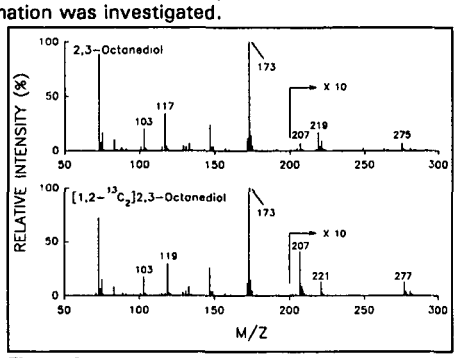

Figure 1

Results

PDH mediated condensation products of incubations with hexanal and either pyruvate or [U-^{13}C]pyruvate reduced with $NaBH_4$, produced mass spectra consistent with the products being 2,3-octanediols. Figure 1 presents the electron impact mass spectra of the TMS derivatives. Major fragment ions are observed for the cleavage of the C2-C3 bond. The ion at m/z 117 increases by 2 daltons indicating that these carbons originated from pyruvate.

Hearts perfused with 2 mM pyruvate and 10-100 μM hexanal released 3 metabolites, namely 2-keto-3-hydroxyoctane (KHO), 2,3-octanediol ((23OD) from endogenous reduction of KHO) and hexanol. Release of KHO and 23OD was proportional to the hexanal concentration (Figure 2), with KHO demonstrating the largest increase. Hexanol was also released in a concentration dependent manner up to 50 μM hexanal after which it attained a plateau.

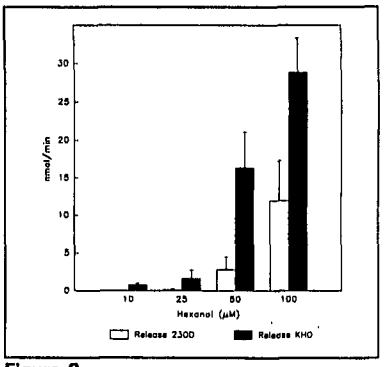

Figure 2

Varying pyruvate concentrations (0.2 mM or 2 mM) resulted in a concentration dependent production of 23OD and KHO (pre-I) as seen in Figure 3. Ischemia also affected the production of metabolites. Both 23OD and KHO increased post-ischemia with KHO demonstrating a significant increase. The production of hexanol was constant regardless of the pyruvate concentration or the influence of ischemia. In all perfusions with hexanal, hexanol production was quantitatively more important than acyloin production. However, hexanol release was independent of any of the variables that were tested, except as might be expected when varying the concentration of hexanal. In contrast, acyloin production could be enhanced by either increasing pyruvate or by inducing ischemia-reperfusion.

Other aldehydes were infused to test the heart's capacity to produce acyloins. Acyloins were observed during infusions of saturated aldehydes (butanal, hexanal, nonanal) but not with unsaturated aldehydes (hexenal) or malondialdehyde in agreement with results obtained in vitro (5).

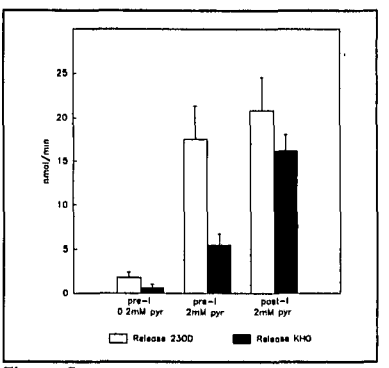

Figure 3

We conclude that PDH can condense saturated aldehydes with pyruvate to form acyloins, both in vitro and in the perfused heart. It is a high capacity reaction equally dependent on the concentrations of aldehyde and pyruvate. The acyloins produced can be enzymatically reduced to 2,3-alkanediols in perfused hearts. PDH can be considered to be a means of detoxifying reactive aldehydes by converting them to stable, diffusible acyloins.

We would like to acknowledge the support of the Medical Research Council of Canada.

Analyte-Analyte Interactions Influencing the PDMS-Yield

W. Tuszynski, F. Kieseling, E.R. Hilf

Fachbereich Physik, Carl von Ossietzky-Universität
PO Box 2503, W-2900 Oldenburg, Germany

Introduction:
The isolation of analyte molecules in a matrix or on a substrate makes PDMS-spectra more reproducible and often enhances the detection sensitivity, especially if the formation of stabile analyte ions is supported by chemical or other process-induced interactions between analyte and matrix/substrate. These interactions have a strong influence on the PDMS-yield. The PDMS-yield is also strongly dependent on analyte-analyte interactions if the analyte concentration is high. For example, high local concentrations which are produced by self-aggregation or cluster formation have a considerable effect on the PDMS-yield. Precise informations about the amount and the formation of molecules on the sample are required for studying these correlations. We applied optical spectroscopy methods for characterizing our samples. The absorption of light from the near IR to UV (via diffuse reflectance) and the fluorescence (steady state and time-resolved) were determined. Many informations about sample composition and structure can be obtained by evaluating the optical spectra. The determination of low analyte concentrations is one of the very useful advantages of this application. For example, a coverage of $6x10^{12}$ adsorbates per cm^2 can be determined precisely enough by the diffuse reflectance method.

Experimental:
The count rates of samples with different dye molecules applied to nitrocellulose (NC) have been determined. The dyes were malachite green (MG), rhodamine 6G (R6G), and chlorophyll-a (Chl-a). The amount of analytes adsorbed on the substrate has been varied in the range from $6x10^{12}$ to $8x10^{15}$ per cm^2 as determined by optical measurements. PDMS-spectra were recorded by our spectrometer OLDA 1 which we built in cooperation with K. Wien, TH Darmstadt. This linear TOF-instrument is equipped with an 80 cm flight tube, two double stage multichannel plates for start or stop signals, and a time digital converter CTM/M2 connected with a DMI-card, both from Y. LeBeyec, IPN Orsay. Mass resolution is about 700. The operating voltage was usually + 10 kV, the run time 30 min. The samples were prepared by applying 5 μl solution to a 1 cm^2 NC film which was made by electrospraying 40 μl of a 2 mg/ml acetone solution on an aluminized polyester foil.

Results:
The count rate of the molecular ion peak increases linearly with the amount of dye molecules at a coverage of less than $8x10^{14}$ analytes per cm^2. This result has been obtained with Chl-a as well as with MG and R6G which are known to be preionized. The count rate of the Chl-a fragment ion peaks shows also a linear dependence at this range of coverage. The count rates turn into saturation between $8x10^{14}$ and $8x10^{15}$ analytes per cm^2. The relative fluorescence yield of R6G samples increases linearly with the amount of R6G on NC at a coverage of less than $5x10^{14}$ per cm^2. The fluorescence first saturates and then decreases with higher values.

Discussion:
The linear dependence of the count rates on the amount of analytes observed at low coverage is attributed to the linearly increasing probability that isolated adsorbates are "hit" by a passing fission fragment. The nonlinear behaviour observed at larger coverage is obviously due to increasing interactions between the analytes. The resulting effect is a competition between adjacent analytes leading to a considerable modification of the count rates and probably of the relative ion yields. The linearly increasing R6G fluorescence at low coverage demonstrates clearly the existence of isolated R6G molecules on the NC. The fluorescence saturates and decreases at higher coverage due to the growing probability of energy transfer processes at smaller distances between neighbouring dye molecules. These processes are produced by dipole-dipole interaction and finally give rise to decreasing fluorescence quantum yields. In consideration of the fluorescence data, the mean distance between adjacent R6G molecules is estimated to be about 6 nm at 8×10^{14} per cm^2, i.e. it slowly approaches the molecular size. Quantitative evaluations of the experimental PDMS data are under way, which start from randomly distributed molecules on the surface, to determine the intermolecular force and the geometry of the desorption area.

Detection of Fullerenes by PDMS in the fmol-Range

W. Tuszynski[1], F. Hillmann[1], J.O. Metzger[2], R. Woisch[2]

[1]Fachbereich Physik, [2]Fachbereich Chemie,
Carl von Ossietzky-Universität
PO Box 2503, W-2900 Oldenburg, Germany

Introduction:

Many research activities on the carbon cluster compounds fullerenes has been started since production of macroscopic amounts was made possible in 1990. Mass spectrometry is one important method for characterizing this new class of compounds and results obtained by different techniques has been published recently. There are also several contributions to this subject at the ASMS conference 1992. We present PDMS spectra of a C_{60}/C_{70} mixture which we obtained by preparing the fullerenes in a ß-carotene matrix.

Experimental:

The count rates of samples with different fullerenes/ß-carotene mixtures have been determined. The amount of ß-carotene was approximately 28 nmol on all samples. The amount of fullerenes has been varied in a range of less than 5 nmol. The samples were prepared by spraying 15 μl of benzene solution on an aluminized polyester foil using an air-brush-like equipment. For comparison, a sample of 5 nmol fullerenes without ß-carotene has also been prepared and measured. PDMS-spectra were recorded by our spectrometer OLDA 1 which we built in cooperation with K. Wien, TH Darmstadt. This linear TOF-instrument is equipped with an 80 cm flight tube, two double stage multichannel plates for start or stop signals, and a time digital converter CTM/M2 connected with a DMI-card, both from Y. LeBeyec, IPN Orsay. Mass resolution is about 700. The operating voltage was usually +/- 14 kV, the run time 15 min.

Results:

The PDMS-spectra of fullerenes prepared directly on an aluminized polyester foil show a much higher yield for positive molecular ions (M^+) than for the negative ones (M^-, see fig. 1). If the fullerenes are embedded in a ß-carotene matrix, much more negative than positive molecular ions are observed (M^- and M^+). As a consequence, the sensitivity for observing negative molecular ions of fullerenes is dramatically enhanced and detection in the fmol-range is made possible. A much higher yield for positive matrix ions (predominantly MH^+) than for the negative ones (predominantly MH^-) are observed in all spectra. In addition, the yield for negative ß-carotene ions decreases with growing amounts of analytes in the matrix but the total ion yield increases.

Conclusion:

ß-Carotene is appropriate for supporting the formation of negative ions of fullerenes. The supporting effect is large enough to detect fullerenes on fmol-samples. The high electron affinity of fullerenes is considered to be the main reason for the dramatically enhanced negative ion formation.

Computer Analysis Tools for PDMS Spectra

J.Curdes, P.Borrmann, E.R. Hilf, W. Tuszynski
Fachbereich Physik, Carl von Ossietzky-Universität, W-2900 Oldenburg, PO Box 2503, Germany

Computer analysis tools have been developed for evaluating PDMS-spectra consisting typically of 65,000 time bins. These include algorithms for efficient data reduction, algebra tools, a program for simulation of the fragmentation process in *PDMS* , and an algorithm which eventually will lead to prediction of cluster formation in *PDMS* .

PEAKS is a program[1] which extracts relevant mass line informations such as amplitude, area, width, asymmetry of relevant peaks in channel spectra by a new method, the *far moments*, in a very efficient way. The spectrum is just scanned once (with no fit of e.g. Gaussians) to extract the experimental lines. The new algorithm just calculates one set of sums (typically 3-4) per time bin of differently weighted channel contents over a region of about one line width, starting well to the left from an expected line. This procedure is extremely fast and works as well for noisy spectra and asymmetric line shapes. It can and has been automatized. The program package is available on request to the authors.
Results demonstrate the high sensitivity for extracting even small lines out of a large noise with no fit. It turned out to be especially useful for analyzing spectra of a Wadden Sea sediment *PDMS* spectrum [2].
The efficient algorithm allows the processing of huge amounts of data (typ. 220 kB / spectrum) on a 286-PC in competitive time. Further development and research is done to identify noise and matrix effects and to subtract these from the original spectrum automatically.

SIMILARY serves the usual algebra to condition and compare spectra. For comparison, differences or an euclidic scalar product is usually used. In both cases, the problem of possible negative terms occurs. To avoid this and to enhance resolution in the region of low similarity, *SIMILARY* provides (besides the usual algebra) a newly designed *linear scalar product* for two spectra Y_1, Y_2, namely $P(Y_1, Y_2) = \sum_\nu \sqrt{Y_1(\nu)Y_2(\nu)}$ By using this method, the similarity P is a physical quantity which we call *comparison-length* . It can be associated with the length of the difference vector in a parameter space of the two spectra. Future development will be to integrate *SIMILARY* together with *PEAKS* into an intelligent package to identify substances more or less automatically.
CRUNCHER calculates the composition of a theoretical *PDMS* spectrum by assuming the chemical bond breaking probabilities for a molecule of known chemical structure to be independent of each other. This reflects the rather short (as compared to bond vibration times) deposition of a large amount of energy as thought of to occur in the PDMS-process (which we call *entropic*). The bond breaking probabilities are fitted to experimental spectra by using a linear scalar-product measure. The breaking algorithm has been given in ref.[1].

For a cobalt complex (bromo-bis(dimethylglyoximato)-pyridino-cobalt(III)-complex). the experimental *PDMS* spectrum of this complex has been taken as an example to test the strength of the method. Four parameter fits have been performed for the break-up probabilities of the Br-Co, Co-pyridine and Br-N bonds. As a powerful method for fits in a parameter space of many dimensions we used a Monte-Carlo start combined with a attached local minimum search. This proved optimal for the case of the here found many side-minima.

The aim is to get values for the breaking probabilities for certain bond types such as C-H, C-C etc. (which should be about the same for different substances) which we then try to explain by microscopic numerical calculations. In this way we hope to elucidate the mechanism which governs this fragmentation process and to enlarge the quality of the predictions made by *CRUNCHER* .

PIMC II is a computer code developed by us to investigate thermal properties of small clusters ($N < 100$) via the Path Integral Monte Carlo method. The thermal properties of clusters like pair correlation func-

tion, specific heat and potential or kinetic energy are calculated for Fermi-, Bose- and Boltzmann quantum statistics as well as for classical Maxwell - statistics. The code is highly vectorized and uses very efficient algorithms. PIMC II runs a factor 20 to 120 faster than PIMC I [3, 4], which includes solely Boltzmann- and Maxwell-statistics.

Example: Denoting the binding energy of Neon clusters [5] for a temperature T with E_n, the second energy differences $\Delta^2 E_n = E_{n-1} + E_{n+1} - 2E_n$ have proved to be a good measure for cluster stability [6]. If $\Delta^2 E_n$ is positive, the process of fragmentation of a Ne_n - cluster into a Ne_{n-1}-cluster and a single Ne-atom is less favorable than the process of fragmentation of a Ne_{n+1}-cluster into a Ne_n-cluster and a single Ne - atom, i.e. positive values indicate high stability of Ne_n-clusters and thereby magic numbers. The result is that only with these quantum mechanical calculation the experimentally known magic numbers are reproduced thus emphasizing the importance of the quantum statistics for the stability of light mass atomic clusters.

The pair correlation function gives the distribution of distances between the atoms of a cluster. For Ne_{13}-clusters at 4.0 K the quantum kinetic energy increases the two-particle distances and broadens the distribution compared to the classical calculation. At 8 0 K the structure gets washed out and the clusters seems to become fluid-like.

First results for ^{3}He-clusters will be presented on ISSPIC VI this year. Simulations for Li and molecular clusters are in progress.

Simulation of the Desorption Process induced by Fast Ionic Atoms, Molecules, or Clusters

B. Nitzschmann, K. Barghorn, E. R. Hilf
Fachbereich Physik, Carl von Ossietzky-Universität, W-2900 Oldenburg, PO Box 2503, Germany

A large Computer Code CLIMPACT has been set up to simulate the Desorption Process induced by fast (keV to MeV per amu) heavy ions, molecules or clusters.

The coupled equations for the Molecular Dynamics for some 10,000 to 100,000 particles are solved for a setup of an array of atoms impinged by a cluster of atoms treated the same way.

The target atoms were assumed to be arranged in an *fcc* crystal structure bound by a two-body Lennard-Jones-type force.

The projectile is allowed to impinge in an arbitrary angle. The trajectories of all particles are followed, showing the forming of a shock wave inside the material, especially if the projectile contains more than one atom (coherent superposition),

Subtle difficulties in such large highly non-equilibrium Molecular Dynamics calculations are given special care.

Boundary conditions at the side of the studied piece of matter should simulate that the piece is just a part of an extended homogenous solid. Thus, e.g. a shock wave should not get reflected at the border of the lattice piece taken. We have proven that this problem can only be solved by introducing **non-local** boundary conditions. We use the simplest version of it adding a friction force to the dynamic equation with its strength and its power-dependence of the velocity dependence determined by studying the case of a linear chain. This force applies to the motion of all atoms within three atomic distances from the boundary layer.

The inherent necessary recognition of next neighbours in each step is done by a grid method which automatically adjusts its size to the momentary occuring relative atom velocities.

Calculations have been performed for a large range of energies, sizes and different angles of the incoming ions. The solid was simulated by a $16 * 16 * 16$ cubic cell bloc.

CLIMPACT is now ready for being applied on a routine basis.

Analysis of Entropic vs. Thermal Fragmentation

Abstract

A first *PDMS* spectrum of the highly volatile *decane* is presented and compared to simulation calculations. It is inferred that fragmentation in *PDMS* is mainly entropic with decane being specifically hot. In addition we compare calculations on the formation of new compounds from the innermost zone close to the primary ion track.

PDMS – Spectrum of Decane

Spectra of volatile materials such as *decane* have been taken at Darmstadt by PDMS. Extreme care has been taken to gain a clean spectrum with no contaminations by sublimating other material from the rest-gas. The fragmentation pattern is typical for positive ion *PDMS* spectra with a relatively high molecular ion peak and a small series of fragments. One of our research lines is the explanation of this *fragmentation process* in *PDMS*.

Entropic Fragmentation in PDMS

The main part of ordinary *PDMS* spectra abundances stems from a large area around the impact ion track. The energy is transferred to the bonds by means of a secondary electron shower in a rather short time as compared to a thermal vibration time. Thus the fragmentation here is thought to be mainly *entropic* which means that probabilities for bond-breaking are almost *independent* from each other because of the high dE/dt, so that there is no time to distribute the enormous amount of energy to other bonds.

A calculation was done using the newly developed code CRUNCHER to simulate the fragmentation pattern by calculating all possible breakup ways of the giver chemical structure. We had to assume different probabilities for equal bonds in order to obtain the amplitude pattern observed. This is in contrast to our assumption that the probabilities are independent from each other because of the entropic nature of the process.

The molecular peak of the *PDMS* spectrum is well represented in this way, which is also true for the main fragment lines, but there are fragments around 12 and 108 *amu* which do not appear in the original spectrum. This and the choice of probabilities lead to the assumption that fragmentation of these chain-type molecules has a strong thermal contribution.in other words, that the "temperature" of the gas is quite high compared to other, less chain-like substances where we have obtained results which come more close to our assumptions of *entropic* fragmentation.

Formation of New Compounds from the Central Plasma Zone

Another point of interest is what happens to the material emerging from the track itself, where all matter has been heavily destructed. The resulting atoms or small fragments form a gas which is ejected from the track[2]. It was suspected that in this gas the *formation of new molecules* takes place What we present here is an example for such a process. The negative ion *PDMS* spectra are believed to be dominated by matter emerging from the ion track. One support for this is the absence of any molecular peak in the negative ion spectra. We identify three different series of Carbon chains in the considered spectra

- A series of $C_2, C_4, C_6, ...(24, 48, 72, ..amu)$
- A series of $C_2H, C_4H, C_6H, ...(25, 49, 73, ...amu)$
- A series of $C_3, C_5, C_7, ...(36, 60, 84, ...amu)$.

We have studied the relative abundances of these three series for Decane. We compared these with spectra taken from entirely different substances, such as Fullerene and β-Carotene. The similarity of the abundance sets of these carbon cluster series is striking. We got strong evidence for a process which is only dependent on the elements contained in the original substance, but not on its molecular structure.

We took care that this effect is not due to rest-gas impurities, by using spectra from different laboratories with entirely different experimental setups in this respect. These series cannot be fragments because e.g. the ratio $C_{2n}/C_{2n}H$ is about the same for decane and fullerene with their very different (n_H/n_C)-ratios of 2.2, and 0, respectively. We give some reasons for the different abundances observed for the three series :

- The shape of the $C_{2n}H$ - series is different from the other two because one of the possible C-sites is already blocked so that the probability of further expansion of the chain is decreased.
- The C_{2n} - series has higher overall yields than the C_{2n+1} - series because the energy balance for the formation of the *even* chains is better due to a higher ratio of triple bonds, which are energetically favoured in the formation process.

Adiabatic Expansion Model for the Formation Process

We have done calculations based on the adiabatic expansion model, which qualitatively predicts the curves. Theoretically, we calculate the PDMS-abundance $f(g)$ for C_n for the ions coming from the innermost zone around the ion impact track by assuming a cylindrical area of hot and dense completely atomized matter at the beginning, which then is followed by an adiabatic expansion out of the primary impact hole. The sequential addition of Carbon atoms during the expansion leads to carbon-'clusters', the formation of which is stopped when the density of the expanding material becomes too low. Modelling and simplifying to an analytical expression we get [1]

$$f(g) \approx g^{1/12} I_{1/4}(g^{2/3}/\sigma) \exp(-g^{4/3}/2\sigma)$$

where σ is an thermo-hydrodynamical integral but proportional to the monomer sticking probability, which we take to be proportional to the number of active ends of the molecule. The absolute amplitude of the three cases is taken to be $1 : 1/2 : 1/4$ for $C_{2n}H$, C_{2n}, and C_{2n+1}, respectively.

Molecular Ion Formation in Plasma Desorption by Hydride Abstraction

*P.Demirev, B.Daya, G.Brinkmalm, D.Fenyö, P.Håkansson,B.U.R.Sundqvist,
Dept. Rad. Sciences, Uppsala University, Box 535, Uppsala, 75121 SWEDEN

Plasma desorption (PD) mass spectrometry has been one of the first particle bombardment techniques successfully applied for formation of gas-phase ions of non-volatile and thermally labile biomolecules. The usefulness of PD for assignment of molecular weights is determined by the fact that various types of intact molecular ions from different species are formed and observed in the mass spectra of the respective compounds. As in other desorption ionization techniques the main type of positive molecular ions are those corresponding to the neutral sample molecule with attached proton or (most often alkali metal) cation : $[M + (n + 1)Alk - nH]^+$. Radical (odd-electron) molecular ions: $M^{+\cdot}$, obtained by loss of an electron from the neutral molecule have also been observed in PD mass spectra of biomolecules. We have studied recently specific aspects of the formation mechanism of cationized adducts and radical ions in PD by employing as a probe the initial radial velocity of the ejected ions [1,2].

So far there have been only a few cases when $[M - H]^+$ molecular ions are observed in PD mass spectra of biomolecules. A specific example of a compound exhibiting $[M - H]^+$ ion in PD is the neutral lipid cholesterol (Fig. 1).

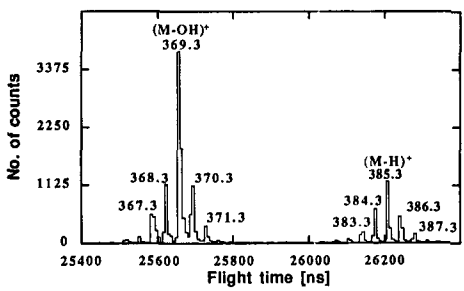

Fig. 1 Positive ion PD mass spectrum of cholesterol - the molecular ion region.

In this study the initial radial velocity distribution of ejected cholesterol molecular ions is reported and used for elucidating the mechanism of molecular ion formation by hydride abstraction in PD. It is also compared to previously obtained data on the initial radial velocity distribution of radical and protonated positive molecular ions from different biomolecules including the structurally similar compound - ergosterol (exhibiting $M^{+\cdot}$ as the most intense peak in its spectrum at m/z 396).The velocity distributions of $[M-H]^+$ ion for cholesterol and $M^{+\cdot}$ for ergosterol are compared in fig 2. Ergosterol molecular ions have almost two times higher mean radial velocity as compared to cholesterol molecular ions (-562 ± 21 m/s versus -291 ± 62 m/s). The initial radial

velocity data for cholesterol (fig. 2) demonstrate that the **[M-H]+** cholesterol molecular ions have an angular distribution which is more symmetric along the surface normal. In contrast, ergosterol has angular distribution with a maximum in a direction away from the direction of the incoming MeV primary ion. Our interpretation of the formation of **[M-nH]+** ions in PD invokes the possibility of a gas-phase (selvedge) "self"-chemical ionization type reaction between desorbed species (including charged and neutral molecules and fragments) that leads to hydride abstraction. Self-chemical ionization type hydride abstraction reactions are well-known gas-phase ion molecule reactions for e.g. saturated hydrocarbons. Formation of cholesterol molecular ions in a selvedge process involving interactions between different ejected species results in directional randomization and "smearing" of the directional correlation, typical for ejection of biomolecular ions in PD.

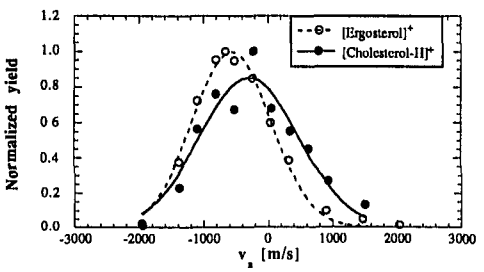

Fig. 2 Radial velocity distribution of the cholesterol **[M-H]+** (•) and ergosterol **M+·** (o) molecular ions. The data points have been fitted with a Gaussian curve.

A Compact Ion Acceleration Lens with Wide Aperture for Time-of-Flight Mass Spectrometry

L. Schmidt, H. Jungclas, H -W. Fritsch, P. Köhl
Klinikum der Universität Marburg - Klinische Nuklearmedizin, Baldingerstraße
D-3550 Marburg, Germany

INTRODUCTION. Ion sources in time of flight mass spectrometry, especially in PDMS, are sometimes extended up to 1 cm^2. Acceleration is usually accomplished by homogeneous electrostatic fields, employing high-transmission grids. By means of computer simulations we investigated the possibility to apply simple electrostatic acceleration lenses, similar to the approach of Della Negra et al. [1].
The initial problem was how to design an inhomogeneous acceleration field which releases simultaneously generated ions into the field-free drift space at the same time-of-flight independent from the location of the ionization event. The optimizations aimed for a solution, which combines a large area of acceptance with extreme compactness and simple principles of construction.

COMPUTER SIMULATIONS. Simulations of electrostatic lenses were performed on a 33 MHz PC-AT with the PC-Version of the SIMION-code. The trajectories were calculated for ions (m/z 100) desorbed from a 7 mm target (8 kV acceleration voltage) with zero eV initial energy. Equidistant time-of-flight markers (0.2 s) reveal the development of the ion front curvature along the beam.
SIMION parameters: grid spacing 0.25 mm, 400 x 40 points mirrored, voltage scaling 1 V, accuracy level 100, cylindrical symmetry.

EXPERIMENTAL. Two calculated lens geometries were constructed and experimentally tested on a linear PDMS instrument in comparison with conventional acceleration (90% transmission grid, sample-grid distance 8.5 mm, flight distance 70 cm, sample diameter 7 mm, active MCP-diameter 32 mm).
Time-of-flight spectra were acquired of Verapamil-hydrochloride samples prepared from a 1 mg/ml solution in methanol. The molecular ion distribution around m/z 455 was used to compare mass resolutions and ion yields obtained with the different acceleration configurations. Intensity losses due to an increased beam divergence are most likely indicated by a decreased yield of protons [2].

RESULTS. A simple lens configuration with a single ring electrode of thickness d, aperture radius r and a semicircular profile is suited to form a gridless acceleration field for TOF-MS applications (Fig. 1). For any set of the geometrical lens parameters d_0, D, and r there is an optimum electrode thickness d_{opt} resulting parallel rays, large acceptance and good timing behaviour: $d_{opt} = (r + d_0) 2r / D$ (Fig. 2). The optimum potential U_1 of the ring electrode in a given acceleration lens geometry (characterized by d_0, d, D and r) at a total acceleration potential U_0 is calculated by the empirically derived approximation (very precise for $d = d_{opt}$): $U_1/U_0 = (1 - d_0 / 2D - d / 4D) (1 + d / 3D - (D + d_0) r/3)$. The most compact solution with large acceptance (50% of aperture) and low aberration was found at $r=0.4$ D, $d=0.45$ D, $d_0=D/6$, $U_1 = 0.833\ U_0$ (Fig. 3).

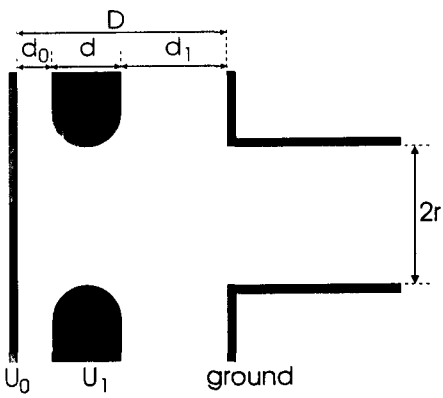

Fig. 1: Basic parameters of a simple lens

EXPERIMENTAL VERIFICATION. The performance of an acceleration lens dimensioned similar to this optimized solution was compared with PDMS-results obtained with conventional grid acceleration. When the lens was utilized mass resolution decreased by about 33%.
It turned out that the decrease of mass resolution is due to the weak ion extraction field of the lens (enhanced influence of initial ion energies). A field strength similar to the grid system has been achieved

with a modified acceleration lens. Then mass resolution was as high as obtained with grid acceleration. The molecular ion yield increased by about 10% as expected, the proton intensity by 30%.

CONCLUSIONS. A simple electrostatic lens can be efficiently applied for ion acceleration in TOF-MS, especially in ^{252}Cf-PDMS. The position, form and thickness of the central ring electrode are essential for optimization of the ion extraction field. The derived formulas make it possible to build-up such an acceleration system without the need of computer simulations. To maintain or enhance the mass resolution, it is necessary to raise the acceleration voltage or to compensate for the ion energy distribution by means of a reflectron.

Processing the Assembly Protein from Simian Cytomegalovirus. **A.S. Woods, A.R. Welsh, W. Gibson and R.J. Cotter. Dept. of Pharmacology and Molecular sciences, The Johns Hopkins Medical School, Baltimore, MD 21205**

B-capsids of Cytomegalovirus (CMV) contain a phosphorylated protein that is absent from mature virion, the assembly protein (AP), a 37-kDa molecule believed to be involved in the capsid assembly. The genomic region encoding the AP has been cloned, sequenced and found to be organized as a nested set of four in-frame, 3'-coterminal genes, suggesting that the viral genome could give rise to four independently transcribed 3'-coterminal RNAs coding for four overlapping in frame, carboxy-coterminal proteins.

Mature AP is processed from a slightly larger precursor: the pre-AP by C-terminal cleavage. Determining the cleavage site is of importance because knowing the amino acid (aa) at the site could indirectly help in the determination of the type of protease acting at that cleavage site.

The AP was enzymatically digested and the MW of the resulting peptides (pptd) determined by PDMS and compared with the molecular weights (MW) calculated from the sequence to reveal the carboxyterminal fragment. Endoproteinase-Lys C (Lys C) and Endoproteinase-Glu C (Glu C) were utilized. The molecular ion (MH^+) of the resulting pptds are compared to expected MH^+ calculated from the deduced aa sequence. Both Lys C and Glu C digest fragments accounted for every aa from 1 to 277. Fraction (Fr) 24 of Lys-C digest gave a MH^+ of 903.3, the calculated MH^+ for **SAERGVVNA** is 902.5. Fr 23 of glu-C digest gave a MH^+ of 616.2, the calculated MH^+ for **RGVVNA** is 615.4. These results suggest that the $\mathbf{Ala}_{277}$ is thelast residue in the aa chain (Fig. 1). To verify the above results *on foil* digests with carboxypeptidase P were done on both terminal pptds. The spectrum of Fr 24 shows a reduction in size of peak 903.3 and the appearance of a new peak at m/z 462.2, that could be generated by SAERGVVN - GVVNA or 903.3 - (71+114+99+99+57) = 463.3 amu. The spectrum of Fr 23, shows a new peak at m/z 547.6 which could be generated by RGVVNA - A or 616.3 - 71 = 545.7, confirming that the last

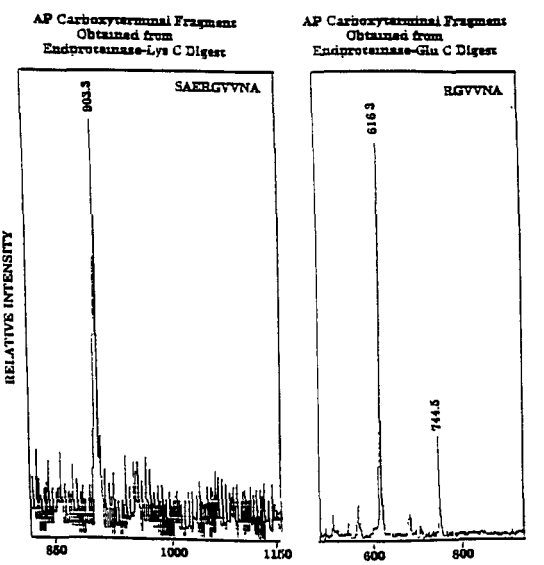

Figure 1: Assembly Protein Carboxyterminus

residue on the AP is an alanine. The identification of Ala_{277} as the carboxyterminus of the mature AP enabled the recognition of a consensus proteinase (Assemblin) cleavage sequence of V/L-X-$A^{\downarrow}$-S/V at the carboxylic end of all herpesviruses AP homologs. This finding also predicts that the mature enzyme is generated by cleavage at YVKA$^{\downarrow}$S. The cleavage site of the AP and of Assemblin are highly conserved domains in all Herpes viruses, confirming the major role these sites play.

Fr 28, 32 and 43 from Lys C and Fr 37 from Glu C digests gave MH^+ that were 80 units larger than expected suggesting phosphorylation sites. To verify the virus was grown in media containing ^{32}P. The AP was purified and digested with both enzymes, and the HPLC Fr from each digest counted. The following Fr were ^{32}P-labeled: Fr 28, 32 and 43 in the Lys C and 31/32, 33/34 and 35/36/37 in the Glu C digests. The GluC Fr were digested with Trypsin, and a spectrum of the digest acquired (Fig.2). The following MH^+ 555.4 (SGALK-HPO_3), 630.4 (SGALKR), 665.6 (MSFPGE), 711.4 (SGALKR-HPO_3), 799.4 (SRSGALK-HPO_3), 1024.6 (SGALKRRR-HPO_3), as well as their MNa^+, and some undigested peptides such as MH^+ 2597.0, 4594.4, and 4950.3 (Fig2).

The above data strongly points to Ser_{144} as the likely and only phosphorylation site on the AP. Further experimental work (not shown here), as well as the fact that the phosphorylation site is highly conserved in the AP of other Herpes viruses tend to confirm our data. these domains are consensus sequences that can be phosphorylated by the host cells protein kinase C, or possibly by a viral enzyme closely resembling protein kinase C.

The fact that there is only one phosphorylation site in the AP of CMV colburn, and that the site is conserved in other herpes viruses strongly suggests that phosphorylation and dephosphorylation of the AP might play a role in its function.

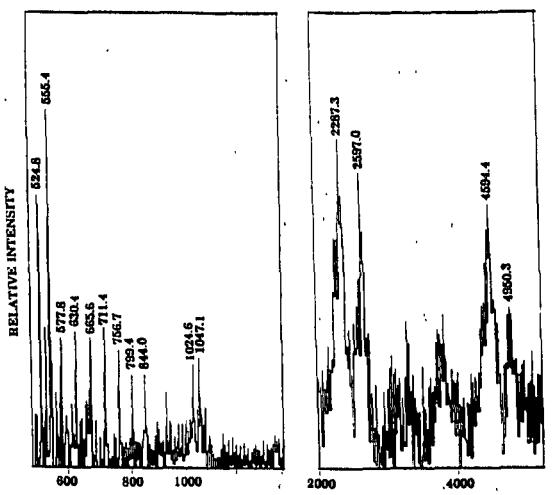

Figure 2: Fractions 31/32 from Endoproteinase-Glu C digest of the AP, redigested with Trypsin

PLASMA DESORPTION MASS SPECTRAL CHARACTERIZATION OF PROTEINS MODIFIED BY PRENYLATION

Prenylation is a post translational modification that is found in many proteins. The attachment of isoprenoid derivatives is needed for the activity of many membrane-bound proteins, possibly because they help direct the protein to the right cellular destination. Proteins modified by either the 15-carbon isoprenoid derivative, farnesyl, or the 20-carbon derivative, geranylgeranyl, are crucial in many signaling pathways.[1] One example of protein prenylation is the yeast mating pheromone, a-factor,[2] which is a 12-residues peptide with a S-farnesylated and carboxyl methylated C-terminal cysteine.[3] A new species of extracellular peptide was found in the studies of a-factor biogenesis in *Saccharomyces cerevisiae*. Its structure was determined to be an a-factor related peptide (AFRP) by using molecular techniques combined with plasma desorption mass spectrometry (PDMS)[4]. PDMS spectra of a-factor and AFRP revealed a fragment ion characteristic of the loss of the farnesyl moiety in addition to the protonated molecular ion.

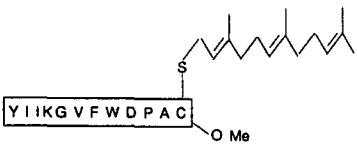

Figure 1. Structure of mature a-factor.

This new species, which was found by SDS-gel analysis of the cell culture medium, migrates slightly faster than mature a-factor. It appears to be related to a-factor since it is absent in an a-factor null mutant (Figure 2). In Fig.2, WT: wild type strain; Null: a-factor deletion mutant, I: intracellular immunoprecipitate; E: extracellular immunoprecipitate; T: total extracellular proteins.

