The MALDI-QITMS systems shown in Figure 1 is unique. MALDI-MS/MS on angiotensin I afforded enough b- and y- type ions to ascertain the sequence of this peptide. In addition, this technique easily allows the sensitive measurement of biomolecules of high molecular weight. Figure 3 shows the mass spectrum of a mixture of 100 pmol of whale myoglobin mixed with 50 pmol of porcine elastase in sinapinic acid, while Figure 4 is the spectrum obtained from 10 fmol of whale myoglobin in sinapinic acid. These amounts are clearly not the limits of detection and better sensitivities may be obtained by optimizing sample preparation and deposition conditions.

Both ESI- and MALDI-QITMS show a great deal of promise as versatile tools for a high throughput, sensitive methodology for the analysis of biomolecules.

Analysis of Azo Dyes Using Electrospray Ion Trap Mass Spectrometery

Hung-Yu Lin and Robert D. Voyksner, Analytical and Chemical Sciences,
Research Triangle Institute, P. O. Box 12494, Research Triangle Park, NC 27709

Environmental contaminants are frequently omitted from surveillance because of the failure of gas chromatography/mass spectrometry (GC/MS) detection. Thermal instability and nonvolatility are the main reasons for these failures. The combination of liquid chromatography with MS (LC/MS) has enabled the detection of many new environmentally important organics. Techniques such as thermospray and particle beam LC/MS have been used successfully to determine certain classes of compounds that are not amenable to GC/MS. However, these LC/MS techniques have shown some limitations ranging from the thermal stability or volatility of the target compound to sensitivity and the ability to generate structural information. These limitations have nearly faded with recent advances in electrospray and quadrupole ion traps.

An electrospray system was interfaced to an ion trap mass spectrometer (ITMS) to analyze azo dyes. The system was optimized to achieve maximum sensitivity. Optimization showed that the time and voltage for gating ions into the trap was 200 msec at 0 V. Ions were injected into the trap held at a helium pressure of 3×10^{-4} torr at a q_z value of 0.1 to 0.15.

Electrospray can efficiently desorb ions formed in solution into the gas phase for mass analysis. Ion current generated by electrospray typically has been far greater than observed by other LC/MS techniques. Although electrospray is a soft ionization technique, structural information can be obtained through collision- induced decomposition (CID) in the ion transport region by adjusting potential of the ion extraction elements. In this way, CID spectra can be generated for all ions formed by electrospray. The combination of electrospray with ITMS amplifies potential sensitivity and specificity while introducing potentially more cost-effective instrumentation. The ITMS has been shown to achieve superior sensitivity over quadrupole instruments and can be operated in the MS^n mode to generate additional structural information. The added MS^n ability can prove advantageous when chemical noise limits CID capability within the electrospray transport region.

Collisional activation of ions originating from various dyes was performed in the electrospray transport region by adjusting repeller voltage, or in the ion trap to provide structural information for the $[M+H]^+$ ions formed. Collisional induced decomposition spectra from both processes were similar (Table 1). Both CID techniques showed the same structurally significant product ions. Often MS/MS in the ITMS resulted in the formation of additional product ions for the compound. Product ions were primarily observed from the cleavage of the azo bond (N=N), N-C bonds, as well as the loss of hydroxy and alkyl functional groups.

The ability to mass select an ion for CID in the ion trap is often preferred, especially during mixure analysis. However, the MS/MS capability of the trap depends on many variables that are often unpredictable. These variables, including tickle voltage (V_{p-p}), tickle frequency (which can vary with space charging), CID time, and q_z value used for trapping and sample concentration, need to be optimized in order to acquire a MS/MS spectrum with a high signal/noise ratio. On the other hand, CID spectra generated within the electrospray transport region are easily obtained. The repeller voltage is set and a CID spectrum is acquired. However, this method is only useful on relatively pure samples, placing more of an emphasis on LC separation.

The overall sensitivity and CID efficiency are excellent for both collisional activation techniques. They show less than 10% loss in total ion current across the collisional activation energy evaluated. Furthermore, better than 80% of the $[M+H]^+$ ion current was converted to product ions with either CID technique. These efficiencies are far superior to magnetic sector (<1%) or quadrupole MS/MS (<50%) techniques.

Further work on investigating the capability of electrospray-ITMS LC/MS for the detection of dyes in more complex water and soil matrices is in process.

Determination of Neuropeptide by Liquid Chromatography/Electrospray Ion Trap Mass Spectrometry

Hung Yu Lin and Robert D. Voyksner, Analytical and Chemical Sciences,
Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC 27709

Introduction

The important function of neuropeptides within the nervous system makes them interesting targets for research in the medical field. Since only trace amounts of neuropeptides are present in biological fluids, it is essential to choose an analytical method which has ultra high sensitivity. Although mass spectrometers have the ability to identify many compounds at trace levels neuropeptides are difficult to analyze due to their thermal instability, low volatility, and high molecular weight.

The ability to produce ions from solution with high ionization efficiency make electrospray a suitable technique in ionizing nonvolatile and thermal labile compounds that are separated by liquid chromatography. The ion trap mass spectrometer (ITMS) offers potentially higher sensitivity and MS^n capabilities, compared to quadrupole MS instruments. These advantages make the electrospray ITMS combination a potentially powerful technique for on-line separation and analysis of neuropeptides.

Experimental

An electrospray interface (Vestec or Analytica) was coupled to an ITMS (Finnigan MAT) as previously reported [1]. Neuropeptide samples contained about 100 ng/μL of methionine enkephalin, α-melanocyte stimulating hormone (α-MSH) α-endorphin or β-endorphin were prepared in 50/50 acetonitrile/water containing 0.1% formic acid. These samples were analyzed by flow injection or spiked into samples for on-line LC/MS. Flow injections were performed using a syringe pump operated at 1.6 μL/min. The LC separations were performed by injecting 5 μL of each sample solution into a 100 x 4.6 mm C_{18} column packed with 3 μ particle, using a gradient of 20% to 100% acetonitrile in water (0.1% formic acid) in 20 minutes at a flow rate of about 200 μL/min. A 70:1 split reduced the column flow to about 3 μL/min into the electrospray interface. Resonance injection was used to extend the mass range of the ITMS in order to detect multiple charged ions from the neuropeptides.

Results and Discussion

Electrospray ITMS could be used to determine the molecular weight of various neuropeptides evaluated in the project. The spectra consisted of $[M+H]^+$ and other multiple charged ions listed in Table 1. The distribution of single and multiple charged ions could be varied by applying a voltage to the repeller or capillary in the electrospray interface. A higher voltage resulted in charge stripping, shifting the ion distribution toward higher m/z values (single charged species). Also, the spectra obtained on the ITMS showed less multiple charged ions than for the same neuropeptide analyzed using the same ES conditions on a quadrupole MS (Hewlett Packard 5989). Several possible explanations for this observation arise form pressure and ion energy considerations. First, the operating pressure of the trap is about 1 mtorr (mixture of helium and nitrogen from the ES system). Secondly, ion injected into the trap as well as ions stored in the trap at higher q_z values can undergo some collisional activation resulting in charge stripping.

Table 1

			m/z (% Relative Intensity)		
Neuropeptide	mw	$[M+H]^+$	$[M+2H]^{+2}$	$[M+3H]^{+3}$	$[M+4H]^{+4}$
Methionine enkephalin	574	574 (100)	288 (6)	-	-
α-MSH	1665	-	834 (32)	556 (100)	417 (19)
α-endorphin	1745	1746 (100)	874 (3)	-	-
β-endorphin	3465	-	-	1156 (52)	867 (100)

Initial evaluation of LC/electrospray-ITMS demonstrated the ability to separate and detect pmole quantities of neuropeptides. A 70:1 splitter was used after the column separation to maintain a near optimal flow rate of 2-3 μL/min into the ES interface. In this way, flow rates of 0.2 mL/min could be readily used for the separation without affecting the electrospray ion current stability. The separation of a mixture of α-MSH and α-endorphin is shown on Figure 1. In this chromatogram the $[M+H]^+$ and $[M+2H]^{+2}$ ions for each peptide can be detected for a 4 pmole sample. The blank analysis indicated the absence of these neuropeptides.

Conclusions

LC/electrospray-ITMS can be used for the detection of neuropeptides with the proper selection of operating conditions. The technique can detect pmole levels of the selected neuropeptides. Future research will investigate LC and electrospray ITMS to detect these neuropeptides in biological fluids at sub pmole levels.

Capillary Electrophoresis Ion Trap Mass Spectrometry

Jae C. Schwartz and Ian Jardine, Finnigan MAT,
355 River Oaks Pkwy., San Jose, CA 95134

Capillary zone electrophoresis is emerging as a powerful technique for the relatively rapid and efficient separation of peptides and proteins. The quadrupole ion trap has also demonstrated unique and promising capabilities for peptide and protein sequencing by mass spectrometry. Consequently, we have coupled CE to an ITMS using an electrospray ionization inlet system in order to evaluate this combination. The experimental apparatus is shown in Figure 1 and a table of operating conditions is given below.

An example separation of a 5 second electrokinetic injection of a 50 pmol/ul mixture of 3 bradykinins and two enkephalins is shown in Figure 2a, with the corresponding mass chromatograms shown in Figure 2b. Mass chromatograms for a 5 second electrokinetic injection of a 2.5 pmol/ul solution of the same mixture are shown in Figure 3. Calculated injection quantities are indicated on the traces.

In general, the singly charged enkephalins behaved well, with the multiply charged species tending to demonstrate slightly lower performance presumably due to interactions with and adsorption to the negatively charged walls of the fused silica capillary. Coated columns have been used to address this problem. An example of the separation of angiotensin I, renin substrate, and substance P using a aminopropyl silylated fused silica column is shown in Figure 4*. The expected increase in chromatographic separation efficiency is observed and is extended to beyond 100000 theoretical plates. Note that the polarity of the high voltage was reversed (negative) since the direction of electroosmotic flow has reversed. Consequently, the elution order has also reversed when compared to separations using normal fused silica columns.

The serial dilution results shown in Figure 5 demonstrate full scan detection limits for leu-enkephalin of below 15 fmol. In fact, Figure 6a shows mass chromatograms for two injections differing by a factor of ten in sample injected of a mixture containing leu- and oxidized met-enkephalin. The mass spectra for these compounds resulting from injection of approximately 8 fmols is given in Figure 6b.

This preliminary data suggests that the combination of CE with an ion trap using electrospray ionization is a viable one producing detection limits below 10 fmols. The enhanced capabilities of the ion trap such as charge state identification, efficient MS/MS and high M/Z range should prove quite useful in future studies. One area requiring further development is buffer and (coated) column combinations which optimize both CE separation efficiency and electrosprayability of analytes. Also, to take full advantage of the ion trap's sensitivity, pulsed ionization/sample introduction methods should be employed. Due to the fast separation times and high chromatographic efficiencies, scan times, acquisition rates, and data compression must be carefully considered.

*We acknowledge and thank Dr. Arthur Moseley of Glaxo for the aminopropyl silylated columns and his advice.

Peptide Sequencing by Quadrupole Ion Trap Mass Spectrometry

Jae C. Schwartz and Ian Jardine, Finnigan MAT,
355 River Oaks Pkwy., San Jose, CA 95134
Charles G. Edmonds, Pacific Northwest Laboratory
P.O. Box 999, Richland Washington 99352

Using electrospray ionization and several example peptides, we have investigated the unique capabilities of the ion trap to produce peptide sequence information. These capabilities, including MS^n experiments, high resolution for charge state determination, and highly efficient fragmentation are shown to yield substantially more sequence information, than can be accessed by other types of mass spectrometers. Several small tryptic-like peptides were first studied using the ESI-ITMS. Excerpts of a study on glu-fibrinopeptide are shown below. The MS/MS ion trap spectrum of the $(M+2H)^{2+}$ shows very good fragmentation and almost complete sequence information including both Y and complementary B type fragments (Figure 1a). In fact, the doubly charged ions of small tryptic peptides fragment so readily that dissociation can occur at a lower **q** value than is usually required for efficient dissociation. This allows lower mass fragments to be observed and also enhances the abundance of the higher mass B ions (Figure 1b). These complementary B-type ions are not observed in triple quadrupole data for this compound. Missing sequence information can be accessed using MS^n experiments to yield complete sequence information (one example is shown in Figure 2).

Excerpts from a more in depth investigation of the larger peptide human growth hormone releasing factor (ESI MS shown in Figure 3), a 44 amino acid peptide with molecular weight 5040 are shown below. The MS/MS spectrum of the $(M+7H)^{7+}$ ion shows abundant fragmentation including complementary pairs of ions (Figure 4). The distinctive activation characteristics of the trap appear to yield many more complementary fragments including higher mass B type fragments not observed in triple quadrupole experiments. We have observed for this particular peptide that the ion trap can achieve highly specific fragmentation producing complementary pairs of fragments. Cleavage exclusively on the C-terminus side of acidic amino acid groups to produce both B and Y complementary ions has been observed for pentuply charged pseudomolecular ions and fragment ions (Figure 5). This phenomenon is similar the action of the enzyme V8 protease in the condensed phase. This highly selective fragmentation seems to be sensitive to energy deposition and charge state as well. By performing a host of higher order experiments including MS/MS/MS (Figure 6) and MS/MS/MS/MS (Figure 6) on these complementary and other ions, one can access important cleavages between nearly every amino acid along the backbone and therefore give nearly complete sequence information even for this large peptide. Difficulty in sequence ion assignment due to unknown charge state or overlapping peaks may be overcome using the high resolution capabilities of the ion trap, for example in the MS/MS/MS data of a multiply charged intermediate ion (Figure 8).

Although the practical sequencing of unknowns still presents a complex challenge, these preliminary qualitative results suggest that the ion trap's unique capabilities may be ideally suited for gaining maximum sequence information of peptides. These capabilities include production of unique, complementary, and efficient fragmentation, charge state identification, and MS^n experiments.

MICROBORE HPLC/ELECTROSPRAY IONIZATION/ION TRAP MASS SPECTROMETRY OF BIOMOLECULES

Gary J. Van Berkel, Roswitha S. Ramsey, Scott A. McLuckey, and Gary L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365.

Over the last several years we have reported on advances in the analysis of ES derived ions using an ITMS modified to sample from ambient air (1-7). As an example of the sensitivity of the device, flow injection experiments at 1-5 μL/min afforded detection of 18 femtomoles injected for octaethylporphyrin, demonstrating the expected detection limits from the coupling of low flow rate separation techniques, such as capillary-bore HPLC and capillary electrophoresis, with the ES/ITMS. Detection limits in the low picomole range have been obtained for porphyrins and proteins when operating at flow rates as high as 40 μL/min with 1.0 μm-i.d. packed columns. While the sensitivity of the on-line condensed-phase separation/ES/ITMS is excellent, this coupling can compromise many of the other desirable features of the ITMS. In this paper, some of the problems faced with dynamic range, mass accuracy and calibration, mass resolution, and single frequency collisional activation (CA) and MS/MS are overviewed. The remainder of the discussion focuses on three methods other than single-frequency CA that can be used to obtain structure information in on-line applications.

Dynamic Range. Automatic gain control, AGC, which automatically varies the ionization (or ion injection) time to avoid accumulating "too many" ions in the trap, was developed to increase the dynamic range for separated compounds entering the trap. However, an inherent compromise in increasing the ionization time for minor component detection is a loss of peak resolution. As ionization or ion injection time increases, the number of data points across a peak will decrease.

Mass Accuracy and Calibration. The analysis of high mass biomolecules by ES often necessitates extension of the nominal m/z range of the trap from 650 to as much as 3000. This is most easily accomplished using the technique of resonant ejection. When resonant ejection is used to multiply the m/z range, peak position is dictated by a number of factors including the m/z of the ion of interest, the resonant ejection frequency and amplitude, the speed of the fundamental rf amplitude scan, and the He pressure in the trap. Since power absorption in resonant ejection has a z/m dependence the mass scale is slightly nonlinear. Therefore, calibration must be done with ions of known m/z over the range of m/z of interest using as similar experimental conditions as possible.

Mass Resolution. Obtaining high resolution spectra in on-line applications is problematic for several reasons. First, because resolution and scan speed are inversely related, a decrease in scan speed reduces the data points per peak. Secondly, signal/background decreases as resolution increases (i.e., less ion current per unit time). Third, the number of ions in the trap have a significant effect on resolution and this number changes as the peak elutes.

Single Frequency CA. A practical limitation in obtaining structurally informative fragmentation using the normal single frequency method of CA is imposed by the mass-selective nature of the process. The m/z ratio of an ion must be known in advance so that the parameters affecting CA can be optimized (e.g., q_z, tickle amplitude, time, and frequency). When an on-line separation involving compounds of unknown mass is performed, CA cannot be pre-optimized or optimized at present on the chromatographic time scale. The compounded tuning requirements in MS^n experiments, which are often needed to obtain additional structural information, make acquisition of such data on-line highly impractical (4).

Alternative Fragmentation Methods. As with other ES interfaces, the voltages on the aperture plates and lenses in our interface can be adjusted so that the molecular species generated by ES can be fragmented through energetic ion/molecule collisions in the interface region upon transport to the ion trap. Fragmentation may also be induced upon injection of ions from the interface into the ion trap by adjustment of the rf voltage amplitude (low mass cutoff) on the ring electrode during ion injection. In reference to on-line applications, interface fragmentation and injection-induced fragmentation are of added utility because they are both non-mass-selective means to promote fragmentation. In addition, the variable parameters used to control fragmentation in these two techniques may be controlled automatically as components elute using the ITMS software. Thus, molecular weight and structure information may be obtained in one analysis for each component as it elutes from the chromatographic column (5).

Recently our group has demonstrated that random noise applied to the end-caps of the ITMS is an effective means for CA of trapped ions in MS/MS experiments (8). This technique is a simple and inexpensive approach to overcoming the single frequency CA drawbacks of frequency tuning, space charge effects, limited fragmentation, and the inability to activate parent ions over a range of m/z values. The relaxed tuning requirements associated with random noise CA make this dissociation technique ideal for MS/MS in on-line separation applications for which the limits of single-frequency CA are most severe. An example of on-line microbore HPLC/ES/MS/MS using random noise CA is shown in Figure 1. In this experiment, two injections of the porphyrin hematin were made, the first with the random noise signal off, the second injection with the noise signal on. The resulting ion current profiles and mass spectra demonstrate acquisition of the hematin mass spectrum, which is devoid of fragment ions, and the structurally informative product ion spectrum produced via random noise CA. As with interface and injection-induced fragmentation described above, random noise MS/MS product ion spectra may be obtained for alternate mass scans allowing for the acquisition

of molecular weight and structure information in a single experiment. However, by adding additional control logic as shown in Figure 2 it was possible to perform random noise CA during alternate mass scans without the need to download separate scan functions. All data are acquired into a single data file, but can be deconvoluted following the experiment to yield a data file of mass spectra and another data file with the MS/MS spectra of each eluting component. By performing experiments in this manner, the rate of data acquisition is not compromised, as is the case when a key sequence program is used due to computer overhead, allowing more data points to be acquired across an eluting peak. Figure 3 shows the acquisition of random noise CA MS/MS spectra for the on-line microbore HPLC separation of the porphyrins hematin and mesoporphyrin IX dimethyl ester. In this example, as the respective porphyrins elute from the column their respective mass spectra and MS/MS spectra are recorded in an alternate fashion. Note in the ion current profiles that the molecular ion and major product ion intensities for the respective porphyrins maximize on alternate scans.

Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831.

Two of the major challenges which face the field of elemental mass spectrometry are the development of versatile atomization/ionization sources for direct solids analysis and methods for reducing the impact of isobaric interferences found on commonly employed quadrupole and sector based instruments. The combination of radio frequency glow discharge (RF-GD) sources with Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR or FTMS) is one technique which addresses both problems.

A demonstration project was conducted at ORNL where an external RF-GD ion source was coupled to a commercial FTMS instrument (Nicolet FTMS 2000, EXTREL FTMS, Madison, WI) and is illustrated in Figure 1. The ion transfer system utilized the lensless method developed by Weller, et al (ASMS, 1988) for laser desorbed ions. The RF-GD source was contained in a 2.75" CF cross and separated from the main vacuum system by a skimmer cone. An intermediate differential pumping chamber was separated from the FTMS pumping system by a 0.375 " conductance limit. The differential pumping chamber attached directly to the "analyzer" flange of the FTMS-2000. When operating the RF-GD source at 100-500 mtorr, pressures in the FTMS analyzer cell were ca. 2 X 10-7 torr. The RF-GD external source experiments showed that large ion signals could easily be obtained without complex trapping schemes which produced mass spectra with excellent signal-to-noise ratios and resolving powers in the range of 75,000 for m/z 56 ions. Resolutions were limited by the pressure at the analyzer cell resulting from the size of the conductance limit between the external source and the main vacuum chamber and the size of the differential pumping system. SWIFT ion excitation methods easily compensated for the large number of matrix ions by ejecting them from the analyzer cell. The skimmer cone could be gated with a small voltage (ca. -20V) to block ion introduction into the system during the excite/receive events of the FTMS pulse sequence.

The figures show the results obtained on several NIST samples. The NIST 1103 Brass sample shows good ratios for the Cu and Zn omponents. Expected peaks are observed for the Ar+ and ArH+species. Minor components down to around 1 % are observable without any ion ejection techniques. The NIST 1263 Steel sample demonstrates the moderate resolution attainable even with the high pressures in the ICR anlyzer cell.

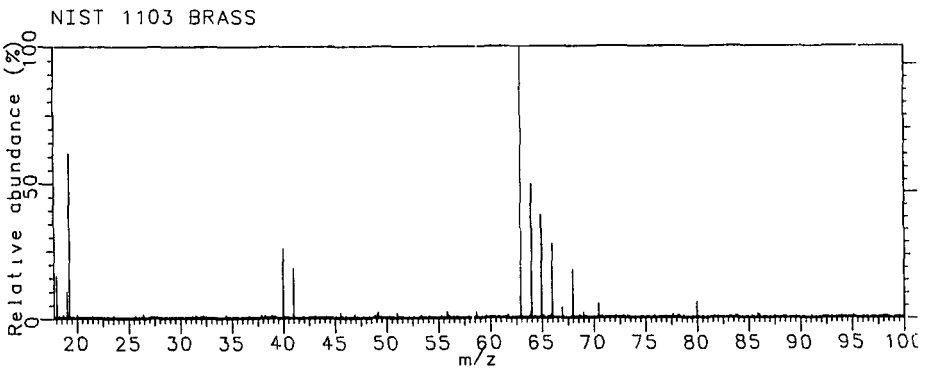
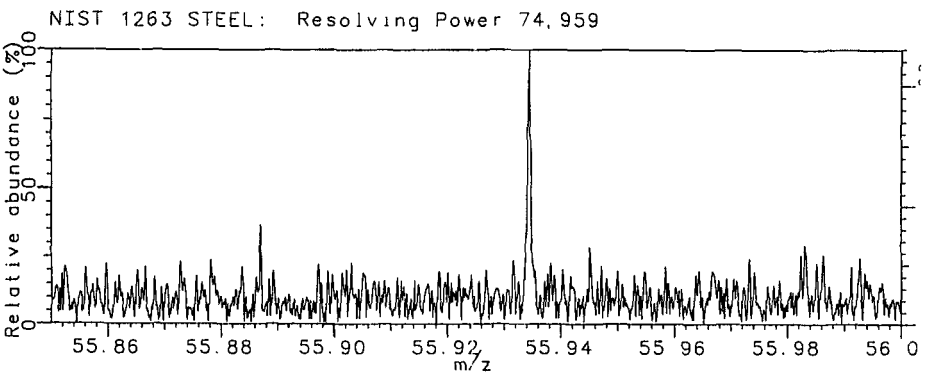
This abstract was prepared in connection with work done under Contract No. DE-AC09-89SR18035 with the U.S. Department of Energy. By acceptance of this abstract, the publisher and/or recipient acknowledges the U.S. Government's right to retain a nonexclusive, royalty-free license in and to any copyright covering this abstract, along with the right to reproduce and to authorize others to reproduce all or part of the copyrighted abstract.

The use of a lensless ion transfer system greatly simplifies the construction of an external ion source. The external source system generates currents at the analyzer cell (as measured on the DIP probe) of the order of 100's of nanoamps. Such beam currents are comparable to this RF-GD source when mounted on beam-type instruments, demonstrating that the lensless ion transfer system is very efficient for injecting ions into the analyzer cell region.

The success of these preliminary experiments has resulted in the design for an RF-GD/FTMS instrument optimized for obtaining high resolution mass spectra. The optimized system will include increased differential pumping, small conductance limits between differential pumping zones, and an ion gate to prevent ions from leaving the external source during the FT-MS excitation/detection times. The increased differential pumping speed will be obtained by a redesigned analyzer side vacuum box with greater conductance, a larger external source diffusion pump (2400 vs 1200 l/s), and increased conductance between the pump and the differential pumping chamber. Assembly of the new instrument will begin in early 1992.



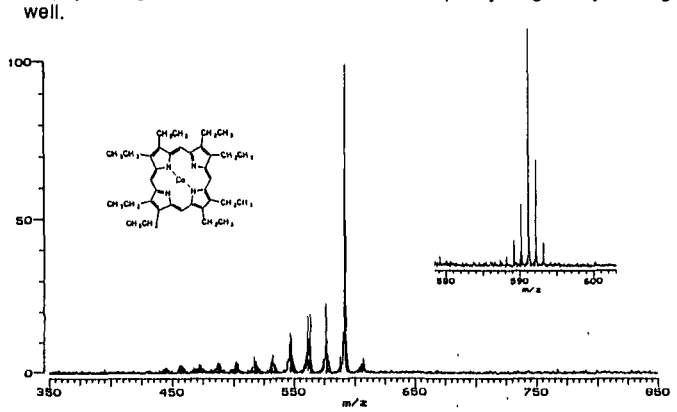


Analysis and Photodissociation of FIB Produced Metallo-Porphyrins in an External Source Q-FTMS

Sesi McCullough-Catalano and Carlito B. Lebrilla
Department of Chemistry
University of California, Davis CA 95616

The mass spectral analysis of porphyrins and metalloporphyrins has been of great interest due largely to their biological and environmental importance[1]. These large, relatively nonvolatile molecules have been ionized by many methods including electron impact[2], fast atom bombardment (FAB)[2,3] and electrospray[4]. Until very recently these last two ionization methods have been used mainly in combination with sector instruments, where photodissociation (PD) is very difficult to perform. Although FTMS is ideally suited to PD studies, high pressure ion sources have not previously been compatible with the low pressures required in Fourier Transform Mass Spectrometry (FTMS). Consequently there are very few porphyrin PD studies reported in the literature, especially of FAB produced porphyrins[5,6]. Using an external source quadrupole FTMS built in our laboratory at UC Davis, equipped with a fast ion bombardment (FIB) source, we have recently obtained PD spectra for several Fe, Co and Ni octaethyl (OEP) and tetraaryl substituted metalloporphyrins. Unlike some other biomolecules we have analyzed on the Q-FTMS, metastable decay of metalloporphyrins has not been observed. The time between ion injection and detection was varied from 1 millisecond up to 2000 milliseconds, with no appreciable change in the appearance of the spectra. The long time scale of the FTMS experiment allows very high resolution spectra to be obtained, with little or no matrix interference.

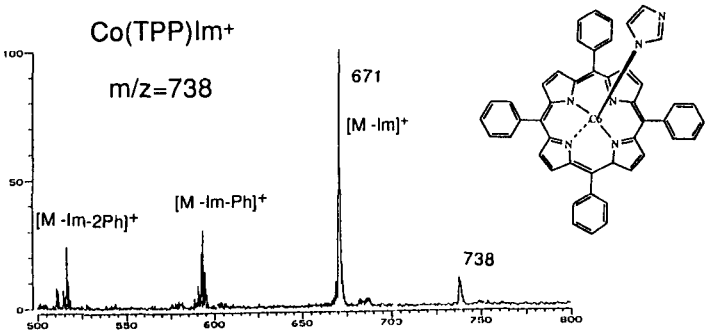
To perform the analyses, the porphyrins are dissolved, usually in methylene chloride, placed on a copper probe tip containing m-nitrobenzyl alcohol matrix and ionized by a beam of 7-10 KeV Cs ions from an Antek Cs gun. The ions are then transported from the source to the analyzer cell via a set of quadrupole rods operated in the RF only mode. The FIB spectra of metallooctaethyl porphyrins show consecutive losses of up to 8 methyl groups as the major fragmentations, due to β C-C cleavage at the pyrrole position of the porphyrin ring. For the metallotetraphenyl (TPP) porphyrins, loss of two phenyl groups is observed from α C-C cleavage at the meso position of the porphyrin ring. If there are substituents on the phenyl rings, they undergo β cleavage as well.



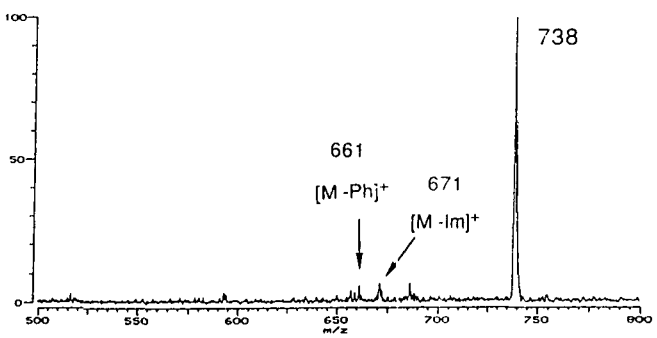
Broadband Acquisition of Co(OEP).

Inset: High Resolution (Narrowband) Acquisition of Co(OEP) molecular ion (m/z=591). Resolution = 8700.

For the PD studies, a normal FIB spectrum is obtained, and then the desired parent ion is isolated using double resonance techniques The unfocussed beam from a Lambda Physik EMG101 excimer laser (193 nm) is directed into the analyzer cell through a quartz window. The analyzer cell is equipped with 90% transmittance gold mesh to allow the laser beam to enter the cell. A PD spectrum is then obtained which normally consists of 50 scans. A comparison of FIB and PD spectra can be made. In most cases, the fragments observed are the same in the FIB and PD spectra for a given metallooctaethyl or tetraphenyl porphyrin, although the degree of fragmentation may vary. An exception is the behavior of a ligated metalloporphyrin, $Co(TPP)Im_2$ (Im=imidazole), where the imidazole is coordinated to the metal center. This porphyrin is synthetically prepared with two Im ligands, only one of which is retained in the FIB ionization process. In the FIB spectrum, there are peaks due to $[M\text{-}Im]^+$ as well as $[M\text{-}Im\text{-}Ph]^+$ and $[M\text{-}Im\text{-}2Ph]^+$. In addition to these fragments, the PD spectum contains a peak corresponding to $[M\text{-}Ph]^+$.



Normal FIB Spectrum of $Co(TPP)Im^+$.



Photodissociation of $Co(TPP)Im^+$. A small peak at m/z=661 corresponding to loss of a phenyl ring with retention of the imidazole ligand is observed.

EXPERIMENTAL STUDIES OF EXCITATION ELECTRIC FIELD INHOMOGENEITIES IN A CUBIC FT/ICR CELL

B.A. Hearn, D.W. Mitchell, and S.E. DeLong
Department of Geological Sciences
University at Albany, Albany, NY 12222

Theoretical calculations of ion motion[1] in a cubic FT/ICR cell[2] predict that excitation at certain resonance frequencies away from the cyclotron frequency can cause appreciable changes in the ICR signal by perturbing the radial and axial modes of motion. Double resonance FT/ICR experiments[3] have been employed to investigate changes in the signal due to resonances at $\omega_+ \pm 2\omega_z$, $2\omega_z$, $3\omega_+$, and $2\omega_+$.

Experimental conditions included a magnetic field of 3.0 T, a 2" cell in a Nicolet/Extrel/Millipore FT/ICR mass spectrometer, 9 x 10-8 torr benzene, and a beam voltage of -20 V. For the resonances at $\omega_+ \pm 2\omega_z$ and $2\omega_z$, the perturbation pulse was followed by excitation at the cyclotron frequency. Plots were made of the peak height for m/z 78 as a function of the perturbation frequency in the vicinity of each resonance. For the resonances at $2\omega_+$ and $3\omega_+$, in which the resonance strength depends on the initial cyclotron radius, excitation was first done at the cyclotron frequency, followed by excitation at the perturbation frequency.

The top figure shows the FT/ICR peak height as a function of the perturbation frequency for excitation near $\omega_+ \pm 2\omega_z$. The resonance at $\omega_+ - 2\omega_z$ decreases the z-amplitude if the initial cyclotron frequency is small, so the signal is enhanced due to more efficient detection of the signal near the center of the cell. On the other hand, excitation near $\omega_+ + 2\omega_z$ increases the z-amplitude, leading to ejection along the z-axis, hence a lower FT/ICR signal. Excitation near $2\omega_z$ causes an increase in the z-amplitude, leading to ejection along the z-axis.

Excitation near $2\omega_+$ and $3\omega_+$ was predicted to cause an increase in the cyclotron radius. Peak heights as a function of the perturbation frequency near these frequencies can show an increase or decrease in the FT/ICR signal, depending on the phase of the perturbation pulse and whether or not the cyclotron radius was large enough to cause radial ejection. The bottom figure shows the raw peak height as a function of the perturbation frequency pulse in the vicinity of $3\omega_+$. Moderate perturbation pulses increase the signal, while the strongest pulse reduces the signal due to radial ejection.

Excitation at certain resonance frequencies away from the cyclotron frequency causes significant deviations in the FT/ICR signal from ideal linear behavior. The well-known resonances at $\omega_+ \pm 2\omega_z$ and $2\omega_z$ are very strong. The resonances at $2\omega_+$ and $3\omega_+$ are weaker, but can be significant under certain conditions. In FT/ICR experiments where more than one frequency is used for excitation, excitation at the stronger resonances should be avoided, if possible, to minimize changes in relative peak heights.

QUANTITATIVE EVALUATION OF MULTIPLE ON-RESONANCE EXCITATION EVENTS IN THE FTICR EXPERIMENT

D.E. Riegner, J.S. Anderson, and D.A. Laude, Jr.; Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX 78712

Factors affecting the total ion signal magnitudes in Fourier transform ion cyclotron resonance mass spectrometry (FTICR) continue to be of fundamental importance to the development of this instrument as an analytical tool. The distribution of the ion cloud due to multiple excite events and the subsequent detection efficiency of those ions are discussed here in terms of how to approach obtaining quantitative CID results. Specifically, three different effects of multiple on-resonance excite events will be evaluated. The first effect to be analyzed is the loss of low-mass product ion signal magnitude due to axial ejection. The second effect is the undesirable variation in precursor ion signal magnitude due to de-excitation of the ion bundle. Finally, the effect of the initial single frequency excitation on the subsequent excite efficiency is discussed. Recommendations as to experimental methods of minimizing the quantitative errors associated with these effects are presented.

CID was performed on molecular ions of phenylether, analine, and n-butylbenzene. Each of these compounds was admitted into the vacuum chamber of a Nicolet FTMS-2000 mass spectrometer via a high precision leak valve to give a sample pressure of 8×10^{-8} above a background pressure of 9×10^{-9} torr. The collision gas used was argon and it was admitted at a static pressure via a second high precision leak valve to a CID pressure of 8×10^{-7} torr.

The relative abundances of the precursor and product ions of phenylether at three different center of mass collision energies yield ratios of the m/z=77 to m/z=142 that decrease with an increase in collision energy of the precursor. Since the energy threshold for the formation of the m/z=77 ion is higher than that for the m/z=142 ion, the ratio would be expected to increase with increasing tickle energy. Instead, the decrease in ratio indicates that a mass dependent ion loss process involving CID fragment ions is occuring.The use of increased trap potentials in the CID experiment should indicate whether or not the mass dependent ion loss is occuring along the z-axis. Ratios of the product ions m/z=77 to m/z=142 were measured at increasing trap potential. The results are plotted in Figure 1 which indicates an increase in the ratio with trap potential until it

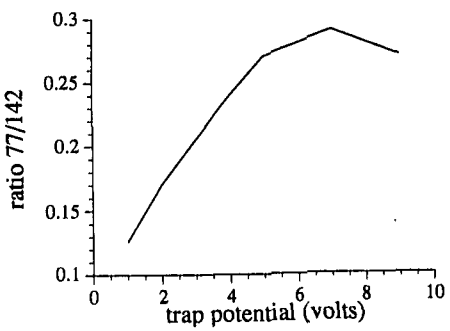

Figure 1

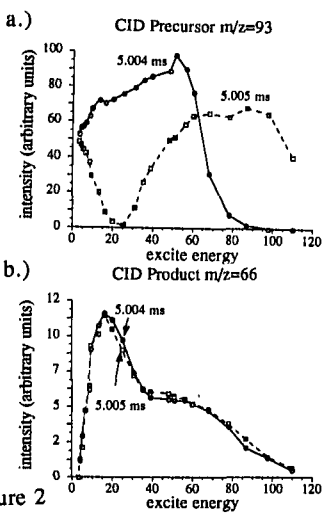

Figure 2

levels off at about 5 volts. These data suggest that the increased trap potential does improve the trapping of the lower mass fragment and therefore indicates that the m/z=77 ions were being lost axially as the radial extent of the precursor ion increased.

Following a CID tickle pulse, precursor and products of aniline at two different collision delay times were detected by FTICR at increasing excite voltages. Changing the delay time altered the phase of the ion bundle with respect to the second excite pulse. In Figure 2a the presence of a minimum in the excite profile for the precursor at a 5.005 ms delay is indicative that the ion bundle has been de-excited due to the second excite being applied out-of-phase with the cyclotroning ions. At increasing excite voltage the ions are eventually re-excited as indicated by the increase in signal magnitude. Notably, the product excite profiles in Figure 2b do not indicate de-excitation at either of the delay times. This is explained by the fact that the product ions are only excited into coherence for detection and no other excite is applied to de-phase the ion bundle. Quantitative results for this CID experiment would be inaccurate if the dephased signal intensity of the precursor is used.

Collisional cooling provides a means to correct the problems shown in Figure 2 and obtain relatively constant signal magnitudes at various excite energies even when the precursor has been de-excited. Shown in Figure 3 are double resonance excite profiles for naphthalene molecular ion at increasing collision delay times. The profiles do not indicate a shift in the deflection point as the delays are increased, yet at longer times the profiles start to flatten out yielding a loss in definition of the deflection point. This suggests a randomization process whereby the ions are ultimately distributed in an annulus in the cell prior to the second excite event. This is more reasonable than an energy loss process which would be illustrated by a shift of the deflection point to lower energy as the delay time is increased, due to the decreasing radius of the ion bundle upon de-excitation. For the CID experiment there will be an optimum delay time and pressure combination to provide efficient cooling and minimize the possible de-phasing effects.

In the CID experiment of n-butylbenzene the use of smaller initial excite energies leads to less variation in optimum detect voltage for the precursor signal magnitude at various delay times. Figure 4 illustrates the optimum detect voltage for the 134 m/z molecular ion of n-butylbenzene at several in- and out-of-phase delay times for three different initial excite energies. As smaller initial excite energies are used the optimum detect voltage approaches a constant value independent of the delay time between the tickle and the excite to detect Therefore, the use of smaller initial excites would alleviate the variations in optimum detection voltage. Of course this is not a possibility if high energy dissociation products are desired.

INITIATION AND CONTROL OF COHERENT MAGNETRON MOTION IN THE FTICR TRAPPED ION CELL

*C. L. Hendrickson, S. C. Beu, and D. A. Laude, Jr.; Department of Chemistry and Biochemistry
The University of Texas at Austin, Austin, Texas 78712

An increasing number of FTICR experiments are being conducted in which the spontaneous initiation of coherent magnetron motion occurs. Although previously thought to be significant only under high pressure conditions, we have observed that resistive wall destabilization at low pressure can promote the rapid excursion of ions from the cell. Thus it is important to understand the processes responsible for initiation of the coherent motion so that measures can be taken to minimize negative consequences. The purpose of this work is to evaluate the susceptibility of several ionization techniques to coherent magnetron motion, to distinguish whether the ions which participate in this motion are the same ions necessary for cyclotron excitation and detection, and to elucidate the factors which promote the effect. Also, given the negative consequences of the coherent motion, techniques to control coherent magnetron motion are being evaluated.

Growth of Coherent Magnetron Motion Resistive wall destabilization of magnetron motion is due to Ohmic heating caused by current flow through resistors in the detection circuitry. In previous work we demonstrated an inverse relationship between the growth rate of the magnetron radius and trap voltage, ion number, and circuit resistance for the EI experiment. It might be expected that similar results would be obtained for other ionization methods, and Figure 1 presents such evidence. Shown in Figure 1 are plots of retention time vs. 1/R and $1/V_{trap}$ for laser desorbed ions. The predicted linear relationship is observed and is an indication that resistive cooling of the motion is the primary growth mechanism at low pressure for these externally generated ions.

Initiation of Coherent Motion Two factors were considered in evaluating the tendency for coherent magnetron motion to be initiated, the initial radial displacement of the ion cloud and the lifetime of the injection event relative to a single magnetron period. If injection is rapid and ions are displaced from the centerline of the cell, then the coherent, asymmetrically disposed ion population that results would be most likely to undergo rapid growth. This is demonstrated in Figure 2 using LDI. Shown in Figure 2a is the transient resulting from ion injection through a 0.5 cm hole displaced 1 cm from the centerline of the cell. Magnetron growth is initiated immediately and within 200 ms, all ions

FIGURE 1

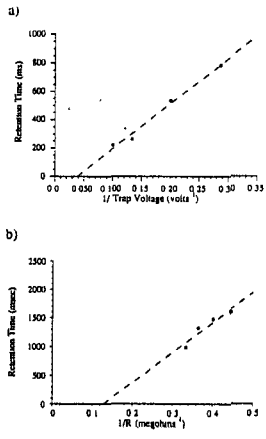

FIGURE 2

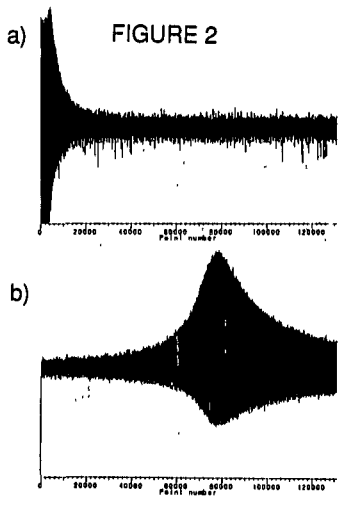

are ejected from the cell. Presented in Figure 2b is the transient resulting from ion injection through a 0.5 cm x 2 cm length cylindrical tube centered on a mask. The cylinder ensures that only ion trajectories along a relatively small solid angle centered on the z-axis would be able to enter the cell. Consequently the rate of magnetron growth is about an order of magnitude lower.

Electron Beam Ion Trapping Experiments in which coherent magnetron motion was generated using electron ionization have indicated that the ions which are formed are likely being trapped in the space charge potential well of the electron beam for some or all of the beam event. This phenomenon was examined by performing EI first along the centerline of the cell and then at an initial radius of 6 mm. Comparison of the retention times of the magnetron transients, which are shown in Figure 3, reveal two distinct differences. First, as expected, the retention times of the off-axis events are shorter than for the on-axis events. Second, distinct peaks in retention time are unexpectedly generated for two of the off-axis events. This peak can be explained by considering the probable consequences of trapping in the electron beam. In Figures 3a and b, the electron current and therefore the potential well created are held constant while the number of ions being formed is increased. The retention time initially decreases as more ions are released in a highly coherent bunch upon termination of the beam. When the well is "full", ions leak out prior to termination of the beam, thus destroying the coherence and increasing the retention time. Eventually the growing ion density overwhelms the steady state electron density and the retention time once again decreases.

Control of Coherent Magnetron Motion In order to minimize the negative effects of magnetron motion, control of the motion is being explored. Because the magnetron radius decreases as the mode gains energy, heating of the motion would be desirable. One answer is to apply an rf excite at the magnetron frequency. However, this requires knowledge of the phase of the motion. To control the phase, a short dc pulse was applied to the excite plates of the cell which induced a well-controlled E x B drift of the ions. Examination of the transients showed that a constant magnetron radius and phase was reproducibly obtained. This allowed the timing of a second excite, which was applied at the magnetron frequency, to be tuned to either excite or cool the mode. Examples of these excites are shown in Figure 4. For an out of phase excite, shown in Figure 4a, cooling takes place and growth of the motion is observed. Figure 4b shows a partial decrease in magnetron amplitude when the excite is in phase with the motion. Proof that the ions are collapsing to the center of the cell is that after excitation of the mode, resistive wall destabilization causes the ions to again spiral out toward the cell plates.

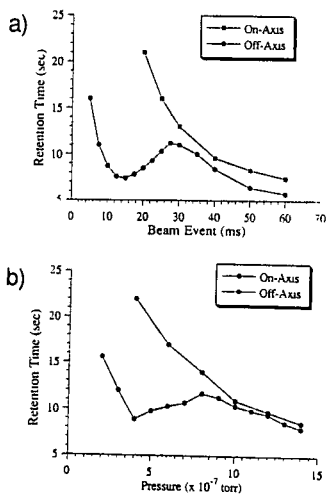

FIGURE 4

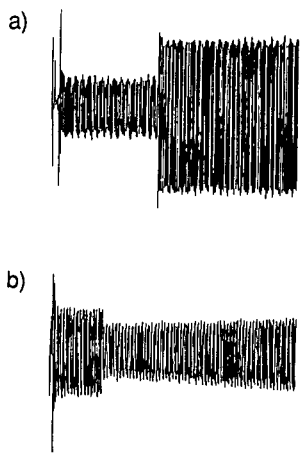


TWO-DIMENSIONAL LINE-BROADENING MODEL FOR FTICR

*C. L. Hendrickson, S. C. Beu, and D. A. Laude, Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, Texas 78712

There remains a problem in FTICR that mass resolution is unexpectedly degraded at high mass. Therefore, it is important that the forces behind these mechanisms be elucidated and corrected in order to make high resolution spectra routinely obtainable. We are exploring the possibility that ion-ion interactions are responsible for this resolution problem at high mass. It is commonly observed that spectra of large ion populations exhibit frequency shifts and line broadening due to Coulomb forces. Modeling of Coulomb interactions has been accomplished previously by several groups [1,2] These models have shown that, in two dimensions, the instantaneous position-dependent force between ions results in a mutual cyclotron frequency modulation, the average effect of which is a shift in the measured cyclotron frequencies. However, none accounts for spectral line broadening. Here we propose a two-dimensional Coulomb line broadening model for the general case of two unlike ions orbiting around a common center. The instantaneous position-dependent force between these ions results in a mutual cyclotron frequency modulation which occurs at the difference between the ion cyclotron frequencies. We find that such modulation will result in spectral line broadening when the period of the frequency modulation is comparable to the experimental observation time. Such a case exists when analyzing ion populations consisting of relatively high mass ions with small differences in mass.

Following from previous work [1,2] it is possible to calculate the Coulomb force between the ions. We assume an average distance between ions based on the magnitudes of their respective Lorentz and Coulomb forces. Therefore we model with r_1 and r_2 differing by that distance. Figure 1 depicts a simple attempt to model this situation. Here the perturbing ion is split into two equal pieces, one with $r_1 > r_2$ and one with $r_1 < r_2$. In this case, instead of an infinite force at = 0 the force is zero as the effect of each piece cancels that of the other piece. This model insures a finite frequency-shifting force over all which allows for study of the time-dependence of this force. Using this model the expression for the radial Coulomb force becomes equation 1. This equation provides

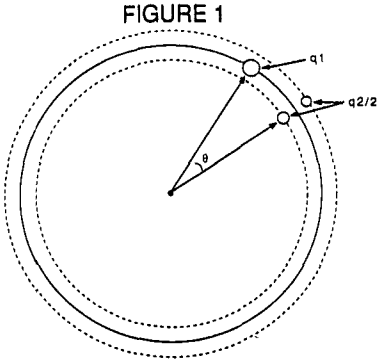
$$F_{\perp} = \frac{kq_1q_2}{2}\left[\frac{(r_2-(r_1+\Delta r)\cos\theta)}{(r_2^2+2(r_1+\Delta r)r_2\cos\theta+(r_1+\Delta r)^2)^{3/2}}\right]+\left[\frac{(r_2-(r_1-\Delta r)\cos\theta)}{(r_2^2+2(r_1-\Delta r)r_2\cos\theta+(r_1-\Delta r)^2)^{3/2}}\right] \quad (1)$$

a time-dependent analytical expression from which a shift in cyclotron frequency can be obtained. This frequency shift is given by equation 2. Using equation 2 a time domain signal can be

$$w_1 = \frac{F_{\perp}}{q_1 r_1 B} \quad (2)$$

simulated which contains this time-dependent frequency modulation. The signal can then undergo

FIGURE 1



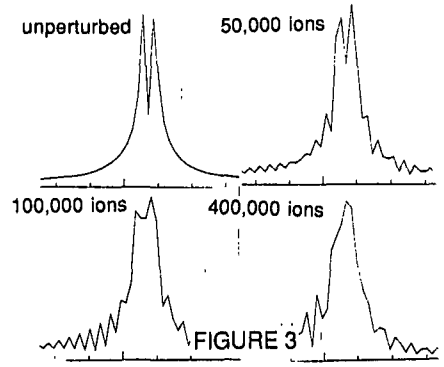


FIGURE 3

Fourier transformation in order to examine the effects of the modulation in the frequency domain.

Line broadening predicted by the model occurs only when the period of the modulation is comparable to the observation time. This implies that the frequency difference between ions must be very small which explains the insignificance of this mechanism for low mass measurements. At higher mass this requirement becomes a natural occurrence not only because the frequency difference between ions gets smaller but because isotope peaks are increasingly prominent in the mass spectrum. Experimentally, it is at approximately m/z 2000 for a 3.0T magnet that high resolution FTICR spectra are no longer routinely acquired. Therefore, we consider as a model a peptide at mass 2000 with equal abundance M and M+1 ions. The modulation period for ions of m/z 2000 and 2001 is 87 ms, a time which is comparable to a medium resolution FTICR detection event. Presented in Figure 2 are comparison spectra for modulated and unmodulated transients, all acquired for 150 ms. Ion pairs at at two different masses are presented. At lower mass, several modulation periods are completed during the observation time, therefore no line broadening is observed and side bands appear. However, when the masses considered are m/z 2000 and 2001, the period of the modulation (87 ms) is comparable to the observation time (150 ms) and substantial broadening is evident.

Equation 1 predicts an increasing Coulomb force as the number of ions involved increases. It might then be expected that Coulomb line broadening would also increase with increasing ion number. This indeed is true and is shown in Figure 3. If Coulomb effects are not included ions of m/z 2000 and 2001 are nicely resolved using a 150 ms acquisition time. If the Coulomb modulation is included, broadening occurs and worsens as ion number is increased. When 400,000 ions are included in each point charge, coalescence of the two peaks is complete.

It is important to consider situations in which line broadening would not occur. For example, it was shown that broadening does not occur when the modulation period is much shorter than the observation time. This suggests that systems which introduce higher frequency modulations would not suffer from this broadening mechanism. Obviously this occurs at low mass, but it is also a consequence of some high mass ionization processes. Specifically, electrospray ionization, cluster formation, and laser desorption of polymers all generate envelopes of systematically varying mass-to-charge states that would produce higher frequency modulation. It is also possible that the superposition of all of the modulations between ion packets would average to zero (or close to zero), thus eliminating the mechanism.

Competitive Ionization and Reaction Pathways in Laser Desorption/FTICR of Porphyrins

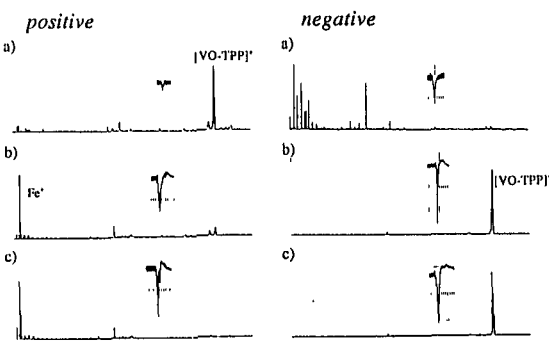
J. Ha and D. A. Laude Jr., Department of Chemistry and Biochemistry
The University of Texas at Austin, Austin, Texas 78712

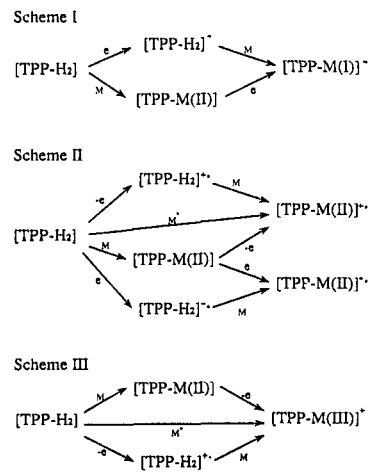
The ionization of tetraphenylporphyrin (TPP-H_2) in a laser desorbed metal ion plasma is examined by FTICR. At lower laser irradiance in the presence of an alkali metal salt, cation-attachment processes are favored [1]. More recently, it was demonstrated that selective metallated porphyrins form from laser desorbed metal cations that subsequently reacted with gas-phase porphine in the trapped ion cell [2]. However, generation of metallated porphyrin anions directly from the metal was not observed, with the explanation given that metal anion precursors are not formed in good yield by LDI. From an analytical perspective, appropriate control of the experiment, including especially sample preparation and laser conditions, is critical to provide the necessary regents to generate the porphyrin product of interest for structure determination or subsequent reactions. Of more general interest is whether reactions occuring in the high energy laser generated plasma are in any way consistent with the results observed for porphyrin chemistry that occurs in solution. This finding is important because it suggests that plasma ignition LDI might be used for generating important bioporphyrin species for subsequent gas phase reaction in the trapped ion cell with detection by FTICR.

Competitive reaction pathways observed to generate abundant molecular ion species include electron detachment, cation attachment, charge exchange, metallation and transmetallation in the positive ion mode and electron capture, metallation, and transmetallation in the negative ion mode. For example, LDI of TPP-H_2 on stainless steel yielded a positive ion spectrum with $[TPP\text{-}H_2]^{+\cdot}$ as the base peak. Metallation products $[TPP\text{-}M]^+$, cation-attachment product $[(TPP\text{-}H_2)+K]^+$, and fragment ions corresponding to the loss of phenyl group from $[TPP\text{-}M]^+$ and the metallation products also were observed. The negative ion spectrum of TPP-H_2 on stainless steel was similar to the positive ion spectrum and included $[TPP\text{-}H_2]^{+\cdot}$ as the base peak, metallation reaction products, and fragment ions. However, notable distinctions from the positive ion spectrum included the absence of cation-attatchment products and a negligible metallation product ion from reaction with Al which was present from sandblasting the probe tip.

The generation of e^- and M^- from the metal substrate by laser plasma ignition is a controlling factor in the spectra which are generated. In general, cation attachment reactions dominate positive ion spectra below the laser irradiance threshold for plasma ignition, although the metallation product

Figure 1





from $[TPP\text{-}H_2]^{+\cdot}$ reaction with the metal atom, M, can be observed. Under plasma ignition conditions, positive ion spectra include $[TPP\text{-}H_2]^{+\cdot}$ formed by charge exchange with M^+ and a strong metallation product. Negative ion products are not observed in the FTICR spectrum when a plasma is not formed. However, under plasma conditions, the intense negative ion spectra that are observed feature $[TPP\text{-}H_2]^{-\cdot}$ which is formed by attachment to thermal electrons. Metallation products are also observed, evidently from reaction of $[TPP\text{-}H_2]^{-\cdot}$ with neutral M. Support for the role plasma ignition plays was obtained from depth profiling studies of $TPP\text{-}H_2$ deposited on a metal substrate. LDI/FTICR spectra obtained from successive firings at TPP-VO on stainless in the same probe position at high laser irradiance are shown in Figure 1. The initial firing on fresh sample does not ignite the metal substrate. Subsequent laser firings on exposed metal do yield a dense plasma of e^- and M^+ that participates in reactions with $TPP\text{-}H_2$.

Metallation reactions involving $TPP\text{-}H_2$ and various laser desorbed metal substrates (M = Al, In, Fe, Cr, Au, Cu, and Sn) were examined. Positive ion metallation products are observed both in the absence of a plasma through reaction of $[TPP\text{-}H_2]^{+\cdot}$ with M, and by a second pathway under plasma ignition conditions through reaction of $TPP\text{-}H_2$ with M^+. In negative ion mode, metallation is only observed under plasma ignition conditions through reaction of $[TPP\text{-}H_2]^{-\cdot}$ with M. A generalized reaction Schemes I-III is developed for $TPP\text{-}H_2$ reactivity with the metals which is consistent with formation of stable metal oxidation states in the metallated porphyrin. Specifically, the metalloporphyrin must exist as either $[(TPP)\text{-}M(II)]^{+\cdot}$ or $[(TPP)\text{-}M(III)]^+$ to be observed in positive ion spectra and $[(TPP)\text{-}M(I)]^-$ or $[(TPP)\text{-}M(II)]^{-\cdot}$ to be observed in negative ion spectra. Thus for example, Al and Au with stable III states only form positive ion metallation products. Table 1 summarizes metallation results for all metals and also indicates the significance of the plasma formed on second and later laser firings to the products observed.

Indium is distinguished from the other metals by the observation of additional products, $[(TPP\text{-}H_2)\text{-}In]^+$ and $[(TPP\text{-}H_2)\text{-}In]^-$ which may be intermediates in the metallation reaction and $[TPP\text{-}2In]^-$, a dimetallation product. LDI of $TPP\text{-}H_2$ on a stainless steel substrate yielded $[TPP\text{-}H_2]^{+\cdot}$ or $[TPP\text{-}H_2]^{-\cdot}$ which were isolated and allowed to react with the gas phase In neutral. The indium attachment product and the metallation product increased with time but no In^+ was formed. It is interesting that indium neutral undergoes a complexation reaction rather than charge transfer even though In (IP=5.8eV) has a lower ionization potential than $TPP\text{-}H_2$.

ADVANCES IN MULTIELECTRODE OPEN TRAPPED ION CELL DESIGNS FOR FTICR

*V. H. Vartanian, S. C. Beu, D. A. Laude, Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX, 78712.

Recently we described a new electrode configuration for the trapped ion cell of a Fourier transform ion cyclotron resonance spectrometer that was distinguished by the collinear extension of the trapping electrodes in the plane of excite and detect electrodes (1). This open cell design differed from previous trapped ion cells designs for FTICR that positioned the trap plates perpendicular to the other trap plates. With respect to trapping the ions, the use of open trapping electrodes is similar in concept to previous efforts by physicists to confine electrons and antiprotons for high precision measurements. Practical advantages include increased conductance, the elimination of charging and contamination on trap plates, and both simplified and more efficient introduction of charged particle beams. This latter factor is important for external source applications. The increased flexibility of the open cell derives from the potential to use any combination of collinear electrode segments as trapping, detection, and excite plates and thereby increase the dimension or number of trapped ion cells without physical alteration of the electrode assembly. With appropriate modification of electrical circuitry, these electrodes could simultaneously serve more than one function, with the potential for significant improvement in cell performance (1). For example, the excitation electrodes could be capacitively coupled to trap plates, thereby creating an axially homogeneous excite field over the entire length of the trapping potential well. Not only would the axial component of the excite field effectively vanish with consequent elimination of z-axis ejection during excitation, but with the opportunity to now use very low trap potentials, the deleterious effects of the radial trapping electric field would also diminish. To be presented are results from the successful assembly of a capacitively coupled open trapped ion cell in which the excite pulse is also applied to the trap electrode segments extending from the two central excite electrodes.

Experimental. Two capacitively coupled open cells one approxiating a cubic cell and one approximating an elongated cell of aspect ratio two were evaluated for this work. The aspect ratio for the open cell is defined as the distance between trapping potential maxima (located near the center of the trapping electrode assemblies) divided by the width of the cell. Thus for example, an aspect ratio of two was achieved here by assembling twelve 5 cm x 5 cm aluminum plates in an open orthorhombic array. The four interior plates served traditional functions with each of two opposing electrode pairs used for excitation or detection. The two groups of four exterior plates were used as trapping electrodes. In addition, to accomplish the distributed excite, the trap plates extending from either side of the excite plates were capacitively coupled, as shown in Figure 1, with a circuit that included 1 kΩ blocking resistors (part # MS220, Caddock Electronics, Riverside CA) and 0.10 μF coupling capacitors (part # PHI C41C104K, T.T.I., Fort Worth, TX). The circuit elements were mounted at the cell to minimize the length of shielded radiofrequency leads and thus the total reactive load on the excitation amplifier. To maximize the generality of the open cell design, a support flange assembly was constructed that allows the easy modification of electrodes.

Open Cell SIMION. SIMION calculations were performed for the capacitively coupled open cell and compared to an uncoupled open cell and to a closed elongated cell. Shown in Figure 2 are comparison isopotential contours with ±100 V applied to excite plates of an uncoupled elongated open cell and a capacitively-coupled elongated open cell. For closed cells and the uncoupled open cell, most of the excite field lines must ultimately terminate at the trapping electrodes positioned adjacent to the excite plates. This necessarily introduces field curvature and thus an axial component to the excite field. In contrast, for the coupled open cell the excite is also applied to the trap plates and a uniform collinear series of isopotential contours is observed to extend well beyond the trap potential maxima located near the center of the trapping electrodes. In effect, with respect to the axial dimension of the cell, the excitation field conforms to the infinite electrode approximation of an ideal trapped-ion cell.

Axial Ejection Studies. Experimental data to verify the predictions based upon the SIMION calculations were conducted. For axial ejection studies, the trap potential was set to 0.5 V for various cells including the capacitively-coupled open cell, the identical open cell without the distributed excite, and a closed orthorhombic cell of 5 x 5x 10 cm dimension. Perfluorotributylamine (PFTBA) was introduced through a precision leak valve to 5 x 10^{-8} torr. Electron beam currents of a few μA and beam periods of a few ms were selected to generate ion populations well below the space charge limit of the cell. A linear frequency sweep at 3200 Hz/μs over a

FIGURE 1

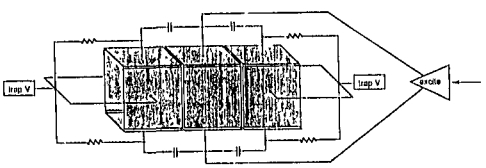

FIGURE 2

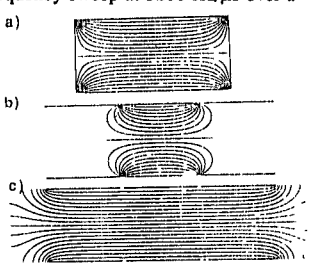

full 2.667 MHz bandwidth was used to excite the ions. In successive experiments, excitation power was varied over a range from 110 V_{pp} at 0 dB attenuation to 20 V_{pp} at 15 dB attenuation. Excitation was followed by broadband detection with a 2.667 MHz bandwidth and acquisition of 16 K data points. Peak intensities were extracted from each spectrum for ions at m/z 69, 131, 219, 264, 414, and 502.

Resulting excite profiles for the three cells are presented in Figure 3, in the form of absolute abundances of PFTBA ions as excitation energy is increased. Presented in Figure 3a is the result typical of broadband excitation in closed trapped ion cells, in this case for a 1.0 V trapping potential in an elongated cell at 3.0T magnetic field strength. Approximately correct relative abundances are observed only at very low excite energies that generate spectra with significantly reduced signal-to-noise. At higher excite voltages, severe axial ejection is evident from the selective ejection of low mass ions. Presented in Figure 3b are abundance profiles for the uncoupled open cell at an effective trap potential of 0.4 V. At these low trap potentials the closed cell used to acquire the data in Figure 3a was incapable of generating spectra with m/z 69 as the base peak at any excite level that generated detectable spectra. In contrast, relative abundances for the uncoupled open cell achieve fairly good ratios at excite levels below 50% of optimum levels. Presented in Figure 3c are PFTBA ion abundance profiles acquired at 0.4 V effective trapping potential with the capacitively coupled open cell. Near ideal abundance ratios are observed with proportional increases in absolute mass abundance observed over the entire range of excite levels. The rapid truncation of the signal beyond about 80 V excitation energy corresponds to the expected mass-independent radial ejection of all ions. Profiles exhibiting this behavior are not observed with conventional closed cells unless trap potentials are increased and efforts are taken to collapse the ion population to the bottom of the potential well.

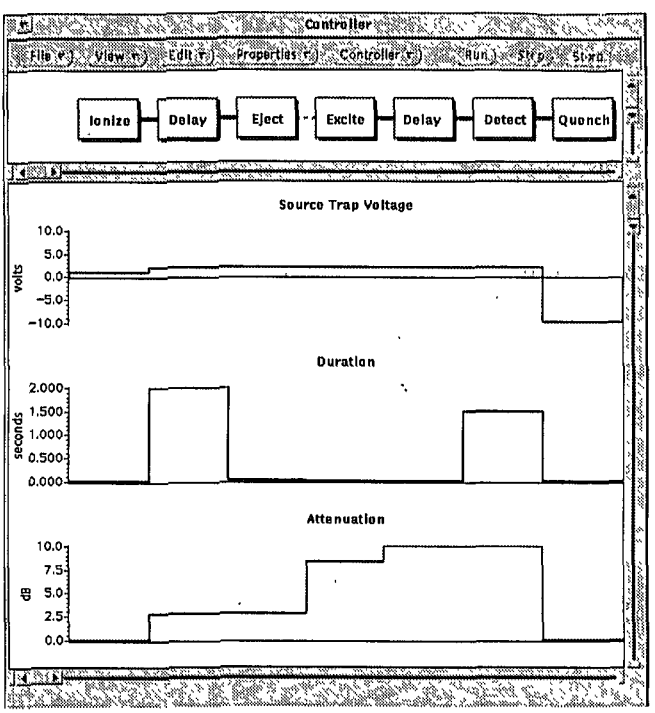
New Method for Creating, Describing and Modifying FT/MS Instrument Control Sequences.

*Michael Dunk; EXTREL FTMS, Inc., 6416 Schroeder Road, Madison, WI 53711-2424

Control sequences for FT/MS instruments are typically described with pulses by using a timing diagram. The width of the pulses show the relative duration of each experimental event. Complex experimental sequences are difficult to describe by using this notation when multiple parameters change in the same pulse, or when experiments consist of more than one control sequence. The graphical representation in the new software describes FT/MS instrument control sequences by using time-slice objects. A time-slice in a control sequence is a period of time when all experimental parameters are constant. The graphical description of a sequence consists of time-slice objects equally spaced across the top of the display. Individual parameters important to the experiment are plotted below, with all transitions in parameter values occurring at time-slice boundaries.

This graphical representation is used when creating experimental sequences, when modifying parameters to tune the instrument, and can be printed in PostScript® for publication. All parameters and time-slice objects can be manipulated by using a mouse or through the command line. Any set of parameters can be assigned to a variable, allowing control of the entire set. Common sections of control sequences, such as quenches or SWIFT™ excite events can be grouped and stored separately as templates. The sequence description and templates are stored as text, for easy viewing and printing. New experimental methods include multiple detects, linked sequences, and conditional repeating of sequences (do loops). User created software modules can be executed to perform conditional analysis, the results used to modify or optimize control parameters.