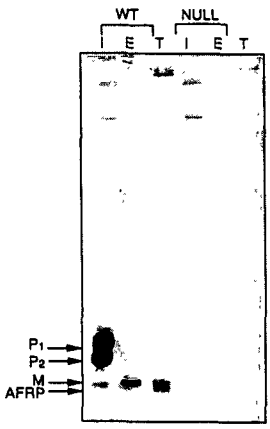

Figure 2. SDS-PAGE analysis of immunoprecipitated and non-immunoprecipitated a-factor related species.

a-factor and AFRP were purified from the culture medium by a simple two step purification method, which involves exposure of the culture medium to a polystyrene resin to which a-factor and AFRP adhere, followed by reverse phase HPLC separation. HPLC fractions were analyzed by a-halo activity and radioactivity (^{35}S-Cys). Particular fractions were analyzed by PDMS to determine the molecular weight. All of PDMS spectra were obtained on a BIO-ION Nordic (Uppsala, Sweden) BIN-10K PD-TOF-mass spectrometer. Nitrocellulose (NC) coated sample foil (ABI, CA) was used in this experiment.

For the a-factor fraction (F61), PDMS analysis (Figure 3) indicates a peak corresponding to M.W. of 1631.3 Da, which matches the calculated M.W. (1630.7) of mature a-factor. The major peak in AFRP fraction (F55) is 1071 Da, which is the M.W. predicted if AFRP is comprised of the 7 C-terminal amino acids of mature a-factor, including the farnesyl and methyl groups on Cysteine and an additional mass of 16 dalton.

To prove that AFRP is truly derived from the a-factor gene (*MFA1*), we have also analyzed AFRP synthesized in strain containing an *mfa1* point mutation. For mutant $A_{11} \rightarrow S_{11}$ (Figure 4), the observed M.W. of both a-factor and AFRP correspond to that expected for the particular mutant allele, plus the 16 extra daltons, similar to WT AFRP. For another mutant $I_2 \rightarrow M_2$ (Figure 5), only a-factor shows an altered M.W. but AFRP does not, since the mutational alteration lies outside of AFRP. These results indicate that AFRP is indeed derived from the *MFA1* gene and has common C-terminal portion with a-factor.

Fragment ions characteristic of the loss of the farnesyl moiety were observed in the PDMS spectra,

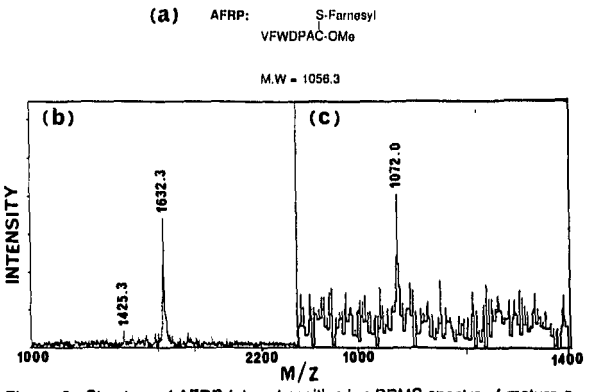

Figure 3. Structure of AFRP (a) and positive ion PDMS spectra of mature a-factor (b) and AFRP (c) from *MFA1*.

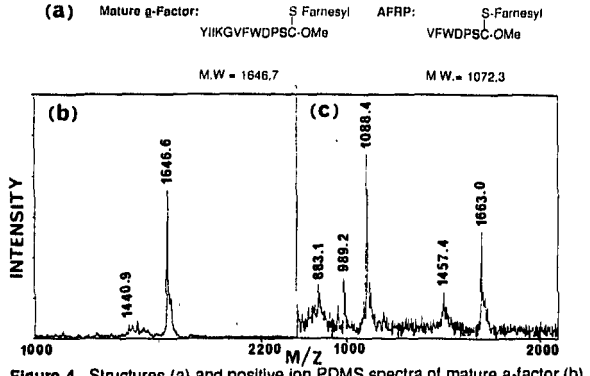

Figure 4. Structures (a) and positive ion PDMS spectra of mature a-factor (b) and AFRP (c) derived from *mfa1* containing point mutation of $A_{11} \rightarrow S_{11}$.

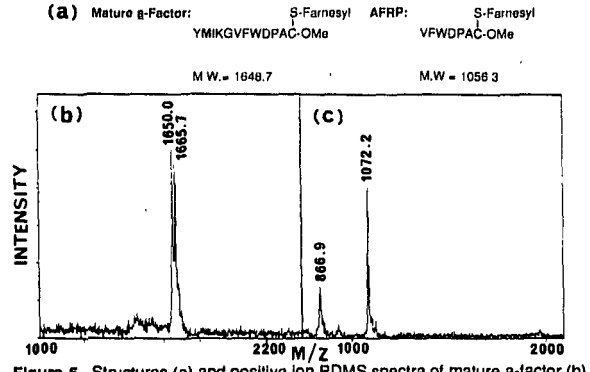

Figure 5. Structures (a) and positive ion PDMS spectra of mature a-factor (b) and AFRP (c) derived from *mfa1* containing point mutation of $I_2 \rightarrow M_2$.

especially in the spectra of AFRP, in addition to the protonated molecular ion. The mass difference between this fragment ion and protonated molecular ion is about 205. This fragment not only confirms the existence of farnesyl group, it also indicates that the 16 extra Daltons do not arise from oxidation of double bonds in the farnesyl group.

This study demonstrated that combined molecular biological techniques and mass spectrometry can be a powerful, sensitive, and fast method to study protein structures and modification.

The results of this study show that PDMS can be used in the structural analysis of prenylated proteins and peptides. A particularly useful feature of this method is the unique fragmentation pattern resulting from generation of a species representing the loss of the farnesyl moiety.

The peptide structure of a-factor related peptide (AFRP) was determined in this study. It is comprised of the 7 C-terminal amino acids of mature a-factor, including the farnesyl and methyl group on cysteine residue and additional mass of 16 Da.

This 16 daltons may be due to the S-oxidation of cysteine or oxidation on the ß-position of aspartic acid; further experimentation will be required to examine these possibilities.

Study the Interactions of Peptides and Proteins with Transition Metal Ions by ^{252}Cf-PDMS

*Zhaohong Hu and R. D. Macfarlane
Department of Chemistry
Texas A&M University
College Station, TX 77843

Using ^{252}Cf-PDMS, the interactions between several metal ions and angiotensin II, bovine insulin, and RNase A have been studied. Our results show that the specific metal ion binding sites in the peptide and the proteins can be identified as well as the molecular ions.

The influences of the solution pH, the peptide-metal ion molar ratio, the reaction temperature, and the reaction time have all been investigated. Pd(II) forms complexes with ANGII from pH 2 to 8, whereas the acidic pH completely inhibits the formation of ANGII-Zn(II) complexes. At room temperature, different metal ions display different reactivities. The equilibrium of ANGII-Pd(II) reaction is reached within 20 minutes. ANGII-Zn(II) exhibits the same reactivity. On the other hand, ANGII-Pt(II) complexes cannot be detected at room temperature until the reaction has continued for 3 days. The effect of reaction temperature is not important to ANGII-Zn(II) and ANGII-Pd(II), but it is dramatic to the foramtion of ANGII-Pt(II) complex formation. The molecular ion $(M+PtCl)^+$ is comparable to $(M+H)^+$ when the reaction proceeds for 1 hour and $(M+PtCl)^+$ totally suppresses $(M+H)^+$ after the reaction proceeds for 10 minutes at 80°C. The influence of the molar ratios (the relative concentrations of a peptide/proteins to a metal ion) to the complexation is straight forward. Under the proper solution pH, the higher the metal ion concentration is, the higher the relative intensity of $(M+\text{Metal ion})^+$ will be.

Comparing the spectrum of ANGII-Zn(II) to the ANGII spectrum itself, two groups of Zn(II)-containing peaks can be identified. The first group relates to the N-terminal ions which follow a general formula of $(a_n+Zn-2H)^+$ (n = 2, 4, 5, and 6). The $(a_n+Zn-2H)^+$ ions are structurally isoelectronic to the a_n^+ ions. These peaks symbolize that the N-terminus is a Zn(II) binding site. The second group concerns the C-terminal ions. The Zn(II)-containing species detected are $(x_3+Zn-H)^+$, $(y_3+Zn-H)^+$, $(z_3+Zn-3H)^+$, and $(w_4+Zn-2H)^+$. They are all generated from the bond cleavages in the vicinity of His-6 residue. These data indicate that the imidazole ring of His-6 residue is a Zn-binding site.

The result of ANGII-Pd(II) shows the multiplely coordinated molecular ions with a formula of $(M+nPd-mH)^+$ (where n=1 to 5). The intensities of these peaks indicate that several Pd(II) ions can attach to one ANGII molecule, but only one of them is tightly bound. In the fragment ion region, a_2+Pd is extremely intense. Its relative intensity to $(M+Pd-H)^+$ counts 80 %.

The other a_n+Pd peaks (n = 4 to 7) are also observed. These data demonstrate that a Pd(II) ion is tightly bound to the N-terminal end of ANGII.

There are two primary differences of bindings between ANGII-Pd(II) and ANGII-Zn(II). First, the affinity of Pd(II) to ANGII is much higher than that of Zn(II). The relative intensity of $(a_2+Pd-2H)^+$ is much more abundant than $(a_2+Zn-2H)^+$, even though Zn(II) concentration used is higher. In other words, higher Zn(II) concentration is required in order to detect the Zn(II)-fragment ions. Secondly, based on the fragmentation analysis, two Zn(II) binding sites are recognized in ANGII, whereas only one Pd(II) binding site can be identified in ANGII . There is no evidence to support His-6 as the second binding site to Pd(II).

The three dimensional structure of a protein governs its metal ion binding sites to a great extent. The effect of the 3D structures distinct protein-metal interactions from peptide-metal ion interactions. Changes in the three dimensional structures induced by the metal ion binding often result in the activity change of the proteins.

Bovine insulin consists of two chains which are crosslinked by the two disulfide bonds. In the mass spectrum of bovine insulin, significant molecular ions and fragment ions are detected. Compared the two chains, the B-chain generates a much more abundant pseudo-chain peak than the A-chain. Furthermore the fragment ions detected are dominated by the B-chain fragments. This observation can be well explained by the fact that there is no basic amino acid residue in the A-chain and there are four in the B-chain. Among the B-chain fragments are both the N-terminal and the C-terminal ions. The result of insulin-Pd(II) shows that there are three groups of peaks in the mass region of m/e 2500-6500. These peaks indicate that two Pd(II) ions are bound to one insulin molecule and more specifically, to the B-chain of the protein molecule. By analyzing the fragment ions, the following peaks are easily recognized: a_3+Pd, a_4+Pd, a_5+Pd, a_7+Pd, and a_5+2Pd. The intense a_5+Pd peak signifies the binding of a Pd(II) to the His-5 residue in the B-chain. The peak a_5+2Pd depicts that the two Pd(II) ions bound to the insulin are actually bound to the first five residues in the B-chain.

RNase A contains one single peptide chain which encompasses several loops formed by the crosslinking disulfide bonds. RNase A displays not only the molecular ions (from $(M+H)^+$ to $(M+5H)^{5+}$), but also quiet a few fragment ions. All the fragments are generated from the out-side-loop peptide segments at the two termini. The loop structures prevent the formation of fragmentation. The a_n ions (from a_{10} to a_{20}) are the major fragments.

The spectrum of RNase A-Pd(II) only displays the doublely and triply charged molecular ions can be identified. The detection of the two molecular ions inform us that as many as nine Pd(II) ions are attached to one RNase molecule. The examination of fragment ions indicates that the His-12 residue is a strong Pd(II) binding site, which is known to be one of the residues involved in the enzyme active site.

Fragmentation Studies of Ribonuclease A

David M. Bunk and Ronald D. Macfarlane
Department of Chemistry, Texas A&M University
College Station, TX 77843-3255

The MeV fission fragments used in ^{252}Cf-PDMS are capable of inducing prompt, sequence-specific fragmentation of proteins as large as 29 kDa (1). While the fragmentation of peptides has been thoroughly characterized, the sequence-specific fragmentation of large, intact proteins has not been the focus of fundamental studies. We, therefore, began an investigation of the fragmentation of one model protein, ribonuclease A (RNase A), to determine the factors which influence fragmentation using the fragmentation of peptides as our benchmark. RNase A, while large compared to other molecules used in fragmentation studies, is a small protein (124 residues, 13,682 Da) such that chemical modification of specific sites of the protein can be performed without difficulty. By examining the fragmentation pattern of RNase A after modifying the basic/acidic residues, after reducing the disulfides, and after the three-dimensional conformation of the protein has been altered, the factors which influence the fragmentation of this protein can be determined.

Experimental. The N-terminal ethyl-triphenylphosphonium (2,3), the guanidinated (4), the O-methylesterified, and the reduced and S-pyridylethylated derivative of RNase A were prepared using published or standard procedures. The RNase A and its derivatives were purified by RP-HPLC prior to PDMS analysis. Approximately 200-250 pmol of protein was used for each mass analysis; spectra were acquired for 720 min on a linear ^{252}Cf-PD mass spectrometer with a 52-cm-long field-free region.

Results and Discussion. The fragmentation pattern in the positive ion PD mass spectrum of RNase A (Figure 1a) is composed of N-terminal fragment ions from the N-terminal region of the protein. The fragmentation of RNase A appears to conform to many of the factors related to structure and sequence that influence the fragmentation of peptides. Fragmentation of RNase A begins after arg^{10}, the first strong protonation site from the N-terminus. We have previously shown (5) that lysine residues, because they have lower proton affinities, are less likely to be protonated in peptides than arginine residues. The lack of fragment ions before the a_{10} ion in the spectrum of RNase A, despite the presence of basic lysine residues at positions 1 and 7, suggests that substantial protonation of these residues is not occurring for this protein. We verified this hypothesis by converting all lysine residues of RNase A to homoarginine (har), changing weakly basic primary amines into guanidino groups possessing high proton affinities. A portion of the fragmentation pattern of the guanidinated RNase A is shown in Figure 1b All of the fragment ions originating after arg^{10} in the spectrum of the native protein are present in Figure 1b. But, the spectrum of the guanidinated RNase A also contains a complete series of N-terminal fragment ions originating before arg^{10}, demonstrating that protonation is occurring on har^{1} and har^{7} of the guanidinated RNase A.

Another characteristic of the fragmentation pattern of RNase A (Figure 1a) is the sudden drop in fragment ion intensity after the d_{14} fragment ions, after an acidic aspartic acid residue. A possible explanation for this fragmentation behavior is that deprotonation of acidic asp^{14} quenches the fragment ion formation for fragments containing this residue. To evaluate this hypothesis, the acidic sites of RNase A were converted to their methyl esters and the fragmentation of the O-methylesterified RNase A was examined. The intensities of the fragment ions in the PD mass spectrum of the O-methylesterified RNase A were observed to be nearly identical to those of the native protein. This result indicates that deprotonation of asp^{14} is not occurring to any noticeable extent to affect the positive fragment ion yields.

As the fragmentation of RNase A stops at cys^{26}, the first disulfide cross-link, we examined the fragmentation of the reduced and S-pyridylethylated RNase A to determine whether the disulfide at cys^{26} is affecting the fragmentation of the native protein. The fragmentation of the reduced and S-pyridylethylated RNase A was nearly identical to that of the native protein, indicating that the disulfide was not preventing more extensive fragmentation of RNase A from being observed. While reducing did not affect the fragment ions in the spectrum of RNase A, reduction completely quenched the formation

of molecular ions of the protein. This suggest that the disulfides of RNase A are necessary structural elements for the formation of stable molecular ions in PDMS.

Identification of Primary Structure and Modification Sites of Fatty Acid-acylated Lipoproteins by ^{252}Cf-Plasma Desorption Mass Spectrometry combined with Capillary Electrophoresis

W. Weinmann, C. Maier and M. Przybylski, Faculty of Chemistry,
University of Konstanz, P.O. Box 5560, D-7750 Konstanz, FRG.

The covalent modification of proteins with fatty acids and lipids has recently found increasing interest in biochemistry and structural biology. Fatty acid acylation and lipid modification have been assigned to important biological functions such as membrane attachment and as mediators in intracellular signaling pathways (1,2).
In addition to the N-terminal myristylation which occurs cotranslationally and was found to be catalyzed by a specific transferase evidence for the posttranslational covalent modifications of proteins with palmitic acids has been obtained both for a variety of viral and mammalian proteins (3). Covalent modification has been most often recognized by incorporation of radioactive fatty acid, however the sites of modification have been identified only in few cases. Mass spectrometry has recently developed into a powerful method for the direct molecular weight determination of proteins and identification of primary structural modifications such as fatty acid-acylation. In recent studies the structure of the pulmonary surfactant associated protein SP-C has been elucidated as a vicinal bis-cysteinyl-thioesterpalmitate using ^{252}Cf-plasmadesorption mass spectrometry (PDMS) in combination with Edman-degradation and selective deacylation with DTT in NH_4HCO_3 -solution (4).

Capillary electrophoresis (CE) has been developed in recent years as a powerful separation method which is currently finding growing application to the characterization of peptides and proteins because of its high sensitivity in the pico- to femto-molar range at high separation efficiency obtained at very low flow rates and small sample volumes. UV-detectors are successfully used for the detection, in contrast, the identification of separated compounds is at present a major problem of CE, particularly in the analysis of multi-component mixtures.
In this study an isolation and transfer method for CE-separated polypeptides has been developed, which is feasible to direct subsequent analysis by PDMS or other desorption-ionization mass spectrometric methods (Figure 1).
This "off-line" isolation/microtransfer procedure was applied to peptides and small proteins, as well as to mixtures of Edman-degradation products as a means for manual microsequencing in combination with PDMS. PDMS analysis of several CE-separated peptides revealed mainly unmodified molecular ions, in some cases - especially for PITC-coupling products and for peptides with tryptophane-residues (Figure 2) - structural (oxidative) modifications occured under the CE separation and isolation conditions. Applications to fatty acylated peptides and proteins will be subject of future experiments.

Solvent-Derived Metal Oxides in Electrospray Mass Spectrometry of Metal Salt Solutions

Z.L. Cheng, J.C.Y. Le Blanc, K.W.M Siu, Roger Guevremont and S.S. Berman
Institute for Environmental Chemistry, National Research Council of Canada
Montreal Road, Ottawa, Ontario, Canada K1A 0R6.

Further to our investigation on the electrospray mass spectrometry of aqueous metal salt solutions [1], the electrospray mass spectra of MX_2 and MX_3 salts (where X is typically halide or nitrate) in a variety of protic and aprotic solvents, and solvent mixtures were examined. For MX_2 salts, a good correlation between MOH^+ response and MOH^+ solution concentration was observed under conditions where collision energy was nominally zero. Under this condition, metals (e.g., Cd, Ba and Mn) whose salts do not hydrolyse significantly in aqueous solution exhibit zero hydroxide response, while those (e.g., Cu, Co, Zn, Ca, Mg and Pb) that do hydrolyse significantly have significant response. These results cannot be explained by a consideration of second ionization potentials [2] or hydrolysis constants. Instead, they are in accord with the solution chemistry of these metal salts. For MX_3 salts, the $M(H_2O)_m^{3+}$ ions are sufficiently acidic that they are efficiently reduced to $M(OH)(H_2O)_n^{2+}$ in the gas phase via collision-induced dissociation.

The predominant species observed in a MX_2 solution in alcohol were $M(ROH)_n^{2+}$, $MX(ROH)_n^+$ and $M(RO)(ROH)_n^+$; ROH being CH_3OH, CH_3CH_2OH and $CH_3CH_2CH_2OH$. Fewer oxides were observed in methanol than in aqueous solution. Similar to the solvent water, no $M(CH_3OH)_m^{3+}$ ions were observable when a solution of MX_3 in methanol was sprayed; the predominate species for this solution was $M(CH_3O)(CH_3OH)_n^{2+}$.

Contrary to those in protic solvents, the electrospray mass spectra of MX_3 solutions in aprotic solvents, such as acetonitrile and DMSO, have $M(solvent)_m^{3+}$ ions as their principal species. This is illustrated in Figure 1, which shows electrospray mass spectra of 2 mM solution of yttrium (III) bromide in (a) water and (b) DMSO. This discrepancy in species stems apparently from the presence or absence of labile protons in these two classes of solvent. Within the two aprotic solvents, the mass spectra of the solutions of MX_2 and MX_3 tested were qualitatively similar except for copper (II) salts. Figure 2 shows the electrospray mass spectra of (a) 2 mM copper (II) nitrate in DMSO and (b) 2 mM copper (II) bromide in acetonitrile. The principal species observed in DMSO is $Cu(DMSO)_n^{2+}$ while those in acetonitrile is $Cu(acetonitrile)_n^+$ (some $Cu(DMSO)_n^+$) may also be observed in (a)). The presence of Cu^+ species in the electrospray mass spectrum of a Cu(II) salt in acetonitrile is in accord with known copper solution chemistry in acetonitrile. The existence of Cu^+ in acetonitrile is due to the exceptional ease of reduction of Cu(II) to Cu(I) and the exceptionally high stability of Cu(I) in that solvent. The presence of $Cu(DMSO)_n^+$ has been assigned a gas-phase reduction of $Cu(DMSO)_m^{2+}$ [2]. While we do not have sufficient information to assess the relative importance of gas-phase versus solution-phase contribution to the $Cu(DMSO)_n^+$ ions observed in Figure 2(a), one general conclusion on gas-phase charge reduction of the type $M(aprotic\ solvent)_m^{n+}$ to $M(aprotic\ solvent)_p^{(n-1)+}$ seems clear: this is not significant; even for copper (II), where reduction to copper (I) is relatively easy, the contribution from gas phase is still minor (compare Figure 2(a) and (b)).

A series of experiments were performed in which an aqueous metal salt solution of was sprayed into an atmosphere containing a second, more strongly complexing solvent vapour introduced by direct

liquid evaporation. When the solvent in the vapour form was considerably stronger than water (e.g. DMSO), the electrospray mass spectra would look similar to those of the salt dissolved in the stronger solvent. The species observed were the results of a gas-phase solvent exchange reaction, which could prove analytically useful as a means to preserve original solution species information that would otherwise be distorted. For example, spraying of an aqueous solution of LaX_3 in an atmosphere of DMSO preserves the La^{3+} for detection. Further work is needed to endorse the effectiveness of this approach; preliminary results, however, are encouraging.

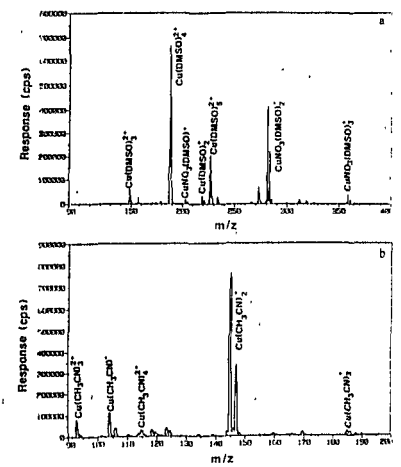

Figure 2

Protein Titration Curves Measured by Electrospray Mass Spectrometry

*Michele Kelly and Catherine Fenselau, Department of Chemistry and Biochemistry, University of Maryland, Baltimore County, Baltimore, MD 21228

Electrospray spectra of both cations and anions have been measured for equine myoglobin, bovine α-lactalbumin, and hen egg white lysozyme, infused in solutions with pH values across the range 2.5 to 11. Both positive and negative ions could be detected at all pH values where the proteins could be dissolved. As in other studies, the ranges of the charge states reflect functional groups in the proteins, and also folding or extension of the protein.

Horse heart myoglobin, bovine α-lactalbumin and hen egg white lysozyme were obtained from Sigma Chemicals (St. Louis, MO) Positive ion spectra for lysozyme were obtained in deionized and redistilled water with the pH adjusted from 2.5 to 11. Reduction of lysozyme's disulfide bonds was performed by adding a ten-fold molar excess of dithiothreitol to the lysozyme solution, and ions of both signs were recorded from a 50% methanol solution at pH 4. Positive and negative ion spectra of α-lactalbumin and myoglobin were obtained in deionized and redistilled water containg 50% methanol. Solutions were made acidic with glacial acetic acid and basic with 30% ammonium hydroxide. Protein concentrations were 100 μM unless the limit of solubility was below this value, in which case the solutions were saturated. Electrospray mass spectrometry was performed on a Hewlett Packard 5988A (Palo Alto, CA) quadrupole mass analyzer fitted with a Vestec (Houston, TX) electrospray source and a Phrasor (Duarte, CA) high energy dynode detector. Measurements were confirmed using ionspray mass spectrometry on a Sciex API III (Thornhill, Ontario), triple quadrupole instrument. All samples were infused using a Harvard (South Natick, MA) syringe pump at a flow rate of 3 or 5 μL/min.

Electrospray spectra were obtained of anions and cations of equine myoglobin (pI = 7) at pH 3.5 and at pH 10.0. Experimentally, the heme attachment is prominent in both cationic and anionic spectra when sprayed from solutions originating from basic pH. This is expected because the heme noncovalently attaches to the protein in its folded state at basic pH. Cationic and anionic spectra were subsequently obtained for myoglobin at all pH's where the protein was soluble (Figure 1).

The titration curve of bovine α-lactalbumin (pI = 5) also shows results obtained in both cation and anion modes over the pH range studied. The maximum charge state in each sign observed at each pH value and the charge state of the most abundant ion are plotted in Figure 2. A calculated curve depicting the expected protein net charge in solution has been superimposed on the experimental data.

A different situation is seen in the case of lysozyme where the tertiary structure is essentially maintained over the pH range studied. Thus, only positive ion spectra of native hen egg white lysozyme (pI = 11.0) were obtained from pH 2.5-10. Lysozyme contains very few acidic amino acid residues, 9, which may be inaccesible since no anionic spectra were obtained for the oxidized protein.
In order to test this hypothesis, lysozyme was reduced with dithiothreitol and infused from a solution at a pH of 4.0. A positive ion spectrum reflected the greater accesibility of basic amino acids with the maximum charge state shifting from 13+ to 17+ charges. An anionic spectrum of the same solution yielded a maximum of 10- charges, which is the maximum expected from 9 acidic residues plus the carboxyl terminus. This experiment illustrates again that both positive and negative ions can be formed, irrespective of the pH of the infusion solution, and suggests that even functional groups of the "wrong" sign (anions at pH 4) must be accessible to the solvent to be charged in electrospray.

These studies carried out with both thermally-assisted and nebulization-assisted electrospray sources show that both positive and negative ions can be formed by this technique, regardless of the pH of the infusion solution, and suggest that the polarity of the field is considerably more important in determining the sign of the ions detected than the titration in solutions of individual functional groups. This understanding will enable the analysis of unknown samples in either polarity at whatever the optimal solution conditions are for the protein of interest.

INTRODUCTION

Ethylenediaminetetraacetate (EDTA) is a powerful chelating agent, being widely used for the removal of metal ions interfering with industrial processes, e.g. photographic developing, paper production and textile dyeing. Because EDTA is hardly removed by waste water treatment, the resulting release into the aquatic environment potentially causes the mobilization of heavy metals bound to solid surfaces[1]. For this reason, determination of the processes that control the fate and behavior of EDTA in the environment is crucial. While the rate of biodegradation of EDTA is too slow to provide removal during biological sewage treatment, photodegradation of the Fe^{III}-EDTA complex occurs with a half life of 4 to 12 hours. EDTA degradation products have been measured by GC-MS[2], after formation of the N-trifluoroacetyl-n-butyl esters. Direct detection of the complex requires desorption ionization methods that work well with polar compounds, such as fast atom bombardment (FAB)[3] or electrospray ionization (ESI).
The mechanism of photodegradation is not yet fully understood. *Lockhart and Blakeley* found that the subsequent loss of $\{CH_2COO\}$ is the major pathway at low pH. The question arises, whethere the degradation involves Fe^{II}. The investigation of the mechanism of degradation is aimed at clarifying the role of iron in the degradation of this complex.

METHODS

The Fe^{III}-EDTA complex was formed by mixing equal amounts of equimolar aqueous solutions of $FeCl_3$ and Na_2EDTA. Concentrations were 10^{-3}M and the pH 2.5 during irradiation. The mixture was kept under synthetic air at 25°C and exposed to light from a Xenon lamp, with a power of 200 Watt. Aliquots were taken at 20 min intervals.
All samples were run on a Finnigan TSQ700, fitted with an Analytica electrospray source. The samples were diluted 1:1 with methanol, containing 10% acetic acid and then infused directly at a flow rate of 2µl/min. The voltage applied to the needle was -4.3 kV, the curtain gas was kept at 70°C and the multiplier at 1.4 kV. Scan time was 1 s over a mass range of 10 - 450 d. All solvents used were HPLC-grade and the chemicals were purchased from Merck, Darmstadt.

RESULTS AND DISCUSSION

The Fe^{III}-EDTA complex absorbs at 258 nm (pH 4). The concentration of formaldehyde, the end product of the degradation, increases with time (figure not shown). In figures 1 and 2, the degradation was followed by ESI/MS. Figure 1 represents the unexposed mixture (time 0), while Figure 2 was acquired after 100 min of exposure to the light of a Xe-lamp (200 Watt). The signal at m/z 346 corresponds to Fe^{III}-EDTA + $2H^+$. M/z 309 is an unknown contaminant in the ion source. With time, m/z 346 decreases, while the signals at m/z 56, 73, 115, 263, and 287 increase. Tentative assignments relate m/z 73 to $Fe^{II}OH$, m/z 115 to $Fe^{II}Ac$, m/z 263 to the loss of CH_2O from EDTA and m/z 287 to the loss of $\{CH_2COO\}$ from the Fe^{III}-EDTA complex. The signal at m/z 56 could be Fe^{I} generated through redox reactions. The problems encountered for the interpretation of these results are caused partially by the unclear role, which Fe^{II} plays in the photodegradation and by the fact that the ESI source can induce redox reactions. Even though the loss of only one $\{CH_2COO\}$ group could be seen, electrospray still has a great potential for the investigation of a complex system like Fe^{III}-EDTA. Accurate mass determination and MS/MS experiments should further the understanding of this system.

Characterization of Cationic, Anionic, and Nonionic Surfactants by Positive and Negative Ion Electrospray Ionization Mass Spectrometry

G. J. Harvey and J. C. Dunphy, The Procter & Gamble Company
Sharon Woods Technical Center, Cincinnati, OH 45241

Introduction: Synthetic surfactants are ideally suited to analysis by electrospray ionization mass spectrometry as they are polar, ionic, and non-volatile. Traditional methods of surfactant analysis have involved complex derivatization reactions followed by gas chromatography; or non-specific titrimetric methods. Fast-atom bombardment mass spectrometry has greatly simplified surfactant characterization but still suffers from discrimination effects in the analysis of mixtures of surfactants, and those with widely differing alkyl chain lengths. In this work we have determined that electrospray ionization (ESI) mass spectrometry can be used for the rapid analysis of ionic, nonionic, and zwitterionic surfactants including mixtures of different types, for unique applications in industrial problem-solving.

Experimental: A Finnigan TSQ-700 mass spectrometer and data system was used for electrospray ionization using the Finnigan ESI source. A Harvard syringe pump was used to provide a constant flow (infusion) of analyte at 0.5-2 uL/min into the source. Sample preparation involved diluting the raw material and or the finished products in the electrospray solvent. For fast-atom bombardment (FAB) analysis, a Finnigan 4500 mass spectrometer equipped with a Xe FAB gun was used. Typically for FAB analysis, solvents were removed from the sample prior to analysis and the sample was taken up in glycerol.

Results & Discussion:
Conditions for Analysis: In a survey study, several surfactants, each representing a different surfactant class, was analyzed by ESI/MS in the infusion mode, to determine optimal experimental conditions for analysis in both positive and negative ion modes. Below is a table indicating those conditions:

Surfactant Type	Mode	Needle Voltage	Bath gas	Solvent(s)	Ions observed
Anionic	-	-(3-4) kV	O_2	alcohol/H_2O	A^-
Anionic	+	+(2-3) kV	N_2	alcohol/H_2O	$(A^-)2(C^+)$
Cationic	+	+(2-3) kV	N_2	alcohol/H_2O	C^+
Nonionic	+	+(2-3) kV	N_2	alcohol/H_2O	$(M+Na)^+$
Zwitterionic	+	+(2-3) kV	N_2	alcohol/H_2O	$(M+Na)^+$

In summary, we have found that the positive ion mode is more robust and more sensitive than the negative ion mode. While we have been successful in using combinations of methanol/water, acetonitrile/water, and IPA/water up to 80% water for ionization we have found that IPA/water is optimum for most surfactants. Detection limits in the positive ion mode are in the high femtogram range. Finally, in most cases, no fragmentation is observed (in contrast to FAB mass spectrometry).

ESI/MS in Industrial Problem-Solving: For certain applications, ESI/MS serves very well for the analysis of surfactants in products, especially for mixtures and in competitive product finger-printing. The relative lack of discrimination effects makes this possible. For example, routine FAB/MS analysis of a hard surface cleaner formulation (Figure 1) revealed the presence of a zwitterionic with a cocoamidopropyl hydrophobe (fragment ions at m/z 240, 268, 296). No molecular ions were observed. However, the ESI mass spectrum (Figure 2) contains $(M+Na)^+$ ions, identifying the hydrophilic portion of the surfactant as a hydroxysultaine. In addition, the ESI/MS revealed the presence of an unexpected alkylethoxylated nonionic ($(M+Na)^+$ ions at m/z 493, etc.), not detected in the FAB spectrum. Further ESI work revealed that the nonionic was a minor constituent in one of the raw materials.

Conclusions: ESI/MS can be easily applied to the rapid characterization of many surfactant types, and mixtures of surfactants, with virtually no sample preparation. In some cases more information is obtained than can easily be obtained with FAB/MS. We are continuing to probe quantitative flow-injection and LC/MS applications for trace surfactants in complex matrices, such as environmental samples.

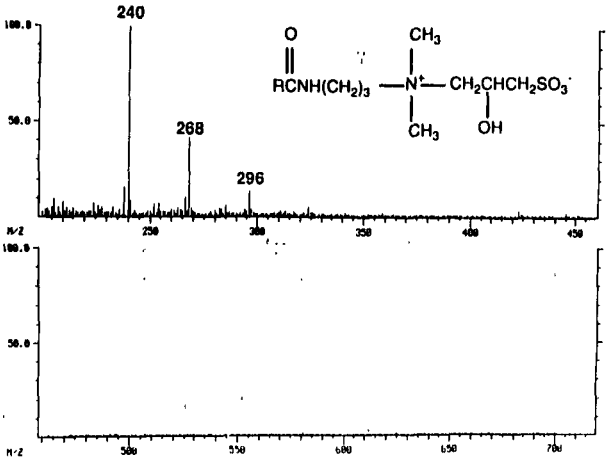

Figure 1. Positive ion FAB mass spectrum of cleaner formulation, showing fragment ions characteristic of a cocoamidopropyl zwitterionic surfactant.

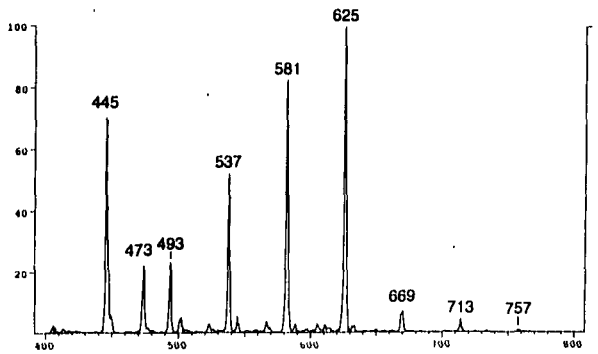

Figure 2. Positive ion ESI mass spectrum of cleaner formulation, showing sodiated adducts of the cocoamidopropylhydroxysultaine surfactant (m/z 445, 493), and sodiated adducts of an unexpected alkyl ethoxylated nonionic (m/z 473, 537, etc.).

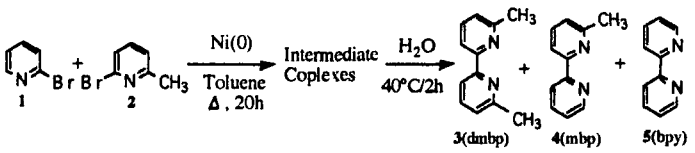
Study of Mixed Coupling Reaction of 2-Bromopyridine and 2-Bromo-6-methylpyridine with Raney-Nickel by ESI-MS

Yunhui Wu and Stephen R. Wilson
Department of Chemistry, New York University
4 Washington Place, New York, N.Y. 10003

Transition metals such as Cu, Ni and Pd have been widely used for a long time for the reactions of diaryl coupling. Recently, during our research study on syntheses of bipyridyl-transition metal complexes, we attempted to carry out the Raney-nickel coupling reaction for the synthesis of 6-methyl-2,2'-bipyridyl. With the help of our newly established ESI-MS source, we were able to follow the reaction by detecting the intermediates and the products. It turned out that ESI-MS can be used very efficiently for studying reactions involving metal ions, and even possibly supply some important information about the mechanism.

In our mixed coupling reaction, we used stoichiometric amount of 2-bromo-pyridine (**1**), 2-bromo-6-methylpyridine(**2**) and degased Raney-nickel and conducted the experiment under the same condition as reported[1].



We have observed that the mixed couplig reaction has much more than expected three intermediates. There are at least eight complexes formed as intermediates as shown below.

$(bpy)NiBr_2$	$(mbp)NiBr_2$	$(dmbp)NiBr_2$
6	**7**	**8**
$(bpy)_2NiBr_2$	$(bpy)(mbp)NiBr_2$	$(mbp)_2NiBr_2$
9	**10**	**11**

$(mbp)(dmbp)NiBr_2$	$(dmbp)_2NiBr_2$
12	**13**

The ESI-MS spectrum of the solid intermediate is shown in Figure **1**. Although the spectrum looks complicated, however all the peaks are from the above intermediates. Under high repeller voltage(50 V), the ESI-MS spectrum becomes simpler (Figure **2**).

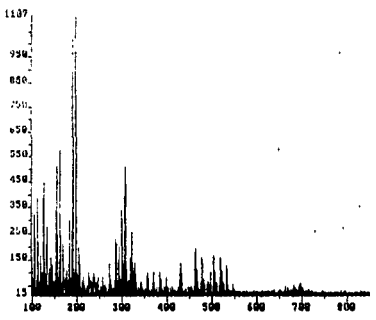


Figure 1. ESI-MS spectrum of the intermediates in CH_3CN under nomal condition[2](repeller voltage = 20 V)

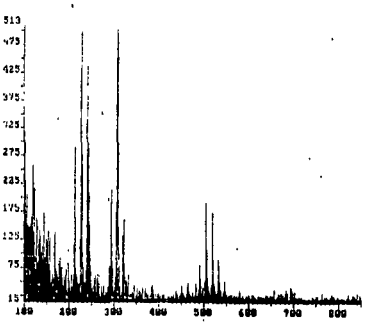

Figure 2 ESI-MS spectrum of the intermediates in CH_3CN under the same condition as Figure 1 except the repeller voltage= 50 V

The formation of complexes **9-13** may suggest that even for the simple coupling reaction there could be more than one intermediate. Besides,under high repeller voltage the reduction of Ni^{2+} to Ni^{+} during the electrospray ionization process[3] needs to be further investigated although same phenomenon occurs in other types of ionization processes such as fast atom bombardment[4].

Solvent Effects in Negative Ion Electrospray Mass Spectrometry

A. Kamel Harrata and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148

Progress in negative ion electrospray mass spectrometry (ESMS) has not occurred at the same pace as that of positive ion ESMS work. A major difficulty which has hampered advances in the negative ion mode is the aggravated problem of electrical (corona) discharges presumably caused by electrons emanating from the metal capillary held at a few thousand volts negative, relative to a counterelectrode. In our case, this counterelectrode is a converging nozzle which separates the ionization chamber (at atmospheric pressure) from the first pumping region of the mass spectrometer.

This study has investigated the effects of different chlorinated solvents on negative ion signals in ESMS. Specifically, we have investigated the manner in which a series of chlorinated solvents (i.e., 1,2-dichloroethane, dichloromethane, chloroform, and carbon tetrachloride) affect the electrospray onset voltage, discharge behavior, analyte signal intensity, and the propensity to form multiply-charged ions in the negative ion mode.

If experimental conditions such as the outer radius of the metal capillary, the distance between the capillary and the counterelectrode, and the permittivity of the vacuum are held constant, then, according to the equation of Smith[1], the onset voltage will be proportional to $\gamma^{1/2}$, where γ is the surface tension of the solution. Using dipalmitoyl-L-α-phosphatidic acid as the test analyte dissolved in 10% methanol and 90% chlorinated solvent (selected from the above list), no significant difference between electrospray onset voltages was observed for the solvents studied (Fig. 1a). From Smith's equation, the variation in onset voltages is expected to be only a few percent. In fact, the small differences in measured onset voltage values are comparable in magnitude to the experimental error in determining individual measurements.

In monitoring the corona discharge onset for each solvent, a general trend indicating increased discharge suppression with increasing percent weight of chlorine in the solvent has been observed (Fig. 1b). Repeating the above experiments in the presence of the electron scavenger gas sulfur hexafluoride (SF_6) leads to higher values for the corona discharge onset for all solvents (Fig. 1c). Unlike the situation where no electron scavenger gas is used, in the presence of SF_6, the corona discharge onset occurs at voltages which are are quite similar for all the solutions examined, indicating a discharge suppression capability of the SF_6 gas which overrides the more subtle discharge suppression capabilities of the chlorinated solvents.

The intensity of the test analyte signal as a function of electrospray chamber temperature for each chlorinated solvent has been examined (Fig. 2). The highest signal was obtained using chloroform as the solvent. Maximum signal intensity was achieved at chamber temperatures near 50°C for all solvents studied (Fig. 2). The

1. Smith, D.P.H. *IEEE Trans. Ind. Appl.* (1986) IA-22, 527

influence of the various solvents on the negative charge state distribution has also been investigated using the disodium salt of 'cardiolipin' as the test compound. The ratio of the abundances of doubly-charged / singly-charged ions (i.e., intact molecules deficient in two vs. one sodium ions) changes dramatically depending on the solvent used. The ratio appears to descend with decreasing dipole moment of the solvent (Fig. 3). This result can be attributed to an increased capacity for solvation of ions by solvents having higher dipole moments.

The Relationship Between the Distribution of Pre-Formed Multiply Charged Protein Ions in Aqueous Solution and the Multiply Charged Ions in an Electrospray Spectrum

Roger Guevremont, K.W.M. Siu, J.C.Y. Le Blanc* and S.S. Berman, Institute for Environmental Chemistry, National Research Council of Canada, Montreal Road, Ottawa Ontario Canada K1A 0R6

The ions observed in electrospray mass spectrometry appear to originate from preformed ions in aqueous solution. In recent work we have investigated the speciation of metals in aqueous solution, and have considered the role of droplet evaporation in electrospray mass spectrometry. Preliminary results suggest that the ions are formed early in the ES process, and therefore the composition of the aqueous phase from which the ions are evolved more closely resembles that of the bulk solution than previously thought possible. The characteristic profile of multiply charged ions observed in the electrospray spectrum of proteins appears to originate from an array of pre-formed multiply charged protein ions in aqueous solution. An aqueous solution equilibrium model based on the pKa's of acidic and basic sites on proteins can be used to compare the distribution of ions in solution to the shape of the ion abundance profile in the electrospray mass spectrum[1]. The aqueous solution chemistry of several proteins is available from experimental data including pH titration data appearing in the literature[2-6].

Electrospray measurements were performed using a TAGA 6000E (SCIEX Inc., Thornhill, Ont. Canada) triple quadrupole mass spectrometer. To ensure reliable measurement of relative ion abundance data, the mass resolution was decreased from unit mass resolution to the extent that two or more measurements were taken near the apex of every peak. Samples were continuously infused at a rate of 20μL/min through a 100μm ID stainless steel capillary held at ±3.2kV. Stable operation of electrospray was achieved with the needle approximately 1.5 cm from the instrument orifice, and with a measured stable current of between 70 and 120 nA (positive ion mode), and between 1.0 and 1.6 μA (negative ion mode). Myoglobin (horse skeletal muscle), lysozyme (hen egg white), β-lactoglobulin (bovine milk), and pepsin (porcine stomach mucosa) were obtained from Sigma Chemical Co. (St. Louis MO, USA), and were used without further purification. The pH of solutions was adjusted with acetic or formic acid (positive ions) and piperidine (negative ions). All samples were prepared in methanol/water mixtures.

The distributions of ions in the positive ion electrospray spectra of myoglobin, lysozyme and B-lactoglobulin agree well with the distribution of ions in reported pH titrations of these proteins. The

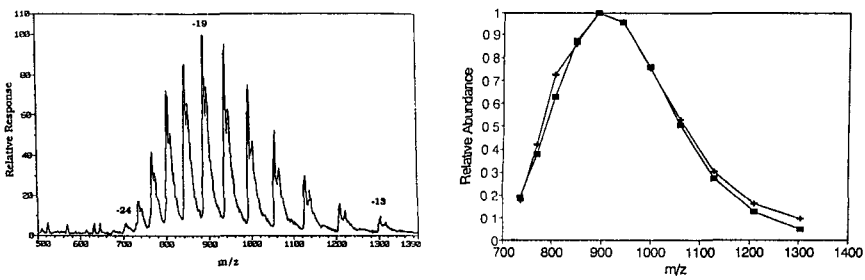

Fig. 1 (a) Myoglobin 20μM in DDW:Methanol:Piperidine (47.5:47.5:5) and measured pH of 11.00. (b) Ion abundance profiles of multiply charged myoglobin: ■ profiles calculated from aqueous solution equilibrium model, + experimental results.

pKa's of the individual acidic and basic sites of lysozyme have been reported[4,5]. Calculation of the distribution of positively charged lysozyme ions in solution matches well with the shape of the distribution of ions in the electrospray spectrum.

The distribution of ions in the negative ion ES spectrum of myoglobin, B-lactoglobulin and pepsin have been compared to the aqueous solution chemistry of these proteins. Other than for pepsin, the agreement is good. The spectra of pepsin appear to have anomalously wide ion distributions. It has been observed however, that with addition of dithiothreitol (which breaks disulfide bridges), and addition of urea (to the extent allowed in ES), the spectrum of pepsin gets progressively more narrow. Clearly the conformation of the protein plays a significant role (via electrostatic interactions) in the acid-base properties of the acidic and basic sites on the molecule, and thus leads to a modified distribution of ions in solution, and thus to a modified electrospray spectrum.

Analysis of cyanobacterial microcystin-LR toxin by on-line liquid chromatography electrospray ionization mass spectrometry

G.K. Poon[1*], C. Edwards[2], K.A. Beattie[2] and G.A. Codd[2]
[1]Drug Development Section, Cancer Research Campaign Laboratory, Institute of Cancer Research, Sutton, Surrey, UK. [2]Department of Biological Sciences, University of Dundee, Dundee, UK.

Most of the species of cyanobacteria (blue-green algae) which produce the annual blooms and scums, common in eutrophic lakes and drinking water reservoirs, are capable of forming potent toxins. Of these, the microcystins, a family of cyclic heptapeptides, have caused the deaths of domestic, farm and wild animals in many countries over several decades. Consumption of drinking water contaminated by the toxins can seriously affect human health and there is an interest in the tumor-promoting potential of the microcystins. Hence there is a need to detect, quantify and confirm the identity of these compounds for safety evaluation. Liquid chromatoraphy electrospray ionization mass spectrometry (LC-ESI-MS) is capable of fullfilling these criteria.

Experimental

Sample preparation for mass spectrometry: Toxic bloom material containing *Microcystis aeruginosa* was collected from Hartbeespoort Dam in South Africa in August 1987. The lyophilized cells were extracted twice in 5% acetic acid (0.5 g/50 ml w/v) for 30 min with continuous agitation. The extracts were centrifuged at 3,000 x g for 10 min. Both supernatants were pooled and filtered through a GF/C filter to remove particular material. The filtrate was applied to a preconditioned environmental C18 Sep Pak. The cartridge was washed with 20 ml 25% methanol and peptides were eluted with 100% methanol, concentrated *in vacuo* and the residues were retained for analysis.

Mass spectrometry: Purified toxins were dissolved in a mixture of methanol:water (50:50 v/v) containing 1% acetic acid. Each of these solutions were infused at 1 μl/min with a Harvard Apparatus infusion pump into a Finnigan TSQ 700 triple quadrupole mass spectrometer fitted with an electrospray source. Full scan spectra were acquired in the positive ionization mode.

Combined LC-MS: HPLC separation was achieved using a 150 x 1 mm microbore column packed with 5μm ODS material. The mobile phases were consisted of water and acetonitrile, both containing 0.1% acetic acid. A gradient elution was employed at a flow rate of 45 μl/min. The effluent was directed to a Valco tee splitter. One outlet was connected directly with a fused silica capillary to the UV detector fitted with a micro flow cell (2.4 μl volume, 6 mm pathlength). UV detection was at 240 nm. The other outlet was linked to the stainless electrospray needle. The split ratio was maintained at 11:1 (UV:MS) so that approximately 3.5 μl/min of the effluent entered the ESI source.

Results

Analysis of the peptide toxins has shown that compounds with molecular weights less than 1000 amu are more likely to give their intense singly charged protonated molecules $[M+H]^+$, whereas for toxins with molecular weights over 1000 amu, their corresponding doubly charged ions $[M+H]^+$ predominate.

A typical example of LC-ESI-MS analysis of bloom material collected in South Africa is described. The reconstructed ion chromatograms after LC-MS analysis are shown in Figure 1, indicating the presence of mcyst-YR (m/z 523 and 1045), mcyst-LR (m/z 995), mcyst-FR (m/z 515 and 1029), mcyst-WR (1069) and mcyst-RR (m/z 520). Their corresponding structures and the mass spectrum of microcystin-LR are displayed in Figures 2 & 3.

This report has demonstrated that LC-ESI-MS is a simple, reliable and sensitive analytical technique for detecting microcystin-LR and its analogues. This approach has unequivocally broadened the scope for determination of toxins from cyanobacterial natural bloom materials and cell culture extracts.

PRACTICAL CONSIDERATIONS FOR SUCCESSFUL ELECTROSPARY LC/MS

Paul C. Goodley, Alex Apffel and Steve Fischer
Hewlett-Packard Co., 1601 California Ave., Palo Alto, CA 94304

Electrospray Ionization techniques have shown to extend the use of mass spectrometry by providing significantly better sensitivity and most importantly extending the mass range of conventional mass spectrometers by factors of 30 to 50 times.

Electrospray Ionization (ESI) is a very powerful analytical tool and can be applied successfully to a broad range of compounds provided the following considerations are maintained:

1.) Accurate liquid flow control
2.) Careful flow configuration
3.) Consider the solution chemistry for the analytites
4.) Set the ESI needle configuration for desired ion mode
5.) Maintain a low volume liquid plumbing system

Many possible configurations for ESI exist as shown in Figure 1.

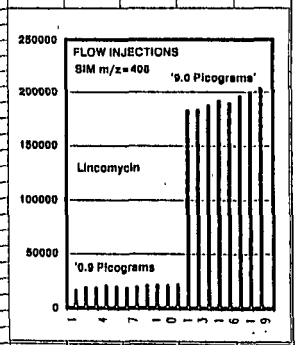

Figure 3. Flow injection analysis of Lincomycin at 0.9 and 9 picograms using SIM conditions

The needle configuration is often the key to successful ESI. The needle configuration must be determined based on the mode of analysis, the solution chemistry required and the flow rates to be used. In Figure 1, the upper configuration is used where high percentages of aqueous solution is required for solubility of compounds such as peptides, sugars or proteins. This configuration allows for the use of a sheath liquid and a focusing gas. The lower configuration is used more for higher flow rates (¢5uL/min.) and may be used as a sheath gas or a sheath liquid.

Excellent reproducibility can be obtained as shown in Figure 3, which is a series of flow injections made using the needle configuration shown in Figure 2. The flow rate was 17 uL/min. of methanol and water (50 /50). The peaks represent the raw area counts from a SIM experiment, of single manual injections of 0.9 picograms and 9.0 picograms of Lincomycin, an antibiotic. The reproducibility is shown in the table at less than 4%, demonstrating the goodness of the process.

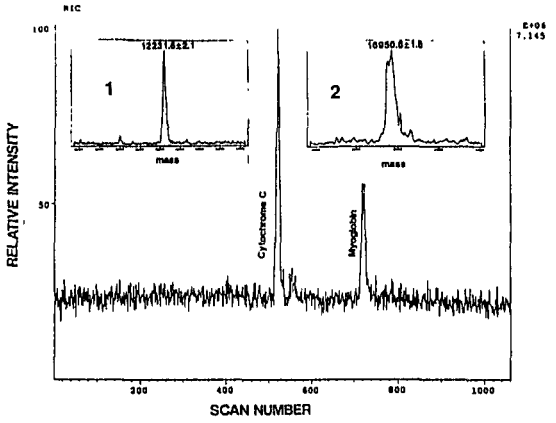
CAPILLARY ELECTROPHORESIS-ELECTROSPRAY MASS SPECTROMETRY: TRANSIENT ITP PRECONCENTRATION AND BUFFER EFFECTS

*Toni J.Thompson, Paul Vouros, Frantisek Foret, and Barry L. Karger, Department of Chemistry, Barnett Institute, Northeastern University, Boston, MA 02115

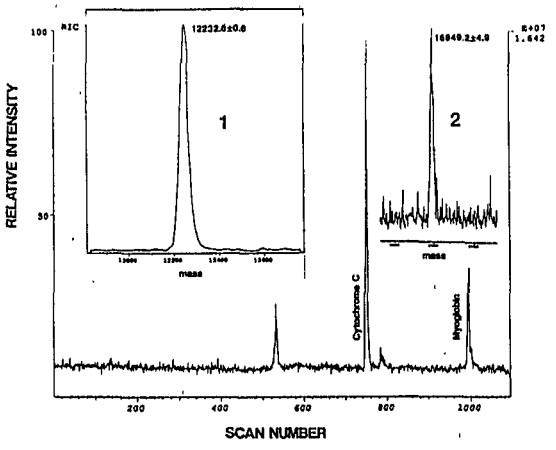
The goal of this work was to investigate the coupling of capillary electrophoresis with electrospray ionization (ESI) mass spectrometry (MS) for protein analysis. We first investigated capillary zone electrophoresis (CZE)-MS. A well known problem with this approach is the need to inject small volumes of large concentrations to obtain detectable peaks in the reconstructed ion current (RIC) electropherogram. We were able to observe seven proteins at only 10^{-5}M sample concentrations by CZE-MS. We then turned to capillary isotachophoresis (CITP) to improve the detection levels for the proteins. CITP allows large volumes of samples of low concentration to be injected on column. CITP-MS has disadvantages as well, however. The mass spectrometer cannot scan at the speed required to detect the narrow zones found with trace quantities of analyte. One may improve the separation by adding spacer compound(s) which have mobilities intermediate to those of the analytes. When attempting to analyze unknowns, this is at best difficult.

We therefore turned to transient ITP preconcentration as a technique which combines the advantages of both ITP and CZE in a single step. This technique focuses a large volume of sample injected into the column into a narrow zone. This narrow zone has a concentration approaching that of the background electrolyte (BGE). In this study, ammonium acetate buffer (0.02M at pH=4.4) was added to the sample. The ammonium ions are of higher mobility than the background electrolyte (BGE)(6-aminohexanoic acid). Therefore the ammonium acetate acts as a temporary leading electrolyte while the BGE acts as the trailing electrolyte. The ammonium ions move through the BGE due to their greater mobility and in a short time, the sample zone is surrounded by only BGE. At this time CZE separation occurs and the zones separate. This technique allowed the injection of 750 nL of sample onto a 50 cm X 75 μm i.d. capillary (filling about 30% of the capillary). The sample concentration was 10^{-7}M. The signal to noise ratio for this analysis was better than 30:1. Therefore, the detection level was improved by two orders of magnitude. It is important to note that transient ITP preconcentration can be applied to any interface system and is not limited to the instrumental conditions shown here.

An interesting feature evident in all RIC electropherograms containing ß-lactoglobulins and 6-aminohexanoic acid, was the presence of an additional peak in the deconvoluted spectrum at 130 *U* higher than the protein. The peak corresponded to a complex formed between the protein and the BGE. The charge states on the peaks which produce this deconvoluted peak are identical to those of the protein. This result indicates that possible complexation must be kept in mind in selecting the BGE to be used to optimize the analysis.



CZE-MS (full scan m/z 600 - m/z 2000) of 9.0μM cytochrome c and 4.5 μM myoglobin in the 6-aminohexanoic acid buffer and using a 50nL injection volume yielding an injected quantity of 430 fmol and 260 fmol respectively. The background electrolyte is 0.02M 6-aminohexanoic acid at pH=4.4.



CZE-MS (full scan m/z 600- m/z 2000) of 450 nM cytochrome c and 270 nM myoglobin in 0.01M ammonium acetate buffer and using a 750 nL injection volume yielding an injected quantity of 326 fmol and 195 fmol respectively. The background electrolyte is 0.02M 6-aminohexanoic acid at pH=4.4.

Atmospheric Pressure Ionisation Mass Spectrometry (API-MS) of Macrocyclic Antibiotics.

Duncan K. Bryant, Brian M. Stockton, and Frank Cottee.
SmithKline Beecham, Old Powder Mills, Tonbridge, Kent, England.

The use of atmospheric pressure ionisation mass spectrometry (API-MS) as a technique for mass analysis of biopolymers is now well documented[1]. It is now becoming increasingly clear that API-MS is also an excellent ionisation method for the analysis of smaller organic molecules, which are of interest to the pharmaceutical industry. We have analysed a number of highly functionalised macrocyclic compounds in the milbemycin class. One of these, namely moxidectin (Figure 1), is the subject of this study.

Ionspray Mass Spectrometry was performed on a Sciex API-III triple quadrupole mass spectrometer (Toronto, Canada). Chemical ionisation mass spectrometry of moxidectin gives little molecular weight information or structurally useful ions. However, pneumatically assisted electrospray or ionspray yields abundant pseudomolecular ions of moxidectin in both positive and negative ion modes. In positive ion mode protonated, ammoniated, and sodiated molecules are seen weighing 640, 657, and 662 Daltons respectively. For milbemycins which do not contain a nitrogen atom only an abundant ammoniated molecule is observed in positive ion MS. CID MS/MS produces fragment ions that are all protonated and are even electron species; hence even numbered ions contain 1,3,etc N-atoms, and odd numbered ions contain 0,2,etc N-atoms (Figure 1). The generation of aromatic fragment ions appears to be one of the major driving forces. MS/MS of ammoniated milbemycin species also yields protonated fragment ions.

Atmospheric pressure chemical ionisation (APCI), a technique not dissimilar to ionspray, has also been used to analyse moxidectin. However, clustering is more extensive and considerable fragmentation is observed, even at low orifice voltages. In general, we find that ionspray is a more versatile technique for analysis of organic molecules, although sensitivity is comparable.

MS/MS v In-source Fragmentation

Spectra obtained by CID MS/MS and in-source fragmentation are similar for moxidectin Spectra obtained by in-source fragmentation however, contain some additional peaks between 600 and 640 which are impurities in the sample as well as peaks arising from solvent clustering. To compare sensitivity a 10^{-6}M solution of moxidectin was used for analysis. For in-source fragmentation 6.3pmol was consumed in order to achieve a S/N ratio of 2 for the fragment ion at 528, while for MS/MS about 9pmol was required. However, at low analyte levels cluster ion formation at low mass (<300amu) can drown out all analyte signals in this region hence CID MS/MS is preferable.

Figure 2 shows extracted ion chromatograms plotted against (a) orifice voltage, and (b) collision gas thickness (CGT). It can be seen from Fig. 2a that the ammoniated molecule is very susceptible to in-source fragmentation and requires an orifice voltage of only 80V for almost complete fragmentation. The protonated molecule is less susceptible to in-source fragmentation while the sodiated molecule actually increases in abundance as the orifice voltage is increases suggesting that it does not fragment in the source at all. Also shown is an ion chromatogram of the major fragment ion, 528, which is maximised at about 85V and then decreases as the orifice voltage increases, presumably because it itself is fragmenting. Fig. 2b also shows the ion chromatogram of this fragment which maximises at a CGT of about 300×10^{12} molecules cm^{-2}. The absolute intensity of this fragment ion is considerably lower than that in the in-source fragmentation experiment (Fig. 2a) indicating that CID MS/MS is a somewhat less efficient technique for fragmentation compared with in-source fragmentation.

Acknowledgement: We would like to thank Dr. R. J Dorgan of SmithKline Beecham Animal Health for supplying moxidectin.

Characterization of Oligonucleotides by ESI/MS, LC/ESI/MS, and CZE/ESI/MS

M.A. Moseley and S.E. Unger, Department of Drug Metabolism,
Glaxo Research Institute, Research Triangle Park, NC 27709

Oligonucleotides are being evaluated for use as drugs which block the genetic message for the production of disease-related proteins (1). The target for these drugs is a specific nucleotide sequence on single stranded messenger RNA, which codes for the disease-causing proteins, or the double stranded DNA from which the messenger RNA is transcribed. These oligonucleotide drugs are comprised of a sequence of bases which is complementary to that of the targeted DNA strand, and thus they are referred to as *antisense oligonucleotides*. Due to their high molecular weights (10 to 25 bases, MW 3000 to 8000) and instability, the isolation and characterization of antisense oligonucleotides and their metabolites is problematic. For ESI/MS characterization of oligonucleotides (first reported by Covey, et al. (2)), the analysis of picomole levels of oligonucleotides has been shown to give accurate molecular weight measurements of oligonucleotides (up to 76-mers) (3) using quadrupole instrumentation, and ESI/MS/MS has been used for structure elucidation (4).

While constant-infusion analyses are sensitive and accurate, the results suffer when performed in the presence of other molecular species. For complex mixtures, such as a biological sample of antisense oligonucleotides and their metabolites, a separation step using LC or CZE is necessary, preferably on-line with the ESI/MS system. We have successfully applied reversed phase ion-pairing chromatography (using C18 LC stationary phases and 10 mM triethylammonium acetate (pH 7.0) ion-pairing buffer) to the on-line separation of mixtures of oligonucleotides, using both microbore LC columns (1 mm id, column flow rate 50 µL/minute, split 50:1 to ESI/MS) as well as nanoscale capillary LC columns (50 µm id, column flow rate 300 nL/minute, 100% to ESI/MS) (5) (Figure 1) . We have also successfully applied CZE/ESI/MS to the analysis of mixtures of oligonucleotides, giving separation efficiencies of over 200,000 plates from the analysis of less than 10 femtomoles of an oligonucleotide (Figure 2). Bare fused silica CZE columns (50 µm id, 1 m long) were used with 5 mM ammonium acetate buffer (pH 8.0). A Finnigan TSQ-700 triple quadrupole mass spectrometer was used for this work.

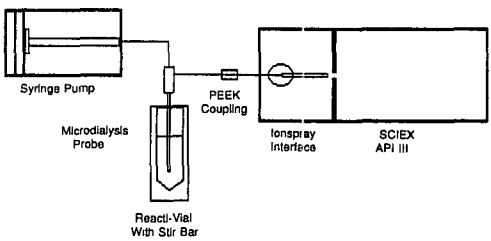
Microdialysis Sampling Combined With Ionspray Mass Spectrometry for On-Line Reaction Monitoring

Edward H. Kerns, Steven E. Klohr, Kevin J. Volk, Mike S. Lee, Ira E. Rosenberg, Bristol-Myers Squibb Pharmaceutical Research Institute, 5 Research Parkway, Wallingford, CT 06492

The microdialysis probe has been shown to be an advantageous apparatus for sampling fluids and living tissues (1). We have previously reported fundamental studies of an apparatus combining microdialysis sampling on-line with tandem mass spectrometry (MS/MS) via an Ionspray (2) interface or a thermospray interface (3) for the continuous monitoring of drugs in physiological fluids at the picomole level. A similar system may also be used for the continuous monitoring of micro-scale reactions. Model reactions involving the carboxypeptidase Y digestion of Substance P and [Lys^3]-Bombesin were studied. Reactants and reaction products were continuously sampled using a microdialysis probe and monitored by Ionspray MS.

An apparatus combining microdialysis and Ionspray mass spectrometry is shown in Figure 1. Microdialysis was performed using model CMA 10 microdialysis probes and a CMA 100 syringe pump from Bioanalytical Systems, West Laffayette, IN. Acetic acid (0.1%) was used for dialysis fluid at a flowrate of 5 µL/min. Substance P, and carboxypeptidase Y were obtained from Sigma. Peptides were dissolved at a concentration of 80 ng/uL in ammonium acetate buffer (50 mM, pH 6.0) with a final volume of 0.5 mL. Reactions were performed at 25 °C in a 1 mL Reacti-Vial equipped with a stirring bar. The CMA 10 microdialysis probe was coupled directly to the Ionspray interface of a SCIEX API III tandem quadrupole mass spectrometer. Reactions were initiated by the addition of carboxypeptidase Y to the buffered peptide solution.



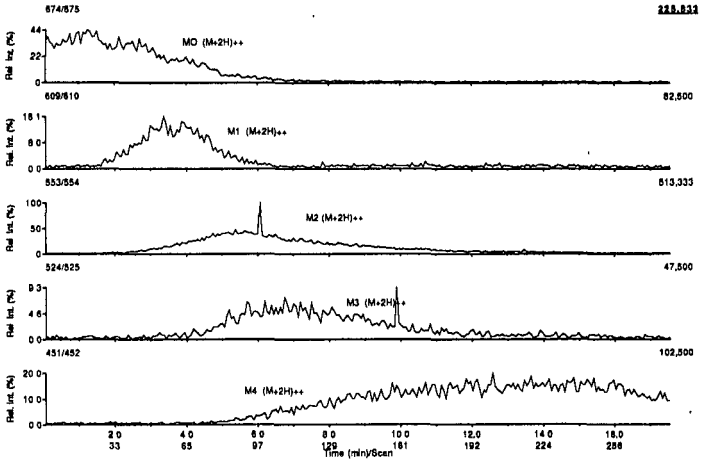
APPARATUS

FIGURE 1

Mass chromatograms of from the carboxypeptidase Y digestion of Substance P show the reactant (M0) and peptide products (M1-M4) in Figure 2. The carboxypeptidase Y digestion of [Lys^3]-bombesin has been similarly studied. The time-course of appearance and disappearance of reaction products and their structures provide insight into reaction kinetics and mechanisms. Microdialysis is an effective technique for sampling reactions in progress for several reasons. The microdialysis membrane separates reaction vessel and Ionspray ionization medium, permitting independent optimization of reaction conditions and MS ionization conditions. Also, the reaction proceeds with little disturbance due to the dialysis membrane separation. The microdialysis membrane also does not allow diffusion of enzymes, thus maintaining the concentration of enzyme in the reaction vessle. In addition, the characteristic flowrate of microdialysis (2-10 µL/min) is compatible with flowrates used for optimum performance of electrospray sources. Electrospray ionization is advantageous in this application for observing unstable or labile reaction intermediates or products. Using this technique reactions may be monitored in real-time without the need for sample storage and time-consuming HPLC separations. Continuous stirring of the reaction vessel enhances microdialysis and reaction efficiency.

FIGURE 2

APPEARANCE OF SUBSTANCE P DIGESTION PEPTIDES MONITORED BY ON-LINE MICRODIALYSIS / IONSPRAY MS



Future investigations will be conducted with smaller scale reactions using smaller reaction vessels, incorporating smaller diameter tubing and optimizing mass spectrometer sensitivity. Reaction monitoring on-line with microdialysis can be used to study kinetics and mechanisms of a range of enzymatic and organic reactions. On-line reaction research provides insights on short-lived or unstable intermediates. The broad compound response characteristics of mass spectrometry and the low energy ionization of electrospray make them applicable to study of a wide range of reactant and product types not readily observed using chromatographic techniques. MS/MS techniques may be used on-line with microdialysis for substructural analysis and screening.

A Comparison of Bovine β Casein Tryptic Digest Analysis using LC-Electrospray-MS and LC-Continuous Flow FAB-MS

D.Jones, M.Kimber and C.Moore

Kratos Analytical, Barton Dock Road, Manchester, M31 2LD, UK

Introduction

On-line analysis of complex biological mixtures is an area of great interest to biochemists. A number of liquid chromatography interfaces (such as Thermospray™ and particle beam) are available to the mass spectrometrist at the present time. However only two ionization techniques offer both an LC interfacial capability and suitable sensitivity for most biological materials. These are bombardment techniques such as FAB or LSIMS and electrospray. In this poster a comprehensive study has been conducted of these techniques, applied to the analysis of a tryptic digest of the protein, β-casein.

Experimental

Both electrospray and CF-FAB studies were performed on a Kratos I H mass spectrometer. ESP spectra were obtained by scanning from m/z 2500 to 100 at 3 seconds per decade. CF-FAB spectra were acquired from m/z 2750 to m/z 50 at 10 seconds per decade. In both cases, resolution was maintained at nominally 1000 (10% valley).

Much of the experimental detail regarding solvent systems used for LC-CF-FAB separation is the subject of a previous publication [1]. The LC separation and introduction system to the mass spectrometer was common to both studies.

For the electrospray investigation, tryptic components were separated using an acetonitrile/water/TFA gradient using a 1mm x 150mm ODS2 column with a flow rate of 50µl min^{-1}. An alternative separation using 0.05% formic acid in place of TFA was used in other parts of this investigation. Post column addition of 50µl min^{-1} of acetonitrile was found to be beneficial for electrospray work.

The β-casein (Sigma Chemical Co.) was digested in 100 mM tris buffer at pH 8.5. Trypsin (Boehringer Mannheim) was activated with 0.01% trifluoroacetic acid and added to the protein such that enzyme to substrate ratio was 1:100. Digestion was achieved by incubation at 37° for 4 hours. The reaction was quenched using 1% TFA and analysed without further treatment.

Results

Much of the data associated with the CF-FAB/LSIMS analysis of β-casein has already been presented[1]. Peptides identified during that analysis are summarised in Table 1. Some of the electrospray results are presented here with a summary of identified peptides also included in Table 1.

Electrospray ionisation (both loop injection and LC-ESP-MS) enabled several components to be easily identified from prominent protonated molecular ions. The preferred solvent for these separations was the previously described water/acetonitrile/TFA gradient system. However we found that this suppressed spectra from some of the lower molecular weight peptides. For instance, with this solvent, the most prominent peptides observed in the total ion chromatogram were from the late eluting higher molecular weight components. Most of these have been identified.

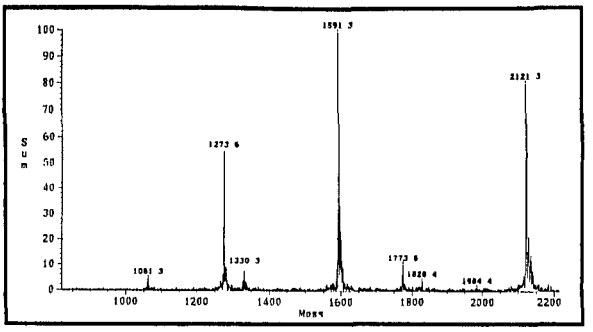

Figure 1: Mixed ESP spectrum from co-eluting high mass peptides

The final peak observed in the chromatogram consists of two co-eluting peptides of molecular weight 5319 and 6362. These are both expected tryptic components, predicted from the proposed structure of β-casein. The mixed spectrum is shown in Figure 1. When deconvoluted using MACH 3 electrospray processing software, this is simplified to the spectrum shown in Figure 2, the molecular ions can be seen clearly. Interestingly, these spectra were only observed with this solvent system. Repeated attempts with formic acid and acetic acid separation failed to reproduce a satisfactory spectrum of these peptides. On the other hand, better sensitivity for lower molecular weight components was observed when TFA was excluded from the solvent system.

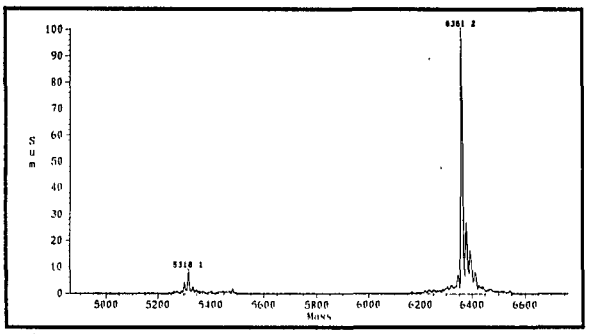

Figure 2: De-convoluted mixed ESP spectrum from co-eluting high mass peptides

Conclusion

CF-FAB/LSIMS and electrospray are complementary techniques. For low molecular weight species, CF-FAB appears to exhibit better sensitivity and yields simple spectra with easily interpreted fragmentation patterns. However, sensitivity is limited for the higher mass peptides (m/z > 2000). In this case electrospray is the preferred method of analysis. Electrospray mass measurement accuracy for higher mass components is excellent when deconvoluted from the multiply charged ions, despite the limited number of scans across the chromatographic peak. The charge distribution for some larger tryptic fragments lies at relatively high mass indicating that scanning experiments should still be performed over a fairly wide mass range (2,500 to 100).

Microbore HPLC/Electrospray MS in Metabolic and Clinical Investigations

Cathy Kletke, Esther Roitman, Francis Bitsch and Cedric Shakleton
Children's Hospital Oakland Research Institute, Oakland, CA 94609, USA

While ESMS is most widely known for its use in protein and peptide analysis, Henion and co-workers have demonstrated its efficiency for the analysis of small molecules, *e.g.* steroid sulfates[1].

Until now TSP/LCMS has been in routine use in our laboratory in clinically diagnostic tests and for stable isotope metabolism studies. This technique with its large solvent flow rates is essentially insensitive so we have been adapting our methods to improve sensitivity through use of microbore HPLC/ESMS. Our HPLC system is composed of a Michrom HPLC with Vydac C_{18} 1x150 mm column operated at 40 µl/min. The solvent system was water containing 10mM of ammonium acetate, methanol and/or acetonitrile. The HPLC is interfaced with a VG BIO-Q Electrospray mass spectrometer and the column eluent is split 10:1 allowing a flow-rate of 4 µl/min to be analyzed. The probe design allows a solvent make-up. Typically, 2µl/min of acetonitrile are added to the eluent prior to nebulization.

We have found that our compounds of clinical interest (cholesterol sulfate, androstanediol glucuronide, glycyrrhetinic acid) give negative ion spectra essentially identical to those given by TSP; spectra dominated by the molecular anion $(M-H)^-$.

The sensitivities achieved by HPLC/ESMS using Selective Ion Recording are comparable to those obtained by GC/MS. Figure 1 shows the HPLC/SIR traces of the molecular anions of three androgen steroid glucuronides. The amount injected was 15pg for each glucuronide. The measurement of steroids in urine and plasma can give many informations on disorders of steroid synthesis and metabolism. We have used HPLC/ESMS using SIR for the quantification of the different metabolites of tetrahydrocortisone and detection of an enzyme defect in patients with apparent mineralocorticoid excess syndrome (AME).

SIR was also used for the quantification of cholesterol sulfate in plasma, an indicator of a deficiency of steroid sulfatase. This deficiency is responsible for recessive X-linked ichthyosis[2].

Sulfamethoxazole acetate is an analyte we determine in metabolic probe studies following pg

administration of ^{13}C labelled acetate and sulfamethazole. We routinely quantify the $[M-H]^-$ and $[M+1-H]^-$ ions (*m/z* 294 & *m/z* 295, *respectively*) by HPLC/TSP MS to determine the isotope incorporation. Preliminary data demonstrate that isotope incorporation can be determined by HPLC/ESI MS with an accuracy comparable to that achieved by the existing HPLC/TSP MS technique[3].

HPLC/ESMS was shown to be a method of choice for sensitive, fast and reliable analysis of various compounds of clinical interest. Analysis was rapid since no hydrolysis or derivatization of drug metabolites was necessary.