An instrument control script containing two sequences and command script that varies the excite attenuation was described to demonstrate the flexibility of the new method.



Very-Large-Memory Stored Waveform Inverse Fourier Transform Excitation

*Richard Hein, and Zhenmin Liang, EXTREL FTMS
6416 Schroeder Road Madison, WI 53711-2424

Introduction

Memory-based waveform generation for ion excitation in Fourier Transform Mass Spectrometry (FT/MS®) allows complex pre-experiment excite waveform tailoring, which leads to savings of analysis time and more flexible experiments. The traditional FT trade-off of time versus resolution has limited applications to either low-resolution wide-mass range, or high-resolution narrow-mass range. The practical considerations of how much time is spent on waveform calculation and the available size of waveform memory also limits applications requiring multiple, serial waveforms.

Although multiple, serial waveform experiments have achieved ultra-high resolution selectivity, each waveform's attenuation requirement has to be determined empirically. This is especially true of mixed SWIFT and frequency swept (chirp) excites, as the ending phase of the chirp is not controlled and subsequent excitation can either add or subtract to the ion radius.

Hardware improvements have addressed 1) decreasing the SWIFT calculation time, and 2) increasing SWIFT waveform memory.

1.0 Calculation Improvements.

The Odyssey FT/MS Data Stations use limited instruction set (SPARC) processors to attain high computation speeds. A scaled architecture provides for improved processing throughput with increased computing resources (especially program and data memory). Typical Data Station configurations calculate large waveforms (512k words, to 1 megaword) in one twentieth the time of previous processors. This has the practical implication of allowing for rapid iterations between tailoring the desired waveforms and application of the waveform to observe ions.

2.0 Extended SWIFT Waveform Memory

Advances in the production of random access memories has made available denser and faster devices. EXTREL's SWIFT Module has been developed to allow growth with these semiconductor advances. The basic system included 1,048,576 12-bit waveform words. An Extended Memory Option increases this by 3 megawords. By using a programmable logic device (PLD) addressing scheme, the address space can flexibly adapt to newer, higher density memories for an extension to 8 megaword memories. With this addressing scheme in the motherboards, as well as the Extended Memory board, up to 16 megaword may be addressed.

3.0 Experimental

A 512k word SWIFT waveform corresponding to a 0.2 Dalton wide notch to isolate the m/z 192 species of bromochlorobenzene was generated and placed in the "front-end" of the experiment sequence. A wide-mass SWIFT was used to excite ion for detection. Both wide mass and heterodyne types of detection were used ("rear-end").Typical broadband spectra are shown in Figure 1a. Tuning was done with 10 us ionization events and a 10 uA emission current. The

calculated excitation power attenuation requirement was 16.5 dB. Under these high emission current conditions, the signal tuned throughout the 16- 22 dB range. Then the ionization event was reduced to 3 ms and 2 uA. A series of data collects showed isolation of the $[C_6 H_4 Cl^{37} Br^{79}]^+$ from $[C_6 H_4 Cl^{35} Br^{81}]^+$ throughout the 17 to 20.5 dB range of excitation power attenuation. Figures 1b and1c shows the isolation and expanded region of a spectrum taken at 18 dB attenuation.

In order to examine whether even larger SWIFT waveforms were effective, the 0. 2 Dalton notch isolation experiment was duplicated with a 1 megaword waveform (Table 1), and similar results were obtained. The extent of a long (0.25 second) excitation event had only a minor affect on the signal. Isolation of the two peaks requires a front-end resolving power of approximately 250,000, or 1 second of excitation at m/z 192 on a 3 Tesla system, which could not be attained without heterodyne-SWIFT. However, direct mode isolations in the 10's of thousands can be easily applied to the "front-end" of an analytical problem.

4.0 Conclusions

Large waveform Stored Waveform Inverse Fourier Transform techniques adds to the spectrometrist's capabilities by affording front end high-resolution excitation capabilities over wide mass ranges. More predictable ion radii and energies result from the consolidation of several sequential excitations into one. Improved tuning information provides rapid isolation and analysis on ion species of very close mass-to-charge ratios.Through processing speed enhancements, there can be rapid interaction between the set-up and analysis stages of an experiment.

A Comparison of Methods For Generating SWIFT™ Waveforms

*R. Kent Wenger, Zhenmin Liang, and Joseph Campana, EXTREL FTMS, Inc., Madison, WI 53711

Introduction

Stored Waveform Inverse Fourier Transform (SWIFT) excitation provides an important advance in Fourier Transform Mass Spectrometry (FT/MS®) by allowing the user to specify an (arbitrarily complex) ideal mass spectrum to be used for excitation, rather than a chirp or single frequency.

In theory, the translation from mass spectrum to time-domain waveform can simply be done by a mass-to-frequency conversion (mass and frequency are approximately inversely proportional) and an inverse Fourier transform. However, practical considerations make it necessary to phase scramble (to reduce the peak amplitude of the waveform) and apodize or low-pass filter (to reduce Gibbs oscillations at the corners of spectral bands) in the process of converting from the frequency domain to the time domain. The methods used for each part of the generation procedure interact with each other, producing complex results.

Methods for generating SWIFT™ Waveforms are evaluated by their effect on the measured spectra of hexane The methods that are compared are the standard (Goodman/Hanna) method[1], the Ohio State method[2], and the Guan method[3].

Methods

The methods of generating SWIFT Waveforms are studied by using various SWIFT Waveforms to excite ions produced by the electron ionization of hexane. The resulting spectra are compared. The only difference in experimental conditions between spectra is the SWIFT Waveform used to excite the ions. All spectra are accumulations of 50 scans (each scan taking 16.4 milliseconds).

The voltages of the SWIFT Waveforms are normalized to 104 to 106 volts peak-to-peak so that no method is favored or handicapped by a difference in peak voltage reduction. The only exception to this is data is collected with a lower voltage SWIFT Waveform to specifically study the effect of a greater amount of phase scrambling on the spectrum.

Many of the other basic properties of the SWIFT Waveform are the same for all of the data. For example, all of the SWIFT Waveforms have the same DAC rate, resolving power, and number of points, and they all use the same Requested Excite Spectrum (mass excitation bands)

The default condition for SWIFT Waveforms (when the phase coefficient is positive) is that the highest frequencies are excited first in the waveform and the lower frequencies are excited last.

Results

FIGURE 1. SWIFT with notches, standard method, Blackman-Harris 3 term apodization.

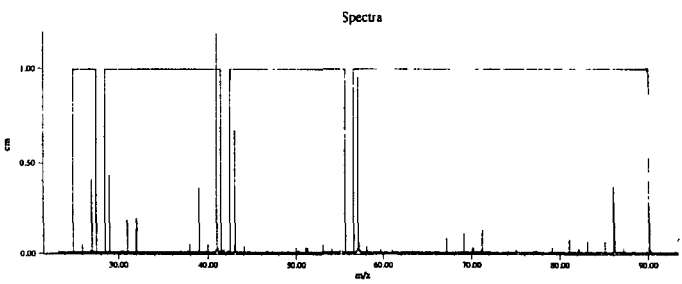

FIGURE 2 SWIFT with notches, standard method, Blackman-Harris 3 term apodization, reverse sweep.

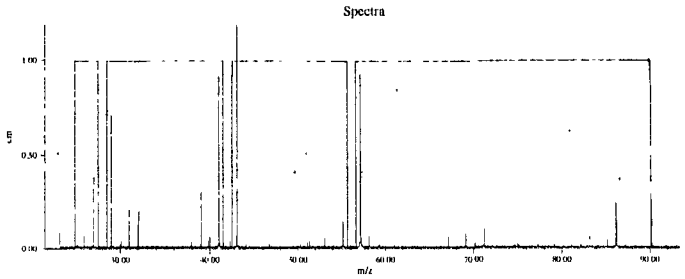

FIGURE 3. SWIFT with notches, Guan method, 2 filter passes, averaging 3 points

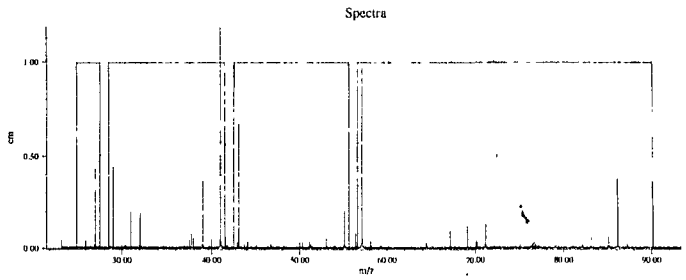

Conclusions

- Of all factors considered, reversing the frequency sweep direction has the greatest effect on the peak heights in the sample spectrum. Ironically, this has no effect on the Actual Excite Spectrum. (See FIGURE 1 and FIGURE 2.)
- The Guan method (filtering the frequency spectrum) performs similarly to apodization as evaluated by both the Actual Excite Spectrum and the sample spectrum. It has the advantage of being more easily configured to vary the amount of filtering. (See FIGURE 3)
- Changing the amount of phase scrambling also has some effect on the sample spectrum.
- The Ohio State method also produces slightly different results than the standard method.
- The suitability of various methods of generating SWIFT Waveforms cannot be evaluated simply by examining the Actual Excite Spectra. The effect of reversing the sweep direction shows that the actual behavior of the ions in the cell is more complex than simply parking at the orbit corresponding to the amount of energy produced by the waveform at their resonant frequency

ACCURATE MASS MEASUREMENT IN FTMS WITHOUT CALIBRATION STANDARD

Zhenmin Liang
EXTREL FTMS (*now part of Millipore*), 6416 Schroeder Road, Madison, WI 53711-2424

Introduction

In Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT/MS), accurate mass measurements are routinely performed. Mass calibration with calibration standard (internal calibration) provides a mass accuracy in the low (2-3) ppm range for real world samples. The stability of the magnetic field of a super-conducting magnet provides a foundation for obtaining accurate mass information, without the use of a calibration standard in acquiring the mass spectrum. Mass accuracy by using a calibration table obtained separately (external calibration) can be as accurate as that by internal calibration. There is, however, an obstacle that sometimes limits the accuracy of mass measurement, namely, the effects of trapping electric field and space-charge. Meek et. al. developed a method that adjusts the electric field term in the calibration equation based on a known ion peak to correct these effects [1]. In some cases, a known peak may not be present in the mass spectrum. However, the mass difference between ions may be more readily available. McLafferty and Williams has proposed that mass differences may be used for mass calibration [2]. Based on this idea, some routines are designed to perform mass calibration by using mass differences.

In the most widely use mass calibration procedure in FT/MS, Constant a and Constant b in Equation 1 are determined by fitting the equation with some ion peaks of known masses.

$$m/z = \frac{a}{f} + \frac{b}{f^2} \qquad (1)$$

A modified equation can be derived from Equation 1 to be used with known mass differences, as shown in Equation 2.

$$\frac{m_2 - m_1}{z} = a\,\frac{f_1 - f_2}{f_1 f_2} + b\,\frac{f_1^2 - f_2^2}{f_1^2 f_2^2} \qquad (2)$$

where m_2 and m_1 are the masses of two ions with known $m_2 - m_1$. f_2 and f_1 are their corresponding cyclotron frequencies. Mass calibration in FTMS can now be accomplished by using Equation 2 or a combination of Equations 1 and 2.

Results and Discussion

Mass calibration based on Equation 2 is studied by using a mass spectrum of PFTBA. The mass spectrum also contained a few background ion peaks. As an example, four mass pairs were used to test this procedure, which include (502, 414), (264, 219), (100,69), and (131,100). The results are shown in Table 1.

As mentioned above, the magnetic field of a super conducting magnet FT/MS system is stable over a long period of time. Constant a in Equations 1 and 2 does not change under typical experiment conditions over a period of months. Therefore, a known value of mass difference (between m/z 502 and 414) can be used in Equation 2 to adjust the electric field term (Constant b). The results based on this method are shown in Table 2.

Finally, when a spectrum contains a known peak and a pair of ions of known mass difference, calibration can be performed by using the two data points. This is demonstrated by using the m/z 69 peak and the mass difference between m/z 502 and 414, and combining Equations 1 and 2. The results are shown in Table 3.

1 Ion Cloud Radial Expansion Due To Resonant Coupling For Anharmonic Trapping Wells. *C. L. Holliman, D. L. Rempel, and M. L. Gross,* Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588-0304.

Today, ions with *m/z* on the order of 500,000 have been matrix assisted laser desorbed [1] but not into an FT mass spectrometer. The largest ion observed in FTMS is an order of magnitude smaller at m/z 31,830 [2] and does not represent the upper mass limit of FTMS.

The use of positively charged trapping plates to confine ions in the axial direction of an FTMS cell, results in a radial electric field. This radial field produces an additional outward force on the ion and creates an axial position dependent shift in the cyclotron frequency as well as a reduction in the critical mass of the cell. Two routes may by taken to reduce or eliminate the adverse effects of the radial field. The first is to produce a radial electric field which is invariant with the ion's axial position, and is realized with a quadrupolar potential or harmonic well. The second is to reduce the trapping field at the center of the cell thereby reducing the radial electric field, and would be ultimately realized with a particle-in-a-box potential [3] or anharmonic, well.

Mass dependent parametric resonances involving the coupling of the ion's radial and *z* motions result in radial expansion of the ion cloud in the nearly harmonic cubic cell. A parametric resonance exists when the frequency of the natural radial oscillation is equal to a *z*-mode harmonic which is $2n$ times the fundamental *z*-mode oscillation. There is a transfer of energy from the magnetron mode to the cyclotron mode, resulting in an increase in the amplitude of *both* modes. As the well becomes more anharmonic, the coupling between the *z* and radial modes should become stronger. In these traps, wider and stronger resonances are expected to occur.

The mass ranges and severity of these resonances were predicted by numerical calculations and verified by scaling experiments [4] which showed a corresponding loss of signal over the same mass ranges. Here a similar set of calculations are used to predict the location and severity of parametric resonances for a series of anharmonic wells that approximate a particle-in-a-box and an elongated trap.

Particle-in-a-box potentials were modeled with a cubic trap of size $a = 0.0254$m consisting of trapping plates split into an outer segment at ground and a disc electrode at 1 V [5]. As the relative diameter of the disc becomes smaller, the well becomes more anharmonic. A variable order multistep predictor-corrector method was used to numerically integrate the combined system of optic axis and transfer coefficient differential equations. The maximum radius of the ion cloud for the time 50ms after ionization, but before excitation, was calculated to first order for an of ensemble of ions created from a neutral population at 300 K (such as possible with EI) and matrix assisted laser desorption at several A_z values.

Numerical results are shown for relative disc diameters of 50% and 3.125%. The insets show the polynomial fit (line) and the trap potential series solution (circles) and demonstrates the disc in cube trap configuration can be used to approximate particle-in-a-box trapping wells. As the potential becomes increasingly anharmonic, there is a dramatic increase in the complexity of mass discriminating behavior. The assumption that if electric field inhomogenaities are confined to small regions of the cell, they will play a small role in ion behavior may not be true. For example, the 3.125% disc model predicts resonant coupling over an extensive mass range even for thermal ions. These resonance calculations suggest that the particle-in-a-box ideal may not be an appropriate goal for future cell designs.

In the elongated trap, resonance coupling is mot as severe, although longer z-mode times require longer trapping times in order to obtain definitive cyclotron frequencies. Thus there is more time for radial expansion to occur.

It is evident from these calculations that the development of ion "cooling" strategies are important for the realization of higher mass performance in anharmonic wells. The resonance behavior shown here does not occur in a quadrupolar potential well. This fact recommends the quadrupolar well as an appropriate ideal for future trap designs.

ION CLOUD MANIPULATION USING THE RF-ONLY MODE AS AN IMPROVEMENT FOR HIGH MASS DETECTION IN FTMS.

Cliffton B. Jacoby, D.L. Rempel, C.L. Holliman, and M.L. Gross, Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, Nebraska 68588-0304.

The tools are limited for the reduction of radial ion cloud distribution size in Fourier transform mass spectrometry (FTMS). Marshal et al. has shown that if the state of the ion cloud has not been severely degraded or dephased, it is possible to reduce the cyclotron radius of the ion cloud by application of a resonant excitation waveform that is 180° out of phase with respect to the ion cloud [1]. While Brown and Gabrielse have used inhomogeneous excitation fields at the lower magnetron side band frequency to reduce the cloud's radial size by "cooling" the magnetron motion [2].

Ionization methods such as matrix assisted laser desorption (MALD), electrospray ionization (ESI), and fast atom or ion bombardment (FAB or SIMS) produce ions with high kinetic energy distributions. The use of deeper wells (> 10 v) to trap energetic ions results in poor performance due to larger electric field inhomogeneities.

Smalley and Russell have shown translational dampening via non-conservative methods by cooling the ions energies via "waiting room" type experiments [3,4]. This technique allows for the use of more moderate trapping wells which improves detection performance.

Here, the incorporation of a temporary dynamical trapping mode event (RF-only-mode event) into the FTMS sequence to shape the ion cloud to aid in its subsequent excitation and detection is demonstrated. It is shown that the RF-only-mode event focuses a broadly distributed ion cloud to the z-axis. When combined with trap electric field compensation, the use of the RF-only-mode substantially improves the detection of ions that are initially located away from the z-axis.

The RF-only-mode in the FTMS sequence is based on the work of Bonner, March and Durup with the quadrupolar ion storage device, or QUISTOR [5]. In the above work it was shown that under higher pressures, collisions with helium neutral molecules will focus ions toward the center of the trap.

The normal trap plates of a 0.0254-m cubic trap at 1.2 tesla have been replaced with a set of segmented trap plates consisting of a disc of 0.0127-m diameter separated by approximately 0.000254-m from the outer segment. The two segments of each trap plate may be held at the same potential, 1.0 volt, for normal FTMS operations, or held at different potentials as in the case of a compensated trap, 1.0 volt on the disks and 1.7 volts on the outer segments. These segmented trap plates also allow us to quench from the trap, by application of a potential of -1.0 volt on the outer segment of the plates, any portion of the ion cloud that has been excited to a radius greater than 0.00635-m. The RF-only-mode event was implemented by modulating the segmented trap plates with a 800 V, 1.3 MHz sinewave for 4 seconds during the delay interval of the sequence. During the first second in which the RF event was active, the cell was pressurized with helium to approximately $3X10^{-3}$ torr, through a pulsed Varian variable leak valve model 951-5100. A 3 second delay was implemented after the RF event to complete the removal of the neutral helium.

Benzene at a pressure of approximately $1.2X10^{-7}$ T was ionized, along the z-axis, by a 20-eV electron beam of 100nA for a period of approximately 15-ms. A 2 second delay after ionization was used in all experiments, to allow the z-mode amplitudes to dampen, before any additional operations in the sequence.

The cross section of the ion cloud after the rf-only-mode event was obtained by applying a magnetron excitation quenching the outer segment of the cell and then detecting those ions which have a magnetron radius less than or equal to the radius of the trap disk segment. This signal is indicative of t
he changes in ion number as the unexcited magnetron phase and amplitude distribution is incrementally translated beyond the radius of the disk was obtained. A cloud with a small magnetron radius distribution is expected to produce a level, high amplitude complex area until a relatively sharp decrease to noise occurs. A cloud with a broad distribution is expected to produce a more gradual decrease in complex area starting at shorter and persisting for longer magnetron excitation times when compared to the results for a small cloud.

The extent of focussing by the RF-only-mode can be seen in Figure 1. After ion formation, the cloud was expanded to approximately 50% of the cell size, to mimic a diffuse cloud, via magnetron mode excitation. The RF-only-mode was then applied. In the cross section curve without the RF event, the initial signal is low, as a result of the majority of the ion cloud having a magnetron radius beyond the radius of the disc and being quenched from the cell. At longer magnetron excitation times after the RF-only-mode event, it is apparent that a portion of the ion cloud is brought within the confines of the disk electrode, and therefore not removed from the cell. However, at longer excitation times

of 4.625ms, the ion cloud in its entirety, is translated to a position were it was almost completely quenched from the cell. The RF data in this curve, however, shows the effect of the ion cloud being focussed to the center of the cell. This is obvious in the level complex area at short excitation times, followed by a comparatively rapid decline in complex area as the ion cloud is translated beyond the radius of the disk at 2.125ms.

In Figure 2 we show a set of four spectra obtained with an ionization event of 100nA for 15ms under the same conditions except whether or not compensation and the RF-only-mode is used. In all cases, the initial ion cloud was expanded to approximately 50% of the cell size to mimic a radially diffuse cloud. All spectra show 1.25kHz region of the mass range for the molecular ion of benzene at m/z 78. Spectra A, in which no compensation or RF events were used, shows no detectable signal. Spectra B shows that with the use of only the RF event, the ion cloud is focussed to yield a marginal signal with a signal to noise ratio of about 2:1. In spectra C, with the use of compensation only, we again see no detectable signal. The use of the RF event and compensation are combined in spectra D. Here we see a signal that has been successfully focussed via the RF event, and detected under compensated trapping conditions, to yield a peak with a S/N of about 18, and a resolution of 32.5K (FWHH).

In this work, we have demonstrated a method that reduces the radial size of an ion cloud. Cross section curves indicate that the ion cloud shape after the RF event is independent of the shape prior to the RF event. We propose that with this method it would be possible to tune the instrument with an ion cloud produced by electron impact and then analyze ions produced by MALD without needing to change the excitation and detection parameters, thus standardizing the operation of the instrument. We also propose that with the use of the RF-only-mode, the high kinetic energy of MALD or similarly produced ions can be removed by collisions with pulsed helium within the interior of the trap, thus providing a much improved trapping efficiency.

Laser microprobe mass spectrometry (LMMS) employs the interaction of a focused UV beam with solids to produce ions from a micro-volume in the μm^3 range. Instruments using time-of-flight (TOF) MS have shown that LMMS represents an excellent tool for the qualitative investigation of organic and inorganic components in surface layers and micro-objects. In practice, local analysis involves heterogeneous samples. Hence, it is essential to maximize the information obtained from each single laser pulse.

In this respect the FTMS technology with its inherent high mass resolution and excellent mass accuracy offers promising perspectives. The pulsed nature of FT-ICR allows the entire mass spectrum resulting from a single laser pulse to be recorded.

The use of an external ion source allows an optimal design of the laser optics and leads to efficient sample handling. In this contribution we report the first adaptation of a laser microprobe external ion source to a commercially available FT mass spectrometer.

A schematic of the experimental setup is shown on the figure below. A quadrupled Nd:YAG laser is used with 266 nm wavelength, 10 mJ/pulse and 10 ns pulse length. The UV light is directed using a set of five anti-reflection coated 90° quartz prisms (P_i). The polarized UV beam is first attenuated using a combination of a rotatable halfwave plate (HWP) and a fixed polarizer (POL). The beam divergence is reduced by a (x2.5) beam expander (EXP) and the final beam diameter (6mm) is defined by the diaphragm (DIA). The focusing lens (L) is mounted inside the vacuum chamber. For ease of operation a He/Ne pilot laser is used. The two beams are superimposed using a quartz plate (BC). The visible spot of the He/Ne laser on the target indicates the impact point of the UV laser beam.

With the current setup a spatial resolution of better than 5 microns can be achieved. The sample size is 20x20mm. The sample is mounted on a XYZ manipulator with a positioning resolution of 2 microns. The sample is exchanged conveniently through a vacuum lock without venting the source chamber. The sample can be observed through two independent microscopes: A high magnification microscope coupled to a CCD camera and a high resolution monitor is used to adjust the sample position in the plane of the laser focus. A low magnification binocular is used for coarse positioning of the sample.

Ions can be created by laser only with or without electron impact (EI) post ionization. The ions are extracted from the source, guided through the restrictions of the differentially pumped vacuum system and finally injected into the ICR trapped-ion cell through an electrostatic ion optics. Once the ions are trapped in the cell the experiment proceeds according to the standard procedures of the FT-ICR technology.

Our research focuses on the analytical methodology with the optimization of the instrumental parameters and laser irradiation conditions in relation to the sample micro-morphology. A point of major interest concerns the use of EI. EI post-ionization of laser desorbed neutrals offers an significantly increased area of application of the method. The comparison of the results from the FTMS instrument with the one from the TOF microprobe yields interesting information about the ion formation under focused laser irradiation.

An External Source for Fourier Transform Mass Spectrometry

Carl F. Ijames and Sanford P Markey

Section on Analytical Biochemistry Laboratory of Clinical Science,
National Institute of Mental Health, Bethesda, MD 20892

FTMS is well known as a high resolution, high mass range technique, potentially well suited for the analysis of large biomolecules. However, the best performance is achieved at the lowest pressures, making it difficult to interface high pressure sources such as electrospray ionization to FTMS. The location of the trapped ion cell in the center of a high field superconducting magnet further complicates access and restricts pumping speeds To circumvent these difficulties, several workers have constructed sources external to the magnetic field. The ions are guided through the fringing field of the magnet to the cell, where they are trapped and analyzed. The most popular technique for this ion guide is to use a radio-frequency only quadrupole, although electrostatic lenses have also been employed. We have designed and constructed a general purpose external source which incorporates electrostatic lenses to transport the ions into the magnetic field. The lens system includes a gap sufficiently large to allow insertion of a gate valve to isolate the external source chamber from the FTMS vacuum system. As the external source chamber is interfaced with what is traditionally the lower pressure "analyzer" cell region of the commercial dual cell FTMS, conventional operation and probe access to the other ("source") cell region remain unaffected. Thus, full laser desorption and in-cell electron impact ionization capabilities are retained.

The present transport optics conduct approximately 10 per cent of the ions produced in the external source through the cells, and provide a pressure ratio of ~1400 and ~500 between the external source chamber and the first cell region, and between the first and second cell regions, respectively. This performance was evaluated by thermally generated K^+ ions, produced from a potassium aluminosilicate emitter mounted in the external source chamber. Conventional gated trapping, where the front trap plate is briefly grounded to admit a pulse of ions which are then trapped, can be performed in either cell, with first cell signals approximately 5 per cent higher than in the second cell. Accumulated trapping, performed in this case by placing 0.9 V across the transmitter plates, was also evaluated.[1] In the first cell, accumulation times of 0.5 s produced signals equal to those from gated trapping, while longer accumulation times produced proportionally greater signals. However, second cell accumulated trapping produced signals 30 times less intense. Matching the trap potential to the kinetic energy distribution of the ion beam is critical in accumulated trapping. Using a trap potential only 0.5 volt above or below the optimum reduced the signal by a factor of three.

Next, the potassium emitter was replaced by a single stage Whitehouse-style electrospray interface. Currents of up to 15 pA were detected at the external source chamber conductance limit, but less than 1 pA was detected at the conductance limit dividing the two cells, and no current (less than 0.1 pA) was detected at the collector after the second cell. Using accumulated trapping, electrospray ionization spectra were recorded in the first cell for diisopropylethylamine and polyethylene glycol 1000 (Figure 1), both at a concentration of 10^{-4} M in methanol. The mass resolution in the PEG 1000 spectrum was limited by the high pressure, 5.6×10^{-7} torr, to 2,500 full-width half height at m/z 516. This spectrum is the result of co-adding 25 30 s accumulations. By using a 45 s accumulation time and manually closing the gate valve after the first 30 s the pressure was reduced to 6×10^{-8} torr and the resolution increased to 14,000 FWHH (8 scans co-added; Figure 2). This resolution is sufficient to clearly resolve the ^{13}C isotopes and thus permit direct determination of charge state. Note that the peaks are spaced at 0.5 m/z for the +2 ions and 1.0 m/z for the +1 ions.

Future efforts will be directed at improving the sensitivity of the ESI/FTMS system by improving the ion-optical design of the gate valve/injection lens assembly and incorporating a two stage electrospray interface to increase the available current.

The Development of a Novel Electrospray Ionization-Fourier Transform Mass Spectrometer for the Investigation of Large Biomolecules

*B.E. Winger, J.A. Loo, H.R. Udseth, A.L. Rockwood and R.D. Smith, Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352.

We report here the development of a novel, 7 Tesla, electrospray ionization-Fourier transform mass spectrometer (ESI-FTMS) whose characteristics will allow for fundamental investigations of large multiply-charged biomolecules at ultrahigh vacuum. Figure 1 is an illustration of the instrument layout. Ions are generated in an external electrospray ionization source which is mounted on a translatable bellows stage, and sampled into the FT mass spectrometer. Ion injection into the ICR cell is accomplished using the method developed by McIver et al., which involves the use of a ~1-meter RF-only quadrupole to guide the ion beam into the magnetic field. Several design features have been implemented to eliminate the deleterious effects due to the intense molecular beam formed via atmospheric pressure sampling. One of these is the development of a set of mechanical shutters which are used to isolate regions of lower pressure except during the ion injection step. The shutters are operated via the use of a miniature solenoid located inside the vacuum system. This allows molecular beams formed in the higher pressure region to be blocked, substantially reducing the operating pressure in the cell. In addition, the ESI source is positioned off-axis at a 45° angle. An RF-only quadrupole, whose geometry results in deflection of the ion trajectory, serves to further reduce the gas load originating from the intense molecular beam.

A total of 6 differential pumping stages are used in order to attain a base pressure in the analyzer cell of less than 10^{-10} torr. The analyzer region pumping system consists of turbomolecular and titanium sublimation pumps in combination with a custom cryopanel system. The cryopanel system consists of two concentric tubes, one of which is a radiative heat shield and the other acting as the cryopump, operating at 15-20 K. Both tubes are attached to a high capacity, closed cycle helium refrigerator. .

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under contract DE-AC06-76RLO 1830.

High-Resolution Tandem Mass Spectrometry of Large Molecules with a 6.2T Fourier-Transform Mass Spectromety

John P. Quinn, Michael W. Senko, Francis M. Wampler, Yueer Shi, Mei-Yi Zhang, Steven C. Beu, and Fred W. McLafferty

Fourier-transform mass spectrometry (FTMS) has useful features for large biomolecule analysis: ultrahigh resolution (resolving powers of 10^5-10^6), high mass-measuring accuracy, non-destructive ion detection, and simultaneous ion detection over a wide m/z range (1). The coupling of an electrospray ionization (ESI) source to FTMS permits the formation and introduction of multiply-charged biomolecular ions up to more than 10^5 Da (2), whose peaks appear in the more convenient m/z range of 500-2000. The trapping of selected ions in the FTMS cell provides a unique capability for various dissociation modes in tandem mass spectrometry (MS/MS) (3), and ion-molecule reactions (4) that can probe the gas phase structure and chemistry of biomolecules.

A number of improvements have been made to our earlier 2.8 Tesla FTMS (1). The magnetic field strength has been increased to 6.2 T and two new cryogenic pumps (each 1500 L sec-1) have been installed on the last two stages of the differential pumping system. The larger pumping capacity permits operation of the ESI source at atmospheric pressure with negligible change in FTMS cell pressure. An open trapped cylindrical ion cell (5,6) with pulsed gas introduction is employed for improved sensitivity and flexibility for MS/MS options.

To increase the signal, the simplest method for trapping ions in the cell is accumulated trapping. This involves keeping the trap plates at a static potential while the ions are injected into the magnet. The pressure dependence of ion accumulation suggests a collisional mechanism for trapping the ions in the cell. In order to minimize the pressure for analysis after ion trapping, pulsed gas valves are used to create short-lived increases in pressure. The ESI source in its present design produces a rather broad distribution of ion kinetic energies. Narrowing this energy distribution will increase the signal during accumulated trapping events, because more ions will have energies compatible with energies accepted by the trap potentials.

Frequency-sweep excitation parameters were found to have a dramatic effect on spectral quality for the electrosprayed ions. While narrow-bandwidth forward-sweep excitation provides excellent spectral quality, a severe degradation of signal-to-noise ratio is evident at larger excitation bandwidths with forward sweep. However if the sweep direction is reversed the spectral quality achieved at large bandwidth is identical to that achieved with narrow bandwidth. Such effects are similar to axial ejection problems encountered with low m/z ions, but are unexpected for ions in this m/z range. Experiments to determine the mechanism of this effect are currently underway.

Using a 193 nm excimer laser, photodissociation was attempted on a variety of peptides and proteins. The peptide Gramicidin S showed very efficient dissociation, with many structurally significant fragments. Proteins of greater molecular weight showed less fragmentation, with the protein Ubiquitin giving only the B_2 through B_5 fragments.

One of the inherent difficulties with electrospray is determing the charge associated with a peak. High resolution spectra provide charge information in the distance between 13C isotope peaks. Two computer methods have been developed to simplify charge determination. The first is human like, and works by finding peaks and measuring the distance between them. The second method fourier transforms the peaks of interest and determines charge by their frequency of occurance. The fourier method has been shown to be superior in determining the charge of a poorly resolved cluster of peaks.

The combination of electrospray ionization with FTMS provides unique capabilities for the analysis and characterization of large biomolecules. While much of the potential of the electrospray/FTMS combination has been realized, there remain many opportunities for further development. For example, traditional ion dissociation techniques have proven to be relatively ineffective for very large ions and new approaches may ultimately be required. Also, little is known about the dynamics of massive highly charged ions and the consequences of such dynamics on FTMS trapping, excitation, and detection performance. Finally, the potentially large information content of electrospray/FTMS spectra will require the generation of computerized spectral interpretation and data reduction algorithms. Continued development of the instrument and associated techniques along these lines should ultimately provide unparalleled mass spectral performance.

Characterization of an FT/ICR Instrument Based on a Permanent Magnet

*Loreen C. Zeller,[1] James M. Kennady,[1] Joseph E. Campana,[2] and Hilkka I. Kenttämaa[1]

[1]Department of Chemistry, Purdue University, West Lafayette, Indiana, 47097-1393 and [2]Millipore/EXTREL FTMS, 6416 Schroeder Rd., Madison Wisconsin, 53711-2424.

An FT/ICR mass spectrometer based on a 0.4 T permanent magnet has been studied. This instrument has a single, screened 3.5 cm cubic cell. The vacuum is maintained by a 100 lpm diffusion pump and has a base pressure of $\leq 1 \times 10^{-8}$ Torr. Samples are introduced into the instrument through one of two leak valves, a set of pulsed valves or a heated solids probe. The performance of this instrument was characterized by studying the mass resolution and mass accuracy and the stability of the magnetic field over time. The capabilities of the instrument for multiple stage mass spectrometry and for the measurement of rate constants were examined.

The stability of the instrument was studied by daily calibration with perfluoroterbutylamine. The stability as measured by drift in the magnetic field is excellent for at least 19 days, Figure 1a. Measurement of the ionic masses for six fragment ions of the calibration compound further attest to the excellent stability, Figure 1b.

The ultra high mass resolution and mass accuracy characteristic for high-field FT/ICR instruments has not yet been attained in this low-field instrument. However, resolution of 27000 at m/z 69 and 33000 at m/z 131 are still great enough for the separation of many isobaric peaks. Similar observations were made upon measurement of the mass accuracy: 5 ppm at m/z 69 is comparable to high-field instruments and is greater than the accuracy achievable using other small ion traps.

The effect of the screens on the electric field experienced by the ions was investigated by varying the trap plate potential while the screens were grounded. Figure 2 demonstrates that the trap potential has little effect on the measured mass of ions over the range of 0.5-1.4 V, suggesting that the grounded screens decrease the curvature of the electric field in this small cell.

The 70 eV electron ionization mass spectrum of the calibration compound measured on this instrument compares favorably to that measured on a commercial high-field instrument (EXTREL FTMS 2001). Chemical ionization was demonstrated by using cyclobutanone in a self-chemical ionization experiment. The resulting spectrum again compared favorably to the spectrum obtained using similar conditions in the commercial high-field instrument.

Multiple stage mass spectrometry was demonstrated for different chemical systems. An MS/MS experiment, Figure 3, was performed to calibrate the ion gauge prior to the measurement of a rate of reaction. MS/MS/MS has also been demonstrated using the cylcobutanone system.

Finally, the capability for the measurement of rate constants was explored by measuring the rate of reaction of the isolated molecular ion of cyclobutanone with neutral cyclobutanone. The same reaction was studied in the commercial high-field instrument using similar reaction conditions. In the low-field instrument, a rate of 4.6×10^{-10} $cm^3 molecule^{-1} s^{-1}$ was measured, whereas the rate in the high-field instrument was 4.8×10^{-10} $cm^3 molecule^{-1} s^{-1}$. These two numbers are within the limits of the experimental error for rate measurements in FT/ICR mass spectrometers.

Cooling and Axialization of Heavy Ions by Quadrupolar Excitation and Buffer Gas Collisions in FT/ICR Mass Spectrometry

Shenheng Guan, Lutz Schweikhard, and Alan G. Marshall†
Departments. of Chemistry (and Biochemistry†),The Ohio State University,
120 West 18th Avenue, Columbus, OH 43210

In a recently developed method for cooling of heavy ions in a Penning trap mass spectrometer [1], ions are excited by an azimuthal quadrupolar field at the unperturbed ion cyclotron orbital frequency, $\omega_c = \omega_+ + \omega_-$, (i.e., the sum of the reduced cyclotron frequency, ω_+, which would be observed by conventional dipolar excitation and detection, and the magnetron frequency, ω_-). Magnetron motion can thereby be converted completely into cyclotron motion [2], which can then be cooled very efficiently by the collision of ions with buffer gas molecules. Axialization and cooling of the cyclotron motion (i.e., shrinkage of the ICR orbital radius) can be achieved without attendant expansion of the magnetron orbit. The trapping motion is cooled as well.

In this work, we adapt and extend the above method in several ways. First, we employ broadband detection and Fourier transform data reduction, for simultaneous detection of ions of a wide range of mass-to-charge ratio. Second, in place of a single hyperbolic trap, we use dual cubic traps. Finally, we use multiple-frequency SWIFT excitation to axialize and cool ions of two m/q-ratios simultaneously. The effects of quadrupolar excitation amplitude and frequency on trapping efficiency are also studied. In summary, by use of the dual-trap configuration, we are able to combine the advantages of quadrupolar excitation for ion axialization and cooling with all of the usual advantages of conventional FT/ICR dipolar excitation and detection.

Experiments were carried out on a standard Extrel FTMS-2000 spectrometer. Conventional azimuthal dipole-excitation/dipole-detection for the source trap was changed to azimuthal quadrupolar excitation geometry, by connecting together the two pairs of opposed electrodes to the two differential (i.e., 180° phase difference) outputs of a standard excitation amplifier (see Fig. 1). The cubic trap provides a good approximation to an azimuthal quadrupolar excitation field near the center of the trap [4]. A trapping potential of +5 V or +10 V was used, with argon as the buffer gas. We have been able to store benzene molecular ions for 20 seconds at high pressure (10^{-5} mbar) in one half of a dual trap, as demonstrated by subsequent transfer of those ions to the other half of the dual trap for ICR excitation and detection [3].

The axialization/cooling method should prove especially valuable for increasing FT/ICR/MS detection sensitivity of externally injected ions. Additional applications to ion-molecule reaction chemistry include: (i) Because ions can be cooled both internally and externally to the temperature of the neutrals, side reactions due to high-energy species can be eliminated. (ii) The long trapping period at high pressure allows for many ion-neutral collisions and therefore makes possible the study of reactions with low ion-molecule reaction rate constants. (iii) Monitoring of competing reactions can be "channeled" by trapping only the product ions of interest. (iv) Product ions formed by off-axis collisions of cyclotron-excited parent ions with neutrals can be cooled and brought back on-axis for improved detection sensitivity and mass resolution. MS/MS performance for high-mass ions (e.g., peptides) should be especially enhanced. Work supported by N.S.F. (CHE-9021058), N.I.H. (GM-31683), and The Ohio State University.

Petroleum Analysis by FTMS

Zhenmin Liang and Joe E. Campana

EXTREL FTMS (*now part of Millipore*), 6416 Schroeder Road, Madison, WI 53711-2424

Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FT/MS) has been known for its ultra-high resolution and high accuracy mass-measurement capabilities. There has been few reports of FT/MS in the analysis of petroleum samples, which generally is most demanding in the above features. In this presentation, we demonstrate the use of FT/MS to obtain accurate masses, to perform MS/MS on an isobar, and to perform ultra-high resolution mass spectral measurements for petroleum samples.

The analysis was performed on an EXTREL FTMS-2001 mass spectrometer. The petroleum samples were introduced via a solids insertion probe heated to 150-250 °C during data acquisition.

Accurate mass measurements can be performed under medium to high (>4,000 FWHH definition) resolution. Table 1 lists some of the masses from the mass spectrum of a weathered petroleum sample and the most likely formulae according to the mass measurements. This mass spectrum exhibits a resolution of 10,000 at m/z 200. The calibration is achieved by using an external calibration table. (e.g. a calibration table obtained independent the the sample spectrum.) Space-charge induced mass error can be minimized by: 1) adjusting the electric field term in the calibration equation based on a known peak in the sample spectrum (a diffusion pump oil ion peak in this case) [1]; or 2) by adjusting the ionization conditions of the calibration spectrum so that the m/z of a known ion peak (the pump oil peak) in the sample mass spectrum is accurate based on the external calibration table. We found that the second procedure in external calibration adjustment provide good mass accuracy over a wider mass range than the the first procedure.

The MS^n capability also makes FT/MS useful in structure elucidation, especially when Stored Waveform Inverse Fourier Transform (SWIFT™) excitation is available for high resolution ion isolation. As an example, $[C_{13}H_{27}]^+$ at m/z 186.1222 (5% abundance relative the base peak at m/z 95) were selected from the other ion (including $[C_{14}H_{15}]^+$ at m/z 178.10, m/Δm = 2,000, as shown in the inset of Figure 1). Collision-induced dissociation (CID) was performed, which resulted in the mass spectrum in Figure 1.

Ultra-high mass resolution spectra were obtained by using the scheme described elsewhere [2]. Briefly, a wide mass range ultra-high resolution mass spectrum can be achieved in FT/MS by performing multiple ultra-high resolution mass spectral detections of smaller mass ranges. In the detection of each smaller mass range, SWIFT excitation is used to eject ions outside of the detected mass range. The SWIFT ejection improves the mass resolution by reducing the space-charge effects. In addition, folded-back (aliasing) ion peaks are also avoided. In Figure 2, a mass spectral segment of a petroleum sample is displayed. The resolving power of the mass spectrum is 250,000, as illustrated by the inset plot in the figure. Table 2 shows accurate masses of some ions obtained by external calibration and their most probable formulae.

In summary, FT/MS is a powerful tool in the mass spectral analysis of petroleum samples. The mass accuracy and the ease in obtaining the measurements is unique in any high performance mass spectrometer. The high resolution ion selection for MS/MS analysis is also useful in all complex mixture analysis. Finally, the ultra-high resolution is practically accessible and useful.

Identification of the components of low boiling point crude oil and liquid coal samples is a challenging task for mass spectral analysis. A typical distilled oil sample contains more than a thousand compounds with molecular weights ranging from about 100 to 600. At each nominal mass, there may be as many as 50 isomers and isotopic combinations. For a sample containing sulfur, a mass spectrometer with a resolving power of several hundred thousand is needed to separate unequally abundant species containing SH_4 *vs.* $^{12}C_3$ (0.0034 u mass difference). Double-focusing sector mass spectrometers can attain a resolving power of 100,000 or more, but generally with a severe loss in sensitivity. In Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR/MS), sensitivity does not decrease (and can even increase) with increasing resolving power. Moreover, FT/ICR mass resolving power can routinely reach 200,000 for species of 0.1 % relative abundance at m/z up to 300 or more.

Ultrahigh FT/ICR/MS resolving power for oil sample analysis poses the following practical problems: 1) introduction of all sample components with a wide range of boiling points into the mass spectrometer without discrimination, 2) sample introduction stable over several hours, 3) maintenance of a large pressure difference between the MS analyzer and the sample inlet system, 4) isolation of ionic species of a range of m/z ratios, and 5) high-resolution detection of ions of low relative abundance.

Mass analysis was carried out at 3.0 tesla on an Extrel FTMS 2000 dual-trap instrument. SWIFT excitation was generated from a homebuilt accessory. The crude oil fractions were vaporized and introduced into the source trap of the mass spectrometer through a heated glass inlet system. The inlet system was heated to 300 °C and a glass transfer line guided the heated oil vapor into the high vacuum chamber. A conductance limit with an approximate ID of 10 μm located on the transfer line near the main body of the inlet system provided stable (≥2 hours) sample introduction from a 10 μL sample. After sample introduction, mass spectra were taken every 5 min until the source chamber pressure stabilized at 0.8×10^{-8} torr (i.e., low enough for high-resolution performance). The stability of the inlet system ensures reliable data acquisition and provides sufficient time to optimize experimental conditions.

The strategy for high resolution detection of mixtures proceeds as follows: (1) low-energy (~10 V) electron ionization to produce $M^{+\cdot}$ ions with minimal fragmentation; (2) broadband excitation/detection to determine the overall molecular weight distribution of the sample, and to establish the mass range for mass-selective ion ejection; (3) SWIFT broadband ejection to remove ions of all m/z-ratios except for a spectral segment containing the ions of interest; and (4) high resolution heterodyne-mode broadband detection of ions with m/z values in the selected range.

Figure 1 (top) shows an ultrahigh resolution FT/ICR mass spectral segment, $260 \leq m/z \leq 290$ from an Amoco crude oil fraction with a large number of sulfur-containing compounds. (The drop-off in signal at each end of the spectrum is due to partial ejection during the selection of that mass spectral segment.) The mass resolving power ($m/\Delta m$ = 200,000, with Δm taken as the magnitude-mode peak full width at half-maximum peak height) achieved simultaneously throughout the displayed mass range is evident from the mass scale-expanded spectrum in Figure 1 (bottom). Ions of six different chemical formulas are baseline-resolved at m/z 274, including an obvious SH_4 and $^{12}C_3$ doublet. This work was supported by Amoco and The Ohio State University.

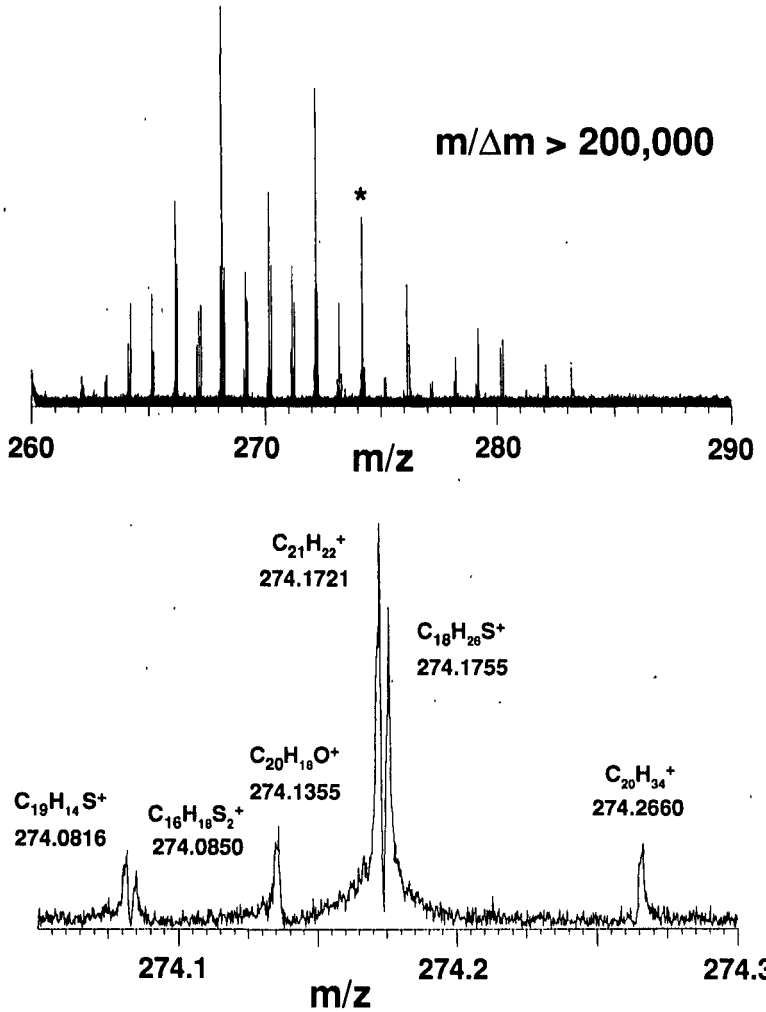

Figure 1. SWIFT-extracted FT/ICR mass spectral segment (top), and scale-expansion of the isotopic peaks at nominal m/z = 274 (bottom). Note the baseline resolution of the $SH_4/^{12}C_3$ mass doublet. This example shows mass resolving power of 200,000 for components whose relative abundance in the original mixture is less than 0.1%.

OXIDIZED HYDROCARBONS CHARACTERIZED BY ON-LINE LC/MS AND NEGATIVE ION CHEMICAL IONIZATION

Annandale, NJ 08801

We have investigated the feasibility of negative ion chemical ionization (NICI) for the characterization of oxygenated hydrocarbons. We found that long chain alcohols, ketones and acids yield predominant $(M-H)^-$ anions under NICI conditions using isobutane as a reagent gas, shown in Figure 1. Since the ionization is a dissociative thermal electron attachment process, it is expected that ionization cross section of the process depends on both the polarities and functionalities of the molecules. Figure 2 illustrates linear relationship between molar sensitivity and molecular weight of alcohols and ketones. The relative sensitivity of each compound is highly dependent of its molecular type and carbon number, which renders difficulties in quantification if calibration compounds are not available. However, NICI facilitated the determination of oxidized hydrocarbons due to its high selectivity to oxygenated hydrocarbons over non-oxygenated hydrocarbons [1].

We have used on-line LC/MS in combination with NICI for characterizing a severely oxidized lubricant oil. The oxygenated hydrocarbons are separated by HPLC according to the polarity of the functional group, shown in Figure 3. A comparison of mass spectra obtained by 70 eV EI, isobutane positive ion CI, and negative ion CI is shown in Figure 4. It is evident that NICI yields the cleanest spectrum for displaying the molecular ion distribution. The elemental compositions of oxidized hydrocarbon molecules are determined by accurate mass measurement at a resolution of 10,000. Table 1 lists the oxygenated hydrocarbon types and their abundances determined by high resolution NICI. Most of oxidized hydrocarbons are found to be long chain alcohols, ketones, esters, and acids. The total number of oxygen atoms in the molecules ranges from 1 to 4. Figure 5 shows the carbon number distribution of alcohols and acids which represent lightly and severely oxidized hydrocarbons. The carbon number distribution of lightly oxidized hydrocarbons, such as alcohol, is very close to that of their parent hydrocarbon molecules. On the other hand, severely oxidized hydrocarbons, such as acids, have very different carbon number distributions than their precursors.

COMPARISON OF CS_2 CHARGE EXCHANGE AND LOW VOLTAGE ELECTRON IMPACT AS IONIZATION TECHNIQUES FOR HYDROCARBON CHARACTERIZATION

Kuangnan Qian and Chang S. Hsu
Exxon Research and Engineering Company
Clinton Township, Route 22 East
Annandale, New Jersey 08801

Low voltage electron-impact ionization (LV/EI) has been commonly used in petroleum industry for the compound type analysis of aromatic fractions of fossil fuels since 1956[1]. In this technique, the electron beam energy is generally set below 10 eV so that aromatic hydrocarbons can be selectively ionized with minimum fragmentations. Thus, LV/EI provides quantitative measurements of molecular ions for the determination of aromatic compound type distribution in a hydrocarbon mixture. However, by reducing electron beam energy the mass spectrometric (MS) sensitivity is not only significantly reduced but also greatly affected by small variations in electron beam energy.

We recently investigated the feasibility of using CS_2 charge exchange (CS_2/CE) reaction as a low energy ionization technique for hydrocarbon analysis. A VG-70 VSE double focusing mass spectrometer equipped with a Hewlett Packard 5890 GC and Varian Vista 5500 LC was used for this study. GC/MS was used for the relative sensitivity measurements of model compounds, while LC/MS was employed for analysis of high boiling petroleum distillates. Detailed description of LC/MS methods can be found elsewhere[2].

Unlike the most of CS_2 charge exchange studies reported in the literature, we use a low energy electron beam to ionize CS_2 at high source pressures (chemical ionization conditions). Under these conditions the formation of a large number of fragment and cluster ions that have different recombination energies than CS_2^+ can be avoided. Table 1 lists the abundances of ionic species formed from CS_2 under the 70-eV and 10-eV EI conditions. The low energy CS_2^+ ions are used as reagent ions for our charge exchange experiments.

A comparison between LV/EI and CS_2 charge exchange (CS_2/CE) was made using xylene as a reference compound. The ratio of the most abundant fragment ion of xylene at m/z 91 to its molecular ion (m/z 106) is used as an indicator of fragmentation of aromatic compounds under LV/EI and CS_2/CE conditions. Figure 1 compares the degree of fragmentation as a function of nominal electron beam energy in LV/EI and CS_2/CE. It is desirable to keep the ratio below 2% for minimal fragmentation, that is, the nominal electron energy has to be set below 10 eV for both ionization techniques. A drawback associated with LV/EI is the dramatic decrease in MS sensitivity as shown in Figure 2. As electron energy is decreased from 16 eV to 10 eV, the abundance of molecular ion is decreased by 50 times. Accompanied with the sensitivity loss is the deterioration of mass measurement stability, which makes accurate mass measurement by high resolution MS difficult. CS_2/CE is more sensitive than LV/EI over the entire electron energy range studied. Below 10 eV, CS_2/CE is at least an order of magnitude more sensitive than LV/EI.

Another difficulty in using LV/EI for the quantification of hydrocarbons is the lack of model compounds for sensitivity calibration. It was found that CS_2/CE yields rather uniform sensitivities for aromatic hydrocarbons with different ring structures. Figure 3 compares the relative molar sensitivities of PNAs in CS_2/CE and LV/EI. The uniformity in sensitivity eliminates the need of calibration compounds for sensitivity calibrations.

Both LV/EI and CS_2/CE are compatible with moving belt LC/MS. Figure 4 compares aromatic ring distributions of a petroleum distillate determined by HPLC with a evaporative mass detector (EMD), and moving belt LC/MS with LV/EI and CS_2/CE. It can be seen that LV/EI tends to over-estimate 2+-Ring aromatics and under-estimate 1-ring aromatics. This is consistent with the observation that LV/EI sensitivity increases as number of aromatic rings as shown in Figure 3. CS_2/CE, on the other hand, shows a fairly good agreement with EMD results. However, the relative abundances of compound types with the same aromatic core structure determined by LV/EI and CS_2/CE show very little difference. An example is given in Figure 5 which shows compound type distributions of di-aromatic thiophenes in a petroleum distillate. All of the compound series shown are either aromatic or hydroaromatic with two aromatic rings.

The processes used for the conversion of Alberta bituminous sand into synthetic crude oil are complex and involve several upgrading steps. An important step consists of breaking down the bitumen by hydrocracking, which causes molecular transformations leading to the buildup of polycyclic aromatic compounds (PACs), often alkylated[1]. The identification of these compounds is a fundamental task in the study of heavy gas oils (HGO) and pitches, not only for the optimization of the production processes, but also from the point of view of environmental pollution and health, owing to the mutagenic and carcinogenic properties of PACs. A major problem in the determination of PACs in such materials is the extreme complexity of the mixtures, even after extensive fractionation.

The combination of high performance liquid chromatography (HPLC) or supercritical fluid chromatography (SFC) with mass spectrometry is a powerful tool for the characterization of PACs in these complex samples due to the complementary resolving power of each technique. The use of on-line HPLC/MS allows resolution of ambiguities in mass spectrometric characterization of several isomeric alkylated species. We report on the use of a moving belt interface as a means of interfacing HPLC and packed column SFC to a mass spectrometer for the characterization of the aromatic content of HGO and pitch samples obtained from Syncrude Canada Ltd. (Fort McMurray, Alberta, Canada). The ease of compatibility of the moving belt with EI sources makes it very suitable for the analysis of PACs.

The samples were first chromatographed on KOH-treated silica columns for removal of acids and/or very polar compounds[2], then on dual packed silica over alumina columns for the isolation of PACs[3]. The PAC fractions were concentrated and analyzed by HPLC/UV, HPLC/MS and SFC/MS. Reversed phase HPLC experiments were conducted using a C_{18} column and a water-acetonitrile-dichloromethane gradient. For reversed phase SFC analyses, a C_{18} column was also used and the mobile phase was 100% CO_2. Normal phase SFC experiments were performed using a silica column and pentane (with a small proportion of methanol) was used as the mobile phase. Pressure programming was effected in both SFC modes. The column effluents were deposited onto the belt via a heated nebulizer and MS detection was performed in the EI mode.

The HPLC/MS reconstructed ion chromatograms (RICs) of Figure 1 show the elution of alkylated phenanthene and dibenzothiophene species contained in the HGO. Both traces show the presence of several isomers. Altough isomer peaks are well resolved on a given RIC, other substances of different molecular weights are in fact coeluting, yielding ambiguous mass spectra such as those of Figure 2. These spectra feature molecular ion peaks as well as $(M-15)^+$ peaks due to the loss of methyl groups from alkylated species. HPLC/MS allowed moderately alkylated compounds with M.W. up to ca. 320 to be eluted with reasonable chromatographic quality. Alkylated polycyclic aromatic hydrocarbons (PAHs) as well as PAHs containing nitrogen, sulfur or oxygen heteroatoms were found in the samples. Heavier compounds, mostly highly functionalized species, were eluted in large unresolved envelopes toward the end of the chromatographic runs and were thus not identified on an individual compound basis. Reversed and normal phase SFC/MS did not allow resolution of individual isomers and thus were used as secondary tools to confirm the presence of species detected by HPLC/MS. Reversed phase experiments allowed the elution of the moderately alkylated species (M.W. < 320), whereas normal phase SFC allowed the detection of compounds with M.W. up to 950, eluted by groups of similar molecular weights as shown by the TIC trace of Figure 3. Highly functionalized species eluted in the last portion of the run (320 < M.W. < 950) were still not separable as individual compounds. These heavier species are minor in the HGO sample, but become predominant in the pitch sample.

On-Line GC/MS Analysis of High Pressure Reactions

Jacek P. Dworzanski, Huaying Huai, Neil S. Arnold and Henk L.C. Meuzelaar
Center for Micro Analysis and Reaction Chemistry,
University of Utah, Salt Lake City, UT 84112

The growing demand for real-time monitoring of industrial processes performed in reactors under conditions of high pressure and temperature indicates that MS technology, especially in combination with GC preseparation potential, could fulfill many current requirements. To achieve these goals we have expanded the application of our valveless vapor sampling inlet for on-line analysis of atmospheric gases and vapors by "transfer line" GC/MS [1] (Fig.1) to monitor chemical processes at high pressures (1000-2000 psi) through the construction of a special capillary restrictor to reduce the pressure to near ambient conditions. The restrictor effluent is coupled to the automatic vapor sampling inlet via a dilution chamber. This allows repetitive GC/MS analyses to be obtained at 1-15 minute intervals.

A schematic representation of our approach to monitor high pressure chemical processes is shown in Figs. 1-3. In Fig. 2 an experimental set-up for studies of high pressure (supercritical phase) pyrolysis of jet fuels is presented. Whereas Fig.3 shows the configuration used for the investigation of hydrogenation and hydrodeoxygenation of coal-model compounds under various process conditions. Both reactors are of the flow-through type, hence in both cases effluents were passed over protective SS frit filters (0.5 μm pores) where a minute portion (< 1μl/min) of this stream was diverted into a heated interface consisting of a 1-2 m long 0.01-0.025 mm i.d, fused silica capillary tube acting as a restrictor to reduce the pressure from 1000-2000 psi to near ambient conditions. A special dilution chamber, incorporating a Hewlett-Packard split type GC injector insert was kept at 300 C while attached to the automated vapor sampling inlet. The latter enables continuous dilution of analytes with a stream of He and pulsed sampling of vapors (according to the scheme shown in Fig. 1) [1] onto a long [30 m x 0.25 mm i.d., RTX-5 (Fig. 2)] or a short "transfer line" [1 m x 0.15 mm i.d., CP-SIL 5CB (Fig. 3)] fused silica capillary GC column coupled to Hewlett-Packard MSD and IRD detectors or to a modified, mobile miniaturized Finnigan MAT ion trap mass spectrometer [2], respectively.

Gas chromatograms of a JP-7 jet fuel sample subjected at 1500 psi to different temperatures from 1020 F to 1250 F with a mean residence time of ca. 2 s are presented in Fig.4a and in Fig. 4b. Concentrations of major decomposition products are plotted as a function of temperature. Under these supercritical conditions the main decomposition products are dominated by 1-alkenes, with the highest yields of short chain components (i.e., ethane, propene, butene) and aromatics. Fig. 5 illustrates dibenzyl ether decomposition under both thermal and catalytic ($3Co8Mo/\gamma\text{-}Al_2O_3$, sulfided before use) reaction conditions. As seen, the first products can be detected, depending on the presence or absence of a catalyst, at 250 C or 330 C, respectively. Kinetic profiles of the decomposition of dibenzyl ether under thermal and catalytic conditions are shown in Fig. 6 and demonstrate a several times higher rate of the substrate decomposition to toluene in the presence of a catalyst while under thermally controlled conditions GC/MS data revealed six products, namely: benzene, toluene, benzaldehyde, dibenzyl, 2- and 4-methyldiphenylmethanes in accordance with free radical mechanisms[3].

Kinetic parameters and yields of primary and secondary decomposition products of jet fuels as well as model compounds in coal liquefaction processes have been obtained in a fraction of the time needed for conventional off-line measurements and indicate that the proposed approach may be easily applied to a broad range of existing reactor types and potential processing environments.

BASE OIL ANALYSIS THROUGH USE OF MASS SELECTIVE DETECTOR MASS SPECTROSCOPY AND FOURIER TRANSFORM INFRARED SPECTROSCOPY

T. H. Wang and J. Torres, Pennzoil Products Company, P.O. Box 7569, The Woodlands, Texas, 77387

A new, direct, fast base oil analysis by low resolution Mass Selective Detector (MSD) Mass Spectrometric and Fourier Transform Infrared (FTIR) Spectroscopic analyses for determining up to 25 saturate and aromatic compound types in oils is demonstrated (Table 1). Usually three ASTM methods (ASTM D-2549, D-2876 and D-3239) are necessary to perform base oil analysis and the time required is one to two days per sample. This analysis can eliminate the need for physical separation or high resolution mass spectroscopic method. Sample analysis covers a wide range of boiling points (200-1100°F).

Ten minute averaged mass spectra were obtained by using Brunfeldt Inlet and MSD for Robinson Total Oil Analysis. The ratios of saturates/aromatics were obtained by FTIR spectroscopy using Nicolet Partial Least Square software (PLS) to determine saturate and aromatic concentrations. The experimental procedures are shown in Figure 1.

Using different calibration factors, one can obtain different saturate/aromatic split ratios which can be verified by FTIR analysis. Use of this custom software for hydrocarbon type calculation enables one to perform hydrocarbon type analysis of base oils in a timely and efficient manner.

By using this method, one can significantly reduce the time required to analyze petroleum fractions by current ASTM procedures and produce accurate, repeatable and reproducible results. The correlation between MSD and ASTM D-2007 methods for both saturates and aromatics is 0.99. The correlation between MSD and NMR spectroscopic methods for both saturates and aromatics is 0.95 (Figure 2). The correlation between MSD and FTIR spectroscopy for both saturates and aromatics is also 0.95 (Figure 3).

Table 1: Hydrocarbon Type Analysis of Base Stock J

	Z Number	Base Stock J (wt%)
Paraffins	+2	16.8
1-ring cycloparaffins	0	21.0
2-ring cycloparaffins	-2	13.3
3-ring cycloparaffins	-4	13.6
Total Saturates		64.7
Alkylbenzenes	-6	7.6
Naphthenebenzenes	-8	3.6
Dinaphthbenzenes	-10	3.2
Naphthalenes	-12	2.6

An Inductively Coupled Plasma (ICP) is potentially an ideal ionisation source for determining the isotopic composition of elements. It offers many advantages over the traditional method of isotopic ratio analysis by Thermal Ionisation Mass Spectrometry (TIMS). These include ionisation of all the metallic elements, considerably simpler sample preparation and a significant decrease in sample analysis time. However, because of the inherent instability of the ion source, plasma systems have so far failed to achieve the precision and accuracy that is routinely demonstrated by TIMS.

An ICP source has been coupled to a double focusing magnetic sector mass analyser equipped with seven Faraday detectors. This method of data acquisition allows the simultaneous measurement of isotopes which is independent of signal intensity variations. The major components of this mass spectrometry system are the ICP source, a 10 cm electrostatic filter and a 27 cm radius magnet with an effective dispersion length of 54 cm. The ions entering the mass spectrometer are accelerated by a potential of 5700 V applied to the sampler and skimmer cones.[1]

As with all ICP ion sources the heavier isotope is transmitted in preference to the lighter, thus isotope ratio measurements show mass discrimination. This discrimination is mass dependent and time independent. For example, uranium and hafnium exhibit a mass bias of $\approx$0.6% amu^{-1} and $\approx$1.5% amu^{-1} respectively. Measured isotope ratios can be corrected for mass discrimination in three ways: 1) with reference to standard materials 2) by internal normalisation, when at least two stable isotopes exist 3) with a spike element, where spike and sample elements favourably overlap, this technique being unique to ICP-MS.

High precision and high accuracy isotope ratio measurements of U, Pb, Hf and Nd, comparable to those obtained by TIMS are shown. Sample analysis time has been significantly reduced and sample preparation considerably simplified. An external precision (%RSD) of 0.012 has been shown for the $^{235}U/^{238}U$ measurement of six samples of NBS SRM U-500, measurement time for all six samples being 30 minutes. Comparable levels of external precision have been obtained for the $^{235}U/^{238}U$ measurement of NBS SRM U-010 and SRM U-970.[1] Similarly, an external precision (%RSD) of 0.035 has been shown for the $^{208}Pb/^{204}Pb$ measurement of six samples of NBS SRM Pb-981. Further improvement in the precision of lead isotope ratio measurement was achieved by spiking the lead solution with thallium.[2,3] Thallium allows an internal mass bias correction and removes the need for a separate calibration analysis. Measurement of six samples of NBS Pb-982, internally normalised to the $^{205}Tl/^{203}Tl$ ratio revealed $^{208}Pb/^{204}Pb$ = 36.702±0.022, $^{207}Pb/^{204}Pb$ = 17.141±0.009 and $^{206}Pb/^{204}Pb$ = 36.711±0.021[4] compared with the NBS certified values of 36.744±0.050, 17.159±0.025 and 36.738±0.037 respectively.

Measurement of six La Jolla neodymium samples, where internal normalisation to $^{146}Nd/^{145}Nd$ is possible, revealed a $^{143}Nd/^{144}Nd$ ratio of 0.511824±0.000034 (2 sigma) compared to the accepted value of 0.511859. Measurement of six samples of La Jolla spiked with a similar concentration of samarium revealed a $^{143}Nd/^{144}Nd$ ratio of 0.511854±0.000058 (2 sigma). Similarly measurement of six samples of JMC 475 hafnium, normalised to $^{179}Hf/^{177}Hf$,[5] revealed a $^{176}Hf/^{177}Hf$ ratio of 0.282194±0.000020 (2 sigma) compared to the accepted value of 0.282195±0.000015 (2 sigma). Measurement of six samples of JMC 475 hafnium spiked with a similar concentration of lutecium revealed a $^{176}Hf/^{177}Hf$ ratio of 0.282213±0.000023. Thus accurate isotope ratio measurements are possible when the sample solution contains interfering isotopes. Solution concentrations in all the above cases was in the range 0.5-1.0 ppm. The sample solution was

recirculated during the analysis of neodymium and hafnium.