Capillary Electrophoresis / MS and MS / MS of Peptides and Drugs

Iain Mylchreest , Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

The analysis of small peptides and small polar drugs is demonstrated using the combination of capillary electrophoresis and mass spectrometry (CE/MS). The interface between the two techniques utilizing an electrospray source and the sheath flow method previously described[1]. The work described uses a bare fused silica column, 50 um i.d. and 60 cm in length. The analytical buffer in all cases was 0.05 M acetic acid and this work demonstrates the surprising utility of this simple system for the separation of a variety of compound classes. The sheath liquid used throughout this study was optimized at 60/40 isopropanol/water 1 % acetic acid with a flow of 2-3 ul/min.

The performance of the system is demonstrated with the sequential electrokinetic injections of ile-ser-bradykinin (M=1260) showing that detection limits in a full scan mode are easily obtainable below 50 fmol actually injected.

Simple separations of small peptides are shown with the analysis of a series of bradykinins and met and leu enkephalin injected at levels of 70 to 130 fmol, all the components giving good response in the RIC and producing standard electrospray type spectra.

The ability to perform automated MS/MS experiments is demonstrated with this mixture, providing CE/MS/MS daughter ion sequence information on the leu-enkephalin at the 70 fmol level. A series of ten angiotensin peptides is also separated at the 200 fmol level giving resolution of six peaks. The multiply charged spectra generated allowing elucidation of the respective co elutions.

Capillary electrophoresis is not only limited to the analysis of biological samples and simple separations of the sulfonamide drugs is shown along with CE/MS/MS of these compounds allowing structural information to be elucidated from low picogram amounts of material injected.

The analysis of real plant extracts by CE/MS is shown for the indole alkaloids from the plant Catharanthus roseus. Resolution of at least 18 components is seen. The most important being a series of dimeric indole alkaloids from the Vinblastine family (M=810) which are important anticancer drugs found in very low levels in the plant leaves. The ability to analyze these types, and low levels of compounds in complex matrices demonstrates the potential analytical use of CE/MS and MS/MS for similar applications involving small polar drugs in complex matrices.

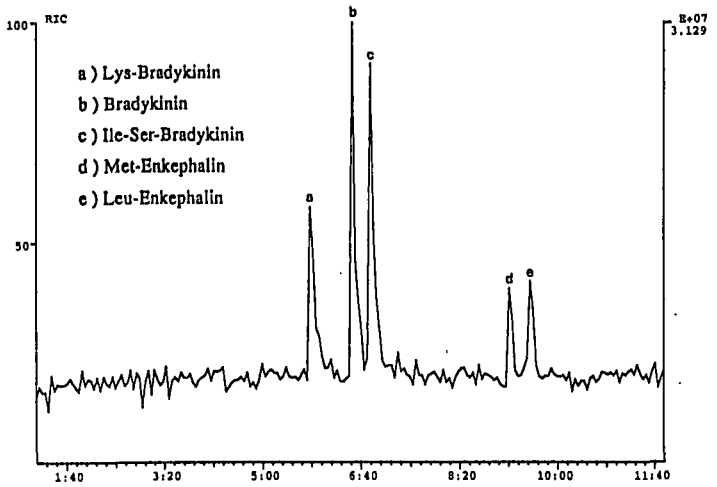
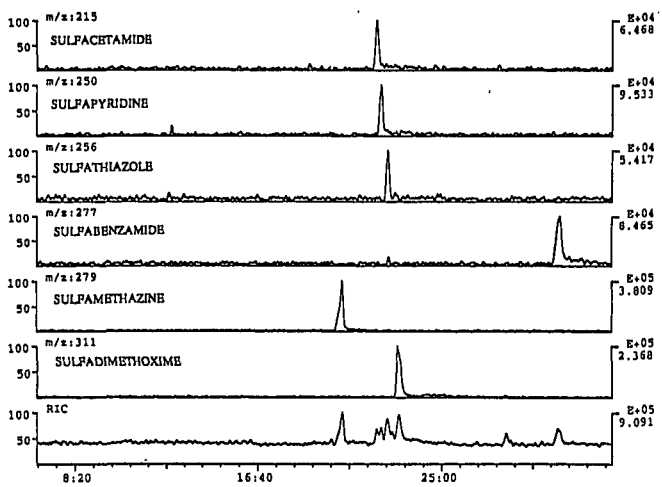
CE/MS OF SMALL PEPTIDE MIXTURE (70 - 120 FMOL INJECTED)



CE/MS OF SULFONAMIDE DRUGS WITH MASS CHROMATOGRAMS OF THE MAJOR COMPONENTS



ASSESSMENT OF METALS IN A METALLOPROTEIN BY ELECTROSPRAY MASS SPECTROMETRY

Xiaolan Yu, Marek Wojciechowski, Catherine Fenselau
Department of Chemistry and Biochemistry, University of Maryland
Baltimore County, Baltimore, MD 21228

INTRODUCTION: Metalloproteins are involved in many biochemical processes. The metals they bind and the number of metal ions bound are often crucial to maintaining three dimensional structures and proper functioning. We have evaluated ESMS for analysis of metal ions coordinated by metalloproteins, using a rabbit liver metallothionein[1] (molecular weight ~7000), which naturally binds mixtures of up to 7 Cd and Zn dications. We demonstrate that ESMS can be used to determine how many and which cations are chelated per molecule of protein, and also the molecular distributions and relative abundances of various complexes in the sample.

METHODS: Rabbit liver metallothionein 2 (MT-2) purchased from Sigma was first demetallated and then purified by reversed phase HPLC to give apoMT-2a. The apoMT-2a was then reconstituted in 500 mM Tris/HCl buffer at pH 8.6 in an Ar-purged glove bag to give MT-2a with 7 equivalent of metal ions (Cd_7-MT-2a or Zn_7-MT-2a). Cd_7-MT-2a was also treated with pH 3.5 HOAc to yield Cd_4-MT-2a. Electrospray ionization mass spectrometry was performed on a Vestec electrospray source fitted to a Hewlett-Packard 5988A quadrupole mass spectrometer. Metal content determination was performed on a Varian AA-1475 atomic absorption spectrophotometer, using a Varian GTA-95 graphite tube atomizer.

RESULTS: The pH of the water/methanol solution used for electrospray was critical to successful analysis, since the protein is denatured and the metal ions are lost at pH below 3[2]. Consistent with the loss of tertiary structure, the apometallothionein was detected with its most abundant ions in a charge state of 6+ at pH 2.5, while the folded metallothionein complexes were observed with lower charge states (higher m/z value) at pH 4 (Figure 1 and 2). As clearly shown in Figure 1, ESMS can be used to determine how many and what cations are coordinated per molecule of protein, and also the molar distributions and relative abundances of various complexes in the sample. In this particular spectrum, we see metallothionein in a metal-free form, metallothionein with 4 Cd^{2+}, 5 Cd^{2+}, and 6 Cd^{2+} coordinated, with relative abundances at 10%, 81%, 5%, and 4%, respectively. In order to confirm the ESMS technique, we have also analysed these samples using graphite furnace atomic absorption which provides only net ratios of metal to protein. As shown in Table 1, ESMS results correlate well with that from atomic absorption in this study.

a Metal content is expressed as molar ratio (moles of metal per mole of protein).
b. Molar ratios are based on an average of two determinations. Uncertainties are calculated from five measurements in each determination.
c. Relative abundance is calculated from peak height. Uncertainties are estimated to be around 5 percentage points.

CONCLUSIONS: 1. Metallothionein-metal (Cd, Zn) clusters and possibly other peptides with Cys-metal complexes are stable and can be ionized and analysed by ESMS, under modified ES solvent conditions (pH 4 with acetic acid). 2. With essentially the same amount of sample but only one-tenth of the time required for graphite furnace atomic absorption, ESMS can determine molar distributions and relative abundances of various complexes in the sample, in addition to how many and what cations are coordinated per molecule of protein. We conclude that ESMS is a useful technique for qualitative and quantitative assessment of metals in metalloproteins.

ELECTROSPRAY IONIZATION MASS SPECTROMETRY AND ITS ENVIRONMENTAL APPLICATIONS

J. M. Long and L. J. Sears, Montana State University, Department of Chemistry and Biochemistry, Bozeman, MT 59717

INTRODUCTION

The electrospray ionization (ESI) source, designed and fabricated at MSU, shown in Figure 1, was installed on a VG TRIO quadrupole mass spectrometer. Analyte solution flow rate of ~2 μL/min is achieved by a syringe pump using a 1 mL-syringe barrel connected to a 20-cm length of 75-μm fused silica tubing attached to a stainless steel needle (129 μm i. d.). Progress is being made in using a gold-coated 50 μm fused silica capillary instead of the conventional stainless steel needle. Three to four kilovolts potential is applied to the needle and the resulting electric field produces a spray of charged droplets that undergoes a cascade of "Coulombic explosions" producing smaller and smaller droplets until the analyte is desorbed from solution. The spray is directed toward a resistively heated 22-cm stainless steel transport capillary (0.5 mm i. d.), held at a potential of 45-150 volts (v), through which the analyte ions enter the ESI source. The ions after leaving the transport capillary are focused through a set of five electrostatic lenses into the analyzer region of the mass spectrometer. These lenses and their potentials are: skimmer (+11 v), extractor (-16 v), focus 1 (+6 v), focus 2 (+11 v), focus 3 (-80 v), and focus 4 (-18 v).

Although ESI/MS is famous for its capability of analyzing high molecular weight molecules such as proteins and peptides in the 10,000-60,000 dalton range, this technique can also be used to analyze molecules in the lower molecular weight range of a few hundred daltons.

EXPERIMENTAL

Environmentally significant compounds (~100-500 daltons) such as pesticides/herbicides that are polar, nonvolatile and thermally labile are not readily analyzed by conventional gas chromatography/mass spectrometry (GC/MS). A viable alternative is ESI/MS. To date thirty pesticide/herbicide samples from the classes of carbamate, diquat, organochlorine, organophosphorus, phenyl urea, phthalimide and triazine have been analyzed using ESI/MS. Compounds analyzed are: Propoxur, Linuron, Diuron, Siduron, Coumafuryl, Diquat Dibromide, Methomyl, Warfarin, Chlorpyrifos, Glyphosate, Molinate, Carbaryl, Mexacarbate, Diphacinone, Amitrole, Rotenone, Antu, Ethion, Carbofuran, Endosulfan, Thiometon, Anilazine, Endothall, Folpet, Methidation, Chloramben, Phosfolan, Mephosfolan, Pyrethrins and Trifluralin.

The degree of parent ion fragmentation can be controlled by varying the potential difference between the transport capillary and the skimmer lens. Potential difference ~40-50 v produces predominantly the $(M+H)^+$ ions.

Although there are many important variables to consider in using ESI/MS choice of solvent system is one of the most important. The following pesticides were analyzed at selected transport capillary/skimmer potential differences in 50/50 mixture methanol/water, pure methanol, 50/50 mixture of acetonitrile/water and pure acetonitrile: Propoxur, Amitrole, Rotenone and Diphacinone. Shown in Figures 2a and 2b are total ion current as a function of capillary/skimmer potential difference for the first three solvent systems listed above.

RESULTS AND DISCUSSION

ESI/MS is a valuable technique for the analysis of environmentally significant compounds such as pesticides and herbicides. Two solvent systems that may used are a mixture of either methanol/water or acetonitrile/water. Total ion current appears to be in the same range in the methanol/water and acetonitrile/water systems and much lower for all four compounds run in pure methanol. Solvated

species in the acetonitrile/water system are more intense than corresponding ones occurring in the methanol/water system. No signal was obtained using pure acetonitrile. Sensitivities achieved on some of these compounds are in the picomole to femtomole range.

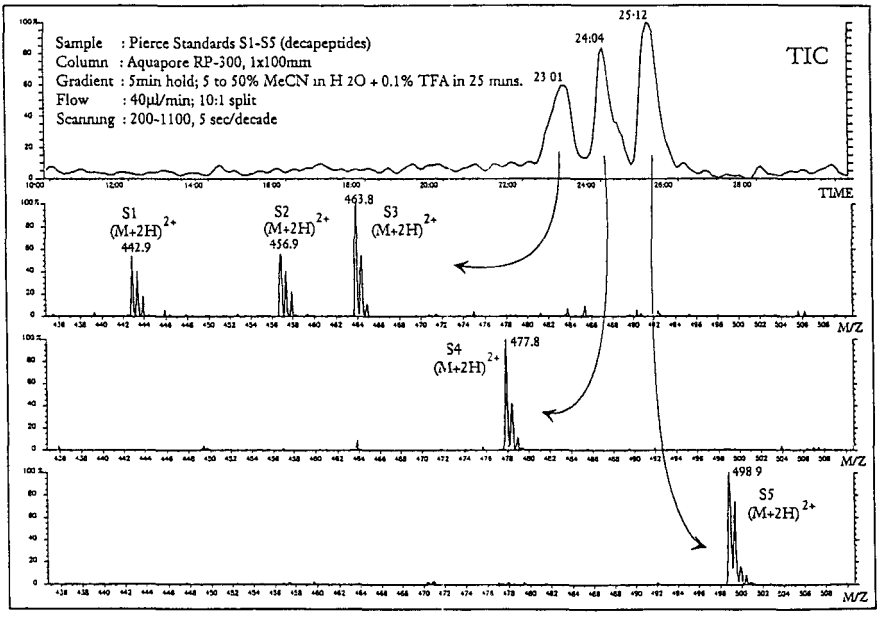
ELECTROSPRAY LC/MS ON A HIGH PERFORMANCE MAGNETIC SECTOR MASS SPECTROMETER

Woolfitt, A.R., Bateman, R.H., Major, H.J., Phillips, A.M., and Ley, I.J., VG Analytical, Fisons Plc., Floats Road, Wythenshawe, Manchester, M23 9LE, England.

An electrospray ion source has been designed and manufactured for a VG AutoSpec high performance double focusing magnetic sector mass spectrometer. It incorporates two differentially pumped intermediate regions between the atmospheric pressure chamber and high vacuum, and has been described previously (Bateman et al, Proc. 39th ASMS Conf. Mass Spectrom. Allied Topics 1991, 244-245).

The high resolution capability of the AutoSpec enables both charge determination for ions carrying as many as 10 charges, and, if suitable reference compounds are present, mass measurements with accuracies of within 3ppm to be achieved at flow rates of between 1 and 5 microlitres/minute.

The figure shows the results from an LC/MS analysis of a standard test mixture consisting of five decapeptides (Pierce S1-S5). A microbore gradient HPLC system operated at 40 microlitres/minute was coupled to the electrospray ion source via a low dead volume splitter (10:1 split, constructed from a ZDV tee and a length of fused silica). The peptides were observed primarily as their doubly charged ions, their charge state being clearly discernible from the isotope spacing.



The Use of Gaussian Curve-fitting to Model Electrospray Charge State Distributions

*Robert J. Anderegg and Greg King, Glaxo Research Labs, Research Triangle Park, NC 27709 and Sciex, Thornhill, Ontario L3T 1P2

Electrospray ionization mass spectra of large molecules are characterized by a series of charge states, representing the molecule of interest bearing multiple cations. Once the charge state of these ions is determined, each becomes an independent measure of the molecular mass of the macromolecule. Fenn noted that the distribution of these charge states was approximately Gaussian if the spectra were plotted as abundance vs. charge, rather than the more usual abundance vs. m/z (1). Other workers have suggested that the position of the charge-state distribution can be related to instrumental parameters or to the solution conformation of the protein (2-5). To date, changes in this distribution have generally been noted as qualitative observations or by listing the most abundant charge state or m/z value. In an effort to more easily characterize the charge state distributions of electrospray mass spectra, we are using a computer program to find the best-fitting Gaussian curve for the spectrum. The center (u) and standard deviation (s) of the Gaussian curve are reported and can serve as metrics by which to measure shifts in charge state distribution caused by instrumental or solution parameters.

Two methods of curve fitting were explored. Initially, the spectra were replotted as ln(abundance) vs charge using a commercial graphics program (CricketGraph). It is readily demonstrated that a Gaussian curve plotted in this way is described by a second order polynomial of the form:

$$\ln(a) = A + Bx + Cx^2$$

where a is the measured abundance, x is the charge, and A, B, and C are constants (6). The graphics program can compute best-fit values for A, B, and C, and return a correlation coefficient related to the goodness of the fit. The standard deviation (s) and the mean (u) of the Gaussian curve are then calculated using the relationships:

$$C = -(1/2s^2) \quad \text{and} \quad B = u/s^2$$

The second approach was to incorporate the curve-fitting directly into the software package for the Sciex mass spectrometer. As in the previous method, a mean, standard deviation, and correlation coefficient are reported. In cases where both methods were used on the same data, the results were comparable, although the CricketGraph approach was more time-consuming because of the additional data handling required.

Figure 1a shows an electrospray mass spectrum of the antiviral protein from pokeweed (Phytolacca americana) seeds, molec. mass 29 810, plotted in the usual format, relative abundance versus m/z. Figure 1b shows the same spectrum re-plotted in the relative abundance versus charge format. The difference between adjacent members of the series is now constant, and the familiar Gaussian-like distribution is more readily apparent. Figure 1b also shows the theoretical Gaussian curve generated to best fit the data.

There are a number of situations that commonly arise in electrospray mass spectrometry that can distort the Gaussian profile. For small polypeptides, the distribution of charge states reflects, to some extent, the number of basic residues in the peptide (4). This means that charge state distribution may cut off at low m/z when the number of basic sites is exceeded, distorting the Gaussian curve. The curve-fitting routine was unaffected by this distortion, correctly assigning the center of the distribution.

A potentially more serious problem arises for very large proteins, or for proteins analyzed at high orifice potential. The mass range of the Sciex quadrupole is 2400 and is frequently insufficient to see the

entire charge state distribution envelope. One would still like to be able to characterize these distributions, and, for example, observe the effect of changes in concentration or solution pH, even though the complete distribution is not represented. Fig. 2 shows the electrospray mass spectrum of transferrin, MW ca. 79 650. A series of charge states is apparent, but the mass range cuts off before the maximum of the distribution is observed. When these data are analyzed, u and s can still be calculated as 33.1 and 2.7, respectively.

The curve-fitting routine can also be used to describe spectra with more than one distinct distribution. This phenomenon may reflect the presence of two protein conformers in solution (2,5), or may have some more mundane, instrumental explanation. The two lobes are curve-fit separately allowing the entire distribution to be described.

Curve-fitting the charge state distributions from electrospray mass spectra provides a convenient way to describe the spectra, even when the distributions are distorted or poly-modal. The center of the Gaussian (u) is a useful metric to characterize the mass spectrum and the changes that result from varying instrumental or solution conditions. The width of the Gaussian (s) is less useful, since it is largely unaffected by most controllable variables we have investigated.

Conformational Stability of Heme Proteins *in Vacuo*

Yasuo Konishi and Rong Feng, National Research Council Canada, Biotechnology Research Institute, 6100 Royalmount Avenue, Montreal, Quebec, Canada H4P 2R2

It is commonly accepted that the amino acid sequence determines the most stable native conformation of a protein. However, until now, no experiment has confirmed this assumption, because it can be examined only if the protein is isolated *in vacuo*. In this study, we isolated proteins *in vacuo* using an ionspray triple quadrupole mass spectrometer (API III LC/MS/MS system, SCIEX) and developed a unique application of mass spectrometry to characterize proteins.

Horse myoglobin (hMb) was used in this study due to the different masses of native hMb (17568.0 Da with a specific heme attachment) and unfolded apo-hMb (16951.5 Da). In order to characterize native conformation, native hMb prepared in neutral pH was isolated *in vacuo* by the ionspray technique. The average molecular weight measured from its mass spectrum (Fig. 1A) is 17,566.9 ± 1.4 Da, corresponding to hMb with its heme attachment. Oxymyoglobin ($MW_{obs.}$ = 17,600 Da and $MW_{calc.}$ = 17,600.0 Da), which carries its heme (Fe^{2+}) and oxygen, was also observed. As expected, no oxygen attachment was observed in ferrimyoglobin (Fe^{3+}). Thus, the ionization and the desolvation of Mb in the ionspray technique do not unfold the protein and the hMb retains its native or native-like conformation during its msec traverse in the mass spectrometer. Along these lines, Ganem et al., (1) have reported mass spectra of cytoplasmic receptor-ligand complexes, which are also characteristic of native protein.

In order to characterize denatured conformation, hMb was denatured, releasing its heme in 10% acetic acid. The mass spectrum showed separate peaks of apo-hMb and the heme with no trace of their complex, revealing that the protein and the heme were completely dissociated *in vacuo* (Fig. 1B). However, the dissociation of the heme from the polypeptide does not prove the conformational unfolding of the protein, because apo-hMb may assume a folded structure in solution at neutral pH (2). If, on the other hand, the protein cross-section is larger than that of the native protein, we can assume that the protein is unfolded. The argon collision gas was introduced at the second quadrupole to characterize the large cross-section of the unfolded protein, which had many collisions with the gas and a large scattering loss; native protein with a small cross-section had fewer collisions with the argon gas, resulting in a small scattering loss. A collision gas thickness, that was adjusted to reduce the signal intensity of hMb in Fig. 1A by 50%, resulted in a 90% reduction of the apo-hMb signal intensity in Fig. 1B. This demonstrates that the apo-hMb in Fig. 1B had a larger cross-section than the hMb in Fig. 1A and unfolded in the absence of solvent.

Protein unfolding *in vacuo* was studied further. Nitrogen curtain gas at the orifice not only removes the solvent associated with the protein but also heats the protein molecules by transferring the collisional energy to the internal energy of the protein (3,4). Horse Mb accelerated by a high orifice voltage (160 V) released 45% of its heme and was converted to apo-hMb. However, this does not prove the conformational unfolding of the protein at the orifice, since the heme may simply have

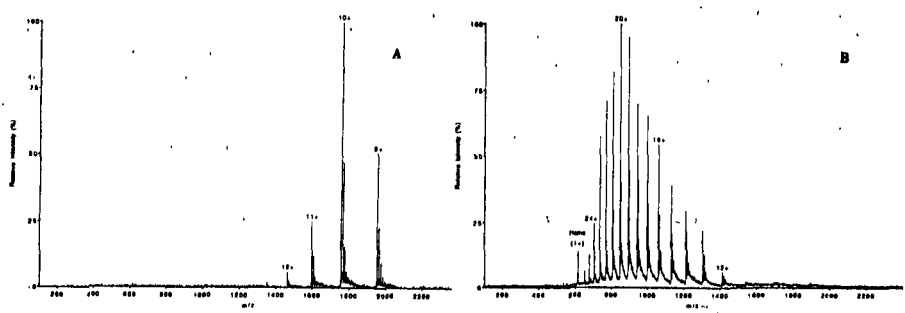

Figure 1. Mass spectra of horse myoglobin (hMb) (0.1 mg/mL) (A) at neutral pH and (B) in 10% acetic acid with charge states of 9+ to 12+ and 12+ to 26+, respectively. Horse Mb molecules at neutral pH have fewer charges than those of denatured apo-hMb in 10% acetic acid, reflecting the compact hMb structure (5).

fallen out of the binding pocket. Another collision was introduced at the second quadrupole to examine the compactness of the apo-hMb generated at the orifice. This changed the fractions of hMb and apo-hMb from 55% and 45% without collisions at the second quadrupole to 72% and 28% with collision at the second quadrupole, respectively, indicating more scattering loss of the apo-hMb than the hMb. Hence, the apo-hMb generated at the orifice unfolded during its msec traverse from the orifice to the second quadrupole.

The final aspect examined was the energy to unfold proteins. In this experiment, argon collision gas at the second quadrupole heated up hMb (z=10+, m/z =1758) and induced the protein unfolding. The collisions of the native proteins with the argon gas at the second quadrupole generated three new peaks corresponding to the heme and two apo-proteins, which were resulted from the loss of the Fe^{2+} and Fe^{3+} hemes, respectively (Fig. 2). To estimate the degree of unfolding, these two apo-protein peaks were integrated and normalized by all three protein peaks (one native protein and two unfolded apo-protein peaks). The unfoldings of horse myoglobin (z=9+, m/z=1953), whale myoglobin (z=9+, m/z=1980) and α chain of human hemoglobin (z =8+, m/z=1969) were measured at various collision gas thicknesses with an center-of-mass collisional energy of 3.0 eV. The results (Fig. 3) showed that horse myoglobin and whale myoglobin (not shown in Fig. 3) *in vacuo* were fairly stable and required the same argon gas thickness of 4.2 x 10^{14} cm^{-2} to unfold 50% of the proteins, whereas α chain of human hemoglobin required 7% less argon gas thickness (3.9 x 10^{14} cm^{-2}) for its 50% unfolding. Protein characterization *in vacuo* excludes all external factors such as solvent, salts, pH and pressure. Thus, the unfolding energy measured in this study must be the intrinsic property of proteins. Further characterizations of proteins *in vacuo* may elucidate the fundamental roles of amino acid sequence in the structure and function of proteins.

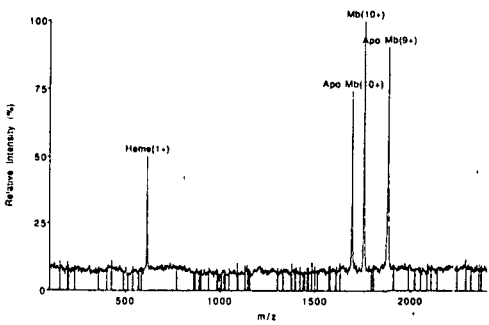

Figure 2. Horse Mb (z=10+, m/z=1758) is unfolded by the argon collision gas at the second quadrupole. Depending on the charge state of ferrous or ferric ions in the heme, the Mb (z = 10+) generates apo-Mb (z =10+ or 9+) at m/z 1696 or 1884, respectively. In the case of Fe3+, the heme (z =1+) is observed at m/z 616.5.

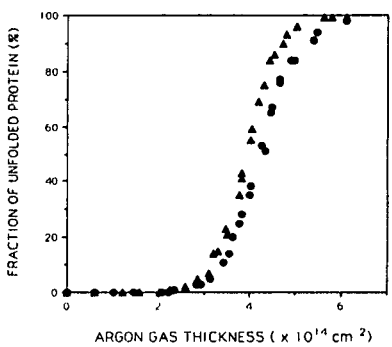

Figure 3. The unfoldings of (●) horse myoglobin (z=9+, m/z=1953) and (▲) α chain of human hemoglobin (z = 8+, m/z =1969) were measured as a function of the argon collision gas thickness at the second quadrupole with a center-of-mass collisional energy of 3.0 eV.

Tandem Mass Spectrometry of Multiply Charged Proteins with Electrospray Ionization

Joseph A. Loo and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P. O. Box 999, Richland, WA 99352

In conjunction with proteolytic digestion and tandem mass spectrometry (MS/MS), complete sequence information for proteins can be obtained. However, a potential gain in speed and sensitivity can be realized from collisionally activated dissociation (CAD) of *intact* proteins, provided improvements in CAD efficiency, instrument performance, and increased understanding in the CAD process of large molecules are obtained.

We have previously demonstrated that limited sequence information for proteins as large as ribonuclease A (13.7 kDa) [1] and serum albumins (66 kDa) [2] can be obtained from CAD of multiply charged molecules generated by electrospray ionization (ESI). Even for "known" compounds, difficulties in interpretation of *low resolution* MS/MS spectra arise because of the possibility of multiply charged product ions. However, probable assignments can be determined by searching for features common to most MS/MS spectra we have examined. For example, aids for interpretation of CAD mass spectra of multiply charged precursor ions include:

- A *progression* of product ion charge states (*e.g.*, y_{25}^{2+}, y_{25}^{3+}, y_{25}^{4+}).
- Product ion *series* (*e.g.*, y_{25}^{2+}, y_{26}^{2+}, y_{27}^{2+}, ...).
- MS/MS of product ions ("MS/MS/MS") to confirm assignments (and provide additional structural information). Product ions can be generated in the atmospheric pressure/vacuum interface by increasing the voltage difference between the nozzle and skimmer elements, or in the quadrupole collision cell (Q2). Fragment ions produced in the interface region can be selected by Q1 and be further dissociated in Q2.
- Tandem mass spectrometry of structurally related molecules (*e.g.*, variants, sequence homology) help to identify the approximate location of dissociation, and thus the assignment of the product ion due to the expected shifts in *m/z*.

Dissociation of <u>bovine carbonic anhydrase</u> (29 kDa, 259 residues) produces a progression of charge states for several product ions (*e.g.*, y_{67}^{6+}, y_{67}^{7+}, y_{67}^{8+}). Fragmentation is directed towards the COOH-terminal region of the polypeptide. Dissociation of the amide bond to a *proline* residue is favored for a number of proteins studied, especially carbonic anhydrase.

The presence of *complementary ion pairs*, which in sum (mass and charge) account for the entire molecule, alleviates some problems of interpretation of tandem mass spectra. Simple algorithms can determine whether two product ions are possibly complementary. MS/MS of the $(M+34H)^{34+}$ of carbonic anhydrase (Fig. 1) produces several sets of complementary ion pairs (*e.g.*, y_{67}^{7+} -- b_{192}^{27+}, y_{61}^{7+} -- b_{198}^{27+}, y_{67}^{8+} -- b_{192}^{26+}, y_{61}^{8+} -- b_{198}^{26+})

<u>Transferrins</u> are iron-binding glycoproteins of approximately 79 kDa, widely distributed in the physiological fluids of vertebrates. The available amino acid sequences for several species show a high degree of homology (sequence alignment). Product ions can be produced by molecular dissociation in the atmospheric pressure/vacuum interface. Because of the known sequence homology, these product ions can be compared and assigned as a series of multiply charged b_n ions from the NH_2-terminal region near residue 60. Although the sequence for bovine transferrin is *unknown*, the fragmentation pattern is consistent with the other transferrins studied and can be assigned from the measured peak spacings.

Reduction of disulfide bonds with 1,4-dithiothreitol expectedly allows higher charged molecules to be produced, and *unexpectedly* releases a small, 6 - 8 kDa peptide from the COOH-terminus for the *mammalian transferrin proteins* studied (Fig. 2). Tandem mass spectrometry data for the released peptide from human transferrin is consistent with the expected amino acid sequence for the COOH-terminus.

Measured M_r of COOH-Terminal Transferrin Peptide

Species	*M_r (exptl)*	*M_r (sequence)*	*Residues*
Human	6485.1 ± 0.4	6484.4	624-679
Rabbit	7752.6 ± 0.6	7752.9	609-675
Bovine	6066.2 ± 0.6	n.a	n.a

Dissociation of large, multiply charged proteins can be induced. However, for CAD of larger proteins, higher *m/z* resolution (*e.g.*, Fourier transform MS) may be necessary to assign product ion charge states.

Protein Folding Changes Induced by Disulfide Bond Scrambling Alters the Electrospray Charge Distribution

Karl R. Clauser, Barbara P. Moffat, and John T. Stults
Protein Chemistry Department , Genentech, Inc.
460 Point San Bruno Blvd., South San Francisco, CA 94080.

Introduction

The distribution of multiple charges seen in electrospray mass spectra of proteins is dependent upon many parameters including the solvent employed, the electrospray source voltages, the number of basic amino acids in the protein, and the tertiary structure of the protein. When protein unfolding is induced by reduction of the solvent pH, the resulting electrospray charge distribution is shifted (1). We describe here examples of charge distribution shifting induced solely by alteration of protein conformation through disulfide bond scrambling.

Results and Discussion

The proteins IGF-1 and a modified version of Prorelaxin form non-native disulfide bonds when recombinantly expressed in the cytoplasm of *E. coli*. When the different disulfide-linked forms (native and misfolded) of each protein are analyzed by electrospray mass spectrometry under identical solvent and instrument conditions, the resulting multiple charge distributions are different. Since the disulfide-linkages are the only variable introduced, this suggests that protein three dimensional structure must be partially preserved within the electrospray ion source.

Which Protein Sites Have Altered Charging?

In comparing mass spectra which show a charge distribution shift, one is tempted to ask if particular sites on the protein are susceptible to folding dependent charging, and if so what are those sites? The maximum charge state observable for proteins in positive ion mode should represent the sum of the number of amino termini and the number of basic amino acids (Arg, Lys, His and in some instances Gln) present in the molecule. Hence, charging should only occur at these basic sites.

When evaluating the charge shift for Modified Prorelaxin (Figure 1) it is helpful to examine notable features of the X-ray crystallographic structure of native Relaxin.(2) The structure shows two salt bridges. It seems reasonable that these salt bridges are absent in the misfolded version of the Modified Prorelaxin molecule and present in the native version. One is therefore tempted to speculate that these salt bridges in the native Prorelaxin molecule remain intact during electrospray ionization and prevent charging of the participating Lys and Arg residues. Thus, the charge distribution shift to two charged states higher with the misfolded Prorelaxin may result from the salt bridge absence leaving the Lys and Arg accessible to acquire charge.

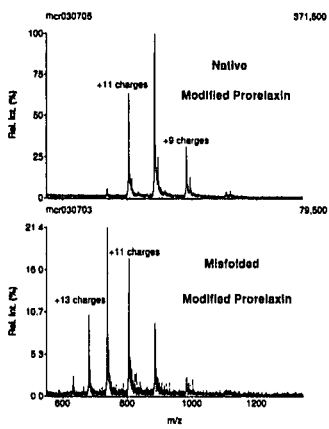

Figure 1

Electrospray mass spectra obtained while 0.5 - 2 pmoles/ul protein was directly infused into a Sciex API 3 mass spectrometer equipped with the Ionspray source at a rate of 1.5 ul/min using a solution of 20% acetonitrile / 1 % acetic acid.
, The orifice voltage was 95.

Extent of Protein Unfolding

The charge distribution shifts shown in Figures 1 and 2 suggest that protein folding is preserved to some extent within the electrospray ion source. In order to assess the extent to which protein unfolding has occured, ionization parameters must be considered.

The solvent employed in these experiments (20% acetonitrile / 0.1 or 1% acetic acid) alone may be sufficient to partially unfold the proteins. The selected solvent was used to ensure good quality ionization. However, to reduce the extent of unfolding the % organic was purposefully chosen to be less than that required to elute the protein from a reversed phase HPLC column.

The inability to obtain electrospray mass spectra of non-covalently linked protein multimers suggests that much protein tertiary structure is disrupted during ionization. However, it is noteworthy from Figure 3 that the ability to distinguish the IGF-1 disulfide configurations is particularly sensitive to the orifice voltage selected, and disappears above ~110 volts. Thus the potential which causes droplet desolvation should have a greater impact on protein folding than the high voltage which enables the electrospray. While it is reasonable to expect ionization to disrupt most protein tertiary structure, it may prove useful to consider the time from ionization to detection with the time necessary to completely unfold a protein.

Summary

The disulfide bonds in certain proteins may be scrambled, thus altering the protein's three dimensional structure without changing its mass After separation, different disulfide-linked forms of a protein can be distinguished by electrospray mass spectrometry, because the resulting multiple charge distributions for each form are distinct. This suggests that changes in protein folding are partially preserved within the electrospray ion source, and affect the accessibility of basic sites in the protein to acquire charge. While solvent and source voltage effects may combine to disrupt most protein tertiary structure, these experiments demonstrate that disulfide bonds sufficiently constrain an ionized protein to alter the microenvironment at certain chargeable sites.

For each of the 4 proteins analyzed by this method to date a charge distribution shift of up to two charge states can be observed between the native and misfolded forms. In each case the misfolded form is shifted to higher charge state.

Deconvolution of Electrospray Generated Multiply Charged Spectra of Mixtures Using a Three Dimensional Technique

*B. A. Andrien, M. Labowski, and C. M. Whitehouse
Analytica of Branford, Inc.
Branford, CT 06405

A three dimensional surface analysis technique has recently been developed for the determination of molecular weight from a mass spectrum of multiply charged ions. The three unknowns for any given m/z data point (x_i) in a mass spectrum of multiply charged ions are molecular weight (M_r), adduct ion mass (m_a), and charge state (i)[1].

$$x_i = \frac{M_r}{i} + m_a$$

Two dimensional approaches preselect the adduct ion mass (m_a) and calculate an intensity (H) for a given molecular weight (M_r) by summing all the contributions (h) from all possible charge combinations[1]:

$$H(M_r) = \sum_{i_{min}}^{i_{max}} h\left(\frac{M_r}{i} + m_a\right)$$

The three dimensional deconvolution technique, when applied to a mass spectrum of multiply charged ions makes no assumption regarding adduct ion mass so that the adduct mass is retained as a variable on the deconvolution surface. Thus, intensity (H) for a given molecular weight (M_r) and adduct ion mass (m_a) is found by summing all the contributions (h) from all possible charge combinations[2]:

$$H(M_r, m_a) = \sum_{i_{min}}^{i_{max}} h\left(\frac{M_r}{i} + m_a\right)^*$$

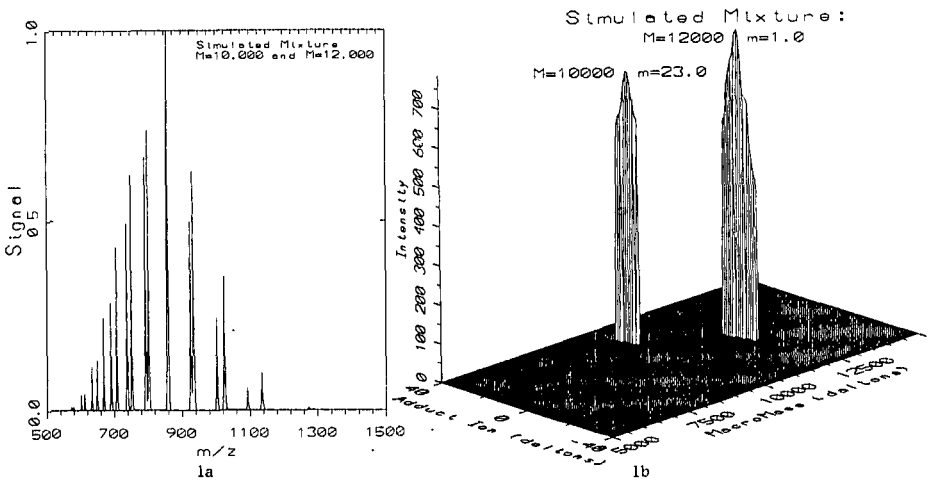

Figure 1 a) Simulated electrospray ionization mass spectrum generated from two molecules with different adducts. b) Three dimensional deconvolution spectrum.

Figure 1a is a simulated electrospray ionization mass spectrum generated from two molecules M_{r1}=10000 and M_{r2}=12000, with the M_{r1} having only Na^+ adducts and M_{r2} having only H^+ adducts. To determine the molecular weights of these two molecules by a two dimensional deconvolution, two calculations need to be performed, one at each adduct mass. There is also the possibility that an incorrect assignment can be made in molecular weight in the two dimensional case due to charge shifted peaks. Charge shifted peaks occur when the coherence from the original spectra peaks are generated and the charge assigned to the peak is higher or lower then the true value. These peaks are an artifact of both the two and three dimensional calculations but their origin is less obvious, and it is less intuitive to reject them as an artifact in the two dimensional case. The three dimensional deconvolution, shown in Figure 1b, determines both the molecular weights accurately while avoiding molecular weight mis-assignment problems. Finally, with only a single species and an incorrect arbitrary selection of the adduct mass, an incorrect molecular weight assignment can be with the two dimensional deconvolution, while this mistake is avoided with the three dimensional deconvolution.

Figure 2a shows the electrospray ionization mass spectrum of a mixture of horse heart cytochrome-C (M_r=12360), hen egg lysozyme (M_r=14306), and sperm whale myoglobin (M_r=17199)(concentration 0.01μg/μL each in ½% acetic acid 1:1 methanol:water) with a resolution = 800. The three dimensional deconvolution, shown in Figure 2b, displays the molecular weights and adduct ion masses for each species. Errors in the molecular weights are due to calibration errors in the m/z scale, discrete step size in the m/z range, and the limited resolution of the mass analyzer. Finally, any error in a m/z value is significant because it is multiplied by the number of charges on that peak.

The three dimensional deconvolution has distinct advantages over the two dimensional deconvolution in terms of assessing the uncertainty for a molecular weight assignment, working with mixture analysis, and identifying mass analyzer m/z calibration errors.

The Application of Maximum Entropy to the Interpretation of Electrospray Mass Spectra.

J.C. Cottrell, B.N. Green and S.A. Jarvis, Fisons Instruments, VG BioTech, Tudor Road, Altrincham WA14 5RZ, UK. & A.G. Ferrige, The Wellcome Research Labs., Beckenham, Kent, BR3 3BS, UK.

Introduction

Electrospray Mass Spectrometry (ESMS) is unique in being able to measure the molecular mass of a protein to better than 0.01%. This accuracy also applies to mixtures provided the components in the mixture differ sufficiently in mass to be adequately treated by the processing software. Hitherto, this mass difference has been limited to 12Da in 15867 or 0.08% in mass [1].

With the majority of instrumental techniques, and ESMS is no exception, situations often arise where the analysis of mixtures is compromised by overlap between two or more of the components present. Clearly, in these cases, some means of improving the resolution would be beneficial. One, seemingly obvious, approach would be to increase the mass spectrometer resolution. Unfortunately, this approach has limited value because, in many cases, the resolution is mainly determined by the fundamental isotopic distribution of the elements in the molecule and not by the performance of the quadrupole mass analyser. As initially produced by the spectrometer, the electrospray spectrum of a protein mixture consists of a series of multiply charged ions on a mass/charge (m/z) ratio scale, for each component in the mixture. Several methods have been described to simplify such spectra, whereby the series from each component is transformed to a single peak on a true molecular mass scale (the zero-charge spectrum). One method, employed in our laboratory, faithfully transforms the m/z spectrum into a molecular mass spectrum, but does not resolve components which are not resolved in the original data. Also it requires the charge states of the peaks in the multiply charged ion series to be identified before transformation.

Various mathematical techniques have been employed to deconvolute overlapping data. Here we apply the most recent and sophisticated of these, Maximum Entropy (MaxEnt), to the processing of ESMS data and show that the enhanced resolution allows hitherto unresolved proteins to be separated and accurately mass measured. Furthermore the MaxEnt method automatically generates the zero-charge spectrum without first assigning the charge state of the ions in the m/z spectra.

Globin Doublets from Haemoglobins

Two haemoglobins (Hbs) each containing normal β-globin (15867.2) and a β-variant in equal amounts were analysed. The β-variants were β-Quebec-Chori (15879.2)[1] and β-Hafnia (15858.2) giving equal intensity doublets separated by 12 and 9Da respectively. A third sample comprising an equi-molar mixture of sheep and cow Hbs was also analysed. Here the sheep (15047.1) and cow (15053.2) α-globins differ in mass by 6Da.

12Da doublet

As expected, the two β-globins separated by 12Da were sufficiently well resolved (80% valley) to allow their masses to be measured to within 0.5Da (40ppm)) from the transformed spectrum without resolution enhancement. Nevertheless, the same data processed by MaxEnt showed substantially improved resolution (base line separation) and the accuracy of the mass determination was preserved.

9Da doublet

In this case the two β-globins separated by 9Da were not sufficiently resolved in the transformed spectrum to allow their individual mass determination. The resolution enhancement produced by MaxEnt processing showed the two β-globins resolved almost to the baseline with both components mass measured to within 0.5Da (40ppm) of their expected masses.

6Da doublet

Here the two α-globins occurred as a single peak in the transformed spectrum(Fig 1, upper). However, in the MaxEnt derived spectrum (Fig 1, lower), the two α-globins were sufficiently well resolved to allow their mass measurement to within 0.9Da (60ppm).

Horseradish peridoxase (HRP)

HRP (Sigma, P8375) was analysed over the m/z range 1700-2700. HRP is a 308 amino acid protein with 4 disulphide bridges (Mr = 33893.2) and 8 N-linked glycans [8($GlcNAc_2$,Man_3,Fuc, Xyl) = 9368.6].[2] Also 60% of the molecules lack the C-terminal serine. The molecular mass of the complete glycoprotein (excluding haem) is 43261.8. The transformed spectrum (Fig 2, upper) allowed plausible assignments of the major components to be made[3] from their molecular masses and the literature data. However, the higher resolution exhibited by the MaxEnt processed data (Fig 2, lower) revealed a substantial number of additional peaks, which allowed the number of assignable components to be doubled.

Computer Aided Interpretation of Low Energy ESI/MS/MS Spectra of Peptides

Joe X. Zhou and Ian Jardine
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134

INTRODUCTION :

Recent technological innovations to tandem mass spectrometry (MS/MS) have made this technique a powerful tool for peptide sequencing (1, 2). Although MS/MS data can be generated rapidly, interpretation of the resulting mass spectra can be a severe bottleneck to rapid analysis. Computer programs have been developed over the years to assist interpretation of FAB tandem mass spectral data obtained under both high-energy (3, 4, 5) and low-energy collision (6) conditions. Recent advances in electrospray ionization promises to extend the MS/MS technique further in peptide primary structure elucidation (7). The spectral interpretation, nevertheless, still remains a formidable task. Here, we describe some of our approaches in developing computer programs in assisting the electrospray low-energy CID spectra of peptides.

EXPERIMENTAL:

The computer program was written in C language and X Windows with Motif graphical user interface and runs on DECstation 2100, 3100, and/or 5100. It has been integrated with Finnigan's ICIS II data system and Finnigan's biochemical analysis software package PEPM. The workstation is equipped with a RISC processor, 16 Mbyte of internal memory, and 660 Mbyte of disk space. The input data consists of the raw MS/MS spectrum acquired on a Finnigan's TSQ 700 mass spectrometer with an electrospray source through either infusion or on-line HPLC separation. Computation time ranges from seconds to over several minutes (< 3 min.) depending on the size of the peptide.

ALGORITHM OUTLINE:

The interpretation algorithm follows the general strategy previously developed for FAB low-energy collision MS/MS mass spectra (6) with specific characteristics of electrospray data utilized. It consists of three major steps: the raw data processing, the partial sequence extension, and the final sequence scoring.

Raw CID spectra are automatically processed and converted into modified product-ion spectra ready for interpretation. This includes data smoothing with Gaussian distribution and background subtraction done with the modified version of Ishikawa's algorithm (3).

Subsequences are sequentially extended with each individual amino acid, including any unusual amino acids if specified, one at a time from either end. The predicted fragment ions of different charge states are compared with product-ion spectrum of the peptide. Scores are calculated after each extension based on the occurrence and intensity of fragment ions of type A, B, Y", and their neutral losses,at all possible charge states up to the charge state of the parent ion. Rules based on the characteristics of ESI/MS/MS data are used to derive the score calculation. The list of partially extended sequences are then sorted according to their scores and a fixed number of partial sequences are kept for next extension cycle. This process continues on a particular sequence until its mass reaches that of the parent within the specified tolerance, and this sequence is saved for final scoring. Otherwise, it is discarded.

In the final step, predicted fragments of each completed sequence obtained from previous step are compared with the product-ion spectrum and scores are calculated. The final scores are based on three values: the number of peaks of the product-ion spectrum accounted for by the sequence, the overall intensities of predicted fragment ions of that sequence including characteristic low mass ions (immonium ions) (2), and averaged continuity factors of sequence ion B and Y" over all charge states. Final scores are formulation of those three factors and normalized over the length of individual peptide. The continuity factors are based on the number of consecutive sequence ions of the same fragmentation scheme, e.g. Y", at fixed charge state. This is used because of the observation that consecutive sequence ions of the same type and of same charge state are often present in the electrospray product-ion spectrum. Finaly, proposed sequences are listed in descending order of their scores for output.

The minimal requirement for user input by the program are the mass-to-charge (m/z) ratio and the charge state of the parent ion, although other information can be provided to the program, such as amino-acid composition and terminal residues, if known.

RESULTS AND DISCUSSION:

The results of interpretation of ESI/MS/MS spectra of peptides from this program are summarized in the following table. Peptides of varying sizes are used. Note that we have made no attempt to differentiate between leucine and isoleucine, and between lysine and glutamine because their masses are indistinguishable in quadrupole mass spectrometric analysis. The program arbitrarily assigns an Ile (I) and Gln (Q), respectively, to the sequence instead. Most of the peptides

tested are singly or doubly charged tryptic or tryptic-like peptides.

For small or medium sized peptides (usually < 1200 daltons), nearly complete sequence information is often obtainable by the program as shown in Table 1. In comparison with product spectra obtained from FAB (6), electrospray MS/MS tends to generate less fragments. For most tryptic peptides, we see little B type of sequence ions and dominant Y" ions at m/z values above the doubly charged parent. This reduces the complementary nature of N-terminal, *e.g.* A and B, and C-terminal, *e.g.* Y", sequence ions often used in FAB MS/MS spectral interpretation. On the other hand, it decreases the complexity of product-ion spectra and simplifies interpretation. However, it may often produce gaps in the resulting spectrum if fragment ions are missing. This is especially true with larger peptide and the presence of glycine in the sequence. Since complete sequencing is often unattainable, features are incorporated into the program to allow partial sequence elucidation even though complete sequence can not be determined (see sequences marked with * in Table 1).

CONCLUSION:

Initial results indicate the program is successful to a certain extent. Most of the peptides we have used for testing are small or medium sized tryptic or tryptic-like peptides with one or two charges. For non-tryptic peptides, we do not anticipate any problem since the fundamental algorithms still apply as long as spectra are reasonably good. However, larger peptides will often create problems because they tend to produce less fragment s and carry more charges and, thus, make the interpretation more difficult. Nonetheless, partial sequence information can often be obtained providing such features are integrated into the program. Although development of a general approach to interpret product-ion spectra of higher charge states is particularly difficult, the algorithm described still possesses considerable value since most of tryptic peptides carry two charges or less, and a computer program in assisting interpretation will speed up primary structure elucidation of those peptides dramatically.

Methods for Probing the Higher Order Structure of Protein Ions in the Gas Phase

Richard D. Smith, Karen J. Light-Wahl, Rachel R. Ogorzalek Loo, Brian E. Winger, Joseph A. Loo, and Alan L. Rockwood
Pacific Northwest Laboratory, Richland, WA 99352

Introduction

The most immediate information obtainable by mass spectrometry for proteins is the molecular weight. Serious efforts are also being made to obtain primary structural information (i.e., sequence) based upon ion dissociation methods [1]. However, one would also like to learn about aspects of higher order structure generally determined by noncovalent interactions. One must ask if there is the potential for obtaining information about the secondary, tertiary, or quaternary structure of proteins by mass spectrometry. The general answer to this question is yes. For example, using electrospray ionization (ESI), the charge state distribution obtained for protein molecular ions has been correlated with structure or charge state in solution [2].

However, a correlation between the ESI charge state distribution and solution conformation does not provide information on whether elements of higher order structure are preserved in the gas phase after ESI. On one hand, ESI is perhaps the "gentlest" ionization technique, involving only mild heating of the molecular ion. On the other hand, the relatively rapid removal of solvent is a prerequisite for obtaining "high quality" ESI mass spectra, and complete solvent removal would be expected to destabilize higher order structure. Destabilization is also expected to be strongly driven by Coulombic forces due to multiple charging [3]. Thus, although there have been a number of isolated cases showing noncovalent associations in the gas-phase (i.e., heme-apomyoglobin, protein dimer ions, etc.), ESI *may* result in the general loss of the noncovalent associations necessary to preserve higher order structure. To investigate this question, we have applied various experimental methods to determine whether structural differences in solution may persist, in some form, after ESI.

Experimental Methods

An Extrel single quadrupole mass spectrometer and a modified Sciex TAGA 6000E triple quadrupole mass spectrometer were used for these studies. The studies used an ESI source developed at our laboratory, described previously [4], and either nozzle-skimmer or capillary-skimmer interfaces, also described previously [1,5,6]. Somewhat different methods and techniques were used for each study. Specific methods involved: (A) collisional attenuation, (B) collisional dissociation, (C) proton transfer reactions, and (D) H/D exchange in low energy reactions with D_2O. The specific methods and results are discussed separately.

Results and Discussion

A. Collisional Attenuation Studies

Initial CID studies of protein molecular ions in a triple quadrupole instrument revealed the general feature that the onset of collisional attenuation required relatively high target gas densities [7]. This "induction period" was ascribed to the need for multiple collisions to activate ions sufficiently to cause dissociation on the observational time-scale. The induction period was found to be somewhat dependent on the molecular ion internal energy due to excitation in the ESI source or interface [7].

Our recent studies have shown that with a capillary inlet under mild heating conditions (producing less internally excited, (i"cool" molecular ions), more rapid collisional attenuation is observed than for somewhat "hotter" molecular ions using the same inlet and interface conditions. This behavior is ***opposite*** that observed for ion formation in the nozzle-skimmer interface, and is opposite that expected if the loss (i.e., attenuation) is primarily due to dissociation. In subsequent studies we examined the collisional attenuation of proteins formed from both their native and denatured conformations in solution, as well as the cysteine-cysteine disulfide-bound and disulfide-reduced forms. Within experimental uncertainties, the attenuation behavior observed in both comparisons is identical, suggesting that structural effects upon collisional attenuation are be small.

B. Collisionally Induced Dissociation (CID) Studies

Significant differences in CID spectra result from the presence of additional covalent linkages, as evident from comparison of MS/MS spectra for protein ions from the disulfide-bound and disulfide-reduced forms. In contrast to this, MS/MS spectra for ions formed from the native and denatured solution conformations of cytochrome *c* and myoglobin, for example, show no significant differences. This result is not surprising since CID is the end result of a multistep collisional activation process occurring over a period as long as ~10^{-4} s. It seems probable that any differences in ion structure due to noncovalent associations may be lost during heating prior to low energy CID.

C. Low Energy Protein Transfer Reaction Studies

The proton transfer reactions of protein molecular ions formed from various solution conformations have been studied. Reactions were conducted at near-atmospheric pressure using a "Y" tube reactor, described previously by Ogorzalek Loo et al [8]. Reagents, typically amines, were introduced into the capillary to react with the protein ions at various pressures and temperatures. It was found that as amine pressure is increased, proton transfer reactions cause a shift in the protein charge state distribution to ***lower charge*** (i.e., to higher *m/z*). Above certain pressures, reaction rates become very low, and little or no additional shift in the charge state distribution is observed. It was concluded that reactivity is substantially governed by Coulombic effects and, hence, charge proximity [8]. Thus, structural differences for gas-phase protein ions (that also give rise to substantial differences in relative charge sites), might be expected to alter the final charge state distribution after reaction.

In cases where structural differences are certain to exist in the gas phase, as in comparison of the disulfide-bound and disulfide-reduced forms of proteins, the expected differences in charge state distribution after reaction are observed. Similar studies have been conducted to compare the reactivity of protein molecular ions formed from the native and denatured solution conformations of proteins such as cytochrome *c* and myoglobin. Our results to date have not yet shown any significant differences in the final charge state distribution for proteins where solution phase structural differences are due to noncovalent associations.

D. H/D Exchange Studies

Isotopic (H/D) exchange in high pressure ion-molecule reactions of protein ions with D_2O was studied. The experimental arrangement was similar to that used for the proton transfer studies (C). It was found that gas-phase H/D isotopic exchange occurs rapidly at high pressure. Greater H/D exchange for the disulfide-bound form of proteins was observed than for the disulfide-reduced form. [9]. The greater reactivity of the disulfide-bound protein is tentatively attributed to a greater Coulombic effect (due to barrier lowering) for the more constrained structure. In contrast, comparison for protein ions formed from the native and denatured solution conformations showed no significant differences in H/D exchange.

Conclusions

1. Proton transfer reactions and H/D isotopic exchange in high pressure ion-molecule reactions, as well as lower pressure CID processes, readily distinguish structural differences due to disulfide-bound and disulfide-reduced proteins. For the case of proton transfer reactions and H/D exchange studies, it appears that significant differences in gas-phase structure due to noncovalent association, if they exist, should be distinguishable.

2. Studies for protein ions in the gas-phase formed from a limited set of native and denatured conformations in solution have not yet revealed significant differences. These results suggest that either (a) the noncovalent associations leading to these structural differences have not been preserved in the gas phase for the cases studied, and relaxation to indistinguishable structures occurs for these proteins, or (b) the methods are not sufficiently sensitive to detect residual structural differences.

Internal Energy Effects on the Solvation and Reactivity of Multiply Charged Biomolecules for Electrospray Ionization Mass Spectrometry

Karen J. Light-Wahl, Brian E. Winger, Alan L. Rockwood, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P.O. Box 999 Richland, WA 99352

Recent interest in probing the preservation of solution conformations of proteins into the gas phase via electrospray ionization mass spectrometry (ESI-MS) has led to questions of the gentleness of the electrospray process. The preservation of some noncovalent associations has been observed with ESI-MS under controlled conditions. Common mechanisms employed to desolvate ions (e.g. collision energy, thermal energy, and countercurrent gas flow) may destroy the associations and structural differences desired. Mild interface conditions which do not completely desolvate the ions may be required to probe these higher order structures and weak associations. The extent of solvation and the charge state distribution observed in the ESI spectra obtained for proteins can be affected by the design and operating conditions of the vacuum interface. For these studies, a capillary interface was used to control the thermal energy of the ions prior to entering the vacuum expansion region as well as control of the collisional energy in the expansion region.

For small proteins such as bovine ubiquitin, mild interface conditions often result in the observation of two ion distributions corresponding to the unsolvated $(M+nH)^{n+}$ ions and a distribution of unresolved solvated $(M+nH+mS)^{n+}$ ions (where S refers to solvation molecules such as H_2O and MeOH). This is shown in Figure 1 where the amount of solvation increases with charge state.

Small peptides were used to verify the solvation distributions and determine their identity. The resolvable solvation for leucine-enkephalin obtained under mild interface conditions with ESI-MS is shown in Figure 2. The solvation of the $(M+H)^+$ ion of leucine-enkephalin is from both MeOH (from the sheath flow) and H_2O, as labeled. A bimodal distribution of unsolvated and solvated peptide ions is observed here for leucine-enkephalin. The use of countercurrent N_2 flow at the entrance of the interface capillary affects the solvation observed. The solvation is dominated by MeOH molecules in the absence of N_2 flow and primarily H_2O solvation in the presence of a countercurrent N_2 flow. This is most likely the result of more effective evaporation of MeOH relative to H_2O with the countercurrent N_2. The extent of solvation can also be affected by interface conditions such as capillary heating and capillary-skimmer voltage difference.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830.

ESMS OF PROTEINS: WHY MORE CHARGES THAN EXPECTED? PART II

*William T. Moore, Terry B. Farmer, Marc J.-F. Suter, and Richard M. Caprioli

The Analytical Chemistry Center and the
Department of Biochemistry and Molecular Biology
The University of Texas Medical School
Houston, Texas 77030

The maximum charge states observed in the ESI mass spectra of proteins and peptides correlate for the most part with the number of basic groups in the polymer suggesting that there are chemical determinants (alpha-NH_2, Arg, Lys, & His) accounting for the protonated species observed. The work of Fenn et al.[1] on the ESIMS analysis of polyethylene glycol suggests that the number of charge states afforded by the sodiation of this polymer is a result of primarily physical determinants. In some instances the ESI mass spectra of proteins and peptides indicate "extra charge states" (protonation) numbering higher than the constituent basic groups. The question addressed is whether these peptide polymer "extra charge states" are a result of either chemical or physical determinants. We have chosen a synthetic peptide analog approach to address this question.

In Part I of this study we focussed on a specific case, the bovine growth hormone tryptic peptide #9 (bGHT9).[2] This peptide contains two basic groups but presents a strong +3 charge state upon ESIMS analysis.[2,3] Through the ESIMS analysis of several structural analogs of this peptide, we concluded that one out of two possible glutaminyl residues acted as a proton acceptor.[2] Interestingly, as shown in Fig. 1 the putative glutaminyl proton acceptor in bGHT9 occupied an amino acid residue position where strongly basic amino acids (Arg & His) were present in respective homologous prolactins (PRL's). This result led us to propose the biochemically significant hypothesis that certain glutamines present in certain unique micro-environments may act as proton acceptors.[2]

In the present study (Part II) we address the general applicability of the hypothesis by examining the next most logical case, the synthetic murine Prolactin (mPRL) peptide that is homologous to bGHT9. Of the six species-specific prolactins presented in Fig.1 only the mPRL homolog has a glutamine in the critical "proton acceptor" position brought to our attention by our Part I studies involving ESIMS analysis of bGHT9 analogs. The mPRL homologous peptide contains only a single basic functional group, the N-terminal alpha amino group. In accordance with our thinking, as shown in Fig. 2A, we found that the mPRL homolog also possessed an "extra charge state" (+2). Since the mPRL peptide contains only a single basic functional group, the assumption was that any charge state higher than +1 ion would be interpreted as an "extra charge state". Surprisingly, the extra charge state (+2) observed in the mPRL synthetic peptide analog, however, was found to be present in all of the ESIMS spectra for all the mPRL structural analogs except that for an eight residue truncated derivative where only a +1 was observed (data not shown). The results indicate (Fig. 2B) that the apparent extra charge state (+2) is glutamine independent which necessitates a modification of our original hypothesis. From these data, we hypothesize that there still is a biochemically significant conservation of the basicity as indicated by the apparent extra charge state (+2) observed in the ESIMS analysis of the natural mPRL peptide. However, the hypothesis changes in our consideration of the role of glutaminyl residues in that the determinants for the extra charge state may be encoded in the overall more complex peptide structure. There is a caveat, however, that needs to be considered before fully embracing any modification of the original hypothesis. The assumption that the +2 extra charge states observed upon ESIMS analysis of the mPRL peptide analogs are similar in quality to the +3 extra charge state seen in the bGHT9 study may not be valid. A +2 state may be observed for any random sequence peptide of permissible length. In our experience some peptides have been observed to have only +1 states. However, these have been short peptides comprised of less than 10 residues. The resulting minimal charge state observed for any random sequence peptide 10 residues or longer containing no basic groups needs to be established. The question to ask is whether these peptides will always provide predominant +2 charge states upon ESIMS analysis and whether this +2 charge state is determined by physical processes similar to those perceived accounting for the multiple charging (sodiation) of polyethylene glycol.[1] Predominant +2 charge state ions

have been observed in the early ESIMS studies of small peptides.[4] Furthermore, for future study focused on the possible chemical determinants afforded by glutaminyl residues, another set of prolactin peptide analogs should be prepared. As shown in Fig. 2C, the synthetic mPRL homolog synthesized with an added C-terminal Arg appeared to yield a weak +3 multiply charged species. All the critical glutamine substitution mPRL analog peptides should be resynthesized with C-terminal Arg residues and the influence of glutamine substitutions on the +3 "extra charge state" should be evaluated in this set.

Single Changes in the Charge State of the Peptide (GHHPH)nG Correlate with the Number (n) of Multiple Internal Repeat Units

An investigation by Electrospray Ionization Mass Spectrometry

+(present address: PE SCIEX, Thornhill, Ontario, Canada)

SUMMARY

The precise contributions of peptide amino acid composition, sequence, and conformation to the multiply-charged states observed by electrospray ionization (ESI) mass spectrometry are not known. To investigate the electrospray ionization (ESI) of biomolecules and the feasibility of using ESI mass spectrometry to monitor ligand-induced alterations in peptide conformation, we have prepared a closely related series of metal-binding peptides $(GHHPH)_nG$ (for n = 1 to 5). These peptides represent portions of the surface-exposed metal-binding domain on the human plasma and milk protein known as histidine-rich glycoprotein (HRG). The *optimum* charge state observed for each of the HRG peptides $(GHHPH)_nG$ for n = 1 to 5 was always equal to the number of internal GHHPH repeat units (n) plus one. The *maximum* charge state ever observed for each peptide was equivalent to the optimum charge state plus one (i.e., n + 2). These relationships were observed for the HRG peptides infused in water alone and in water containing up to 3% (v/v) acetic acid. Furthermore, in every case, the addition of bound Cu(II) ions (a maximum of 1 Cu bound per GHHPH internal repeat unit) had no effect on either the *optimum* or the *maximum* observed charge states.

INTRODUCTION

Electrospray ionization (ESI) mass spectrometry is useful for the accurate mass determination of intact peptides and proteins. The high mass accuracy and upper molecular mass detection limits that can be achieved by ESI are related to the generation of intact molecular ions with multiple charges. The degree of peptide/protein protonation observed in solution is determined by the solvent exposure and pK_a values of ionizable residues. These properties are dependent on conformation.

We are currently investigating alterations in the secondary and tertiary structures of specific protein surface metal-binding domains that result from the occupancy of these domains by various transition metal ions. Both matrix-assisted UV laser desorption/ionization time-of-flight mass spectrometry (1-6) and ESI (7,8) have been useful in the identification and characterization of specific peptide-metal ion complexes.

One objective of this investigation was to determine the relative contributions of imidazole N atoms (within adjacent His residues in the GHHPH multiple repeat sequence) to the ESI charge envelope (optimum and maximum charge states). A second objective was to determine the contribution of peptide bound Cu(II) ions to the observed charge states. We report here that the optimum and maximum observed charge states observed by ESI can be predicted by 1) the number of GHHPH tandem repeats (not the total number of His residues) and 2) the observed chemical reactivity (e.g., metal-binding) as determined in solution.

EXPERIMENTAL

ESI was performed with solutions of peptide in water alone or with up to 10 mM ammonium acetate using a Vestec Model 201 single quadrupole mass spectrometer as described previously (7,8).

RESULTS

The 25-residue metal- and heme-binding domain (G365-H389) of human HRG is composed of five tandem repeats of the 5-residue core sequence Gly-His-His-Pro-His (GHHPH). The $(GHHPH)_nG$ peptides (for n = 1 to 5) were evaluated by ESI in a variety of solutions. The observed relationship between the number of internal repeat units (n) and the observed charge states is presented Figure 1.

CONCLUSIONS

The optimum charge state observed by ESI for the HRG peptides $GHHPH)_nG$ was determined by the value of n (i.e., the number of tandem GHHPH repeats) and *not* by the total number of His residues. The value of (n) was also determined to predict the number of added Cu(II) ions bound by this series of HRG peptides in solution. The maximum charge state observed by ESI, always one additional charge above the optimum charge state (i.e., n + 2), was likely due to a contribution from the amino terminus. Bound Cu did not contribute to the observed charge state for three likely reasons: 1) protonated His residues do not participate in Cu(II) binding

(i.e., protonation precludes binding), 2) the interaction of Cu(II) with imidazole N atoms is of the coordinate covalent type, 3) the addition of bound Cu(II) apparently does not induce a conformational change significant enough to alter the protonation of other ionizable sites within the molecule.

Applying Ion-Molecule Reactions to Studies of Gas-Phase Protein Structure

R. R. Ogorzalek Loo, J. A. Loo, and R. D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P.O. Box 999, Richland, WA 99352

The question of whether remnants of solution phase differences in protein higher order structure persist in the gas phase is examined by carrying out proton transfer reactions on ions generated by electrospray ionization (ESI) of different solution conformations. If dramatic differences were observed in the reactivities of *equally* charged ions generated from two solution conformers, those differences could provide evidence that some structural differences persist.

Ion-molecule reactions were carried out in the atmosphere-vacuum interface of a quadrupole mass spectrometer by employing a "Y"-shaped capillary inlet-reactor.[1,2] The inlet-reactor was fabricated from 1 mm i.d. stainless steel tubing soldered to a post through which a Y-shaped channel had been drilled. To aid in desolvation and in examining temperature dependences, the reactor was electrically heated. Countercurrent gas flow was not employed. Dimethylamine (DMA), trimethylamine (TMA), or diethylamine (DEA) were delivered to one inlet arm in a controlled manner. Because this quadrupole-based experiment does not directly measure reaction rates for individual charge states, several assumptions pertaining to relative reaction rates are important. Those assumptions are discussed in reference 2.

Cysteine-cysteine disulfide-reduced and disulfide-intact proteins were compared as systems for which it is known that structural differences persist in the gas phase. Our recent studies[2] reacting DEA with bovine pancreatic trypsin inhibitor (M_r 6512), hen lysozyme (M_r 14 306), and bovine albumin (M_r 66 430) showed dramatic differences in charge state distributions between disulfide-intact and disulfide-reduced proteins to which equal amounts of DEA had been added. It was argued that increased electrostatic repulsion causes a disulfide-intact protein to be more reactive to proton transfer than an *equally* charged, disulfide-reduced protein. In extending those studies, we have observed similar behavior in DMA reactions with bovine albumin, hen lysozyme, and other *disulfide-containing proteins such as* α-*lactalbumin*, (M_r 14 175) *and bovine proinsulin* (M_r 8681).

The reactivities of bovine cytochrome *c* (M_r 12 231) ions sprayed from denatured (5% HOAc/H_2O, methanol sheath) and native (H_2O, H_2O sheath) solutions were examined with DMA in a 150°C capillary inlet (Figs. 1 and 2). In contrast to the α–lactalbumin results, ions generated from both cytochrome *c* solutions shifted to approximately the same charge states after addition of equal amounts of DMA. Similar behavior has been observed in cytochrome *c* reactions with DEA and with TMA in a 150°C reactor and also with DMA in a 95°C reactor. Differences in relative intensities of the charge states remaining after proton transfer reaction (e.g., the $(M+8H)^{8+}$ charge state is the most intense in Fig. 1b, but $(M+7H)^{7+}$ is most intense in Fig. 2b) may simply reflect the large differences in the charge states before reaction (Figs. 1a and 2a). However, we cannot rule out the possibility that small differences in proton transfer rates for equally charged ions from different conformers may also contribute to these differences.

Addition of equal amounts of DMA (150°C or 100°C inlet reactor) or DEA (150°C) to ions generated from different solution conformations of bovine ubiquitin (M_r 8565) also yielded similar final charge states. However, in contrast to the temperature dependence observed for DMA reacting with

cytochrome *c* (i.e., average charge state of ion *population* decreases with increasing temperature), reactions of DMA and DEA with ubiquitin all proceeded farther at lower temperatures (i.e., average charge state increases with increasing temperature).

Reactions of myoglobin (M_r 17 568) and apomyoglobin (M_r 16 951) with DMA (150°C, 100°C) or TMA (150°C) yielded similar final charge states, as well, despite the fact that myoglobin in the native solution retained its noncovalently associated heme.

These results suggest that for the non-disulfide linked proteins studied under these experimental conditions, either there are not significant differences in gas phase higher order structure, or proton transfer reactions are not a sufficiently sensitive probe of higher order structural differences arising from noncovalent interactions. It is possible that direct measurement of proton transfer reaction rates for individual charge states may show differences attributable to higher order structure.

Matrix effects in atmospheric pressure ionization mass spectrometry (API-MS)

***J.R. Gilbert, B. Bell, G.J. Kallos, The Dow Chemical Company, Analytical Sciences Laboratory, Midland, Michigan 48667.**

Atmospheric pressure ionization mass spectrometry (API-MS) has recently received renewed attention due to advances in electrospray ionization coupled with the ability of API-MS to detect compounds in air with extremely high sensitivity. The sensitivity of the API source makes it ideally suited for use in the real-time analysis of trace components in ambient air applications such as fence-line and environmental monitoring. One potential limitation in using API for these applications is the loss of instrument sensitivity in the presence of interfering compounds. In API-MS, analyte ions are generally formed through the interaction of analyte molecules with a population of reagent water cluster ions. The presence of several analyte compounds in the API source can effect its response to an individual analyte by depleting this population of reagent ions.

The formation of analyte ions in the API source has been shown to depend upon both the gas phase basicity (GPB) of the analyte molecule and the energy of dehydration of the analyte:reagent adduct ion.[1] Analyte compounds with GPBs below approximately 200 kcal/mol generally exhibit a rough correlation between GPB and sensitivity. Analytes with GPBs above 200 kcal/mol most often have higher sensitivity in the API source with little increase in sensitivity with increasing GPB. We were interested in studying the interaction of a variety of binary analyte:matrix systems in the API source to determine if a predictive correlation could be obtained between the GPB of a 'matrix' compound and the level at which it interferes with the detection of an analyte in the API source.

The interference of compounds in the API source was investigated using a locally constructed API source coupled to a Finnigan 4600 mass spectrometer. A series of studies were performed to evaluate the API source response to a constant level of analyte in the presence of a second 'matrix' component. The concentration of the matrix compound was varied from sub ppb to ppm levels while observing the analyte ion (MH^+) signal intensity. This experiment was repeated for several analyte and matrix compounds of varying gas phase basicity.

Figure 1 The interference of several matrix compounds with A) 0.83 ppm pyridine (GPB = 209.8 kcal/mol) and B) 0.84 ppm methyl acetate (GPB = 205 kcal/mol) in the API source.

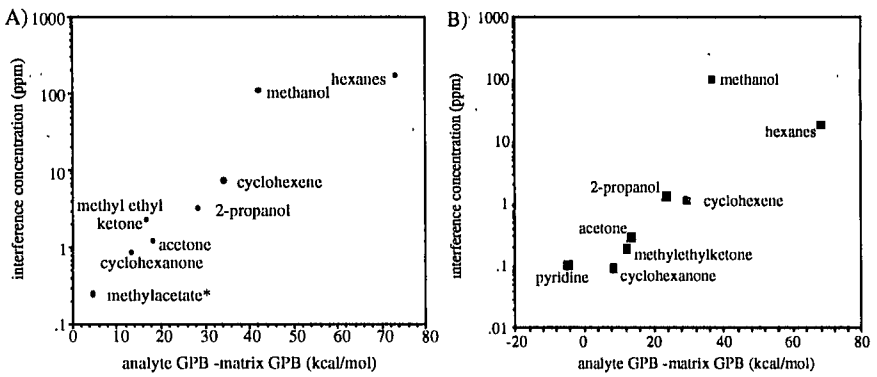

Figure 2 The interference of several matrix compounds with A) 1.08 ppm cyclohexanone (GPB = 196.6 kcal/mol) and B) 0.94 ppm acetone (GPB = 191.6 kcal/mol) in the API source.

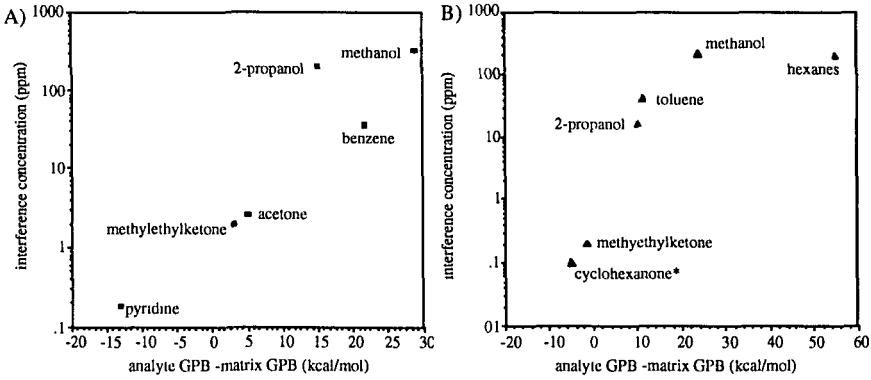

This series of studies shows that a strong correlation exists between the interference of compounds in the API source and their gas phase basicities. This correlation is related to both the competition for the reagent ions in the API source and the presence of a sufficient reagent ion population for ionization. Positive API is generally used to detect high GPB analyte compounds (greater that 190 kcal/mol). In these studies, analyte compounds with GPBs greater that 190 kcal/mol exhibited a strong correlation between the matrix compound GPBs and their interference in the API source. Matrix compounds with high GPBs competed strongly for the available reagent ions, producing interferences at relatively low concentrations. Matrix compounds with low GPBs did not compete strongly for the available reagent ions, and thus produced interferences only at higher concentrations. These relationships should prove useful in predicting the applicability of API/MS to atmospheric monitoring environments in which several compounds may be present simultaneously.