The advantages of this system can also be applied to alternative sample introduction methods such as Laser Ablation (LA). Multiple collection LA-ICP-MS has proven to be a simple, accurate and precise technique for the analysis of isotopes in solids.[6] Analysis of lead in NIST 610 glass revealed $^{208}Pb/^{204}Pb$ = 36.949±0.041, $^{207}Pb/^{204}Pb$= 15.508±0.019 and $^{206}Pb/^{204}Pb$ = 17.050±0.018 compared to values of 36.989±0.024, 15.506±0.010 and 17.049±0.012 respectively, determined by TIMS.[7] Each laser ablation figure represents the mean of 6 analytical studies performed over a 6 day period. Each study consisted of isotopic ratio measurement at 12 sites, the measurement of each site lasting 5 seconds. Crater diameter was approximately 50 microns in each case. The simplicity of LA-ICP-MS should be compared to the dissolution of a glass matrix, extraction and purification of the lead and about 30 minutes of analysis time required using TIMS.

The results described here represent initial work on a prototype system. We believe that the significant advantages of multiple collection ICP-MS and LA-ICP-MS have been clearly demonstrated. The double focusing multiple collector ICP-MS offers an extensive range of future isotope ratio applications in both liquids and solids. Furthermore we are confident that using more efficient nebulisation systems, analyte concentrations can be reduced to less than 50 ppb.

Townsend-Discharge Nitric Oxide Chemical Ionization of Hydrocarbons in a Triple-Stage Quadrupole Mass Spectrometer (TSQ)

Siu T Teng* and Douglas M. Fast, Finnigan MAT, San Jose, CA

Introduction

Recently, Townsend-Discharge Nitric Oxide Chemical Ionization (TDNOCI) performed in a quadrupole mass spectrometer experienced a certain renaissance. Since it is convenient and has no deteriorating effect of the electron-emitting filament, the mass spectra are simple and yield molecular weight information

The present work is primarily to show basic hydrocarbons' mass spectra under TDNOCI on a TSQ 7XX type of instrument, experimental vanables that can influence the mass spectra fingerprints, its MS/MS capability to control the fragmentation pattern, the operating parameters, and, along with other workers, serves to reemphasize the usefulness of theis analytical tool to the mass spectrometry community.

Experimental

The applied discharge voltage ranged from 1200-1600 Volts, ion source temperature was kept at 150°C, and ion source pressure was estimated at 5-10 Torr. The reproducibility and stability were tested at eight hours continuous operation on three consecutive days. Higher ion source temperature may signigicantly reduce the $[M+NO]^+$ ions The reagent gas pressure can be controlled by tuning at NO^+ ions and its dimer ions at m/z 60. THe consumption of nitric oxide reagent gas was very low. When utilizing the MS/MS technique, low energy collision in the range of 5-30 eV should be sufficient to yield the targeted daughter spectra of most hydrocarbons under TDNOCI mode Argon was used as collision gas.

Results and Discussion

The TDNOCI mass spectra of alkanes, olefins, and naphthenes exhibit a common predominant peak at $[M-H]^{+\cdot}$ while benzenoid aromatics exhibit the maximum intensity at $[M+NO]^+$ in contrast to the polycyclic aromatics which have a major peak at $M^{+\cdot}$. The summary of 31 basic hydrocarbons' mass spectra under TDNOCI is shown in Table 1. The MS/MS daughter spectra for Eicosane, molecular weight of 82, showed that at collision energy less than -5 eV the major molecular ions were still intact, which indicates the low excess energy and relative stability toward fragmentation. At -9 eV collision energy most of the molecular ions were fragmented and mass spectra with a distribution of the homologues ions concentrated at m/z 99 were obtained. *Fig. 1 is a comparison of two isomers of nominal masses at 106 amu Both isomers have major* peaks at $[M+NO]^+$ but Xylene exhibits a second peak at $M^{+\cdot}$ in contrast to Ethylbenzene, which has a second peak at $[M-H]^{+\cdot}$.

Summary

The mass spectra of TDNOCI are of good quality, simple, and yield molecular weight information. By manipulating experimental parameters such as ion source temperature, reagent gas pressure, and collision energy, one can influence the resulting mass spectra. The specificity and selectivity of this technique allow differentiation of isomeric hydrocarbons. In some instances, the need for high resolution instruments to differentiate between compounds having the same nominal masses may even be eliminated.

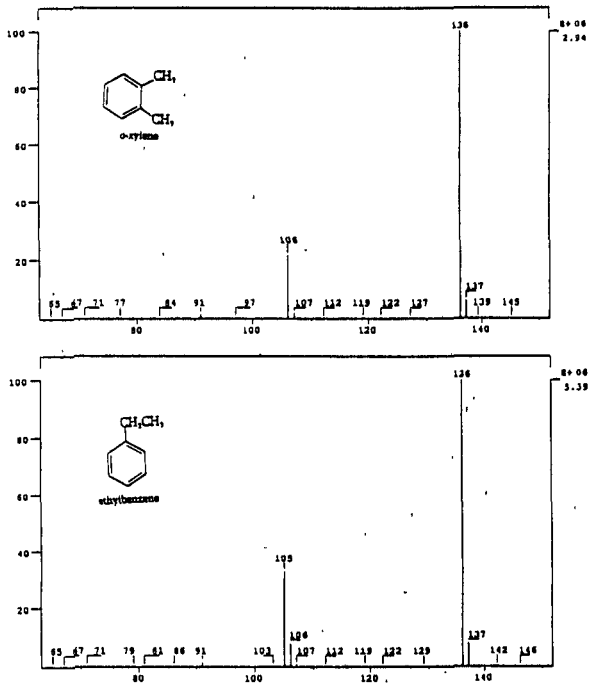

Fig. 1: Comparison of two isomers with nominal masses of m/z 106.

	Relative intensity in %			
	$M^{+\cdot}$	$[M-H]^{+}$	$[M+NO]^{+}$	
Alkanes	10 — 20	100	<1%	
Olefins	5 — 40	20 — 10	10 — 100	
Naphthenes	5 — 1	100	1 — 40	
Benzenoid Aromatics	5 — 40	1 — 9	100	
Polycyclic Aromatics	100	NA	<<1%

COMPARISON OF METALLOGEOPORPHYRINS IN CRUDE OILS USING PLASMA DESORPTION MASS SPECTROMETRY

Karl V. Wood and Connie C. Bonham
Campus-wide Mass Spectrometry Center
Department of Chemistry
Purdue University
West Lafayette, Indiana 47907

Plasma desorption mass spectrometry has been shown to have potential as a means for analyzing metallogeoporphyrins.[1] Detection limits in the low nanogram range for a single standard metallogeoporphyrin spiked in a crude oil have been obtained. One reason for investigating the potential of plasma desorption mass spectrometry is the considerable advantage it offers over electron impact or chemical ionization in terms of ion source contamination. In addition, a number (up to eight) of samples can be loaded into the instrument at one time and subsequently analyzed. Of particular interest in the analysis of porphyrins are the carbon number distribution and the DPEP/ETIO ratio which can be used to estimate the maturity of a given crude oil. While previous PDMS studies could address the carbon number distribution of the porphyrin homologs present PDMS did not have the necessary mass resolution to separate the DPEP and ETIO components. The addition of a reflector unit however, has enabled unit mass resolution to be obtained in the mass range of interest. In this study, the PDMS spectra of a number of crude oils will be compared with their respective CI spectra with particular attention focussed on the calculated DPEP/ETIO ratio.

The metallogeoporphyrins were obtained from the oil samples using conventional extraction/separation techniques. The resulting fraction is then dissolved in a 50/50 chloroform/hexane solution and applied to a silica Sep-pak cartridge, prewetted with 50ul of hexane. The cartridge is then washed with 2ml of hexane and the metallogeoporphyrins are eluted with 4ml of chloroform.

The plasma desorption mass spectra were obtained on a BIOION 20R (Applied Biosystems AB Uppsala, Sweden) mass spectrometer. The eluted porphyrin samples were evaporated under a stream of nitrogen and reconstituted in a small amount of chloroform (approximately 50ul) prior to electrospraying onto a nitrocellulose-coated mylar target. The samples were inserted into the Bioion sample carousel for mass analysis. The acceleration potential used for this study was 17000 volts. For consistency a sampling interval of one hour was chosen for the normal mode analyses and two hours for the reflector mode analyses.

The chemical ionization mass spectra were obtained on a Finnigan 4000 mass spectrometer using isobutane as the reagent gas. The porphyrin samples were loaded into a sample vial, inserted into the mass spectrometer via a solids probe and then volatilized by heating. The standard porphyrin (vanadyl (IV)-etioporphyrin-I) was purchased from Midcentury Chemicals (Posen, IL) and used directly after a purity check with isobutane chemical ionization. Figure 1 shows the reflector mode data for the standard porphyrin at 10ng target loading. As can be seen the degree of fragmentation is minimal in the 10ng sample indicating there should be little concern that fragment ion intensity would interfere with determining carbon number distribution or calculating DPEP/ETIO ratios because 10ng of a metalloporphyrin is considerably more than the amount any single metalloporphyrin homolog would contribute to a given sample.

Figure 2 is the comparison of the reflector mode PDMS spectrum (2a) from an Anna Shale oil with the chemical ionization mass spectrum (2b). The similarity with respect to signal to noise is obvious and the comparison of the calculated DPEP/ETIO ratios is shown in Table I, along with the other oils studied.

These results indicate DPEP/ETIO ratios obtained from plasma desorption mass analysis are in agreement with conventional isobutane chemical ionization analyses. The PDMS ratio calculations utilized both the M^+ and the $(M+H)^+$ since these ions both have significant ion intensities as evidenced by the results shown for the standard metalloporphyrin. This complicates the ratio calculation. (Note: Even in isobutane chemical ionization the M^+ has an appreciable ion intensity relative to the $(M+H)^+$.) In addition, PDMS analysis of metallogeoporphyrins does not result in any ion source contamination unlike conventional mass analysis which involves thermal heating to volatilize the sample.

An Ion Microprobe Study of Small-Scale Chemical Variations that Occur in Certain Diagenetically Altered Limestones

[3] Dept. of Geology, University of Alberta, Edmonton, Alberta, Canada

Insight into the diagenetic history and evolution of carbonate rocks is provided by their trace element concentrations. Unfortunately, small-scale chemical zonations cannot be analyzed by bulk techniques, and the electron probe can only provide useful information on Fe, Mn, and Sr concentrations >500 ppm. Potentially, the ion probe can provide quantitative trace element analyses on spots <20 microns in diameter, at detection limits of 1 ppm or less, if proper standards and techniques are developed. Trace element contents of diagenetic calcites from the Nisku Formation have been analyzed, and these variations related to fluid compositions during diagenesis and variations in parental carbonate material.

Techniques for the analysis of trace elements in carbonates using a Cameca 4f-ims ion microprobe have been developed. Au coated samples were analyzed using a 2 to 5 nanoamp $^{16}O^-$ primary beam at 17 kV. Positive secondary ion counts were measured for B, C, Na, Mg, Al, Ca, Fe, Mn, Sr, and Ba using an automated peak-switching routine. Peak positions were calibrated each morning, and were checked before each analysis during pre-sputtering and magnet cycling to minimize hysteresis effects. Spots were pre-sputtered for ten minutes to allow the secondary ion signals to stabilize. All elements except Al, Na, and B stabilized within two minutes, and after ten minutes the signals from these three elements varied less than 10% during the rest of the analysis period. Ten cycles of data were collected, and total analysis time was ~30 minutes for each spot. During the analysis, the shape and position of the Ca secondary ion energy distribution was monitored and sample voltage was automatically varied to compensate for any charging.

Standard energy offset techniques were used to minimize potential molecular interferences on the masses of interest. Since molecular ion yields decrease much more rapidly than elemental ion yields as higher energy ions are sampled, the proportion of molecular species is much smaller at higher energies. We found that by shifting the sample offset voltage by 70 V relative to the center of the ion energy distribution, clean peaks could be obtained for all elements of interest. ^{54}Fe was used to avoid the $^{40}Ca^{16}O$ peak that interferes with ^{56}Fe, even at high energy offsets.

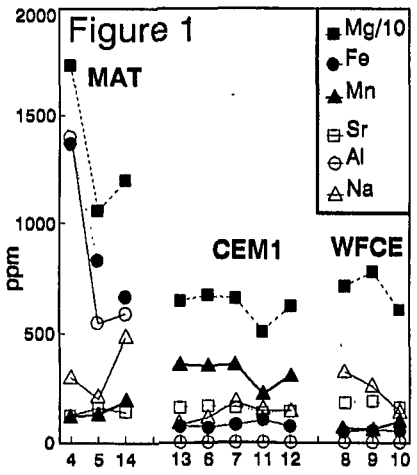
Ion intensities were empirically calibrated using a suite of carbonate standards that were developed. Although internal precisions of ion probe analyses are generally quite good (<10% for elements other than Al and Na), the external accuracy is limited by the homogeneity of the standards and the quality of the bulk analyses (INAA and AA). Finding homogeneous carbonate standards is very difficult, and obtaining precise bulk analyses of some low abundance elements (Al, B, Ba) is a problem.

In order to quantify the secondary ion intensities, the intensity of each element of interest must be referenced to the measured ion intensity of an element of known concentration. C (concentrations assumed from stoichiometry) and Ca (concentrations measured on the electron probe) have been investigated as reference species. Differences in the resulting analyses are within analytical error, and so C is used, eliminating the requirement to analyze each spot on the electron probe before using the ion probe. Absolute ion yields change from session to session due to slightly different tuning conditions and electron multiplier response. These variations were checked by multiple analysis of a standard during each session, and most elements varied <10% over a period of 4 months.

The ion probe was used to study carbonate samples from the Nisku Formation of the Western Canada Sedimentary Basin, which has undergone a complex diagenetic history. Reefal portions of the Nisku Formation have been the loci for fluid and hydrocarbon migration, and many of the diagenetic

"The submitted manuscript has been authored by a contractor of the U S Government under contract No DE-AC05-84OR21400 Accordingly, the U S Government retains a nonexclusive royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so for U S Government purposes."

textures are too fine to sample by conventional bulk techniques. Sample N-19 is composed primarily of two carbonate phase domains. One consists of an original silty limestone matrix (MAT), which was recrystallized early in the diagenetic sequence. The second domain consists of an isopacheous, white fibrous calcite cement (WFCE) which is a primary high-Mg calcite that recrystallized to low-Mg calcite fairly late in the diagenetic sequence (Machel, 1986). These two phases are separated by a thin calcite of uncertain origin (CEM1). It is either a recrystallized primary aragonite or an atypically recrystallized high-Mg calcite. A series of spots traversing the three carbonate phases were measured using the ion probe.



Results of the ion probe analysis of N-19 are plotted in sequence across the boundary region, from MAT, through CEM1, and into WFCE (Fig. 1). Both WFCE and CEM1 have similar Al and Mg contents, and there are no apparent trends relative to distance from the boundary with MAT. WFCE and CEM1 also have similar Fe contents. The Al, Mg, and Fe contents of MAT are much higher as compared to CEM1 and WFCE. Although not yet quantified due to lack of precise bulk standard analyses, Ba and B are partitioned among the three phases in a manner similar to Mg, Al, and Fe. Sr contents in all three phases are relatively constant. Na contents are similar but variable in all three phases (100-300 ppm). Mn distributions are distinct compared to other elements. WFCE has relatively low Mn contents (50-100 ppm), as does MAT (120-190 ppm). However, the thin cement zone that separates them (CEM1) has considerable higher Mn contents (220-360 ppm).

The high Al, B, and Ba contents of MAT are consistent with the presence of very fine clay impurities, presumably inherited from the original silty lime mud that recrystallized to form MAT. With the exception of Mn, WFCE and CEM1 have similar trace element contents. Since WFCE is considered to have recrystallized from a high-Mg calcite (Machel, 1986), it is likely that CEM1 also formed from a high-Mg calcite rather than a primary aragonite. The differing Mn contents in WFCE and CEM1 suggest that redox potentials were variable on a very fine scale in the sample. The coupled low Mn and Fe contents of WFCE are consistent with recrystallization in an oxygenated environment with a high redox potential. A much lower Eh in the thin microenvironment of CEM1 is implied by the higher Mn content. The inferred low Eh for CEM1 suggests that the border between MAT and WFCE may have been the site of organic decay during precipitation and/or recrystallization.

In this sample as in other Nisku samples, trace element concentration of phases determined by the ion probe are similar (within 50%) to bulk ICP analyses of the same phases (Machel, 1986). Given the heterogeneity of the Nisku samples, and the fact that bulk samples are drilled from the center of large "pure" areas while the ion probe analyses were done in finely intergrown areas, this agreement is quite good. The ion probe study reveals that compositional variability is preserved on a very local scale (10-100 microns), and allows analysis of phases that are too fine for bulk characterization.

Elemental Analysis of Metals and Sulfur in Crude Oil and Sediment Bitumens by ICP-MS

Lawrence L. Griffin, Dale A. Hubbard, Michael Snyder
Department of Marine Sciences, Texas A&M University, Galveston, Texas 77553-1675
Wendy Keeney-Kennicutt, Mahlon C. Kennicutt
Geochemical and Environmental Research Group, Texas A&M University, 833 Graham Road, College Station, Texas 77845

Crude oils may be characterized by a variety of intrinsic tracers. Trace metal ratios and sulfur abundance are among inorganic characteristics which serve as tools to identify oils within a common basin or between basins with common genetic source rocks.

Vanadium to nickel ratios and sulfur content have been characterized in crude oils. Vanadium and nickel are the major metals in petroleum; their relative proportions are considered characteristic of the depositional environment during early diagenesis. Near surface sediment bitumens are the extractable organic components of surficial sediments. Bitumens are considered possible indicators of oil seepage or migration and are important to surface geochemical oil exploration[1].

Vanadium and nickel may be determined in crude oil by various techniques including: atomic absorption spectroscopy (AAS), inductively (or directly) coupled plasma OES (ICP), and neutron activation analysis (NAA). AAS and NAA do not provide aqequate determination of sulfur. Organic dilution ICP-OES is not applicable to small bitumen samples.

We have employed a microwave digestion/ICP-MS technique for simultaneous determinations of ^{51}V, ^{60}Ni, ^{65}Cu, ^{66}Zn, and ^{208}Pb in crude oil and bitumen samples. Sulfur is detectable as ^{34}S for sample concentrations from ca. .05 to .3 per cent, for sample dilution factors in the range 200:1 to 500:1. Bitumen extracts may be as small as 5-10 milligram but yield reproducible V/(V+Ni).

Here we report comparative analyses by our methods for 21 crude oils which have been previously characterized for vanadium and nickel by two or more other techniques: AAS, ICP, NAA, and for % sulfur content by LECO furnace methods. For subsets of the samples we also present replicate digestion results and determinations for small mass samples which mimic bitumens.

Crude oils (ca. 0.1g) are digested under clean conditions in 6.0 ml of HNO_3 in teflon-lined digestion bombs in a pressure controlled microwave digestion oven (CEM MS-81D) at 190 psi for 60 min, and diluted quantitatively to ca. 20 g with nanopure water.

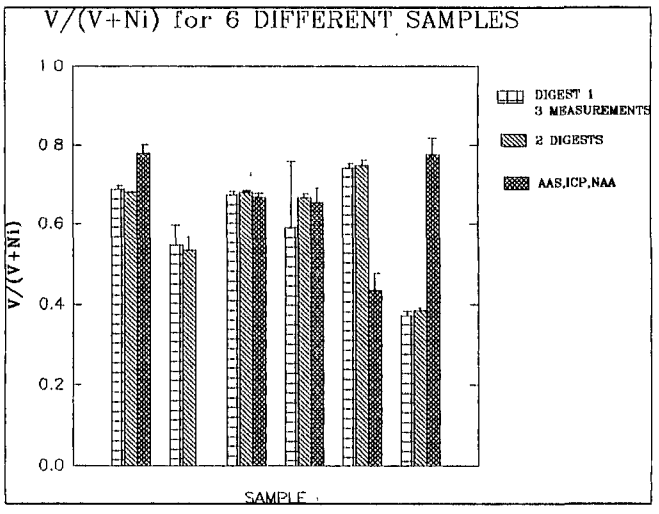
Smaller mass samples are transferred via glass-distilled methylene chloride, digested in small-volume vessels (7 or 3 ml) and diluted to ca. 3 g.

Elemental analysis of V as ^{51}V, Ni as ^{60}Ni and S as ^{34}S is conducted using a Perkin Elmer Sciex ELAN 500 with platinum cones (1250 W RF power, standard Ar flow conditions). Triplicate determinations are performed for each sample.

1 M. C. Kennicutt, et. al, Marine Chemistry 24 39-59 (1988).

MEAN RELATIVE PERCENT STANDARD DEVIATION OR PERCENT RANGE

	V	Ni	S	
1 DIGEST 1 MEAS.	7.56	5.41	24.5	(21 CRUDES)
1 DIGEST 3 MEAS.	14.97	9.24	56.1	(21 CRUDES)
2 DIGEST 1 MEAS. EACH	6.88	5.69	53.9	(8 CRUDES)
AAS, ICP, NAA	5.50	62.75	N/A	('9 "High Range" CRUDES)



We conclude:

1. Microwave HNO_3 digestion followed by ICP-MS analysis results in reported concentrations for V and Ni which generally reproduce values for other methods.

2. Multiple digestions of aliquots of crude oils yield V, Ni and S values concentrations comparable to single digestions.

3. Low mass samples ("bitumens") yield V/(V+Ni) results which reasonably reproduce values for larger samples.

RADIO FREQUENCY POWERED GLOW DISCHARGE MASS SPECTROMETRY UTILIZING A 40.68 MHZ EXCITATION POTENTIAL

Douglas C. Duckworth, D.H. Smith, and R.L. McPherson; Oak Ridge National Laboratory, Oak Ridge, TN 37831

R. Kenneth Marcus and C. Shick; Department of Chemistry, Clemson University, Clemson, SC 29634.

Introduction

Radio frequency (rf) powered glow discharge sources are used to sputter atomize and ionize electrically insulating and conducting materials directly, eliminating the need for matrix modification. We have interfaced a 13.56 MHz glow discharge to a double focusing mass spectrometer (VG9000) and have demonstrated its operation with both alloys and glass matrices. One limitation of rf discharges is modulation of the ion energy. This modulation in energy results from the applied rf excitation potential. We have been able to substantially reduce the ion energy spread, and in this work, we demonstrate this improved performance of the 13.56 MHz glow discharge and compare its operational characteristics to a 40.68 MHz discharge and a dc powered glow discharge.

Experimental

The rf discharge source was interfaced to a VG9000 glow discharge mass spectrometer. This instrument is a double focusing dc powered glow discharge mass spectrometer of reverse geometry. Relative ion energy measurements were performed by scanning the accelerating voltage at constant magnetic field and ESA potential. Significant improvements in the ion energy distributions were observed due to the inclusion of an rf choke in series with the accelerating voltage power supply.

Results

RF modulation, a common problem in rf glow discharge mass spectrometry, is a time-dependent broadening of the ion energy distribution and is related to the rf excitation potential sustaining the discharge. It is often characterized by a broad (20-60eV) saddle-shaped energy distribution. Direct current discharges are characterized by well-defined energy distributions. The relative dc discharge ion energy distribution observed in this study was 11.5eV (FWHM).

RF modulation is usually attributed to modulation of the plasma potential at the rf frequency. RF modulation in our system has been traced to rf potentials superimposed on the accelerating voltage. As mentioned, a high frequency choke has been installed, resulting in greatly reduced ion energy distributions. These distributions are shown below as a function of both excitation frequency and relative pressure at a constant power of 60W. (Actual discharge pressure cannot be measured directly but are expected to be on the order of 0.5-2.0 torr). Energy distributions, measured as FWHM, are not greatly dependent on pressure or frequency and have an nominal 11.5eV energy spread. This is similar to the dc energy distribution; however, symmetry is lacking. Ion energy distributions were found to be independent of power (11.5eV, FWHM).

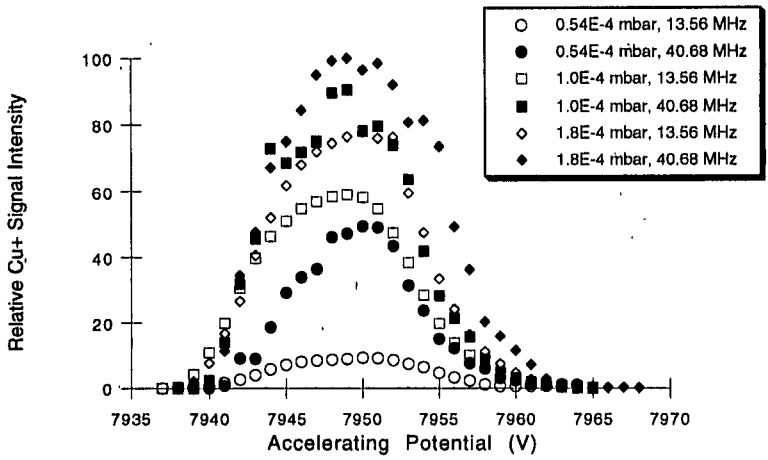
Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes."



This figure also illustrates the direct dependence of the ion current on pressure. Also, for each pressure, the ion current is greater for the 40.68 MHz discharge. Signal intensities at 13.56 MHz are 1.3-5 times less, depending on pressure. Detection limits at 40.68 MHz (8-10 ppb) are better than those of the 13.56 MHz discharge by a factor of 3-5. The 40.68 MHz sensitivity is equivalent to that observed with the dc discharge (1kV, 2mA). Resolution at 13.56 MHz is 1.5-2 times less than the dc, but is a significant improvement. The contours of the energy profiles above provide an indication of the stability of the ion beam which, unlike 13.56 MHz, was very poor at 40.68 MHz. This instability is thought to be associated with incomplete filtering/shielding of the rf noise which is more severe at 40.68 MHz.

The dc self-bias voltages were compared at 40.68 and 13.56 MHz and were found to be linear with power with 13.56 MHz having the greater bias. Sputter rates were also compared due to the discrepancy between dc bias and absolute signal intensity. The average sputter rates for 13.56 MHz, 40.68 MHz, and dc discharges were measured to be 0.85, 2.2, and 8.8 mg/hr, respectively. The fact that the 40.68 MHz discharge has a lower dc bias than the 13.56 MHz discharge but a higher sputter rate is due to more efficient coupling of the rf power at higher frequencies. Although the dc discharge has a higher sputter rate, the dc and the 40.68 MHz discharge have similar signal intensities, demonstrating the high ionization efficiency in the rf plasma.

Ratios of various analytes and other discharge ions to copper as a function of discharge type were measured. No major differences were noted except for the copper-containing molecular ions which were lower in the dc discharge. These may dissociate at the higher dc discharge pressures.

Analyte concentrations in NIST 1103 brass were calculated. Calculations were performed on data generated by all three discharge types using relative sensitivity factors measured at 13.56 MHZ. The results for each discharge source (13.56 MHz, 40.68 MHz, and dc powered) were all within a factor of two of the certified values, indicating similar relative sensitivity factors for the three sources.

Analysis of Copper Alloys by Glow Discharge Mass Spectrometry

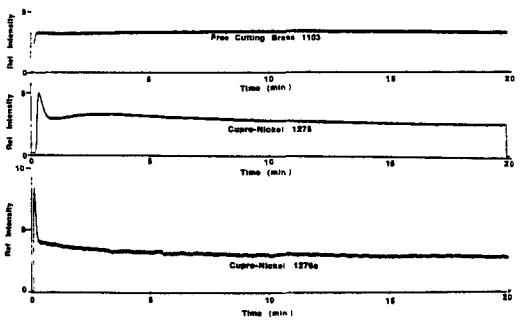
Paula R. Cable, Charles R. Shick, Jr., and R. Kenneth Marcus,
Department of Chemistry, Clemson University, Clemson, SC 29634

Radio frequency glow discharge mass spectrometry has proven to be an effective technique for the analysis of both conductive and nonconductive solid samples. The emphasis in our laboratory has been to develop a family of rf-GDMS sources which will allow for analysis of a wide variety of matrices including glasses, ceramics and alloys, which all present particular problems for the analytical chemist. Glasses and ceramics have two analytical drawbacks; they do not readily lend themselves to solution-based methods, and they are non-conductive by nature. rf-GDMS effectively deals with these adversities in that analyses are performed with no matrix modification and the rf mode of operation overcomes the nonconducting barrier. The other type of compounds which are particularly amenable to rf-GDMS analysis are alloys. These samples are not only multicomponent, but also display a wide range of concentrations of each constituent. We present here results of a study of several copper alloys which proves, by the use of relative sensitivity factors (RSF's) and temporal profiles that the rf-GDMS technique is, in fact, a sensitive, stable method of analysis of alloys.

The study employed NIST Free cutting brass (SRM 1103), NIST Cupro-Nickel (SRM 1275), and NIST Cupro-Nickel (SRM 1276a). The analysis was performed using an Extrel double quadrupole instrument equipped with C50 electronics. The glow discharge source was a six-way cross configuration with a direct insertion probe (DIP) attachment for sample introduction. Spectra were output to an X-Y recorder and were gathered with a time constant of 300 ms and a sweep speed of 1 AMU/s. The temporal stability diagrams were performed in single ion mode with a 1 AMU/s sweep speed and 30 ms time constant. All RSF calculations were performed without the aid of a computer program.

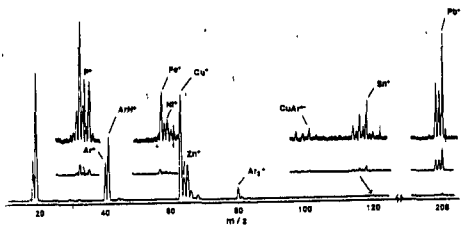
In order to obtain presputter times for the RSF study, break-in plots were recorded for the three alloys used in this study. The results are shown below. NIST SRM 1103 stabilizes in less than 1 minute while NIST SRM 1275 and NIST SRM 1276a require approximately 5 minutes to achieve a steady state signal. Based on these results, each sample was sputtered for 20 minutes prior to collecting RSF data.

Temporal Response of $^{63}Cu^+$ for Various Copper Matrices



Shown below is spectrum of SRM 1103 which typifies scans taken during this study. The presence of H_2O^+ and H_3O^+ at m/z 18 and 19, respectively suggest some signal dampening; however, the relative intensities of all species in the alloy are comparable to certified values. The spectra have been magnified by 10x, 100x, and 1000x respectively, from the bottom to the top of the page. RSF's were calculated based on the major isotopes of each element.

RF Glow Discharge Mass Spectrum of SRM 1103 Brass
at 0.70 Torr



RSF results varied from 0.024 to 5 565 for the range of samples with relative standard deviations from 0.00 to 1.7 within a sample. Intra-sample precisions, defined as [RSF stnd.dev./Avg. x 100, ranged from 1.6-12.7% for all alloys. The calculated concentrations, based on RSF values, closely followed certified values for the three samples.

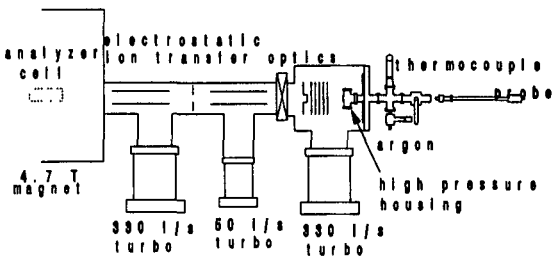
Glow Discharge Ionization on a High Mass Resolution External Ion Source Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

CH Watson[a], CM Barshick[b], J Wronka[a], FH Laukien[a], JR Eyler[b]
[a]Bruker Instruments, Inc., Manning Park, Billerica, Massachusetts, 01821
[b]Oak Ridge National Laboratories, Oak Ridge, Tennessee, 37831
[c]Department of Chemistry, University of Florida, Gainesville, Florida, 32611

This work demonstrates the benefits of coupling a glow discharge source with a Bruker Apex 47e external ion source FT-ICR mass spectrometer to generate high mass resolution data on a series of NIST steel samples. Detection limits for 9 elements in NIST steel samples were determined to range from 100 ppb to 5 ppm. High mass resolution measurements on these elements were in excess of 250,000 (FWHM). Mass accuracies on the order of 1 to 3 ppm were achieved without internal calibration and internal calibrants provided mass accuracies at the sub-ppm level.

An illustration of the glow discharge/external ion source FT-ICR instrument is shown in Figure 1. The glow discharge source is attached in place of the normal source body of a Bruker Apex 47e external ion source FT-ICR mass spectrometer. The instrument is pumped by turbomolecular pumps with separate pumps for the source region (330 l/s), ion optic transfer region (50 l/s), and analyzer region (330 l/s). No additional pumping or modification of the instrument, other than removal of the EI/CI source to accommodate the glow discharge source, was required.

Figure 1. External glow discharge ion source



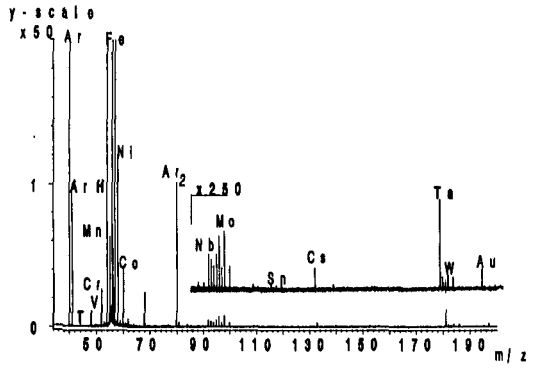
The pressure outside the glow discharge source was maintained at 8 x 10^{-4} torr and an analyzer pressure of 7 x 10^{-9} torr was achieved. Samples were mounted directly on the glow discharge probe and introduced into the glow discharge source housing by means of a standard direct probe insertion port. Analyte materials, usually consisting of metal rods 1 to 3 mm in diameter and 8 to 12 mm long, were held at a potential of -1000 to -1500 volts and sputtered/ionized in the argon atmosphere.

The ions exiting from the high pressure source body were accelerated to 3 kvolts, and focussed through the ion optics into the analyzer cell located inside the bore of a 4.7 tesla superconducting magnet. The ions were accumulated for 20 ms in the ICR analyzer cell and mass analyzed. Broadband data were acquired by digitizing the time-domain spectrum over a mass range of 15 to 1500 amu. High mass resolution measurements made by digitizing the time-domain spectrum for 500 ms over a 2 kHz window.

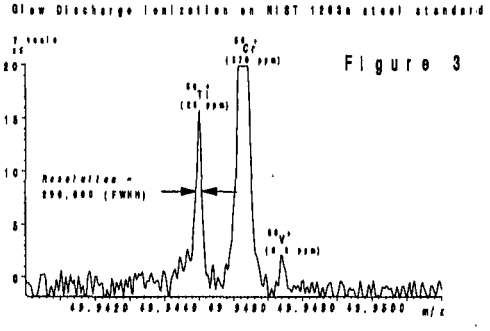
A broadband spectrum of the NIST standard 1261a steel shown in Figure 2 demonstrates the type of information available in a quick survey analysis. This spectrum was obtained by summing

256 transient signals. The y-scale has been expanded to improve the visibility of the components in lower concentration. Here even the isotopic pattern of W is observed at the 53 ppm level.

Figure 2. Glow discharge ionization on NIST 1261A steel standard



To demonstrate the high mass resolution of this technique, a high mass resolution spectrum, m/Δm = 290,000 (FWHH), shown in Figure 3, was obtained around the m/z 50 region from a NIST 1263a steel standard. This spectrum demonstrates the ease with which ICR can resolve the closely spaced metal isotopes at m/z 50 (^{50}Ti, ^{50}Cr, ^{50}V).



A glow discharge ion source coupled with an external ion source FT-ICR mass spectrometer offers high mass resolution that can eliminate problems associated with closely spaced isotopes, provides stable mass calibration, and offers reasonable detection limits. Unlike conventional mass spectrometers, the FT-ICR technique gains sensitivity with higher mass resolution. In addition to the analytical applications the ICR ion trapping ability combined with the glow discharge source is capable of providing a variety of metal ions for subsequent analysis by ion/molecule reactions or other studies.

TEMPORAL EVOLUTION OF ANALYTE IONIZATION IN MODULATED GLOW DISCHARGE MASS SPECTROMETRY

Department of Chemistry, West Virginia University,
Morgantown, West Virginia 26506, U.S.A.

INTRODUCTION

Glow discharge mass spectrometry (GDMS) is a powerful and reliable technique for trace elemental analysis of solid materials. Most GDMS systems operate in a steady-state mode, in which power is applied to the glow discharge, either as a direct current (dc) or an oscillating potential in the radio frequency (rf) range. As an alternative, the glow discharge power can be modulated at a low frequency. The modulation of the plasma permits higher instantaneous operating voltages and currents, resulting in higher sputter yields and enhanced ion signal intensities. In a modulated GD, the fundamental ionization processes vary throughout each on-off cycle of the plasma. This variation permits the temporal separation of analyte signals from background signals, allowing discrimination against spectral interferences.

In this study, a square-wave pulse generator operating at 50 Hz and 25 % duty cycle (5 ms on and 15 ms off) was used to drive a high voltage dc power supply. The resulting temporal ion signals of a selected mass-to-charge ratio were traced with an oscilloscope on a sub-millisecond time scale. The ion signal profiles are compared with the results obtained from time-resolved optical measurements.

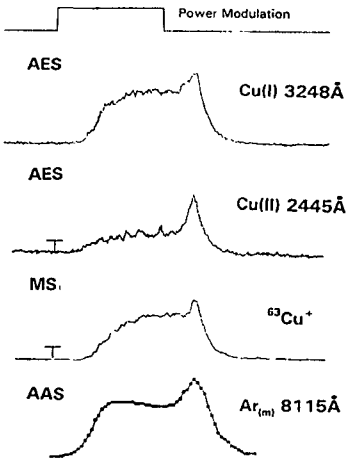

Figure 1. Temporal signal profiles

RESULTS AND DISCUSSION

Figure 1 illustrates the temporal signal profiles observed with atomic emission, ionic emission and mass spectrometry. It is clear that the time-dependent mass spectrometric signal of ionized sputtered species (Cu in this case) increases in intensity soon after the discharge power switches off in each cycle. This is in contrast with the gas species (such as $^{40}Ar^+$, $^{40}Ar^1H^+$, $^1H_2{}^{16}O^+$) ion signals that decay rapidly upon the cessation of discharge power. Atomic emission and ionic emission signals exhibit similar afterpeaks following the pulse termination, demonstrating that the effect is plasma-based and not ion-optics induced. Real-time atomic absorption studies track the argon metastable population during each on-off cycle and reveal a time-resolved population profile similar to that of the ion signals. These results indicate that the increase in metastable argon atom population arises from the recombination of argon ions with slow moving electrons, and that the increase in sputtered ion signals results from the domination of Penning ionization during the post-pulse time regime. In addition, similar ion signal

profiles are observed for metal argide, which are in support of the Associative ionization in the afterglow as well.

Additional experiments were conducted to investigate the role of argon metastable in the discharge plasma. In this study, methane served as a metastable quenching reagent. A controlled amount of CH_4 gas was added to the discharge to reduce the metastable population. It is observed that compared to the plateau region, the afterpeak in argon metastable profile decreased drastically with the addition of CH_4. Similarly, sputtered ion signal profiles exhibit a great reduction of afterpeak with CH_4 addition, A comparison of this effect on signal profiles of $^{63}Cu^+$ and $Ar_{(m)}$ is shown in Figure 2. The results indicate that the chemi-excitation or chemi-dissociation collisions between the argon metastable and methane molecules reduced argon metastable population in the plasma that would otherwise have been available for the ionization of sputtered species. This also demonstrates the dependence of sputtered atom ionization on metastable argon atoms.

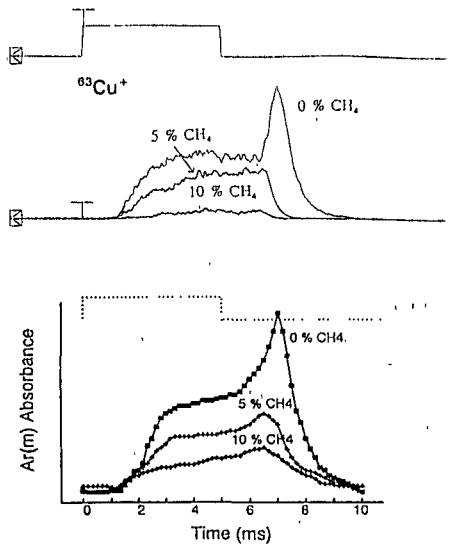

Figure 2. Effect of CH_4 on signal profiles

It is worth noting that the ion profiles are strongly dependent on various operating parameters, such as discharge pressure, power and sampling distance. Minimal afterpeak signal appears for sputtered species at low discharge pressures. The afterpeak/plateau ratio increases with pressure. Metastable argon atoms exhibit a similar pressure-dependent trend in atomic absorption studies. In a constant current mode, decreasing pressure results in an increase in the applied voltage and power. More energetic electrons are present in the plasma, reducing the --- of recombination processes. Investigation of the change in ion signal profiles with variation of the discharge power also reveals that appearance of the afterpeaks occurs at a longer time scale with a higher applied power. For example, the position of the afterpeak shifted from 1.8 ms to 2.25 ms after voltage termination as the power increases from 1.1 W to 7.8 W. This is a result of the energy dependence of the electron collision cross section. The rate of ion-electron recombination decreases as the electron kinetic energy increases. If a high power is applied, it takes longer time for the energetic electrons to slow down and recombine with Ar^+ in the plasma. The sampling distance exerts an influence on the ion profiles of the sputtered species as well. The ratios of afterpeak vs. plateau decrease as this distance increases, in agreement with the observations at the metastable argon atom population. At a sampling distance of 25 mm the afterpeak is not visible in the profile, demonstrating the spatial dependency of the Penning Ionization process.

Sputtered ion signals from two different time-regimes, plateau and afterpeak, were studied in terms of their relative kinetic energy and kinetic energy spread. Ion profiles were observed to change as a function of bias applied to a Bessel Box kinetic energy analyzer.

High Resolution GD-MS for the Qualitative and Quantitative Analysis of all Elements in a Single Experiment.

D.S.Jones, J.R.Chapman and P.A.Ryan

Kratos Analytical, Barton Dock Road, Manchester, M31 2LD

Introduction

This poster presentation describes a new, high performance instrument for glow discharge analysis based on a CONCEPT double-focusing magnetic sector mass spectrometer of forward geometry. The normal operating resolutions are 4,000 and 10,000 (10% valley definition), continuously variable up to at least 20,000 to provide maximum separation of interfering sample components. Transmission loss in changing from 4,000 to 10,000 resolution is less than a factor of 3. Samples can be changed and loaded via a vacuum interlock by means of a probe-based sample holder. Suitable operating pressures are achieved using turbomolecular pumps. This instrument provides:

1. Quantitative data from analyses in the continuous scanning mode. This mode provides detection and quantitation at least at the ppm level for all elements in a single experiment.
2. Accurate mass data to confirm the identification of peaks detected in the survey scanning mode.
3. Quantitative data from analyses in the selected ion monitoring mode. This mode provides detection and quantitation at least at the ppb level for specified elements.
4. Isotope ratio data which may be used to confirm quantitative data acquired in either mode.
5. Linked scan data which may be used to distinguish atomic and molecular ions e.g. M_1^+ from M_2H^+.

Ion Detection

The standard ion detection system is based on a new high performance, high bandwidth pre-amplifier and offers access without gain switching to analogue and pulse counting data from a single multiplier. Count rates up to 10^5 cps are measured by pulse counting while higher count rates are measured by a parallel analogue recording system. Data system control ensures a smooth transition between the two outputs. A dynamic range in excess of 10^9 can be obtained using this system.

Survey Scans (1)

Survey scans at 4,000 or 10,000 resolution offer an analysis from matrix to ppm levels which is complete within less than 15 minutes. The magnet scans used in this mode are highly reproducible so that mass assignments, based on a simple preliminary magnet calibration, are sufficiently precise (Table 1) to be converted directly into an elemental composition for each peak recorded. Full peak profile data is automatically stored during survey scans so that any unresolved components may be examined following scale expansion. Individual components of each unresolved group are also labelled with their composition.

Table 1: Mass and composition assignments from survey scan on NBS steel at 4,000 resolution

Measured Mass	True Mass	Identity	Error amu	Error ppm
97.9057	97.9055	^{98}Mo	0.0002	2
99.9076	99.9076	^{100}Mo	0.0000	0
180.9495	180.9480	^{181}Ta	0.0015	8
181.9485	181.9483	^{182}W	0.0002	1
182.9527	182.9503	^{183}W	0.0024	13
183.9518	183.9510	^{184}W	0.0008	5
185.9545	185.9543	^{186}W	0.0002	1

Survey Scans (2)

The quality and reproducibility of quantitative data obtained with this instrument is illustrated in Table 2. NBS steel 661 was used as calibrant to calculate relative sensitivity factors from scanning experiments at 4,000 resolution. Eight sets of data were acquired over 1 day. Relative sensitivity factors showed less than 5% relative standard deviation. The greatest standard deviation, observed with non-metallic elements such as sulphur, may be associated with concentration of these elements at grain boundaries within the sample. The same Table also shows quantitative data from NBS steel 661 using NBS steel 664 as calibrant. An excellent level of agreement is evident.

Table 2: Relative sensitivity factors and quantitative analysis of NBS steel 661

	RSF		Composition	
Element	Average	% Std Dev	Measured	Certified
Iron	1.00	-	95.66	95.6
Nickel	1.68	2.2	2.01	1.99
Chromium	1.65	4.9	0.692	0.69
Manganese	1.25	1.6	0.655	0.66
Silicon	1.35	4.5	0.228	0.223
Molybdenum	1.06	5.2	0.203	0.190
Copper	3.90	5.1	0.0410	0.042
Cobalt	1.02	1.6	0.0407	0.032
Niobium	0.60	1.3	0.0231	0.022

Tungsten	1.18	1.3	0.0194	0.017
Titanium	0.32	1.8	0.0194	0.020
Sulphur	1.38	4.2	0.0179	0.015
Phosphorus	2.13	4.9	0.0145	0.015
Vanadium	0.57	2.1	0.0108	0.011
Zirconium	-	-	0.0078	0.009

Alternative Experiments

An initial survey scan may be followed by the monitoring of selected ions where the analysis of specific elements at ppb and ppt levels is desired. Excellent sensitivity is available for selected ion monitoring carried out at 10,000 resolution. The data system provides complete software for the quantitation of elements from scanning or selected ion monitoring experiments and for the calculation of relative sensitivity factors for use in these analyses.

Other experiments can be implemented with the software available. For example, linked scanning of the magnetic and electric sectors yields novel types of analytical information. For example, one experiment in this study used the linked scan technique to record ions which decompose by the loss of one mass unit during transit through the analyser. In other words, the scan identified hydride molecular ions, which may interfere with quantitation. In this case, iron (m/z 57) and argon (m/z 41, 37, and 39) hydrides were easily distinguished.

Mercury Determination by GC-MS Using Li Bis(trifluoroethyl)dithiocarbamate as the Chelating Agent

Suresh K. Aggarwal[1,2], Michael Kinter[2] and David A. Herold[1]
[1]VA Medical Center / University of California, San Diego, CA 92161
and [2]University of Virginia, Charlottesville, VA 22908

INTRODUCTION

Organic mercury (Hg) compounds are used as preservatives in paints and agricultural products. Metallic Hg is widely used for industrial purposes and also in dentistry. Recently increased interest has been directed towards the possible adverse effects of Hg in dental work; however, most of the reports did not use optimum analytical methods. Determination of Hg in biological and environmental samples is important because of its toxic effects. The use of stable isotope dilution GC-MS analysis of the chelated Hg would provide an excellent analytical method. However, previous analytical problems with chelated trace metals analyses by GC-MS have been shown to result from memory effects. Hence, it is mandatory to demonstrate the absence of significant memory effects with each element, chelating agent and instrument system.

EXPERIMENTAL

Standards: Mercuric oxide (31.84 atom % ^{196}Hg, Oak Ridge National Laboratory, Oak Ridge, TN) was used as an internal standard for isotope dilution. Enriched ^{196}HgO was dissolved in 1 M HNO_3. Dilute solutions of the internal standard were prepared from this stock solution. The internal standard was calibrated by reverse isotope dilution using natural Hg as the primary standard.

Sample Preparation: For these studies, we used a 20 mM solution of lithium bis(trifluoroethyl)dithiocarbamate, Li(FDEDTC), in an acetate buffer at pH 3 to prepare the $Hg(FDEDTC)_2$.

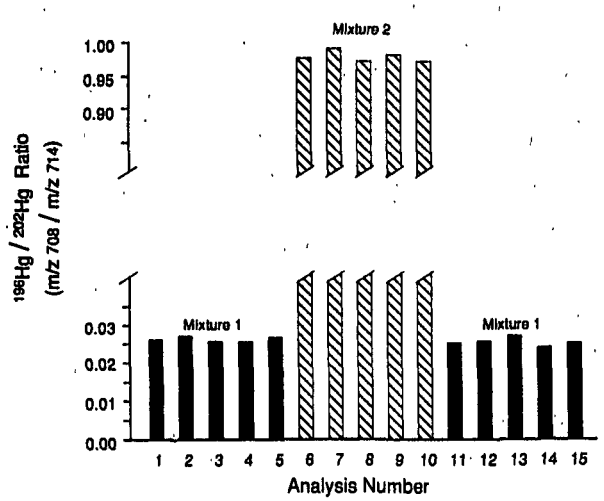
Analysis: A 10m x 0.32mm bonded-phase DB-1 fused silica capillary column was used with on-column injection. The fragmentation pattern of $Hg(FDEDTC)_2$ was obtained using 70 eV electron ionization in a Finnigan MAT-8230 mass spectrometer. The molecular ion was at m/z 714 with associated Hg isotope peaks. Since this was the most abundant Hg containing species, it was used in for the quanitative analysis. Replicate analyses were performed by injecting 1 μL of the chelate in CH_2Cl_2 on several days. Selected ion monitoring with voltage peak switching was used for data acquisition and isotope ratios were determined by integrating the chromatographic peak area.

RESULTS AND DISCUSSION

The sharp symmetrical chromatographic peak and no appreciable memory demonstrated the applicability of Li(FDEDTC) as a chelating agent for Hg determination by GC-MS. Overall precision values of 1.6 to 2.3% were obtained when measuring Hg isotope ratios at 10 ng levels. Memory effect in the sequential analyses of samples with widely different isotope ratios was evaluated by preparing two synthetic mixtures with *m/z* 708 / 714 ratios, corresponding to ^{196}Hg / ^{202}Hg, differing by a factor of 30. Mixtures were prepared by mixing solutions of natural $Hg(NO_3)_2$ and enriched ^{196}HgO (31.84 atom % of ^{196}Hg) dissolved in 1 M HNO_3. The results of the sequential analyses of these two mixtures are shown in the Figure below. The absence of any memory effect and the precision of the replicate measurements of the isotope ratios are clearly demonstrated.

CONCLUSION

Stable isotope dilution GC-MS using Li(FDEDTC) as a chelating agent is a sensitive method for Hg determination. There is no appreciable memory effect and precision is excellent.



GC/MS Method for the Simultaneous Measurement of Plasma Leucine and Proline Enrichments in Tracer Studies

T. E. Chapman, T. Hiramatsu, J. Cortiella, S. Marchini and V.R. Young

Laboratory of Human Nutrition
Clinical Research Center
MIT, Cambridge, MA and
Shriners Burns Institute, Boston, MA.

Leucine and proline kinetics in man were studied using safe, non-radioactive stable isotopically labeled probes. The study is part of a series of protocols exploring dispensable and indispensable amino acid requirements. The method uses [5,5-^{2}H] proline and [1-^{13}C]leucine which are given by the primed constant intravenous isotope infusion technique. Following an infusion for eight hours in the fasted and fed states measurement of the plasma amino acid enrichments was carried out.

Specific extraction of the amino acids was carried out by cation exchange chromatography of200 µl acidified plasma The amino acids were eluted with ammonium hydroxide and eluate evaporated to dryness. A tertiary butyl dimethyl silyl derivative was prepared by heating for 60°C for 60 min with N-methyl-N-(tert-butyl dimethylsilyl) trifluro acetamide. Measurement of plasma amino acid enrichments was carried out on a Hewlett Packard 5988A GC/MS system equipped with a HP5890 Series II gas chromatograph. Chromatography was carried out on a Durabond 1301 fused silica capillary column. Selective ion monitoring was carried out at the M-57 fragment ions at m/z 302.2 and m/z 303.2 for endogenous and [1-^{13}C] leucine,respectively (Figure 1a and 1b). Selective ion monitoring was carried out at the M-57 fragment ions at m/z 286.2 and 288.2 for endogenous and [5,5-^{2}H] proline,respectively(Figure 2a and 2b). After an infusion period of 120 min. an isotopic plateau was reached which was approximately 4 and 2% for leucine and proline respectively. All isotope enrichments were measured against calibration graphs prepared from mixtures containing 0 to 10% enrichments. The slopes for leucine and proline were 0.91 and 0.64 respectively, with correlation coefficients of 0.995 or higher. The y-intercepts were 27 and 9.8%, for leucine and proline, respectively. The reproducibility of the calibration graphs was excellent the coefficient of variation of the slopes was 1.7 and 4.7% (n=12 and 10) for leucine and proline, respectively. The reproducibility of the y-intercept measurement was also high, 0.39 and 0.33 %for leucine and proline, respectively. The intra-assay reproducibility was determined by passing four aliquots of an enriched plasma sample, through the whole analyses, this was 2.5 and 2.1% for leucine and proline, respectively. The inter-assay reproducibility was determined by passing seven samples through the whole analysis over a 6 week period and was 3.2 and 7.0% for leucine and proline respectively. The GC/MS method is an improvement of our earlier one, as both leucine and proline could be measured in the same run. This is in contrast to the previous method where n-acetyl, n-propyl derivatives were prepared, and leucine enrichments measured by electron impact ionization, and proline by chemical ionization.

Calculation of the leucine and proline fluxes were carried out using the rates of isotope infusion and measurement of tracer dilution in plasma. In a normal (control) diet the leucine flux was 115 and 106 µmol/kg/hr in the fasted and fed states,and proline 109 and 111 µmol/kg/hr in the fasted and fed states. However, after a four week diet devoid of proline the leucine flux remained normal at 106 and 101 µmol/kg/hr in the fasted and fed state but the proline flux dropped significantly to 67 and 52 µmol/kg/hr in the fasted and fed states. Previous studies by us indicated that a one week diet devoid of proline did not alter proline kinetics.

HIGH PRECISION ISOTOPE RATIO MEASUREMENTS BY GC/MS

Bruce W. Patterson and Robert R. Wolfe
Shriners Burns Institute and Univ. of Texas Medical Branch, Galveston, TX

Precision is critical when measuring isotope ratios for *in vivo* tracer kinetic studies due to the low levels of enrichments achieved above relatively high natural abundance backgrounds. We have observed that the isotope ratios measured in many applications (fatty acids, glycerol, glucose, etc.) by electron ionization selective ion monitoring gas chromatography/mass spectrometry may have as much as 5% relative error between and within runs. In this report we demonstrate that several instrument tuning parameters affect the sensitivity, accuracy, and precision of isotope ratio measurements for methyl palmitate at natural abundance.

Isotope ratios were measured on a Hewlett-Packard 5971A Mass Selective Detector quadrupole interfaced to a model 5890 GC equipped with a 5 m x 0.25 mm HP-1 capillary column. One μl volumes of methyl palmitate [$(m+0)^+$ ion MW = 270.255] (0.2 to 2.0 mM in heptane; 54-540 ng) were injected. Electron ionization (70 eV) was performed using selective ion monitoring (SIM) for the molecular ion cluster at *m/e* 270.25, 271.25 and 272.25. Tuning performance was optimized on the 264 amu ion of PFTBA.

Following a standard mid-mass AutoTune for optimum 264 amu performance, the (m+1)/(m+0) ratio varied between 18.5% (54 ng sample injected) and 20.1% (540 ng) (n=6 samples in concentration series). Taken as independent replicate measures, the 271/270 ratio averaged 19.21 ± 0.54% (relative error, 2.8%). Isotope ratios were strongly positively correlated with concentration, such that there was little scatter of the data points around the concentration trend. Thus, the precision inherent in the isotope ratio measurements would be much higher if the concentration dependency could be eliminated or corrected for on a theoretical basis.

The sensitivity of isotope ratios to sample concentration was altered between repeller voltage settings of 12, 15 (AutoTune value) and 19.8 V (the maximum limit) at a constant spectral resolution peak width of 0.6 amu (see Figure 1). Increasing repeller voltage increased the sensitivity (larger peak areas), and reduced the dependence of isotope ratio on peak area. A repeller setting of 19.8 V was used for all further studies.

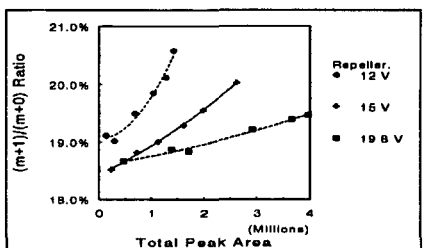

Figure 1

The effect of varying the mass spectral resolution (peak width) on isotope ratios was initially evaluated using the PFTBA tuning compound. The peak width (width of the 264 ion at half-height) was varied from 0.3 to 0.7 amu. Repeller and electron multiplier voltages were kept constant. The sensitivity increased 4-fold over this range. The accuracy of the isotope ratio was dependent on spectral peak width. The PFTBA isotope ratio (265 ion/264 ion) was elevated at small peak widths (ratio = 6.5 % at peak width 0.3 amu), and approximated the theoretical value for the $C_5F_{10}N$ ion (5.82%) at the largest peak width examined.

The concentration dependence of methyl palmitate isotope ratios was evaluated for different spectral peak widths (see Figure 2). As with PFTBA, peak widths ≥ 0.6 resulted in increased sensitivity and improved accuracy for methyl palmitate isotope ratios compared to the nominal AutoTune peak width of 0.50 amu. Although still concentration dependent, the theoretical (m+1)/(m+0) ratio (19.0%)

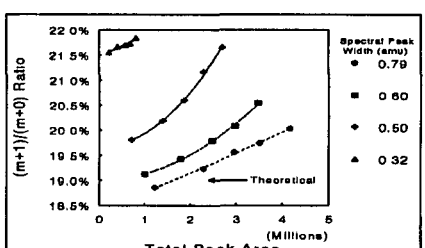

Figure 2

was observed at low concentration only for larger peak widths. However, peak width alterations did not substantially alter the concentration dependency of isotope ratios.

The calibration of the mass axis was found to affect the accuracy of isotope ratios. To simulate this, the instrument was first tuned manually (repeller = 19.8 V, 264 peak width = 0.6 amu) with the mass axis calibrated to the PFTBA tuning ion at mass 264.00 amu. The SIM method was then altered to assign various mass defects to the $(m+0)^+$ ion (see Figure 3). The mass defect of 0.25 (closest to the calculated MW of 270.255) resulted in the highest isotope ratios which most closely approximated the theoretical value at low concentration. Mass defects ± 0.05 amu from this target reduced the ratios slightly, and mass defects of ± 0.15 from this target further reduced the ratios (the value of 270.10 also had an altered concentration dependency).

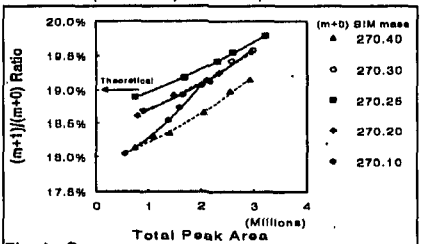

Figure 3

Within-run variations in isotope ratio in this study resulted from a 2nd order concentration dependent non-linearity. A linear fit of $(m+1)^+$ areas vs. $(m+0)^+$ areas from the ratio values reported above as though they were independent replicate measures resulted in systematic deviations and a non-zero intercept (r^2 = 0.99928), whereas a 2nd polynomial provided a zero intercept and a nearly perfect fit (r^2 = 0.999992):

$$Area_{271} = (0.1820 \pm 0.0006) \times Area_{270} + (8.43 \pm 0.32) \times 10^{-9} \times (Area_{270})^2$$

The concentration-corrected isotope ratio for this sample would thus be the 1st order coefficient (18.20 ± 0.06%, relative error of 0.3%); this is an order of magnitude less relative error than the replicate isotope ratio measures described above.

At this time we cannot be certain of the mechanism(s) responsible for this non-linearity. However, our data is consistent with the possibility that hydride abstraction during ion-molecule reactions may be occurring, whereby $(m+0)^+$ ions abstract a hydrogen from uncharged molecules and are converted to $(m+1)^+$ ions. The frequency of ion-molecule reactions decreases with larger repeller voltages as the residence time of ions in the source is reduced; we observed a decreased concentration dependence with increasing repeller voltage (Figure 1). We also observed that the dependence of $(m+1)^+$ peak area on $(m+0)^+$ peak area was exactly described by a 2nd order curve, again consistent with an ion-molecule collision reaction which is expected to follow 2nd order kinetics.

We conclude that the standard AutoTune function does not provide reproducible and accurate isotope ratios for methyl palmitate at natural abundance for this instrument. Significant improvements in sensitivity and accuracy are obtained by increasing the repeller voltage and spectral peak widths. Between-run variations in isotope ratios are largely caused by very minor differences in spectral peak widths and mass axis calibration tuning conditions which lead to inaccuracies in isotope ratio measurements. Significant improvements will result from the use of very stringent criteria for setting spectral peak width and mass axis calibration with manual tuning rather than using the AutoTune function. Within-run variation in methyl palmitate isotope ratios is largely due to a 2nd order concentration dependency between isotopomer peak areas. This effect was reduced (but not eliminated) by increasing the repeller voltage which should reduce the frequency of ion-molecule collisions. Isotope ratios can be determined from the first-order term resulting from a second-order fit between measured peak areas for different amounts of sample analyzed, thereby mathematically eliminating the concentration dependency.

A New Ion Counting Device for Simultaneuos Isotope Ratio MS

H.-J. Laue, P. Bach, Finnigan MAT GmbH

INTRODUCTION

The isotopic analysis of cometary matter requires the investigation of particles in the size of 10 µg or less. The grains of interest are unadultered primary condensates from the stars in which the elements were produced (stardust). To analyse these individual grains, an isotopic ratio mass spectrometer with a specialized performance is needed.

EXPERIMENTAL REQUIREMENTS

The number of the registered ions is the entity which determines the ultimate precision of the measurement. Measurements with a statistical uncertainty of 1% require 10^4 ions of the particular isotope to be registered. Taking into account the relative abundance of this particular isotope, the abundance of the element to be measured in the grain and the ionisation yield of the ion source, the grain then must have a mass of 10^9 atoms at least which corresponds to a midsized grain of about 10^{-13} g depending on the atomic weight of the element [BEG1]. The whole sample has to be used for the measurement. Running a sample to exhaustion may not appear difficult [CAL2]. If one minute is assumed to be the minimum reasonable time period for a single measurement, one has to handle an ion beam of $3*10^{-17}$ A, which clearly is by far too low for using a Faraday-cup as a collecting device. Ion counting is necessary.

To avoid contamination, handling of the cometary samples should be kept to a minimum. If possible, the crystals should be loaded directly onto the evaporation filament in the ion source without any chemical treatment. Knowing that the direct loading technique may cause sudden increases of the ion beam (so called bursts), it is absolutely necessary to employ a mass spectrometer which allows to measure all the different isotopes of interest simultaneously in order not to loose a significant quantity of ions by peak jumping.

This means, the detecting device which is necessary for this kind of experiments should be a multiple channel ion counting detector with its channels being able to be adjusted corresponding to the different masses of the isotopes.

EXPERIMENTAL SET UP

We now use up to six newly developed detector channels which may be equipped with either a channeltron used as a counting detector or a Faraday-cup if more intensive ion beams are expected at this channel location. A center channel can be operated either in counting mode or Faraday mode. Switching the mode is possible during the operation of the instrument. The channeltrons are independently connected to computer controlled adjustable high voltage power supplies. The carefully shielded signal lines of the channeltrons are connected via vacuum BNC-feedthroughs with special signal preamplifiers, discriminators and signalshapers to their individual pulse counters. Special emphasis was given to achieve a constant dead time in order to correct the results in agreement with the poisson statistics [BAY3].

RESULTS

An ion entering a channeltron causes a countable signal at the feedthrough. The intensity of this signal is typically 60 mV height and 8ns (FWHM) width measured on 50 Ω. The noise of the signal line is typically less than 0.25 mV causing an average darknoise of the system, which is less than 0.1 cps per channel. The darknoise is measured by closing the beam valve having all the high voltages still switched on and integrating the registered counts for some minutes. Short pulses of less than 10 ns width should allow to measure count rates up to 10^6 cps and should still have a reasonable ratio of duty cycle to idle time which make mathematical corrections meaningful. However, exposing the channeltrons for a longer period of time to relatively high ion currents causes a decrease in the intensity of the pulse height at the end of the channeltron by a factor of two. Measurements should therefore not exceed higher pulse rates than $5*10^5$ cps for a longer period of time.

Cross talk from one channel to the other, which occurs necessarily by using channel plates as counting elements has not been observed [WAC4]. The abundance sensitivity is about 2*10-6 for uranium isotopes as in the standard MAT 262 instrument equipped with Faraday cups.

The stability of the channeltron gain is measured by using a known standard ratio of two isotopes. One isotope is measured in a Faraday cup, the other one is investigated in a channeltron. The measured ratio is then compared with the theoretical value. The channeltron gain changes typically less than 2% in one hour.

Calibrating of the channeltrons happens either by jumping an individual ion beam into the different channels or with a known ratio of a reference sample.

Measurements of the uranium isotopes are possible by moving the channels close to the center channel, whereas measurements of atoms with smaller atomic weight require the positioning of the channels with a certain distance from the center channel depending on the mass to be measured. While adjusting the channels, it is not necessary to switch off the high voltages of the channeltrons. Measurement of the Uranium standard U005 were achieved by registering mass 238 in a Faraday-cup, whereas all the minor isotops were registered in counting channeltrons. In spite of the low intensity of the minor isotopes of typically less than 1000 cps, the results were in good agreement with the specified values with a standard deviation of less than 2%.

CONCLUSION

Improvements obtained so far by testing the multiple ion counting device make further investigations promising. Chances are high, that this device will help to investigate the isotope ratio of cometary matter.

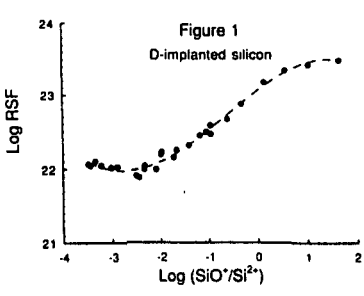
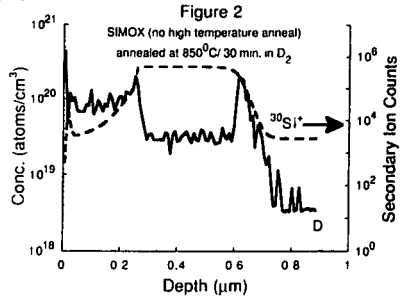
SIMOX (separation by implanted oxygen) material has been widely used in silicon-on-insulator (SOI) technology because of its radiation-hardening performance and the high speed and low power usage of devices made on it. The starting material is made from an n-type Si(100) wafer that was implanted with oxygen at doses ranging from 1.8 $\times 10^{18}$ to 2.0 $\times 10^{18}$ atoms/cm^2, and at energies from 150 to 200 keV. Subsequent annealing of this material at high temperature is necessary to reduce the crystalline damage caused by the high-dose oxygen implantation, and to create a stoichiometric SiO_2 layer beneath the silicon layer. In the annealing processes, the impurities from the furnace tube and the annealing gas species can be incorporated into the material[1]. These impurities, even at low levels, can degrade device performance. In this study, we annealed the SIMOX samples in deuterium gas at 850^{0}C and 1000^{0}C, and used secondary ion mass spectrometry (SIMS) to quantify the deuterium concentration with depth for these annealing conditions.

Depth profiles of D in annealed and unannealed SIMOX were obtained with a secondary ion microscope using a focused and rastered argon primary ion beam. To quantify the deuterium concentration at the Si/SiO_2 interface, we generate the relative sensitivity factors of D in silicon as a function of oxygen backfill pressure using argon bombardment of a D-implanted silicon sample. The primary current for all measurements was kept constant at 1 μA while the oxygen backfill pressure was varied between 2.3 $\times 10^{-5}$ and 2.0$\times 10^{-2}$ Pa. We monitored D^+, Si^{2+}, $^{30}Si^+$, and SiO^+ in all depth profiles. For each oxygen backfill pressure, we calculated the sensitivity factor of D relative to Si and the matrix ion species ratio (MISR)[2] SiO^+/Si^{2+}. Fig. 1 shows a plot of deuterium RSF vs. the matrix ion species ratio (SiO^+/Si^{2+}). The RSF values are nearly constant for MISR values between 10^{-4} and 10^{-2} (unoxidized Si). Log RSF values show a linear dependence on log MISR for MISR values between 10^{-2} and 10^1, as the Si becomes more highly oxidized.





The RSF calibration curve generated from the data in Fig. 1 can be approximated by a fourth-order polynomial function:

$$\log(RSF) = 23.051 + 0.520x + 0.071x^2 - 0.050x^3 - 0.0031x^4 \quad (1)$$

where x is $\log(SiO^+/Si^{2+})$. The point-by-point deuterium RSF through the SIMOX structure can be calculated via equation (1).

The deuterium profile of the SIMOX sample that had not undergone high temperature annealing (HTA) but was annealed at 850°C for 30 min. in deuterium is shown in Fig. 2. The D levels are at 7×10^{19}, 3×10^{19}, and 3×10^{18} atoms/cm^3 in the damaged Si, SiO_2, and Si substrate, respectively. There is a substantial amount of deuterium pile-up at the Si/SiO_2 interfaces. Fig. 3 shows the HTA SIMOX sample that was also annealed at 1000°C for 30 min. in D_2. Most of the deuterium has diffused through the upper silicon layer and is retained in the SiO_2 layer (3×10^{19} atoms/cm^3). Again, we see a substantial amount of the deuterium piling up at the Si/SiO_2 interfaces. Figure 4 shows the deuterium profile of a HTA SIMOX sample that has not undergone deuterium treatment. In this sample the deuterium is at the instrumental background level for these analytical conditions.

Figure 3

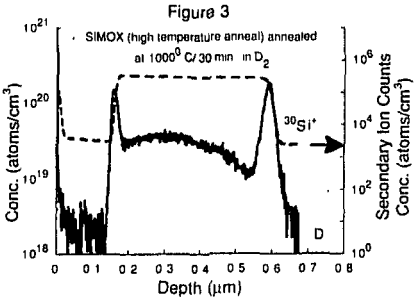


Figure 4

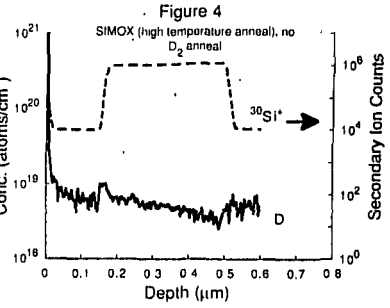

In summary, we have found in this study that the deuterium from D_2 gas, intentionally introduced during annealing of SIMOX at 850°C and 1000°C, is diffused into the SiO_2 layer and accumulates at the SiO_2/Si interfaces.

Multi-layered structured samples of 0.5 μm Al-Si(1%)-Cu(0.5%) / 0.1 μm Ti(10%)-W(90%) / 0.04 μm Ti / Si(100) substrate were fabricated using sputtering deposition process.[1] Portion of these raw samples were subjected to annealing treatment at 450°C to obtain the annealed samples. Secondary ion mass spectrometry (SIMS) was used to analyze these multi-layered samples. The information about elemental redistribution caused by the annealing treatment is inferred from the depth profiles. The implications of interfacial diffusion upon annealing are discussed.

SIMS depth profiles were performed on a CAMECA IMS-4f using both oxygen and cesium primary beams with the impact energy of 8 keV and 14.5 keV for positive (O_2^+/POS) and negative (Cs^+/NEG) secondary ions respectively. Both normal resolution (M/ΔM = 300) and high resolution (M/ΔM = 4000) modes were used. The crater depths were measured with a Dektak 3030 profilometer. The sputtering time, x-axis, of all profiles were converted into depth. In this conversion process, usually only the final depth was needed to convert the sputtering time into depth scale. For multi-layered samples, however, the sputtering rate might be changed dramatically from layer to layer. To remedy this problem, in this study the entire depth was reconstructed by using several sputtering depths.

During the depth profile process, the sputtering rates of the raw samples were much higher than those obtained from the annealed samples. This might be attributed to the recrystallization of the sample upon annealing. Both the O_2^+/POS (Fig.1) and Cs^+/NEG (Fig.2) distribution profiles of the raw samples show that the major components such as Al, Si,

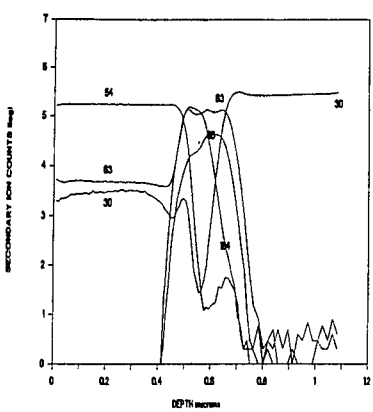

Fig.1 Depth profile of raw sample under O_2^+/POS mode in normal resolution

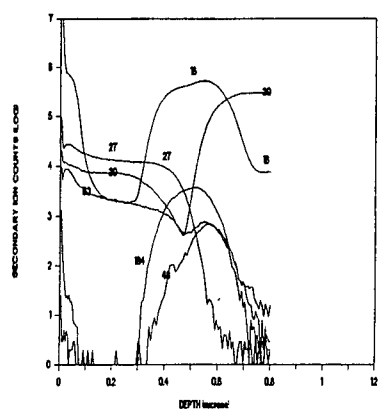

Fig.2 Depth profile of raw sample under Cs^+/NEG mode in normal resolution

Ti, W and Si (substrate) all have normal distributions. Sharp decay at the interfacial region is noticed under O_2^+ beam. However, the ^{63}Cu shows an abnormal distribution with depth down to 0.7 μm. According to the sample structure, Cu should only exist at the Al-Si-Cu layer which is the top 0.5 μm layer. It was reported that ^{63}Cu is readily interfered by ^{63}TiO.[2] High resolution profile (Fig.3) reveals that an abnormal high abundance of m/z 63 from 0.4 μm to 0.7 μm depth below the surface was mainly due to TiO, but not Cu. The O profile measured with Cs^+ beam indicates the presence of O on the sample surface and Al-Si-Cu/TiW interface. The interfacial O may be incorporated during the layer deposition process or absorbed from the residual environment during the SIMS analysis. The latter cause is also responsible for the poor detection limits of O. A peculiar peak of Si profile at the Al-Si-Cu/TiW interface is noticed under both O_2^+/POS and Cs^+/POS modes. However, this phenomenon does not occur under the Cs^+/NEG mode. The cause is still not clear.

Upon annealing, the profiles of Al, Cu, Ti, and W show pronounced tailings (Fig.4). Diffusions to the upper layer are also observed with the profiles of Ti, W, Si and O. Detailed analysis of the W and Si profiles reveals that the Al-Si-Cu layer is rich in W and depleted of Si. These depleted Si diffuse to the Al-Si-Cu/TiW interface evidenced by the unusual interfacial peak. This accords with the literature report that interfacial Si nodules are formed by Si diffusion.[3]

The Accurate Analysis of Lead in Blood - Standards and Methods Development.

*R.D. Vocke, K.E. Murphy and P.J. Paulsen,
National Institute of Standards & Technology,
Inorganic Analytical Research Division, Gaithersburg, MD 20899

Lead poisoning has been recognized as the nation's No. 1 environmental threat to children and blood lead content is considered to be the most reliable indicator of exposure to elevated amounts of lead. As the new CDC action levels move to lower concentrations, the analysis of lead in blood becomes a daunting challenge, as the most commonly used methods in the U.S. (Electro-thermal atomization atomic absorption, Delves-cup atomic absorption and Anodic stripping voltammetry) are comparative methods that are both matrix and standard dependant. When units of SRM 955 (Lead in Porcine Blood) were no longer available, CDC supplied NIST with four levels of a bovine blood containing endogenous lead. NIST has characterized and certified this material resulting in the issuance of a new standard for Pb in Blood (SRM 955a). The certification of this standard was done by isotope dilution mass spectrometry (IDMS) using an Inductively Coupled Plasma Mass Spectrometer (ICP-MS). The relatively simple chemistry required for the ICP-MS facilitate control of Pb blanks. A rigorous measurement protocol ensured Pb concentration data of a quality comparable to that obtainable by TIMS. The table above summarizes the data for the four levels.

SRM 955a - Lead in Blood

Vial No.	µg/dL	µmol/L
955a-1	5.01 ± 0.09	0.242 ± 0.004
955a-2	13.53 ± 0.13	0.653 ± 0.006
955a-3	30.63 ± 0.32	1.478 ± 0.015
955a-4	54.43 ± 0.38	2.627 ± 0.018

Note: The uncertainties are 95%/95% statistical tolerance intervals and reflect the combined effects of measurement imprecision and variability of actual lead concentration among vials.

Prior to issue, this standard was used in a round-robin to assess the status of analytical quality in *the public health and private laboratories where the less accurate and matrix dependent* instrumentation are typically employed. Twenty one participants provided data that suggest that the various state proficiency programs and the CDC Blood Lead Level Reference System have made major progress in improving the quality of blood lead measurements. The data suggest that uncertainties in the ±10% range may be attainable for these methods, even at the lower blood lead levels.

We are developing a more precise and accurate method for Pb determination based on a simplification of the technique of IDMS. Traditional IDMS for an isotopically variable element like Pb requires two separate analyses to fully characterize a sample. Using a ^{204}Pb spike and capitalizing on the low and relatively constant abundance of ^{204}Pb in nature, a <u>single</u> analysis of a spiked sample should give not only an accurate Pb abundance over a wide concentration range, but also the sample's Pb isotopic composition.

Boron Determinations in Botanical Materials Using ICP-MS Isotope Dilution, E. S. Beary and P. J. Paulsen, NIST, Gaithersburg MD, 20899.

Boron was certified in three new botanical SRMs (Peach, Apple and Tomato Leaves) using inductively coupled plasma mass spectrometry (ICP-MS) quantified by isotope dilution. Boron is an essential trace element in human nutrition, and is present at homeostatic levels in plants. It is used in several commercial industries; in the preparations of disinfectants and drugs, and in the production of the chemically stable borosilicate glass. Boron is also used as an additive in rocket fuel, hard and refractory alloys and high quality steels. Industries, from cosmetics to steels, require accurate and precise boron determinations.

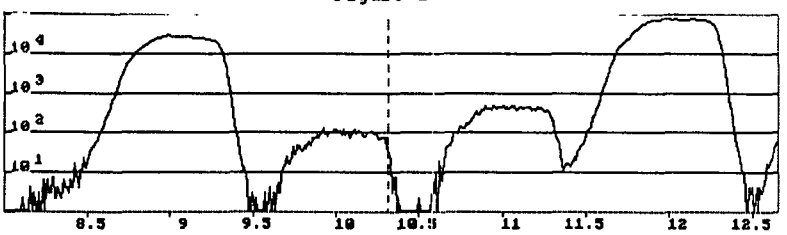
Accurate quantitation of boron is difficult by any analytical technique requiring chemical pretreatment, since boron compounds are known to be volatile. We used ICP-MS isotope dilution in order to minimize the effects of boron volatility. In isotope dilution an enriched isotope of the element of interest, in this case ^{10}B, is added to the sample. Quantitative data are based on the measured isotope ratio established during dissolution/isotopic equilibration and not quantitative recovery of the analyte. This provides tremendous analytical leverage for the determination of volatile elements, and since the boron present in botanical materials is easily solubilized, boron losses are not likely to occur prior to isotopic equilibration. Mannitol has been used to prevent boron losses in non-oxidizing media. It is not effective during wet oxidation of organic materials since the mannitol is decomposed along with the matrix. In our experiments we compared dissolutions in traditional teflon beakers, teflon bombs and quartz flasks with condensers. In test samples, recoveries were variable (20-100%) while analytical results had precisions of 1-2% rsd. The experiments indicated that all of the volatile loss occurred during the evaporation step and after dissolution/isotopic equilibration. In the analysis of Peach and Apple Leaves we compared open beaker dissolution with closed system dissolution in a teflon bomb. The Tomato Leaves were dissolved in quartz flasks fitted with condensers. For the analytical samples, harsh evaporations were avoided in all three dissolution systems.

The volatility of boron is also a problem in its instrumental measurement. One of the symptoms of volatility is growing signal intensity as well as a changing isotope ratio due to cross contamination. During a six minute mass spectrometric run of a spiked tomato leaf sample at pH 2, the signal intensity increased almost 70%, and the precision (rsd) on the measured isotope ratio was more than 14%. It was evident from this experiment that cross contamination of samples can occur. Therefore, an appropriate wash solution was essential to accurate boron determinations. Wash solutions containing HNO_3, HCl and NH_4OH with and without mannitol were tested. The NH_4OH/mannitol solution provided optimum washout and the lowest background. In addition, this solution was

effective in preventing the deposit of sample in the tubing and/or nebulizer and spray chamber of the ICP-MS. Therefore, all dissolved samples were neutralized with NH_4OH and redissolved in 2% NH_4OH/mannitol solution prior to introduction into the ICP-MS.

The second potential instrumental problem relates to the shape and size of the ^{12}C peak relative to the ^{11}B. Since complete decomposition of the organic matrix was sacrificed to avoid very large boron losses (up to 80% loss can occur during aggressive decomposition procedures), considerable carbon remained and was a possible source of biased results. Imprecise data which are biased high would indicate that this potential source of error was not in control. For this reason we monitored the size and shape of the ^{12}C peak in each sample. The shape of the ^{12}C peak was compared to the ^{9}Be peak as shown in Figure 1.

Figure 1



A summary of the boron results in botanical SRMs are shown in Table 1. The precision on each analysis was better than 1.5% rsd. The average blank was about 170 ng using the teflon digestion systems (Peach/Apple) and 300 ng using the quartz apparatus (Tomato). The ^{10}B spike was calibrated against two gravimetrically prepared solutions of SRM 951, H_3BO_3. Aliquots of the natural solutions were mixed with aliquots of the spike, and isotope ratios were measured. The spike concentration was calculated to be 4.52812 µmol/g with a precision of 0.28%. These results are indicative of the precision attainable by ICP-MS.

Table 1. Concentration of B in Leaves µg/g

Leaves	Average	RSD	n
Peach Leaves	29.45	0.8%	6
Apple Leaves	25.88	1.4%	5
Citrus Leaves (control)	29.3	----	1
Tomato Leaves	33.46	1.26%	6
Peach Leaves (control)	29.17	----	2

Gas-phase Ionization of Chromium Hexacarbonyl by Cesium Fast Atom Bombardment

Toshihide Nishimura*, Russell H. Robins†, and Wayne K. Duholke†
Control Research & Development, Upjohn Pharmaceuticals Limited, 23-Wadai, Tsukuba-city, Ibaraki 300-42 Japan; †The Upjohn Company, Kalamazoo, MI 49008 U. S. A.

Since Barbar et al. first demonstrated that the fast atom bombardment technique can ionize large polar and nonvolatile compounds whereas their mass spectra were not attained until then, FAB ionization has thus been a powerful means for molecular weight determination of biomolecules and their structure elucidation. This ionization technique has been referred as a soft ionization due to particle bombardment to a liquid matrix resulting in a predominant formation of molecular protonated ions. Numerous discussions have appeared on where and how $[M^+]$ and $[MH^{+\cdot}]$ are formed in FAB ionization. Williams et al., Bursey et al., and Spiteller et al. suggested that $[M^+]$ and $[MH^{+\cdot}]$ ions are already present in a matrix and are sputtered by fast atom bombardment without ionizing neutral species. Similarly, Cooks and co-workers suggested that FAB mass spectra of neutral molecules can be understood by high secondary ion yields when these are existing as ionic species in the matrix. Spiteller et al. showed that liquid compounds containing no acidic hydrogens result in the production of $[M^{+\cdot}]$ ions highly energetic with low yield by fast atom bombardment. On the other hand, it has been noticed since early stage of FAB ionization studies that the electron ionization (EI)-like fragment ions are also intensively observed in FAB mass spectra which seem to result from so-called gas-phase FAB ionization. This gas-phase FAB ionization seems to be greatly responsible for 'hard' aspects of FAB ionization, and therefore we have investigated fragmentation of the chromium hexacarbonyl ion and have extracted internal energy distributions of this molecular ion using knowledge of the breakdown diagram given by threshold photoelectron-photoion coincidence spectroscopy.

Theories for collisional translational-vibrational energy transfer predicts that the single collisional excitation probability for the vibrational excitation $v_n \rightarrow v_{n+1}$ accompanying the energy transfer of $\mathscr{E}$, can be described by

$$P_{n,n+1} = (n+1)\,\zeta\, exp(-\zeta) \qquad (1)$$

using the adiabatic parameter ζ when a species being excited is treated as one-dimensional harmonic oscillator. The plot of $ln\,(P/\mathscr{E})$ against $\mathscr{E}$, therefore, should be linear with a "negative" slope. An excitation mechanism occurring in collision-induced dissociation (CID) mass spectrometry could be explained by such the translational-vibrational energy transfer. However, such plots of experimental internal distributions for gas-phase FAB mass spectra (Fig. 1) have revealed a linearity but with a "positive" slope (Fig. 2), and different acceleration voltages at a FAB source did not influence on internal energy distributions. These results attained above seem to suggest a possible occurrence of resonant ionization resulting from ion-molecule reaction between an active species and a target molecule as follows:

A resonant ionization mechanism for a molecule M due to energy transfer from an active species A^{**}, which could be an super-excited atom or an ion, approximates its excitation probability as

$$P \propto \mathscr{E}\, exp(\beta\,(\mathscr{E} - \mathscr{E}' + IP)) \qquad (2)$$

where IP is the ionization potential of a molecule, $\mathscr{E}'$ is the internal excitation energy of an active species to be transferred, E' is the transferred energy to the molecule, and β is the positive coefficient in the energy gap law. Therefore, the plot of $ln\,(P/\mathscr{E})$ against $\mathscr{E}$ should become linear as indeed shown by our experimental results although ionization to higher electronic states of the molecular ion could complicate ionization cross section.

Possible resonant ionizations include the Penning and charge exchange processes. Penning ionization is one of reactions caused by an atom excited to a state of a large quantum number which is called a highly excited Rydberg atom (A^{**}). Since one Rydberg electron is separated far from the ion core, any Rydberg atom behaves like a hydrogen. Lifetime of an Rydberg atom is approximately proportional to its principal quantum number, and its enormous size often results in very considerably high cross sections for its collisional reactions. Among them Penning ionization of the target molecule, M, by xenon and helium are wellknown:

$$A^{**} + M \rightarrow A + M^{+} + e^{-}, \qquad (3)$$

However, knowledge of a super-excited cesium atom leading to a Penning process has been known little

although the associative ionizations of the Rydberg cesium atoms of $8\,^2P_{1/2}$ were reported.

The charge exchange process occurs due to a resonant transfer of the recombination energy of $A^+ + e^- \rightarrow A$ to a target molecule M:

$$A^+ + M \rightarrow A + M^+ . \qquad (4)$$

However, Cs^+ can not ionize organic molecules because of its low recombination energy (RE) of 3.89 eV although that due to the doubly charged cesium ion remains as a possible candidate since its maximum recombination energy

$$Cs^{++} + e^- \rightarrow Cs^+ , \qquad RE = 21.2\ eV \qquad (5)$$

is sufficient to ionize organic molecules. Identification of such an active species or ionization mechanism, further investigation will be required on FAB beams.

ACKNOWLEDGMENTS We gratefully acknowledge Drs. A. J. Taraszka, J. B. Landis, and A. Sonoda for their support of this work under the delocalized project for technology development on mass spectrometry.

Introduction

Although the energetic structure of CO^{2+} has been the subject of a number of theoretical and experimental investigations, there is still some ambiguity concerning the configuration of the ground state. Several recent theoretical studies have computed that the lowest lying $^3\Pi$ and $^1\Sigma^+$ states cross in the Franck-Condon region [1-4]. Two of these investigations identified the $^3\Pi$ state as the ground state [1,2] while two calculate that the $^1\Sigma^+$ state lies slightly lower at the equilibrium radius of the CO molecule [3,4].

In the present study, double charge transfer (DCT) spectroscopy has been used to measure the double ionisation energies of CO^{2+}. As spin is conserved in reactions between small ions and small molecules, a judicious choice of the projectile ion enables the multiplicity of the states populated to be chosen. In the present investigation, triplet projectile ions were used to measure the energy of the $^3\Pi$ state. As experimental and theoretical evidence places the energy of the $^3\Pi$ state at 41.1 ±0.5 eV, a projectile ion with a high ionisation energy and electron affinity (F^+) was chosen as this leads to an increase in the cross-section for the population of dication states in the higher energy bracket. As a large discrepency (more than 2 eV) exists in the results of three previous DCT studies which investigated singlet states of CO^{2+}, H^+ projectile ions were also used to determine the energies of the lower singlet states of this dication.

Experimental

The experiments were carried out on a ZAB-2F mass spectrometer. H^+ and F^+ ions were generated by dissociative electron ionisation of H_2O and CHF_3 respectively in a combined EI/CI source and were accelerated to a translational energy of 5 keV. Calibration of the energy loss scale was achieved by repeating the experiments using Ar as the collision gas. Unless stated otherwise, the uncertainties in the double ionisation energies determined in this study are ±0.5 eV.

Results and Discussion

Fig.1 shows the spectra obtained when F^+ ions (Fig.1a) and H^+ ions (Fig.1b) were incident on CO molecules. Variation of the target gas pressure illustrated that peaks 1-4 were due to double electron capture in two sequential collisions whereas peaks I-IV were caused by double electron capture in a single collision. The double ionisation energies evaluated from peaks II-IV are found to be 41.8, 41.9 and 46.2 eV respectively.

Spin conserved reactions between ground state $F^+(^3P)$ projectile ions and ground state CO molecules dictates that peaks I and III give information on triplet states in CO^{2+}, thus peak I infers that a triplet state with an energy of 39.3 eV was populated. This is in good agreement with a kinetic energy release measurement of 39.6 eV [1] which was attributed to the $^3\Pi$ state. Recent calculations however, [2-4] place the energy of this state as much higher as do other kinetic energy release studies. It is probable therefore that peak III (41.9 eV) should be assigned to the population of the $^3\Pi$ state and that peak I is caused by a component of $F^+(^1D)$ in the incident beam reacting with the $a^1\Sigma^+$ state. Peak II demonstrates the population of a singlet state at 41.8±0.3 eV in excellent agreement with a recent DCT investigation [1]. The full width half maximum (FWHM) of peak II is 3.75 eV and may include components due to reactions resulting in the population of both the $a^1\Sigma^+$ and the $b^1\Pi$. Peak IV was attributed to the population of a singlet state at 46.2±0.5 eV.

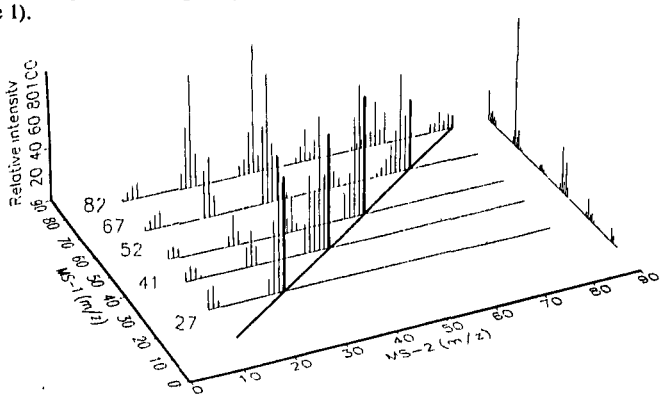
Survivor Ion Mass Spectrometry

Ming Gu* and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington, Seattle, WA 98195

A new method is presented for obtaining neutralization-reionization ($^{+}NR^{+}$) mass spectra of survivor ions with a tandem quadrupole-acceleration-deceleration (QADQ) mass spectrometer. All ions in a selected mass region of an electron-impact or chemical ionization mass spectrum are allowed to pass through the first quadrupole analyzer operated in the RF-only mode. Following acceleration the ions undergo neutralization (Xe or CH_3I at 70% transmittance) and reionization (O_2 at 70% transmittance), are decelerated by a constant nominal retarding potential (-8 → 0 kV), energy-filtered, and mass analyzed. This allows to selectively monitor those ions that have not dissociated upon collisional neutralization, neutral transport and collisional reionization. The survivor ion scan represents a diagonal projection in the typical two-dimensional data matrix provided by MSMS. (Figure 1).



The survivor ion relative intensities differ significantly from those of the precursor ions. This is due to triple filtering by 1) neutralization cross sections, 2) kinetic stability of the intermediate neutrals, and 3) reionization cross sections. The survivor ion mass spectra also differ significantly from the standard $^{+}NR^{+}$ mass spectra of parent ions. In general, increased ion relative abundances are observed for stable odd-electron ions (e.g. $C_2H_2^{+}$, $C_2H_4^{+}$, $C_2H_4O^{+}$, $C_3H_6^{+\cdot}$, $C_4H_2^{+}$, $C_4H_6^{+\cdot}$, etc.) that are neutralized to stable molecules, and for even-electron ions (e.g. CH_3OH^{+}, $C_3H_3^{+}$, $C_7H_7^{+}$, etc.) that form stable radicals (Figure 2). The three-fold modulation of ion/neutral currents due to different ion/neutral structures or internal energies results in amplification of small differences in ion relative intensities in the original (EI or CI) mass spectra. Because of their better life expectancy odd-electron ions give intense peaks in SuIMS, while isobaric overlaps (e.g. ^{13}C satellites of even-electron ions at adjacent *m/z*) are suppressed.

Survivor ion mass spectra are found to be useful for isomer differentiation and mixture analysis. Isomeric hexenes (1-, 2-, and 3-), hexenols (2-, 3-, 4-, and 5-), cyclohexene, cyclohexanol and isomeric hexadienes are readily distinguished through their survivor ion mass spectra. By contrast, very small differences are observed in SuIMS of isomeric xylenes whose Xe/O_2 $^{+}NR^{+}$ mass spectra are also indistinguishable. Statistical analysis of C_6H_{10} isomers electron impact and survivor ion mass spectra shows slight enhancement in the overall

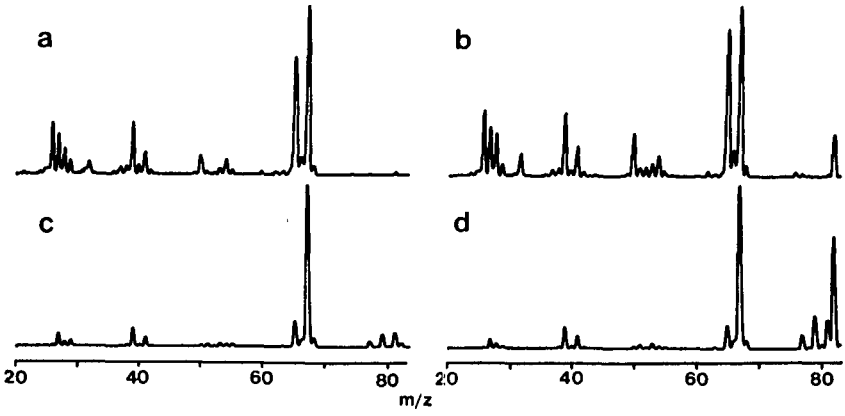


Figure 2. Survivor ion (top) and electron impact (bottom) mass spectra of 3-methyl-1,4-pentadiene (a,c), and 3-methyl-1,3-pentadiene (b,d).

variance in the latter. Analysis of ion groups, e.g. *m/z* 72-82, 60-67, 36-43, and 24-29 shows that most variance in SuIMS is localized in the relative abundances of C_6H_x and C_5H_x, while those of C_3H_x and C_2H_x are essentially identical for all isomers. The normalized residuals of the C_3H_x ion relative abundances are given in Table.

Implementation of survivor ion mass spectrometry is not limited to the QADQ instrument, but can be carried out on tandem sector and hybrid mass spectrometers equipped with dual collision cells for neutralization and reionization.

NEUTRALIZATION TARGET [NT] MASS SPECTROMETRY WITH THE VG ANALYTICAL ZAB-R MASS SPECTROMETER

R. W. Smith, D. Suh, P. C. Burgers, J. K. Terlouw and R.H. Bateman*

McMaster University, Department of Chemistry, Hamilton, Ont. L8S 4M1, Canada
*VG Analytical, Wythenshawe, Manchester M23 9LE, England

This contribution describes the use of the new ZAB-R mass spectrometer for research in the field of Neutralization-Reionization Mass Spectrometry [NRMS]. The three sector BEE instrument is based on the non-extended geometry of the ZAB-2f. An Autospec magnet [B] precedes the specially designed 2nd ffr housing which has the form of a rectangular box with an easily removable lid and side panels. Using four valves, the box may be quickly isolated from the pumping system and the other sectors. This allows rapid access to the three collision cells and the lens assemblies which are mounted on an optical bench. The first two cells are used for neutralization experiments: both are equipped with a deflector electrode and inlet systems for permanent gases and organic vapours. Mounted on one side of the second neutralization cell, perpendicular to the flight path of the ion beam [1], is a Quadrupole mass analyser. This is used to obtain spectra of ionized target molecules and their charged fragments produced in the neutralization cell by charge transfer with the incoming beam of fast moving (keV) ions. These spectra are termed "Neutralization Target" [NT] mass spectra. Following the second sector, a ZAB ESA, there is a box type enclosure which houses the third sector, an Autospec ESA.

Table 1 shows selected TMA NT mass spectra and relative neutralization efficiencies for TMA and Xe for a series of projectile ions with widely different recombination energies (RE). In all NT and NR experiments the TMA and Xe pressure (ionization gauge reading) was kept the same and oxygen was used for reionization.The resulting overall main beam transmission ranged from 78 - 90 % depending on the mass of the projectile ion. Relative neutralization efficiencies were obtained using $C_6H_5I^{\bullet+}$ as the internal standard. The summed value for all quadrupole signals resulting from the neutralization of $C_6H_5I^{\bullet+}$ by TMA was set at 1000.

The results in Table 1 show that in general the extent of dissociation of the ionized target reflects the difference between the RE of the projectile ion and the IE of the neutralization target. When the neutralization is near resonant there is little dissociation of the ionized target and the efficiency is high · compare the $C_{10}H_8^{\bullet+}$ - ionized naphthalene - and $C_6H_5I^{\bullet+}$ data for TMA with those for the endothermic reduction with Xe. Note also that the survivor ions in the [TMA,O_2] NR spectra are much more intense than those in the [Xe,O_2] spectra.

Surprisingly, strongly endothermic neutralization reactions - H_3O^+ or $CH_3OH_2^+$ with TMA - give rise to extensive dissociation of the ionized target. The efficiency of these reactions is low. Exothermic neutralizations yield NT spectra that also exhibit extensive dissociation, as exemplified by the reduction of F^+ [RE = 17.4 eV] with TMA [IE = 7.8 eV]. The efficiency of this reaction is higher than the a priori less exothermic reaction with Xe [IE = 12.1 eV]. Inspection of the PES of TMA shows that there is an excited electronic state c. 1.5 eV below the RE of F^+ and thus neutralization with TMA may be more resonant than that with Xe. Table 2 shows more NT mass spectra of TMA ions produced by (formally) strongly exothermic reduction reactions. These spectra can be rationalized in terms of the formation of TMA ions in specific excited electronic states, the energy requirement for its dissociation reactions and the accessibility of excited states of the reduced projectile ion. For example, the NT spectra reveal that the reduction of Ne^{++} and $N_2^{\bullet+}$ but not Ar^+ by TMA produces ions/neutrals in specific excited electronic states.

Neutralization-Reionization Mass Spectrometry. Carbon Cluster Energetics, Heavy Ion Neutralization Efficiencies, and Surface Induced Neutralization

Mei-Yi Zhang, Aberra Fura, Russell A. Chorush, Ilan Vidavsky, Peter B. O'Connor, and Fred W. McLafferty

Chemistry Department, Cornell University, Ithaca, NY, 14853-1301

Neutralization of multikilovolt cations or anions by charge exchange collision with a stationary target gas can be considered as a vertical Franck-Condon process. Crucial to NRMS experiments is the ionization energy (IE) of the neutralization target gas,[1] which affects the energy defect of the neutralization reaction. The efficiency of the neutralization step for fast heavy ions was examined in detail.

The neutralization yield of $C_6Br_6^{+\cdot}$ (IE = 8 eV) using Hg (IE = 10.4 eV) as a neutralization target is a factor of 3 and 13 higher than that of sodium (IE = 5.3 eV) and xenon (IE = 12.1 eV), respectively. The cross section for $C_6Br_6^{+\cdot}$ and Hg is proportional to ion kinetic energy increasing linearly from 2 to 11 keV, with no maximum or change of slope observed. Hg neutralization cross section for $C_6I_6^{+\cdot}$ (IE = 8 eV), $C_6Br_6^{+\cdot}$, and $C_6Cl_6^{+\cdot}$ (IE = 9.0 eV) are 6.5, 13, and 16 $Å^2$, respectively, inversely proportional to the energy defects of their charge exchange reactions. However, the Hg cross section of $C_6F_6^{+\cdot}$ (IE = 9.9 eV) is lower (13 $Å^2$), although this is nearly a resonant process. Of the fast fragment ions from ionized perfluorotributylamine undergoing Hg charge exchange, the cross section for $CF_3^{+\cdot}$ is the smallest (7 $Å^2$), but surprisingly high for $C_8F_{16}N^{+\cdot}$ (21 $Å^2$), $C_9F_{18}N^{+\cdot}$ (21 $Å^2$) and $C_9F_{20}N^{+\cdot}$ (27 $Å^2$) possibly reflecting their increasing ion size.

The dissociation and charge exchange of small neutral and ionic carbon clusters (C_1-C_7) generated from the corresponding mass selected precursor ions were also studied by collisionally activated dissociation (CAD) and by NRMS. The precursor ions were formed by dissociative electron ionization of linear, branched and cyclic precursor molecules. The cross section and product abundance measurements showed the odd-numbered cationic and neutral carbon clusters to be more stable than their adjacent even-numbered ones, whereas the converse is true for the negative ions, as also observed previously.[2,3] The CAD cross sections increase in general with increasing size, but that of C_7^+ (prepared from toluene and cycloheptatriene) is significantly lower than those values for C_4^+ - C_6^+ ions indicating that a higher fraction of C_7^+ ions prepared from cyclic precursors have cyclic structures. Neutralization with high ionization energy targets, such as Hg (IE = 10.4 eV), yields negligible neutral dissociation. On the other hand, C_4-C_6 clusters completely dissociate when K (IE = 4.3 eV) is used, whereas only C_4 and C_6 show complete dissociation with Na (IE = 5.1 eV). All show an intermediate dissociation with Ca (IE = 6.1 eV) indicative of the fragment appearance energies. However, C_2 showed relatively little dissociation even with K; this could be due to the formation of electronically excited state of

C_2* having a life time sufficiently long for it to be reionized and detected (≥0.4 microsecond).

From the above energetic considerations and product abundance measurements, it was possible to designate a more accurate heats of formation and ionization energies of these small carbon clusters from various experimental[4] and theoretical[5] values reported previously. The heats of formation values chosen from the present work are 717, 815, 801, 971, 1030, 1203 kJ mol^{-1} and the IE values are 11.1, 12.1, 11.4, 11.3, 10.7, 10.1 eV for C_1-C_6 clusters respectively.

Surface-Induced Neutralization (SIN) is currently being investigated as a new method that does not require metal vaporization or extra vacuum pumping for dissociative neutralization. Targets of low ionization energy yield neutrals of higher internal energies that can be of key importance in isomer differentiation studies. Using both a polished stainless steel surface and a Si wafer, neutral beams of up to 1% of the precursor ion beam have been observed. Outgassing the stainless steel surface at 250°C caused no marked difference in this efficiency. Reionization of the neutral beam from CH_3CO^+ as the precursor yields CO^+ dominantly. In preliminary experiments to differentiate the isomers 1-butene and 2-butene, the $(M - CH_3)/(M - H)$ ratio of 1-butene is 3x that of 2-butene, consistent with their structures. The efficient dissociation of large neutral molecules is under investigation.

The Tandem Flowing Afterglow-Selected Ion Flow Tube (FA-SIFT) has been employed to obtain the gas phase acidities of deuterated ethanols using collision-induced dissociation (CID) of cluster ions.* The qualitative order of acidities of ethanols was obtained by the fragmentation ratios of various ethoxide-ethanol clusters. Quantitative acidities were determined from the relative fragmentations of clusters between ethoxide and alcohols with known acidities. A calibration line of the fragmentation ratios of ethoxide with methanol, d_3-methanol, n-propanol, and n-butanol clusters versus the known acidities of the alcohols allows the acidities of the deuterated ethanols to be determined (Figure 1). We find that both α and β deuterated ethanols are weaker acids than undeuterated ethanol with α deuteration having a more pronounced effect. The acidities, relative to undeuterated ethanol [$\Delta H_{acid}(CH_3CH_2OH) = 377.5 \pm 2$ kcal/mol)] are $\Delta\Delta H_{acid}(CD_3CH_2OH) = 0.20 \pm 0.15$ kcal/mol, $\Delta\Delta H_{acid}(CH_3CD_2OH) = 0.35 \pm 0.15$ kcal/mol, and $\Delta\Delta H_{acid}(CD_3CD_2OH) = 0.50 \pm 0.15$ kcal/mol. In a separate set of measurements, we have studied the negative ion photoelectron spectroscopy of a set of ethoxide ions to determine the electron affinities of the corresponding ethoxy radicals. The electron affinities decrease with increasing deuterium substitution. We find: $EA(CH_3CH_2O) = 39.55 \pm 0.16$ kcal/mol, $EA(CH_3CD_2O) = 39.48 \pm 0.16$ kcal/mol, $EA(CD_3CH_2O) = 39.41 \pm 0.16$ kcal/mol, and $EA(CD_3CD_2O) = 39.27 \pm 0.16$ kcal/mol; the relative error bars are ±0.05 kcal/mol. The corresponding O-H bond strengths of the deuterated ethanols can be extracted from these acidities and electron affinities. We find that α deuteration increases the O-H bond strength by 0.3±0.2 kcal/mol while β deuteration has a negligible effect. The bond dissociation energies, relative to undeuterated ethanol [$D_{0,0K}(CH_3CH_2O\text{-}H) = 102.2 \pm 2$ kcal/mol] are $D_{0,0K}(CD_3CH_2O\text{-}H) = 102.3 \pm 0.2$ kcal/mol, $D_{0,0K}(CH_3CD_2O\text{-}H) = 102.5 \pm 0.2$ kcal/mol, and $D_{0,0K}(CD_3CD_2O\text{-}H) = 102.5 \pm 0.2$ kcal/mol. Gaussian 90 *ab initio* calculations were employed to calculate the relative acidities, electron affinities, and dissociation energies of deuterated and nondeuterated ethanols, ethoxy radicals, and ethoxide anions. The results are in good agreement with our experimental values (Table 1).

An Investigation of Energy Transfer in Ion/Surface Collisions using Self-Assembled Monolayer Targets

D.E. Riederer, Jr., M. Morris, T. Ast, and R.G. Cooks, Department of Chemistry, Purdue University, West Lafayette, IN 47906

C.E.D. Chidsey, AT&T Bell Laboratories, Murray Hill, NJ, 07974.

Surface induced dissociation (SID) is an effective method for depositing large internal energies into ions at relatively low collision energies. Until recently, most SID was performed using stainless steel targets covered with background hydrocarbons, and most data on translational to internal energy conversion are based on these uncharacterized surfaces [1]. In the present study, we address the energetics of ion/surface collisions using well characterized, long-chain, self-assembled monolayer surfaces which are comprised of thiols bound to a gold substrate. In particular, $CF_3(CF_2)_{11}(CH_2)_2$-S-Au, $CD_3(CD_2)_{15}$-S-Au, $FcCO_2(CH_2)_{11}$-S-Au, and untreated stainless steel were used and are denoted by F, D, Fc, and SS respectively (Fc=ferrocene). The measurements include i) the internal energy deposited into metal carbonyl ions as a function of the target surface, ii) the partitioning of internal energy between the ion and target, and iii) the effect of small changes in the angle of incidence. These experiments were performed using a BEEQ hybrid mass spectrometer, with the surface located between the two electric sectors, designed for the study of ion/surface collisions [2].

The average internal energy deposited into $Cr(CO)_6^{+\cdot}$ colliding with each surface was determined by the relative abundance of the $Cr(CO)_n^+$ (n=0-6) fragment ions (Figure 1), and the known appearance energies for the formation of these fragments using a previously described method [3]. The spectra in Figure 1 were obtained at a collision energy of 25eV and with incident and scattering angles of 55° and 90° respectively. Under these conditions, the D, Fc, and SS surfaces (all hydrocarbon-like) produced similar ion internal energies, having values of 3.0, 2.7, and 2.8eV, respectively. These values represent 11-12% conversion of the ion translational energy to internal energy and compare well with a recently published value of 13% for $W(CO)_6^{+\cdot}$ colliding on hydrocarbon covered SS [4]. The fluorinated surface resulted in deposition of 4.7eV into internal energy, which corresponds to a 19% translational to internal energy conversion efficiency. When the $W(CO)_6^{+\cdot}$ ion was used on the F target similar conversion efficiencies of 18% and 20% were found at collision energies of 30eV and 50eV, respectively. The higher internal energies deposited by the F surface are thought to be due to the increased mass of the target species and suggests that the collisions with these surfaces are of the impulsive type, in which the ion interacts with groups on the target surface rather than with an infinitely massive target.

In addition to estimating internal energies, we have measured the kinetic energy (KE) distributions of ions leaving the surface after the collision. The average KE of ions leaving the surface was used to estimate the inelasticity, Q, of the collision process

$$Q = E_1 - E_2 = \epsilon_{ION} + \epsilon_{SURF}$$

where E_1 and E_2 are the kinetic energies of the ion before and after the collision. The KE lost during the collision is partitioned between the internal energies of the ion, ϵ_{ION}, and surface, ϵ_{SURF}. Since ϵ_{ION} is known from the mass spectrum, the energy deposited into the surface, ϵ_{SURF}, could also be determined. These measurements are shown schematically in Figure 2 for $W(CO)_6^{+\cdot}$ colliding with the F surface at 50eV. The SID mass spectrum indicates that the nacent scattered ions have an average internal energy of 9eV. The KE distribution shows that the ions have an average KE of 7eV, which means that the $W(CO)_2^+$ ion must have been formed from an excited $W(CO)_6^{+\cdot *}$ leaving the surface with approximately 10eV. From this we conclude that upon a 50eV collision upon a perfluorinated target, on average 9eV (18%) goes to internal energy and the activated $W(CO)_6^{+\cdot *}$ ion leaves the surface with 10eV (20%) of kinetic energy, leaving 31eV (62%) deposited into the target surface.

Preliminary studies show only small changes in the SID mass spectrum as the incident angle is varied over the range $\pm 10°$ around 55°. Investigations involving changes to the scattering angle, and KE distributions as a function of the scattering angle, are currently underway.

DISSOCIATIVE COLLISIONS OF PEPTIDES AT SURFACES

A.L.McCormack
California Institute of Technology, Pasadena CA 91125
V.H.Wysocki and A.R.Dongre
Virginia Commonwealth University, Richmond VA 23284-2006

Amino acid sequence analysis of peptides and proteins by tandem mass spectrometry continues to be a rapidly expanding field. The majority of these investigations have been performed using low- and high energy collision-induced dissociation (CID). Surface-induced dissociation (SID) has been shown to effectively dissociate a variety of molecules, including peptides (1). Here we report the results of a systematic study designed to assess the utility of SID in the structural analysis of peptides. A general goal of this research was to explore the fragmentation of a variety of peptides, ranging in mass and amino acid sequence, and to assess the structural information afforded by traditional means of fragmentation. The surface type also influence the appearance of the surface-induced dissociation spectra.

The instrument used in this investigation consists of two Extrel quadrupoles arranged in a 90° geometry and has been described previously (2). In this investigation, ions were produced by LSIMS (Cs^+ bombardment). The collision surface includes stainless steel, a self assembled monolayer of octadecanethiol (3) or 2-(perfluorooctyl)-etanethiol on thin gold foil.

Figure 1 shows the 50 eV SID spectra recorded on the peptide, fibrinopeptide A. The series of b-type ions allows the assignment of residues 1-4 and 6-16. The amino acid sequence, ADSGEGDFLAEGGGVR, is afforded by the spectrum. This spectrum illustrates the unique nature of fragmentation by SID as compared to low- and high energy CID.

In general SID spectra are remarkably similar to low-energy CID spectra; however, side chain specific sequence ions, which are generally observed only in high-energy CID spectra (4), are also observed in SID spectra. The ion W_8, observed in Figure 1, identifies Leucine as the 9th residue in the peptide . Table 1 shows the peptides investigated in this study; residues which are predicted to afford d- or w- type ions are bolded and those observed are underlined.

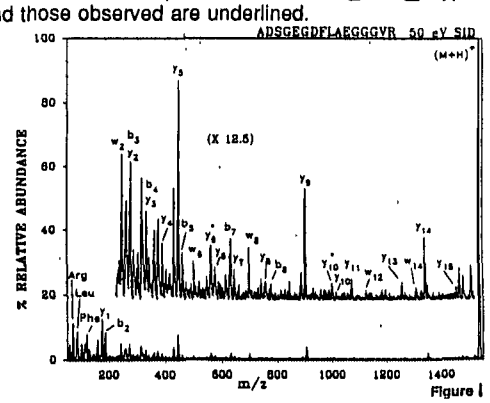

Figure 1

The SID spectrum of Angiotensin III on two different types of surfaces, namely 2- (perfluorooctyl)-etanethiol and octadecanethiol (3) on gold foil indicate a difference in the extent of fragmentation.

More extensive fragmentation is observed for collisions with the 2-(perfluorooctyl)-etanethiol surface (Figure 2) than for collisions with the octadecanethiol surface (Figure 3).

The study of the dependence of surface type on the extent of fragmentation for different surfaces is currently under progress.

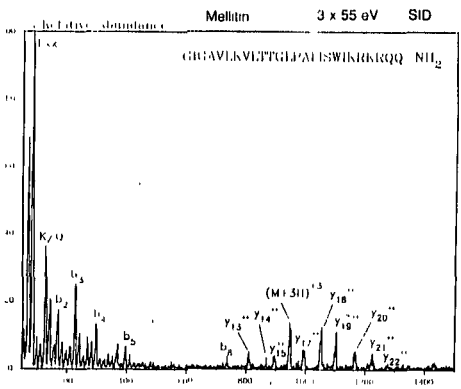
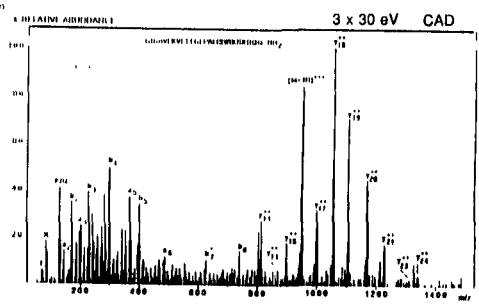
Surface-Induced Dissociation of Multiply Charged Ions formed by Electrospray Ionization

J.L. Jones and V.H. Wysocki
Department of Chemistry
Virginia Commonwealth University
A.L. McCormack
California Institute of Technology

Electrospray (ESI) is an ionization process in which highly-charged molecular ions can be generated. It has become extremely useful in the biochemical field where molecular weight determination and sequence information can be obtained for proteins. We have employed surface-induced dissociation (SID)[1] to activate ions formed by electrospray because large amounts of internal energy can be deposited in a controllable fashion. The instrument used is a tandem quadrupole mass spectrometer (mass range 4000) in a 90° configuration. Our first ESI/SID spectrum was reported last year at this meeting. Since then we have removed a restrictive ELFS-(Extrel) lens; resulting in the enhancement of sequence information. The goal of this work is to investigate the ion/surface collision products that are detected when multiply-charged species collide with various types of chemically modified gold surfaces (i.e., 1-octadecanethiol (CH_3 thiol) and 2-(perfluorooctyl)ethanethiol (CF_3 thiol)). Peptides investigated include angiotensin I, angiotensin III, bradykinin, renin substrate and mellitin. Various charge states of these peptides were allowed to collide with the surface and the resulting fragments resemble those reported by gas-phase collisional activation.[2] A representative spectrum of this can be seen for the triply-charged state of mellitin. Predominate fragments that result are a, b and y series ions. Doubly-charged peptides produce both doubly- and singly- charged fragments.





The singly-charged ion of leucine enkephelin was chosen to compare the extent of fragmentation detected by electrospray ionization/SID to liquid secondary ion mass spectrometry/SID. To achieve the same mass spectrum as LSIMS, the collision energy had to be increased to > 45 eV with ESI/SID on the CH_3 thiol surface and 25 eV on the CF_3 thiol surface. This suggests that electrospray ionization produces colder ions than those resulting from liquid secondary ion mass spectrometry.

Surface Induced Dissociation (SID) of Polyatomic Anions

*T.E. Kane and V.H. Wysocki, Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284

Investigations of polyatomic ions undergoing surface collisions have been largely concerned with positive ions.[1] The purpose of the work described here is to investigate the analytical utility of surface-induced dissociation for structural characterization of anions. We report dissociation data obtained for small nitroaromatics and ethylcyclohexanone-2-carboxylate. Experiments were performed on stainless steel and self-assembled monolayer films on gold. The three self-assembled monolayers investigated were prepared by the spontaneous assembly of octadecanethiol, perdeuteroicosanethiol, and 2-(perfluorooctyl)-ethanethiol on gold. The total ion chromatogram was obtained using a multiple surface holder, whereby one of up to four surfaces may be positioned into the ion path while continually acquiring data. The surface holder was repositioned for the center of each surface resulting in the step pattern in Figure 1. The data in Figure 2a-c show that the degree of fragmentation is dependent on both the type of surface and the collision energy. The narrow, variable internal energy distribution associated with SID results in increased abundance of lower molecular weight fragments as the collision energy is increased from 20 to 40 eV. This affect can by seen for all of the surfaces investigated by this group. The individual degree of fragmentation, however, and the overall amount of ion current detected differs from one surface to another.

The fluorinated surface clearly results in greater fragmentation with greater total signal for both the trinitrotoluene and ethyl cyclohexanone-2-carboxylate data shown.

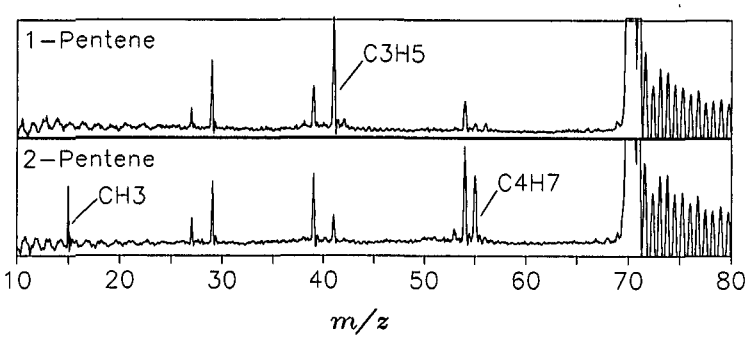
Neutral Unimolecular Fragmentation Patterns of Organic Compounds Studied by Photodissociation Photoionization Mass Spectrometry

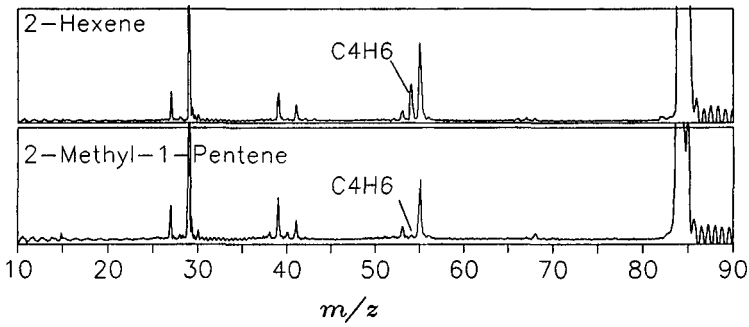
*S.E. Van Bramer, P.L. Ross, and M.V. Johnston, University of Delaware, Department of Chemistry and Biochemistry, Newark, DE 19716

In conventional mass spectrometry ionic fragmentation is used to obtain structural information. In Photodissociation-Photoionization Mass Spectrometry (PDPI/MS), ultraviolet radiation from an excimer laser (193 nm) is used to induce neutral fragmentation. The neutral photodissociation products are then softly ionized with coherent vacuum ultraviolet radiation generated by frequency tripling in rare gas mixtures. Neutral fragmentation is useful because neutral rearrangement barriers are often higher than ionic rearrangement barriers. As a result, neutrals are less likely to isomerize prior to fragmentation. If a molecule isomerizes prior to fragmentation, it will be difficult to distinguish the corresponding mass spectrum from that of the isomer.

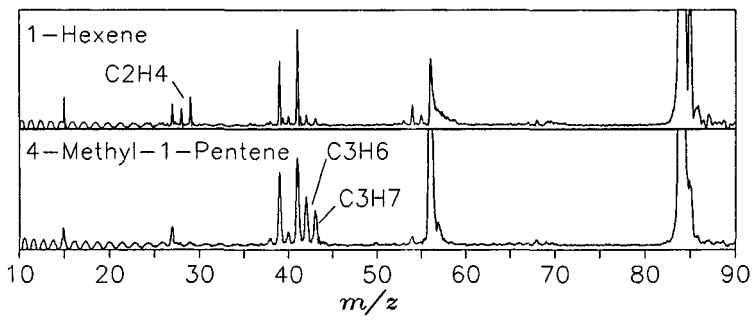
The location of double bonds in alkenes is often difficult to determine because H rearrangement effectively moves the double bond prior to fragmentation. Neutral fragmentation of alkenes, however, is directed by the double bond and the primary fragmentation mechanism is cleavage of the β C-C bond. This provides enough information to determine the location of the double bond in *n*-alkenes. For example, β-cleavage of 1-pentene forms $C_3H_5^{\bullet}$ and $C_2H_9^{\bullet}$ while 2-pentene forms $C_4H_7^{\bullet}$ and $CH_3^{\bullet}$. When these photodissociation products are softly ionized, the isomers are readily distinguished by the mass spectra (shown below).



Branched and linear alkenes often produce isomass β-cleavage fragments. Secondary fragmentation of the allylic β-cleavage products can be used to distinguish structural differences that are not apparent from the primary β-cleavage products. Both 2-hexene and 2-methyl-1-pentene produce $C_4H_7^{\bullet}$ and $C_2H_5^{\bullet}$. Because the $C_4H_7^{\bullet}$ fragments are structurally different, secondary fragmentation of $C_4H_7^{\bullet}$ can be used to distinguish 2-hexene and 2-methyl-1-pentene. $C_4H_7^{\bullet}$ produced from 2-hexene undergos loss of $H^{\bullet}$ to form 1,3-butadiene. $C_4H_7^{\bullet}$ produced from 2-methyl-1-pentene can not form as stable a product after $H^{\bullet}$ loss, so little $C_4H_6^{+\bullet}$ is observed in the PDPI/MS spectrum shown below.



If two isomers produce identical allylic β-cleavage fragments, secondary fragmentation of the saturated radical can provide structural information. 1-Hexene and 4-methyl-1-pentene both produce isomass β-cleavage products with identical allylic fragments. However, 1-hexene produces n-$C_3H_7^{\bullet}$ while 4-methyl-1-pentene produces iso-$C_3H_7^{\bullet}$. iso-$C_3H_7^{\bullet}$ looses $H^{\bullet}$ to form C_3H_6 while n-$C_3H_7^{\bullet}$ undergoes C-C bond cleavage to form $CH_3^{\bullet}$ and C_2H_4. Differences in the relative abundances of these fragments is seen in the PDPI/MS spectra and can be used to distinguish 1-hexene from 4-methyl-1-pentene (shown below).



The PDPI/MS spectra of several compound classes were studied. Nitro-alkanes lose NO_2 to form a saturated radical which is useful for studying the secondary fragmentation of $C_nH_{2n+1}^{\bullet}$. Alkynes undergo β-cleavage which can be used to determine the location of the C≡C. Difunctional compounds containing a carbon-carbon double bond undergo predominant β-cleavage similar to alkenes. Amines and Ketones also show strong PDPI/MS spectra but the fragmentation patterns are difficult to interpret.

Dissociation of Low Energy CS_2^+ Ions: A Crossed Beam Study

Yibai Chen, Kevin Norbash, John Trainor, Anil Shukla* and Jean Futrell, Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

INTRODUCTION

Energy and angle resolved CID of CS_2^+ ions studied at both low and high kinetic energies have been explained by invoking that isolated electronic states are responsible for the unusual variation in relative abundances of CS^+ and S^+ fragment ions which showed two crossovers [1]. A related study using z-deflection to monitor angular scattering at kilovolt energies showed only one crossover [2]. This angular dependent relative abundances were explained by Todd et al. on the basis of kinetic energy release during the dissociation process [3]. At low collision energies, however, relative intensity of CS^+ increased with collision energy (and hence with heavy mass neutrals) but decreased with scattering angle [4]. Since internal energy transferred into an ion is expected to increase with scattering angle, it was suggested that different electronic states of CS_2^+ are populated in the collision process which exhibit different collision energy and angular dependences. Since we can readily distinguish, using our tandem hybrid molecular beam mass spectrometer, different activation and dissociation mechanisms by monitoring energy and scattering of fragment ions simultaneously, we have extended our study to CS_2^+ ion CID to explore these issues.

RESULTS AND DISCUSSION

This paper constitutes a progress report on our investigation of the dynamics of collisional activation and dissociation of CS_2^+ ion. The scattering contour diagrams (Figs. 1 & 2) for Reactions (1)
and (2) were obtained at a center-of-mass collision energy of 17.2 eV, chosen as the crossover point in relative abundances of the two product ions.

$$CS_2^+ + Ar \;\text{-->}\; S^+ + CS + Ar \qquad (1)$$

$$CS_2^+ + Ar \;\text{-->}\; CS^+ + S + Ar \qquad (2)$$

Despite the limited data set, our experiments provide definitive information regarding several points raised by earlier research. For example, our results support the earlier conjecture that the production of CS^+, Reaction (2), proceeds via a mechanism which different from Reaction (1). The energy deposition for the Reaction (1) matches quite well the thermochemical threshold for S^+ and CS in their ground states. In contrast, Reaction (2) requires that energy considerably in excess of thermochemical threshold be deposited in the activation step. Concentric circles passing through the product ion intensity maxima at the thermochemical threshold for Reaction (1) and for the thermochemical threshold and the excited state channel

$$CS_2^+ + Ar \;\text{--->}\; CS^+(C^2\Sigma^+) + S + Ar \qquad (3)$$

emphasize quite different mechanisms followed by the two reactions.
These contour diagrams also shed some light on the role of kinetic energy release in the dissociation step on angular dependence of product ion abundances in this system. At the collision energy investigated, the mean deflection angles for both channels are nearly the same. The major impact of large kinetic energy release is to broaden the width of the product distribution considerably. This is illustrated quantitatively in the P(T) diagram (Figure 3) for the Reaction (1). The low number of degrees of freedom in the products, and the likelihood that dissociation coordinate is parallel to the C-S molecular axis, rationalizes the large kinetic energy release.

The present results provide another example of the unusually large and efficient conversion of translational energy into internal excitation in CID processes. It is very likely that a curve-crossing mechanism similar to the acetone ion CID is involved in this case also [5].

VACUUM ULTRAVIOLET PHOTOIONIZATION AND PHOTOFRAGMENTATION TIME-OF-FLIGHT MASS SPECTROMETRIC STUDY OF CH_3SCH_3 AND CH_3S

K. S. Norbash and C. Y. Ng, Ames Laboratory, U.S. Department of Energy, and Department of Chemistry, Iowa State University, Ames, Iowa 50011

J. H. Futrell, Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716

Abstract:

We have measured the translational energy releases of the laser photodissociation processes: CH_3SCH_3 + hν (193 nm) → CH_3 + CH_3S [process (1)] and CH_3SCH_2 + H [process (2)]; and CH_3S + hν (193 nm) → S + CH_3 [process (3)]. The onsets of the translational energy distributions for photofragments of processes (1) and (2) allow the direct determination of 74.9 ± 1.5 and 91 ± 2.5 kcal/mol for the dissociation energies of the CH_3-SCH_3 and H-CH_2SCH_3 bonds at 0 K, respectively. The threshold observed for S formed by process (3) is consistent with the conclusion that S atoms are formed in the ^3P and ^1D states. The photoelectron-photoion coincidence (PEPICO) spectra for $CH_3SCH_3^+$, $CH_3SCH_2^+$, CH_3S^+ (or CH_2SH^+), and CH_2S^+ resulting from CH_3SCH_3 have been measured in the wavelength region of 900-1475 Å. The PEPICO study allows the construction of the breakdown diagram for the formation of $CH_3SCH_2^+$, CH_3S^+ (or CH_2SH^+), and CH_2S^+ from energy-selected $CH_3SCH_3^+$ ions. Combining the energetic information obtained from the photofragmentation and photoionization experiments, we have estimated the ionization energy of the CH_3S radical.

Introduction:

Dimethylsulfide is one of the industrial organosulfur pollutants emitted to the atmosphere due to the incomplete combustion of coal and oil.[1] Oxidation of organosulfur compounds such as CH_3SCH_3 ultimately leads to the formation of SO_2.[2] The absorption spectrum of CH_3SCH_3 shows a strong absorption band in the wavelength region of 190-210 nm.[3] Previous ultraviolet photolysis studies[4] suggest that the primary ultraviolet photodissociation process of CH_3SCH_3 involves the breaking of the C-S bond. The oxidation rate for CH_3SCH_3 is found to increase in the presence of ultraviolet radiation.[5] Therefore, the study of the ultraviolet photochemistry of CH_3SCH_3 is relevant to the detailed modelling of the atmospheric sulfur chemistry cycles.

Results and Discussion:

Figures 1(a)-1(c) show the TOF spectra for CH_3S observed at θ = 30° and delay times of 450, 500, and 550 μs, respectively, between the trigger pulses for opening the pulsed molecular beam valve and for firing the ArF excimer laser. The fast peak centered at ~ 350 μs is due to process (1). The broad peak in the range of ~ 500-1000 μs decreases significantly relative to the fast peak as the nozzle stagnation pressure is decreased, indicating that it arises from the formation of CH_3S^+ fragments in the electron impact ionization of dimer and cluster species of CH_3SCH_3. As a result of slippage in the supersonic expansion, the velocity for CH_3SCH_3 is expected to be slightly greater than those for the dimer and higher clusters. As pointed out in previous reports,[6,7] it is possible to minimize the fragmentation effect of dimers and clusters by selecting a specific delay time between the opening of the nozzle and the firing of the laser. The lower intensity of the slow peak relative to that of the fast peak observed in Fig. 1(a), compared to those observed in Figs. 1(b) and 1(c), indicates that the CH_3SCH_3 beam sampled by the laser at a delay time of 450 μs contains the fewest dimers and clusters. Therefore, the delay time of 450 μs is used for the measurements of all the TOF spectra presented below.

The PEPICO spectra for $CH_3SCH_3^+$, $CH_3SCH_2^+$, CH_3S^+, and CH_2S^+ in the wavelength region of 900-1450 Å are depicted in Figs. 2(a)-2(d), respectively. The IE of CH_3SCH_3 and the AE's for $CH_3SCH_2^+$, CH_3S^+ (CH_2SH^+), and CH_2S^+ determined from the PIE and PEPICO spectra are in good agreement.

The CH_3SCH_3 molecule has a C_{2v} symmetry. The HeI photoelectron (PE) spectrum of CH_3SCH_3 in the IE region of 8.5-13.7 eV exhibits three peaks at 8.7, 11.3, and 12.7 eV, which are assigned to the removal of an electron from the $3b_1$, $8a_1$, and $5b_2$ molecular orbitals, respectively.[8] The first electronic band is sharp because the $3b_1$ orbital is essentially a non-bonding 3p orbital of the S atom. The vertical IE's of these three electronic bands are marked by arrows in Fig. 2(a). The low energy peak in the $CH_3SCH_3^+$ PEPICO

spectrum is identified as the $CH_3SCH_3^+(3b_1^{-1})$ ground electronic band. The peak at 1160 Å corresponds to the low energy shoulder of the $CH_3SCH_3^+(8a_1^{-1})$ electronic band. In the energy region between the first and second CH_3SCH_3 PE bands, the HeI PE spectrum shows negligible PE intensities. Finite PEPICO $CH_3SCH_3^+$ intensities observed between the first and second PE bands are due to autoionization. The $CH_3SCH_3^+$ PEPICO intensity drops abruptly to the noise level as the $CH_3SCH_2^+$, CH_3S^+ (CH_2SH^+), and CH_2S^+ fragment ions appear.

MASS SPECTROMETRY OF SIMPLE ORGANIC COMPOUNDS EMPLOYING A RARE-GAS METASTABLE BEAM SOURCE

D. Faubert, G. J. C. Paul, J. Giroux[1] and M. J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7
[1]Dephy Technology, 360, rue Franquet, Sainte-Foy, Quebec, Canada, G1P 4N9

The initial use of a rare-gas metastable atom beam generated by a corona discharge as an ionization source for mass spectrometry is described. Experimental evidence suggests that Penning ionization upon collision of the analyte with metastable atoms (reaction 1) is the major ionization process taking place in the ion source.

$$A^* + BC \longrightarrow A + BC^+ + e^- \qquad (1)$$

Penning ionization involves the electrophilic reaction of a metastable atom (A^*) with an analyte (BC) resulting in an ionic state of the analyte (BC^+), the ground state of the atom (A) and the ejected electron in a continuum state (e-). The excited atom attacks a molecular orbital of BC from which an electron is transferred into a vacant orbital of the excited atom.