Poorer correlation was observed for analyte compounds that have GPBs below 190 kcal/mol, or whose primary ionization mechanism is charge-exchange rather than interaction with water cluster reagent ions. This poor correlation may be due to differences in the method of ion formation for these compounds. The presence of compounds that are ionized through charge-exchange may decrease the reagent ion population through competition for available corona electrons This ionization mechanism differs greatly from that of higher GPB compounds that are generally formed through chemical ionization. These results may be worthy of further investigation, but because of the lower response of the API source to these low GPB compounds, they are not commonly analyzed using API/MS.

In -Situ Environmental Monitoring of Organic Aerosols and Vapors by Transfer Line GC/MS

Jacek P. Dworzanski, Neil S. Arnold, Xiansheng Nie and Henk L.C. Meuzelaar
Center for Micro Analysis and Reaction Chemistry
University of Utah, Salt Lake City, UT 84102

Pollutants discharged into the air are generally present at very low concentrations which may fluctuate rapidly, depending on environmental conditions. Therefore, real time detection and quantification by GC/MS requires high sensitivity and rapid sampling techniques. To meet these requirements special vapor and aerosol sampling modules have been developed in our laboratory and field tested. The modules consist of a sampling unit and a low-dead volume Curie-point thermal desorption inlet [1] interfaced to a temperature programmable "transfer line" capillary column [2] which is coupled to a ruggedized, miniaturized Finnigan MAT ion trap mass spectrometer (ITMS), the so-called MINITMASS [3].

A schematic diagram of the sampling procedure followed by on-line flash desorption and GC/MS analysis is shown in Fig. 1. Volatile organic air pollutants were enriched on the Tenax-GR sorbent wrapped in a ferromagnetic foil with a 315 C Curie-point temperature, whereas aerosols were collected on prebaked quartz fiber filters, using a portable air sampling pump. From the sampled filters 2 mm strips were cut and positioned inside of a special glass reaction tube lined with a ferromagnetic foil (Curie-point, 315 C). Flash desorption of organics from the strips and from the Tenax-GR sorbent was achieved by fast inductive heating of the foil (ca. 1000 C/s) up to the Curie-point temperature. Total heating time was 10 s under a continuous flow of helium that carried analytes into a fused silica capillary column (Fig. 2). Subsequent to sample desorption, a 1.8 m long 0.18 mm i.d. capillary column, coated with DB-1 (0.4 μm film thickness), was temperature programmed at high rate that allowed for fast GC separation and MS analysis of analytes. The short capillary column was contained inside of a stainless-steel tube, which was resistively heated and controlled by an IBM compatible computer to provide high temperature programming speeds (e.g., up to 20 C/s).

An example of analysis results for volatile organic air pollutants collected in the Nogales, Arizona area and separated using a capillary column with an average carrier gas velocity of approximately 200 cm/s, is shown in Fig. 3a as a total ion current chromatogram and selected ion chromatograms. This is contrasted with a profile of pollutants collected in parallel but analyzed using a long fused silica capillary column (30 m, 0.25 μm i.d., DB-1, 0.25 μm film thickness) [Fig. 3b]. The comparison of air pollutant profiles presented in Fig. 3 indicate that similar data suitable for identification and quantification of volatiles in air may be obtained almost 20 times faster using a short column approach. A typical chromatogram of the semivolatile organic compounds thermally extracted from aerosols collected on a quartz filter in the Nogales, Arizona area and analyzed with a long capillary column is shown in Fig. 4, whereas normalized concentration profiles of selected pollutants measured in the same area are presented in Fig. 6. Factor analysis was used for comparison of aerosol density and particle size distribution data as well as wind speed and direction with variations of normalized selected ion profiles of the pollutants. The results presented in Figs. 5-7 point out that identification and quantification of major groups of pollutants can be performed via this technique to distinguish and identify organic aerosol emission sources.

Real-Time Multi-Point Environmental Monitoring Using a Process Mass Spectrometer

Randall E. Pedder, David L. Halpern, Luke Kephart, Jim Woodle, Joe Schwab, and Ted Brackmann.
Millipore Corporation, Extrel, 575 Epsilon Drive, Pittsburgh, PA 15238

Introduction. Increased awareness of environmental issues has led to a commitment by industry and government (EPA, OSHA, NIOSH) to control emissions of harmful pollutants. Current demands call for monitoring of air from numerous exhaust ducts, perimeter points, and ambient locations with very short loop times to provide continuous information. An Extrel Questor process mass spectrometer has been configured for monitoring ambient air at as many as 50 sampling points, with cycle times on the order of 10 to 15 seconds per point. The analyte gas mixture is measured by selected ion monitoring (SIM), followed by real-time conversion of measured ion intensities into component concentrations, which are archived using a PC based data system.

Typical Application. Sample gas is almost totally "normal" air with ppb to ppm of one or more compounds of interest. Concentrations must be monitored "continuously" with data archived and alarms sounded when limits are exceeded. There are multiple sampling locations which are remote (tens to hundreds of feet) from the analyzer. There is a maximum allowable time between "fresh" measurements from each sampling point (i.e. dead time). Analyte samples may be chemically active (sticky).

Experimental. All analyses were performed using an Extrel Questor Process Mass Spectrometer: 3/4 inch Quadrupole mass filter with 2 - 200 a mass range, dual filaments, and Dual Faraday/electron multiplier detector. Dynamic range using Faraday collector is 10 ppm to 100%. Dynamic range using the electron multiplier is 10 ppb to 100 ppm. SIM dwell time: 300 ms per component. Operational Mode: totally automated in both calibration and acquisition. Transfer line is deactivated fused silica transfer line directly into ionizer, maintained at up to 300°C. Sample flow rate into ionizer: 2 millitorr-liters per second. Sample Preparation: All sample mixtures were created in-house from neat liquids using a simple gas dilution system.

Sampling System Considerations. Choose sample line and valve materials which are compatible with the application, and heat trace where necessary to prevent condensation. Typical ambient air applications use all-Teflon materials to minimize reactions and stickiness. Filter all sample using at least seven micron in-line filter to remove particulate matter. Use large diameter tubing for high conductance and minimum clearing delays. Sampling system and environmental housing each typically exceed the cost of the analyzer itself. See Figure 1 for a block diagram of Questor Ambient Sampling Inlet.

Per-point Analysis Speed. Figure 2 represents the results from two complete cycles of a simple two sample point analysis system. Valve 8 contains 1 ppm toluene and 50 ppb methylene chloride in air. Valve 9 contains 50 ppb toluene and 1 ppm methylene chloride in air.

Limits of Detection. Two calibration curves are presented in the Figure 3, one for methylene chloride (blank, 50 ppb, 1 ppm, 10 ppm), and one for toluene (blank, 50 ppb, 1 ppm). The Questor mass spectrometer offers a wide linear dynamic range for these compounds, down into the ppb range. Statistics for the limit of detection of methylene chloride, benzene, and toluene are presented as follows:

Compound	Concentration	R.S.D.	L.O.D. (3 $S.D._{blank}$ * Sens.)
Benzene	40 ppb	6.4%	
Toluene	50 ppb	14.7%	12 ppb
$MeCl_2$	50 ppb	25.4%	36 ppb

Conclusions. The unique problems associated with ambient air monitoring require great attention in engineering an ambient air sampling system. The Questor process mass spectrometer has the sensitivity, dynamic range, and analysis speed to serve effectively as an ambient air analyzer.

DEVELOPMENT OF A REAL-TIME AIR MONITORING INTERFACE FOR THE ITS-40 ION TRAP MASS SPECTROMETER.

C.V. Thompson, M.B. Wise, A. V. Blalock, and G.B. Hurst, P.O. Box 2008, MS-6120, Analytical Chemistry Division, Oak Ridge, National Laboratory, Oak Ridge, TN, 37831-6120.

A direct air sampling interface has been developed for real-time continuous monitoring with a Finnigan MAT Corporation ITS-41 ion trap mass spectrometer. The basic concept for this interface was derived from earlier studies in which a Finnigan ITMS ion trap mass spectrometer was configured and evaluated for direct air monitoring applications. The ITS-41 is so designed that the optimum operating pressure of the instrument is amenable to air sampling, and it is rugged enough to permit continuous exposures to a harsh air environment. The operating mechanism of the ion trap is also particularly amenable to air sampling, as the concentration of analyte ions can be maximized in the trap through manipulation of the RF field and controlled introduction of helium as a buffer gas.

An important feature of the direct sampling interface is the pulsed addition of helium into the sample stream. Earlier experiments in which helium was mixed with the air sample in a continuous fashion showed that this method tended to dilute the analyte concentration in the air to unacceptably low levels. Experiments were also conducted in which the air sample and helium were added through separate capillary restrictors in the instrument interface, with similarly unsatisfactory results. In this work, a TTL signal from the ITS-41, synchronized with the scan function for the analyzer, is output to the air sampling interface for actuation of the solenoid valve to pulse the helium flow. Additional fine control of the helium pulse is achieved through circuitry which allows for introduction of a delay in the valve actuation and control of the duration of the actuation. These fine controls permit the optimization of analyte ion concentrations in the analyzer. We believe that the segmentation of the air sample with helium permits maximum ionization of analyte molecules in the air sample, followed by an immediate introduction of an optimum amount of helium to buffer the ions and "cool" their kinetic energy. No other helium buffer is added to the instrument. Results from the ITS-41 have been very encouraging for the real-time detection of volatile organics such as benzene, trichloroethylene, and tetrachloroethylene in air, with instrument detection limits demonstrated in the 1 to 20 ppb range. Figure 1 is a picture of the ITS-41 equipped with the air monitoring interface. Figure 2 is a spectrum of an air sample containing trichloroethylene and tetrachloroethylene, taken from the excavation of an underground storage tank, which was analyzed with the air sampling interface.

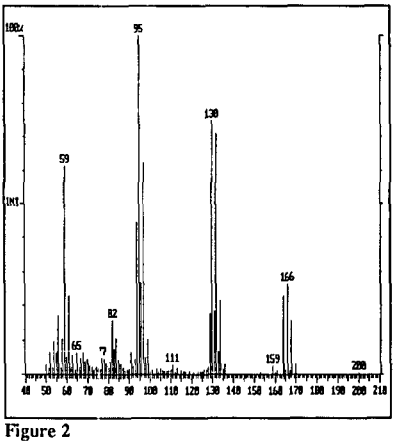

Figure 2

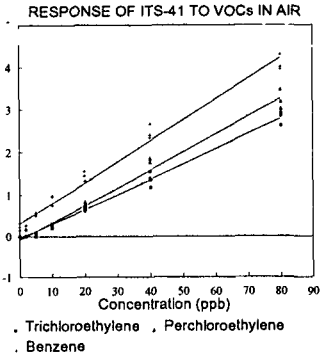

Figure 3

Detection limits for benzene, trichloroethylene, and tetrachloroethylene as determined from 95% confidence intervals about the linear regression of the data, are 16, 11, and 14 ppb, respectively. Figure 3 is a plot of calibration data for the analysis of these three compounds in air. Preliminary experiments with some less volatile compounds have demonstrated instrument detection limits of less than 10 ppb for naphthalene, less than 50 ppb for methyl salicylate, and less than 500 ppb for di-isopropylmethylphosphonate (DIMP). Future studies with the interface will include extensive field testing and investigations of its applicability to drug testing.

Introduction

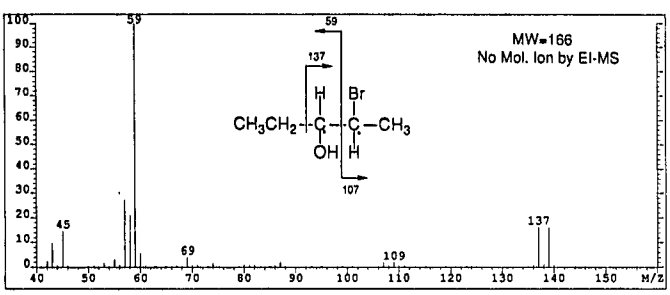
Since the discovery of potentially harmful trihalomethanes in chlorinated drinking water, alternative disinfection methods have been sought. The principal alternative method is ozonation; however, little is known about the identity, precursors, or mechanism of formation of ozonation disinfection by-products (DBPs). In particular, almost nothing is known about the identity or formation of DBPs in the presence of bromide, which is so efficiently oxidized by ozone, that it can singularly determine the ultimate DBPs formed. Furthermore, brominated DBPs are generally more toxic than their chlorinated analogs. Therefore, ozone disinfection may present a greater human health risk than chlorination in areas where natural bromide levels are high, such as in coastal cities like Los Angeles. Recently, using multispectral techniques (combination of mass and infrared methods), we have precisely identified 22 brominated compounds in ozonated natural water containing bromide. Of these 22 compounds, 15 were of a previously unreported group of unusual 5-carbon brominated alcohols--bromohydrins (Br and OH groups residing on adjacent carbon atoms). Our preliminary work that describes the identification of the most concentrated bromohydrin is reported in a recent publication.[1]

Experimental

Multispectral identification techniques included gas chromatography coupled with low and high resolution electron-impact mass spectrometry (GC/EI-MS), low resolution chemical ionization mass spectrometry (GC/CI-MS), and Fourier transform infrared spectroscopy (GC/FT-IR). CI-MS experiments utilized two gases: methane and 2% ammonia/methane. GC/MS analyses were performed on either a VG 70-SEQ high resolution hybrid mass spectrometer or on a Finnigan 4500 quadrupole mass spectrometer. GC/FT-IR experiments were performed on a Digilab Model FTS-60 FT-IR spectrometer. Natural water samples were collected from University Lake, Orange County, NC, and were used as received. The total organic carbon (TOC) of the water was 8.0 mg/L, and the ambient bromide level was 0.03 mg/L. Ozonation reactions were performed by using a Union Carbide Model #SG 4060 ozone generator) in doses of 1.0 mg O_3 per mg TOC.[2]

Results and Discussion

The identification of the bromohydrins presented a challenging problem for several reasons. First, only 1 of the 15 bromohydrins was present in mass spectral libraries. Second, EI mass spectra were nearly void of structural information--virtually none of the compounds exhibited a molecular ion, and spectra contained relatively few distinguishing ions. Third, the common method for generating



EI mass spectrum of one bromohydrin identified (2-bromo-3-pentanol).

molecular ions, methane CI-MS, was not successful. The key to identifying these compounds was to use a series of unconventional identification techniques: 2% ammonia in methane CI-MS, high resolution EI/MS, and infrared spectroscopy (IR). With the use of the novel gas mixture of 2% ammonia in methane, CI-MS revealed molecular ions, and high resolution EI-MS yielded empirical formulas for the few ions that were present in the EI spectra. IR spectroscopy provided functional group information, including the unusual presence of two OH stretching peaks, which usually would indicate the presence of two OH groups on a single molecule. However, because CI-MS and high resolution EI-MS indicated that there was only one oxygen atom present, the IR data was further interpreted to reveal the existence of two co-eluting conformers of a hindered alcohol, in which one conformer exhibited intramolecular hydrogen bonding, and the other did not. Using a computational chemistry system which permits both molecular mechanical and quantum mechanical calculations, we obtained energy-minimized structures of the bromohydrins. These calculated structures confirmed the possibility of two conformers, and also clearly showed the electron density overlap of the hydrogen bond (between the OH and Br). One other unusual aspect of the bromohydrins identified in this study was the existence of several chromatographically separable stereoisomers. Several sets of diastereomers were observed, due to the presence of two chiral carbon atoms on the 5-carbon bromohydrins. Due their structural similarity to isoprenes, we believe that the bromohydrins most likely arise from terpenes than from humic material, which is commonly assumed to give rise to virtually all drinking water DBPs.

In conclusion, most of the 22 compounds identified had structures based on either a bromo-methyl-butanol, bromopentanol, dibromopentanol, dibromopentane, or tribromopentane, including several sets of *RR/SS* and *RS/SR* diastereomers.

APPLICATION OF LIQUID IONIZATION MASS SPECTROMETRY TO ANALYSIS OF ORGANIC COMPOUNDS IN AQUEOUS ENVIRONMENTAL SAMPLES

T. Kobayashi, H. Nagahara, T. Kaneko,
Y. Yokoyama, K. Kobayashi and M. Tsuchiya

Laboratory of Analytical Chemistry, Faculty of Engineering
Yokohama National University

Organotin compounds are biocides and have been widely used for antifouling agents for ships and fishing nets. Recently, much attention has been expressed concerning the safety of these compouds in the environmental cycle. The developmenmt of better analytical methods has been required for the determinaion of the various orgaontin compounds present in environmental and biological samples. Liquid ionization (LI) (1) is a soft ionization method for mass spectrometry providing qualitative information with high sensitivity for both volatile and non-volatile organic compounds, regardless of polar and non-polar, in a mixture.

A Shimadzu GCMS-QP300 quadrupole mass spectrometer equipped with an LI ion source was used (2). One microliter of a sample solution was deposited on the sample holder. Mass spectra were scanned from m/z 10 to 500 and recorded every 2.4 s, while heater current was linearly increased (0.26A/min) from 0 to 0.6A. Thermal desorption (TD) profiles gave information about the degree of separation between components. A selected ion monitoring (SIM) technique was applied to detect trace amount of organotin compounds. Four peaks corresponding to the analytes were selected and their intensities were recorded every 1.25 s.

LI mass spectra of several standard organotin compounds commercially available gave a couple of intense peaks corresponding to $(M-Y)^+$, where Y were alkyl, Cl and the like. Various types of organotin compounds were detected with similar sensitivities, without any derivatization (Fig.1).

A mixture of 2-methylbutanol and octanol was found to be a good matrix for tributyltin chloride (TBTC). It was also found that this matrix mixture (20% each in benzene) should be added on a sample probably because TBTC is volatile. In contrast, a matrix like t-butylalcohol was good for triphenyltin chloride (TPTC). Detection limits by SIM for TPTC using standard solution were about 0.3ng, TBTC were about 0.3pg. These detection limits are useful for sea water.

LI mass spectra of a hexane extract from sea shells (blue mussel) directly measured showed the intense peaks at m/z 369 and m/z 257 corresponding to cholesterol (MH^+-H_2O) and palmitoyl moiety of constituents, in the blue mussel respectively (Fig.2). A Sephadex LH-20 (Pharmacia) column was used for preliminary separation of TBTC and TPTC from other constituents in the extracts. Figure 3 shows mass spectra of fractions containing TBTC and TPTC respectively. TBTC and TPTC were separated each other with only a small amount of other constituents in sea shells (Fig.3).

The present method, including pretreatment with a LH-20 column and detection by LI-MS, is promising method for organotins in the sea

shells. Determination of organotin compounds in actual marine samples and sea waters seems to be possible using proper internal standards which are now under study.

A Comparison of Analytical Techniques for Measurement of Volatile Hydrocarbons in Ground Water

by Curtis S. Phinney and Isabelle M. Cozzarelli
U.S. Geological Survey, 431 National Center, Reston, VA 22092

Determination of monoaromatic hydrocarbons in ground water is a standard procedure for many laboratories, because observation of certain of these species is considered indicative of petrochemical contamination. Most studies of ground-water contamination have focused on the fate of benzene, toluene, ethylbenzene, and the xylenes (BTEX) because of the toxicity of these compounds and their relatively high solubilities and mobilities in water (Wilson and others 1986; Barker and others, 1987). Recent studies have shown that a broad range of C6-C10 aromatic hydrocarbons is present in ground water contaminated with crude oil (Eganhouse and others, in press), landfill leachates (Först and others, 1989), and gasoline (Baedecker and others, 1991). This study investigated the relative merits of two analytical methods, a pentane/water microextraction followed by gas chromatography with flame-ionization detection (pentane/GC-FID), and purge and trap stripping of the sample with helium followed by gas chromatography with ion-trap mass-spectrometer detection (open-loop/GC-ITD).

The specificity, sensitivity, and reproducibility of the two methods are compared for high and low concentrations in ground-water samples from two well-characterized locations near a subsurface gasoline spill in Galloway Township, New Jersey (Fischer and others, 1991). These two techniques are compared in the analysis of C6-C10 aromatic hydrocarbons, which are routinely measured during investigations of petroleum-product contamination in ground-water systems.

Ground-water samples were collected from two 1/4" stainless steel nested monitoring probes, screened at 18' and 22' depths, respectively. The probes were sampled with a peristaltic pump attached directly to the stainless-steel tube with silicone tubing. Ten replicate samples were collected for analysis by each technique from both locations. Collected volumes were approximately 250 mL for pentane/GC-FID and 40 mL for open-loop/GC-ITD analysis. Samples were preserved with mercuric chloride and deuterated *ortho*-xylene was added as a recovery surrogate prior to being placed on ice for shipment to the lab. Analytes were extracted with 2.0 mL pesticide grade pentane for pentane/GC-FID analysis. Appropriate volumes (20-400 uL) were introduced to a Tekmar 2000 liquid sample concentrator for open-loop/GC-ITD analysis.

Using the open-loop/GC-ITD method, it was possible to identify 35 C6-C10 aromatic hydrocarbons, compared to 21 components identified by the pentane/GC-FID method. Higher specificity, sensitivity and variability were observed for samples analyzed by the open-loop/GC-ITD method compared to those analyzed by the pentane/GC-FID method. Component concentrations determined by the two techniques were generally in good agreement, although concentrations measured by pentane/GC-FID were often higher . For example, difficulty in resolving benzene from interferences e.g., cycloalkanes sometimes resulted in considerably higher benzene and "BTEX" concentrations by the pentane/GC-FID method compared to open-loop/GC-ITD. At the low concentration, mean BTEX concentrations (n=10) were 661 ug/L by pentane/GC-FID compared to 490 ug/L by open-loop/GC-ITD. These interferences did not have as great an effect on the high concentration samples e.g. 5,077 ug/L compared to 5,089 ug/L, respectively.

The use of brand, firm, or trade names in this paper is for identification purposes only and does not constitute endorsement by the U.S. Geological Survey.

Open-loop stripping followed by mass-spectrometric detection yields results that are somewhat more variable than pentane/GC-FID, but the increased sensitivity and selectivity of open-loop/GC-ITD is significant. The ability to identify and quantify components that are poorly resolved chromatographically provides an opportunity to improve an understanding of the behavior of individual monoaromatic hydrocarbons in ground-water systems.

Table 1. Selected C_6-C_{10} Aromatic Hydrocarbons in Gasoline Contaminated Ground Water

Compounds	Low Level Site				High Level Site				Limit of Quantitation	
	Pentane/FID		Open-Loop/ITD		Pentane/FID		Open-Loop/ITD		Pentane/FID	Open-Loop/ITD
	mg/L	C.V.	mg/L	C.V.	mg/L	C.V.	mg/L	C.V.	(µg/L)	(µg/L)

MEASUREMENT OF ALPHA AND BETA PINENE AND LIMONENE IN WATER AND EMULSION SAMPLES.

*David W. Berberich and Robert G. Orth, Monsanto Company, 800 North Lindbergh Blvd., St. Louis, MO., 63167, Mailzone U1F.

The goal of this project was to determine the amount of alpha and beta pinene and limonene in scrubber water for the evaluation of scrubber efficiency. Certain samples were modified with surfactant to determine if the surfactant improved the scrubbing efficiency.

Analysis was performed using a Varian Saturn GC/MS system. Prior to analysis, the water samples, emulsion samples, and spikes were extracted with hexane by adding 9 mL of sample and 3 mL of hexane into 25 mL vials. Sodium chloride was added to the emulsion samples to achieve a more distinguishable phase separation. The gas chromatograph was operated in the split mode of operation utilizing a J&W DB5 30m fused silica capillary column. The mass spectrometer was operated in the electron impact ionization mode at 20 micro amps filament current with a fixed ionization time of 50 micro seconds. The mass spectrometer was scanned from m/z 15 to m/z 150.

A high and low spike were analyzed for both matrices encountered (i.e. water and emulsion). The spikes were prepared by adding 7.74 ug (low spike) and 77.4 ug (high spike) of each component to the 9.0 mL of sample. The extraction procedure for the spikes is identical to the procedure for the samples. One sample was analyzed in triplicate to show reproducibility of the method. A laboratory water blank was also analyzed.

The results for the quality assurance and quality control (QA/QC) samples are summarized in Table 1. All of the spiked samples are corrected for the concentration of the compounds of interest in the non-spiked samples. The emulsion samples were not homogeneous (i.e. two phases an aqueous and organic phase were clearly visible). The emulsion samples (low spike emulsion Test1 and FC Emulsion Test1 #1-3) were sampled after the original sample was mixed in an effort to obtain a homogenous representation of the sample. All other emulsion samples were taken from the aqueous portion of the sample without mixing. This mixing of the emulsion spike may account for the large differences in the percent recoveries for the low spikes of the emulsion (i.e. percent recoveries varied from 180% to 250%). We suspect that the organic phase contributed to recovery yields > 100%.

The QA/QC data for triplicate injections of FC Emulsion Test 1 indicated a reproducibility of 4% for the pinenes and 13% for the limonene. The laboratory water blank was blank (i.e. no compounds of interest were detected). The 8.6 ppm standard analyzed for QA/QC purposes yielded results within 5% of the predicted values for the compounds of interest. The calibration curves for the standard compounds of interest (three orders of magnitude) had correlation coefficients of > 0.995.

The results for the spiked samples indicating percent recoveries are summarized in Table 2. Due to the great variation in the % recoveries for the low spike emulsion samples the percent recoveries reported for the high spike are used to calculate sample concentrations in Table 3. The water samples yield percent recoveries that varied from 85% to 140% recovery. Average values for the percent recoveries were used to determine concentrations in Table 3.

The results from the five sample analyzed are summarized in Table 3. Two of the water samples had concentrations of the compounds of interest below the limit of quantitation. The sample Water RJ1 Test1 had an alpha pinene concentration of 160 ppb and no detectable concentrations of beta pinene and limonene. The water samples were corrected for % recovery based on the QA/QC spikes. The sample FC Emulsion Test1 had an alpha pinene concentration of 57 ppm, beta pinene 26 ppm, and limonene 4.5 ppm. The sample FC emulsion had an alpha pinene concentration of 58 ppm, beta pinene 28 pm, and limonene 4.8 ppm. The emulsion samples were corrected for % recovery based on the QA/QC high spike.

These analyses were inconclusive as to the efficiency of the scrubber with and without the surfactant present. The major difficulty associated with these analyses was the separation of the emulsion and organic phases. The emulsion samples were not completely homogeneous; hence, a representative sample was difficult to obtain. This may account for

the high percent recoveries for the low spikes. Also, a blank surfactant sample was not analyzed; therefore, background levels of the compounds of interest in the surfactant were undetermined.

Table 1. QA/QC Samples.

Sample	Alpha pinene (ppm)	Beta pinene (ppm)	Limonene (ppm)
Low Spike 860 ppb Emulsion Test1	2.1	1.5	1.9
High Spike 8.6 ppm Emulsion Test1	3.4	6.3	11
Low Spike 860 ppb Water RJ1 Test1	0.64	0.94	1.1
Low Spike 860 ppb Water RJ1 Test1	0.69	1.0	1.0
High Spike 8.6 ppm Water RJ1 Test1	8.0	11	12

FC Emulsion Test1 #2	11	10	3.3
FC Emulsion Test1 #3	10	10	3.0
Water Blank	ND	ND	ND
8.6 ppm	8.8	9.0	9.0

ND - Not detected LOD (0.040 ppm is based on S/N = 3 for lowest standard)

Table 2. Percent Recoveries For Compounds Of Interest.

Sample	Alpha pinene (% recovery)	Beta pinene (% recovery)	Limonene (% recovery)
Low Spike 860 ppb Emulsion Test1	250%	180%	220%
High Spike 8.6 ppm Emulsion Test1	40%	73%	140%
Low Spike 860 ppb Water RJ1 Test1	77%	110%	120%
High Spike 8.6 ppm Water RJ1 Test1	93%	130%	140%

% Recoveries are based on the sample spikes.

The internal standard was added after the samples were extracted.

Table 3. Quantitative Results For The Samples.

Sample	Alpha pinene (ppm)	Beta pinene (ppm)	Limonene (ppm)
FC Emulsion Test1	57	26	4.5
FC Emulsion	58	28	4.8
Water Sample 2RJ	ND (0.047)	ND (0.033)	ND (0.031)
Water Sample RJ1	ND (0.047)	ND (0.033)	ND (0.031)
Water Sample RJ1 Test1	0.16	ND (0.033)	ND (0.031)

Water samples are corrected for recoveries.

Emulsion samples are corrected for high spike recoveries.

ND - non detectable (LOD - Limit of Detection based on S/N)

Determination of Atrazine in Water at Low and Sub-PPT Levels by Using Solid-Phase Extraction and GC/HRMS

Z. Cai[1], V. M. S. Ramanujam[1], M. L. Gross[1] and R. L. Spalding[2] (1) Midwest Center for Mass Spectrometry, (2) Water Center, University of Nebraska, Lincoln, Nebraska-68588

Atrazine is one of the most widely used herbicides for a wide variety of crops. Residues of this herbicide are frequently found in environmental samples of soil and water. Currently used analytical techniques for atrazine and related herbicides involve GC, GC/MS and HPLC with detection limits of 10-200 ppt (*1-3*). Lower detection limits, however, are required for assessment of contamination in deep water aquifers such as the Ogallala (*4*). Low detection limits are also required to determine the effectiveness of water treatment methods and to support study of the migration, dissipation and degradation of herbicides (often isotopically labeled) that are purposely added to the environment (*5*).

The most significant barriers to lowering detection limits are background signal and sample interferences. These grow exponentially as the detection limit is lowered because the instrument is operated at higher sensitivity, and the sample extracts are concentrated several fold.

Magnetic sector, high resolution mass spectrometry (HRMS) provides high sensitivity and high specificity and allows many interferences to be resolved. Combined with GC, HRMS has been used for many years with success for the analysis of chlorinated dioxins and related materials. However, GC/HRMS has yet to be applied to the trace analysis of atrazine and related herbicides.

Atrazine and the spiked internal standard $^{13}C_3$-atrazine were removed from water samples by solid-phase extraction using a C-18 bonded silica cartridge. The GC/HRMS analyses were performed on a Carlo-Erba GC/Kratos MS-50 double-focusing MS with the MS operated in EI mode with resolution 10,000 (10% valley definition). High resolution EI mass spectra for native atrazine and $^{13}C_3$-atrazine were obtained (Figure 1). This provided the necessary information for the selected ion monitoring (SIM) which was operated in mass profile mode (*6*). Three ions were selected for the analysis of atrazine: *m/z* 200.0703 and *m/z* 203.0805 as the quantitation ions for native atrazine and $^{13}C_3$-atrazine, respectively, and *m/z* 202.0674 as the confirmation ion for the identification of atrazine. The identification was based on examination of mass profile peak shape, central mass shift, isotopic ratio of *m/z* 202.0674 to *m/z* 200.0703, and the retention time of GC separation. The area of mass profile peaks of the quantitation ions enabled the quantitative analysis of atrazine.

The mass spectrum of $^{13}C_3$-atrazine (Figure 1b) illustrates that the labeled atrazine has no significant signals at *m/z* 200 and *m/z* 202. Therefore, the internal standard does not interfere with the analysis of native atrazine when both compounds are present. On the other hand, the native atrazine may slightly interfere with monitoring of *m/z* 203.0805 which is the quantitation ion of $^{13}C_3$-atrazine. The spectrum of native atrazine (Figure 1a) shows a signal at *m/z* 203.0696 with an abundance of 3.2 %, which results from ^{13}C and ^{37}Cl contribution to the $[M - 15]^+$ fragment ion. Since the percentage of this isotope contribution is either in standard or in sample constant, an area correction can be used to minimize the analytical error. However, the correction is not very necessary when the concentration of native atrazine is similar to or less than the concentration of the spiked $^{13}C_3$-atrazine. Moreover, a relative response factor of native atrazine relative to $^{13}C_3$-atrazine was used to improve the method accuracy. Figure 2 shows the linear dynamic range over three orders of magnitude, which was obtained by a calibration test.

Recovery of atrazine in water by the solid-phase extraction was tested for 3 different concentration levels: 1, 5, and 10 ppt (Table 1). Since the isotopically labeled internal standard was added into the water samples prior to the sample preparation, the recovery should not affect the method accuracy and precision. The detection limit can, however, be improved when good recovery is achieved. Table 2 shows the detection limit for atrazine at a signal-to-noise ratio of 3. The accuracy and precision of the method were assessed by spiking eight 500-mL samples of NANOpure water with both native (1 ppt) and labeled (5 ppt) atrazine. The average relative error for the determination of atrazine is less than 15% indicating that the method achieved an accuracy of nearly 90%. The method precision given as relative standard deviation (RSD) is better than 15% (n=8) for the standard water samples.

Table 3 shows the results of analyses for some real water samples: (1) from Ogallala aquifer wells with different depths, in which no atrazine was detected before by using a GC/quadrupole MS; (2) from the deep primary aquifers southeast of Grand Island, Nebraska; and (3) from a tap in the chemistry department, University of Nebraska. The results of the blank and duplicate samples show the excellent accuracy and high reliability of the method.

The described method was successfully used to analyze atrazine at low and sub-ppt levels in more than 50 environmental water samples and can be expanded to the metabolites of atrazine as well as other related herbicides present in the enviroment.

DETERMINATION OF ATRAZINE IN WATER AT THE SUB-ppt LEVEL BY USING SOLID-PHASE EXTRACTION AND HIGH-RESOLUTION FAB-MS

K.A. Caldwell, V.M. Sadagopa Ramanujam, Z. Cai, and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304.

Atrazine is used to control weeds in corn, soybean, wheat, barley, and sorghum crops, and it is the most widely used herbicide in the Midwest. Residues of atrazine have been detected in soils, surface waters (including rivers and lakes) and ground water. Detection limits for present analytical procedures are in the range of 0.01 to 0.5 ppb. Because the levels of atrazine in deep water aquifers, such as the Ogallala, are expected to be lower, more sensitive detection methods are needed to assess contamination.

We developed an ultra-trace analysis method, based on the use of solid-phase extraction and high-resolution FAB mass spectrometry, for the determination of atrazine in natural waters and tap water. The determinations were compared to those obtained from a complimentary method[1] incorporating capillary GC/HRMS to validate the FAB method.

Sample Clean Up and Preparation. a. Ground Water and Water from the Ogallala Aquifer. Prior to use, a C-18 solid-phase extraction cartridge (Waters Chromatography, 1,000 mg) was washed sequentially with 5 mL of methanol, dichloromethane, ethyl acetate, methanol, and distilled water by passing the solvents through the cartridge at a flow rate of approximately 2 mL/min.

All water samples (500 mL) were spiked with $^{13}C_3$-atrazine. For low-level samples, the final concentration of the internal standard was 5 ppt, and for high-level samples it was 50 ppt. The spiked samples were aspirated through the pre-washed C-18 cartridge at a flow rate of approximately 10 mL/min.

Both native and $^{13}C_3$-atrazine were eluted by passing 2 mL ethyl acetate through the cartridge at a flow rate of approximately 2 mL/min. The extract was dried with approximately 0.5 g anhydrous sodium sulfate (pre-purified by Soxhlet washing with methanol for 48 hours). The eluant was evaporated to 20-50 uL by using a slow stream of nitrogen. The dried eluant was analyzed by both capillary GC/HRMS[1] (1-2 uL on-column injection) and high-resolution FAB-MS.

b. Tap Water. Tap water samples (5 mL) were collected into a centrifuge tube and then spiked with 5 ng of $^{13}C_3$-atrazine (final internal standard concentration = 1,000 ppt). The spiked water was analyzed *directly* by using the procedure described below. Dichloromethane (300 uL) was added to the remaining sample which was then vortexed for approximately 2 minutes, and then the undried organic layer was analyzed.

Sampling and Storage. Samples of ground water (MLE and MLW series) were collected by the University of Nebraska Water Center from wells located southeast of Grand Island, Nebraska, and samples of water (Og series) from the Ogallala aquifer were collected from wells located near Shelton, Nebraska. Tap water samples were obtained from the chemistry department of the University of Nebraska in Lincoln. All natural-water samples were collected in pre-cleaned brown bottles and stored in a cold room.

Mass Spectrometry and Analysis. A Kratos MS-50 TA equipped with an Iontech FAB gun and a Kratos FAB source was tuned to a resolution of 10,000 (10% valley definition). The concentrated eluants from the solid-phase extractions (1-3 uL), the liquid-liquid extracts (1-4 uL), and the unextracted, spiked tap water (1-5 uL) were analyzed by placing the liquids in 0.2 uL of a DTT/DTE matrix. Narrow scans (300 ppm sweep width) over the following ions were collected by using a Kratos Mach-3 Data System: $[\text{Atrazine}+H]^+$ (*m/z* 216.1016), $[^{37}\text{Cl-Atrazine}+H]^+$ (*m/z* 218.0988, confirmation ion), and $[^{13}C_3\text{-Atrazine}+H]^+$ (*m/z* 219.1117, internal standard).

Because the DTT/DTE matrix contains two sulfur atoms, which have a negative mass defect, the mass regions of the monitored ions were relatively free of matrix-derived background ions, because the major background ions were of lower mass-to-charge ratio than those of the analyte ions.[2]

The volume of matrix that provides the greatest sensitivity was determined by placing 0.1 to 1.0 uL of the matrix, both with and without added atrazine, on to the probe. The background ion abundance at each mass region was approximately constant for each volume. For a constant amount, the absolute abundance of the $[\text{Atrazine} + H]^+$ ion increased as the volume of the matrix was decreased down to 0.2 uL, below which it decreased.

Quantification. Atrazine was quantified by comparing either the peak heights or the peak areas of the $[\text{Atrazine} + H]^+$ and $[^{13}C_3\text{-Atrazine} + H]^+$ ions. A linear calibration curve was obtained from 2 pg to 1000 pg (200 pg $^{13}C_3$-atrazine internal standard) by using the peak areas. For the analysis of the samples, if the interferences were low, then both peak heights and peak areas provided accurate quantitative data. If there was an incompletely resolved interference peak, however, then the heights of the centers of the peaks provided more accurate data than the peak areas (i.e. the data more closely matched those obtained from the capillary GC/HRMS analysis).