In this work four rare gases; helium, neon, argon and krypton, are employed as metastable beam sources for the analysis of aromatic and aliphatic compounds. The excitation energies of the metastable atoms are: $He^*(^3S_1, {}^1S_0)$ = 19.8, 20.6eV, $Ne^*(^3P_2, {}^3P_0)$ = 16.6, 16.7eV, $Ar^*(^3P_2, {}^3P_0)$ = 11.6, 11 7eV, $Kr^*(^3P_2, {}^3P_0)$ = 9.9, 10.6eV. The use of a metastable atom beam, produced externally from the ion source, for ionization, provides an advantage over conventional glow discharge sources where a variety of reactive species (electrons, ions, metastables) are formed and charactization of the ionization processes that follow is difficult. Another advantage of the metastable atom beam source is that by selecting the appropriate rare-gas, metastable species of a desired internal energy can be generated and the ionization processes which occur in the source can be easily controlled. Selective ionization within a mixture of analytes can be achieved in this manner.

The apparatus employed consists of a metastable beam source, displayed in Figure 1, and a single quadrupole mass spectrometer. The metastable atoms are produced by a dc discharge established along the gas flow through a small gas nozzle (d = 0.15 mm). The discharge (V =~350 V, I = 5-10 mA) is maintained between a cluster of sharp needles (cathode) and a cone-shaped skimmer (grounded anode). A high voltage spark (~4 kV) between the auxiliary electrode and the skimmer (see Fig. 1) is used to initiated the discharge. The discharge is sustained across a 50 mbar pressure gradient created by differentially pumping the gas nozzle. Under our working conditions, the ion source pressure is 5×10^{-4} mbar and the ion source temperature is 170°C. The metastable beam flux measured for He^* is $1.2\text{-}1\ 5 \times 10^{15}\ s^{-1}sr^{-1}$.

All studied reactions were of types (1) and (2) where reaction (2) occurs if the excitation energy of the metastable species is high enough to effect bond breakage within the analyte.

$$A^* + BC \longrightarrow A + B^+ + C + e^- \qquad (2)$$

A representative example of the mass spectra obtained for aromatic compounds utilizing the four rare gases as metastable beam sources, is shown in Figure 2. For anisole, on changing the metastable atom beam from He^* through to Kr^* (Fig. 2a-2d), the extent of fragmentation of the analyte is seen to dramatically decrease. For He^*, the extensive fragmentation present in the mass spectrum (Fig. 2a) is similar to that obtained under EI(70eV) conditions while for Kr^* only the molecular ion is observed. It follows from the mass spectra shown in Figure 2 that for ionization by metastable atoms, the abundance of fragment ions depend on the energy transferred to the analyte on collision, i.e., on the excitation energies of the metastable atoms. For the most energetic metastable atoms, He^* and Ne^*, it is interesting to note the presence of molecular ions in the mass spectra (Fig. 2a, b) despite the large transfer of energy upon reaction. This can be explained in terms of a vertical transition (Franck-Condon principle), where the ejected electron takes all the excess energy of reaction.

The mass spectra for a representative aliphatic compound, 2-butanone, generated upon collision with He^* and Kr^* are shown in Figure 3. Increased fragmentation of the analyte is observed for He^* (Fig. 3a) relative to Kr^* (Fig. 3b) reflecting the greater internal energy of these metastable species. Hence, the trend of increased fragmentation of the analyte with increased excitation energy of the metastable atom holds for both aromatic and aliphatic compounds. In this work, it has been demonstrated that both hard and soft EI-like ionization of organic molecules can be achieved using the metastable atom source by selecting the appropriate rare-gases. Hence, both the molecular weight and structural information of the analyte can be obtained by this technique.

A useful analytical application for the metastable beam source is the selective ionization of certain analytes under appropriate conditions. An example of this is shown in Figure 4. For phenol dissolved in a 1:1 mixture of water and acetonitrile, peaks originating from water and acetonitrile are dominant in the mass spectra generated by Ne* bombardment (Fig. 4a), while for Kr*, ionization of only the compound of interest, phenol, occurs (Fig. 4b). This is a consequence of the lower excitation energy of Kr*. As almost every common mobile phase employed in liquid chromatography mass spectrometry have an I.P. greater than the internal energy of Kr*, the Kr* metastable atom beam can be utilized for selective analyte ionization in that technique.

A comparison was made of the total ion current (TIC) values for various organic analytes using Ne* with those obtained via electron impact. At present, a difference of a factor of five in favor of EI over the neon metastable beam source exists. Two parameters which are anticipated to improve the extent of Penning ionization in the source are the widening of the ion source entrant hole in grounded anode and a shortening of the distance between the grounded anode and the ionization chamber (see Fig. 2). Work is presently underway to achieve the same sensitivity for metastable atom beams as obtained by EI.

DISSOCIATIVE CHARGE EXCHANGE OF HIGH TRANSLATIONAL ENERGY $W(CO)_6^{2+}$ IONS

L. Lu, R. Susič, D. E. Riederer,Jr., D. Žigon and R. G. Cooks
Chemistry Department, Purdue University, West Lafayette, Indiana 47907

T. Ast
Faculty of Technology and Metallurgy, University of Belgrade, Yugoslavia

A knowledge of energy transfer associated with collision processes is of fundamental significance to a great number of mass spectrometric studies. When high translational energy doubly charged ions collide with neutral gaseous targets, one of the processes that takes place is the dissociative charge exchange, which, in the case of $W(CO)_6^{2+}$ can be represented by the sequence

$$W(CO)_6^{2+} + G \rightarrow W(CO)_6^{+\cdot *} + G^{+\cdot} \qquad (1)$$

$$W(CO)^{+\cdot *} \rightarrow W(CO)_n^{+\cdot} + (6 - n)\ CO \qquad (2)$$

The choice of the thermometer molecule $W(CO)_6$ is based on its characteristic fragmentation, since it shows consecutive CO losses as the only major dissociation sequence. In such cases it was shown that the measured product ion distribution can be transformed to an approximate internal energy distribution of the activated parent ions (P(ε) curves)[1].

In order to evaluate the effects of the nature of the target in this process, fifteen different collision gases have been employed. they include monatomic, diatomic and polyatomic species of widely different mass and ionization energy (Table 1). The experiments were performed on a BE sector instrument; $W(CO)_6^{2+}$ ions were accelerated to 7 keV translational energy prior to collisions with target gases maintained at $3\text{-}5\times10^{-6}$ torr pressure. Figure 1 shows typical examples of P(ε) curves obtained for four collision gases. From the P(ε) curves average values of internal energy deposited were calculated for each collision gas and are listed in Table 1.

In order to compare the performances of different collision gases, the charge exchange efficiency σ was defined as

$$\sigma = \frac{\sum I_{W(CO)_n^+}}{\sum I_{W(CO)_6^{2+}}} \times 100 \qquad (3)$$

where the numerator represents the sum of ion abundance of all of the charge exchange products, and the denominator represents the abundance of the precursor doubly charged ion before any collision gas is introduced. The σ values are also listed in Table 1.

Based on the results of this study the following main conclusions were drawn:

(i) In the keV range of collision energies, large amounts of internal energy are deposited upon charge exchange and the distribution of energy is very broad.

(ii) There is a weak correlation of internal energy deposition with target ionization energy: counterintuintively, higher ionization energy targets result in larger internal energy deposition[3]. This suggests important contributions from a mechanism of direct excitation to the repulsive state of the products.

(iii) The overall appearance of the P(ε) curves is very similar to those reported for high energy collisional activation[1], suggesting a common excitation mechanism to both types of processes, presumably direct electronic excitation.

(iv) Polyatomic targets are much more efficient in effecting charge exchange than are monatomic and diatomic targets. This behavior correlates with their lower ionization energies and it could be ascribed to the greater number of allowed curve crossings within the range of internuclear distances appropriate for long-range electron transfer processes.

(v) Charge exchange in the keV range of collision energies differs considerably to that observed for low energy (eV) collisions[4]. In the latter case, the energy deposited is controlled by the thermochemistry of the reaction and the process was found to proceed via the Landau-Zener curve-crossing mechanism at large internuclear distances.

Table 1. Summary of data for the dissotiative charge exchange of $W(CO)_6^{2+}$ with different targets

Target	IE(eV)[a]	ΔH(eV)[b]	σ(%)[c]	ε[$W(CO)_6^{+\cdot}$](eV)[d]

The Collision Induced Emission of Radiation by Ions and Neutrals

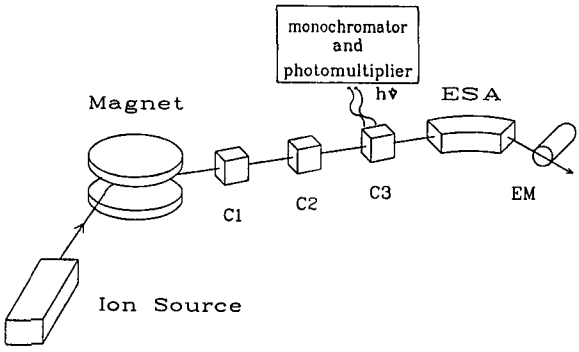
J.L. Holmes, *P.M. Mayer and A.A. Mommers, Chemistry Department, University of Ottawa, Ottawa, Canada K1N 6N5.

Recently we have undertaken a study of the light emitted by collisionally activated species in a mass spectrometer. Normally, it is the mass spectrum of the ionic products of the collisional activation process which are detected and analyzed. Two questions were asked concerning this process. The first is whether or not electronic excitation of the species involved occurs, in which case there should be radiative transitions to lower electronic states. The second, of course, is the practicality of observing and analyzing this radiation. These two questions have been answered positively and preliminary results have been reported [1,2]. Of particular interest at the present time is not so much the behaviour of simple diatomic and triatomic species, but rather the relationship between polyatomic ion structure and this collision induced emission of radiation. Earlier results employed wavelength cutoff filters to analyze the near ultraviolet and visible region of the spectrum (180-680 nm). Even though the resolution of the spectra obtained was severely limited, some important general conclusions could be made about the technique. The first was that for the simple diatomic, $H_2^{+\bullet}$, and triatomic, H_3^+, emissions are predominantly from excited state *neutral* molecules formed upon charge transfer with the target gas. This may hold to be true for more complex ions as well. The second conclusion concerns the excitation of the target gas molecules themselves. Evidence for emissions from excited target gas species was observed only in the cases where the charge transfer reaction between the ion beam and target species was exothermic, i.e. IE(target) < IE(neutralized ion). As for the correlation between ion structure and the collision induced emission of radiation, it was found that the three $C_2H_4O^{+\bullet}$ isomers acetaldehyde, ethylene oxide and vinyl alcohol have significantly different emission spectra [1,2]. The same result was obtained for two $C_2H_5Cl^{+\bullet}$ isomers [1].

This work represents our first results obtained with the use of a grating monochromator to analyze the emitted radiation. The resulting spectra have greatly improved wavelength resolution over those obtained with wavelength cutoff filters. However, the inherent losses in sensitivity incurred with the introduction of the monochromator has made it difficult to obtain spectra. The most fundamental problem concerns the proximity of the monochromator to the observation cell (fig.1). Present instrumental limitations require it to be 22 cm away, resulting in the amount of radiation successfully entering the monochromator being a fraction of that exiting the cell. The problem has been temporarily dealt with by connecting the cell to the monochromator with a fibre optic cable. Unfortunately, the fibre optics only transmit radiation in the visible region of the spectrum and so the results presented here are for the spectral region 400nm to 680 nm only. In the near future further modifications to our VG ZAB-2F mass spectrometer will place the monochromator within 3 cm of the collision cell, greatly increasing the amount of radiation analyzed, and hence improving the quality of the results.

The general experimental set up now in place is shown in fig.1. A mass selected ion beam traverses the experimental region of the mass spectrometer passing through three collision cells, C1, C2 and C3. Target gas can be introduced into any of the three cells and radiation emitted by the excited state species formed is observed from C3 which has a quartz window in one wall and a highly reflective interior. The above stated difficulty concerning the proximity of the monochromator to C3 means that emissions from excited state species formed in C1 and C2 are too weak to analyze at the present time. For this reason the results reported here are for collisions in C3.

Figure 1



We have obtained the collision induced emission spectra for the three $C_2H_4O^{+\bullet}$ isomers acetaldehyde, $CH_3CHO^{+\bullet}$, ethylene oxide, $\overline{CH_2CH_2O}^{+\bullet}$, and vinyl alcohol, $CH_2{=}CHOH^{+\bullet}$ using both helium and oxygen target gases. Due to the low sensitivity of the present apparatus and also to the lack of knowledge about the excited states of these polyatomic species, the spectra obtained are not interpretable in terms of transitions between specific electronic levels. However, what is obvious from an inspection of the spectra is that the isomers exhibit different spectral structure. Thus, this technique provides unequivocal identification for these three isomers, and hence can be used to supplement the CID mass spectra when identifying a $C_2H_4O^{+\bullet}$ ion of unknown structure. If the above hypothesis that most of the emitted radiation comes from the excited state neutral species formed upon charge exchange between the ion and the target gas is found to be accurate, it may be possible, with future apparatus, to obtain emission spectra which yield information concerning the actual electronic states involved.

Spectroscopy and Fragmentation of Alkylamines Investigated by Laser Ionization

F. Moritz, M. Dey, J. Grotemeyer*

Objective

The fragementation of alkylamines have been investigated by various mass spectrometric techniques through the years [1]. Recently Multiphoton Ionization (MUPI) was succesfully applied to alkylamines through a Rydberg Excitation at the Nitrogen atom [2].

We obtained the MUPI and single photon ionization (SPI) mass spectra of all isomeric propyl- and butylamines as well as n-pentylamine and of some deuterium labelled compounds in a Reflectron Time of Flight (RETOF) mass spectrometer.

Experimental

The mass spectrometric system consists of a jet chamber, an ion source and a RETOF-MS. The sample is either seeded into the jet through a high temperature inlet system or directly vaporized into the argon stream and then expanded in a jet valve.

MUPI is performed using a frequecy doubled dye laser between 230 and 240 nm. Frequency tripling of the third harmonic (355 nm) of a Nd.YAG-laser in a mixture of xenon and argon at 115 torr allows SPI with 118 nm radiation [3].

Results

The alkylamine molecular ion formed either with MUPI through a (2+0)-photon process ($h\upsilon$=5.2 eV) or with SPI ($h\upsilon$=10.5 eV) have an excess energy of 1-2 eV over the IE (8.5-9.5 eV). α-cleavage is the main fragmentation reaction for all investigated amines. The fragment ion shows a weak metastable broadening. For most of the investigated amines MUPI and SPI results are nearly the same except a more intense fragmentation with SPI. MUPI is known to have a propensity rule which leads to the formation of ions with less excess energy than with SPI.

With resonant multi photon ionization (REMPI) the signal intensity is enhanced by ionization through an intermediate state. For jet-cooled amines sharp absorption bands are observed (see figure 1) , whereas "hot" amines show only little dependence on the laser wavelength. REMPI also provides a selective ionization method by choosing the resonant wavelength for a compound. For example, it is possible to ionize selectively R-NH_2, R-NHD and R-ND_2 (R=t-butyl).

Deuteration either at the nitrogen or the α-carbon shifts the maximum in the intermediate state spectrum to shorter wavelenghts. This effect is more distinct for N-deuteration (n-propylamine: from 238.6 nm for R-NH_2 to 235.75 for R-ND_2).

Contrary to the literature [2] this shift indicates clearly that not a Rydberg excitation but a n-π^*transition into a S_1-state as a real intermediate state is responsible for ionization.

The formation of a distonic ion from the molecular ionis well known from EI studies. Investigating deuterated compounds we found that a δ-H is necessary to observe hydrogen scrambling.

Collision-Induced Dissociation of Protonated Adenine

Chad C. Nelson and James A. McCloskey
Department of Medicinal Chemistry, University of Utah, Salt Lake City, Utah 84112.

The collision-induced dissociation of protonated adenine and adenine monomethylated at positions N-1, C-2, N-3, N^6, and N-7 have been studied by tandem mass spectrometry using models extensively labeled with ^{13}C, ^2H, and with ^{15}N at each of the five nitrogen atoms.[1] These data are used to gain understanding of the mechanisms of dissociation of protonated heterocycles in general, and as a basis for the applications of tandem mass spectrometry to structural studies of adenine derivatives and other nucleic acid constituents.

The main dissociation pathways of protonated adenine, shown in Scheme 1, were determined from products resulting from collisional activation of MH^+(Figure 1) and by direct analysis of the first-step dissociation product ions of adenine and selectively-labeled adenines. Following collisional activation at 30 eV translational energy under multiple-collision conditions, protonated adenine undergoes decomposition along four independent major pathways (Scheme 1). These dissociations are: (1) expulsion of NH_3, found to be derived in approximately equal proportion from endocyclic N-1 and exocyclic N^6; (2) loss of NH_2CN, derived almost exclusively from N(1)-C(6)-N^6; (3) formation of NH_4^+directly from the protonated molecule; and (4) sequential expulsion of three molecules of HCN, which occurs in the first step by highly selective loss of N-1 and C-2. These pathways are of minor occurrence in the EI mass spectrum of adenine and in the CID mass spectrum of the odd-electron adenine molecular ion ($M^{+\cdot}$), except for sequential elimination of HCN which is also a prevalent process. The origin and site selectivity of neutral molecules eliminated in the principal dissociation reactions was established primarily from isotopic labeling distributions in the CID spectra of the [^{15}N]adenine isomers. Proposed mechanisms of dissociation are based on initial opening of the pyrimidine ring at N(1)-C(6) or at N(1)-C(2), resulting from protonation of N-1 in the primary ionization process.

Activation of protonated adenine under single-collision conditions results in deposition of less internal energy, such that virtually no fragmentation occurs beyond the first step of each of the four principal pathways. Under these conditions, greater selectivity in favor of loss of N-1 in expulsion of NH_3 occurs, but less effect is observed on the other three pathways. The prominent ammonium ion (NH_4^+), derived mainly from N-1, bears four of the six hydrogens in protonated adenine and is a remarkable product of extensive hydrogen rearrangement in which conformational flexibility of the proposed ring-opened protonated molecule permits transfer of three additional hydrogens to N-1.

Mass spectra of protonated methyladenine isomers and their ^{15}N- and ^2H-labeled analogs strongly support the occurrence of reaction paths analogous to those of adenine, and demonstrate the charge-localized pyrimidine ring to be the initial site of dissociation reactions.

MOLECULAR MODELING AND COLLISION-INDUCED DISSOCIATION MASS SPECTROMETRIC STUDIES OF CATIONIZED ALCOHOL ETHOXYLATE SURFACTANTS

Henry T. Kalinoski *, Anthony Cece and Karl F. Moschner
Unilever Research U.S. 45 River Road Edgewater, NJ 07020

Alcohol ethoxylates are nonionic surfactant mixtures of significant interest to the detergent, cosmetic and personal products industries. Characterization of these materials for use as ingredients in consumer products is required to ensure final formulation properties, performance and quality. Various forms of mass spectrometry, including collision-induced dissociation tandem mass spectrometry (CID MS/MS), have been used to characterize alcohol ethoxylate nonionic surfactant mixtures (1-3). When fast atom bombardment (FAB) ionization is used to ensure adequate parent ion abundance for CID MS/MS, alkali metal salts are usually present in the FAB matrix, leading to the production of alkali metal cationized parent ions. The cationizing species used can influence the ability to produce structurally significant fragment ions profoundly. Contrasts in the extent and type of fragment ions produced in CID MS/MS of cationized alcohol ethoxylates suggest a variety of mechanisms control the decomposition of the various gas phase ion-molecule complexes. The present study used molecular modeling to assist in understanding the decomposition mechanisms of CID MS/MS and to explain the formation of the fragment ions found. Energy calculations used in the molecular modeling were compared with the observed CID fragment ions, supporting mechanisms for ion decomposition.

Nonionic, linear alcohol ethoxylates were studied using fast atom bombardment (FAB) and direct chemical ionization (DCI) to prepare parent ions for CID MS/MS on a tandem quadrupole mass spectrometer. Salts of lithium, sodium and potassium were added to the glycerol FAB matrix to form cationized molecules for CID MS/MS. As ammonium adduct ions could not be formed in FAB, DCI using ammonia, isobutane and ammonia-d_3 to produce ammonium adduct ions and protonated molecules.

As in previous studies (1-3), structurally significant fragment ions could not be formed from sodium or potassium cationized molecules at the CID energies available on the tandem quadrupole system. Protonated molecules and ammonium adduct ions readily formed fragment ions, suggesting certain decomposition mechanisms. Although a range of parent species were chosen, certain characteristic fragmentation patterns were observed, allowing a minimum number of complexes to be studied via molecular modeling. Only a few mechanisms appeared operable, explaining the families of related fragment ions observed.

Starting geometries of ion-molecule complexes were generated using the SYBYL software suite and semiempirical molecular orbital calculations were carried out using MOPAC. As it was found that much of the hydrocarbon tail of the surfactant molecule did not participate in the CID fragmentation, mono- and triethoxylated propanol could be used as model systems to reduce computational problems to a manageable size.

Molecular modeling calculations indicated energetically preferred ion-molecule complex conformations and suggested certain mechanisms for the decomposition of the complex ions. These suggested mechanisms would lead to diagnostic fragment ions, predominantly protonated poly(ethylene glycol) ions, at mass-to-charge (m/z) values of (44n + 19). The calculations also indicated that these ions could undergo further transformations to release energy and produce lower molecular weight fragment ions. CID MS/MS spectra of protonated molecules and ammonium adduct ions confirmed to predictions indicated by the modeling. The modeling also indicated that an initial oxygen-ion bond is energetically unfavorable when the ion is sodium, precluding certain bond weakenings that would favor facile (low-energy) decompositions. Indications were that lithium interacts somewhat intermediate between sodium and the proton, although this was not able to be fully explored. The role of the ammonium ion in the decomposition of the ammonium adduct was probed, indicating an active participation by the ammonium ion. The role of ammonium suggested by the modeling work was tested through CID MS/MS studies of adducts formed using ammonium-d_3.

Molecular modeling provides a valuable additional tool in the characterization of the mechanisms of ion decomposition under CID MS/MS conditions. The modeling also suggested further experiments to allow a more complete understanding of CID MS/MS mechanisms. Positive ion DCI using ammonia is an excellent approach to form abundant parent ions for CID MS/MS. All of the possible experiments could not be completed, so further work on complexes with other cations and other surfactants (including ionic materials) will be performed.

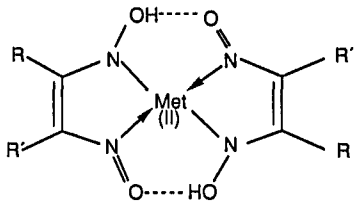
Gas-phase fragmentation of Ni(II), Pd(II) and Pt(II) complexes of dioximes of α-diketones

M. G. Santana Marques and A. J. Ferrer-Correia
Department of Chemistry, University of Aveiro
3800 Aveiro, Portugal

The complexes of divalent VIIIA group metals of dioximes of α-diketones with the general formula



where R and R'= H, CH_3, C_2H_5, C_3H_7, C_6H_5, C_4H_3O and Met = Ni(II), Pd(II) and Pt(II) have been studied by using electron impact mass spectrometry and MIKES techniques. Although the mass spectra of some of these complexes have been studied before[1-3], evidence from MIKES techniques, in special CA MIKES, has been so far very scarce.

For almost all the mass spectra the base peak is the molecular ion, $MetL_2^{+\cdot}$ (L is the conjugate base of the α-dioxime) and for the platinum complexes the molecular ion is also the main contributor for the total ion current. For the nickel and palladium complexes abundant peaks can be found at m/z values corresponding to structures as MetLHNO+, MetLH+·, Met(RCN)OH+ and Met(RCN)+·. Doubly charged molecular ions are found for almost all the platinum complexes and for some of the palladium complexes.

The data obtained from metastable MIKE spectra is not abundant because there are few unimolecular fragmentations of the molecular ions of these compounds, the most important being losses of OH, for the compounds with alkyl R and R'substituents

The collision induced fragmentation spectra, on the other hand, provide a lot of information. In the CAMIKE spectra of the molecular ions of the Ni(II) complexes the most abundant ions are

(with few exceptions) the MetLHNO+ ions. Other abundant ions are MetLH+· and $MetL_2$-OH or $MetL_2$-NO for the compounds with non saturated ring R and R´substituents.

The spectra of the Pd(II) compounds have many common features with the Ni(II) compounds, such as abundant MetLH+ and Met LHNO+ ions, although in the case of the first the MetLH+· ions are.the most abundant..

The spectra of the Pt(II) complexes are different from the spectra of both Ni(II) and Pd(II) complexes. The MetLHNO+ and MetLH+ ions are not very abundant and their spectra show ions such as Met (L-H)-2NO which are not present in the spectra of the complexes of the two other metals. These fragment ions (and others which are only present for the Pt(II) complexes) contain parts of the ligand that can be considered as non- classical ligands and whose abundances are not directly dependent on the formal oxidation state of the metal center.

As a rule, the gas-phase behavior the complexes of the divalent VIIIA group metals studied, Ni(II), Pd(II) and Pt(II), depends mainly on the metal center, although the fragmentations patterns of Ni(II) and Pd(II) complexes have many similarities between themselves. In general, the differences are smaller between the Ni(II) and Pd(II) complexes, and greater between the Pt(II) complexes and any of the others. The influence of the different ligands is comparatively small (specially when R and R´are alkyl groups) and is most important in the case of Pt(II) complexes, due to the high stability of metal-ligand π bonding.

Acknowledgements

We are indebted to Professor M. L. Gross and the MCMS for the use of the equipment necessary for the MIKE spectra. We also want to thank INIC for financial support (scholarship given to M. G.S.M)

STUDY OF THE DECHLORINATION MECHANISM OF PCB IN A MASS SPECTROMETER USING ^{35}Cl LABELLED PCB'S

F. Lépine*, S. Milot*, M. Reimer**, O.A. Mamer**
*Institut Armand-Frappier, Université du Québec, Laval, Qc, Canada
**Biomedical Mass Spectrometry Unit, McGill University, Montreal, Qc, Canada

In order to study the regioselectivity of the dechlorination of PCB's in Electron Impact (EI) mass spectrometry, seventeen PCB congeners were synthesized. These congeners bear one or two isotopically pure ^{35}Cl atom at specific positions around the biphenyl nucleus. These labelled PCB's were synthesized by chlorination, using isotopically pure $^{35}Cl_2$, of four tetrachlorobiphenyls, namely congeners 47,52,54 and 77 according to the IUPAC nomenclature. Upon chlorination of each of these congeners, mixtures of various mono and di ^{35}Cl labelled PCB's were obtained. They were identified by their GC relative retention time (RRT) by comparison with the RRT of the 209 PCB congeners published in the litterature with a similar capillary column. Identification of the various labelled PCB's produced also allowed to specify the position of the labels around the biphenyl nucleus.

These four PCB mixtures were analysed by GC-MS in selective ion monitoring mode. The ions monitored were those corresponding to the chlorine isotopes only, for ions containing one, two and three chlorine atoms less than the molecular ion. The P+2 and P+4 peaks of each cluster, normalized with the P peak were compared with tables listing these normalized values for a molecule containing the same number of chlorine atoms and for decreasing values of the $^{37}Cl/^{35}Cl$ ratio. This comparison gave the $^{37}Cl/^{35}Cl$ ratio in the ion of interest. After simple calculations, the residual value of the added ^{35}Cl in the ion is obtained and gives the relative reactivity of the label at this position.

For the PCB's bearing only one ^{35}Cl, the reactivity at various position decrease in the order ortho $>$ meta $\geq$ para. Two labelled congeners also show a greater residual ^{35}Cl in their M-2Cl than in their M-1Cl ion, thus proving that loss of Cl_2 occurs directly from the molecular ion in the ion source.

For the PCB's bearing two ^{35}Cl, the reactivity at the various positions is the same as observed above. Two pairs of identical congeners were observed but for the position of their labels which were in the ortho and meta positions. The percentage loss of the label at these two positions arise to 100% of the added ^{35}Cl for the M-1Cl ions. This indicates that the para position is inactive in these two congeners and that there is no randomization of the Cl atoms around the biphenyl nucleus under EI conditions.

Tandem Mass Spectrometric Fragmentation Study of Surfactants at Various Collision Energies After Ionization by Fast Atom Bombardment and Laser Desorption.

D. Weil, P. Lyon, R. Pachuta, 3M, 3M Center, St. Paul, MN 55144
and Colin Moore, Kratos Analytical, Ramsey, NJ 07432

The utility of fast atom bombardment (FAB) and laser desorption (LD) for the characterization of surfactants has been well documented. Many commercial surfactants are mixtures of several different components or oligomers of a specific surfactant Therefore, molecular weight and structural information are required to characterize these materials.

Cationic surfactants such as quaternary amines are not amenable to electron ionization but can be ionized by using FAB[1], LD[1], SIMS, electrospray or thermospray ionization methods. These techniques are particularly useful for molecular weight determinations, but they are generally less useful for determining structural information. Tandem mass spectrometry (MS/MS) with the above ionization methods can be used to generate fragment ions from pseudo-molecular ions, from which structural information can be obtained[2].

The scope of this study includes the following objectives: comparison of low energy versus high energy collisions from various ionization and instrumental methods; fragmentation pathway determination based on MS/MS studies; and determination of the effect that ionization method has on the M_w distribution.

The FAB experiments were performed on a Kratos CONCEPT IS, CONCEPT hybrid mass spectrometers (ISQ and IHQ) and a Kratos MS-50 HMTA mass spectrometer, all operating at 8 kV accelerating potential. The LD experiments were performed by using a 3T EXTREL FTMS-2000 mass spectrometer equipped with a high-power pulsed CO_2 laser to ablate and ionize the surfactants. The output energy of the laser was estimated to be on the order of 0.05J per pulse. Ion activation prior to MS/MS analysis was accomplished by either low energy collisions (0-500 eV) with Ar or Xe or high energy collisions (> 1keV) with He. Mass analysis to give the fragment ion spectra was accomplished by using linked scans on a 2 sector instrument, quadrupole scans on a hybrid instrument, and SWIFT™ pulsed excitation on a FTMS instrument.

The positive-ion FAB, thermospray and LD mass spectra obtained from dimethyldicocoammonium chloride (Arquad 2C-75) compares well with previously published spectra[2]. The molecular ions at *m/z* 382, 410, 438, and 466 correspond to $[R_1R_2N(CH_3)_2]^+$, where R_1 and R_2 are the C_{12}, C_{14}, and C_{16}, groups. The high-mass species correspond to the trisubstituted quaternary amines, $[R_1R_2R_3NCH_3]^+$. The major fragment ions observed in the FAB and LD spectra arise from the loss of a neutral alkane from the molecular ion and the loss of both long alkyl chains to form *m/z* 58 $[CH_2{=}N(CH_3)_2]^+$. Energy resolved MS/MS data (Figure 1) indicate that these fragment ions arise from a high energy fragmentation pathway.

The low energy MS/MS FAB and LD spectra of a cationic surfactant gave second generation ion spectra that showed a strong dependence on the collision energy. At the low collision energies, the fragmentation pathway favored both formation of $[C_nH_{2n+4}N]^+$ from alkene elimination and of $[C_nH_{2n+1}]^+$ ions from long-chain alkyl fragmentation (Figures 2A-2C). The energy resolved mass spectral data and linked scan data (Figure 3) show that as the collision energy was increased the fragmentation pathway shifted to formation of $[C_nH_{2n+2}N]^+$ and

$[CH_2{=}N(CH_3)_2]^+$ via an alkane elimination. The parent ion scans for *m/z* 57, 58, 212 and 214 were used to confirm the fragmentation pathway shown in Scheme I. The MS/MS spectrum of *m/z* 536 $[R_1R_2R_3NCH_3]^+$ shows that the ions at *m/z* 368, 366, and 212 occur from alkane and alkene eliminations. The fragmentation of the trialkylmethylquaternary amine explains how the $[R_1R_2NHCH_3]^+$ and $[R_1R_2N{=}CH_2]^+$ ions arise in the full FAB spectra and the high laser power LD spectra.

The high-resolution excitation and detection capability of LD/MS/MS enables the elemental composition of the fragment ions from *m/z* 382 to be determined without an internal calibrant compound. The mass measurement errors range from 2.0 ppm for *m/z* 214 to 28 ppm for *m/z* 58.

Internal Energy Distribution of Collisionally Excited Chromium Hexacarbonyl Ions

Toshihide Nishimura*, Russell H. Robins†, and Wayne K. Duholke†
Control Research & Development, Upjohn Pharmaceuticals Limited, 23 Wadai, Tsukuba-city, Ibaraki 300-42 Japan; †The Upjohn Company, Kalamazoo, MI 49001

The collision-induced dissociation (CID) technique is widely used in various fields of modern mass spectrometry. Since Thomson's first finding of the decomposition of collisionaly excited hydrogen molecular ions, CID mass spectrometric studies have made a great contribution to the structure elucidation of gaseous organic ions which is of central importance in ion chemistry. Furthermore, recent inovations in ionization techniques have set new mile stones in mass spectrometry. Modern ionization methods including fast atom bombardment (FAB), thermospray (TSP) and electrospray (ESP) techniques can ionize large and nonvolatile biomolecules, and have made it possible for mass spectrometry to explore its applications in biological science such as sequence determination of peptides and proteins even at the level of less than a nanogram. Coupled with these new ioniztion techniques, CID mass spectrometry has been useful for attaining structural information of biomolecules via structure driven fragmentation of the prominent pseudo-molecular ions produced by such soft primary ionization methods.

Although the collision excitation process and the resultant internal energy deposition within analyte ions are not well known, a major excitation process seems to be the translational-vibrational energy transfer. Such mechanisms govern the appearance of observed CID MS/MS spectra but are little understood because internal energy distribution of a molecular ion excited by collision has been little studied. Most of FAB MS/MS studies have been are formed using one of two types of commercially available spectrometers. One is the magnetic sector instrument employing a linked scan for high energy CID in the field-free region (FFR1 or FFR2) with the collision energies of one to several ten keV. Another is the triple quadrupole instrument in which the second quadrupole filter is used as a collision cell and CID occurs under low collision energies less than several hundred eV. It is known that MS/MS mass spectra of molecules having relatively high molecular weights obtained on both high and low energy instruments are considerably different. These may be brought about partially from difference in transmission of ions depending on their ion kinetic energies attained especially by fragmentation in a field free region of a magnetic sector instrument since fragment ions will gain ion kinetic energies proportional to their mass, and CID mass spectra will be intrinsicaly influenced by the extent of internal energy deposition in collisional acivation taking place.

Then we have investigated energy deposition in collisional activation directly using the detailed breakdown diagram of the chromium hexacarbonyl ion which is well determined by threshold photoelectron-photoion coincidence mass spectrometry because the breakdown curves individual fragment ions are restricted to the specific internal energy regions of the molecular ion. Vibrational excitation functions were extracted in order to understand collisional excitation processes taking place on both the instruments.

Internal energy distributions of $Cr(CO)_6^+$ have been extracted from its CID mass spectra measured at several collision energies using both the magnetic sector and triple stage qudrupole instruments. The excitation functions derived from these energy deposition functions seem to suggest that the $0 \rightarrow 1$ collisional vibrational excitation is responsible for high energy CIDs at field-free regions on the magnetic sector mass spectrometer(Fig. 1), and therefore it has been indicated that for a large pseudo-molecular ion CID will suffer from low energy excitation, which may be estimated to be less than 1 eV for the collision energies of 1 to 5 kV. On the triple quadrupole mass spectrometers, vibrational excitation due to the ladder excitation mechanism occurs by multiple collisions and results in energy deposition much higher than 1 eV (Fig. 3). Detection cutoff of small fragment ions also determins a profile of CID MS/MS spectra acquired on a magnetic mass spectrometer (Fig. 2). These results may explain of a great difference observed in profiles of CID mass spectra measured with both a magnetic sector and triple quadrupole mass spectrometers.

Acknowledgments We gratefully acknowledge Drs. A.J. Taraszka, J.B. Landis, and A. Sonoda for their support of this collaborative work under the delocalized project for technology development on mass spectrometry, and also thank Ms. M. Kanai at the Finnigan MAT Instrument Japan Inc. for her providing CID mass spectra measured on a Finnigan TSQ-700 mass spectrometer.

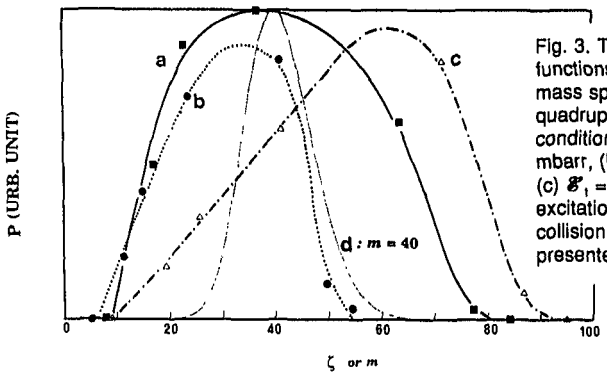

Fig. 3. Typical experimental excitation functions P(ζ) extracted from the CID mass spectra obtained on the triple quadrupole instrument under the following conditions: (a) $\mathscr{E}_t$ = 20 eV; P_{Ar} = 0.20 mbarr, (b) $\mathscr{E}_t$ = 49 eV; P_{Ar} = 0.20 mbarr, (c) $\mathscr{E}_t$ = 20 eV; P_{Ar} = 0.67 mbarr. The excitation function with the definite collision number, m = 40, is also presented as the dotted line denoted by *d*.

Time-Resolved Photodissociation and Radiative Relaxation Kinetics for Ferrocene Ion

R. C. Dunbar and J. D. Faulk
Chemistry Department
Case Western Reserve University
Cleveland, OH 44106

Introduction

Information about gas-phase ions of organometallic compounds like ferrocene is meager. Time-resolved photodissociation can address:

-What is the unimolecular fragmentation rate?

-What is the activation energy (or bond strength) for dissociating a Cp ring from ferrocene ion?

-What is the infrared radiative relaxation rate of the ion?

Methods

Ferrocene ion was formed by electron impact, trapped in the ICR ion trap, and photodissociated by two photons of 355 nm light:

$$Fe(Cp)_2^+ \longrightarrow Fe(Cp)^+ + Cp.$$

Time-resolved photodissociation. The amount of photofragment was measured as a function of the delay between the laser pulse and the ICR detect pulse.

Ion thermometry. The dissociation rate increases with excess energy in the parent ion. A dissociation rate rate measurement thus lets us probe the instantaneous internal energy of the ion.

Ion Cooling Rate. Using the thermometric probe technique the internal energy of the ions was probed as a function of the cooling time between the electron beam pulse and the laser pulse.

Results

The top figure shows the time-resolved photodissociation curve. The dissociation rate derived from this is 7.8×10^4 s^{-1}. RRKM extrapolation to zero rate leads to a bond strength of 3.7 eV.

The lower figure shows a cooling curve. After the collisional cooling contribution was subtracted, a rate constant for infrared radiative cooling of 0.28 s^{-1} was found.

Conclusions.

The metal-ring bond strength in ferrocenium ion is 3.7 eV.

The infrared radiative cooling rate is 0.28 s^{-1}.

UNUSUAL ISOTOPE EFFECTS ON THE LIFETIME AND RELAXATION PATHWAY OF A NEW HIGH ENERGY METASTABLE STATE OF OXYGEN

K.S. Griffith and G.I. Gellene, Department of Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN 46556.

The charge exchange of O_2^+ on alkali metals has been studied previously by several groups using neutralized ion beam techniques sensitive only to dissociative processes. In those experiments the neutralization products were identified as the $^{1,3}\Pi_g$ Rydberg levels which rapidly predissociate. We investigated this reaction using a neutralized ion beam technique which is sensitive to both dissociative and nondissociative products. Briefly, ions formed by electron ionization in a high pressure source are accelerated to 5 keV and magnetically mass-resolved. The ions then enter a neutralization chamber containing a few mTorr of metal atoms (Na or K). Both neutrals and ions exit the chamber, and the ions are deflected by a pair of electrostatic plates. The neutral beam, which spreads as species dissociate, travels to a translatable detector, which samples the intensity as a function of the angle. Metastable products show up as a spike of intensity centered around θ=0. In a second experiment, an additional slit is placed after the neutralization chamber, which allows us to investigate the dissociation of the metastable species. A typical set of profiles is shown.

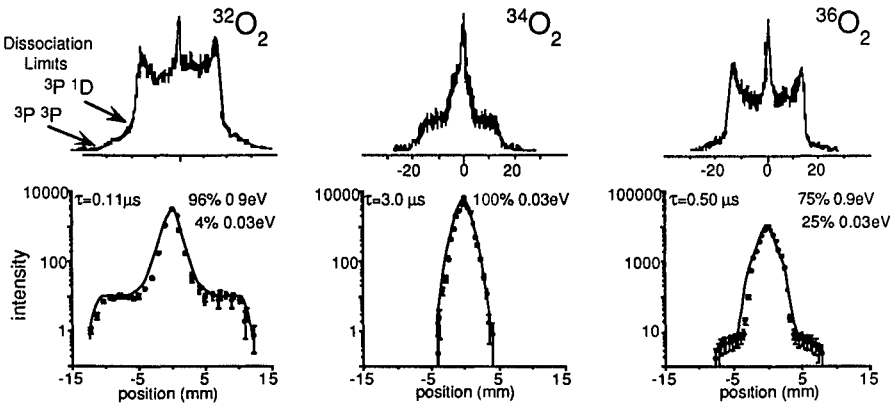

Figure 1. Intensity is shown as a function of distance off center. The top profiles have been scaled such that center heights are identical; contributions from the dissociative portion were comperable. In the bottom profiles, points are experimental, the solid curve is from the model (see text).

Our results for the dissociative products are in complete agreement with previous work. Surprisingly, however, undissociated O_2 in a long-lived metastable state was also observed. Using a model of our double slit experiment that included a geometric apparatus function, a probability of dissociation with time, and a probability of kinetic energy release, we were able to model the experimental results. It was found that the "wings" were best modelled by a single energy, and the inner "spread" was best fit by a sum over a range of energies, while a single energy could give a good result. The results were not unique in that a finite range of lifetimes could be modelled. By measuring the dependence of the normalized intensity of the metastable (I_m/I^o) as a function of time after formation, apparent lifetimes were obtained (See Figure 2a). These lifetimes were overestimated because of our inability to distinguish between signal from undissociated species and species that dissociated with very small energy releases. This was corrected for by using the model of our system, which allows us to determine the amount of dissociative signal, for a given lifetime, that is counted as undissociated. The results of this analysis are in Figure 2b.

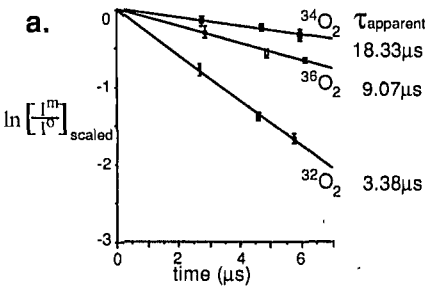

Figure 2a. Log of scaled normalized metastable intensity as a function of time after formation.

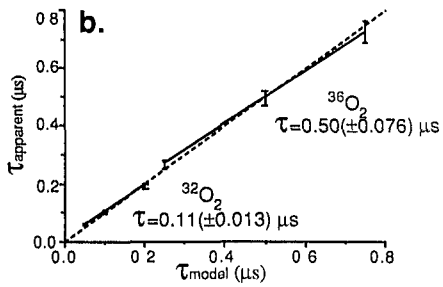

Figure 2b. Corrected apparent lifetime *vs* model lifetime. $^{36}O_2$ could not be analyzed as the double slit profile was featureless.

Previous work has shown that O_2^+ ($^4\Pi_u$) and O_2^+ ($^2\Pi_g$,v=1,2) cannot be responsible for the production of this metastable, and that high vibrational excitation in the ion favors production. It has also been determined that the metastable cannot be a high Rydberg level of oxygen. Because the metastable relaxes dissociatively, it cannot be identified with any of the known metastable states of O_2, all of which lie below the first dissociation limit. Since the "wings" of the double slit experiment are best represented by a single kinetic energy release, and the inner "spread" by a sum over a range of energies, we conclude that there are two relaxation pathways, one predissociative and one radiative. Inspection of the predicted bound states of oxygen reveals only one candidate that can account for the predissociation, $1\,^1\Delta_u$. Calculation of the Franck-Condon overlaps of the first five vibrational states of $1\,^1\Delta_u$ with the repulsive state that predissociates it, $2\,^3\Delta_u$, reveals that the v=2 level FCF's vary significantly with mass (See Figure 3.), and this variation can account for the difference in the predissociative lifetimes of the isotopic variants. We were further able to use the experimentally determined predissociative lifetimes to estimate the spin orbit coupling between $1\,^1\Delta_u$ and $2\,^3\Delta_u$ at 18(±2) cm^{-1}. There are two states to which our bound state might radiate to give a very small energy release, $2\,^3\Pi_g$ and $3\,^3\Pi_g$. Preliminary calculations indicate that the $2\,^3\Pi_g$ has a much larger dipole radiative transition probability, and that the largest probabilities are for energies less than 0.03eV, in agreement with experimental results. Thus we have identified the metastable species as the v=2 level of the previously unobserved $1\,^1\Delta_u$ state of oxygen.

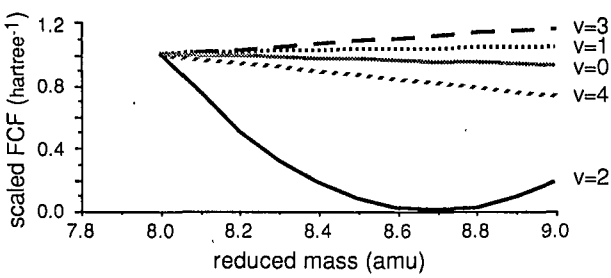

Figure 3. Franck-Condon overlaps between $1\,^1\Delta_u$ and $2\,^3\Delta_u$ as a function of reduced mass. The FCF's have been scaled to all be 1 at the reduced mass of $^{32}O_2$; the actual FCF's of v=0,1,3,4 were all approximately an order of magnitude greater than v=2 at that reduced mass.

NEUTRALIZATION-REIONIZATION WITH A LASER

M.J. Polce, H. Saigusa, F.A. Wiedmann, M.J. Nold, and C. Wesdemiotis
Chemistry Department, The University of Akron, Akron, OH 44325-3601
P.A. Bott, VG Analytical Ltd., Wythenshawe, Manchester M23 9LE, UK

The immediate objective of our present research is to examine the practicality of utilizing laser generated photons to reionize fast neutral beams created in our VG Autospec mass spectrometer [1]. Replacing gaseous targets used for neutralization with photons would permit precise variation of the energy to be deposited, so that selective ionization, as well as, variable degrees of fragmentation would be obtainable. This capability would augment the application of the NRMS technique [2] which has allowed the neutral beams formed inside a mass spectrometer to be "seen".

Here we describe the modifications undertaken to our instrument to evaluate the photoreionization of neutralized beams by laser light. Redesign of Cls-2 and Cls-3 makes possible interfacing with a Quanta-Ray DCR Nd:YAG pulsed laser. Vacuum tight UV grade fused silica windows installed in the top of the mass spectrometer housing permit introduction of a crossed laser beam through similar windows into either of the new gas collision cells from the z-direction (see Fig. 1). The laser beam exits the cells through the same ports, after reflection on MgF_2 overcoated aluminized mirrors mounted on the cell bottoms. This still allows conventional NRMS studies. The pulsed Nd:YAG laser was run under normal Q-switched operation at a 10Hz repetition rate. A harmonic generator using KD*P crystals was positioned to produce a 266nm beam with a pulse width of ~5ns. A dispersing prism was utilized to separate the collinear fundamental (1064nm), 2nd harmonic (532nm), and 4th harmonic (266nm) beams. Two prisms direct the 266nm laser beam onto a spherical lens for defocusing before passing through a cylindrical lens which is used to fashion the photon beam into a rectangular shape. Finally, a mirror reflects the laser light onto the neutral beam.

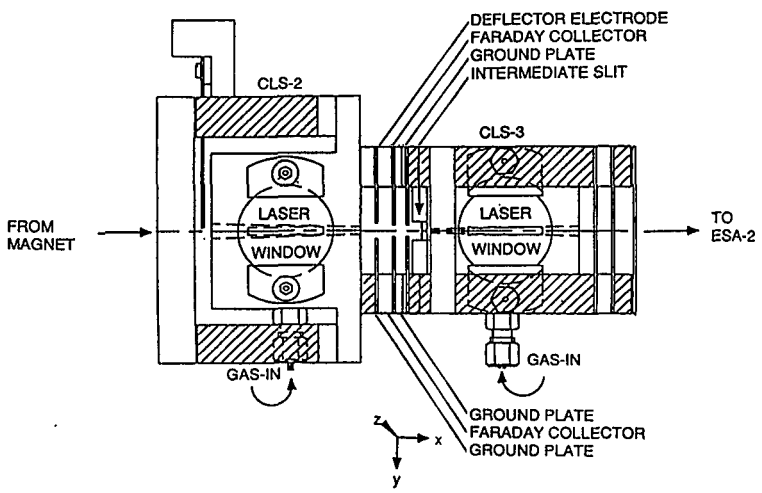

FIGURE 1

P-Xylene cations were produced by 70 eV electron ionization in the source, accelerated to 8keV, and mass-selected. In the +NR+ Xe/266nm experiments, p-xylene radical cations are reduced in Cls-2 by collisions with Xe. The unneutralized fraction is removed by electrostatic deflection (indicated by "/") and the remaining beam of fast neutrals is crossed with 266nm photons in Cls-3 along 20mm. The neutral beam, traveling in the x-direction, is ~8mm high (z-axis) and has a width (y-axis) of ~0.3mm in Cls-3. New experiments, involving phase sensitive detection, have recently been initiated to combat the low duty cycle of the laser. A Pomona Electronics photodiode detector head is positioned to trigger a Stanford Research Systems two channel gated photon counter. In theory, this would allow collection of the signal only while the laser pulse is on. Furthermore, one should be able to record the count with the laser on and subtract it by that with the laser off, resulting in a net reionization signal without any background signature.

Initial experiments have provided no definitive experimental evidence for reionization by photons. Possible reasons include:
(1) Neutralization by gaseous collisions may create neutrals with a disparity of energies. This could complicate their ability to efficiently absorb photons of only one specific wavelength.
(2) Diffusion of the neutralization gas into the reionization cell seems to produce a considerable background which may suppress weak photoreionization signals. Results show the majority of background signal seems to be caused by Xe reionization inside of Cls-3.
(3) Data collection of the reionized neutral is hampered by the short time period the laser is on versus the time it is off. Preliminary data, involving phase sensitive detection, disclose no statistical difference in counts with the laser on versus off.

Since the merits of this technique deserve further study, we plan the following future experiments:
(1) Consider using metastable decomposition of protonated dimers to produce ground-state neutrals.
(2) Examine alternative chromophore containing chemical systems that may improve promotion of multiphoton ionization.
(3) Explore placement of a physical partition between the neutralization and reionization cells to minimize Xe diffusion problems.
(4) Investigate the application of a gated integrator and boxcar averager to enhance signal detection.
(5) Probe the possibility of utilizing fiber optics to guide laser photons directly into the reionization cell.

Automation of Mass Spectrometric Analysis

Dana E. DeJohn and Anne B Giordani
Parke-Davis Pharmaceutical Research Division, Warner-Lambert Company
2800 Plymouth Road, Ann Arbor, MI 48105

Our laboratory has automated the sample preparation, data acquisition, and data analysis of the electron (EI) and chemical (CI) ionization mass spectra needed to support the synthetic effort of a large medicinal chemistry research program. The instrumentation used for this automation includes a sample preparation robot (Zymark® BenchMate™ workstation) and a mass spectrometer (Fisons Instruments (VG Biotech) Trio-2A mass spectrometer and LabBase™ data system) equipped with an autosampler and an automated direct exposure probe. These instruments are integrated with a laboratory information management system (LIMS, Beckman Instruments Computer Automated Laboratory System™).

Most of the investigators who submit samples for mass spectrometry analysis also request an NMR analysis. A preweighed sample for both analyses is submitted in a single vial along with a submission sheet which contains the investigator's sample identification number, the choice of NMR solvent, and the empirical formula for the proposed structure. This information is entered into the LIMS. The LIMS generates bar-coded work lists for the NMR and mass spectrometry laboratories which are used for both sample preparation and data analysis. The mass spectrometry work list includes the sample identification number, the NMR solvent, and the proposed molecular weight.

The samples for NMR analysis are robotically prepared by the workstation. Using the mass spectrometry work list, 10 µL of samples which also have a mass spectrometry request are diluted with 200 µL of methanol and the diluted solutions placed in autosampler vials. For samples which have only a mass spectrometry request, preweighed samples are diluted with methanol and the solutions are placed in autosampler vials. The vials are then loaded into the mass spectrometer's autosampler rack.

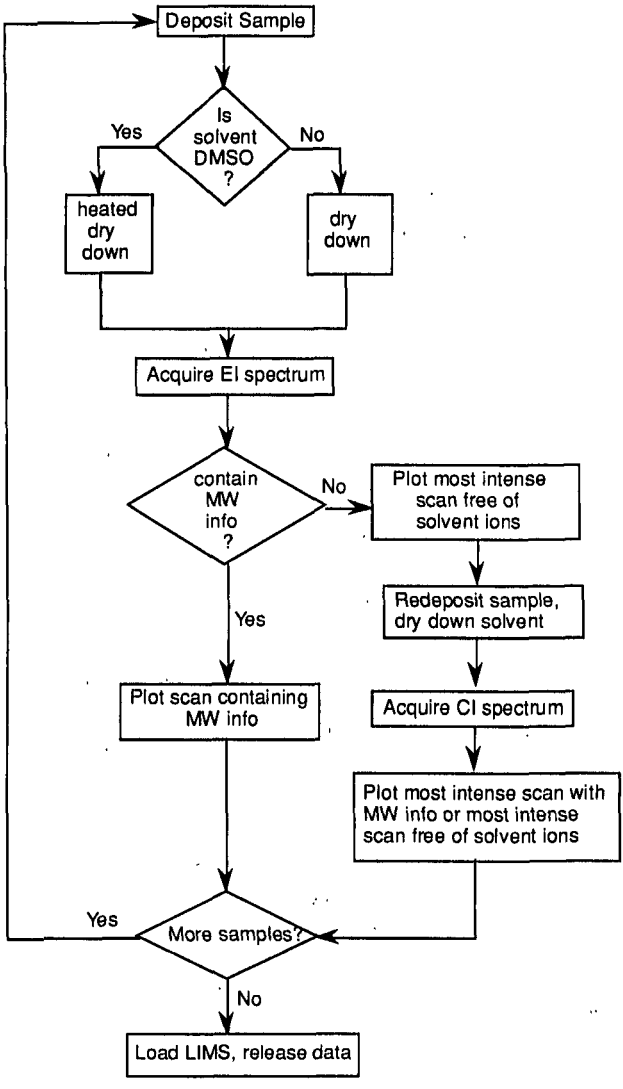
The flow diagram on the next page summarizes the automated data acquisition and data analysis process. Data acquisition and analysis have been automated through macro programming. The information from the mass spectrometry work list (sample identifications and molecular weights) and the appropriate direct exposure probe programs are entered into a file. The automated acquisition macro enters the information for the first sample into the mass spectrometer's acquisition page and assigns a data file name. The mass spectrometer signals the autosampler to deposit the sample onto the direct exposure probe. After the solvent evaporation procedure has been completed, the automated probe moves into the instrument and the EI data are acquired.

After the EI data file is acquired, the data analysis macro searches the file for scans that contain peaks consistent with the molecular weight information. The search uses a plot of the ion current for the m/z value equal to one plus the molecular weight of the proposed structure (the peak representing the ^{13}C isotope of the molecular ion or the peak representing the protonated molecule). If found, the most intense, unsaturated scan is hardcopied and the next sample is analyzed. If the molecular weight information is absent or below a set intensity threshold, the data analysis macro uses a plot of the summed ion currents from m/z 100 to 700 to find the most intense scan free of peaks arising from residual solvent and hardcopies the scan. The mass spectrometer then signals the autosampler to deposit the sample on the direct exposure probe again and the sample is automatically reanalyzed under CI conditions. The data analysis macro examines the CI file in a manner analogous to the EI data analysis process and then the next sample is analyzed.

With automated operation, we have realized the following benefits:

- The tedious and repetitive tasks of sample preparation and sample introduction have been relegated to robots.
- Automatic data processing has minimized the staff time required for data analysis.
- The laboratory is able to readily handle the current sample load of approximately 1200 samples per month.
- Smaller amounts of sample (~ 2 µg) are consistently applied to the direct exposure probe, helping reduce the rate of ion source contamination.
- As an aid for interpretation, complementary EI and CI data are generated for samples that differ from their proposed molecuar weight.
- Short turnaround times give the rapid structure confirmation crucial to the productivity of the drug discovery and development programs.

DATA ACQUISITION AND ANALYSIS FLOW CHART



Development of Site-Selective Gas-Phase Ion-Molecule Reactions of Antibiotics

Erika S. Eichmann and Jennifer S. Brodbelt
Department of Chemistry and Biochemistry
University of Texas, Austin, Texas, 78712.

The toxic side effects and pharmacokinetic properties of antibiotics, and in particular the type of drugs known as aminoglycoside antibiotics, have of recent years been under close scrutiny. The unparalleled clinical efficacy of this class of antibiotics, which includes such well-known drugs as streptomycin and neomycin, is somewhat overshadowed by the dose-related toxicity of all of its members. The advantages of these drugs have stimulated great interest in preparation and analysis of aminoglycosides, and in the search for possible solutions to the problem of the dangerous side effects. For this reason, a greater understanding of the chemical nature of this class of drugs is especially necessary

We are particularly interested in the structure-activity relationships in antibiotics, and the mechanisms by which these relationships are mediated. Our emphasis lies mainly in the investigation of functional group interactions within large molecules and their specific effects on the reactivity of the whole molecule. We have therefore undertaken a systematic study of the functional groups and ring systems commonly found in antibiotics. As a first target, we have chosen tobramycin, a tricyclic aminoglycoside antibiotic. The principle objectives of this preliminary effort included division of the target into small, easily manipulated monofunctional and difunctional subunits, reaction of these subunits with a variety of reagents, and implementation of laser desorption techniques in a quadrupole ion trap for volatilization of the more involatile subunits and for tobramycin as a whole. Computer modelling techniques were also used to predict reactivity, and to assist in the interpretation of experimental results.

The aminoglycoside antibiotics were chosen for this initial study in part because they have easily divided structures. All members of this class consist of sugars, aminosugars, and various simple ring systems linked together by glycosidic bonds. It is therefore reasonable to divide the molecule at these junctions. The resulting fragments are then either comercially available, or can be adequately modelled by similar sugars or aminosugars. The structure of tobramycin and its subunits are shown below, in Figure 1. There is conceivably some long-range interaction between the functionalities on the different ring systems of this molecule, and this must be taken into account. However, this can be treated as a separate factor, and considered after the individual reactivities have been elucidated. After the behavior of the subunits is defined, large and larger models, and eventualy the target molecule, can be studied. Another feature of these antibiotics is the small number of *types* of functional groups within the molecule. The structure of tobramycin possesses only hydroxyl groups, ether linkages, and primary amine groups. These three functionalities can interact with all of its surrounding functional groups. In actuality, however, these ring systems are fairly rigid, and only certain of the many permutations leads to electronic or steric interaction. A qualitative determination of the degree of interaction between any two functional groups can be obtained by the examination of molecular models. In this way, all of the sterically or configurationally impossible interactions can be eliminated, and a much more reasonable list of possible permutations remains. Likewise, those interactions which are expected to be the strongest can be recognized.

Although the rotationally hindered molecules having the exact carbon skeleton are the best possible difunctional models, reasonable approximations of their reactivities can be made by using smaller, linear compounds which have the same functional group separation, but are rotationally free. Thus, these small models will likely have a more diverse reactivity than the conformationally fixed cyclic models. This last approximation is only valid if the structural restriction is taken into account, but serves as a good first approach. In this way, the vast number of models for the interactions between any two specific functional groups can be reduced to a few. For example, consider the compounds ethanolamine, ethoxyethylamine, and ethoxyethanol (Figure 2).

The only product observed upon reaction of ethanolamine with the dimethyl ether 45^+ ion was $(M + 13)^+$. The behavior of this product upon collisional activation indicates that the primary reactive site of the substrate is the amine group. Only two fragmens are observed: the 44^+ ion and the loss of water. The loss of water from the product ion must necessarily mean that the hydroxyl group is not the reactive site, at least for a significant portion of the sample. The mechanistic details of the formation of the 44^+ have been discussed elsewhere, and support this argument. Thus, the dominant functionality is the amine group.

Changing the above substrate hydroxyl group to an amino group dramatically changes the

nature of the compound. The product observed was $(M + 15)^+$, as opposed to the $(M + 13)^+$ product ion seen for ethanolamine. The methyl cation attachment product ion $(M + 15)^+$ is commonly observed with ethers and diethers. However, whereas the *ether* $(M + 15)^+$ dissociated primarily by losing 46 mass units, the $(M + 15)^+$ formed here gave exclusive loss of methylamine upon collisional activation. This fragmentation pathway is best explained by methyl cation attachment at the amine group, rather than at the oxygen site. Thus, the dominant functional group is again the amine, although a completely different reaction is occurring.

Again, slight modification of the substrate from the above amino ether to a hydroxy ether caused a dramatic change in reactive behavior. The only product observed upon reaction of methoxyethanol with the 45^+ ion ofdimethyl ether was $(M + 13)^+$. We know from previous studies that an ether functionality cannot undergo the reaction necessary for the formation of this product, and therefore that the reactive site must be the hydroxy group. The fact that this was the only product formed indicates that the hydroxy group is the group of dominant reactivity in this molecule. The dissociation behavior of the ion is consistent with this assertion: the only observed fragment is due to loss of formaldehyde, a common pathway followed by activated hydroxyl-site $(M + 13)^+$ ions.

In the hope of finding useful new, and perhaps biologically relevant, reagents for this and other projects, we have tried a variety of different compounds, both organic and inorganic. The compounds chosen included various silylating, phosphorylating, and acylating agents, as well as compounds similar to dimethyl ether. All of these had either been shown to be selective reagents for functional groups such as those in question, or had been shown to react easily with these functionalities in solution, under a variety of conditions. In the gas-phase, some of these have given reagent-specific product ions, which may prove to be useful for functional group distinction Efforts in this area are continuing.

As our search for new reagents continues, we are also pursuing the other aspect of this project: the characterization of larger and more complex aminogycoside subunits. To this end, we are using laser volatilization methods. Significant attention is currently being focussed on laser desorption of sugars and aminoglycosides, and future efforts will be directed towards post-ionization of laser-desorbed neutral molecules.

We have recently begun to use computer calculations, both to assist in the interpretation of experimental data, and in attempts to predict reactivities of substrates and reagents, and to rationalize the results of ion-molecule reactions. We have undertaken a similar course in this work, but for the purposes of modelling the *predicted* behavior of substrates, rather than the *observed* behavior. As an example, we first considered one of the subunits of tobramycin. We have considered possible reaction at each site separately, and based on the results observed for the monofunctional and difunctional subunits, predicted the probable product structure in each case. The data obtained indicate that the nitrogen-site (M + 13)+ product ion is the most favored of all of the proposed products. This is consistent with the previous assertion that the nitrogen site of the models dominates their reactivity.

Simultaneous Determination of Differential Nitroglycerin Metabolism and Kinetics by Two Routes of Administration

*J. C. Joshi, M. J. Hayes, M. Leal and M. L. Powell

Drug Development Department, Pharmaceutical Division
CIBA-GEIGY Corporation, Ardsley, New York

Nitroglycerin (glycerol trinitrate, GTN) is a potent vasodilator used in the treatment of angina. The primary metabolites of GTN are 1,2-glyceryl dinitrate (1,2-GDN) and 1,3-glyceryl dinitrate (1,3-GDN). The kinetic behavior of nitroglycerin is such that major fluctuations in plasma levels are produced with changes in posture, physical activity and ingestion of food. The intrinsic variability in plasma concentrations of nitroglycerin is so high that it is difficult to produce acceptable statistical power in bioavailability/bioequivalency studies. In this work, the intrinsic variability was addressed by the simultaneous dosing of transdermal nitroglycerin and intravenous [^{15}N]-nitroglycerin. This allowed for compensation of the inherent variability of nitroglycerin levels.

The aim of this work was to develop and validate a GC/MS method that would simultaneously quantitate the plasma concentration levels of GTN, [^{15}N]-GTN, 1,2-GDN and 1,3-GDN. The internal standard used was butane-1,2,4-triyl trinitrate (BTN). A method was successfully developed and validated over the concentration range of 50 - 5000 pg/ml. Samples (1 ml) were extracted with pentane/ethyl acetate (90:10). Extracts were concentrated and analyzed directly by GC/MS. Separation was accomplished on a 25 m x 0.32 mm HP Ultra 1 capillary column. Mass spectrometry was carried out under negative ion methane CI conditions with selected ion monitoring of fragment ions at m/z = 62 for GTN, BTN, 1,2-GDN, and 1,3-GDN and m/z = 63 for [^{15}N-GTN]. Figure 1 shows a chromatogram at the limit of quantification.

Calibration curves were generated using $Y = AX^B + C$ as the mathematical model and were represented by a plot of the amount added versus the measured peak area of labeled, unlabeled nitroglycerin or dinitrate metabolites/butane-1,2,4-triyl trinitrate. Recovery and reproducibility assessments indicate good accuracy and precision over the validated concentration range. Table 1 contains the inter- and intra-day precision data for GTN, [^{15}N-GTN], 1,2-GDN and 1,3-GDN.

This method was applied to a two-treatment, randomized crossover study to compare the in *vivo* performance of an enhanced-flux experimental transdermal system with a commercially available Transderm-Nitro system. Each subject was randomized into one of two dosing sequences, experimental followed by commercial or commercial followed by experimental. Simultaneously a stable isotope labeled [^{15}N]-nitroglycerin solution was infused at a constant and known rate. Nitroglycerin along with both of the metabolites exhibited plasma profiles with significant fluctuations in plasma concentrations. However, the metabolic profiles exhibited smaller fluctuations due to the differences in elimination half-life (35 to 70 minutes for 1,2-GDN and 1,3-GDN compared to 2-3 minutes for GTN). Since these fluctuations were also noted in the plasma profile of the stable isotope infusion, the fluctuations observed reflect variations in systemic clearance with time rather than changes in delivery of the transdermal system. Figure 2 is a representative drug profile from a typical subject given one of the unlabeled transdermal systems and a simultaneous stable isotope labeled infusion.

This method provides the ability to simultaneously quantitate unlabeled and stable isotope labeled nitroglycerin and its dinitrate metabolites. This provides significant advantages in clinical studies where the variability in nitroglycerin plasma levels poses significant problems. The labeled nitroglycerin results allow corrections to be made for changes in clearance with each subject acting as his own control. Furthermore, the absolute bioavailability can be determined from the ratio of AUC values and the relative amounts delivered by the intravenous versus transdermal dosage forms. The application of this type of method for a drug like nitroglycerin, a compound with high intrinsic variability in plasma levels, is particularly attractive since it may allow for acceptable statistical power to be achieved in a bioequivalence study with a reasonable number of subjects.