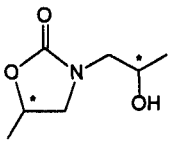
Quantification of 3-(2-hydroxypropyl)-5-methyl-oxazolidinone (HPMO) from Aqueous Environmental Samples by Isotope Dilution Gas Chromatography/Mass Spectrometry

W. N. Howald and D. J. Porubek

Department of Medicinal Chemistry, University of Washington, Seattle, WA 98195

INTRODUCTION

The hygroscopic diastereomeric alcohol, 3-(2-hydroxypropyl)-5-methyl-2-oxazolidinone (1), HPMO, is the principal reaction product of di-2-propanolamine when employed in industrial acidic gas (CO_2) removal processes, and a component found in the groundwater discharged from a superfund site in Kent, Washington to the Seattle/Metro Renton treatment plant. To examine the fate of this discharge and evaluate both its possible effects on the treatment facility and the environment, a reliable and sensitive analytical method capable of low level detection and quantification was required.



1
(*) chiral centers

Of the several analytical methods developed for the analysis of HPMO only the EPA Method for Semivolatile Organics (SW846) has incorporated mass spectrometric (MS) detection. However, the hydrophilic character of the molecule, combined with the inherent specificity and sensitivity limitations of the protocol, have shown this method to be of limited utility in submicrogram and low sample volume analyses. This work describes the determination of HPMO in groundwater, sludge and *in vitro* sources utilizing a stable isotope labelled internal standard and offers an assessment of the sensitivity, precision and accuracy of the technique in the quantification of the compound.

METHODS

HPMO & [15N]HPMO were prepared and authenticated in-house. [15N]HPMO was employed as an internal standard in the assay. The electron ionization mass spectrum of the internal standard was found to be in agreement with that of unlabelled compound. The mass spectrum of the purified compound showed the isotopic composition of the [15N] analog to be 97.6 atom % excess.

Similar procedures were used for the analysis of groundwater and sludge samples. In the case of groundwater, 0.10 and 1.0 ml aliquots were used for samples believed to contain more than or less than 10 ppm HPMO, respectively. For fluid and pressed sludge samples, a fixed volume of 2 ml was taken and in the latter case, 2 ml of distilled water were added to facilitate extraction. To each groundwater and sludge sample was added either 250 ml or 25 ml of an aqueous internal standard solution containing [^{15}N]HPMO (4 mg ml^{-1}), depending upon anticipated analyte concentration. The samples, saturated with NH_4SO_4 (~1.3 g ml^{-1}), were extracted with dichloromethane : isopropanol 85:15 v/v (2 x 10 ml) and the dried extracts treated with BSTFA:pyridine 1:1 v/v (50 ml) to form the TMS ethers of the analyte and its internal standard.

For the generation of standard curves, 1 ml aliquots of each of seven aqueous stock solutions containing increasing amounts of HPMO (0.001, 0.010, 0.050, 0.500, 1.00, 2.00 and 10.00 μg ml^{-1}) were processed in the same manner as the samples. Standards corresponding to the concentration ranges of 0.500 to 10.00 mg ml^{-1} and 0.010 to 1.00 mg ml^{-1} were used for groundwater and sludge samples, respectively. With each sample set, one of two control water samples were assayed to monitor the precision and reproducibility of the method. Control stocks containing 0.100 and 5.0 μg ml^{-1} of HPMO were stored at -20 °C and used throughout the study.

Analysis of the derivatized extracts was carried out using an HP 5970A MSD quadrupole mass spectrometer operated in the EI mode at 70eV electron energy, 220μA emission current, ~200°C source temperature and GC interface temperature of 280°C. The instrument was directly interfaced to a 30 m fused silica column (0.25mm i.d., 0.25 μm film thickness) coated with the bonded phase DB-5 (J & W Scientific) employing Helium as carrier gas (5 p.s.i. head pressure). Samples (1-2 ml aliquots) were injected in the splitless mode (injector temperature, 250°C) onto the column at 120°C. The column oven temperature was then programmed linearly at 5 °C min^{-1} to 200°C and then stepped to 250°C. Detection was performed in the SIM mode, monitoring m/z 187.1 and 188.1, corresponding to the $[M-CO_2]^{+\cdot}$ of the HPMO-TMS derivative and its [^{15}N] analog with a 100 ms/ion dwell.

Quantification was based upon the ratio of the sum of the areas measured for the analyte to the sum of the areas of the [^{15}N] labelled analog. Individual ion intensities were integrated using standard HP 59979C ChemStation™ software. The summed peak areas of [^{15}N]HPMO-TMS were corrected for the natural isotopic abundance derived from the unlablelled HPMO-TMS in the samples. The correction factor was determined empirically by GC/MS analysis of HPMO stock-solutions prepared with each sample set.

Response ratios for the analyte relative to internal standard were calculated and used for the generation of the standard curves or the determination of analyte concentration in submitted and control samples.

RESULTS

The extremely hydrophilic nature of the analyte and the difficulties in the development of an efficient extraction procedure, particularly at low concentrations and from complex sludge matrices, required the use of an internal standard with physical and chemical properties similar to that of HPMO. The selection of the [^{15}N] stable isotope analog of HPMO as an internal standard resulted in the elimination of these difficulties, as well as chromatographic interferences observed in some experiments.

The SIM method for the determination of HPMO-TMS derivative was investigated in the constant volume of the [^{15}N]HPMO-TMS internal standard solution. The fragment ions at m/z 187 and 188, corresponding to the $[M - CO_2]^{+\cdot}$ ions of the TMS derivatives of HPMO and [^{15}N]HPMO, respectively, were monitored. These ions were selected for the determination by SIM over other nitrogen-containing ions in the spectra, m/z 216 ($[M - CH_3]^+$) and m/z 172 ($[216 - CO_2]^+$), because they exhibited no ion interferences in sample analysis and were the most abundant ions at high m/z for the analyte and its internal standard.

The derivatization of the hydroxyl group of HPMO with several types of trimethylsilylation reagents was investigated. It was found that the reaction proceeds quantitatively at 40 °C for 30 min with BSTFA in the presence of pyridine. The best concentration of BSTFA in pyridine was found to be 50% (v/v). The TMS derivative showed a high detection sensitivity for the SIM method with the complete separation of the diastereoisomers.

To allow for possible origin dependent variations in the formation of the diastereoisomers, the sums of the observed peak areas were used in all calculations. A constant reflecting the degree of ion overlap from the analyte into the internal standard was determined empirically by the SIM GC/MS of HPMO on each day of analysis. This constant was then used to correct the observed peak areas of [^{15}N]HPMO for the contributions arising from the natural abundance of ^{13}C and ^{29}Si occurring in the unlablelled HPMO of each sample. For the generation of standard curves, the corrected, summed peak area ratios of the analyte to the internal standard were plotted against the known HPMO concentrations. Over the concentration ranges of 0.010 - 1.00 mg ml^{-1} and 0.500 - 10 mg ml^{-1} the standard curves were found to be linear with correlation coefficients greater than 0.996.

The intra-day variability was determined by the analysis of triplicate extracts of control samples throughout the day and was less than 6.2% at a water sample concentration of 0.100 μg ml^{-1}. The inter-day reproducibility showed coefficients of variation of less than 7.0% in all cases. Furthermore, it was found that the calculated concentrations were in good agreement with the predicted values.

Sufficiently high sensitivity was achieved to allow this method to be used to measure concentrations of HPMO ranging from 100 to 0.003 μg ml^{-1} in over 200 groundwater, sludge and *in vitro* bio-degradation samples. The detection limit for HPMO using this method was 0.001 μg ml^{-1} (40 pg on-column, S/N *ca.* 7:1).

CONCLUSION

A GC/MS method has been developed which allows the quantification of HPMO as its TMS derivative from aqueous samples after a simple extraction procedure. The technique has proven to be rapid, sensitive and reliable. The high specificity of the GC/MS in combination with the exact control of sample recovery, using [^{15}N]HPMO as an internal standard, provides precise and accurate determination of the analyte, with a detection limit of 40 pg on-column. To date, this analytical procedure has been successfully utilized in the analysis of HPMO in over 200 low volume (0.1 to 2.0 ml) samples collected in environmental and *in vitro* bio-degradation studies.

Simple Membrane Inlet Sources for Analysis of Volatile Organics in Water

Stephen A. Ruatta, Julius Perel and John F. Mahoney
Phrasor Scientific, Inc., Duarte CA 91010

Introduction

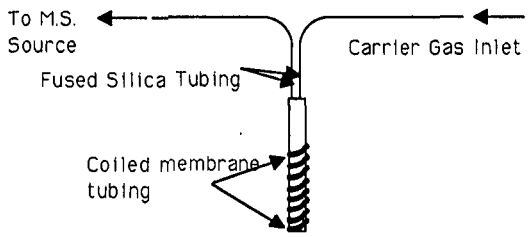
The use of semipermeable membranes made of silicone and other materials can be used as a reasonable and inexpensive method for inletting a number of compounds into a mass spectrometer for analysis. Particularly when dealing with aqueous systems containing relatively low mass compounds (<200 amu), the hydrophobic nature of many of these membranes is ideal because of their ability to allow diffusion of organics into the mass spectrometer while preventing the passage of water.

We discuss here some preliminary results obtained using Silastic® silicone tubing using two different sampling assemblies. The advantages and disadvantages of each are discussed.

Experimental

Because the sampling requirements were different, we built the following two membrane inlets shown below. Both inlets utilized Silastic® (Dow Corning) tubing (0.012" ID x 0.025" OD). The Silastic tubing was connected to fused silica tubing by sliding one over the other and making a permanent vacuum tight seal with Torr-Seal® vacuum epoxy. In both cases, the sample was introduced into our HP5982 mass spectrometer via the DIP inlet. The relative ease of both construction and use make these devices interesting and relatively rugged inlets.

The "in-situ" membrane inlet shown in the diagram below was designed to be placed into the solution to be analyzed so that the solution could be monitored as a function of time. A gas stream (He, N_2 or air) flows through the membrane tubing and then transports the organic analytes that pass through the membrane (by viscous flow) to the EI source of the mass spectrometer for real-time analysis.

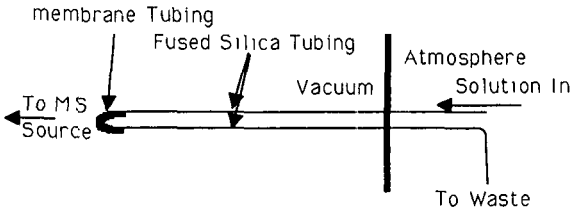


The second inlet shown in the following diagram was designed to allow a series of analyses to be made by the user. The aqueous matrix is pumped continuously through the membrane tubing and a sample is injected into the flow. These experiments utilized flows of at least 5ml/hour and a injection volume of 0.1µl. Mixing of the sample and extra matrix is minimized by the small tubing size and relatively short tubing length. Typical mass spectrometer source pressures during operation were $<1 \times 10^{-5}$ Torr.

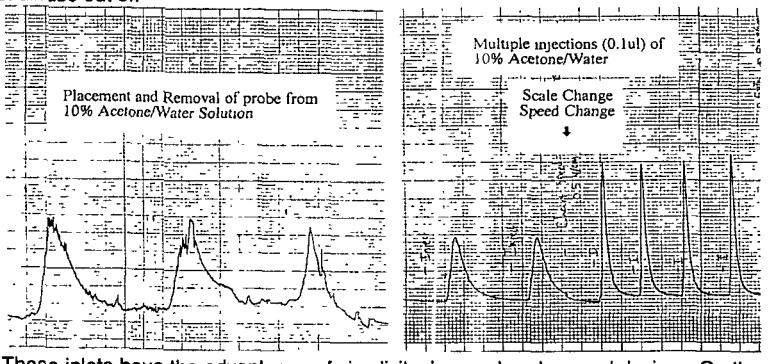
Results and Discussion

A list of compounds that we have found easily detectable are listed below:

Chlorodifluoromethane (Dusting Gas)	
Benzene	Trichloromethane
Acetone	Methanol



In the two Figures below are shown the results of multiple injections while using both inlets. The sequential probe results are shown on the right while the "in-situ" probe results are shown on the left. These preliminary results show that the sensitivity of these devices is fair. The "in-situ" probe also shows significant tailing of the sample between pure water rinses. This is likely due to the low gas flow and large membrane volume that the analyte must diffuse out of.



These inlets have the advantages of simplicity, low cost and rugged design. On the other hand, their sensitivity at this time is rather low. While this can certainly be improved, there are limitations based on the membrane properties that may not be avoided:

Since the sample is absorbed by the membrane and must be allowed to diffuse out between samples, the time between samples may not be very short. This is particularly a problem with the coiled membrane.

These membranes have a finite permeability to the compounds of interest that may place an ultimate limit on their sensitivity for these compounds. However, detection of various compounds at the sub-ppb level has been shown to be possible with similar membrane technology[1].

Conclusions

While the use of these types of membrane inlets will probably never replace techniques such as 'Purge and Trap' for sensitive analyses, in circumstances requiring rapid qualitative analyses for relatively high concentrations of organics in water, membrane inlets have some advantages:

- They are simple to build, use and maintain.
- They are inexpensive.
- They place a minor load on the vacuum system.

Further work on these systems to achieve increased sensitivity will continue.

High-Density Neutral Atoms Beam Generator Conjugated with TOFMS for Investigations of Chemical Erosion in Controlled Fusion "Tokamak" System.

N.N.Koudriavtsev, O.A.Maziar, A.M.Sukhov
Moscow Institute of Physics and Technology Dolgoprudny, Moscow Region, 141700,Russia FAX, (095) 408-58-77.

Investigations of chemical erosion of solid materials are of significant importance for developing of fusion plants such as "Tokamak", stellarators etc., because impurity ions arising in this processes are injected into the plasma and give rise to deviations from the normal running of the plants [1].These processes are also important at orbital flight of the vehicles. In contrast to the high energy (>1 keV) pure physical ion scattering, mechanism of plasma - wall interactions including low energy (1-10 eV) ions and neutral atoms is not clear yet which stimulate its experimental investigation.

In this work corpuscular beam generator based on electromagnetic shock tube is realized. Experimental setup consists of electromagnetic shock tube constructed as recommended in [2] and supplied with conical skimmer in the endplate, vacuum tank with high speed pumping, TOFMS for interaction control. Strong shock waves in the shock tube channel (Mach number M=15-50) provide effective dissociation and partial ionization (about few percents) of the gas flow behind them. The skimmer role is to form collisionless beam, which freely moves in the vacuum tank and interacts with solid sample.

Translational energy of the particles depends upon their masses and lies in the interval 1-15 eV modeling conditions in fusion systems and at orbital flight. Beam behind the skimmer contains ions and neutral atoms and molecules in definite fractions, which can be effectively monitored by variation of shock wave Mach number. The generator operates at the frequency up to ten pulses per second. The typical beam densities have high value up to 3 10^{12} cm^{-3}. The steady-state durations realized in each impulse are 35-50 msec. Integrated intensity of the beam achieves 10^{18} $cm^{-2}s$ which is sufficient for getting dose ~ 10^{22} cm^{-2} in short time interval of few hours. Such value of dose is supposed to be characteristic for plasma-wall interaction during 6-8 months fusion plants running [3] and during one year of orbital flight.

Beam composition and chemical composition of the gas in the interaction region measurements are carried out by means of time-of-flight mass-spectrometer. The mass number registration upper limit of the TOF MS is 1000 Daltons, resolving power of the mass-spectrometer is 200. In the case of pulsed molecular beam sources it is necessary to use special methods for optimization of beam intensity and generation of ions.

Mass-spectrometer used is supplied with special produced ion source for molecular beam measurements. The electron beam originates below the ionization region at a tungsten filament and is collimated to a diameter of about 7 mm at the point where it intersects the molecular beam. Ionization take place in a fieldfree region to provide a well-defined impact energy and to allow for proper space focusing. The pulsed ion extraction field must be held on long enough to sweep out all ions up to the maximum mass. A

voltage pulse is applied to grid to turn off the extraction field. When this pulse relaxed, the field turns back on and the ions begin their flight to the detector. During the time that the pulse to grid has turned off the extraction field (1000 ns), a second pulse of around 600 ns duration is applied to the gate grid to admit the electrons into the ionization region.

The main parameters of the experimental setup are represented in the Table.

Table

Parameters	Values
a) Gas-Dunamical (in air)	
Mach number of incident shock wave	15-40
Initial pressure in the shock tube channel, torr	0.02-0.1
Mach number of the flow behined shock wave	3.0-4.0
Velociety of the flow behined shock wave, km/s	4.5-12.0
Temperature of the gas behined shock wave, K	6.000-12.000
Duration of the quasi-stationary flow, μs	30-80
molecules velocity in the beam behined skimmer, km/s	5.0-15.0
Density of the beam, cm^{-3}	$\sim 10^{12}$
b) Mechanical	
Shock tube inner diameter, mm	75
Shock tube length, mm	700
Vacuum tank volume, l	40
Pumping speed of the vacuum tank, l/s	500
Repetition frequency Hz	up to 10
Skimmer entrance diameter, mm	1.0
Skimmer half-angle	30^0

Direct Thermal Extraction GC/MS of Soil/Sediment Samples for the Detection of Polycyclic Aromatic Hydrocarbons (PAHs)

Joseph Lech, Elaine Fukuda, Thomas G. Hartman, Robert T. Rosen and Tarik H. Roshdy
Center For Advanced Food Technology, Cook College, Rutgers University

Joseph Brady, John Manura
Scientific Instrument Services, Inc.
Ringoes, NJ 08551

A method has been developed for the qualitative and quantitative analysis of soils for PAHs (polycyclic aromatic hydrocarbons), that could be expanded for detection of other semi-volatile organic compounds. Using direct thermal extraction combined with high resolution capillary GC/MS, three soil matrices were analyzed by short path thermal desorption. The unique feature of this method is that volatile and semi-volatile organic compounds are thermally extracted at 300-320 °C in five minutes from solid matrix samples, and are thermally desorbed into a GC injection port for subsequent analysis by MS. This type of analysis yields rapid chemical screening of a variety of sample matrices as opposed to currently used techniques by the EPA(SW-846 analytical protocols under RCRA) which involve exhaustive solvent extraction, sonication, steam distillation, or SFE. The goals of this research were to establish a more rugged technique that is quick as well as effective, and also that is universal with respect to analytes and sample matrices. Furthermore a one-step direct analysis eliminates the need for hazardous extracting solvents and their inherent disposal costs and provides for an environmentally safe workplace.

The technique of direct thermal desorption (DTD) also known as direct thermal extraction permits the analysis of solid samples without any prior solvent extraction or other sample preparation. Solid samples between 100 and 500 milligrams are placed directly inside the glass lined stainless steel desorption tube between two plugs of glass wool, or even mixed or coated on an inert material. The desorption tube needle is attached to one end of the sample tube. The desorption tube with sample enclosed is then attached to the short path thermal desorption system, purged with carrier gas to remove all traces of oxygen and injected into the GC injection port. The preheated heater blocks are closed around the desorption tube thereby permitting the thermal extraction of the volatile and semi-volatile components present in the sample into the GC injection port. After the desorption period is complete, these components, which have been trapped at the head of the GC column, are subsequently eluted and separated via a temperature program of the GC oven.

Using this technique a standard calibration curve was established with ten PAHs, surrogates and deuterated internal standards(d-8 naphthalene and d-10 anthracene) from 5 ng to 1,000 ng to demonstrate the sensitivity and quantitative linearity of the method. Soil matrices were spiked at the 1 ppm level and all components were excellently recovered in sand and sandy loam samples. Recovery of PAH compounds was variable and highly dependent on the type of soil or sediment analyzed, and although adequate recoveries were observed in sand and sandy loam soils, low recoveries were noted in clay type samples. In addition, an authentic soil sample from an environmentally impacted EPA Superfund site was analyzed to demonstrate the applicability to real world samples and was found to contain a complex mixture of PAHs ranging from naphthalene to dibenzoanthracene. Direct thermal extraction of the soil samples were compared to samples analyzed by established conventional analytical methodologies.

SELECTIVITY ENHANCEMENT IN THE MASS SPECTROMETRIC DETECTION OF POLYCYCLIC AROMATIC HYDROCARBONS CONTAINING A NITROGEN HETEROATOM*

H. Perreault[a b c], L. Ramaley[a], F.M Benoit[d], P.G. Sim[b] and R. K. Boyd[b]
a Dept. of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada
b Institute for Marine Biosciences, National Research Council, Halifax, Canada
c Present address: Dept. of Chemistry, M.I.T., Cambridge, MA, U.S.A.
d Bureau of Chemical Hazards, Health and Welfare Canada, Ottawa, Canada

Polycyclic aromatic compounds (PACs) generally occur as extremely complex mixtures in the environment. Among PACs, polycyclic aromatic hydrocarbons containing a nitrogen heteroatom (PANHs) constitute a very hazardous class of compounds. However, PANHs are usually found in relatively low concentrations in polluted environmental samples. Their chromatographic analysis with universal detectors is often hampered by the presence of highly concentrated polycyclic aromatic hydrocarbons (PAHs). On FID, UV and MS-TIC chromatograms, PANHs appear as background peaks which are most often buried under intense peaks produced by PAHs.

Three mass spectrometric methods have been investigated for selectivity improvement in the characterization of PANHs in mixtures. Two of these methods are used to discriminate between PANHs and other PACs, while the purpose of the third method is to effect a certain degree of recognition among PANH isomers.
1) The combination of gas chromatography (GC) with high resolution MS allows monitoring of PANHs using the reconstructed ion chromatograms (RICs) of their molecular dications at half integral m/z values. Since half mass ions are not likely to arise from fragmentation of other non-nitrogen species, more selectivity is obtained for PANHs than by plotting RICs of their singly charged molecular ion species. This method was originally developed for determination of PAHs using the dications of the first ^{13}C isotope peaks[1].
2) Tandem mass spectrometry of the molecular dications of PANHs offers the possibility of achieving some degree of isomer discrimination[2]. The combination of GC with MS/MS is thus expected to enable simultaneous PANH separation and limited distinction between isomers contained in mixtures.
3) MS/MS studies on the fragmentation of PAH[3] and PANH[2] molecular ionic species revealed that losses of neutral molecules characterized the dissociation patterns. Losses of acetylene (C_2H_2) were observed in the case of PAHs, while losses of HCN (or HNC) occured with PANHs. The monitoring of constant neutral losses (CNL) from the molecular mono- and dications of these species can thus potentially help discriminate between PAHs and PANHs.

All experiments were conducted with a VG Analytical ZAB-EQ mass spectrometer of BEqQ configuration. The EI ionization source was operated at 230°C with a nominal electron energy of 70 eV and a trap current of 100 µA. The accelerating voltage was 8 kV. For the investigation of Method 1, the samples were mixtures of known PACs producing ions at m/z 129 or 179. A DB-5 GC capillary column was used under temperature programming conditions. Post run data analysis allowed the construction of the RICs of interest. For method 2, the double focusing combination of B and E was programmed to step from mass to mass at predefined times, allowing selection of the ions of interest (PANH molecular species M^+ or M^{2+}) as PANHs eluted through the DB-1701 capillary GC column. These ions were subjected to CID reactions. Resulting fragments were analyzed by scanning sector Q. The sample under investigation was a mixture of PANH standards. For the CNL investigations (Method 3), the unimolecular losses of 13.0, 13.5 (losses of acetylene and HCN from M^{2+} species, respectively) and of 26 and 27 (same losses from M^+) occuring in the rf-only quadrupole collision cell were monitored. CNL monitoring was effected by simultaneously scanning B and Q with constant (B-Q) corresponding to the mass of the loss under investigation. Compounds studied were quinoline, acridine, naphthalene and phenanthrene.

Figure 1a shows the GC/MS RIC trace at m/z 179 obtained for a mixture containing 9-ethylfluorene (1), acridine (2) and 9-fluorenylmethylchloroformate (3) among other PACs. The peaks observed are produced by the $(M-15)^+$ ions of 1, the M^+ ions of 2 and the $(M-79)^+$ ions of 3, respectively. By plotting the RIC at m/z 89.5 (Figure 1b), the selectivity of detection of 2 vs. 1 and 3 is enhanced as only one

peak is observed, corresponding to the M^{2+} of 2. Doubly charged ions produced from fragmentation of the other compounds are not significantly observed.
In Figure 2, CID fragmentation spectra of PANH isomers acridine (2) and benzo[f]quinoline (4) obtained by GC/MS/MS are shown. While fragmentation of singly charged molecular ions (a) yields similar spectra for both compounds, the CID spectra obtained for the M^{2+} ions exhibit some differences, valuable for a limited extent of isomer discrimination. Other PANH isomers studied were also differentiable from fragmentation of their M^{2+} ions but not of the M^{+} species.
CNL of 13.5 were monitored but yielded high noise levels due to the low intensity of the M^{2+} and $(M-HCN)^{2+}$ species with respect to other ions present in the conventional spectrum of PANHs. A better alternative was to monitor the CNL of 27, since M^{+} and $(M-27)^{+}$ dominate the EI spectra of PANHs. Results obtained showed good selectivity for detection of PANHs vs PAHs.

MASS SPECTROMETRIC IDENTIFICATION OF INTERMEDIATES IN THE PHOTOCATALYZED DEGRADATION OF NITRO-PAHs AND DICHLOROPHENOLS.

M. Vincenti, P. Piccinini, C. Minero and E. Pelizzetti

Dipartimento di Chimica Analitica, Università di Torino,
Via Pietro Giuria, 5 - 10125 Torino - ITALY.

Heterogeneous photocatalysis has been recently used for the elimination of pollutants (particularly water contaminants), via their rapid degradation (1, 2). In these experiments small amounts of a semiconductor (usually TiO_2) are suspended in the contaminated water, which is subsequently illuminated by the sun or by solar lamps, inducing a sequence of oxidizing processes on the pollutant, up to its complete mineralization.

The detection of decomposition intermediates is important because (i) it allows the comprehension of the oxidizing mechanism and the degradation pathway; (ii) it establishes whether or not more toxic substances than the starting materials are produced in the degradation process. These intermediates are usually produced in trace amounts and during short periods of irratiation time, i.e. they are more labile than the starting pollutant.

Acidic aqueous solutions of the compounds under study were prepared at concentrations of about 10 ppm, and 200 ppm TiO_2 were added. 5 mL aliquots of these suspensions were put in Pyrex glass cells and irradiated for variable time periods (0-30 min) with a 1500 Watt Xenon lamp, equipped with a 340 nm cutoff filter and simulating AM1 solar light.

The irradiated suspensions were subsequently extracted with CH_2Cl_2 for one hour, using continuous-flow liquid-liquid extractors. The organic solution was added with an internal standard, concentrated to 20-50 µL and analyzed by GC-MS. The extraction yield, as measured for the starting materials, ranged from 85% to 100%, although the extraction yields might be much lower for the most polar degradation intermediates.

The concentration of most degradation intermediates is comparable to that of solvent and glassware contaminants. Thus, the use of a selective ionization method such as electron capture chemical ionization (both dichlorophenols and nitro-PAHs have high electron affinity) helped localizing the degradation intermediates in GC profiles Knowledge of these retention times was exploited to extract the corresponding EI mass spectra from the GC-EIMS runs.

For a large number of degradation intermediates, negative ion CI turned out much to be more sensitive (not only more selective) than EI. Unfortunately, the fragmentation of molecular anions depended strongly on the ion souce temperature, and rather high temperatures (about 190°C) were needed in order to avoid peak tailing and signal suppression in the gas chomatograms. Under such conditions, the molecular weight information risked to be misinterpreted. For exaple, a HCl loss from the molecular ion of a dichlorophenol condensation product (see the chemical structure in Fig. 1) can simulate a chemical bond and a dibenzofurane structure

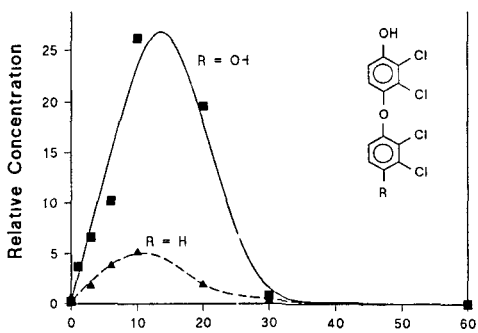

Figure 1

Among the degradation intermediates of dichlorophenols, the condensation products are particularly interesting, since it is important to know whether or not they include dioxins and dibenzofurans and to determine their degradation kinetics. In both EI and CI experiments, performed by scanning the mass analyzer, we found no evidence of polycyclic by-products, but the experiments should be repeated in MID. In contrast, condensation products arising from the reaction of dichlorohydroquinone with the starting dichlorophenol were found in some abundance, expecially from 2,3-dichlorophenol. However, these compounds are degradated as fast as the starting material and are no more detectable in samples irradiated for more than 30 minutes (Fig. 1).

Nitro-PAH derivatives also produce intense ion signal from electron attachment CI experiments, particularly the quinonic and hydroquinonic structures. On the other hand, the retention of the nitro-group on nitro-PAH degradation intermediates was easily checked by several MS/MS experiments, including the neutral loss scans of 30 and 46 mass units in the EI mode, and parent scan of mass 46 in the negative ion CI mode. The case of 2-nitronaphtalene is reported in Figure 2, where several GC peaks corresponding to nitro-compounds are extensively enhanced in the GC-MS/MS profiles.

The observed fast degradation and complete mineralization of nitro-PAHs and dichlorophenols confirmed that photocatalysis is a very promising approach to the fast degradation of water pollutants. These preliminary results point up that the detection and identification of the degradation intermediates requires the utilization of a variety of mass spectrometric techniques including, for example, CIMS, MS/MS and MID.

Real-Time Vehicle Exhaust Analysis Using a Laser TOF Mass Spectrometer

*R.Frey[1], A.Holle[1], H.Betzold[2], W.Ulke[2], U.Boesl[3]
[1] Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4, D-2800 Bremen 33, Germany
[2] Dornier GmbH, Friedrichshafen 1, Germany
[3] Inst. f. Physikal. Chemie, TU München, Garching

Introduction

Research at new dynamic engine test stands concerns the transient engine performance under test conditions. For the dynamic exhaust analysis, there are two main requirements:

- Detection of all individual exhaust compounds,
- Tracking of the exhaust compounds with ms time resolution, e. g. during one and more motor cycle in static and transient engine operations.

This information is fundamental for an understanding of the combustion processes and for the engine developments to reduce emission of pollutants. It is also important with respect to the future engine-out emission limitations set by the legislative.

Such a system for time-resolved engine exhaust analysis is under development in a co-operative research project of Bruker-Franzen Analytik, Dornier, and the Technical University of Munich.

Method

The laser mass spectrometer for time-resolved engine exhaust analysis consists of:

- Sample inlet system for real-time sample transfer from motor to mass analyzer (Dornier)
- Reflector TOF mass analyzer capable to high time resolution and high mass resolution (1) (BFA)
- Ion source using resonance enhanced multiphoton ionization with pulsed tunable UV-laserlight (laser ion source parameters for all exhaust component by TU Munich); additional EI-ionization for survey purposes
- Data acquisition and digitizer system for high repetition spectra rate (Dornier)
- Data system for automated instrument control, for data processing und display of the relevant measurement results (BFA).

The system has been designed for the following specifications:

* Detection of all organic and inorganic exhaust constituents of concentrations higher than 1 ppm
* Simultaneous detection of 10 selectable exhaust compounds with 100 Hz repetition rate and 1 ms time resolution
* Ruggedness for engine test facilities.

Results

First test of the analyzer at the motor test facility (Hochschule Bremen) have been made using multiphoton ionization with the fixed laser wavelength of 266 nm provided by a Nd:YAG-laser with quadrupled frequency and EI ionization.

The mass spectra and time diagrams of individual aromatic components of the engine-out emissions show a sensitivity of 1 ppm, and a mass resolution of 5,000 for mass 92.

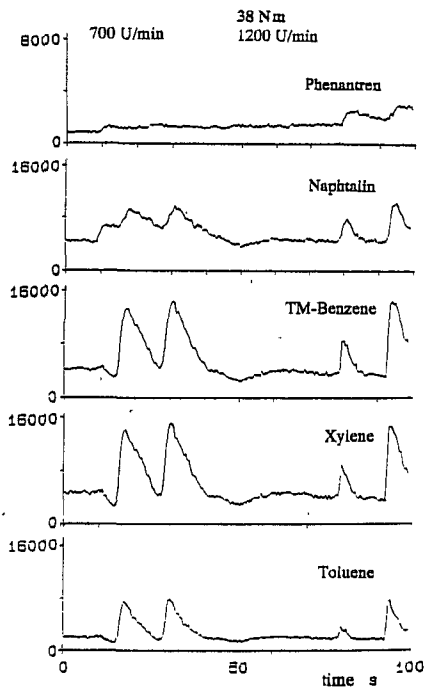

Fig.1: Time diagramm of different aromatic motor exhaust components for sudden motor speed change

Target Tuning for EPA Methods Using Dynamic Lens Ramping

Douglas R. Durham, Hewlett Packard Company
1601 California Ave, Palo Alto, CA 94304

Laboratories using Environmental Protection Agency methods are required to prove that all instrumentation being used is well maintained and is producing reliable results. Mass spectrometers being used in such laboratories must be shown to produce spectra for specific performance compounds that meet EPA published criteria. EPA methods 624 and 625 specify ion ratio criteria for DFTPP and BFB respectively. This paper describes the development of a new efficient tuning algorithm to address the need of such laboratories.

Tuning a mass spectrometer to meet achieve specific ion abundance profile can be tedious and time consuming. Simply tuning an instrument for maximum sensitivity often yields spectra that do not meet the EPA targets. Some form of target tuning must be used to attain acceptable spectra. Target tuning attempts to adjust one area of the mass range without affecting the others. This problem is exacerbated if the tuning compound used is different from the performance compound since one must attempt to map the spectra of the tuning compound to that of the performance compound. This task is an ideal candidate for automation, however given its difficulty, few automated algorithms have been produced.

Most automated tuning procedures attempt to adjust instrument parameters to meet some specified goal. Most strive to maximize overall ion abundance for increased sensitivity. Tuning to match particular ion abundance targets is particularly demanding. The ion abundance of one or more portions of the mass range may be too high while other areas are too low. Most target tuning algorithms take advantage of mass spectrometer parameters which are mass selective, that is they affect one portion of the mass range more than others. Algorithms of this type often sacrifice sensitivity for the purposes of meeting specific target abundances. Clearly an algorithm that could directly achieve the desired targets would be highly desirable.

Dynamic lens ramping, a new capability available for the Hewlett Packard 5989 (MS Engine) and 5971 mass spectrometers allows the implementation of new more direct tuning algorithms. Dynamic lens ramping allows the voltage applied to an ion focusing lens to be varied as a function of mass.

The lens stack of a quadrupole mass spectrometer is used to focus the ions produced in the ion source onto the mass filter. In most cases the voltages applied to the various elements are held static to ensure that the optimal ion count enters the mass filter. As was explained earlier, target tuning entails enhancing some portions of the mass range and reducing others so that the resulting spectra match a given set of ion abundance ratios. One can observe however that all of the necessary modifications of the spectral profile can be achieved though selective attenuation. To enhance a particular portion of the mass range one can simply attenuate the entire mass range with the exception of the desired portion. Reduction of particular abundances can be performed directly. It this is property that allows dynamic lens ramping to be used for target tuning.

Using dynamic lens ramping the ion beam can be "de-focused" over particular portions of the mass range. De-focusing results in attenuation of the ion current. Given controlled attenuation the spectral profile can be varied enough to reach the ion abundance ratios necessary to pass all EPA performance criteria.

Implementing an automated tuning procedure based on this capability is straight forward. The algorithm used is a simple heuristic search where the heuristic function is

based on the difference between the spectral abundance ratios acquired from the instrument versus the target ratios. The procedure is outlined below:

1. Perform a standard autotune to optimize instrument performance.
2. Derive a lens voltage to abundance conversion formula. This formula allows the appropriate amount of attenuation to be achieved.
3. Take a spectral scan. If it matches the desired target ratios go to step 7.
4. For each mass of interest determine the necessary change in abundance to meet the target abundances.
5. Map the abundance to an attenuation factor and use the conversion formula to derive a new dynamic lens ramp.
6. Go to step 3.
7. Print report and save the results to a file for use in the acquisition method.

To prove the reliability of this technique we studied this algorithm with respect to its ability to attain typical target ratios, its ability to produce an instrument tune that will hold for several weeks, and whether it introduced undesirable distortions in acquired spectra.

To test the ability of the algorithm we ran it on 13 different instruments. Each test involved running the algorithm followed by an acquisition of a DFTPP injection under typical Contract Laboratory conditions. In all cases we were able to successfully meet the EPA criteria in no more than three tune/acquisition cycles. Each cycle took 20 minutes so that our experience shows that an instrument should not down for more than 60 minutes for tuning.

We next performed time studies to determine how long an instrument tuned by the algorithm would continue to pass EPA criteria. This is a critical factor since increasing the time between instrument tuning increases instrument up time. Our studies showed that the tune held anywhere from 2 weeks to 6 weeks which is acceptable by the users of the software.

Our final area of study was spectral quality. Given the new nature of the dynamic ramping technique we wished to insure that spectra produce by instruments tuned using this method were typical of those produced by instruments tuned by more conventional means. We acquired spectra from six compounds from the standard analyte list of EPA method 624 that had primary ions in the mass ranges most affected by the algorithm. The spectra were then compared to those acquired by the same instruments tuned by conventional automated tuning procedures, and spectra published in the CRC Handbook of Mass Spectra of Environmental Contaminants. We found no significant deviations between the spectra acquired by instruments with the new tune and the other spectra. Additional use of the algorithm in the context of routine analysis has shown that the spectra are acceptable.