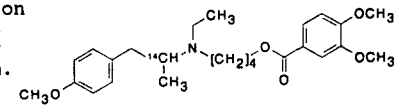
IDENTIFICATION OF MEBEVERINE METABOLITES IN PLASMA AND URINE USING HPLC WITH ON-LINE RADIOCHEMICAL DETECTION, GC/MS, FAB/MS, AND MS/MS

Mary Kay Dirr, Rose M. Clear, Roy L. M. Dobson, and Linda M. Cooper
The Procter & Gamble Company, Miami Valley Laboratories
P.O. Box 398707, Cincinnati, OH 45239-8707

INTRODUCTION

Mebeverine (MEB) is used for treatment of irritable bowel syndrome. In an effort to improve delivery of MEB, a measure of drug absorption as a function of formulation was needed. Because MEB is 100% first-pass metabolized, absorption must be determined by quantitation of MEB metabolites in plasma. However, as structures were not available, it was necessary to identify MEB metabolites. The identification work presented here not only satisfied this need, but provided significant data leading to a better understanding of MEB metabolism.



ANALYTICAL APPROACH

Rats and dogs were dosed perorally with 150 and 25 mg/kg MEB plus 500 and 150 uCi/kg [^{14}C]-MEB, respectively. Plasma and urine were analyzed by HPLC with an on-line radioactivity detector (RAD) to obtain metabolite profiles. Major metabolites were then identified using deconjugation experiments and MS-based techniques. Typically, urinary metabolites were identified first, then corresponding plasma metabolites (much lower levels) were verified.

EXPERIMENTAL

Prep for HPLC/RAD. Urine: Analyzed directly. Plasma: 0.2 to 5 mL treated with acetonitrile to precipitate proteins. Deconjugation: Samples were incubated with beta-D-glucuronidase prior to reanalysis by HPLC/RAD.

HPLC/RAD. C18 column (10 cm x 8 mm), 2 mL/min gradient (methanol/water/TEA/formic acid solvent system), Flo-One Beta Radioactivity Detector.

Prep for MS. HPLC fractions were evaporated to dryness and reconstituted in methanol prior to analysis. Select samples were treated with diazomethane to methylate possible carboxylic acid metabolites prior to GC/MS analysis.

Mass Spectrometric Systems. Analyses were conducted on a Finnigan MAT TSQ46C instrument, in GC/MS (EI and CI), FAB/MS, and FAB/MS/MS modes.

RESULTS AND DISCUSSION

HPLC/RAD. Typical HPLC/RAD profiles in rat and dog plasma are shown. Four major plasma metabolites (A-D) were observed in both species. However, Metabolite D (M-D) dominated in dog, while M-A and M-C predominated in rats.

Deconjugation experiments strongly suggested that M-A and M-D were glucuronide (Gluc) conjugates of M-B and M-E (M-E observed in urine), as evident by changes in HPLC/RAD profiles after enzyme treatment (see figure).

Structure Elucidation. Five major metabolites were identified (see Table).

M-B (Desmethyl MEB Alcohol): GC/(CI)MS showed MW=251. GC/(EI)MS provided a readily interpretable mass spectra.

M-E (MEB Alcohol): GC/(CI)MS showed MW=265. GC/(EI)MS provided a readily interpretable mass spectra.

M-A (Desmethyl MEB Alcohol Gluc). FAB/MS showed MW=427 and apparent fragments consistent with this structure. FAB/MS/MS (daughters-of-427) showed that suspected fragments were indeed due to breakdown of MH^+. A strong 176 d neutral loss was observed (expected for Gluc conjugates).

M-D (MEB Alcohol Gluc). Strong FAB/MS spectra showed MW=441, a neutral loss of 176 d, and fragmentation consistent with this structure.

M-C (Carboxylic Acid Metabolite). FAB/MS showed MW=279. FAB/MS/MS (daughters-of-279) showed fragment ions consistent with this structure. The methyl ester of M-C, analyzed by GC/MS, gave complementary/confirmatory data.

CONCLUSION

Five metabolites of MEB have been identified, using several complementary analytical techniques. All structures are consistent with common metabolic pathways (hydrolysis, O-demethylation, oxidation, glucuronide conjugation).

DRIED BLOOD SPOTS ON FILTER PAPER: A SAMPLE COLLECTION MEDIUM FOR USE IN QUALITATIVE AND QUANTITATIVE DRUG AND BIOCHEMICAL ANALYSIS.

Donald H. Chace, Steven L. Hillman, George G. Pauly, and David S. Millington, Department of Pediatrics, Division of Genetics and Metabolism, Duke University Medical Center, Durham, N.C. 27710

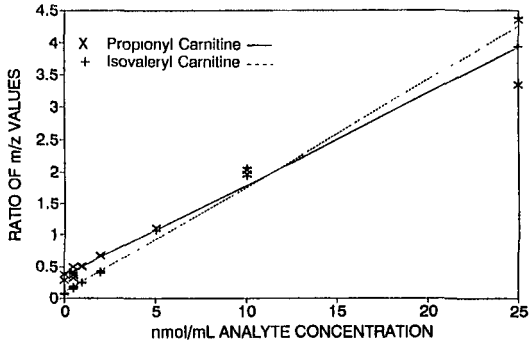
Guthrie Cards, better known as PKU cards, have been used extensively for biological sample collection in newborn screening programs. These cards are composed of 100% pure cotton fibers with uniform absorbency and thickness [1]. When biological fluids are applied to PKU cards and dried, potential biohazards are significantly reduced. PKU cards are also convenient media for sending biological samples to the appropriate diagnostic facilities by mail. In addition, these cards have minimal storage requirements, ie. occupy little space and do not require refrigeration.

Acylcarnitine analysis and quantitation: Two blood spots (12.6 μL, 3/16" diameter) were punched into plastic conical vials. Methanol (400 μL) containing 150 pmol/mL of D_3-acetylcarnitine and 30 pmol/mL of D_3-octanoylcarnitine was added to each tube. After extraction for 30 minutes, the methanol extract was transferred to conical vials and dried at 50°C in a warm air incubator using N_2 produced from a nitrogen generator. After drying, 50 μL of 3 N HCl-methanol was added and heated in an oven at 50°C in a capped vial. After 15 minutes, methanolic HCl was evaporated and reconstituted in 50 μL of a 50:50 methanol:glycerol with 1% octyl sodium sulfate (OSS). For acylcarnitine quantitation, samples of blood (25 μL) were applied to PKU cards. For each assay, the entire dried blood spot was excised from the PKU card and placed in a conical vial. Methanol (500μL) containing 125 pmol of D_9-propionyl and D_9-isovaleryl carnitine (internal standards) was added. *Amino Acid analysis:* Two 3/16" blood spots were punched into a conical vial. Two nmol each of $^2H_3$-leucine ($^2H_3$-Leu), $^2H_5$-phenylalanine ($^2H_5$-Phe) and $^2H_4$-tyrosine ($^2H_4$-Tyr) and 0.5 mL methanol were added to the vial. After 30 minutes, the supernatant was transferred to a 1 mL conical vial, evaporated under nitrogen and incubated with 3M HCL in n-butanol at 65°C for 20 minutes. The esterifying agent was evaporated and the sample reconstituted in 50 μL of methanol:glycerol. *Cocaine Analysis*: Cocaine HCl (3.3 nmol) was added to 1 mL of blood and vortexed. This blood was spotted onto PKU cards and dried. Two 3/16" blood spots were punched into conical vials and extracted with methanol. After 30 minutes, the supernatant was transferred to a clean vial, evaporated under nitrogen, and reconstituted with 50 μL of 50:50 methanol:glycerol in 0.1% OSS.

A VG QUATTRO tandem quadrupole mass spectrometer fitted with a cesium ion gun operated at 10 Kev, and Lab Base data system was used. Both analyzers of the mass spectrometer were optimized at unit mass resolution using standards. Argon was used as the collision gas and the collision energy optimized between 25-30 eV. All MS/MS spectra were recorded in multichannel analysis mode at a rate of 1 sec/scan. Mass ranges of 200 - 500 for acylcarnitine analysis, 125 - 300 for amino acid analysis, and 280-300 for cocaine analysis were scanned.

Acylcarnitines are preformed cations containing a quaternary ammonium group, an acyl group (derived of a fatty acid), and a carboxyl group. The carboxyl group is esterified to enhance the detection of acylcarnitines by LSIMS/MS. This analysis by MS/MS is based on the detection of a common product ion at *m/z* 99 produced by CID of the molecular cation (M^+) of acylcarnitine methyl esters. The analyses of propionyl carnitine and isovaleryl carnitine added to blood (0.5-25 nmol) were linear and reproducible (Figure 1). The correlation coefficients were 0.991 and 0.999 for propionyl and isovaleryl carnitine, respectively. As little as 0.5 nmol/mL added to blood was detectable for both species. The precision at this level as determined by 7 replicate analyses resulted in a calculated CV of 2.9% and 4.9% for propionyl and isovaleryl carnitine (25 nmoL/mL), respectively.

Figure 1: Linear Regression analysis of propionyl and isovaleryl carnitine added to blood spotted on filter paper.



Butyl ester derivatives provided excellent sensitivity and specificity for the detection of amino acids in blood or plasma by MS/MS. The fragmentation of the protonated molecular ($[M+H]^+$) ions of amino acids under collision-induced dissociation (CID) results in the loss of 102 Daltons. Comparison of previously categorized as normal (control group 1), confirmed PKU, or false positive (control group 2) was analyzed. From each profile, the quantitative analysis of Phe and Tyr was easily accomplished from the ion abundance ratio with the internal standards. The ratio of Phe/Tyr was calculated for each sample. The results from each group (ranges and mean ± std. dev.) are plotted in Figure 2. From these data, it appears that the Phe/Tyr ratio is an excellent discriminant for PKU-affected and normal cases.

The structure of cocaine and the fragmentation of the protonated molecular ($[M+H]^+$) ion under collision-induced dissociation (CID) in the tandem mass spectrometer is characterized by a loss of 122 Daltons. As little as 3.3 nmol/mL of cocaine in blood was detected.

The results presented here demonstrate the ability of LSIMS/MS to quantify metabolites from small quantities of plasma or blood. The concept of using LSIMS/MS in drug screening (specifically cocaine) has been demonstrated. Because of the small volume of blood analyzed, detection limits must be very low. Less than 1 nmoL/mL of acylcarnitine metabolites can be detected with CV's of 5% or less. Analysis of blood spots using automated robotic equipment and dynamic LSIMS/MS is under development. Automation will enable the analysis of up to 100,000 samples per year. The versatility of LSIMS/MS enables more than one metabolic profile to be obtained from a single sample analysis. At least 15 diseases can be detected in one analysis. The concept of blood spots on filter paper and its analysis can be extended to drug screening, pharmacokinetic studies, clinical trials, and studies with neonates.

Support for this research was provided by a grant from the State of North Carolina, Division of Maternal and Child Health, Department of Environmental Health and Natural Resources (Raleigh, N.C. No C-05070).

The Role of Mass Spectrometry in Identifying Cefaclor Degradation Products

M. W. Collins, J. L. Occolowitz, S. Baertschi, D. Dorman, and L. Spangle.
Eli Lilly & Company, Indianapolis, IN 46285

INTRODUCTION

Cefaclor is an orally-administered cephalosporin antibiotic with a broad spectrum antibacterial activity. The antibacterial activity is dependent on the presence of the β-lactam functionality which is readily hydrolyzed under aqueous conditions. This instability leads to chemical degradation and the formation of many products. The determination of the structures of the degradation products leads to further understanding of the degradation pathways, ultimately leading to understanding the chemistry, activity, and toxicology of cefaclor.

Mass spectral data, including FAB, EI, FD, HRFAB, HREI, and FAB MS/MS, were collected and interpreted in order to provide clues as to the nature of the structures of the degradation products. We must emphasize that mass spectral techniques did not single-handedly discover the structures of each degradation product; this was accomplished by the co-operative effort of all labs using physical chemical methods, including NMR, IR, UV, and chromatography.

METHODS

FAB and FAB MS/MS mass spectra were generated from a VG ZAB-2SE mass spectrometer (BE). Acquisition of data was accomplished by a VG OPUS (v. 1.5f) data system. Samples were dissolved in "Magic Bullet."

Degradation conditions

Cefaclor (95 g) was dissolved in 19L of .1N HCl and stored at room temperature. The solution was allowed to degrade for three months at which time the parent, cefaclor, was completely degraded.

RESULTS

After three months, the solution of degradation products arising from the strongly acidic conditions was analyzed by RP-HPLC. The chromatogram revealed many degradation products. Because compound E (structure with Table 1) was the most abundant and because so many of the techniques available to the mass spectrometrist were employed in order to elucidate its structure, compound E is used in this poster as a prime example of the process this laboratory used to accomplish structure elucidation of all cefaclor degradation products.

The molecular ion is hard to determine by EIMS because of the complexity of the mass spectrum. An ion at m/z 500, because it is the highest mass ion, is conceivably the molecular ion. The FAB mass spectrum was measured to verify the molecular weight or even to possibly discover it. The protonated molecule arises at m/z 447 revealing a molecular weight of 446 amu. When considering the molecular weight to be 446, a few prominent peaks in the EIMS can be identified. Key fragment ions are m/z 428 ($M^+ - H_2O$) and m/z 402 ($M^+ - CO_2$) indicating the possible presence of a carboxylic acid functional group still existent from cefaclor or hydrolysis of the β-lactam. Also, an ion at m/z 106 ($Ph\text{-}CH{=}NH_2^+$), indicative of cefaclor related products, shows the benzyl amino portion remains intact.

The accurate mass, measured under FAB ionization conditions by the method described in poster 151, for MH^+ was found to be 447.0803. The elemental composition $C_{19}H_{18}N_4O_5S_2$ matches this measured mass with an error of 0.6 mDa (calc. 447.0797).

Because the major functional groups of cefaclor are -COOH and $-NH_2$, the sample was derivatized in three ways in order to determine the presence and number of the aforementioned functional groups. Reaction of compound E with diazomethane increased the MH^+ from m/z 447 to 475 (+28 amu), indicating the presence of two -COOH groups. Reaction with compound E with acetic anhydride in pyridine yielded a product with an MH^+ of m/z 489 (+42 amu), which is interpreted as the presence of an amino group. Finally, reaction

of compound E with diazomethane and acetic anhydride in pyridine increased the MH^+ from m/z 475 to m/z 517 (447 + 28 + 42), confirming the presence of the functional groups above.

FAB MS/MS data were obtained on compound E (Fig. 1) and these three derivatives. Assignments a-f in TABLE 1. show how compound E was changed by the different derivatizations. The helpful information attained by comparing the linked scan of the derivative to the underivatized product is in identifying the part of the molecule each functional group is resident. As an example of this, in Compound E the linked scan shows an ion at m/z 106, previously discussed. The fragmentation is shown in the structure below TABLE 1. A glance at the linked scan for the acetylated product (Fig. 2) shows that the ion which occured previously at m/z 106 is now seen in the spectrum at m/z 148. This information verifies that the increase in mass of 42 amu occurs as a result of the derivatization on the primary amine.

In order to confirm the identities of the fragment ions postulated in TABLE 1, accurate mass measurements of the fragment ions which are very low in relative abundance in the routine FAB mass spectrum, were measured. The technique used to measure these low intensity ions is described in a poster 151. No detail will be given in this poster. Also, these masses were measured under high resolution EI conditions and confirmatory data was attained.

CONCLUSIONS

Many of the tools available to the mass spectrometrist were used for the structure elucidation of the cefaclor degradation products. Different ionization techniques (EI, FAB, FD) were used in order to effect ionization of the products or to retrieve confirmatory and/or complementary data. Accurate mass data on the protonated molecule and on low intensity fragments found in the routine FABMS (but are major ions in the linked scan data) gave elemental compositions. Dervizatizations were helpful to show the presence (or lack thereof) of the primary amine and/or carboxylic acid which are evident in the parent cefaclor.

Examination of the MS/MS data from the derivatized products gave evidence of where these functional groups reside. This process described in this poster combined with the *efforts of the chemists in NMR and IR gave rise to the structure elucidation of the degradation* products of cefaclor.

The Accurate Mass Determination in FABMS Using External Standards and Serial Probe Introduction

John L. Occolowitz, M. W. Collins, J. M. Gilliam
Lilly Research Labs, Indianapolis, IN 46285

INTRODUCTION

The use of external standards for FAB accurate mass offers advantages over the use of internal standards, these include no suppression effects, no constraints due to limited resolution, and a wide range of compounds suitable for mass standards. On the debit side is the drift in operating conditions in the mass spectrometer between measurement of sample and calibrant, and systematic errors which can arise if the configuration in the ion source is different for ionization of standard and analyte. Previously we had developed a probe for a MAT-731 mass spectrometer which resulted in no change in source configuration and gave good data using external standards.[1] Unfortunately the probe/source geometry of our currently used ZAB-2SE did not allow for a similar probe design. The commercial "wobble" probe which allows alternate ionization of sample and analyte did not give consistently good results in our hands, possibly because of changes in source configuration during operation.

Increased demand for speedy accurate mass data to be used in lieu of microanalysis and our desire to measure the accurate mass of ions of low relative intensity which corresponded to significant peaks in CID spectra prompted our investigation of accurate mass determination using serial probe introduction.

METHOD

The external standard used was a mixture of lithium iodide and either PPG 725 or PPG 1200 in "magic bullet." The essence of the method was to take the minimum time necessary to make the measurement to lessen of the effect of drift. Additionally all operating potentials were maintained during the course of the measurement. The arcing which resulted during probe manipulation had no effect on the accuracy of the measurement. The final method chosen used ten summed scans of 1.5 s. duration for the calibrant, a 30 s. interval during which the calibrant was removed and the analyte introduced, ten summed 1.5 s. scans of the analyte, a 30 s. interval in which the analyte was removed and the calibrant introduced, and finally ten summed 1.5 s. scans of the calibrant. This resulted in a total measurement time of 1.75 min.

The first set of calibrant scans were used to calibrate the mass scale and this calibration was used to measure the analyte masses and the apparent masses of the calibrant ions in the third set of scans. Using true and apparent mass of the calibrant ions a drift correction was calculated for the analyte ion using the formula

$$\Delta m = ({}^{1}M_S - {}^{1}M_S' + {}^{2}M_S - {}^{2}M_S')/4$$

which was derived under the assumption that a drift was a linear function of time. In the formula Δm = drift correction, and ${}^{n}M_S$ and ${}^{n}M_S'$ are the true and apparent masses of the two calibrant ions.

RESULTS

The three figures show the FAB spectrum (in "magic bullet"), the CID spectrum of m/z 416 (MH^+), and a accurate mass scan around m/z 336 of a toxin of MW 415. The toxin was thought to contain a sulfate ester and although the loss of 80d. (SO_3) to give an ion at m/z 336 is prominent in the CID spectrum, it is hardly distinguishable from the chemical noise in the FAB spectrum. The high resolution scan using an external standard plainly shows the ions due to the loss of SO_3 and H_2SO_3 which have calculated masses of 336.1672 and 334.1515, respectively.

The table shows all of the accurate mass measurements using external standards and drift correction made in our laboratory during a 3 day period in March 1992. The average absolute errors is better than 2ppm.

Stereochemical Investigation of Metabolic Interrelationships in Valproic Acid Metabolism Using Rat Hepatocytes and Stable Isotope Labeled Substrates

Michael A. Shirley, Pei Hu and Thomas A. Baillie
Department of Medicinal Chemistry, School of Pharmacy, University of Washington

Valproic acid (2-n-propylpentanoic acid, VPA) is an antiepileptic drug with a branched-chain, carboxylic acid structure. Biotransformation of VPA has attracted wide attention since a small proportion of patients receiving VPA have died from liver damage. VPA undergoes metabolism by conjugation and oxidative processes yielding a diverse array of products. 3-Hydroxy-VPA arises both from β–oxidation of VPA and by direct hydroxylation at C-3, while 3-oxo-VPA is formed mainly from oxidation of $\Delta^{2(E)}$-VPA as opposed to 3-hydroxy-VPA (1). $\Delta^{2(E)}$-VPA, $\Delta^{3(E)}$-VPA and $\Delta^{2(E),3'(E)}$-VPA are interconverted by isomerization and reduction processes, and all three serve as precursors of 3-oxo-VPA (2).

The initial dehydrogenation in β-oxidation of VPA is catalyzed by 2-methyl-branched chain acyl-CoA dehydrogenase (3). Incubations of this enzyme with R- or S-2-methylbutyryl-CoA demonstrated a stereochemical preference during dehydrogenation based on the production of different products as a function of side-chain orientation in the enzyme active site (4). Thus, for the second half-reaction carried out by the dehydrogenase, the configuration of the substrate dictated the nature of the product formed by hydride removal. These data suggested that although VPA is a non-chiral compound, the dehydrogenase would likely remove a hydride from the C-3 position of the pro-S side-chain. If side-chain preference during VPA metabolism could be demonstrated, the interrelationships between VPA metabolites modified at the C-2 and/or C-3 position might be clarified. By using the absolute stereochemistry of the starting material as a tool, we reasoned that metabolites of VPA derived from a common intermediate should exhibit the same stereochemical preference for biotransformation on the pro-R or pro-S side-chain of the parent drug. A stable isotope technique was adopted, which employed chiral, ^{13}C-labeled analogs of VPA as metabolic probes (Fig. 1A). Through the use of these specifically-labeled chiral substrates and diagnostic mass spectrometric fragmentations, we obtained information on enantiotopic differentiation in VPA metabolism without having to resort to chiral chromatography.

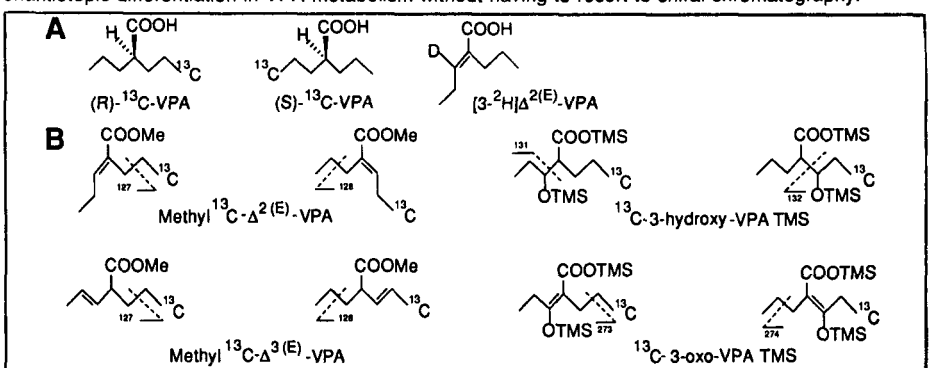

Fig 1A. Structures of substrates for metabolic experiments. B. Derivatized metabolites of interest and diagnostic ions used to establish stereochemical preference for oxidation on prochiral side-chains of VPA.

(R)-[^{13}C]VPA and (S)-[^{13}C]VPA were obtained by enantioselective synthesis using the chiral auxiliaries (4S)-4-isopropyl-2-oxazolidone and (4R,5S)-4-methyl-5-phenyloxazolidone, as described previously (5). [3-^{2}H]$\Delta^{2(E)}$-VPA (Fig. 1A) was a gift from Dr. Kelem Kassahun, and was synthesized from 3-oxo-VPA by $NaBD_4$ reduction, followed by DBU elimination of the corresponding mesylate.

SIM GC-EIMS analyses were carried out using a VG 70-70H mass spectrometer, a Hewlett-Packard 5890 gas chromatograph, and a Maspec PC based data system (Mass Spectrometry Services, Manchester, England). A DB-1 fused silica column (60 m x 0.32 mm I.D., 0.25 μm film thickness, J & W Scientific, Folsom, CA) was used with helium (15 psi head pressure) as carrier gas. GC programming was 40-80°C (10°C min^{-1}), 80-155°C (5°C min^{-1}) and 155-250°C (40°C min^{-1}). Quantitative analyses of ^{13}C-labeled metabolites of VPA were based on the ratios of ion currents from the pairs of diagnostic fragment ions indicated in Fig. 1B. The $[M-C_2H_5]^+$ ions in the spectra of the derivatives of $\Delta^{2(E)}$-VPA and 3-oxo-VPA were attributed to the indicated allylic cleavages, rather than to the alternative, less favorable vinylic cleavages. Peaks in appropriate ion current chromatograms were integrated to provide the relative proportion of each metabolite derived from oxidation of the pro-R or pro-S sidechain of VPA. The ratios of ion currents, for ^{13}C-:^{12}C-containing ions, were corrected for

natural isotopic contributions, and for isotopic and enantiomeric impurity of the starting substrate, resulting in a value for enantiotopic differentiation in the formation of each metabolite of interest. Enantiotopic differentiation in cytochrome P-450-mediated formation of Δ^4-VPA was also determined (1 expt), as described previously (6). To investigate the possibility that the double bond in $\Delta^{2(E)}$-VPA could exist in a metabolic equilibrium between the two isomeric forms depicted in Fig. 2A, [3-^{2}H]$\Delta^{2(E)}$-VPA was used as substrate in a separate incubation with hepatocytes. In this experiment, the ion currents at *m/z* 113 and *m/z* 114 were monitored on the premise that the fragmentation corresponding to an ion at *m/z* 113 could only arise from a branchpoint vinylic cleavage of the deuterated metabolite (Fig. 2B).

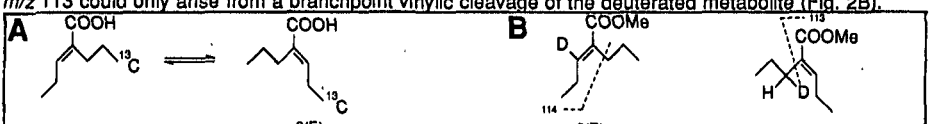

Fig. 2. A. Metabolic isomerization of $\Delta^{2(E)}$-VPA (most likely occurring with $\Delta^{2(E)}$-VPA in the form of its CoA-thioester) B. Diagnostic fragmentations of methyl ester derivatives used to determine which side-chain contained the double-bond in D_1-$\Delta^{2(E)}$-VPA. Since corrections were made for non-deuterated material in the starting compound, additional ion current in the m/z 113 channel would correspond to molecules with the double-bond migrated.

Hepatocytes were isolated from male Sprague-Dawley rats (250g) by collagenase perfusion (7). Following drug incubations (1 mM, 5x10^6 cells mL^{-1}, 2 h), 2 ml outtakes were quenched (1 ml 1N NaOH) and diluted 15 min later (2 ml satd. Na+,K+-tartrate). Addition of 10% HCl (2.5 mL), extraction (2 x 3 mL ethyl acetate), drying ($MgSO_4$) and division of each sample (for formation of TMS or methyl ester derivatives) were followed by N_2 evap. to *ca.* 0.2 mL. BSTFA (100 µL) or ethereal CH_2N_2 (1 mL) was added, the silylating samples heated (60°C, 20 min), and all samples were concentrated to *ca.* 40 µL.

Table 1 shows when (R)-^{13}C-VPA was employed as substrate, metabolism of the S side-chain was favored slightly since the percentages of the corresponding metabolites were greater than 50% S in all cases (mean 58.9%, range 57-61%). These findings were reinforced by the results of parallel experiments in which (S)-^{13}C-VPA served as the substrate for metabolism. In these experiments, the S side-chain was again preferred (mean 53.5%, range 49-56%). Our measurement of enantiotopic differentiation during Δ^4-VPA formation (79% R) agreed closely to those published previously (6). This corroborative finding helped affirm the validity of our *in vitro* system using chiral VPA analogs in rat hepatocyte incubations. The experiment using deuterated $\Delta^{2(E)}$-VPA as a substrate provided evidence for extensive migration of the double bond from the 2-3 to the 2-3′ position. After the 2 h incubation, only 65% of the total [^{2}H]-$\Delta^{2(E)}$-VPA retained the deuterium atom in the original position, the remainder existing in the isomeric configuration (Fig. 2B).

Tbl.1 Enantiotopic differentiation in the metabolism of (R)- and (S)-^{13}C-VPA

Metabolite	Stereochemistry of metabolites	
	%S from incubation with R	%S from incubation with S
$\Delta^{2(E)}$-VPA[1]	57.1±0.4[2]	48.7±0.4
$\Delta^{3(E)}$-VPA	57.3±1.8	55.3±1.1
3-hydroxy-VPA	61.4±2.2	55.7±1.0
3-oxo-VPA	59.7±0.7	54.2±0.5

[1] Although not truly R or S, these metabolites were defined based on the stereochemistry of the of the ^{13}C-VPA precursor from which they arose.
[2] $\bar{x}$±S.E.M.; n=3 for (R) isomer, n=4 for (S) isomer. Corrections were made for natural ^{13}C abundance (A+1 ions m/z 128,132,274), and for isotopic and enantiomeric impurity of each of the starting materials.

Due to the incorporation of ^{13}C stereospecifically in one of the two pro-chiral side-chains of VPA, quantification of the relative abundances of structurally-diagnostic fragment ions provided a means of determining the absolute stereochemistry of the metabolites of interest. β-Oxidation of VPA occurred preferentially on the pro-S side-chain, although the degree of net enantiotopic differentiation was slight, averaging 56% pro-S. The results indicated that $\Delta^{2(E)}$-VPA, $\Delta^{3(E)}$-VPA, 3-hydroxy-VPA and 3-oxo-VPA were products of a common metabolic pathway. The [3-^{2}H]-$\Delta^{2(E)}$-VPA study suggested that extensive migration of the double bond in $\Delta^{2(E)}$-VPA takes place in rat hepatocytes. The cause of this migration currently is unknown, but may represent carbanion inversion or reversibility of the second half-reaction in the dehydrogenase-catalyzed process.

This work was supported by a grant from the National Institutes of Health (GM32165).

Mass Spectrometric Investigation of the Hepatic Microsomal Metabolism of (E)-Δ^2-VPA, a "Second Generation" Valproic Acid. Kelem Kassahun and Thomas A. Baillie, Department of Medicinal Chemistry, University of Washington, Seattle, WA 98195.

Concern over the teratogenic (1,2) and rare hepatotoxic (3) side effects of valproic acid (VPA) has stimulated research in the development of safer, more effective analogues of this widely prescribed antiepileptic drug. A pharmacologically-active metabolite of VPA, 2-*n*-propyl-2(E)-pentenoic acid ((E)-Δ^2-VPA), has attracted particular interest in this regard since it has been reported to be devoid of teratogenic effects in rodent models of teratogenicity (1,4). Moreover, preliminary studies in rats have indicated that (E)-Δ^2-VPA may be less hepatotoxic than VPA itself (5). Based on these considerations, it has been suggested that (E)-Δ^2-VPA may be viewed as a "second generation" VPA.

Although the anticonvulsant properties of (E)-Δ^2-VPA have been studied extensively, there is little information on the metabolic fate of (E)-Δ^2-VPA in mammalian systems. The objective of the present study was to investigate the nature of metabolites of (E)-Δ^2-VPA formed in the microsomal fraction of rat liver.

Hepatic microsomes were prepared from male Sprague-Dawley rats according to standard procedures. Incubations were carried out at 37°C using 1 μM substrate ((E)-Δ^2-VPA, (Z)-Δ^2-VPA or [3-^{2}H]2-propyl-2-pentenoic acid (D_1-(E)-Δ^2-VPA)). Acidified incubation mixtures were extracted with ethyl acetate, concentrated and treated with BSTFA and PFBB to give TMS and PFB derivatives, respectively. Metabolites were quantified by SIM GC/EIMS of the respective $[M-15]^+$ ions of the TMS derivatives of the analytes and internal standards.

Following incubation of (E)-Δ^2-VPA with microsomal preparations and conversion of the products to TMS derivatives, GC/MS analysis revealed the presence of two metabolites, both of which eluted later than the parent compound. The formation of these metabolites was shown to be cytochrome P-450-dependent since omission of NADPH or the use of boiled microsomes resulted in complete suppression of the formation of both metabolites.

Metabolite A, whose TMS derivative exhibited $M^{+\cdot}$ and $[M-CH_3]^+$ ions at m/z 212 and 195, proved to be the doubly-unsaturated (E)-$\Delta^{2,4}$-VPA. This metabolite of (E)-Δ^2-VPA was identified on the basis of its EI mass spectrum and GC retention characteristics, which were identical to those of the corresponding synthetic reference compound.

Metabolite B was an oxygenated derivative of (E)-Δ^2-VPA whose TMS derivative exhibited the same retention time and EI mass spectrum as a known VPA metabolite, namely 3-oxo-VPA. However, the NICI spectra of the PFB derivatives of 3-oxo-VPA and metabolite B were markedly different, the base peak for 3-oxo-VPA being at m/z 113 $[M-PFB-CO_2]^-$ and for metabolite B at 157 $[M-PFB]^-$. (The ion at m/z 113 was absent from the spectrum of the latter). Furthermore, it was established that metabolite B did not result from oxygenation at carbon 3 of the substrate since incubation of (E)-D_1-Δ^2-VPA with microsomes yielded a metabolite which retained completely the deuterium label. Metabolite B was identified as 4-OH-(E)-Δ^2-VPA on the basis of its mass spectrum and GC retention index, both of which were identical to those of the authentic reference compound obtained by synthesis (Fig. 1).

A study of the time course of formation of (E)-$\Delta^{2,4}$-VPA and 4-OH-(E)-Δ^2-VPA from (E)-Δ^2-VPA by rat liver microsomes indicated that the two metabolites were formed in parallel, such that the ratio of the diene to the allylic alcohol metabolite remained constant at 0.45 ± 0.045 throughout the incubation period. Incubation of (Z)-Δ^2-VPA with rat liver microsomes did not produce any detectable metabolites. Also, there was no evidence of any metabolites resulting from allylic rearrangement during the microsomal metabolism of (E)- or (Z)-Δ^2-VPA.

In conclusion, GC/EIMS, GC/NICIMS and stable isotope labelling techniques have been used to identify two cytochrome P-450-dependent metabolites of (E)-Δ^2-VPA in rat liver microsomal preparations as the diene (E)-$\Delta^{2,4}$-VPA and the novel allylic alcohol 4-OH-(E)-Δ^2-VPA. The latter was stable, both metabolically and chemically, towards dehydration and hence did not serve as an intermediate in the formation of (E)-$\Delta^{2,4}$-VPA in microsomal preparations. It may be concluded, therefore, that the diene was formed by direct cytochrome P-450-mediated dehydrogenation of (E)-Δ^2-VPA (6).

The observed time course of formation of (E)-$\Delta^{2,4}$-VPA and 4-OH-(E)-Δ^{2}-VPA supports the view that the two metabolites of (E)-Δ^{2}-VPA arise from a common carbon-centered free radical which partitions between the processes of "oxygen rebound" and "hydrogen atom abstraction" to give the allylic alcohol and the diene, respectively. Stabilization of the allylic radical by resonance appears to favor partition to the diene, as reflected by the marked difference in the ratio of olefin to alcohol obtained for VPA (1.5%) and (E)-Δ^{2}-VPA (45%).

The sub-cellular site (endoplasmic reticulum) at which (E)-$\Delta^{2,4}$-VPA is formed from (E)-Δ^{2}-VPA, together with the fact that this metabolic process yields the relatively unreactive free acid form of (E)-$\Delta^{2,4}$-VPA, may account for the relative lack of hepatotoxicity of (E)-Δ^{2}-VPA compared to Δ^{4}-VPA which is metabolized in the mitochondria to the putative reactive thioester (E)-$\Delta^{2,4}$-VPA CoA (7).

GC/MS CONFIRMATION OF METHYLXANTHINES IN RACING SLED DOGS

Xu, A., Hirsch R., Harris L., Gould S., Wood T.
Harris Laboratories, Phoenix, Arizona
Leach J.
Big Lake Veterinary Clinic, Big Lake, Alaska
Craig, M.
Oregon State University, Corvallis, Oregon

With the popularity, financial investment and rewards involved in sled dog racing on the rise, the pharmacokinetics, control and legally defensible detection of performance enhancing drugs is of great concern.

Certain members of the methylxanthine group of drugs (caffeine, theobromine, and theophylline) are occasionally detected in post race urine samples of racing greyhounds. Prohibited in most racing jurisdictions, administration of these compounds is believed to enhance the performance of the greyhound. These compounds are additionally believed to have similar pharmacokinetic profiles and effects in racing sled dogs. For this reason, we have developed and validated a novel GC/MS procedure to simultaneously confirm the presence of these compounds in canine urine.

Three Alaskan racing sled dogs were orally administered 100 mg of caffeine with blood and urine samples collected at 0, +4, +24 and +48 hours with respect to dosing time. The animals were fed an otherwise routine diet and were maintained on their normal training schedules.

Following an ion pair extraction procedure, the urine samples were initially screened for the presence of methylxanthines by thin layer chromatography (TLC). The analysis utilized the Davidow and TDA solvent systems and an I2KI/ HCl:MeOH(1:1)/ CuCl2 overspray sequence.

The subsequent GC/MS procedure also included the ion pair extraction step. Sample analysis was accomplished using a Hewlett-Packard 5989A GC/MS, employing a capillary column and electron impact ionization. The GC oven temperature was ramped at 20 C/min from 160 C to 260 C. To increase the sensitivity of theobromine and theophylline detection, the extracts were derivatized using iodobutane. One microliter of the derivatized solution was injected in the splitless mode. The ions that were monitored to indicate the presence of each compound were in order of abundance as follows: caffeine, 194, 109, 67; theobromine, 180, 236, 109, 219; theophylline, 180, 236, 95, 207 (Figure 1).

Caffeine, theobromine, and theophylline were detected and confirmed in all post administration samples. Our data indicate that the sled dog metabolizes and eliminates caffeine in a manner similar to the greyhound. However, while it is assumed that the pharmacokinetics of many drugs will be similar in the sled dog and the racing greyhound, more work of this nature needs to be performed to validate that assumption.

GC-MS Identification of Furan Derivatives in a Medicinal Plant

Elizabeth Y. Olavesen, Kai W. Chin, Hanh H. Huynh, and Richard B. Cole*

Department of Chemistry, University of New Orleans, Lakefront Campus,
New Orleans, LA 70148

Different plant species have been used for centuries in the practice of traditional medicine. One such plant is *Plantago major*, an uncultivated perennial species which may be found in meadows and along roadsides throughout Europe, China, and North America. Common names of *Plantago major* are "rippleseed", "broad-leaved", or "common" plantain. Ingestion of fluid extracts from *Plantago major* in the form of "teas" is claimed to be of therapeutic value in combatting a variety of physiological disorders. Anti-inflammatory and anti-bacterial activities have been documented for such *Plantago major* extracts. The plant has also been traditionally used for the relief of internal disorders such as diarrhea and jaundice. In addition, the fresh leaves have been used in the form of a poultice to stop the bleeding of minor wounds, and to relieve the discomfort of insect stings, hemorrhoids and even snakebites.

Our study investigating the chemical composition of *Plantago major* began with the extraction of plant leaves with methanol. The ultimate goal is to identify specific substances contained in the plant which are responsible for the reported medicinal activities. The methanol extracts have been analyzed by Gas Chromatography-Mass Spectrometry employing 70 eV electron ionization. Fresh leaves were extracted in methanol under reflux conditions for 6 hours. The resulting extract was transferred to another flask and the leaves were rinsed with additional methanol which was combined with the extract. The raw, untreated extract was chromatographed on a 5% cross-linked phenylmethylsilicon column and mass analyzed using a benchtop quadrupole mass spectrometer. The total ion chromatogram for the mixture appears in Fig. 1.

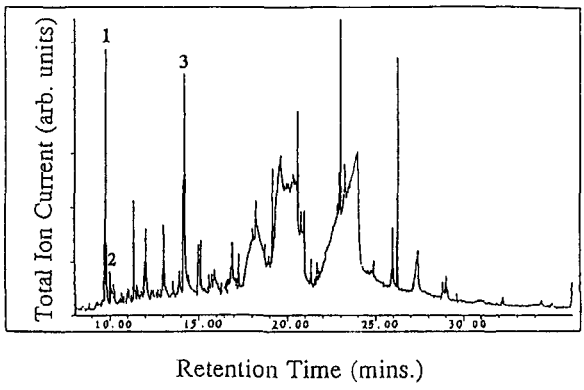

Figure 1. Total ion chromatogram of methanol extract of *Plantago major*.

Among the semi-volatile components that we have identified by GC-MS are several furan derivatives including dihydro-3-methylene-2,5-furandione (Fig. 2), 5-hydroxymethyl-2-furancarboxaldehyde (Fig. 3), and 5-methyl-2-furancarboxaldehyde (not shown). These compounds were quantified using a standard external calibration curve. Standards were made from neat compounds having purities of 95% or greater. Our extracts contained 290 ppm of dihydro-3-methylene-2,5-furandione, 280 ppm of 5-hydroxymethyl-2-furancarboxaldehyde, and 17 ppm of 5-methyl-2-furancarboxaldehyde. To the best of our knowledge, furan derivatives have not been previously identified in *Plantago major*. A variety of medicinal properties have been exhibited by other furan derivatives. Long chain fatty acids and phytol, which are commonly found in green plants, were also identified.

FACILE TRANSFORMATION OF THIOAMIDES INTO AMIDES

Lawrence R. Phillips and Glenn N. Gray

Laboratory of Pharmaceutical Chemistry
Developmental Therapeutics Program
Division of Cancer Treatment
National Cancer Institute
Frederick, Maryland 21702-1201

Summary: *Thioamides are quickly (<1 minute) and quantitatively transformed into their corresponding amides by treatment with hydrochloric acid in methyl sulfoxide at ambient temperature.*

Introduction

Recent interest has focussed on oxidative desulfurization of thioamides, which is known to occur *in vivo*, although the mechanism remains unclear[1,2] Synthetic preparation of amides from thioamides has been accomplished by utilization of a number of reagents[3], although these methods commonly suffer from use of very toxic reagents, long reaction times, inconvenient reaction conditions, and/or extensive reaction processing.

Examination of electron-ionization mass spectra of several thioamide-containing substances shows these compounds to undergo a common fragmentation: loss of 33 amu from the molecular radical cation. We subsequently demonstrated this fragmentation to be loss of SH radical by exact mass measurements.

We were thus prompted to consider thioamides as possessing a labile sulfur atom, thinking the corresponding amide might easily be formed providing that there is some suitable reagent which could function as an oxygen-exchange agent. We have found methyl sulfoxide to behave as such an agent.

Our new method offers the advantages of a quick reaction time at room temperature with quantitative conversion. In addition, no further processing of the reaction mixture is required for instrumental analysis, thus, this method could be used for "derivatizing" thioamides for certain analytical procedures such as gas chromatographic analysis. Finally, the inclusion of analysis by FT-IR provides unequivacol proof of the integrity of the starting thioamide and the product amide moieties.

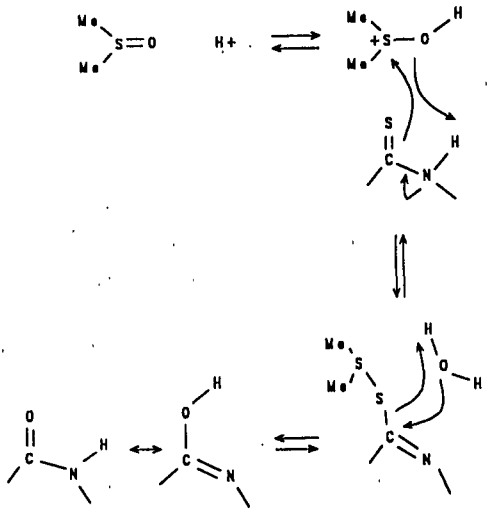
Methods

Transformation of thioamides into amides---Samples of thioamides were dissolved in methyl sulfoxide such that the final concentration of the substrate was about 1 mg/ml: the resulting solution was maintained at room temperature. A 10 ml syringe was filled with the gas in the headspace of a bottle of reagent-grade concentrated hydrochloric acid: the needle of the syringe was placed at the bottom of the reaction vessel and the contents of the syringe were slowly discharged into the reaction solution. No further processing of the reaction mixture was performed prior to instrumental analysis.

Instrumental analysis---The starting and final reaction mixtures were directly analyzed by gas chromatography/gas-phase Fourier-transform infrared spectroscopy/mass spectrometry (GC/FT-IR/MS).

Results

Thioamides are quickly and quantitatively transformed into their corresponding amides by treatment with hydrochloric acid in methyl sulfoxide. The reaction mechanism is proposed as follows:



This mechanism is compatible with the now generally recognized isomerization or stereomutation of sulfoxides by means of a nucleophilic attack on sulfur by oxygen-containing reagents[4].

Conclusions and Future Directions

The transformation of thioamides to their corresponding amides by treatment of the thioamide in methyl sulfoxide with hydrochloric acid is found to be general for secondary thioamides.

The proposed reaction mechanism indicates that the oxygen used to replace the sulfur is derived from the methyl sulfoxide: using an oxygen-labelled methyl sulfoxide (O-18, for example) would easily provide verification.

Since the proposed reaction mechanism indicates that a hydrogen atom on the thioamide's nitrogen atom is involved in the reaction, we would predict that tertiary thioamides (fully substituted nitrogen center) would not undergo this reaction.

Since the proposed reaction mechanism indicates an imine as an intermediate, we would predict that primary thioamides may choose to undergo hydrolysis in preference to sulfur replacement.

MS/MS Analysis of Tetrahydrocannabinol (THC) and THC Metabolites

Chad C. Nelson, Michael D. Fraser, and Rodger L. Foltz
Northwest Toxicology, Salt Lake City, UT 84124

Collision-induced dissociation products from protonated trimethylsilyl derivatives of THC,11-hydroxy-THC, and 9-carboxy-THC were investigated, and dissociation pathways were established using deuterium-labeled analogs. Following collisional activation, the protonated TMS derivative of THC undergoes dissociation principally through the pyran ring moiety. Several alkyl neutral fragments are eliminated from the hexene and pyran ring system, primarily involving carbons from C-6 to C-10a and the exocyclic methyl groups. The CID spectrum of MH+ of THC is shown in Figure 1 and dissociation pathways are described in Scheme 1. The initial site of protonation is thought to occur at 0-5 when using NH_3 for chemical ionization. It is proposed that protonation at 0-5 induces ring opening between O(5) and C(6) in the pyran to form the intermediate structure a, as shown by equation 1 in Scheme 1. Cleavage of the O(5)-C(6) bond may alternatively result in hydrogen transfer to O-5 generating the ion at *m/z* 253 after further dissociation of the pyran ring. Intermediate a permits increased conformational flexability, isomerization, and fragmentation along the alkyl chain and the hexene ring. The exocyclic C_5H_{11} alkyl chain is apparently relatively stable and does not fragment to any significant extent.

CID spectra of protonated 9-carboxy-THC-TMS were compared using ammonia and methane chemical ionization gases. The spectra differ significantly in relative ion intensities and different product ions are observed. For example, neutral losses of 117u and 118u occur in the spectrum in which CH_4 was used for CI, while only the 118u elimination occurs when using NH_3. The differences are attributed to the site of protonation and the dissociation pathways that are derived from the intermediate structure. Loss of TMSOH (90u) is observed in the spectrum of 9-carboxy-THC. however, loss of TMSOD (91u) occurs the spectrum of 9-carboxy-THC-d_6-TMS when ammonia is used for CI, but not with methane CI.

An GC/MS/MS assay was developed for the analysis of THC, 9-carboxy-THC, and 11-hydroxy-THC in blood, plasma, or other physiological fluids. Protonated molecular ions are generated by positive-ion ammonia chemical ionization and several product ions (e.g., *m/z* 265, 293, and 331) are monitored for THC-TMS and 11-hydroxy-THC-TMS. Protonated molecules are collisionally activated at a translational energy of 35 eV (E_{lab}) at a transmission of 40% of the incident precursor ion using argon as the collision gas. The limit of detection is 10 pg/ml when extracting 2 ml of whole blood; the limit of quantitation is 50 pg/ml.

MEASUREMENTS OF NONSMOKERS SALIVARY COTININE BY GC COUPLED WITH A MODIFIED RESIDUAL GAS ANALYZER

E. Davoli and R. Fanelli, Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62, 20157 Milano, ITALY

INTRODUCTION

Cotinine levels in biological fluids are generally accepted as a marker of tobacco smoke exposure (1). The reason lies mainly in the fact that cotinine is the main metabolite of nicotine and that its half-life is very long (15 hours) as compared to nicotine half-life (2 hours) (2).

In Italy, 30% of women in reproductive age are current smokers. Of these, about 50% report quit smoking during pregnancy. Some concern have been raised on the accuracy of reported cigarette smoking. This is of great importance, from an epidemiological point of view, for estimating the quantitative effect of smoking on reproductive deseases, as well as for clinical counselling.

We present here a rapid and simple technique that has been used in our laboratory for validating the status of self-reported tobacco smokers and nonsmokers pregnant women participating an epidemiological study.

INSTRUMENTATION

This technique is a GC-MS method with cotinine d3 as internal standard. The mass spectrometer is a residual gas analyzer (RGA) (RIAL QM 130 CS, Parma, Italy) home-modified to work as an inexpensive organic mass spectrometer. Modifications were mainly in the data system that has been completely substituted with a commercial general-purpose GC-MS VECTOR ONE data system (Teknivent corp. St. Louis, MO). Control of the RGA was performed via RS 232 serial line with resident software written in this laboratory. GC coupling was done with direct introduction of the column in the ion source, in front of the filament. The open ion source was not modified. GC was a DANI 86.10 (DANI S.p.A. Monza, Italy) equipped with a PTV split/splitless injector.

SAMPLE PREPARATION

Saliva samples (500 µl) were spiked with the internal standard (50 ng), basified with 2 ml NaOH 3N and extracted with 3 ml of CH_2Cl_2 (3). The organic layer, after evaporation to dryness under a gentle air stream, was dissolved with 50 µl of CH_2Cl_2. 2 µl were injected in splitless mode in the GC.

GC-MS CONDITIONS

Injector temperature :140 °C; oven: 1 min isothermal at 90°C, then 20 °C/min to 140 °C. Capillary column Supelco SPB5, 0.32 mm ID, 0.25 µm film thickness, 15 m length. SIM monitoring: m/z 98 and m/z 101, corresponding to the base peak of cotinine and cotinine d3 respectively. monitoring of molecular ion was not possible because of the limited mass range of the RGA. Both ions were deriving from an a-cleavage with subsequent loss of a pyridine moiety.

ELIGIBILITY FOR THE STUDY

Eligible for the study were pregnant women at the third trimester of pregnancy, attending to the outpatient Prenatal Service of the Clinica Luigi Mangiagalli (the largest maternal clinic in Milano) in ten randomly selected days. A total of 77 women entered the study. Of all eligible subjects, only 2 women refused to enter the study. In self reported smokers at least 60 minutes were allowed to elapse after smoking the last cigarette before sample collection.

RESULTS

A calibration curve of cotinine vs. cotinine/cotinine d3, prepared in water and processed

with samples (fig. 1) showed good linearity in the range 1-100 ng/ml (r=0.9998) . A typical patient's chromatogram is shown in fig. 2. The cotinine concentration in this particular sample was calculated to be 10.83 ng/ml, close to the limit value for nonsmokers.

Under these instrumental conditions we have been able to detect as low as 1 ng/ml of salivary cotinine in one-ml samples (nonsmokers threshold is generally considered to be 10 ng/ml).

CONCLUSIONS

In our study all women who reported quitting smoking while pregnant had "negative" saliva cotinine levels (3.1 ± 2.5 ng/ml mean ± SD). Furthermore, the mean value of cotinine increased with the number of cigarette smoked per day being 18.6 ± 25.2 ng/ml for less than 10 cigarette per day, and 49.1 ± 49.0 for more than 10 cigarettes per day (mean ± SD).

THE STRUCTURAL CHARACTERISATION, BY CONTINUOUS FLOW-FAB MASS SPECTROMETRY, OF THE H-9 *IN VITRO* METABOLISM OF THE HIV PROTEASE INHIBITOR, SK&F107461

T.J.A. Blake , K.M. Anderson, W. Potts and R. Van Horn
Department of Drug Metabolism, SmithKline Beecham Pharmaceuticals, P.O. Box 1539, King of Prussia, PA 19406.

Introduction: SK&F 107461 (Cbz-Ala-Ala-PheΨ[CH(OH)CH_2]Gly-Val-Val-OMe) is a specific inhibitor (1) of the aspartyl protease encoded by the human immunodeficiency virus type 1 (HIV-1), the etiological agent of acquired immunodeficiency syndrome (AIDS). SK&F 107461 was effective as an inhibitor of HIV-1 protease both in enzyme inhibition assays and in the HIV-infected T-lymphocyte cell culture assay. The molecule was modelled after an oligopeptide substrate and contains a non-hydrolyzable hydroxy-ethylene linkage in place of the scissile peptide bond. The amino terminus is blocked with a carbobenzyloxy blocking group and the carboxy terminus with a methyl ester. Evaluation of this class of compounds involved incubation with HIV infected human H-9 cells. To aid in the pharmacologic interpretation of these studies, the *in vitro* metabolism of SK&F 107461 in H-9 cells was investigated. The structural characterisation of the major metabolites was carried out by means of on-line continuous flow-fast atom bombardment (CF-FAB) mass spectrometry. The H-9 cell supernatant, from a 20 μM incubation of ^{3}H-SK&F 107461, was injected directly onto the chromatographic column and analysed by alternating positive/negative ion CF-FAB. The position of the tritium label is shown below and metabolites identified have been referenced against the radiochemical trace generated from the sample.

Experimental: ^{3}H-SK&F 107461 was incubated at 20 μM with H-9 cells, a human T-lymphocyte cell line, in RPMI-1640 medium containing 10% heat inactivated fetal bovine serum. The cell cultures were maintained at 37°C with 5% CO_2 in a humidified incubator for 5 days. ^{3}H-SK&F 107461 (20 μM) was also incubated without cells as a control. At the end of the incubation period the cells were separated from the medium by centrifugation and the medium extracted using a C_{18} Sep-pack extraction column. The extract (300 nmol of compound related material) was dried under a stream of nitrogen and resuspended in DMSO:acetonitrile:water (5:19:76 v/v; 500 μl). An aliquot (30 μl) was injected onto the chromatographic column for analysis. The LC/MS analyses were carried out using a Hewlett Packard 1090A HPLC coupled to a Finnigan-MAT TSQ 70 triple quadrupole mass spectrometerscanned in alternating positive/negative mode. The chromatographic analyses were performed by reverse phase HPLC on a Hewlett Packard ODS C_{18} 5 μm 100 x 2.1 mm i.d. column. The mobile phases were 0.01 M ammonium acetate (pH 7) and AcN:H_2O:MeOH (75:19:6) both containing 5% glycerol. The flow rate was 250 μl/min and the flow was split (50:1) to divert 5 μl/min to the mass spectrometer. A linear gradient was employed from 100% to 30% ammonium acetate in 25 min.

Results: The radiochemical trace (tritium) generated from the incubation of ^{3}H-SK&F 107461 with H-9 cells is shown in Fig. 1. SK&F 107461 is represented by the single letter amino acid code name Cbz-AAXVV-OMe. The modified middle residue, PheΨ[CH(OH)CH_2]Gly, is represented by the letter X for clarity. X is Phe-Gly where the peptide bond has been replaced by a non-hydrolysable hydroxy-ethylene linkage. Cbz stands for the carbobenzyloxy N-terminal blocking group. The following nomenclature will be used to rationalise the mass spectrometric fragmentation pathways for SK&F 107461, and its metabolites. The b_n ion is generated by cleavage of the nth peptide bond with concomitant hydrogen transfer to the C-terminal side and protonation on the N-terminal side. The y_n ion results from cleavage of the nth peptide bond from the carboxy terminal end and protonation on the C-terminal fragment. The positive and negative ion CF-FAB mass spectra for the parent , SK&F 107461, is shown in Figs. 2. The parent drug is shown in Fig. 2. In the positive ionisation mode, the $(M+H)^+$ ion was observed at m/z 712. The b_3 and b_4 ions were observed at m/z 482 and 581 respectively with the y_3 ion at m/z 436. Loss of water yielded the ion at m/z 694. The majority of the other fragment ions can be assigned to losses from the N-terminal blocking group. The ion at m/z 622 is produced by nucleophilic attack by water at the carbonyl group of the carbobenzyloxy group with elimination of benzyl alcohol (BzOH), an overall loss of 90 Da. Direct elimination of BzOH (108 Da) yielded the low abundance ion at m/z 604. Loss of the Cbz group (134 Da) yielded the ion at m/z 578. The negative ion spectrum was dominated by the $(M-H)^-$ ion at m/z 710 and losses of 90, 108 and 134 Da from the Cbz group which yielded the ions at m/z 620, 602 and 576 respectively. The fragmentation for Cbz-AAXVV and Cbz-AAXV followed an analogous pattern to that of SK&F 107461 . The smaller metabolites, XVV, XVV-OMe and AX / X showed primarily molecular ion data with little fragmentation.

Conclusion: The metabolism of SK&F 107461 in H-9 cells can be rationalised in terms of enzymatic degradation of the peptide analogue by a combination of esterase activity as well as amino, carboxy and possibly endopeptidase action. All metabolites characterised resulted from the removal of either or both terminal blocking groups and amino acid residues.

MASS SPECTROMETRIC METHOD FOR BIOMONITORING OF ANILINE IN URINE AND COMPARISON WITH THE CLASSICAL COLORIMETRIC METHOD

Robert G. Orth and Jay Wendling
Monsanto Environmental Sciences Center
800 N. Lindbergh Blvd.
St. Louis, Mo 63167

Biological markers of exposure can range from direct measurement of a health effect to the analytical determination of a chemical or its metabolite in the appropriate biological media. The points which should be considered in undertaking a valid exposure investigation include the metabolic pathway, the matrix to be sampled, sampling and sample integrity, method of analysis and quantitation, and the use of the results.

The analytical method plays a key role in the evaluation of the exposure. When determining exposure or an internal dose, a highly specific and sensitive method is needed for the chemical or metabolite which is to be monitored. Also, the understanding of the health effects often sets the limits of detection of a chemical or its metabolite. As the understanding changes, the best detection limits obtainable may be needed. This has occurred for aniline where a recent report (1) indicated that aniline should be determined at the best available detection limits. Previous to this report, the Biological Exposure Index (BEI) was set at a level of the major metabolite, p-aminophenol, in urine of 50 mg/g creatinine. This BEI was obtained using exposure data of volunteers (2,3) providing a correlation with TLV based on prevention of methemoglobinemia.

In the determination of exposure to aniline and the comparison to the BEI, a semiquantitative analytical method (4) is presently suggested which measures p-aminophenol (PAP) by a colorimetric method. In order to provide an analytical method which was more specific and faster, an HPLC method was developed and compared to the colorimetric method. In addition, because of the observed background of about 5 mg/L for both the colorimetric and the HPLC methods, a GC/MS method was developed. The GC/MS method also provided detection limits that were significantly less than the colorimetric and HPLC methods.

Sample stability is important and should be checked before a study begins. It was found that PAP was lost from the urine over time such that after 5 days of storage at 4°C, 50% of the PAP was no longer detectable. To prevent this loss during storage and analysis, citric acid was added at a concentration of 0.1M. No significant loss of PAP occurred for storage times up to 16 days. For the colorimetric, HPLC, and GC/MS methods, all the samples were collected and stored in the same manner.

A key step to the methods is the hydrolysis of the urine sample. Each method utilized the same hydrolysis step which is most critical in obtaining a total PAP concentration. Since the metabolites of aniline include PAP conjugates of glucuronic and sulfuric acids, the time of hydrolysis is critical. The possible confounding chemicals include the pharmaceutical PAP derivatives such as acetaminophen which also is metabolized to PAP and the conjugates of glucuronic and sulfuric acids. Urine samples from individuals who had taken acetaminophen were tested for PAP vs time of hydrolysis. It was found that after 3 hours, no change in concentration occurred and this was the point of completion for the hydrolysis.

The methods described begin with the hydrolysis of one mL of urine with 0.2 mL of concentrated HCl at 100°C. After completion of the hydrolysis the pH, was adjusted to 3-4 with 25% NaOH.

The urine was analyzed by HPLC with UV detection at 301 nm. Two Regis ODS-II 25 x 4.5 cm C18 columns were used. The mobile phase consisted of 0.4M K_2HPO_4 at pH 7.5 with a gradient to 1% ACN over 10 minutes and was held for 15 minutes.

The GC/MS method was the same through the hydrolysis except d_4-p-aminophenol surrogate was added. One mL of 2.5 M K_2HPO_4 at pH 7.5 was added to the urine and the PAP was extracted using a C18 solid phase extraction (SPE) column. The C18 column was conditioned with 10 mL of methanol, followed by 10 mL of water, followed by 5 mL of 2.5M K_2HPO_4. After the sample was added to the column, the column was dried with air for 3 minutes. Then 0.75 mL of water was added to the column and the column again dried with air for three minutes. The PAP was eluted with 2 mL of methanol. The methanol was removed by evaporation with dry nitrogen at 55°C, then reconstituted in 1 mL of methanol. This was passed through an Alumina SPE column preconditioned with methanol. The PAP was eluted with 2 mL of methanol which was subsequently evaporated using dry nitrogen at 55°C. The PAP was derivatized with ethyl acetate and trifluoroacetic anhydride at ambient temperatures for one hour. The GC/MS system used was an HP 5987. The GC column was a 30 meter J&W DB5 30 m capillary column using He carrier gas. The GC temperature program started a 100°C for 1 minute then ramped to 160°C at 10°C/min. The quadrupole MS was operated in electron impact mode and used selected ion monitoring of m/z 301.1 for the native and 305.1 for the surrogate. Based on signal to noise, detection limits should be less than 0.1 mg/L.

Since the BEI is based on the colorimetric approach, then a comparison of the three analytical methods was undertaken. The comparison was made using acetaminophen since no aniline exposure samples were available. The results are shown in Table 1. Sample M1 pre-dose shows very good comparison between the three methods. The sample labeled G1 pre-dose showed a level of approximately 8.2 mg/g creatinine for the colorimetric and HPLC methods . These are similar to reported background levels. The more specific GC/MS method detected a significantly different level of 0.66 mg/g creatinine which indicates that the 8.2 mg/g level was not PAP. The colorimetric method for the post dose levels always showed a higher level than the HPLC or the GC/MS method.

In summary, a GC/MS method was developed for the biomonitoring of aniline by determining the amount of PAP in urine. The detection limit was less than 0.1 mg/g creatinine. The GC/MS method was comparable to the colorimetric method so that the values obtained can be compared directly with the BEI and TLV values reported in the literature.

STABLE ISOTOPE CO-ADMINISTRATION FOR THE IDENTIFICATION OF TEBUFELONE METABOLITES IN RAT BILE (EVIDENCE FOR ALKYNE-TO-ALLENE BIOTRANSFORMATION)

Roy L. M. Dobson, David M. Neal, and William K. Sietsema
The Procter & Gamble Company, Miami Valley Laboratories
P.O. Box 398707, Cincinnati, OH 45239-8707

INTRODUCTION

Tebufelone (TE), 1-[3,5-Bis(1,1-dimethylethyl)-4-hydroxyphenyl]-5-hexyn-1-one (or NE-11740), is being evaluated for anti-inflammatory indications. Based on radiotracer studies in rats, systemic TE is completely metabolized prior to elimination. Most metabolites (>90%) are cleared through the bile.

The objectives of this work were: a) to assess the utility of stable isotope co-administration to rapidly screen for unknown drug metabolites in a biological matrix; and b) to obtain structural information on biliary metabolites of TE in the rat following a single peroral dose.

EXPERIMENTAL

Bile Collection. Bile-duct-canulated rats were dosed with 200 mg/kg of 1:1 TE:[^{13}C]-TE plus a [^{14}C]-TE tracer (The tracer allowed metabolites to be followed throughout sample manipulations). Bile was collected over dry ice through 24 hr post dose. The focus of this work is on 8-24 hr samples.

Sample Preparation. Prior to DEP/(CI)MS/MS and GC/MS analysis, 1 mL bile was loaded onto a C18-SepPak cartridge and washed with 2 mL water. Most of the metabolites (60% of radioactivity) were eluted with 1 mL methanol and evaporated to about 100 uL prior to analysis.

Mass Spectrometric Systems and Modes. All analyses were conducted using a Finnigan MAT TSQ4500 tandem MS instrument, used in DEP/(CI)MS/MS, GC/MS (EI and CI), and HPLC/(TS)MS modes. The TS interface was a Vestec 201.

RESULTS AND DISCUSSION

DEP/(EI)MS of Dose Mixture. A dose mixture mass spectrum (F1) provides an indication of the utility of the stable isotope co-administration approach. All ions containing the stable isotope labeled (SIL) carbonyl group appear as isotopic doublets. Thus, TE metabolites will show characteristic doublet features in their mass spectra as well, making them much easier to screen for in the presence of numerous matrix components.

DEP/(CI)MS/MS. "Parents-of" MS/MS experiments were run by setting Quad 3 to pass daughter ions corresponding to fragments of possible TE metabolites while scanning Quad 1. Experiments were conducted in pairs, first scanning for parents of the expected daughter ion, then for parents of the corresponding SIL daughter ion. Results for m/z 233/234 and m/z 231/232 daughter ion pairs provided molecular weight information for side-chain- and t-butyl-modified metabolites (data not shown here).

GC/MS. The methanol fraction was analyzed directly by GC/MS in both the CI (methane) and EI modes. Although the resulting chromatograms were complex, several TE metabolites (M in F2) were readily distinguished from bile matrix components based on their MS doublet features. Of these, structures of five were proposed (four shown in F3) and ultimately confirmed by comparison of GC/MS data with that of authentic standards. M1, M4, and M5 are consistent with metabolites expected as products of known metabolic pathways. However, M2 represents an alkyne-to-allene biotransformation that, to our knowledge, has not yet been reported.

HPLC/(TS)MS. Untreated bile was analyzed directly by HPLC/(TS)MS. The resulting data (F4) was not only complementary in supporting the identity of several identified metabolites, but also provided strong evidence for the presence of a glucuronide conjugate of M5 (MW=492).

CONCLUSIONS

Stable isotope co-administration facilitated rapid screening of crudely prepared bile samples for TE metabolites using MS/MS, GC/MS, and HPLC/MS. In the rat, TE metabolism occurs on both the side chain and the t-butyl portion of the molecule. The presence of M2 cannot be explained based on existing literature and may be evidence for a novel biotransformation.

CONTINUOUS-FLOW FAST ATOM BOMBARDMENT MASS SPECTROMETRY OF ENZYMATIC HYDROLYSIS PRODUCTS OF CYCLIC PEPTIDE DRUGS

R. Kevin Blackburn and Richard B. van Breemen
Department of Chemistry, North Carolina State University
Raleigh, NC 27695-8204

Bioavailability of peptide and peptide analog drugs following oral administration can be limited by poor absorption or degradation in the digestive tract prior to absorption. We have developed an *in vitro* method to determine the susceptibility of peptide and peptide analog drugs to degradation in the digestive tract using immobilized digestive proteases to simulate gastric and intestinal digestion followed by continuous-flow fast atom bombardment (CF-FAB) LC/MS and MS/MS to determine structures of any hydrolysis products (*1*). Four cyclic peptide drugs, polymyxin, bacitracin, vancomycin, and lysobactin were analyzed for susceptibility to degradation by immobilized digestive proteases. Because these compounds have unusual moieties and are not simple peptides, the potential sites of proteolysis cannot be easily predicted. Lysobactin, a naturally-occurring antibiotic (see Figure 1), was recently under development for oral administration but was found to have poor oral bioavailability (2).

Pepsin, chymotrypsin, trypsin, and mucosal peptidases were immobilized onto porous glass beads using published methods (*3,4*). Each of four cyclic peptide drugs (1 μg/μl) was incubated with each of four immobilized enzyme systems for 48 hr at 37°C. 10 μl of beads were used in each 100 μl incubation at a molar ratio of substrate-to-enzyme of 100:1. Gastric digestion was simulated by incubation with immobilized pepsin in 0.1M HCl. Intestinal digestion was simulated by individual incubations with immobilized trypsin, chymotrypsin, mucosal peptidases, or with a mixture of all three enzymes in 100 mM ammonium acetate buffer, pH 7.5. Aliquots (7-10 μL) of each incubation mixture were analyzed by using reversed phase HPLC followed on-line by continuous-flow FAB mass spectrometry using an Applied Biosystems Model 140A dual syringe pump equipped with a Vydac C_{18} narrow bore column (2.1 mm x 15 cm). HPLC separations were carried out at a flow rate of 100 μl/min using a 30 min gradient from 90:10:0.5:0.1 to 10:90:0.5:0.1 water/acetonitrile/glycerol/trifluoroacetic acid. The solvent flow was split post-column so that 5 μl/min entered the mass spectrometer. Positive ion FAB mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system and a frit-FAB continuous-flow FAB interface. Resolution for LC/MS was 1000. The range m/z 1-1500 was scanned in approximately 12 sec so that 3-7 scans were obtained per chromatographic band. Static FAB ionization followed by collisional activation (CAD) and B/E linked scanning of each protonated peptide precursor was used for peptide sequencing.

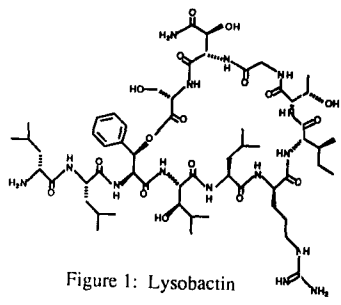

Figure 1: Lysobactin

Polymyxin, bacitracin, and vancomycin were not hydrolyzed enzymatically. However, bacitracin and vancomycin showed extensive degradation at low pH. Lysobactin (see structure in Figure 1) showed rapid hydrolysis of the lactone at pH 7.5 followed by proteolysis by the intestinal proteases. In the gastric digester, the lactone moiety of lysobactin was much more stable and no enzymatic hydrolysis was observed. Figure 2 shows the reconstructed total and selected ion chromatograms for a chymotryptic digest of lysobactin obtained during LC/MS. Figure 3 shows the B/E scan CAD mass spectrum of the chymotryptic hydrolysis product of lysobactin weighing 904. A tryptic product of lysobactin weighing 805 was formed by hydrolysis at what was previously reported to be a D-arginine (2). Since trypsin cleaves only at L-arginine or L-lysine residues, this indicates that the arginine in lysobactin must be at least partially in the L configuration.

Compared to linear (open-chain) peptides (*1*), cyclic peptide drugs were shown to resist proteolysis by digestive enzymes. The poor oral bioavailibility of the antibiotic lysobactin is explained by hydrolysis of the lactone at pH 7.5 followed by extensive proteolysis of the open-chain product. This immobilized digestive enzyme assay could be used to screen potential peptide or peptide analog drugs for susceptibility to degradation in the digestive tract. While this methodology will not replace animal and human bioassays, their use can be minimized because only drugs that are shown to resist digestion would proceed to animal and human studies.

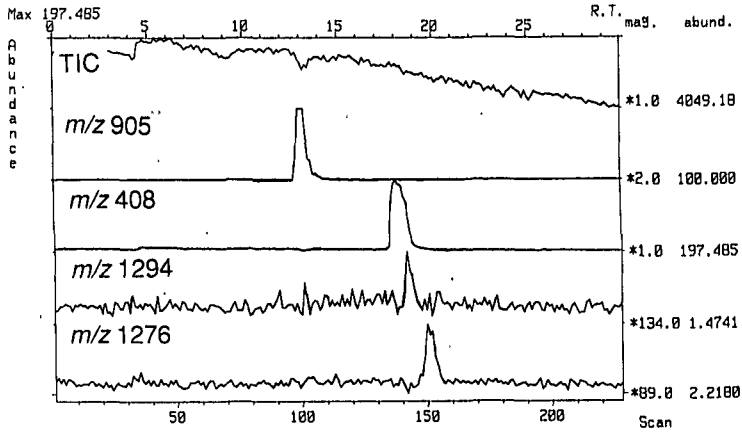

Figure 2: Total and selected ion chromatograms of a chymotryptic digest of lysobactin.

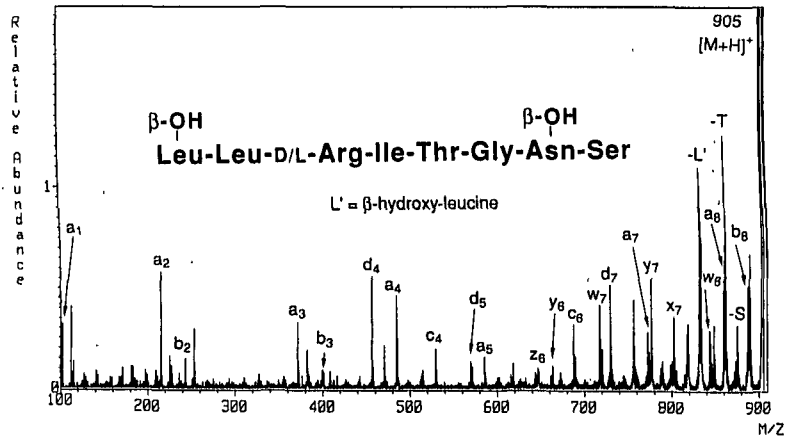

Figure 3: B/E linked scan CAD mass spectrum of the protonated chymotryptic proteolysis product of lysobactin at m/z 905. Product ions are labeled using the nomenclature of Biemann (*5*).

APPLICATION OF FAST ATOM BOMBARDMENT MASS SPECTROMETRY TO SOME BIOCHEMICAL INHIBITOR MOLECULES

Jian Yin, Kenneth L Busch, and James C. Powers
School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332

Serine proteases play critical roles in several physiological processes, including digestion and blood coagulation. Serine proteases are not only a physiological necessity, but can also be of potential danger if their levels are not controlled. Isocoumarins substituted with hydrophobic groups have been found to be excellent inhibitors of several serine proteases. These compounds may be used in vivo to treat diseases such as emphysema, adult respiratory distress syndrome, etc. The structure of these compounds (Figure 1) are such that the side chains contain a precharged ammonium group so that they produce high quality positive ion FAB mass spectra.

Positive ion FAB spectra of isocoumarin derivatives are measured with a VG70SEQ mass spectrometer. A solvent of meta-nitrobenzyl alcohol (m-NBA) provided good results for these isocoumarin derivatives. These compounds were dissolved in the matrix with a concentration of about 30μg/10μl. The instrument was tuned to have 5000 resolution with 10% valley definition. The total ion current was stable during about 100 scans in 5 minutes. Cesium ions of 35 keV energy emitted from a thermionic source were used as the particles in these experiments; the beam size was approximately $2mm^2$

One example of an isocoumarin derivative FAB mass spectrum is given in Figure 2. The structure of this compound is given in Figure 1. The spectrum contains as base peak the intact cation at m/z 575. The sole fragment peak is at m/z 117 as a relative abundance of 50%. This fragment ion represents a cleavage at the C-O bond in one of the two side chains of the isocoumarin derivative. In addition to these structurally informative ions, a series of peaks are also observed that correspond to sequential additions of (153)n mass units to the intact cation, where n = 1-4, and 153 is the molecular mass of m-NBA. A dimer ion of the form $(2C-H)^+$ is present at m/z 1149 (RA 4%). The cluster ion CAC^+ (here A represents the counter ion) also appears in the spectrum

MS/MS experiments are performed to derive additional structure information from these isocoumarin derivatives. Figure 3 is an MS/MS spectrum of the same isocoumarin derivative discussed above. The parent ion is the intact cation of the molecule. Fragment ions observed in the MS/MS spectrum represent cleavages along both side chains of the isocoumarin molecule. Also, charge-remote fragmentation is observed in this MS/MS spectrum.

FAB mass spectrometry produces high quality mass spectra for isocoumarin derivatives dissolved in an m-NBA liquid matrix. The mass spectra contain the intact cations of these compounds as dominant ions and cluster, dimer, and addition ions that provide multiple checks for the indicated value for the molecular mass. The MS and MS/MS spectra show that the C-O bond in the side chain of the isocoumarin compound is most easily broken. Charge-remote fragmentations are observed in MS/MS spectra of some isocoumarin derivatives.

Analysis of Alkaloids Seperated by Empore™ TLC with FAB Mass Spectrometry

*James O. Mullis and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Insitute of Technology, Atlanta, GA 30332, (404)894-4030

INTRODUCTION

We have investigated the coupling of mass spectrometry with Empore TLC media. The coupling methods studied included direct fast atom bombardment (FAB) analysis, as first described by Minard for Empore (1). Various FAB liquid solvents have been explored as ways to extract compounds for direct analysis from Empore. We have also investigated the use of electron ionization (EI) mass spectrometry in conjunction with rapid evaporation of sample molecules from the Empore sheets. In addition, we have shown that the derivatizing agent, BSTFA/1%TMCS can be applied directly to a compound on the Empore surface to form a volatile derivative suitable for EI analysis.

We use the alkaloids noscapine, papaverine, morphine and codeine as model compounds, because their chromatographic separation has been well studied in the literature (2), and because there would be analytical interest in these as potential substances of abuse. Comparisons were made in mass spectral responses obtained from Empore silica sheets and Merck HPTLC silica plates.

EXPERIMENTAL

Several mass spectrometers were used in this study. A VG-70 SE is equipped with a xenon atom beam. Other experiments were carried out with a VG-70 SEQ equipped with a 35 keV cesium ion beam.

FAB EXPERIMENTS: Each TLC sheet or plate was spotted with 10-13 ug of model compound. The spot was then removed using a single hole punch. The hole punch produced a surface approximately 5 mm in diameter (this size is just slightly larger than the FAB probe tip). This excised TLC planchet was then attached with double sided tape to the FAB probe. The surface was then treated with 50-100 uL of FAB solvent. The large volumes were necessary to thoroughly wet the surface. Solvent matrices examined in FAB were; 20/80 hexane/thioglycerol, 50/50 methanol/thioglycerol, 66/33 m-NBA/methanol, 50/50 methanol/glycerol, m-NBA, 5/95 pyridine/glycerol, 5/95 DMSO/glycerol, and finally 5/95 triethylamine/glycerol. Silica, C8 and C18 plates were examined.

EI EXPERIMENTS: The alkaloid samples were excised from the chromatogram as stated in the above paragraph. To introduce the chromatograms into the EI source, the Empore material was rolled up and inserted into the direct insertion probe cup. Alternatively, the excised sample was cut into a small strip, 4 mm x 1 mm. Extraction solvents used for direct removal of the sample from the Empore included methanol and DMSO. Approximately 10 uL of the solvent was delivered into the sample cup for evaporation in the source. Data acquisition was begun immediately before the sample was introduced into the source to ensure that all of the compound extracted was ionized. The probe was not heated during these experiments.

For derivatization reactions on Empore, 10 ug of morphine was applied to the silica and C18 surfaces of Empore. The spot planchet was removed as stated above, and placed into a 1 mL vial. Next, 200 µL of BSTFA/1%TMCS was added to the vial, and the mixture heated for 20 min at 70°C. Later the spot was trimmed into a strip as above, and inserted into the probe cup, and the probe heated to 400°C.

SEPARATION OF ALKALOIDS: The separation was carried out on a 6 x 2.5 cm piece of silica Empore or a 6 x 4 cm piece of Merck aluminum backed silica HPTLC plate via capillary flow. The mobile phase consisted of 1,4 dioxane, hexane, ethanol, and dimethylamine in a volume ratio of 44:48:4:4. The development time for the Empore silica was about 20-30 min, and about 15-20 min for the Merck silica HPTLC plate. The literature method for TLC separation of these alkaloids required modification to provide equivalent separations for both Empore and standard HPTLC.

RESULTS AND DISCUSSION

The FAB spectra of noscapine shown in Figure 1, is a comparison of the sputter efficiencies from Empore silica and Merck HPTLC silica using 50/50 methanol/glycerol matrix and equivalent amounts of sample. In general, the Merck HPTLC plates provide a much better response for noscapine, $(M+H)^+$ (m/z 414), and papaverine, $(M+H)^+$ (m/z 340). The response for Codeine, $(M+H)^+$ (m/z 300), is only slightly better on the Merck plate, and neither plate gives a signal for morphine, $(M+H)^+$ (m/z 286,) at the chosen sample level. This could be due to strong binding of the morphine to the silica surface, supported by the fact that morphine has the smallest R_f value.

Most of the FAB solvent mixtures studied were either too volatile for use in our procedure or they could not wet the surface of the Empore to extract the compound of interest. The only other FAB solvent to work with Empore was 66/33 (v/v) m-NBA/methanol. These preliminary experiments underscore the importance of extraction. They also emphasize that FAB analysis of compounds spotted onto Empore is not the equivalent of FAB analysis of a developed spot. In spotting, complete interaction of the sample with the silica is not assured. At higher levels of spotted sample the material accumulates at the surface; if it is soluble in the solvent selected, it will form that solution, but an "extraction" has not necessarily taken place.

TLC separation of the alkaloids on Empore produces rather broad bands. Iodoplatinate indicator solution was sprayed on the surface of each plate. This stain is reluctant to wet the surface of Empore, and the observed faintness of these bands may be due to this. No response for any of the four alkaloids was seen in the FAB spectra for Empore. On the

conventional plates the bands are much tighter and more concentrated, and therefore darker after development. The more concentrated sample band also results in a higher response for the Merck HPTLC plates. The direct evaporation process in EI from Empore sheets and Merck HPTLC plates was studied using codeine as a model. A blank silica control was used in both cases. The silica HPTLC plate was spotted with 10 ug of codeine, dried, and the entire spot was scraped and the silica transferred to the sample cup. Ten microliters of methanol was then added to the sample cup as the extraction solvent. The same procedure was completed for the Empore, except that the entire spot was removed as a planchet, and a portion of the sample was clipped and transferred into the sample cup. A measured blank for the Empore control and the Merck control was made and showed a slightly lower background signal from Empore. Mass spectra for the real samples using the direct evaporation method showed the molecular ion for codeine, m/z 299, is produced from both the Empore sheets and the Merck plates. The lower limit of detection from Empore is approximately 2 ug for codeine.

Figure 2 shows the EI mass spectrum resulting from direct evaporation of the sample after in situ derivatization on Empore C8 and C18 TLC sheets. Morphine reacts with two TMS groups to give m/z 429. Morphine was derivatized on Empore silica as well.

Finally, overlapping spots on the TLC can be identified by evaporation into the EI source. Noscapine and papaverine were prepared as overlapping spots. The hole punch was used to remove the sample, and the mixture was transferred to the cup. Ten microliters of methanol was used for the extraction. Signals were observed for both papaverine, M^+ (m/z 339), and noscapine m/z 220 [which is (M-193)]. Spatial resolution is only dependent on the device that is used to excise the sample.

CONCLUSION

Direct sputtering of alkaloid samples from Empore by FAB is not as efficient as sputtering from aluminum backed TLC plates due in some part to lower sample densities. Demonstrated evaporation efficiencies from Empore and aluminum backed HPTLC plates are similar. Morphine can be directly derivatized on silica, C18, and C8 Empore using BSTFA/1%TMCS, which offers significant advantages in sample desorption.

The primary advantage of Empore in TLC is the ease of sample preparation for analysis. Conventional HPTLC plates which are brittle and must be scraped to remove the analyte of interest. Spatial resolution for Empore TLC/MS is only limited by the device used to excise the sample.

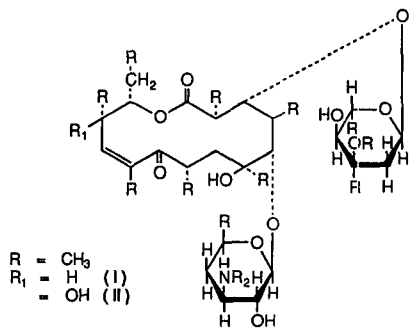
MATRIX ADDUCT IONS IN FAB MASS SPECTROMETRY OF 10,11-ANHYDROERYTHROMYCINS

Qingmei Zha, David S. Casebier and David E. Cane
Department of Chemistry, Brown University
Providence, RI 02912

Erythromycin, first found in a soil sample from the Philippine Archipelago, is an antibiotic substance produced by a strain of streptomyces erythreus. The erythromycin molecule consists of three major subunits. Two sugars, the amino sugar desosamine and the sugar cladinose are linked to erythronolide, the aglycone portion of erythromycin. Since its recognition as a useful antibacterial agent, erythromycin has been modified to improve its properties. Most modifications reported have been focused on the sugar moieties. 10,11-anhydroerythromycins are the examples that modification was made on the main body erythronolide.

The two 10,11-anhydroerythromycin samples are a generous gift from the Abbott Laboratory. The compositions of these two compounds are $C_{37}H_{65}NO_{11}$ and $C_{37}H_{65}NO_{12}$, whose molecular weighs are 699 and 715, respectively. The structural difference between these two compounds is that a hydroxy in sample II is replaced by a hydrogen in sample I.

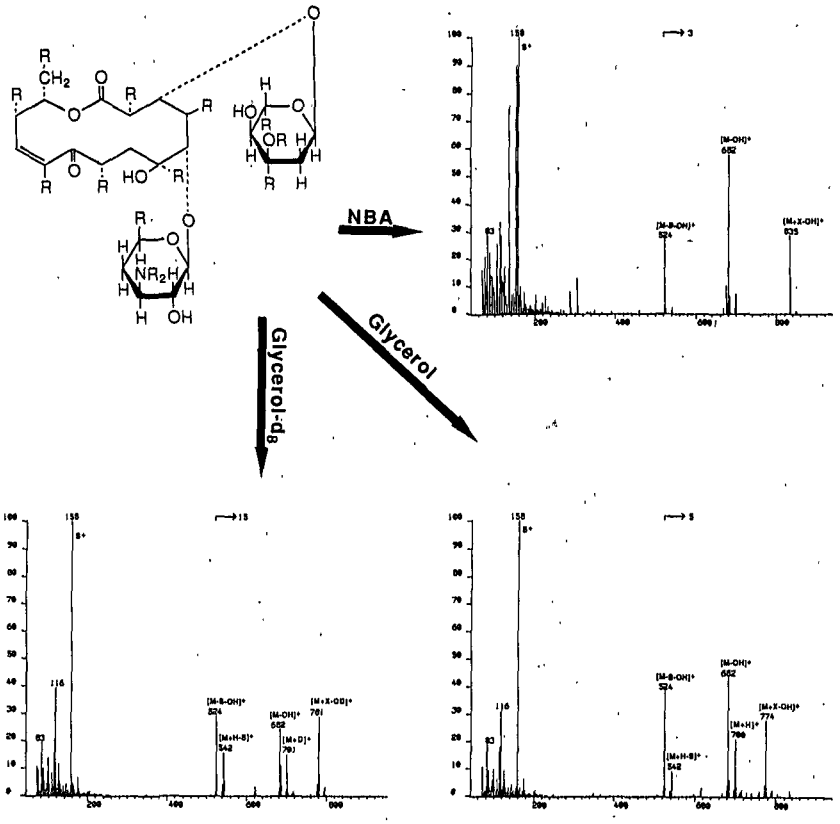


FAB mass spectral analysis of 10,11-anhydroerythromycins was performed on a Kratos MS-80 double focusing mass spectrometer operating at an accelerating voltage of 4 kv. A fast atom saddle-field gun (Iontech FAB-11NF) is mounted on a standard Kratos FAB source. The xenon atom beam was generated with a kinetic energy of ca. 8 kv. The liquid matrices glycerol and 3-nitrobenzyl alcohol (NBA) were purchased from Aldrich, and the deuterium labeled matrix glycerol-d_8 was from Merck Frost, Canada.

FAB mass spectrum of sample I using NBA as a liquid matrix is shown in Fig. 1. The base peak at m/z 158 is the amino sugar desosamine ion S^+. A major peak with the highest mass is observed at m/z 835, which is 136 mass units more than the molecular ion. This ion, at first caused confusion in the interpretation of FAB mass spectrum. It was then noticed that another peak at high mass region is m/z 682, presumably the $[M-OH]^+$ ion. The mass difference between these two ions is 153, which is the molecular weight of liquid matrix NBA. Thus, it is proposed that the peak with the highest mass is a matrix adduct ion $[M+X-OH]^+$, where X denotes the matrix molecule. When glycerol was used as a liquid matrix, the peak with the highest mass is observed at m/z 774 and the $[M-OH]^+$ ion is observed at m/z 682. The mass difference between these two ions is 92, the same as the molecular weight of glycerol. This would indicate that in FAB mass spectrometry of 10,11-anhydroerythromycins, a strong matrix adduct ion $[M+X-OH]^+$ is generated as a major ion. However, the protonated molecular ion $[M+H]^+$ is also observed as a major ion when glycerol was used as a liquid matrix. FAB mass spectrometry of sample II showed the same behavior.

10,11-anhydroerythromycins have a tendency to eliminate a hydroxy group in the generation of mass spectra. There are two major fragment ions, $[M-OH]^+$ and $[M-S-OH]^+$ eliminated a hydroxy group from the molecule during their formations. Since FAB mass spectrometry of 10,11-anhydroerythromycins is characterized by the observation of a matrix adduct ion $[M+X-OH]^+$, whose formation is also related to the loss of a hydroxy group, we were interested whether the hydroxy elimination was from the sample portion or the matrix portion. When FAB mass spectrum of sample I using labeled glycerol-d_8 as a liquid matrix was compared with that using glycerol matrix, two major peak shifts were observed. The protonated molecular ion $[M+H]^+$ became $[M+D]^+$ and the matrix adduct ion $[M+X-OH]^+$ became $[M+X-OD]^+$. This would indicate that in the formation of a matrix adduct ion, the hydroxy elimination is from the matrix molecule.

ACKNOWLEDGEMENT: The authors thank Abbott Laboratory for providing the samples.



CF-FAB, Particle Beam, and Electrospray Ionization Mass Spectrometry of Taxanes

M.J.I. Mattina[1], G. Giordano[2], and W.J. McMurray[2]

[1]Connecticut Agricultural Experiment Station, 123 Huntington Street, New Haven, Connecticut 06504 and [2]Comprehensive Cancer Center, Yale University School of Medicine, New Haven, Connecticut 06510

Taxol (Figure 1) is a naturally occurring diterpene alkaloid with significant anticancer activity. Cephalomannine and Baccatin III, like taxol, are taxane compounds which are produced by the genus, *Taxus*. The biological activity of taxol and cephalomannine is attributed to the side chain at the C13 position. Baccatin III, which contains the taxane core but lacks a side chain at C13, is not biologically active.

In conjunction with a project to screen ornamental *Taxus* cultivars for taxol concentration, it was appropriate to develop a mass spectrometric method for the analysis of biological matrices for taxane content. One of the analytical methods for determining taxol in plant extracts requires SPE clean-up of the crude plant extract followed by HPLC with photodiode array detection (1). Although DCI with MS/MS has been used to assay extracts for taxane content (2), it is desirable to determine if on-line techniques such as CF-FAB, particle beam, and electrospray are also appropriate for this analysis. Recently HPLC with thermospray mass spectrometry has been reported for the analysis of taxol (3).

Accordingly, we present this preliminary study of the mass spectra of taxol, cephalomannine, and baccatin III under CF-FAB, particle beam, and electrospray ionization conditions. The spectra included here illustrate for the first time the mass spectrum of each compound from the molecular weight m/z value to m/z 100. The standards used in this study were obtained from the National Cancer Institute.

Continuous flow fast atom bombardment mass spectra were acquired on a VG Instruments ZAB-SE mass spectrometer equipped with a cesium ion gun. The CF-FAB probe incorporated the coaxial flow design with the outer matrix stream composed of 15% glycerol/85% water and the inner carrier stream composed of 20% methanol/40% acetonitrile/40% water.

A Hewlett-Packard quadrupole mass spectrometer equipped with an HP 59980A particle beam interface was operated in flow injection mode using methanol as the mobile phase at a flow rate of 0.4 ml/min. Both EI and methane electron capture negative ion mass spectra were acquired, although only the ECNI mass spectrum is included here.

Electrospray ionization spectra were acquired on a VG Instruments Quattro triple quadrupole mass spectrometer equipped with an Analytica of Branford electrospray source. Analyte solutions were prepared in 1:1 methanol:water and were introduced into the source using a syringe pump at a flow rate of 1µl/min.

The CF-FAB spectrum shown here (Figure 2) required a taxol solution at 2 to 5 µg/µl concentration levels. This high detection level and the lack of instrument stability over extended operation periods reduced the potential usefulness of this technique.

The taxol particle beam FIA methane electron capture negative ion mass spectrum (Figure 3) was acquired with 20µl injections of 2µg/µl solutions. Again this concentration level was not of interest to warrant further experiments.

Electrospray ionization was carried out on solutions of the three taxanes prepared in 1:1 methanol:water at approximate analyte concentration of 5ng/µl. The full scan spectrum of taxol is shown here (Figure 4). For each taxane the $[M+Na]^+$, $[2M+Na]^+$, and some diagnostic fragment ions are observed in the ESI spectra.

EI, CI and FAB Mass Spectral Identification of Metabolites of RWJ-26899, A Potential Antihypertensive Agent.

*W.N. Wu and J.A. Masucci. The R.W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477.

Introduction

RWJ-26899-002 was evaluated for the treatment of hypertension and angina. It effectively reduced the blood pressure of spontaneously hypertensive rats to normotensive levels with a long duration of action. The objective of this study was to isolate and identify the metabolites of RWJ-26899-002 in rats and dogs.

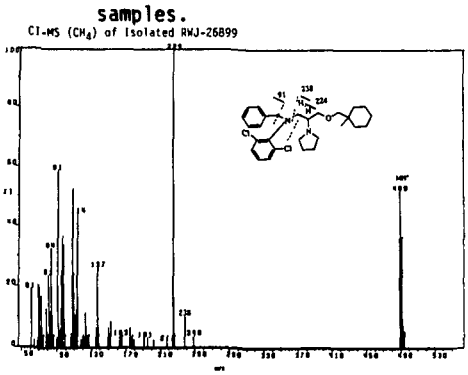
Methods

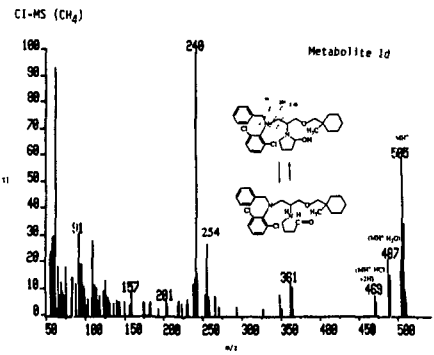
Metabolite Isolation

Following sample purification, individual metabolites were isolated using HPLC peak collection and/or column chromatography methods. Unresolved HPLC metabolite peaks or column fractionation residues were further separated using TLC zone scraping methods.

Metabolite Identification

All metabolites were characterized by desorption CI (NH_3, CH_4) and FAB (thioglycerol) mass spectrometry. Mass spectra of the isolated metabolites and their derivatives were compared with those of synthetic samples, if available, for further structure confirmation. Proton NMR spectra were obtained for the unchanged drug and metabolites in comparison with those of reference samples.





Results

Representative samples of plasma, urine and fecal extracts were pooled and purified for metabolite profiling. Chromatography (column, TLC and HPLC), spectroscopy (NMR and MS) and derivatization were used as appropriate. Fecal extract pools were used for metabolite isolation and identification. Unchanged RWJ-26899-002 and a total of nine metabolites were isolated, identified and quantified. Identified metabolites accounted for >60% of the total radioactivity contained in the fecal extract pool.

Structures of RWJ-26899-002 and its Metabolites

	R_1	R_2	R_3
M-I (RWJ-26899-002)	---	---	H
M-Ia	O	---	H

M-IIb	OH	OH	H
M-IIc	H	H	OH
M-IId	H	OH	OH
M-IIe	dehydrated	H	H

Mass Spectrometry

Chemical ionization spectra were obtained using a VG 7070E and a Finnigan 3300 mass spectrometer. Operating conditions for both spectrometers included: Source Temperature:220°C; Reagent gas pressure: 2 torr; Ionization potential 70 eV; Multiplier voltage:1.8 KeV; Electrometer setting:10^{-7} A/V; Mass ranges: 18-1000 m/z at 1 sec/decade (VG), 50-700 m/z at 1 sec/scan (Finnigan); Sample inlet: desorption probe; Sample size: 5 ul.

Fast Atom Bombardment spectra were recorded using a VG 7070E mass spectrometer. Operation conditions included: Source Temperature: 25°C; Source Type: Ion Tech saddle field design with argon gas at 8 KeV potential and 1 mA current; Multiplier voltage: 1.8 KeV; Electrometer setting: 10^{-7} A/V; Mass range: 18-1000 m/z at 1 sec/decade; Sample matrix: 5 ul thioglycerol; Sample size: 2 ul.

POSTTRANSLATIONAL MODIFICATIONS OF BRAIN AND TESTES, CLASS III β-TUBULIN: STRUCTURAL CHARACTERIZATION BY TANDEM MASS SPECTROMETRY

N. Z. ZHU, A. FRANKFURTER, W. M. BODNAR, J. SHABANOWITZ, AND D. F. HUNT
DEPARTMENTS OF CHEMISTRY AND BIOLOGY, UNIV. OF VIRGINIA,CHARLOTTESVILLE,VA 2290122

FIVE β-TUBULIN ISOTYPES ARE EXPRESSED DIFFERENTIALLY DURING MAMMALIAN BRAIN DEVELOPMENT. ONE OF THESE ISOTYPES HAS BEEN DESIGNED TO AN ISOTYPIC FAMILY DESIGNATED CLASS III (βIII). βIII IS EXPRESSED EXCLUSIVELY BY NEURONS IN THE NERVOUS SYSTEM AND ALSO IN THE SERTOLI CELLS OF TESTES(1). BY ISOELECTRIC FOCUSING, BRAIN βIII EXHIBITS A DEVELOPMENTALLY REGULATED INCREASE IN CHANGE HETEROGENEITY. THIS CHANGE HETEROGENEITY IS PRODUCED BY POSTTRANSLATIONAL MODIFICATIONS LOCALIZED WITHIN THE C-TERMINAL 15 AMINO ACIDS OF THE PROTEIN (2). WE HAVE SHOWN THAT THESE POSTTRANSLATIONAL MODIFICATIONS INCLUDE PHOSPHORYLATION AND/OR GLUTAMYLATION WITHIN THE βIII ISOTYPE-DEFINING DOMAIN(3)

TO FURTHER CHARACTERIZE DIFFERENCES IN THE EXTENT AND NATURE OF βIII POSTTRANSLATIONAL MODIFICATION DURING BRAIN DEVELOPMENT, AND ALSO TO ESTABLISH WHETHER THIS ISOTYPE IN TESTES IS ALSO POSTTRANSLSTIONALLY MODIFIED, βIII C-TERMINAL PEPTIDES ISOLATED FROM NEONATAL AND JUVENILE RAT BRAIN TUBULIN AND JUVENILE RAT TESTES TUBULIN WERE CONVERTED TO THEIR METHYL ESTER DERIVATIVES AND SUBJECTED TO AMINO ACID SEQUENCE ANALYSIS BY MICROCAPILLARY HPLC-ELECTROSPRAY IONIZATION TANDEM MASS SPECTROMETRY.

FIGURE 1 SHOWS A COLLISION ACTIVATED DISSOCIATION (CAD) MASS SPECTRUM (TSQ-70 FINNIGAN MAT) RECORDED ON IONS AT M/Z 806^{2+} THE AMINO ACID SEQUENCE **YEDDDEESEAQGPK** WAS DEDUCED FROM THE 806^{2+} SPECTRUM. THIS SEQUENCE CORRESPONDS TO THE C-TERMINUS OF RAT BRAIN AND TESTES βIII (RESIDUES 437-450). PHOSPHORYLATION OF TYR-437 IN TESTES WAS DEDUCED FROM THE CAD MASS SPECTRUM RECORDED ON THE $(M+H)^{+}$ IONS AT M/Z 902^{2+}.

PRESENTLY, WE HAVE ESTABLISHED THAT THERE IS A SUBSTANTIAL INCREASE IN THE ABUNDANCE OF POSTTRANSLATIONALLY MODIFIED

BRAIN-βIII ISOFORMS DURING THE FIRST THREE TO FOUR POSTNATAL WEEKS AND THAT THE MAJOR PHOSPHORYLATION SITE IN BRAIN βIII IS SER-444. THIS PHOSPHORYLATION OCCURS PREDOMINANTLY ON ISOFORMS WHICH ARE EITHER MONO- OR DIGLUTAMYLATED AT GLU-438. IN CONTRAST, THE PREDOMINANT βIII ISOFORM IN TESTES IS PHOSPHORYLATED AT TYR-437. THIS LATTER RESULT INDICATES THAT SERTOLI CELL βIII IS POSTTRANSLATIONALLY MODIFIED DIFFERENTLY THAN NEURONAL βIII.

New Brunswick, New Jersey

Recent reports suggesting the presence of free toluenediamine (TDA) in the urine of women having polyurethane-covered breast implants[1] have led us to review the analytical methods in current use. We have observed that free TDA is unstable in urine even for short periods of time at room temperature and that it is grossly unstable during long term storage at -20°C. We have also noted that practices commonly employed in TDA assays--*e.g.*, (a) 'stabilizing' TDA in urine with HCl, (b) extracting TDA from urine to organic solvent in strong base, and (c) derivatizing TDA with perfluorinated anhydrides under extreme conditions--can generate TDA artifactually from related diamines and from oligomeric species derived from polyurethane. In addition, avoiding false positives from contamination of glassware and drying apparatus requires constant concern over cleanliness even beyond that usually necessary in drug assays.

Our refined methodology for simultaneously measuring concentrations of 2,4-TDA, 2,6-TDA, and 4-N-acetyl,2,4-TDA in urine from women having polyurethane-coated breast implants incorporates the following:

- To **stabilize TDA** in urine by a method that does not create artifacts, upon collection we buffer urine to pH 3 with Na citrate/citric acid.
- To **avoid strong base**, we extract the analytes into toluene from citrated urine using ammonium phosphate to adjust the pH to 8.
- To **achieve low pg/mL sensitivity**, we derivatize unsubstituted amines to amides with pentafluoropropionic acid anhydride (PFAA) and analyze them by NCI-GC/MS
- To **minimize transacylation of 4-N-acetyl-2,4-TDA** we chose derivatization conditions that limit production of artifactual TDA to 0.05%, thus limiting the upper range of 4-N-acetyl-2,4-TDA to 20 ng/mL
- To **eliminate the chief source of contamination** associated with processing of samples the drying apparatus is cleaned daily.

Negative chemical ionization of the PFAA derivatives yields very clean spectra of all three analytes, with $(M-HF)^-$ the predominant ion in each case. Excellent sensitivity was obtained in the single-ion-monitoring mode. As the lower chromatogram shows, detection at the picogram/mL level for 2,4- and 2,6-TDA was easily achieved. Because of potential health concerns related to the presence of circulating levels of free TDA, the assay was optimized for determining concentrations of 2,4- and 2,6-TDA at the lowest practical levels. Accuracy and precision for these two analytes in the 10 pg - 5 ng/mL range is excellent: coefficients of variation and % deviations from nominal were below 10% for all QC's at all levels. Accuracy and precision of the assay for the 4-N compound is very good over the 0.1 - 15 ng/mL concentration range. The predicted concentration of the low level QC deviated from nominal by less than 25%; those of the mid- and high- level QC's by less than 10%. Coefficients of variation of less than 15% were achieved for the QC's at all levels. An assay optimized for this compound could quantify 4-N-acetyl-2,4-TDA at concentrations in the low picogram/mL range.

The citrate buffer provides good stability for TDA in urine during the time period over which samples are expected to be stored. Experiments involving the spiking of blank and citrated urine with polyurethane foam extracts produced no evidence for the generation of TDA by the citrate. Generation of TDA from 4-N-acetyl-2,4-TDA by the citrate can be ruled out on the basis of the

accuracy and precision data showing our demonstrated ability to quantify the two compounds in the same matrix simultaneously. Even under the mildest derivatizing conditions, however, transacylation of 4-N-acetyl-2,4-TDA produces 2,4-TDA at a level of 0.05%. Thus, quantifying 2,4-TDA at the 10 pg/mL without artifacts in the presence of 4-N-acetyl-2,4-TDA level places an upper limit on the range of the 4-N-compound of 20 ng/mL. Avoidance of strong acids or bases in assays in which oligomers and/or metabolites may be present is of the utmost importance in obviating artifactual generation of TDA.

Determination of Chloramphenicol Residues in Shrimp at sub-ppb Level

F. Aladar Bencsath[1], Steven M. Plakas[1], and Austin R. Long[2]
Food and Drug Administration, [1]Fishery Research Branch, P.O. Box 158, Dauphin Island, Alabama 36528; [2]Animal Drugs Research Center, P.O. Box 25087, Denver, Colorado 80225

Cultured fish and shrimp are increasingly important parts of our food supply. Drugs and other chemicals are often administered to treat or prevent bacterial and other diseases in these animals. The lack of uniform national and international regulations governing the use of drugs and chemicals in aquaculture is a human health concern.

To quantify residues of chloramphenicol (CAP) in shrimp, a gas chromatography method with electron capture detection was developed. This method has been verified at 60 ppb level by gas chromatography-mass spectrometry using a commercial quadrupole mass spectrometer with electron capture ionization. However, the mass spectrometer's sensitivity was not sufficient at lower levels (e.g., 10 ppb) to detect all the five characteristic ions.

We attempted to verify the method at 5 ppb level using a magnetic sector - quadrupole hybrid instrument. At a resolution of 1500, the signal-to-noise (S/N) ratios for the molecular ions (m/z 466 and 468) and two major fragment peaks (m/z 304 and 322) were approximately 10 projecting a detection limit of 1-2 ppb. At a resolution of 3500, the chemical noise was well separated from the signals of interest resulting in an S/N ratio of 400 that implied a detection level of 0 04 ppb.

The meta isomer of CAP was used as an internal standard which fragmented less extensively than CAP. The extent of fragmentation of CAP was very dependent on source conditions. Therefore, additional measures were taken to improve reproducibility. Relatively stable source and ionization conditions could be maintained by introducing the lock mass material (perfluorotetracosane) with the solid probe and introducing sweep-gas (methane) in the gas-handling system. Under these conditions, a relative standard deviation of 4% (N=5) at the 5 ppb level was achieved

GC/MS/SIR 5ppb CAP Standard. S/N > 400!

Quantification of 4-Amino-propiophenone in Blood by Capillary Gas Chromatography-Mass Spectrometry

R.A. Evans and E.M. Jakubowski.
U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, Edgewood, MD 21010-5425.

INTRODUCTION

Methemoglobin, known to protect against cyanide toxicity, is formed after administration of 4-amino-propiophenone (PAPP) in vivo. Optimal phenone chain length for this class of compounds in the controlled formation of methemoglobin has yet to be established. Therefore, any 4-aminophenone drug assay developed should be flexible enough to allow the study of phenones of varying chain lengths. Most studies have focused on methemoglobin levels as a measure of efficacy against cyanide toxicity without any effort to correlate protection to drug concentrations. We have developed, to our knowledge, the first capillary gas chromatography-mass spectrometry (GC-MS) quantitative method for PAPP and related aminophenones in serum and plasma. Metabolic studies have played an important role in the activity of PAPP and related compounds. Addition of PAPP to blood in vitro does not cause methemoglobin formation. However, the hydroxylamine metabolite of PAPP has caused the in vitro formation of methemoglobin. In theory, the hydroxylamine metabolite was oxidized to the 4-nitroso-propriophenone and then was reduced back to the hydroxylamine in a redox cycle. This redox cycle was coupled to the oxidation of hemoglobin (Fe^{++}) to methemoglobin (Fe^{+++}). The only metabolite that has shown activity was the 4-hydroxylamine-propriophenone. Therefore, the hydroxylamine should be monitored if possible.

Our goal was to develop an assay for 4-amino-propriophenone and congeners that would be specific and sensitive. The best candidate method was capillary column GC-MS which combines the resolving power of the capillary column with the selectivity and sensitivity of mass spectrometry.

EXPERIMENTAL

A standard curve was prepared by spiking control sheep blood with PAPP from 0.5-500 ng/mL. The internal standard, 4-amino-acetylphenone (PAAP), was added to 1.0 mL of spiked whole blood followed by centrifugation. The resulting serum was passed through a C_{18} bonded porous silica cartridge and eluted with toluene. The eluent was dried and derivatized with heptafluorobutyrlimidazole (HFBI) at 60°C for 30 minutes. PAHP (p-amino-heptanophenone) and PAOP (p-amino-octanophenone) quantification was performed by using a liquid-liquid extraction directly from the spiked 1.0 mL of serum using toluene. The sample was then reduced to dryness and derivatized. Analysis was performed on a Hewlett-Packard 5970 (electron ionization, EI) or 5971 (chemical ionization, CI) GC-MS.

RESULTS AND DISCUSSION

Assays for PAPP, PAHP, and PAOP were developed in order to achieve an assay capable of quantifying the whole series of available 4-aminoalkylphenones. Preliminary attempts to analyze underivatized the p-aminophenones on a variety of columns yielded poor peak shape and sensitivity in the ug/mL range.

PAPP and PAAP were recovered adequately (60-80%) using either the cartridge or liquid-liquid extraction. However, the more lipophilic members of the series, PAHP and PAOP, had poor recoveries from the solid phase cartridge with only 20-30% recovered. Using toluene liquid-liquid extraction on PAHP and PAOP the recoveries increased to around 60-80%. The working range of the assay was from 500 to 5 ng/mL in serum. The upper range could be extended to 5 ug/mL serum or even higher if necessary.

The corresponding hydroxylamines of PAPP (PHAPP), PAHP (PHAHP), and PAOP (PHAOP) were available and an attempt was made to develop an assay for

any or all of them. Analysis of PAPP yielded peaks only for the parent amine and the 4-nitrosopropriophenone. PHAHP and PHAOP solutions under many different conditions produced only the parent amines, namely PAHP and PAOP. In order to assure that the compounds were indeed the hydroxylamines, melting points were determined and the compounds were analyzed by particle beam LC/MS on a HP 5988. Melting points and LC/MS data indicated that these were indeed the hydroxylamine counterparts of the parent compounds. The chemistry of aromatic hydroxylamines supported the breakdown that was observed under GC/MS conditions. This class of compounds was known to undergo at room temperature a disproportionation reaction similar to the Cannizzaro reaction of aromatic aldehydes. The hydroxylamine is simultaneously oxidized and reduced producing an aromatic amine and a nitroso product. A recent paper on the metabolism of PAPP (Wood et al., 1991) showed that the half-life of PHAPP in whole blood was 1 minute. Therefore, the instability of the aromatic hydroxylamines has forced us to concentrate on the parent aminophenones.

The assay used a mass spectrometer with selected ion monitoring to detect and quantify the analytes. Several ionization modes were assessed. Chemical ionization in negative ion detection yielded the greatest sensitivity (mid pg/mL in serum). However, portability and simplicity were two of the requirements of this assay. Therefore, electron ionization was chosen because it can routinely be accomplished on compact, easy-to-operate, benchtop units. Electron ionization yielded detection limits of approximately 5 ng/mL in serum for all of the derivatized p-aminophenones which has been sufficient to meet the needs of the assay. Fragmentation of the p-aminophenones under electron ionization conditions yielded common ions because of loss of the phenone's alkyl side-chain. Fragment ions at m/z 316 and 331 allowed the monitoring of the entire series of HFBI derivatized p-aminophenones. Under methane positive chemical ionization conditions, fragmentation was less extensive and the protonated molecular ion represented the base ion of the spectrum (> 80% of the total ion abundance).

The final verification of this assay would be its ability to measure the analyte in serum or plasma after administration to an animal test species. Preliminary studies have been performed by injecting a sheep (intravenous) with PAHP. The dose was 8 mg/kg with a total of 73 mg PAHP being injected. Samples were collected every 15 minutes for 12 hr. Peak levels of PAHP were approximately 20 ug/mL plasma measured at 15 min. Additional standards were used in this study to bring the analyte concentrations within range of the standard curve. If necessary, PAHP levels could be monitored for much longer than 12 hr at this dose.

CONCLUSIONS

PAPP and related p-aminophenones after toluene extraction and derivatization with HFBI can be quantified down to 5 ng/mL in serum (or plasma) using capillary column GC/MS in the electron ionization mode. Greater sensitivity was available using methane positive chemical ionization. The p-hydroxylaminophenones, the possible active metabolites, were too unstable to allow quantification by GC/MS. The assay was used to monitor PAHP concentrations versus time after a single IV dose in sheep.

GC-MS METHOD FOR THE DETERMINATION OF KETOROLAC IN HUMAN PLASMA

S. Murakami and I. Massey Syntex Research, Palo Alto, CA. 94304

Ketorolac tromethamine (Structure 1) is a potent non-narcotic analgesic which is approved by the FDA for administration by the oral and intramuscular routes. Syntex is currently investigating the use of a topical gel formulation of ketorolac tromethamine as a local analgesic for the treatment of pain and inflammation in arthritis, tendonitis, bursitis, and sprains and strains. To support pharmacokinetic studies of the formulation, a sensitive and specific GC-MS method has been developed for the quantitation of ketorolac (Structure 2) in human plasma.

In this method, ketorolac and an internal standard (IS, Structure 4) are extracted from acidified plasma with ethyl acetate-hexane. The organic extract is evaporated to dryness and the residue is treated with pentafluorobenzyl bromide (PFBBr) to produce the corresponding pentafluorobenzyl (PFB) ester of ketorolac and the IS (Structures 3 and 5). The reaction mixture is evaporated to dryness and the residue is reconsituted with hexane. The PFB derivative of the analytes are further purified using a silica gel mini-cartridge. The PFB derivatives are eluted with ethyl acetate-hexane, the eluate is evaporated to dryness, the residue is reconstituted in isooctane, and a portion of the solution obtained is injected into a Hewlett Packard 5987a GC-MS operating in the negative chemical ionization (NCI) mode. Under the ionization conditions employed, the PFB esters of ketorolac (Figure 2) and the IS produce intense $[M\text{-}PFB]^-$ ions (m/z 254 and 272 respectively) with little fragmention. Single ion monitoring of the ions (m/z 254 and 272) affords high sensitivity and specificity for the quantification of ketorolac. The sensitivity of the method is 0.2 ng of ketorolac per ml of plasma. Linear calibration curves are obtained in the range of 0.2 to 20 ng of ketorolac per ml of plasma.

The intra and inter-assay variability of the assay has been determined. The intra and inter-assay variability (%CV) at 0.2 ng/ml are 3.1 and 16.1 respectively. The inter-assay variability (%CV) at 0.4 ng/ml is 8.3.

The results obtained using this GC-MS method for the determination of ketorolac in samples of plasma (n = 34) were compared to those obtained for the same samples analyzed using an existing HPLC-UV method. A graph comparing the results between the two methods is shown in Figure 3.

This method has also been used to quantitate ketorolac in human synovial fluid. This method has also been adapted to quantitate ketorolac in human knee tissues. The tissues are solubilized with KOH, the solution acified with HCl, and ketorolac and the added IS were extracted with ethyl acetate-hexane. The remainder of the procedure is identical to that described above for plasma.

In conclusion, a specific and sensitive method for the quantitation of ketorolac in human plasma, synovial fluid, and knee tissues has been developed. This method fulfills the analytical requirements necessary to support pharmacokinetic studies of the topical gel formulation of ketorolac tromethamine.

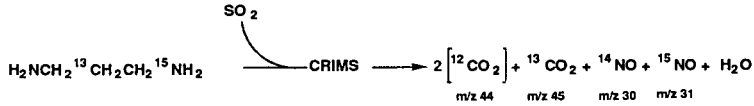
Detection and Identification of *in vitro* Metabolites of ^{13}C-Encainide and $^{15}N_2$-Buspirone using Chemical Reaction Interface Mass Spectrometry (CRIMS)

*Scott W. Womble, Robert Mayol†, Lewis J. Klunk† and Ian A. Blair.
Vanderbilt University, Nashville TN, 37232; †Bristol-Myers Squibb Co., Pharmaceutical Research Inst., Wallingford, CT, 06492.

A new mass spectral technique has been recently developed which can detect stable isotopes in a manner that is independent of the compound's structure. This method was originally reported for interfacing with capillary GC.[1,2] Recent developments have led to an instrument that can be interfaced on-line with a HPLC.[3] This method employs a chemical reaction interface mass spectrometer (CRIMS) to detect ^{13}C and ^{15}N. The CRI is a microwave powered device that decomposes a complex molecule into its oxidized elements. This decomposition results in the formation of stable oxidation products such as CO_2, NO and H_2O (Scheme 1).



Scheme 1.

The isotopic composition of these products can then be determined by use of a quadrapole mass spectrometer using electron impact ionization (EI). Detection of an enriched isotope in the chromatogram allows further identification to be carried out by simply re-running the sample with the microwave power switched off. This affords the EI mass spectra in which the substance of interest can be structurally identified from its fragmentation.

The purpose of this study has been to determine the utility of the CRIMS system in the identification and structural characterization of stable labeled drugs and their metabolites from *in vitro* incubation mixtures. Metabolism studies of ^{13}C-Encainide and ^{15}N-Buspirone were performed using human and rat liver microsomes and the resulting metabolites were identified and characterized using the CRIMS system.

In vitro incubations of ^{13}C-encainide and ^{15}N-buspirone were performed using rat and human liver microsomes as described elsewhere. The resulting metabolites were separated by reverse phase HPLC using the CRIMS system. Figure 1 shows an outline of how the CRIMS system is configured. It uses a gradient HPLC pumping system with normal flow rates of 0.5 to 1.0 mL/min. The effluent from the analytical HPLC column passes into a universal interface where the solvent is vaporized and a helium carrier flow is added. The bulk of the volatile solvent is removed within the universal interface using a membrane separator with a counter current flow of helium. This results in a helium particle beam which is enriched in the sample. This sample containing particle beam travels from the universal interface to the momentum separator, where the remaining solvent and the bulk of the helium is removed through a two stage pumping system. The sample molecules enter the CRI source where an oxidizing gas (SO_2) is added and, due to the high temperatures created by the microwave power (4000-5000 °C), complete combustion to their oxidation products of CO_2, NO, and H_2O occurs. These oxidization products are then detected using EI ionization in a quadrapole mass spectrometer.

In vitro incubations of ^{15}N-buspirone and ^{13}C-encainide were analyzed for the presence of labeled metabolites using the CRIMS system. In the case of buspirone, the major sites of hydroxylation are the 3', 6' and 5 positions, with N-dealkylation resulting in the formation of 1-pryimidinyl piperazine (1-PP). Analysis of the buspirone incubation mixture gave clear identification of metabolites which correspond to the N-dealkylation product, 1-PP, at 7.5 minutes, 3'-OH at 11.5 minutes, 5-OH at 12.0 minutes and 6'-OH at 14.5 minutes with the parent drug appearing at 17 minutes (Figure 2). Trace A is the SIM trace for the unlabeled ^{14}NO content and trace B is the computer generated trace for labeled ^{15}NO content with the natural abundance subtracted. There was an unidentified metabolite at 8 minutes which had not been observed in any *in vitro* incubations before. This metabolite is due to a dihydroxy product such as the 5, 3'-diOH or a 5, 6'-diOH. Both of these metabolites are well known from *in vivo* studies. EI spectra of the

identified metabolites were obtained simply by rerunning the sample with the CRI interface switched off.

In *in vitro* incubations, encainide forms a single metabolite. The metabolite is the O-demethyl encainide. Figure 3 shows the HPLC SIM trace for ^{13}C-Encainide after incubation with rat liver microsomes. Trace A is the SIM trace for the unlabeled $^{12}CO_2$ content, trace B is the SIM trace for the labeled $^{13}CO_2$ content and trace C is the computer generated response for labeled $^{13}CO_2$ content with the natural abundance subtracted. This analysis shows the presence of O-demethyl encainide at 9 minutes and the parent drug at 18 minutes. This figure clearly shows how the use of a stable isotope can be used to identify a metabolite in a complex mixture.

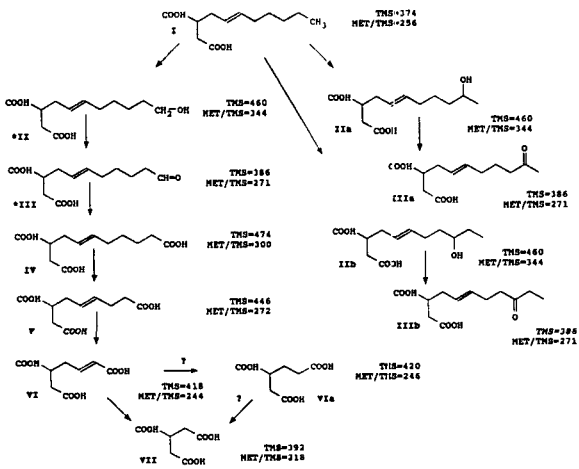
Identification of 2-(2'octenyl)Succinic Acid Metabolites in Urine by GC/MS and GC/MS/MS.

G. Giordano, W. J. McMurray, S. F. Previs, R. D. Welch, P. Rinaldo
Yale University School of Medicine, New Haven, CT; 06510 USA

2-(2'-octenyl) succinic acid (OSA) has been identified in human urine (1). The dietary origin of this compound has been tracked back to casein hydrolysate infant formulas containing corn modified starch (2,3). Upon hydrolysis of the starch in the intestinal lumen, OSA is absorbed as free acid and undergoes extensive metabolism as a combination of ω- and consecutive β-oxidation cycles of the fatty acid side chain. Kelley has reported the identification and semi-quantitative determination of five OSA metabolites in urine specimens from 17 children with a variety of clinical presentations (3). We undertook a study of candidate OSA metabolites by GC/MS/MS analyses using a triple quadrupole mass spectrometer (TQMS) of urine extracts prepared employing multiple derivatization techniques (4). Nine OSA urinary metabolites were identified.



COMPOUNDS II, IIA AND IIB (HYDROXY-DERIVATIVES) The RIC of m/z 445 $[M-CH_3]^+$ ions revealed two peaks (A and B). The corresponding EI, and CI spectra were consistent with a probable molecular weight of m/z 460. The EI spectrum (A) showed a fragment at $[M-117]^+$ ($[M-(CH_3-CH-(OTMS)-]^+$), compatible with the structure of the (ω-1)-hydroxy metabolite (compound IIa). The spectrum (B) contained a fragment at $[M-131]^+$ ($[M-CH_3-CH_2-CH-(OTMS)-]^+$), supporting the identification of the (ω-2)-hydroxy metabolite (compound IIb). Spectra of the methyl/TMS- derivatives revealed two components with a predicted molecular ion at m/z 344, which contained peaks at m/z 117 and at m/z 131, consistent with the proposed structures. CI spectra of the methyl/d_9-TMS derivatives confirmed a single d_9-TMS group. Isomer IIa showed a shift for the fragment m/z 117 to m/z 126. The EI spectrum of isomer IIb, however, showed neither a peak at m/z 140 nor at m/z 131. The RIC of m/z 345 in GC/CIMS/MS product ion analyses contained two peaks. The two product ion spectra were characterized by the difference in the relative abundance of fragment ions at m/z 313 ($[M-CH_3OH]^+$) and at m/z 255 $[M-HOTMS]^+$. The higher abundance of the m/z 255 ion in the spectrum can be rationalised by the participation of the double

bound in the formation of the fragment. Compound II was not detected.

COMPOUNDS III, IIIA AND IIIB (KETO-DERIVATIVES) The presence of two hydroxylated metabolite prompted a search for the corresponding keto compounds. The RIC at m/z 371 corresponding to the $[M-CH_3]^+$ ion of TMS derivatived, showed two peaks. Oximation, also confirmed the presence of keto group in the compounds. The EI spectra of the chromatographic peaks indicated compounds with the probable molecular weight of 386 amu. The fragment ion at m/z 262, (di-TMS substituted succinate), was present in the spectra of both compounds. The mass spectrum of the component in the first chromatograph peak showed a $[M-CH_2CH_2CO]^+$ fragment ion at m/z 329, a peak observed in the spectrum of the proposed 6'-hydroxy compound IIb and consistent with loss of propionyl radical. The corresponding peak at m/z 343, loss of acetyl, was not observed possibly because of limited sample size. GC/CIMS/MS experiments on the methyl TMS derivative were performed to corroborate the location of the Keto groups. The two components show a difference in the relative abundance of the ions at m/z 239 and m/z 211. More direct evidence for the keto group localization was obtained from the minor peak at m/z 228 $[M-(CH_3-C=O)]^+$ and m/z 215 $[M-(CH_3-CH=C=O)]^+$.

COMPOUNDS IV, V, VI, VIA AND VII (TRICARBOXYLIC ACID) A RIC of m/z 474, 446 and 418 of TMS-derivatives, contained three peaks for compounds IV, V, VI respectively. A peak at m/z 403 corresponding to the $[M-CH_3]^+$ peak of the compound VI was detected, at trace levels preventing further structural confirmation. EI spectra from compounds IV and V show the typical fragment ion at m/z 262 (diTMS-). GC/CIMS/MS product ion analysis of the molecular ion of these metabolites showed the combination of three sequential losses of $[CH_3OH]$ and $[HCOOCH_3]$, which indicates the presence of three carboxyl groups in the molecule. The search for compound VI led to the detection of another peak, whose mass spectra indicated the presence of the fragment ion at m/z 262. The apparent molecular weight of this compound was 420 amu. The RIC of m/z 247 of the corresponding methyl/TMS from the GC/CIMS/MS experiments showed three peaks. Only in the MS/MS spectra of the last component were three sequential losses of $[CH_3OH]$ and $[HCOOCH_3]$ observed, indicating a tricarboxylic acid. This compound may represent the missing link in the formation of compound VII. Compound VII, tricarballic acid, was positively identified by comparison of its mass spectrum with that obtained from a commercially available sample.

CONCLUSIONS

1) Nine OSA metabolites have been identified in urine using GC/MS/MS analysis after limited sample preparation and application of various derivatization techniques.
2) Several inaccuracies were found in a tentative identification of OSA metabolites previously reported (3).
3) The correct identification of OSA and its metabolites in urine and the recognition of their dietary origin is of significant value to laboratories performing organic acid analysis by GC/MS, especially when OSA excretion is associate with dicarboxylic aciduria.
4) The correct identification of OSA metabolites in urine represents a necessary step toward the qualitative and quantitative characterization of physiological and hypothetically as normal responses to intake is humans.

This laboratory has developed a four step total synthesis of β-lactams (1, 2, 3). Typically the synthesis produces a mixture of diastereomers even when a considerable degree of stereoselectivity has been achieved. The products are small hydrophilic zwitterionic compounds which are amino-β-lactam carboxylic acids (ABCs). Often the yields on given synthesis are low initially. Mass spectrometry has proven to be at the core of a strategy to confirm rapidly the identity of the ABCs. Exact mass data of suitable derivatives, e.g. methyl esters, confirm the elemental composition. FABMS of these ABCs from many matrices gives no MH^+ ion current above background. Ion pairing of the ABCs at low pH with a surfactant such as octyl sodium sulfate gives a strongly enhanced MH^+ signal (4). Thus, one can verify the molecular weight of the diastereomers separated by chromatography. The fragmentation patterns have proven important in identifying the desired product as well as side products. In short, mass spectrometry provides a reliable analytical tool for the verification, early in the synthetic effort, of β-lactam products from a method with the potential for the facile synthesis of a very large number of potential new antibiotics and β-lactamase inhibitors.

Chromatographic Set-Up. Jacketed columns with internal dimensions 15 cm x 0.8 cm, 30 cm x 2.5 cm and 30 cm x 4.6 cm were obtained from Fisher Scientific. The anion exchange resin used was AG 1-X2 200-400 mesh (Biorad Laboratories). Elution was carried out with a peristaltic pump on the output side of the column or a metering pump (FMI Lab Pump, Model QSY) with all plastic and ceramic pump components on the input side. The effluent was monitored either at 226 nm in a fixed wavelength detector (LKB BROMMA 2138) or at 240 nm in a variable wavelength detector (Varian Varichrom).

Chromatography. The columns were conditioned by washing with 1 N HCl and then washing with water until the effluent was neutral. Water from an ice-water mixture was circulated through the jacket. The gradient was generated from 10 column bed volumes of 0.1 N HCl and passed into an equal volume of H_2O in a mixing chamber connected to the column input. The crude β-lactam was dissolved in H_2O (50 mg/ml) and clarified by filtration or centrifugation. This was applied to the column with a Pasteur pipet and rinsed into the resin with equal volumes of H_2O. The space above the resin (~10% bed volume) was filled with H_2O. Pumping was initiated at 3 ml/min/cm^2. The effluent was monitored at 226 nm or 240 nm. The peak fractions were collected and immediately neutralized with an excess of the volatile, solid, NH_4HCO_3 immediately giving a pH ≈6 or brought to pH 6-7 with triethylamine (TEA). The neutralized fractions were dried in a rotary evaporator where the bath temperature was <50°. The product of this drying was a white powder which was a mixture of NH_4Cl and β-lactam or TEA·HCl and β-lactam.

Desalting. A NH_4HCO_3 neutralized fraction was passed through a Retardion (50-100 mesh) column (25 x 1.5) at 2 ml/cm2. The effluent was monitored at 226 nm. The TEA·HCl was removed by $CHCl_3$ extraction.

Exact mass. The synthetic products were converted to methyl esters by treatment with diazomethane. Analysis of the methyl ester hydrochlorides by direct inlet on a Kratos MS 80 gave the data for calculation of elemental composition.

Fast Atom Bombardment Mass Spectrometry. Aliquots of the fractions were placed in an ion-pairing matrix (4) and analyzed on a VG 250 quadrupole mass spectrometer.

Antibiotic assay. Aliquots of the fractions were placed on 6 mm filter paper disks. The disks were placed on a bed of Mueller-Hinton agar inoculated with the β-lactam tester strain *Bacillus subtilis* ATCC 6633. Each 10 cm Petrie dish contained 10 ml of medium.

The molecular weights are definitive. Exact mass data of methyl esters of β-lactams confirm the elemental composition (Table 1). Routine monitoring of the effluent profiles is more readily achieved by ion-pairing FABMS (4). The low molecular weight zwitterionic relatively hydrophilic components yield the quasi-molecular ions only with difficulty The ion-pairing technique dramatically increases

the MH^+ component of ion current (4). These data are critical as they support the assignment of diastereomeric structures with identical molecular weights as anticipated from the synthesis.

Table 1. Exact Mass Measurements of Synthetic β-Lactams

β-Lactam	Derivative★	Theor.	Found
DL-6-APA	Methyl ester	230.0725	230.0730
DL-7-Aminocepham	Methyl ester	217.0647	217.0643*
	Methyl ester	229.1188	229.1162†
	Methyl ester	272.1736	272.1770
	N-Acetyl	264.1110	264.1115

★Methyl esters made from β-lactam and CH_2N_2. *M+1. †M - 1

The chromatographic separation of synthetic L-APA diastereomers was effected. Aliquots from the fractions were examined by IR and showed characteristic β-lactam carbonyl stretch at 5.65μ; aliquots of each was shown to have antibiotic activity by producing zones of inhibition. The molecular weights were confirmed by ion-paired FABMS analysis according to the procedure of Bennett and Day (4); APA diastereomers give MH^+, m/z=217. The FABMS analysis was carried out at unit resolution; the fractional values are significant to the nearest integer value. It is clear that APA has been fractionated into several components with differing antibiotic activity. Peaks that are not biologically active show no characteristic β-lactam carbonyl stretch band in the IR nor MH^+ m/z=217 by FABMS.

In summary, we have demonstrated that identification of diastereomers of various zwitterionic β-lactams separated by anion-exchange chromatography was confirmed by exact mass measurements and by ion-pairing FABMS.

Identification of Decomposition Products of 1,1'-Ethylidenebis[L-Tryptophan], a Compound Asssociated with Eosinophilia-Myalgia Syndrome

William J. Driskell[1], David L. Ashley[1], James Grainger[1], Sarath R. Sirimanne[1], Eugene P. Mazzola[2], Sam W. Page[2], Larry L. Needham[1], and Robert H. Hill, Jr[1]

[1]Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Department of Health and Human Services, Atlanta, Georgia 30333, USA, and [2]Center for Food Safety and Applied Nutrition, Food and Drug Administration, Washington, DC 20204, USA

At the end of 1989 a new disease called eosinophilia-myalgia syndrome (EMS) appeared in America and West Germany. Epidemiologic investigators traced the cause to an unknown contaminant in L-tryptophan (LT) dietary supplement tablets (1). Of the more than 50 contaminants found in the LT material by high-performance liquid chromatography (HPLC) analysis, a contaminant identified as 1,1'-ethylidenebis[L-tryptophan] (EBT), also known as "peak 97" and "peak E", was the only one that had a marked association with EMS cases (2). This suggested that EBT might be the EMS causal agent or, possibly, a marker for a change in the manufacturing process that produced the causal agent. Our objective in this study was to follow the course of the breakdown of EBT into other products in simulated gastric conditions and to identify those products with thermospray LC-MS, LC-MS/MS, NMR, and FTIR.

When EBT is exposed to simulated gastric fluid (SGF), it gradually breaks down. HPLC analysis with UV detection shows the appearance of LT and 3 additional peaks that we called peaks 1 and 2 and 2'. Peak 1 was at its highest concentration between 15 min and 30 min after exposure to SGF, reaching about 5% of the total 280 nm absorbing material. After about 30 min peaks 2 and 2' start to appear. EBT is almost completely converted to LT and peak 1 and peaks 2 and 2' after 2 hrs.

We purified peaks 1 and 2 and 2' using a Waters C18 microBondapak semipreparative column and a 50:50 acetonitrile:water mobile phase. The purified peak 1 was labile when analyzed using normal thermospray conditions, fragmenting in the source to LT and to what appeared to be peaks 2 and 2'. Changing thermospray conditions by using buffer ionization instead of discharge ionization and by lowering the vaporizer temperature to 70 C and the block temperature to 150 C preserved the molecular ion. In the mass spectrum shown in Figure 1, we identified the two highest masses (the 271 and 287 amu peaks) as sodium and potassium adducts of the molecular mass and identified the 249 amu peak as the MH+ ion. This information and the NMR and FTIR analyses indicate that peak 1 is 1-(hydroxyethylidene)-L-tryptophan (HET). Using the same techniques, we identified peaks 2 and 2' as the structural isomers of 1-methyl-1,2,3,4-tetrahydro-beta-carboline-3-carboxylic acid (MCCA) (Figure 2).