In all this project has been a success, we have shown that using dynamic lens ramping that we are able to meet tune the instrument to meet the EPA methods criteria. We have also shown that an automated tuning algorithm can be implemented to directly perform the tuning required by the EPA. In practice this new automated tuning procedure has proved to save many hours of chemist time. Time otherwise spent tuning the instrument can now be spent for other useful tasks.

SOURCING ENVIRONMENTAL CONTAMINATION BY MEASUREMENT OF LANTHANIDE AND ACTINIDE CONCENTRATIONS USING ICP-MS

J. R. Donnelly, D. Cardenas, and G. W. Sovocool*

Lockheed Engineering & Sciences Co., 980 Kelly Johnson Dr., Las Vegas, NV 89119 and *U. S. Environmental Protection Agency, P. O. Box 93478, Las Vegas, NV 89193-3478

Relating contamination at a location to a specific source is a scientific and regulatory environmental goal. Recently, progress towards this goal was achieved for oil reclamation wastes by ICP-MS analysis for certain lanthanide and actinide elements. The presence and relative concentrations of such elements may provide assistance in the determination of the sources of such petroleum-based wastes.

The ICP-MS technique for inorganic analysis provided data which showed evidence of the source of off-Site contamination. The ICP-MS analytical methodology used in this study was similar to EPA Method 6020 for traditional, regulated metals.

Elevated levels of lanthanum, cerium, neodymium, uranium, and thorium were found at waste oil reclamation facility "D," in contrast to the lower levels found at a second nearby waste oil reclamation Facility ("F"), and to local background levels. Similar, elevated levels were found at nearby Location "R". Levels found at Location "H" were similar to those found at Facility F. The elevated levels at Facility D and Location R suggest that Location R may have been contaminated by Facility D waste disposal practices.

Concentrations found in samples from both Facility D and Location R were:
U 1.9--2.1 mg/kg
Th 9.6--16.2 mg/kg
La 35.7--57.7 mg/kg
Ce 79--139 mg/kg
Nd 14--24 mg/kg

Concentrations found in samples from both Facility F and Location H were:
U 0.09--0.55 mg/kg
Th 0.36--2.34 mg/kg
La 5.0--7.0 mg/kg
Ce 9.0--15.0 mg/kg
Nd 1.8--2.6 mg/kg

Background levels were:
La 1.2-2.3 mg/kg
Nd 0.5-1.1 mg/kg

Lead concentrations were generally high in samples from all four places: 1064 to 21,256 mg/kg, with no distinct trends for location specificity. Background levels of lead were 0.8-11.3 mg/kg.

Osmium was detected in samples from each of the four areas at levels of approximately 17--140 mg/kg. A typical osmium response by ICP-MS is shown in Figure 1. Osmium in the tetroxide form is extremely toxic. The osmium levels found in these samples were probably not indigenous, because platinum and gold, which occur naturally with osmium, were not found in these eight samples. Furthermore, osmium was not found in the background samples. The source of the osmium may have been its use as a metal hardening agent, particularly if machining lubrication oils were recycled at these facilities.

The samples from the four places showed a distinct trend in barium concentrations. Facility D and Location R samples contained about

117--127 mg/kg. Facility F and Location H samples contained at least a factor of ten more barium: approximately 1180--8140 mg/kg. Background samples contained the following levels of barium:
general background: 9.0-22.2 mg/kg
Location R background: 5.8-13.1 mg/kg
Location H background: 9.0-20.2 mg/kg
A typical barium response by ICP-MS is shown in Figure 2.

In summary, the low parts-per-million concentrations of lanthanides and actinides may provide indicators linking oil-reclamation facilities to incidences of specific contamination at other locations. These waste-oil-based sludges typically are not readily distinguishable by comparisons of traditional, regulated inorganic analytes.

An Improved GC-MS Method for Analysis of Lead

Suresh K. Aggarwal[1,2], Michael Kinter[2] and David A. Herold[1]
[1]VA Medical Center / University of California, San Diego, CA 92161 and
[2]Department of Pathology, University of Virginia, Charlottesville, VA 22908

INTRODUCTION

The Health and Human Services' Centers for Disease Control has set new guidelines for lead levels in blood for children. The "threshold of concern" for children has been lowered from 250 μg/L to 100 μg/L. At this level nearly 4 million children under six years of age are considered to have poisoning and consequently to be at risk for mental and intellectual retardation and irreversible physical damage. Studies have shown that Pb may have adverse long term effects on cognitive and motor function at blood concentrations that are significantly below the level that gives rise to clinical symptoms. This has encouraged us to develop GC-MS methods for lead analysis. We have previously shown that cross contamination (memory effects) can restrict the range of lead (Pb) isotopes that can be measured in unknown samples. To overcome this problem we have developed a stable isotope dilution GC-MS method for determining Pb in urine and blood using lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), as a chelating agent with further derivatization of the Pb chelate with 4-fluorophenyl magnesium bromide (4-FPMB). Precision and accuracy of isotope ratio measurements at the 10 ng level was determined. Memory effect was evaluated by the sequential analysis of solutions of natural Pb and enriched ^{204}Pb.

EXPERIMENTAL

Standards: Lead nitrate (70.94 atom% ^{204}Pb, Oak Ridge National Laboratory) used as an internal standard for isotope dilution was dissolved in deionized water with the addition of a few drops of concentrated HNO_3. Dilute solutions of the internal standard were prepared from the stock solution. The internal standard solution was calibrated by reverse isotope dilution GC-MS using a natural Pb primary standard.

Sample Preparation: The $Pb(FDEDTC)_2$ chelate was formed at pH 3 in an acetate buffer using a 20 mM solution of Li(FDEDTC). The final sample was prepared by reacting this in ethyl ether with 4-FPMB. Excess 4-FPMB was destroyed with the addition of 100 μL of water followed with 100 μL of 1 M nitric acid. The resulting $Pb(FC_6H_4)_4$ was extracted into CH_2Cl_2.

Analysis: The samples were analyzed by GC-MS using on-column injection onto a 10m x 0.32mm DB-1 bonded phase fused silica capillary column. Isotope ratios *m/z* 489 / 493 corresponding to the fragment ion $Pb(FC_6H_4)_3^+$ containing ^{204}Pb and ^{208}Pb, respectively, were measured on a Finnigan MAT-8230 mass spectrometer. The Pb isotope ratios were measured by injecting 1 µL of the chelate solution and monitoring the isotopic cluster corresponding to the fragment ion $(M-L)^+$ formed by the loss of one ligand. Selected ion monitoring with voltage peak switching was used for data acquisition and isotope ratios were determined by integrating the chromatographic peak areas.

RESULTS and DISCUSSION

As shown in Figure 1, the $Pb(FC_6H_4)_4$ samples did not show any appreciable memory effect when samples of natural Pb and enriched ^{204}Pb, with ^{204}Pb / ^{208}Pb isotope ratios differing by a factor of 270 were analyzed sequentially. This can be compared to Figure 2 which shows the consequences of memory effect encountered when $Pb(FDEDTC)_2$ samples differing by only a factor of ten were analyzed. Overall precision of 2% was obtained for $Pb(FC_6H_4)_4$ when determining ^{206}Pb / ^{208}Pb and ^{207}Pb / ^{208}Pb isotope ratios in naturally occurring Pb at the 10 ng level.

CONCLUSION

The stable isotope dilution GC-MS method using the 4-FPMB derivatization of the FDEDTC chelate eliminated the problem of memory effect. This method provides a sensitive and precise method for monitoring Pb.

THE ANALYSIS OF COMBUSTION PRODUCTS FROM A METHANOL-FUELED VEHICLE BY ATMOSPHERIC PRESSURE IONIZATION MASS SPECTROMETRY

O. Vega, Instituto de Pesquisas Energeticas e Nucleares IPEN/CNEN-SP, Universidade de Sao Paulo, Sao Paulo, Brazil, CP 11049

R.J. Hughes and R.E. March, Department of Chemistry, Trent University, Peterborough, ON, Canada K9J 7B8

INTRODUCTION

The utilization of alternative fuels such as methanol for automobiles is receiving increasing attention as a strategy to minimize air pollution in metropolitan areas. In the USA, Canada, and Brazil, variable fuel vehicles are already in operation using methanol with small amounts of gasoline as the energy source.

The scope of the present work is to develop analytical protocols for the real-time analysis of gaseous combustion products exhausted from a vehicle engine fueled principally with methanol. The mass spectrometric instrument used in this study is an Atmospheric Pressure Ionization Mass Spectrometer API/MS, SCIEX Trace Atmospheric Gas Analyzer, TAGA 3000.

EXPERIMENT

The gaseous exhausts from a Chevrolet Lumina vehicle were sampled directly into the API source of the Mass Spectrometer. Real-time analysis permitted ready exploration of variation in combustion product concentration as a function of vehicle operating conditions. The vehicle was fueled with pure methanol and with methanol/gasoline mixtures. The results obtained for combustion of methanol-containing fuels are compared with those obtained using unleaded gasoline.

The TAGA mass spectrometer was linked with the outside patio by means of a teflon tube (O.D. 23mm) 10m in length which passed trough a hole drilled trough the wall. The arrangement of the equipment is shown schematically in Figure 1.

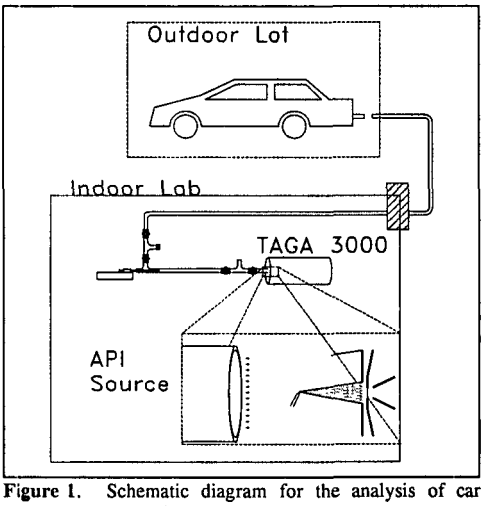

Figure 1. Schematic diagram for the analysis of car exhaust products using the TAGA.

RESULTS AND DISCUSSION

In Figures 2a and 2b are shown the background-subtracted time-averaged mass spectra from gas exhaust produced by the combustion of two mixtures of methanol/unleaded gasoline; 85% methanol (M-85) and 40% methanol (M-40) in unleaded gasoline, respectively. The gas exhaust was sampled directly at the exit of the exhaust pipe. The ions of m/z 18 and 36 are due to protonated ammonia NH_4^+ and monohydrated protonated ammonia $H_2O.NH_4^+$, respectively. The ions of m/z 23 are due to sodium NA^+, m/z 33 is due to protonated methanol $CH_3OH_2^+$, and m/z 51 is due to the monohydrated protonated methanol cluster ion $H_2O.CH_3OH_2^+$. Sodium comes from the salt that is spread around the parking lot at Trent University during the winter time. The ions of m/z 33 and 51 are due to incomplete methanol combustion. The signal intensity due to

protonated water clusters with benzene, toluene, and ethylbenzene (m/z 97, 111, and 125, respectively) were greatest in the mass spectrum corresponding to the mixture with the higher gasoline composition, M-40. The signal intensity due to protonated methanol is much greater in the mixture with the higher methanol composition, M-85. The intensity of protonated methanol in the mass spectrum for M-85, indicates that an appreciable amount of methanol survives combustion.

It appears that the major combustion products of the methanol/unleaded gasoline mixtures include hydrocarbons, alcohols, and aldehydes. The signal intensities due to hydrocarbons are not as intense as those found in the mass spectra of unleaded gasoline combustion products. Some hydrocarbons are common to both systems.

The results of the TAGA analyses of gaseous exhaust products do not indicate any effect from heating the API ion source, varying the idling speed of the car, or ambient temperature.

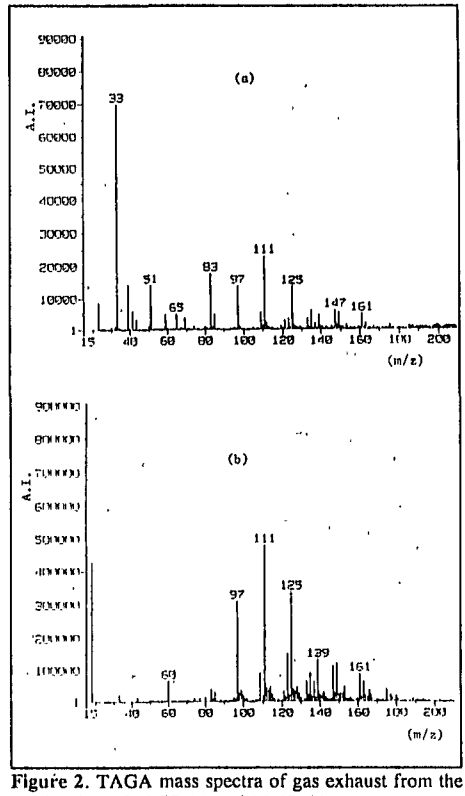

Figure 2. TAGA mass spectra of gas exhaust from the combustion of M-85 (a) and M-40 (b).

CONCLUSIONS

From the results of the present research the following conclusions may be drawn.

(i) The TAGA analyzer (or API/MS) is extraordinarily sensitive for the detection of compounds which are preferentially protonated in the API source.
(ii) A distinct advantage of the API/MS instrument is that it yields real-time analyses.
(iii) The real-time analyses of the gas exhaust made by API/MS are reasonably reproducible.
(iv) Real-time analyses made by API/Tandem Mass Spectrometry would be of great value in this research.
(v) The CHEVROLET-LUMINA vehicle is a very versatile car in that it can run on a variety of fuels and fuel mixtures, apparently without impairment of engine performance.

IDENTIFICATION AND QUANTIFICATION OF HEXACHLOROBENZENE IN D&C RED NOS. 27 AND 28 AND THEIR LAKES BY GC/MS

Adrian Weisz[a] and Denis Andrzejewski[b]

[a]Division of Colors and Cosmetics and [b]Division of Contaminants Chemistry, U.S. Food and Drug Administration, Washington, D.C. 20204

INTRODUCTION: The color additive D&C Red No. 27 (R27, mainly 2',4',5',7'-tetrabromo-4,5,6,7-tetrachlorofluorescein, **1**), its disodium salt, D&C Red No. 28 (R28, **2**), and their lakes, R27L and R28L (**1** and **2** precipitated onto an insoluble substratum, e.g., alumina, at 10-40% total color content), must meet the specifications listed in the *Code of Federal Regulations* (CFR) for batch certification by the U.S. Food and Drug Administration (FDA) [1]. These color additives are synthetically prepared, with the first step in their synthesis being the condensation of tetrachlorophthalic anhydride with resorcinol. GC/MS analyses of tetrachlorophthalic anhydride obtained from different distributors consistently revealed the presence of hexachlorobenzene (HCB, Fig. 1). HCB is a suspected carcinogen [2,3]; therefore, it was of interest to determine whether this contaminant is carried over into the color additives during the manufacturing process.

EXPERIMENTAL: Identification: Each test portion (30-60 g) was Soxhlet-extracted with chloroform for approximately 50 h. D&C Red No. 27 (sample 1, Table 1) was converted to the disodium salt before extraction. The solvent was eliminated by rotary evaporation. The residue was redissolved in 1 ml chloroform and 2 μl was injected into a Hewlett-Packard 5880 gas chromatograph, which was interfaced with an HP-5970 mass selective detector. Full scan data were acquired. The GC/MS fused silica capillary column, 25 m × 0.20 mm i.d., contained a 0.11 μm film of crosslinked 5% phenyl methyl silicone. The GC column temperature was increased from 40 to 270°C at 15°C/min. The total ion chromatogram of an extract of a test portion from sample 4 (Table 1) is shown in Fig. 2.

Quantification: GC/MS quantification of the HCB was performed with a Finnigan Mat quadrupole mass spectrometer interfaced to an Incos 2300 data system. Electron ionization data were obtained at 70 eV electron energy and 0.25 mA emission current at a source temperature of 240°C. The mass spectrometer was operated in the selected ion monitoring (SIM) mode. The GC column and conditions were the same as for the full scan GC/MS analyses. HCB was quantified by measuring the ion area ratios of m/z 286 for HCB to m/z 292 for the internal standard, $^{13}C_6$-HCB. HCB was quantified by using a five-point calibration curve based on analyses of standard solutions that contained internal standard and 0.01, 0.1, 1, 5, and 10 ng/μl of HCB. The instrument response was linear over this range. The HCB standard was recrystallized from 2-propanol.

RESULTS AND DISCUSSION: Samples from 34 certified batches of commercial D&C Red Nos. 27 and 28 and their lakes were analyzed for HCB. These samples represent all the domestic (9) and foreign (4) manufacturers that requested certification for these color additives in the past 5 years. Manufacturers A-I are domestic, J-L are European and M is Japanese. The study includes a sample of the D&C Red No. 27 (sample 1, Table 1) from the animal feeding studies that were used by FDA to evaluate its safety. All the test extracts were found to contain HCB (range 0.02-23.3 ppm, average 2.1 ppm, as shown in Table 1). Recoveries of HCB added to R28 and R27L were 53 and 41%, respectively; the low recoveries were due mainly to loss during the rotary evaporation step [4]. If these low recoveries are taken into account, then the actual amounts of HCB may be twice the reported values.

CONCLUSION: Current regulations for D&C Red Nos. 27 and 28 and their lakes do not specify a limit for HCB. In view of these findings, FDA is considering the need to limit the HCB levels in these color additives.

INTRODUCTION

The characterization of radioactive mixed hazardous waste tanks has received increased interest because of the need to understand the chemistry of the waste prior to disposal or remediation. Organic chelators such as ethylenediaminetetraacetic acid (EDTA),hydroxyethylenediaminetriacetic acid (HEDTA), and their degradation products are present in many of the waste tanks at Hanford. In the case of Hanford waste tank 101-SY, the thermal and radiolytical degradation of chelators have been linked to the production of hydrogen gas. Analysis of chelators is not amenable to gas chromatography (GC) without prior derivatization. Previously, we have reported on derivatization of chelator standards using BF_3/methanol, diazomethane, silylation, and butyl esterification[1]. The BF_3/methanol derivatization method showed the most promise to be applied to radioactive mixed waste. In this study, we applied the BF_3/methanol derivatization GC/MS method to an actual waste sample from waste tank 101-SY. Electron impact and chemical ionization were utilized to identify the components in this methyl ester chelator fraction. In addition, high resolution mass spectrometry was used to obtain accurate mass measurements of identical components found in a synthetic chelator sample (non-radioactive) made to simulate tank 101-SY.

EXPERIMENTAL

A hot cell facility was required for sample preparation and derivatization prior to GC/MS analysis.
Sample preparation: Twenty mL of water was added to a 2-gram composite sample from tank 101-SY. The sample was then vortexed, filtered (0.45μm), and concentrated to dryness over nitrogen gas.
Derivatization: Two mL of BF_3/methanol was added to the sample followed by heat at 100°C for one hour. One mL of chloroform was added followed by 5 mL of 0.1M KH_2PO_4 buffered to pH 7.0. The chloroform layer was removed for GC/MS analysis.
Analysis: Scintillation counting was required to determine the radioactivity in the chloroform extract. GC/MS analysis was obtained on a Hewlett Packard HP 5988 GC/MS system. Both electron impact 70eV and isobutane chemical ionization were used. A fused silica DB5, 30 m x 0.25 mm i.d. (0.25 μm film thickness) column was used in the spitless injection mode at 260°C. The

Analysis: Scintillation counting was required to determine the radioactivity in the chloroform extract. GC/MS analysis was obtained on a Hewlett Packard HP 5988 GC/MS system. Both electron impact 70eV and isobutane chemical ionization were used. A fused silica DB5, 30 m x 0.25 mm i.d. (0.25 µm film thickness) column was used in the spitless injection mode at 260°C. The oven program consisted of 40°C for 1 min followed by 8°C/min to 300°C. A VG 7070 was utilized for accurate mass measurements.

RESULTS AND CONCLUSIONS

Figure 1 shows the electron impact GC/MS total ion chromatogram of the BF_3/methanol derivatized tank 101-SY composite sample. Figures 2-3 are spectra of selected components. Standards for many of these compounds are not available; as a result, the identifications are tentative. Chelators were methylated only at the carboxylic site and not at the hydroxy sites. Peak 1 was identified as nitrosoiminodiacetic acid (NIDA) by high resolution mass spectrometry. This represents one of the first indications of the reaction of the inorganics (high nitrate and nitrite) and the organics. High resolution mass spectrometry will also be used to confirm the tentatively assigned structures of other components.

THERMAL STUDY OF CHLOROGENIC ACID BY ON-LINE THERMOGRAVIMETRY/ GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Henry L. Chung*, John C. Aldridge, and Jessie M. Rivers

R. J. Reynolds Tobacco Company, Bowman Gray Technical Center, Winston-Salem, NC 27102

Chlorogenic acid is one of the major polyphenols in tobacco. Studies of the thermal degradation products of tobacco components have been done to establish precursor-product relationships between the tobacco constituents and cigarette smoke components. The thermal degradation of polyphenols is thought to influence the quality of tobacco smoke.

Thermal analysis has become an important analytical technique with the introduction of modern thermal analytical instruments. An on-line thermogravimetry/gas chromatography/mass spectrometry (TG/GC/MS) system was designed, constructed and used to study the stability, the weight loss, and the thermal degradation products of chlorogenic acid. The on-line TG/GC/MS system employed a Du Pont 951 thermogravemetric analyzer equipped with a 9000 thermal analysis system interfaced to a Hewlett-Packard 5890 GC/5970 MSD system. The TG/GC interface consisted of a heated transfer line, an adsorbent trap packed with Tenax and a six-way valve. Chlorogenic acid was heated and purged with air at a flow rate of 30 ml/min during the heating and purging process. The TG temperature was programed from 50°C to 900°C at 10°C/min. The volatile compounds generated in the TG were swept into an adsorbent trap. The purge gas, after passing through the trap at room temperature, was vented to the atmosphere. After the heating and purging process, the trap was rapidly heated to 200°C and the volatile compounds in the trap were swept into the GC/MS system by helium at a flow rate of 35 ml/min. The volatile compounds were separated by GC. A 60 m X 0.25 mm ID DB-1701 (0.25 μm film thickness) fused silica capillary column was used for compound separation. The GC injection temperature was 250°C. The column head pressure was 25 psi. The column temperature was held at 35°C for 5 minutes and then programmed to 220°C at 3°C/min. An open-split GC/MS interface was used and the temperature was at 275°C. The mass spectrometer was operated at 70 eV in the EI mode. The ion source of the mass spectrometer was maintained at 250°C. The mass range scanned was from 29-500 amu. The volatile compounds were identified by mass spectra. The on-line TG/GC/MS system permits evolution of thermal degradation products of chlorogenic acid by the TG, separation of the volatile thermal degradation products by the GC, and identification by the MS. The thermogram of chlorogenic acid depicts a curve with three plateaus showing sample weight loss as a function of increasing temperature. The first decomposition occurred over a temperature range of 209-306°C with a total weight loss of 15%. The second decomposition occurred between 306-387°C, and involved a further 26% weight loss. The third decomposition was between 387-542°C with 51% weight loss. Thus, a temperature profile of stability and weight loss from chlorogenic acid was obtained. The total ion chromatogram showed that a number of thermally degraded compounds were formed from chlorogenic acid under the condition studied. The volatile compounds were identified by mass spectra. The volatile degradation products were identified as aliphatic acids, aliphatic aldehydes, aliphatic ketones, and derivatives of furan, benzene and phenol. The compounds identified from the thermal degradation of chlorogenic acid and known to contribute to the quality of tobacco smoke were acetic acid, benzoic acid, cinnamaldehyde, hexanal, furfural, heptanal, octanal, nonanal, decanal, 2,3-hexanedione and phenol.

GC/MS Analysis of Butyl Esters of Anionic Surfactants Using Supercritical Fluid/Ion-Pair Extraction.

David J. Miller[1], Steven B. Hawthorne[1], and Jennifer A. Field[2]

[1]Energy and Environmental Research Center, University of North Dakota, Grand Forks, ND 58202
[2]Swiss Federal Institute for Water Resources and Water Pollution Control, Dubendorf, Switzerland

The use of supercritical fluids for the extraction of relatively non-polar organic pollutants from environmental samples has received increasing attention because of the potential to dramatically reduce the time required for sample extraction as well as to eliminate the need for large volumes of liquid solvents. However, quantitative extractions of polar and ionic analytes have required the addition of organic modifiers to CO_2. An alternate approach to increasing extraction efficiencies for ionic species which relies on ion-pairing under SFE conditions has been developed.

Supercritical fluid extraction (SFE) with ion-pair reagent (tetrabutylammonium hydrogen sulfate) has been used to extract anionic surfactants, SAS (secondary alkane sulfonates), and LAS (linear alkylbenzene sulfonates) from European municipal sewage sludge. Quantitative extraction is achieved in 15 minutes (5 minutes static followed by 10 minutes of dynamic extraction with CO_2 at 400 atm and 80 °C) and require only 3 to 5 mL of liquid solvent for sample collection. Since tetrabutylammonium hydrogen sulfate is an injection port derivatizing reagent, extracts are immediately ready for GC analysis. Traditional solvent extraction methods are time consuming, required large volumes of solvent, and the extracted surfactants must be derivatized prior to GC analysis.

Commonly used anionic surfactants consist of homologous series containing alkyl chains in the range of C_{13} to C_{18} for SAS and C_{10} to C_{16} for LAS. Mass spectra of these compounds are very complex. SAS spectra exhibit fragmentation consistent with the alkane nature of the material and a moderate intensity ion at $(M-138)^+$ corresponding to the loss $C_4H_{10}SO_3$. Figure 1 shows the EI spectra of a butyl ester of an isomer of C_{16} SAS. LAS spectra are dominated by ions (m/z 171, 185, 199, 213, and 227) corresponding to C_nH_{2n}-$C_6H_5SO_3$ where n = 1 to 5. Single ion monitoring (SIM) with the $(M-138)^+$ ion for SAS and any of the C_nH_{2n}-$C_6H_5SO_3$ ions for LAS provides the necessary selectivity and sensitivity to obtain quantitative measurements of ca. 5 SAS homologs for a total of 34 isomers and 5 LAS homologs for a total of 33 isomers without requiring any class fractionation after SFE/ion-pair extraction of 100-mg samples of sewage sludges.

HOW TO TRANSFORM A COMMERCIAL RESIDUAL GAS ANALYZER IN AN INEXPENSIVE LOW MASS RANGE GC-MS INSTRUMENT

E. Davoli, L. Cappellini, S. Ferrari[1] and R. Fanelli

Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62, 20157 Milano, ITALY

and ([1]) RIAL S.p.A. Via Novara 6/A, 43100 Parma, Italy

INTRODUCTION

Low molecular weight organic compounds are gaining more and more interest in analytical chemistry. In this class most of the compounds that are responsible for air pollution are present. In June 1989 E.P.A. has published the Method 1624: Volatile Organic Compounds by Isotopic Dilution GCMS. In this method 60 volatile compounds (VOC) characteristic m/z's are listed and all are lower than 200 amu.

We have been exploring the possibilities of using an inexpensive Residual Gas Analyzer (RGA) as a mass spectrometric detector for these analysis. The instrument available to us had the mass range limited to 130, covering 58 of the 60 substances. Our major concern was wether an RGA pumping system could support a GC without separator and if it could be sensitive enough to detect quantities that are significative for trace (ppb level) environmental analysis.

INSTRUMENTATION

The RGA used was a RIAL QM 130 CS (RIAL Vacuum S.p.A., Parma, Italy), whose mechanical and electronic parts are entirely manufactured in Italy. The gas chromatograph was a DANI 86.10 equipped with a split/splitless injector and with a DANI VU65 6 way computer controlled valve. The original data system, designed for RGA operations, was non idoneous for GC-MS analysis and has been completely replaced with a Vector One (Teknivent Corp., St. Louis, MO) data system. RGA control, performed originally from the manufacturer's data system, has been possible with resident software (TSR), written in this laboratory, that was controlling RGA operational parameters like filament current, EM tension, gain and other parameters through COM 1 serial port. On-line air analysis have been performed with a Thermal Desorption Cold Trap Injector (TCT Chrompack BV, Middelburg, Netherlands) controlled from the GC.

The RGA has been coupled directly to the GC with a 25 m CP Sil 5 CB (0.25 mm ID, 1.2 µm film thickness) or with a 10 m CP Sil 5 CB (0.15 mm, 5 µm film thickness) capillary column. The open ion source has not been modified. In order to enhance sensitivity the GC effluent has been brought directly in front of the filament with a 0.5 mm ID fused silica tubing. The GC transfer line has been built with standard ultra high vacuum components and Swagelock fittings. It was thermostated up to 160 °C.

RESULTS

The instrument has been tested for different parameters before attempting analysis. The electrometer has been modified, lowering its integration time, so it could acquire 70 eV, EI like, full scan spectra, at scanning speed >= 1 sec. Sensitivity has been measured injecting splitless benzene: 1O pg showed a S/N ratio > 3. Linearity was tested in the range 50-5000 pg of benzene using benzene d6 as internal standard.

ENVIRONMENTAL ANALYSIS

In fig. 1 a scheme is reported of the instrument in its maximum configuration. In our program we were monitoring benzene and toluene. Using the following program, we have been able to perform continuous air analysis. As can be seen a complete cycle was performed in 4 minutes. In fig.2 a parking lot air chromatogram is shown. In the expanded area a car has been warmed up 5 meters ahead the sampling point.

CONCLUSIONS

It is shown that a commercial RGA with minor modifications can be used as an organic mass spectrometer. The main advantage lies in the low cost of such instruments: it might be of the same order of a multiple GC detector. Secondly the open ion source, certainly with limited sensitivity compared to a closed source, but still enough to solve problems, does not need as much maintenance. In our experience in 9400 hours we replaced only two filaments and never cleaned the source nor the ion optics.

Mass range limitations must be considered, but can be non relevant, as demonstrated in this work, for certain applications, as for example some environmental analysis. 200 amu mass range seems to us to be an optimum value at least for VOC analysis.

Future work is aimed to take advantage of the apparent toughness of the system, and to perform continuous unattended VOC outdoor/indoor air analysis.

Relating Electron Impact Response Factors for Seven GC/Quadrupole Mass Spectrometers for Difficult Analytes. Implications for Environmental Data Assessment for Samples and Standards.

*A. D. Sauter, ADSC, 2356 Aqua Vista Ave., Henderson, NV 89014-3636 and J. Fisk, USEPA-AOB, 401 M Street SW, Washington, D.C. 20460

Concern has been raised in the environmental community due to data integrity, quality, and ultimately the useability of GC/MS data. Such problems suggest a need for new tools to improve the assessment of environmental GC/QMS data. A reference set of EI GC/QMS RF values could be applied to evaluate and compare the standardization process. Moreover, because what we term a reverse response factor (RevRF) can be readily calculated for sample results, such a reference set could be applied as a QC test for all determinations made in actual environmental samples. The importance of reference sets to the application of any measurement technology is difficult to overstate as it is so fundamental to scientific measurements of any kind.

While we have written on the "similarity" of EI GC/MS RF values for quadrupole mass spectrometers of different design, there are a number of practical and other reasons that complicate the attainment of one explicit reference set of values for all analytes. Differences in QMS systems ion source dimensions, ion optics, ion detection devices, and other factors for analyte, internal standard pairs of different chemical, physical, and spectroscopic properties represents a formidable source of potential variation. In fact, due to such problems the theoretician and the practitioner might conclude that the sources of variation of EI GC/QMS systems are so numerous and great that for both fundamental reasons and practical purposes, a reference set of RF values is not attainable. It is interesting to note; however, that the agreement of EI spectra between reference sets and spectra acquired on different QMS systems explicitly required in USEPA methods can be formally shown to require RF agreement between different QMS systems. In other words, qualitative and quantitative analysis are inextricably mathematically linked. In this work we have attempted demonstrate how such a reference set may be employed to evaluate data.

For semivolatile analytes determined in the USEPA ion abundance tune study with the largest interlaboartory RF RSD we classified analytes using data acquired from seven different quadrupole mass spectrometer systems into three classes, as early eluters (Class I), phthalates (Class II) , and others (Class III). For Class I analytes, a single nonlinear function was found that correlated the SRF's of bis (2-chloroethyl)ether, bis(2-chloroisopropyl)ether, phenol and bis(2-chloroethoxy)methane yielding correlation coefficients of 0.957, 0.979, 0.991 and 0.990, respectively. Despite both theoretical and practical difficulties, a powerful reference set of alignment functions may be developed to facilitate comparison of results from GC/QMS systems of different design where the analytes are the most tune sensitive (See Figure 1).

For Class II analytes, the SRF's were not correlated with temperature, although analytes were often well correlated within the class (e.g., the SRF's of di(n)butylphthalate and di(n)octylphthalate across laboratories) when two measurement pairs out of the seven were eliminated. Such within class correlations have not been interpreted at this point, but such observations do help to prioritize further investigation into the laboratories generating the outliers in Figure 2. Originally, we discounted typical phthalate analysis problems; however faced with these observations, it appears that this first pass conclusion was not correct. Hence, using SRF's we were able to correlate five out of seven determinations priortizing the others for further investigation. Such prioritization is important in efficient environmental data assessment.

Finally, using the multivariate Hotelling T square test we identified unique properties of data at all laboratories. Using the SRF's, this test correctly recognized "out of tune" data without looking at spectra, 97 percent of the time throughout the entire study. Additionally, two laboratory unique error conditions were identified including incorrectly reported analytes and calculation errors.

Hence, using SRF's from a sever laboratory GC/QMS study, we were able to correlate response for "tune sensitive" analytes across seven different systems, identify a path for further data assessment for the phthalates, identify "out of tune data" without looking at mass spectra, and identify reporting/calculation errors in the submitted data. These observations demonstrate how inter or intralaboratory GC/QMS data evaluation/assessment could be improved if a reference set of EI GC/MS RF values or alignment functions (where required) would be adopted in environmental applications of the technology.

Method for Analysis of Volatile Organic Compounds Emitted During Municipal Waste Composting Using Thermal Desorption GC/MS. *Brian D. Eitzer, The Connecticut Agricultural Experiment Station, P.O. Box 1106, New Haven, CT 06504.

Disposal of municipal solid waste (MSW) is a problem which faces many communities. Composting is becoming an attractive alternative form of waste disposal, taking wastes and turning them into a useful soil amendment. However, little is known about the organics present in MSW, and even less about how those organics volatilize from a compost pile at the 60°C operating temperature. To investigate this a method of analyzing the volatile organic compounds (VOC) emitted from composting has been developed.

Volatile organics are sampled with precleaned adsorption tubes (Tenax-TA or Supelco Carbotrap 300) placed in a hole in the side of a bottomless plastic carboy worked into the top of a compost pile. 6-30 liters of air are drawn through the adsorption tube with a personal sampling pump. The tubes are analyzed via thermal desorption gas chromatography mass spectrometry using a Tekmar LSC-2000 Purge and Trap with an air sampler desorber accessory which is interfaced to a Perkin-Elmer GC/MS (ion trap).

After a 2 min dry purge to remove excess water the tubes are thermally desorbed at 250°C. The VOC are cryogenically focused in the GC. The temperature program is as follows; -10°C for 2 min, 5°C/min to 180°C, 10°C/min to 220°C, hold for 4 min. The GC oven is temperature programmed to 240°C. The ion trap is operated with automatic gain control on, background 39 amu, scanning from 40-400 daltons at one scan per second. A list of target compounds are quantified using ion chromatograms, this list includes all the VOC listed in SW-846 Method 8240. In addition, the largest peaks in the total ion chromatogram are tentatively identified using the mass spectral search software on the instruments data system.

Results show that many volatile organics are emitted during composting. Table 1. shows that most of the VOC emissions occur during the early stages of composting. Although it is possible that some terpenes are generated during composting and thus give continued emissions. The results also indicate that it will be difficult to exactly identify all the terpenes which are emitted because of the spectral changes which occur across the chromatographic peaks as illustrated in Figure 1 for the most common terpene (most likely limonene).

ESI and MALDI on a Quadrupole Ion Trap Mass Spectrometer

K.R. Jonscher, G.J. Currie, A.L. McCormack and J.R. Yates, III
California Institute of Technology, Division of Biology, 139-74
Pasadena, California 91125

Mass spectrometry has become a powerful tool for the analysis of biomolecules. Electrospray ionization (ESI) [1] and matrix assisted laser desorption (MALDI) [2] techniques have increased the range of applicability of mass spectrometric analysis. Recent developments in quadrupole ion trap technology [3,4,5] will serve to further advance the role that mass spectrometry may play in the study of the complex interactions among molecules that forms the basis for biological systems.

A unique quadrupole ion trap combining components of a Finnigan MAT ITMS and a TSQ 700 has been constructed by J.C. Schwartz at Finnigan MAT. The hyperbolic electrodes have been placed in the TSQ 700's vacuum manifold and the rf signal is directed onto the ring electrode via a ceramic feed. The baffle system of the TSQ 700 enables regions of differential pumping, thus facilitating the interface of external ion sources. Figure 1 schematically shows the MALDI-QITMS configuration. Both LC-ESI and MALDI sources were coupled to the ion trap.

LC-ESI-QITMS is a technique that may be used to separate similar species at sensitive levels; molecular weights were easily obtained for 100 fmol of a mixture of cytochrome c isolated from bovine, tuna and s. cerevisiae, as well as for 250 fmol of a mixture of renin tetradecapeptide and angiotensin I. LC-MS/MS has been demonstrated by collisionally activating peptides in the capillary-skimmer region of the electrospray source. In addition, LC-MS has been used to obtain molecular weights for large molecules at low sample levels. Figure 2 shows the mass spectrum and deconvolution of 25 fmol of bovine cytochrome c loaded onto a 20 μm i.d. fused silica capillary column and isocratically eluted with 20% of 0.5% acetic acid and 80% methanol. When optimized, this methodology will enable the study of mixtures of proteins and peptides such as those found in biosystems.