We showed that under simulated stomach conditions, EBT is almost completely broken down into LT, HET, and MCCA within 2 hrs. Similar results were recently published by Ito et al. (3). If EBT is the causative agent for EMS, these studies suggest that EBT, HET, MCCA, or a combination of the three could be the primary circulating toxicant(s).

DETERMINATION OF ECHINOMYCIN, A POTENT ANTICANCER DRUG BY CAPILLARY-HPLC/ELECTROSPRAY IONIZATION/MASS SPECTROMETRY

R.A. Newman, K.T. MacManus and D.A.Garteiz : M.D. Anderson Cancer Center and TEXms Analytical Services, Houston, Texas, 77060

INTRODUCTION

The development of extremely potent anticancer compounds in conjuction with their administration by prolonged infusion schedules has made analytical determination of these drugs by conventional HPLC extremely difficult. Furthermore, many of these compounds have high molecular weights, in excess of 1000 daltons, poor volatility and are thermally labile. These characteristics rule out the use of GC/MS. We have therefore explored the use of capillary HPLC with electrospray ionization/mass spectrometry (capHPLC/ESPI/MS) as a means of achieving low picogram sensitivity in the analyses of anticancer drugs such as echinomycin, FK-506, Rapamycin and Bryostatin.

EXPERIMENTAL

Plasma extraction: A 1ml of plasma containing drug and the internal standard is added to an activated C2 Bondelute cartridge. the minicolumn is washed with water and the drug eluted with acetonitrile. After drying the acetonitrile, the sample is reconstituted in 25 ul of methanol. A 1 ul aliquot is subjected to capHPLC/ESPI/MS.

HPLC Conditions : An LC Packings Fusica 320um X 150mm C_{18} column was used. A linear gradient from 95:5 (05% aqueous formic acid: acetonitrile) to 100% acetonitrile was used to achieve the separation. the capillary flow was 3.5 ul/minute

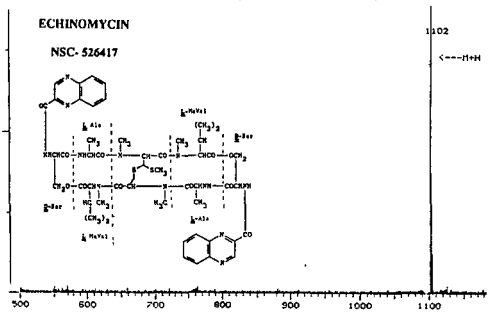

Figure 1. ESPI/MS Spectrum of Echinomycin.

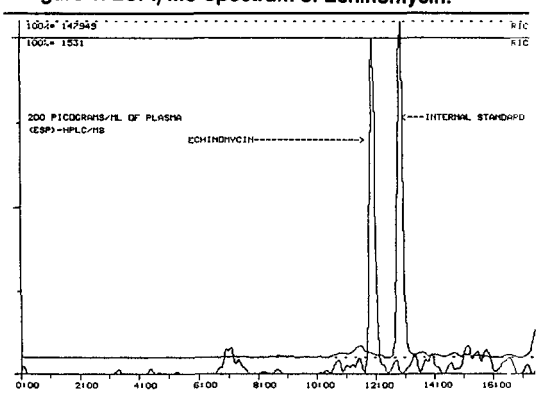

Figure 2 Representative Mass Chromatogram (200pg/ml)

RESULTS

The ESPI spectrum of echinomycin displays its molecular ion cluster at (MH^+) at (m/z 1102). Since essentially 100% of the current resides with the MH^+ cluster, sensitivity is excellent.

Figure 2 illustrates a reconstructed mass chromatogram of a 200pg/ml calibration standard. The signal to noise ratio(S/N) for both compounds is better than 25:1.

In order to determine the accuracy and precision that can be expected with ESPI/MS, a method validation study was carried out using both conventional HPLC and capHPLC/ESP/MS.

Standard curves were prepared and analyzed on each of three separate days. the concentration range for the conventional HPLC approach was from 10 ng Echinomycin per ml of plasma to 250 ng/ml. The lowest point that could be measured by this technique was 10 ng. For the capHPLC/ESPI/MS technique, the concentration range was from 100 pg of echinomycin/ml of plasma, up to, 75 ng/ml. Higher levels could also be quantitated with capHPLC/ESPI/MS by using lower plasma volumes.

The within day accuracy and precision data generated by both techniques is shown in Table 1. For capHPLC/ESPI/MS, at a concentration of 250 pg/ml, % RSD was 10.2, with a % deviation from nominal of 3.2. By comparison, conventional HPLC at a concentration 100 times higher (25 ng/ml), the % RSD was 7.1 with a % deviation from nominal of 2.4.

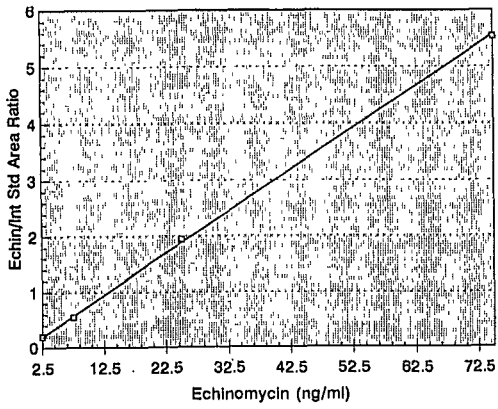

Figure 3 Plot of Area Ratios vs Echinomycin Concentration

Excellent linearity was achieved throughout the entire concentration range. Figure 3 is a plot of the area ratio of the MH^+ intensities (Echinomycin/Internal Standard) versus Echinomycin concentration at the low end of the curve.

CONCLUSIONS

For detection of potent pharmaceutical compounds, or those administered at low doses over prolonged infusions, capHPLC/ESPI/MS provides excellent low level quantitation capabilities. The accuracy and precision data obtained with capHPLC/ESPI/MS is at least as good as that obtained with conventional HPLC, at levels 10 to 100 times lower than can be achieved by conventional HPLC. This technique is being used routinely in our laboratories to carry out bioavailability, bioequivalence and pharmacokinetic studies with a variety of anticancer drugs such as echinomycin.

Quantitative determination of the antibiotic azithromycin in human serum by HPLC/MS.

Hassan G. Fouda and Richard. P. Schneider

Drug Metabolism Department

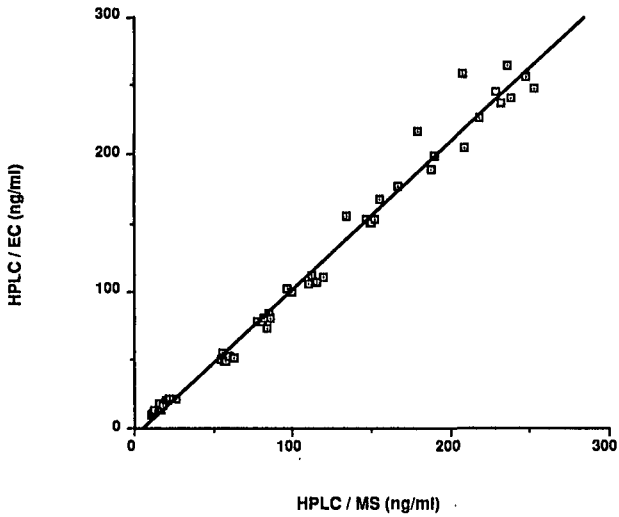
Central Research Division, Pfizer Inc., Groton, CT, 06340

The novel therapeutic agent azithromycin is the first of a new macrolide family referred to as the azalides. Its unique spectrum of antibiotic activity and improved pharmacokinetics are ideal for the treatment of lower respiratory tract infections, skin infections and sexually transmitted diseases. To permit the investigation of azithromycin pharmacokinetics in pediatrics, a specific assay for its quantitative determination in a low volume of human serum was desired. The assay utilizes on-line HPLC and atmospheric pressure chemical ionization (HPLC/APCI).

Deuterium labelled azithromycin was synthesized and utilized as the internal standard of the assay. The drug and the internal standard are extracted from serum and aliquots are injected onto a standard reverse phase HPLC column. The effluent from the HPLC column at 1ml/min is introduced into the atmospheric pressure source of a SCIEX API III mass spectrometer. Azithromycin concentrations in serum are determined by the selected monitoring of the protonated molecule ions for the drug and the internal standard.

The present HPLC/MS assay requires only 50 µl of serum. Its concentration range extends from 10 ng/ml to 250 ng/ml, and its precision and accuracy over that range are 13% or better. The intercorrelation between the assay and a standard HPLC-electrochemical method, requiring a larger volume of serum, has been determined.

The two methods showed an excellent agreement and gave a correlation coefficient of 0.985. The mean ratio of the quantitative results between the two assays ($C_{HPLC\text{-}MS} / C_{HPLC\text{-}electrochemical}$) was 1.02 ± 0.096 (SD). The *y* intercept (5.498) and slope (1.0743) of the regression line was also in agreement with the theoretical relation ($C_{HPLC\text{-}MS} = C_{HPLC\text{-}electrochemical}$). The present HPLC-MS assay can safely be used to investigate azithromycin pharmacokinetics in pediatrics.



Intercorrelation between HPLC / MS and HPLC / electrochemical analytical methods using 50 serum samples from human subjects that received doses of azithromycin.

Thermospray LC/MS Analysis of Penicillin G Residues in Biological Fluids and Tissues of Food-Producing Animals

JOE O. BOISON*, JOHN PATTERSON, JAMES D. MacNEIL, RON GEDIR, and LILY KENG
Food Animal Chemical Residues Section, Health of Animals Laboratory, Food Production and Inspection Branch, Agriculture Canada, 116 Veterinary Road, Saskatoon, Saskatchewan, Canada S7N 2R3

INTRODUCTION

In 1991, we developed a simple, accurate, and reproducible analytical method (limit of quantitaion of 5ppb)for the determination of penicillin G residues in animal tissues (1) by HPLC with UV detection. This method has recently been adapted for the determination of penicillin residues in eggs, biological fluids including plasma (2), tissue fluid, urine, milk, and milk products - yogurt and cottage cheese. In Canada, detection of penicillin at concentrations in excess of the prescribed tolerances of 50 ppb in beef, 10 ppb in turkeys, and zero in swine results in the detention and condemnation of the implicated carcass. Milk found to contain more than 4 ppb of penicillin is declared unfit for human consumption and is not allowed for distribution into the food chain. This paper describes a thermospray LC/MS method, an adaptation of the HPLC/UV method, developed to simultaneously determine and confirm the identity of penicillin-G residues in animal tissues and biological fluids in support of the Canadian regulatory program for veterinary drug residues in food-animal production.

EXPERIMENTAL

1. Weigh 5 g of homogenized tissue or pipet 5 mL of biological fluid into a 50 ml polypropylene centrifuge tube. 2. Add 75 μL of 20 ppm penicillin-V standard solution (internal standard)and add 30 mL of water, 5 mL 0.17 MH_2SO_4, and 5 mL of 5% sodium tungstate soln. Vortex mix for 20 s. 3. Centrifuge and filter. 4. Clean up and concentrate on a pre-conditioned C18 solid phase extraction cartidge. 5. Elute penicilins G and V with 750 L of elution solution (60% ACN, 5% 0.2M NH_4OAc, 35% H_2O). 5. Analyze by Thermospray/LC/MS. A Waters 600-MS Multisolvent Delivery system coupled to a a VG TRIO II mass spectrometer through a thermospray/plasmaspray LC interface. Separation of the penicillins was conducted on a Waters Nova-Pak C18 column (4 m, 3.9 mmX150mm) at a mobile phase flow rate of 0.9 mL/min under the follwoing gradient elution conditions: 0-10 min (100% B) 10-20 min (70%B), and 20-30 min (100% B) where solvent A = 100% ACN and solvent B = 100% ACN:90% NH_4OAc (0.15M). The capillary probe tip and source temperature of the mass spectrometer were operated at 255 degrees centigrade and 180 degrees centigrade respectively.

RESULTS AND DISCUSSION

The response ratio of the ion intensities of the common fragment ion at m/z = 160 for penicillin G and V plotted against penicillin G concentrations is linear from 5 to 400 ppb. The response ratios calculated for penicillin G at different concentrations (n = 5) are reproducible with coefficients of variation of < 10%. Procedure recoveries for penicillin G added to all the matrices were > 86% over the range of concentrations studied. The chromatograms show that penicillin G can be easily confirmed in animal tissues, plasma and milk down to concentrations of 5 ppb with this technique.

CONCLUSION

The simple and rapid procedure described in this paper provides a highly sensitive and accurate method for the isolation, determination and confirmation of penicillin G residues in tissues and biological fluids of food-producing animals by thermospray LC/MS. This method is being used at the Health of Animals Laboratory, Saskatoon, as an analytical support service in the Canadian regulatory program for penicillin drug residues in animal tissues.

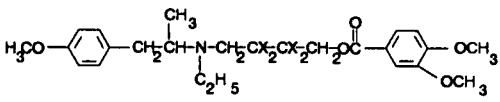
EVALUATION OF SUPERCRITICAL FLUID CHROMATOGRAPHY/MASS SPECTROMETRY (SFC/MS) FOR THE ULTRATRACE ANALYSIS OF MEBEVERINE IN PLASMA

J. David Pinkston*, Kenneth R. Wehmeyer, C. J. Venkatramani, Donald J. Bowling, David P. Innis, Thomas L. Chester, and Hanjiu Liu, The Procter & Gamble Company, Miami Valley Laboratories, P.O. Box 398707, Cincinnati, OH 45239-8707

Mebeverine is a smooth muscle relaxant currently marketed in Europe for the treatment of irritable bowel syndrome. Due to its high first-pass metabolism, ultratrace methods of analysis are required for monitoring mebeverine levels in plasma. The structure below shows that mebeverine, MW 429, incorporates a tertiary amine, an ester, and three ethers. Determination by gas chromatography/mass spectrometry (GC/MS) has been difficult due to thermal degradation and/or adsorption of mebeverine in the chromatographic system.

X = H (MEBEVERINE)



X = D (d4- MEBEVERINE)

Supercritical fluid chromatography (SFC) provides a solvating mobile phase and analysis at lower temperatures than required in GC. But capillary SFC has not traditionally been used for ultratrace analysis. This is primarily due to the small injection volumes required in conventional capillary SFC. However, ultratrace analysis is possible when a detector, such as a mass spectrometer, is used which has sufficient sensitivity and selectivity. Here we describe the ultratrace determination of mebeverine in plasma by SFC/MS.

The instrumentation used for this evaluation consisted of a custom-built capillary SFC unit, Finnigan's direct-fluid-introduction interface, and a Finnigan TSQ-700 triple quadrupole mass spectrometer. Ammonia chemical ionization (CI) was used with 1% NH_3 in CH_4 as reagent gas. Mebeverine and the stable-isotope-labeled internal standard, D_4-mebeverine (MW 433), were spiked into plasma, recovered by solid-phase extraction, and reconstituted in 20 uL of toluene. This solution (0.1 uL) was injected directly on column.

Both mebeverine and D_4-mebeverine give NH_3 CI spectra dominated by their respective protonated molecules at 430 Da/unit charge (m/z 430) and m/z 434 (see Figures 1 and 2). These ions were monitored in selected-ion-monitoring (SIM) mode. A very fast SFC pressure ramp (100

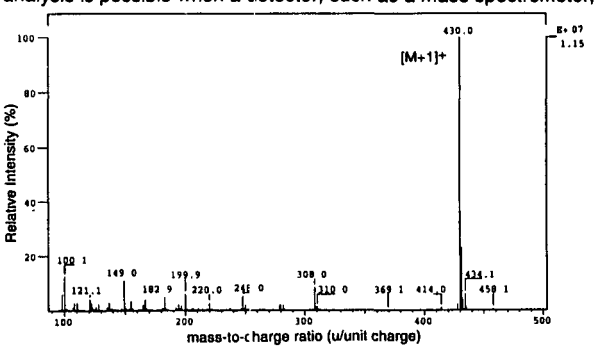


Figure 1: NH_3 CI SFC/MS Spectrum of Mebeverine

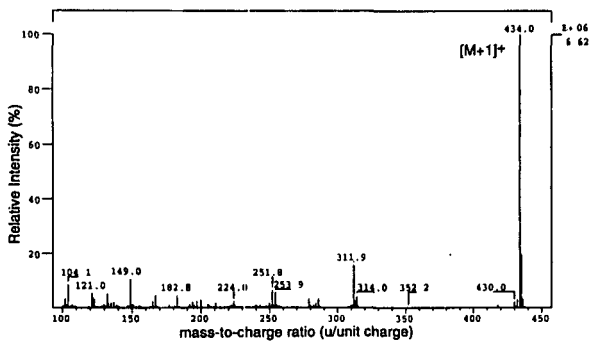

Figure 2: NH_3 CI SFC/MS Spectrum of D_4-Mebeverine

atm/min) provided the sharpest chromatographic peaks and the best signal-to-noise ratios. Despite the poor chromatographic separation resulting from the rapid pressure ramp, the selectivity of the mass spectrometer was sufficient to prevent any obvious interference at the two mass-to-charge ratios of interest in the elution region of mebeverine. Figure 3 shows mass chromatograms at m/z 430 and m/z 434 for a plasma blank. Responses are observed in both chromatograms, but the responses are offset in elution time, demonstrating that the responses are not due to mebeverine and D_4-mebeverine. Figure 4 shows mass chromatograms at the two mass-to-charge values of interest for a plasma spiked at the 6 ng/mL level. This represents 24 pg of mebeverine on column.

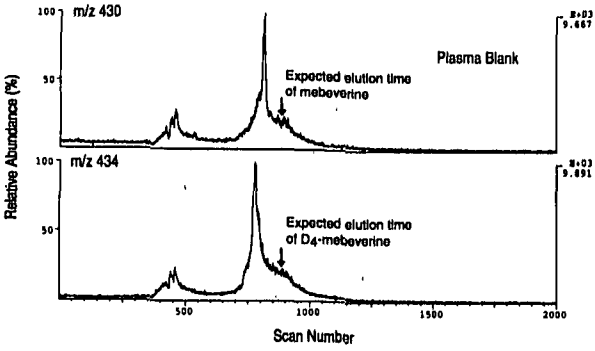

Figure 3: Mass Chromatograms for Mebeverine and D_4-Mebeverine for a Plasma Blank

The response ratio (mebeverine response/internal standard response) for a series of mebeverine standards was linear over a range of 0.6 ng/mL to 119 ng/mL (corresponding to 2.4 pg to 476 pg on column, respectively). The correlation coefficient was 0.9998. Reproducibility (percent relative standard deviation (RSD)) for standards at 3.0 ng/mL, 29.8 ng/mL, and 298.0 ng/mL was determined to be 3.0%, 4.2%, and 2.6%, respectively (n=3). The 3 ng/mL standard was the lowest for which reproducibility data was collected, and thus must be considered the current limit of quantitation for the method. Spiked plasmas were run on three consecutive days. The percent recovery for the 6 ng spike (24 pg on column) averaged 101% with a pooled RSD of 5.0%. The percent recovery for the 60 ng spike (240 pg on column) was 91% with a pooled RSD of 8.1%. These results are satisfactory for samples spiked at these low levels. We did find that the results depend greatly on the activity and previous history of the chromatographic column. Despite this reservation, these results show that SFC/MS is a useful tool for the ultratrace-level determination of thermally-labile and/or active pharmaceutical agents.

In the course of an Indo-American collaborative project on "Bioactive Substances from the Indian Ocean", samples of *Ulva fasciata* were collected and extracted by scientists at the National Institute of Oceanography, Goa, India. *Ulva fasciata* is a green alga that grows off the west coast of India in the Malvan region and has found uses as food, fertilizer and medicine. Fractionation of the alcohol extract obtained from this green algae, showed good antiviral activity; this fraction was designated UF-131. This substance showed antiviral activity *in vitro* and *in vivo*.

UF-131 appears to be the first 2-amido-1,3,4,5-tetrahydroxy-octadecane (structure below) found in a marine alga. This paper will discuss the earlier structural determination of the main component of UF-131. This work was accomplished by chemical methods, IR, NMR and MS: this paper will emphasize the mass spectral contribution to this work. Finally, we will discuss the MS analysis of a second batch of UF-131 that was found to contain two major components.

This research has two important goals:

- First, the characterization of this novel antiviral compound, UF-131.
- Second, to develop a general MS approach for the structural characterization of this series of sphingosine related compounds that are being continuously isolated from the Indian Ocean.

It was shown that LSIMS is essential to any strategy to characterize this class of compounds: LSIMS provided the molecular weight, the molecular formula and the length of the of the fatty chain that makes up the spine of this molecule. EIMS provides a second method for defining the amide fatty chain and provides much confirmational structural data.

Mass Spectrometric Insights into the Biosynthetic Origin of Sulfur in Esperamicins A_1 and A_{1c}

Steven E. Klohr, Kevin J. Volk, Mike S. Lee, Kin S. Lam, Judy A. Veitch, Edward H. Kerns, Salvatore Forenza, and Ira E. Rosenberg
Bristol-Myers Squibb Company, Pharmaceutical Research Institute
5 Research Parkway, Wallingford, CT 06492

Esperamicins A_1 and A_{1c} are potent antitumor antibiotics that belong to the enediyne class of antitumor agents. Produced by cultures of *Actinomadura verrucosospora* (ATCC 39334), they possess a unique mechanism of action involving bioreductive activation and DNA cleavage.[1] The esperamicins illustrate the novel chemotypes and unique mechanisms of action that are frequently observed with natural products. The structural and biological diversity associated with natural products stimulates a world-wide effort to discover novel leads that may result in therapeutic advances.

A structure elucidation strategy involving the coordinated use of tandem mass spectrometry (MS/MS) and high resolution mass spectrometry (HRMS) has previously been developed to provide rapid and accurate insights into the various substructures of unknown natural products.[2] This strategy has been extended to study the biosynthetic origin of sulfur in esperamicin. Similar to the structure elucidation of isolated natural products, sample constraints such as limited quantities and complex mixtures are typically encountered with biosynthetic studies. Furthermore, the difficulty of demonstrating incorporation of labeled species and the expense of labeled precursors add to the challenge. This mass spectrometric method rapidly provides detailed information on the incorporation of sulfur, including the number and location of the ^{34}S atoms in the molecule, and does not require the extensive degredative studies associated with radiolabeled precursors.

The analytical approach utilizes a systematic strategy with MS/MS and HRMS techniques to develop the substructure analysis of the standard, Esperamicin A_1. Full scan, MS/MS, and HRMS techniques were then used to identify substructures of the ^{34}S labeled esperamicins. The labeled compounds were produced by growing the culture in a defined medium using ^{34}S-sodium sulfate as the sole sulfur source. Comparison of the substructures of the native and labeled compounds indicated the number of ^{34}S atoms incorporated and their location.

The full san FAB mass spectrum of ^{34}S-Esperamicin A_{1c} indicates a molecular weight of 1304 (Figure 1). This molecular weight is eight Daltons greater than native Esperamicin A_{1c}, suggesting the incorporation of four atoms of ^{34}S. This was confirmed by high resolution FAB MS analysis with a measured mass of 1304.3630, corresponding to $C_{57}H_{76}N_4O_{22}{}^{34}S_4$ with a deviation of 2.6 ppm. The location of the labeled atoms is determined by comparison of the substructures of the native and labeled compounds (Figure 2). The increase of six Daltons for the neutral loss of the allylic trisulfide in the labeled compound confirms that all three sulfurs of the trisulfide are ^{34}S atoms. The difference of two daltons observed with the trisaccharide substructures confirm the presence of ^{34}S in the thiosugar. Similar results were obtained with ^{34}S-Esperamicin A_1.

LC-MS MAPPING AND IDENTIFICATION OF A LIPOIC ACID COFACTOR IN H-PROTEIN FROM THE PEA LEAF GLYCINE DECARBOXYLASE SYSTEM

V. Mérand[1], *E. Forest[1], P. Thibault[2], M. Neuburger[3], R. Douce[3], J. Gagnon[1], C. Monnet [1]

1 : Institut de Biologie Structurale, Grenoble, France; 2 : NRC, IMB, Halifax, Canada;
3 : CEA, DBMS, Grenoble, France

In the mitochondria of plant leaves, the amino acid glycine is rapidly oxidised into serine, CO_2 and ammonia by the enzyme glycine decarboxylase. The oxidation of glycine is a major metabolic pathway of green leaves and plays a major role in photorespiration. The glycine-cleavage system comprises four protein components referred to as P, H, T and L sub-units. The structure of one of these components, the H subunit, was deduced from cDNA cloning experiments and from conventional Edman sequencing of the N-terminus and CNBr peptides [1]. Although most of the sequence was determined from this preliminary study, results obtained thus far could not identify the position of a lipoic acid cofactor, a rather unusual modified lysine residue which interacts with different active sites in the complex. The tentative assignment of the lipoic acid position could be obtained only through comparison with several other lipoate-bearing proteins of mammalian or bacterial origins [1].

The objective of the present study was first to confirm the molecular weight of the protein, using nebuliser-assisted electrospray (ionspray) mass spectrometry and second to localise its cofactor by combined Liquid Chromatography-Tandem Mass Spectrometry (LC-MS-MS) analyses of proteolytic digests of the H-protein. The full scan LC-MS analysis of the purified H-protein from pea leaf mitochondria is presented in Figure 1a along with the extracted mass spectra of the major components eluting at 13.8 and 14.7 min (Figures 1b and 1c). The mass spectrum of Figure 1b shows two major coherent series of multiply-charged ions from which the molecular weight of each protein can be deduced. The measured molecular weight of the main component (M : 14137 Da) is in good agreement with the mass expected from the protein sequence [1]. An additional component (M : 14290 Da) is also observed in Figure 1b and could correspond to the covalent binding of two β-mercaptoethanol molecules (β-MCE) to the H-protein. The β-MCE is used to keep the protein in a reducing medium. A dimeric form of H-protein with two and three β-MCE is also observed (M : 28426 and 28502) as indicated in Figure 1c.

Peptides arising from *S. aureus* digestion of H-protein were analysed by direct analysis using LC-CF-FAB-MS (with a home-made microcolumn) and ionspray LC-MS. A survey LC-MS analysis, obtained in each case on 300 pmoles of digest, permitted identification of most of the predicted peptides including those corresponding to the covalent binding of two β-MCE units. The fixation of β-MCE appears to take place at the lipoic acid, following the reduction of its disulfide bond, thus resulting in the formation of peptides having two β-MCE units. Additional analyses of a mixture of lipoic acid and β-MCE, using FAB-MS, confirmed that the formation of β-MCE adducts to lipoic acid takes place in solution. The LC-MS analyses permitted identification of a dimer of peptide 120-126 linked by a disulfide bound, thus creating the H-dimer. Following the LC-MS of the*S. aureus* digest, subsequent analyses were conducted to locate the position of the lipoic acid by combined ionspray LC-MS-MS. A total of approximately 600 pmoles was used to obtain a series of MS-MS spectra corresponding to most of the peptides previously identified. Examples of MS-MS spectra obtained from these analyses are presented in Figures 2a and 2b for the peptides fragments 61-75 and 61-78 respectively.

Thanks to the use of a microcolumn avoiding splitting, LC-CF-FAB-MS analysis of the proteolytic peptides involved the consumption of approximately the same quantity of sample than that used in ionspray LC-MS analysis. But, due to the lack of sensitivity, no structural information could be obtained from the LC-CF-FAB-MS-MS spectra of the singly-protonated ions of peptides containing the lipoic acid. With respect to sensitivity considerations and type of information obtained, analyses conducted with ionspray ionisation surpass the corresponding analyses obtained by CF-FAB.

Analysis of Genetically Engineered Antibodies by Electrospray Ionization Mass Spectrometry

James H. Bourell, Paul Carter, Robert F. Kelley, and John T. Stults
Genentech, Inc., 460 Pt. San Bruno Blvd., South San Francisco, CA, 94080

Recombinant antibodies and antibody fragments that are genetically engineered for therapeutic and diagnostic use require accurate structural characterization. Mass spectrometry, with the advent of electrospray and matrix assisted laser desorption ionization, is contributing significantly to the analysis of these proteins (1,2). The murine monoclonal antibody, muMAb4D5, has been shown to inhibit growth of certain human breast tumor cell lines (3). Engineered antibodies and their Fab and $F(ab')_2$ fragments were constructed in an effort to reduce the human anti-mouse response. These "humanized" antibodies contain the hypervariable loops involved in antigen binding from clinically active muMAb4D5 attached to the framework regions of human antibodies. Additionally, these constructs were made by replacing a small number of frame work amino acid residues with those predicted from modeling studies to improve antigen binding efficiency (4). A high level of mass accuracy is required to confirm the correct encoding DNA sequence and proper biomolecular processing of these proteins. Electrospray ionization mass spectrometry has been employed to provide masses with an accuracy of ± 0.02% for various antibody fragments, as shown in Table 1. The 25+ through 21+ ions for one of the Fab fragments is shown in Figure 1. The narrowness of the ion peak shape allows for accuracy to be maintained with equimolar mixtures of Fab proteins differing by as little as 100 Da (1). To obtain reliable mass assignments, proteins should be purified to remove ion-pairing and adducting impurities. The spectrum represented in Figure 1 was acquired from an LC/MS experiment, however, dialysis against ammonium bicarbonate also gave acceptable spectra. Antibodies and their fragments can be reduced to their heavy and light chains which affords masses within the range of greater accuracy. Figure 2 shows the spectrum of the reduced $F(ab')_2$, HuV6. The dialysed protein was infused directly after vacuum centrifugation of the reducing agent, tributylphosphine(TBP). TBP reduction offers several advantages, including a high reactivity and increased volatility that aids preparation for analysis. The most important parameters for generating the mass accuracies reported here are the accurate calibration using a mixture of stable proteins as mass standards, the high level of purity for the analyte protein, and the adjustment of quadrupole DC offset potentials to compensate for the excessive kinetic energy of large ions.

CHARACTERIZATION OF ACRYLAMIDE ADDUCTED HEMOGLOBIN AND PROTEOLYTICALLY-DERIVED PEPTIDES BASED ON ELECTROSPRAY IONIZATION MASS SPECTROMETRY.

*C.G. Edmonds, D.L. Springer, D.M. Sylvester, S.C. Goheen and R.J. Bull, Battelle, Pacific Northwest Laboratories, Richland WA 99352 and Washington State University, Pullman WA 99164.

Hemoglobin adducts have been used to monitor occupational exposure to a number of compounds. Since exposure to acrylamide produces a neuropathy that involves both sensory and motor neurons, we have been obtaining information to support development of a sensitive immunological detection method for this compound. Until recently the most common procedure to identify and characterize hemoglobin adducts has been to cleave the adduct from the protein and derivatize and characterize it by gas chromatography/mass spectrometry. To extend these approaches we examined acrylamide adducted hemoglobin using electrospray ionization mass spectrometry (ESI-MS) in an attempt to identify the adducting moiety as well as obtain information on the amino acids involved and their location within the protein. Initially we incubated ^{14}C acrylamide and purified human hemoglobin (type A_0) under conditions that yielded high adduct levels and separated the α- and β-subunits using reversed-phase HPLC. Under these conditions radioactivity copurified with both subunits. ESI-MS analysis of the intact subunits indicated distinct differences in the ion profile for the adducted and nonadducted species. ESI-MS of the intact β-subunit demonstrated three distinct mass increments of approximately 71, 102 and 136 daltons as shown in Figure 1. Proteolytic digestion with V8 proteinase and direct ESI-MS analysis of the unfractionated mixture of peptides located the first two of these species on cysteine bearing peptides, principally V91-101. Characterization of control and adducted peptide mixtures by HPLC indicated the loss of two UV absorbing components from the former and the appearance of two additional radioactive and UV absorbing entities in the latter peptide mixture separation. ESI-MS of HPLC purified fractions of the V8 proteinase digestion localizes the first of these on the peptide bearing cysteine 93 (V91-101). The measured mass increment for this species (M_r^{Meas} 71.5 ± 1.0 from 8 separate analyses) is consistent with the expected thioether derivative of this residue (M_r^{calc} 71.08). Structure of the second observed adduct (M_r^{Meas} 102.0 ± 1.2, n=8) is unknown but it is likewise localized on cysteine bearing peptides, including V102-121 which bears cysteine 112. Similarly, the structure of the third adducted species (M_r^{Meas} 135.6 ± 0.6, n=4) is unknown and as it does not appear among the adducted peptides we hypothesize that it is not localized on a particular amino acid residue, e.g. the cysteine bearing peptides.

Studies to confirm the cysteine residue as the location of the adducting moiety by tandem mass spectrometry and to further refine the picture of acrylamide adduction in this system are in progress. Structural information obtained by these methods has been used to prepare an adducted synthetic peptide that when administered to rabbits resulted in the production of antibodies which were selective for the acrylamide adduct. These antibodies will be characterized and used to provide dosimetry for more reliable risk assessment estimates.

3 : NRC, IMB, Halifax, Canada

Hemocyanins are high molecular weight copper proteins, present in the hemolymph of molluscs and arthropods. These oxygen carriers play a role comparable to that of hemoglobins for vertebrates. Arthropod hemocyanins are made up of globular polypeptide chains associated in basic hexameric structures. Hemocyanin of the scorpion *Androctonus australis* is composed of 24 subunits, belonging to 8 different polypeptide chains of about 75 kDa each, assembled in hexameric substructures. The Aa6 subunit, present in each hexamer, confers a strong antigenicity to the protein and occupies an external position with one copy at each corner of the protein. This Aa6 subunit is the base of a study concerning topological mapping of epitopes combining results from electron microscopy of immuno complexes, with cristallography of the isolated subunit and determination of its primary structure.
The present work concerns the primary structure determination and the assignment of disulfide bridges of the Aa6 subunit using a variety of complementary analysis techniques.

The purified subunit was cleaved chemically (CNBr) and enzymatically (chymotrypsin). The resulting fragments were separated using preparative HPLC with C8 and C18 columns. The combined use of mass spectrometry (LSIMS and MS/MS) with Edman degradation enabled the sequence determination of about 150 peptides having molecular weights ranging from 300 Da to 5000 Da. These fragments were aligned on the basis of homologies with other known sequences of arthropod hemocyanin subunits. Using about 7 nmoles of purified sample, we were able to caracterize about 99 % (620 residues) of the Aa6 subunit.
The number of disulfide bridges was determined, using nebuliser-assisted electrospray (ionspray) mass spectrometry. We precisely measured the molecular weight of the native subunit (71888 Da) and of the alkylated form, before reduction (72009 Da) and after reduction (72359 Da)(Figure 1). These measurements permitted identification of 3 disulfide bridges and 2 free cysteines.
The position of these bridges was tentatively assigned by LC/ESI/MS analysis of the CNBr fragments of the three forms of the subunit. The peptides containing disulfide bridges were thus identified, leading to the two cross-linking possibilities described in Figure 2.

This study permitted determination of almost the entire sequence and location of its disulfide bridges, using a combination of mass spectrometry, Edman degradation and sequence homologies. A second goal of this project was to build up a strategy for optimization of this methodological approach utilizing limited amount of material. This opens interesting possibilities for other natural products, often available in small quantities.

INTRODUCTION

One emphasis of our research is the synthesis of new modified glucagon analogs. The method previously used for characterization of these glucagon analogs involved chymotrypsin digestion, HPLC separation of the peptides and amino acid analysis of isolated fractions[1]. Although this method is very useful, it is slow and lacks the sensitivity available with mass spectral methods. The need for a simple and rapid method for verifying the structure of the synthetic linear and cyclic glucagon analogs led us to apply FABMS, combined with Asp-N digestion, for their characterization.

The FABMS method described herein provides rapid and unequivocal confirmation of the sequence of a modified glucagon analog, as well as identifying the presence and site of ring formation. The specificity of Asp-N cleavage enables differentiation of glucagon analog isomers which differ only in the position of the cyclic bond.

METHODS

Materials. The cyclic glucagon analogs were synthesized by solid-phase methodology developed in our laboratory[2].

Enzymatic digestion. 0.2 mg of the glucagon analog was dissolved in 250 μg of 1 M NH_4HCO_3 buffer (pH 8.1), containing 2 μg of Asp-N (Boehringer Mannheim Biochemica, Indianapolis, IN). The mixture was kept at 37°C for 30 h and lyophilized.

Mass spectrometry. Ions were produced using 2 mA primary Cs^+ beam in a double focussing (BE) mass spectrometer (AMD Intectra, Harpstedt, Germany) equipped with two KWS MC 68K computer systems for instrument control and data acquisition. The accelerating voltage was 6 kV and the resolution was 2000 (10% valley). A mixture of glycerol and 10% CF_3COOH (1:1) was used as the matrix. The target t^o=12°C using chilled $MeOH/H_2O$ 1:1 v/v.

RESULTS

In order to obtain a full understanding of the mechanism of action of glucagon and its involvement in the diabetic state it is necessary to consider the chemical and conformational features of glucagon which are important for receptor binding and message transduction. Synthetic glucagon analogs can be used as specific biochemical probes to identify and enhance those molecular features essential for recognizing the hepatic membrane receptor and those necessary for transduction of the message to the corresponding physiological response. Using this strategy a large number of glucagon analogs have been synthezised and used in conjunction with biological response measurments[3].

The need for a rapid method of verifying the structure of these synthetic glucagon analogs (Table 1) led us to apply FABMS and Asp-N digestion to their characterization.

The molecular weights of all synthetic glucagon analogs were measured by FABMS and the results are in good agreement with the calculated MH^+ values.

For better structural identification of the synthetic peptides a FAB-mapping of their Asp-N digest was performed. Asp-N cleaves at the N-terminal side of the aspartic and cysteic acid residues. The FAB spectrum of Asp-N digest of glucagon **1** shows signals for all four expected fragments: fragment 1-8, fragment 9-14, fragment 15-20 and fragment 21-29 (Table 2). For the glucagon analogs, the measured MH^+ of the respective fragments reflect the modifications synthetically achieved in glucagon sequence (**2**, **3** and **9-12** Table 2). As Asp-N does not cleave at the N-terminal side of glutamic acid residue, the fragments in which Asp is replaced with Glu remain intact (**4**, **9** and **12**, Table 2). When an aspartic acid residue is involved in lactam bridge,

the Asp-N is not able to recognize it and the corresponding fragment remains intact (**5-9** and **12**, Table 2). Thus, the FAB mass spectra of Asp-N digests of glucagon isomers which differ only in the position of the bridge are very different and allow unambiguous confirmation of the presence and location of the cyclic amide bond (**5-7**). It is interesting to note that Asp-N does not cleave at the N-terminal side of the aspartic acid residue in the cyclic structure (**7**, Table 2). A possible explanation is that Asp-N is not able to recognize the target amino acid because the amide bridge prevents binding.

CONCLUSIONS

FAB-mapping following endoproteinase Asp-N digestion provides a rapid method for unambiguous confirmation of the primary structure of the linear and cyclic glucagon analogs and identification of the presence and location of the cyclic amide bond in cyclic glucagon analogs. Differentiation of isomers, which differ only in the position of the bridge, is possible.

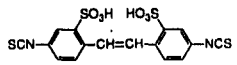
Investigation of the Covalent Binding of Stilbene Disulfonic Acids to Human Recombinant CD4 Using LC/MS

Bradley L. Ackermann, John E. Coutant, Brian T. Regg,
Philip L. Smith, Dale T. Blankenship, and Alan D. Cardin

Marion Merrell Dow Research Institute, Cincinnati, OH 45215

Recently a class of CD4 antagonists, the stilbene disulfonic acids, were shown to block replication of the human immunodeficiency virus type-1 (HIV-1) at multiple stages of the virus growth cycle (*J. Biol. Chem.*, **266**, 13355, 1991). The most potent antagonist, 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS), is believed to bind covalently to Lys^{90} of the V1 loop of CD4 to block interaction with the viral envelope glycoprotein gp120.



(DIDS)

Previous LC mapping of the Asp-N digest of recombinant soluble CD4 (rsCD4) after reaction with DIDS indicated a strong interaction with two Asp-N fragments within the V1 loop (A_5 and A_8). This interaction was monitored by detecting the DIDS chromophore (340 nm) at the retention times for A_5 and A_8 in the LC map. The identities of the Asp-N fragments were established by partial Edman sequence analysis.

The first part of this presentation described the use of packed capillary LC/MS, using both CF-FAB and ES, to provide further structural characterization of the baculovirus-expressed CD4 used in the previous mapping experiments. The sequence verified by LC/MS mapping appears in Figure 1. Also indicated are the observed cleavage sites produced by endoproteinase Asp-N. Figure 2 displays the reconstructed total ion current obtained from the analysis of a 200 pmol aliquot of the Asp-N digest of rsCD4 by LC/ES-MS. These data were acquired using a C18 packed capillary column (250 mm x 0.32 mm) interfaced by a fused silica transfer line to the ES probe of a Finnigan MAT TSQ-700 mass spectrometer. Although the sequence of CD4 is known, the exact structure depends on the system used for expression. In the present example, the exact length of the protein as well as the type of post-translational modifications present were not known prior to analysis. The data acquired from this single injection enabled several structural features to be determined. First, LC/MS mapping enabled the composition of both terminii to be defined and allowed over 98% of the sequence displayed in Figure 1 to be verified. Second, the molecular weights observed for Asp-N fragments A_{13}' and A_{13}'' indicated that the primary N-linked glycan attached at Asn^{271} and Asn^{300} was $(Man)_3(GlcNAc)_2$. Finally, the data also confirmed that the protein was correctly folded since the known connectivity of the three disulfide bonds in CD4 was established. To illustrate this point, Figure 3 contains the ES spectrum for the disulfide-linked fragment A_2 - A_7 (before and after deconvolution) which confirms the disulfide bond between Cys^{16} and Cys^{84}.

The remainder of the work presented were results from an ongoing effort aimed at determining the nature of the interaction between DIDS and CD4. To achieve acceptable sensitivity it was necessary to establish conditions for negative ion LC/ES-MS due to the highly anionic nature of both DIDS and the V1 region of CD4. Several mapping experiments of the Asp-N digest of DIDS-labeled rsCD4 were performed where heart-cut fractions indicating absorbance at 340 nm were collected from either reverse phase or cation exchange and run by LC/ES-MS. In all instances, signals for peptides A_5 and A_8 were detected at levels as low as 300 pmol, however, neither DIDS nor any DIDS-labeled peptides were detected. Low reaction yield is believed to be the primary factor responsible. Efforts are underway to enrich the DIDS-labeled peptides in the Asp-N digest of CD4 to ultimately permit their detection by LC/ES-MS.

INTRODUCTION

Mass spectrometry (MS) is now participating in almost all steps of the structural study of protein variants; Electrospray ionization MS as a tool for the screening of variants detects the molecular weight change that arises from the mutation. Fast atom bombardment (FAB) MS of peptide mixtures identifies the peptide containing the mutation in a complex mixture of peptides from enzymatic digestion. For this purpose, a combination with liquid chromatography (LC/MS) provides an effective and a very efficient peptide map. At the final step of structure elucidation, MS/MS characterizes or confirms the site and the type of mutation. Various types of hemoglobin (Hb) variants have been used in the development of these mass spectrometric strategies.

We present here the structural analysis of three hemoglobin variants: one of which escapes detection by electrophoretical approach and the others have a shift of one mass unit in a relatively large peptide.

We have also investigated the tandem mass spectrometry of a mixture of two ion species of peptides as precursor ion, one of which has normal sequence and is exclusively composed of ^{12}C atoms and the other has single amino acid change causing a one mass decrease and contains one ^{13}C atom.

APPARATUS

FAB/MS and MS/MS were carried out with SX102 mass spectrometer (JEOL) and HX110/HX110 tandem mass spectrometer (JEOL), respectively.

RESULTS

Hb Miyazono

A β chain variant more hydrophobic than normal was detected in a slightly erythremic patient by reverse-phase LC.

FAB/MS of the tryptic digest identified a mutation in peptide βT9. The mass shift of +14 units left seven possibilities. MS/MS of the peptide characterized the mutation as Asp→Glu at position 79. FAB/MS of a V8 protease digest gave the same result.

This was a new variant and the functional study is now in progress.

Hb Hoshida

The presence of a variant was suspected by a peculiar result of a diabetic test of ion-exchange chromatography for glycated hemoglobin.

FAB/MS of the tryptic digest revealed a one mass decrease of peptide βT5 (normal mass: 2057.9), leaving three possible mutations. MS/MS from the precursor ion at m/z2058.9, half of which is contributed by a variant peptide containing one ^{13}C atom, determined the site of mutation as position 43 as shown in Figure 1. FAB/MS of the V8 protease digest confirmed the mutation.

Hb Ube

Electrophoretic screening detected a hemoglobin with an acidic mutation in the α chain.

FAB/MS of the tryptic digest identified a one mass increase of peptide αT9 (normal mass: 2995.5), leaving two possible mutations. MS/MS gave only C-terminal series of fragments and failed to produce sufficient intensity of fragment ions to specify the mutation. In this case, FAB/MS of an Endoproteinase Asp-N digest determined the mutation of α68Asn→Asp.

CONCLUSION

We presented two complement methods to finally characterize single amino acid mutations in protein variants. One is the FAB/MS of peptide mixtures from enzymatic cleavage which is specific to the peptide bond of interest. This strategy is, however, not always applicable to every type of mutations, although the proteinases for specific peptide bonds are increasing in number. The other method is MS/MS. This technique is potentially more universal, but the low sensitivity may obscure the results as was the last case, in which the mutation was present near the N-terminus in a large peptide of about 3,000 daltons and the N-terminal series of fragments was of low intensity.

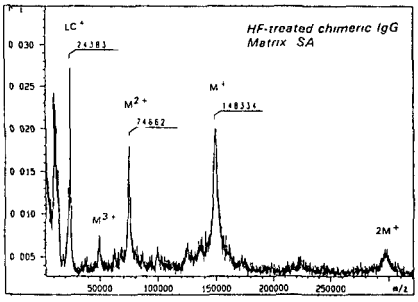
CHARACTERIZATION OF THE DOXORUBICIN CONJUGATE OF A CHIMERIC MONOCLONAL ANTIBODY BY MASS SPECTROMETRY

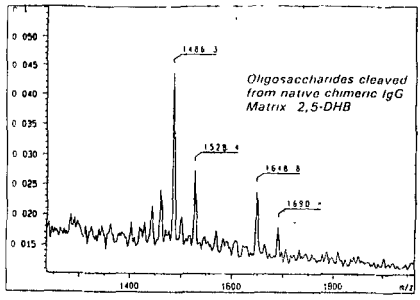
Anthony J. Alexander*, David W. Dodsworth, David H. Kirkley, Barbara Root and Guillermo I. Tous; Bristol-Myers Squibb Co, Pharmaceutical Research Institute, P.O. Box 4755, Syracuse, N.Y. 13221.

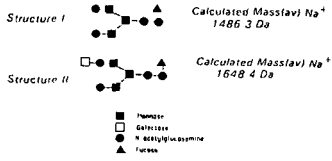
INTRODUCTION: The doxorubicin conjugated species of a chimeric antibody (IgG) is specifically targeted against a tumor site where the conjugated moiety will then be released from the antibody upon internalization. The efficacy of these agents is dependent not only on their degree of specificity for the target antigen, but also on their pharmaco-kinetic properties. These latter can be affected both by primary amino acid sequence and by the degree of glycosylation of the antibody. Siegel et al have shown matrix assisted laser desorption/ionization mass spectrometry (MALDI-MS) to be a particularly elegant method for determining the carbohydrate and conjugated drug content of monoclonal antibodies (1). The technique is rapid, simple, and works in the presence of many commonly used buffering agents, salts, and denaturants, which are often essential to maintain protein stability.

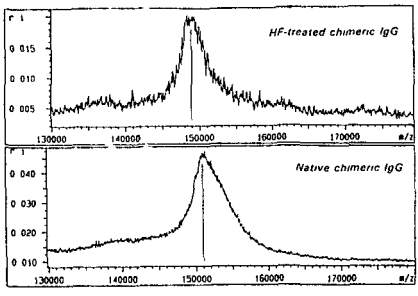
METHODS: The heavy(HC) and light(LC) chain components of the conjugated IgG were isolated using size exclusion chromatography. Deglycosylation of the native antibody was carried out using two different methods: Hydrogen fluoride (HF) cleavage [Immuno-Dynamics Inc. apparatus] and Hydrozinolysis (Glycoprep 1000 glycan release system). The first method destroyed the sugars, whereas in the second both N- and O- linked oligosaccharides were released and recovered. MALDI mass spectra were obtained using both the Bruker Reflex and Finnigan Vision 2000 time-of-flight (TOF) mass spectrometers. Samples containing guanidine.HCl, a known MALDI suppressor, were exchanged into a 0.1% TFA solution. Aliquots of the sample (0.5-1.0 μL) were co-deposited on the sample stage with equal volumes of matrix, either 0.05M 2,5-dihydroxybenzoic acid (2,5-DHB) or 0.1M sinapinic acid (SA), and allowed to air dry. The spectra shown represent an average of 10 laser shots.

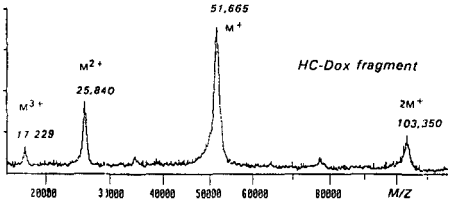
RESULTS AND DISCUSSION: The mass spectra obtained for the native and HF-treated chimeric IgG samples were typical of MALDI mass spectra of antibodies (1). A shift to lower mass and narrower, more symmetric peak shape was clearly evident in the case for the molecular ion of the deglycosylated IgG. The difference in MW corresponds to the mass of the oligosaccharide side chain. Our results showed a shift between the respective peaks centroids of c.a. 2,200 Da. The mass spectra of the oligosaccharide pool showed the presence of at least 8 components. The sodiated ions at m/z 1486 and 1648 are separated by 162 Da. which corresponds to the residual mass of one hexose unit. These masses are consistent with the two most commonly occurring murine IgG carbohydrate structures from hybridomas (2). Based on the cDNA-derived amino acid sequence of the chimeric IgG the anticipated glycopeptide fragment from a trypsin digest is EEQYNSTYR, with NST corresponding to the consensus sequence for N-linked glycosylation. This fragment was found and sequenced by Edman degradation. The results confirmed the sequence except for the asparagine at residue 5, which is consistent with carbohydrate attachment at that position. MALDI-MS analysis of this tryptic fragment gave a MW of 2634.5. This value, less the average mass of the peptide chain (1190.2 Da.), yields a carbohydrate mass which is also consistent with structure I. The mass spectrum of the isolated HC-Dox conjugate showed a shift in the centroided molecular ion mass of + 730 Da., compared to the native HC. This is very close to the expected mass shift for conjugation of a single doxorubicin unit to the heavy chain. However, the broader peak shape obtained is probably indicative of a distribution of species being present, ranging from zero to 3 conjugated anticancer drug molecules. No comparable mass shift (data not shown) was observed for the LC, although the UV absorbance upon isolation of this fragment clearly indicated the presence of the drug.

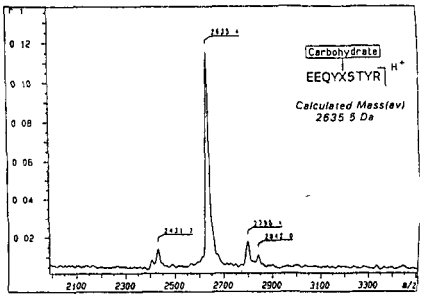


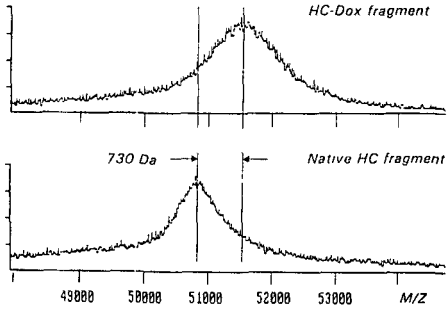












ACKNOWLEDGEMENTS: The authors would like to thank the following people who helped obtain the MALDI-TOF data shown in this poster: Drs. A. Holle, F.J. Mayer at Bruker-Franzen Analytik GmbH and Dr. C.H. Watson at Bruker Instruments Inc. Arnd Ingendoh and F. Hillenkamp at the Institute for Medical Physics, University of Munster.

Broad Band Excitation in the Quadrupole Ion Trap Mass Spectrometer Using Shaped Pulses (Inverse Fourier Transform)

Randall K. Julian Jr., Kathy Cox, R. Graham Cooks, Purdue University, West Lafayette, IN 47907

The standard method for exciting ions in the quadrupole ion trap is to couple an external oscillating electric field to the secular frequency of the ion motion in the z direction. This field is created by applying a periodic potential in dipolar fashion across the endcaps of the instrument. By applying a single frequency, a narrow band of m/z values are excited. This is the basis for ion excitation used for parent ion fragmentation, axial modulation and resonant ejection. This study describes the use of multiple frequency or broad band electric fields to cause excitation over a wide range of m/z values. Unlike swept frequency methods described previously [1,2], this technique uses shaped pulses created via inverse Fourier transforms.

The method for designing shaped pulses for this experiment is identical to Stored Waveform Inverse Fourier Transform (SWIFT), developed by Marshall et. al. for the FT/ICR [3,4]. The frequency domain of the excitation signal is specified as a real spectrum, then phase modulated into real and imaginary components. This complex signal is then transformed via a fast inverse Fourier transform (IFT) into a complex time-domain signal. The real portion of the time-domain spectrum represents the absorption mode and thus is used as the excitation signal. The signal is apodized using a quarter-wave sine window as described by Marshall et. al. [4] to eliminate spectral leakage. The signal is then down-loaded into a Arbitrary Waveform Generator (ARB) which is connected to the endcaps via a balun to create a dipole field. When the entire frequency domain of the pulse is specified prior to the IFT, no external frequency modulation is required. The experimental setup for this method, termed "Full Synthesis" is shown in Figure 1.

Three experiments are demonstrated using broad band excitation: i) parent ion excitation resulting in CID, ii) broad band ejection and iii) matrix ion ejection during ion injection.

Broad band excitation of parent ions is performed by isolating the molecular ion region, then a pulse is applied which contains frequencies covering the entire parent area. Product ions are formed with approximately the same efficiency as single frequency excitation. Broad band ejection of a wide m/z range was also performed on the $Cs(CsI)_3^+$ and $Cs(CsI)_4^+$ clusters. The ring is held at 3386 $V_{(0\,p)}$ which gives $Cs(CsI)_3^+$ a secular frequency of 118.839 kHz and $Cs(CsI)_4^+$ a frequency of 91.811 kHz An excitation pulse was created to excite 85 kHz thru 120 kHz and when applied both clusters are ejected with 100% efficiency with no loss of other clusters. There is a limit to the number of ions which may be trapped before space-charge effects destroy the quality of the mass spectrum during mass selective instability scans. During Cs^+ desorption ionization of a peptide in a glycerol/thioglycerol matrix, large numbers of matrix ions are injected. When the ring voltage is optimized to trap the analyte molecule, the matrix ions are trapped as well. Broad band ejection of matrix ions requires a broad band signal covering a large frequency range near the maximum ion frequency. Figure 2 shows the mass spectrum of 1 μL of a 37.1 pmol/μL substance P sample in a glycerol/thioglycerol matrix with an 80 ms ionization time and a 10 ms multiplier stabilization time. Figure 3 shows the results of applying broad band pulses during ionization resulting in a dramatic increase in parent ion intensity. The pulses used here excite from 80 kHz to 600 kHz, and are approximately 10 ms in duration, with 5 ms of active power. The inset to Figure 3 shows the microscan used and where the pulses were applied.

This study concludes that broad band excitation is possible in the quadrupole ion trap using the same techniques developed for FT/NMR and FT/ICR. It is shown that the adverse effects of large numbers of matrix ions can be countered by their ejection during the ionization stage of the experiment.

Characterization of Cyclic AMP-Dependent Protein Kinase Phosphorylation Sites in Recombinant Tau Proteins

*Russell C. Spreen, Joseph L. Herman, Francis H. Chow, Claudia B. Caputo and Clay W Scott,
ICI Pharmaceuticals Group, A Business Unit of ICI Americas Inc., Wilmington, DE 19897

Introduction: Tau (τ) is a neuronal protein that binds to microtubules and stabilizes the microtubule cytoskeleton. Modified forms of tau constitute a major portion of paired helical filaments (PHFs) which comprise the intracellular tangles characteristic of Alzheimer's disease. Tau is known to be aberrantly phosphorylated in PHFs and certain phosphorylated forms of tau may play an important part in the PHF formation process. Direct characterization of PHFs has been difficult due to poor solubility. Identification of tau phosphorylation processes which lead to PHF formation would provide a valuable starting point for the development of therapeutic agents. Human tau protein is known to exist in six different isoforms ranging in molecular weight from 36.7-45.8 kD. This report details our work in mapping in-vitro cyclic AMP-dependent protein kinase phosphorylation sites on the smallest human tau isoform (τ3r) produced using recombinant methods.

Experimental: Phosphorylated tau samples were prepared by incubating τ3r with ATP (or ^{32}P ATP) and cAMP-dependent protein kinase. The resulting phosphorylated τ3r was purified by HPLC. One nanomole samples of τ3r, phosphorylated τ3r, and ^{32}P phosphorylated τ3r, were enzymatically digested with trypsin, Asp-N, or a mixture of trypsin and chymotrypsin. The digest mixture was fractionated by HPLC and the phosphate containing peptides were located through radioactive counting of HPLC fractions from the digest of ^{32}P phosphorylated τ3r. The molecular weights of phosphopeptides were determined by comparative liquid-secondary ion mass spectrometry (L-SIMS) analysis of nonphosphorylated and nonradioactive phosphorylated proteolysis products. Peptide sequences were proposed by matching the experimental mass against the molecular weight of computer predicted proteolysis fragments. Edman chemistry and phosphoamino acid analysis provided a means of differentiating various potential phosphorylation sites within individual phosphopeptides.

Results: Phosphoamino acid analysis was initially performed on ^{32}P phosphorylated τ3r. Thin layer electrophoresis clearly shows that cAMP-dependent protein kinase phosphorylates τ3r exclusively at serine, limiting the number of possible phosphorylation sites in τ3r to 36. An equivalent analysis of proline-directed protein kinase phosphorylated τ3r demonstrates a different phosphorylation profile when an alternate kinase is used.

Retention time shifts in the chromatographic peaks combined with radioactivity data were used to pinpoint the location of phosphate containing peptides (HPLC retention time decreases with phosphorylation due to increased hydrophilicity). L-SIMS analysis of τ3r fraction 47 and the corresponding fraction from phosphorylated τ3r (fraction 44) are shown in Figure 1. A series of molecular ions, $(M+H)^+$, from overlapping incomplete proteolysis products of τ3r are observed at m/z 1310, 1421, and 1664. The corresponding mono-phosphorylated products (shifted positive by 80 Da) are observed at m/z 1390, 1501 (weak), and 1744 (Figure 1B). One cycle of manual Edman chemistry was performed on the phosphopeptide at m/z 1390 in order to differentiate which of the two serines had been converted to phosphoserine. The mass shift after one Edman cycle showed cleavage of serine (87 Da), not phosphoserine (167 Da), from the N-terminus indicating that phosphorylation must have occurred at the internal serine, τ3r Ser^{155}. Solid-phase sequencing studies on the corresponding fraction from the ^{32}P phosphorylated sample confirmed the proposed sequence for m/z 1744. A release of radioactivity was observed in Edman cycle 5, consistent with the proposed phosphorylation site.

The full HPLC chromatogram of the tryptic digest of τ3r showed a cluster of phosphate containing peaks (radioactive) between 37 and 39.5 min; however, no molecular ions were evident in the L-SIMS mass spectra. Gel electrophoresis of the pooled 37-39.5 minute fractions showed a phosphate containing band at 3-4 kD. The pooled sample was digested with Asp-N, rechromatographed, and fragtions were collected. Fractions 44 and 53 were shown to contain phosphate (via parallel ^{32}P study). The corresponding mass spectra are shown with identifications in Figure 2. Both of the spectra contain components of the largest predicted tryptic fragment, His^{317}-Lys^{348} (MW = 3242.6 Da). Two redundant proteolysis fragments, HLSNVSSTGSI and HLSNVSSTGSIDMV, are shifted positive by 160 Da due to the incorporation of two phosphate groups. Each of the two diphospho peptides contain four possible phosphorylation sites. The location of the two phosphoserines was determined by solid-phase sequencing of the ^{32}P labelled sample to be at Ser^{319} and Ser^{326}.

Two other phospho peptides were located through retention time shifts and radioactive counting of the tryptic fragments from ^{32}P phosphorylated τ3r. The molecular weights of these peptides were consistent with predicted tryptic fragments. The corresponding phosphorylation sites (Ser^{234} and Ser^{266}) were simply assigned to the only serine in each of the peptides.

Summary: The experimental findings are summarized in the L-SIMS map shown below. L-SIMS mapping studies have accounted for 84% of the τ3r structure and 34 of the 36 serine residues. Five phosphorylation sites have been identified and phosphorylation sites in peptides with multiple serines have been confirmed by solid-phase sequencing.

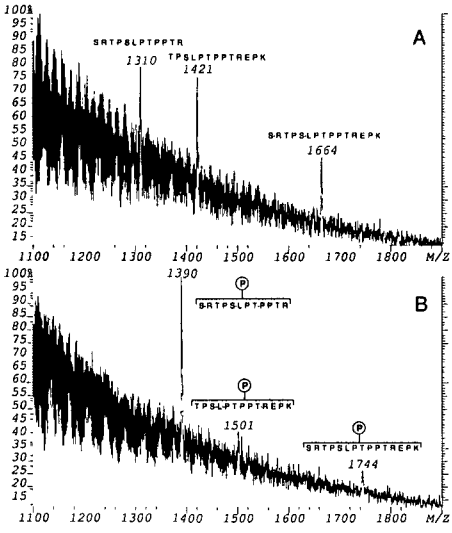

Figure 1 L-SIMS mass spectrum of (A) HPLC fraction 47 from the tryptic digest of τ3r (B) HPLC fraction 44 from the tryptic digest of phosphorylated τ3r. The 80 Dalton shift is consistent with single phosphorylation of three related incomplete tryptic digest products.

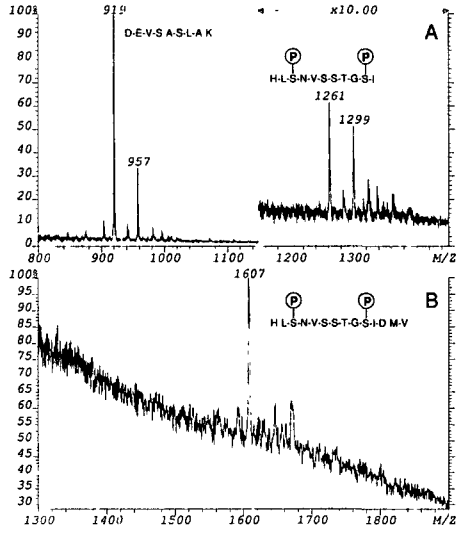

Figure 2. The L-SIMS mass spectra of phosphate containing HPLC fractions 44 (A) and 53 (B) from the Asp-N digest of pooled tryptic fragments of phosphorylated τ3r.

Microcapillary Fused Silica Tubing for On-Line Digestion and Sequence Analysis of Proteins and Peptides by Electrospray Ionization/Tandem Mass Spectrometry

T.A. Dickinson, T.A. Davis, N. Sherman, J. Shabanowitz, D.F. Hunt
University of Virginia, Department of Chemistry, Charlottesville, VA 22901

Use of microcapillary HPLC columns to fractionate and deliver peptides from enzymatic digestions directly to the electrospray ionization source on a Finnigan triple stage mass spectrometer has been described previously in a number of papers from this laboratory. (1) Analysis of samples in the 1-10 pmol range are routine with this procedure.

In an effort to further reduce losses incurred in manipulating low picomole levels of protein samples, we have developed a method of on-line digestion of samples in fused silica capillary tubing. The fused silica tubing is then butt connected directly to the microcapillary HPLC/MS system. Proteins are digested in the tubing, the resulting peptide fragments are flushed onto the head of a microcapillary C-18 column with 0.1M acetic acid, fractionated with a linear gradient of acetonitrile, and eluted directly into the mass spectrometer for sequence analysis.

Peptides associated with the Class II Major Histocompatibility Complex were enzymatically digested with sequence grade trypsin in 12.7cm of 100um fused silica capillary tubing. This length and diameter enable one microliter of sample to be added to the capillary tubing. Various methods of pre-treatment of the capillary tubing were employed in order to minimize adsorption of peptide to the walls of the tubing and to obtain the highest yields possible. The methods of pre-treatment include silating the walls of the capillary tubing with either aminopropyltriethoxysilane or dimethyldichlorosilane, and incubating the tubing with trypsin for several hours prior to addition of sample. Comparison of results obtained with synthetic peptides, as well as naturally occurring peptides, reveals that pre-treating the capillary tubing with dimethyldichlorosilane results in nearly complete recovery of undigested and digested peptides (figures 1 and 2). The amount of digestion that took place was comparable to digestion in Eppendorf tubes with much less material being used The most loss of material was obtained from the aminopropyltriethoxysilated capillary tubing experiments. The yields for both the peptides alone on the capillary tubing and the digestion experiment were extremely low. Four of the five synthetic peptides loaded were adsorbed to the walls of the tubing. Digestion was observed in only 10-20% yields for this experiment. Both untreated fused silica capillary tubing and tubing treated with trypsin for an extended period, showed digestion of peptides. However, a large amount of self-digested trypsin fragments was observed, which could interfere with the analysis of samples containing more complex mixtures. As the results indicate, on-line enzymatic digestion of protein and peptides in capillary tubing pre-treated with dimethyldichlorosilane not only reduces the loss of material due to sample handling, but also uses less material with which to start.

Efforts to perform collisionally activated dissociation of peptide fragments generated in the dimethyldichlorosilated capillary tubing are currently underway.

Mass Spectrometric Analysis of the Modifications of Lens Crystallins and Determination of the Rate Constants

W. Qin*, J. B. Smith and D. L. Smith; Department of Medicinal Chem. & Pharm., Purdue University, West Lafayette, IN 47907

Carbamylation, a proposed post-translational modification of lens crystallins, may lead to the loss of lens transparency that is associated with cataract. It has been proposed that removal of the charge at lysyl residues by carbamylation might lead to conformational changes that permit disulfide bonding between cysteines and subsequently lead to cataract formation. Incubation of the lens crystallins with aspirin renders the proteins less reactive toward carbamylation and decreases the formation of high molecular weight aggregates attributed to disulfide bonding. Since the ε-amino group of lysine and the N-terminus can be acetylated, it has been proposed that acetylation competes with, and therefore may prevent carbamylation of lysyl residues. These reactions are illustrated bellow.

$$KOCN + protein\text{-}NH_2 \text{ -------> } protein\text{-}NH\text{-}CONH_2$$

$$aspirin + protein\text{-}NH_2 \text{ -------> } protein\text{-}NH\text{-}COCH_3$$

However, lysine acetylation does not explain the effect of aspirin on aggregation and disulfide bonding. We have used fast atom bombardment mass spectrometry (FABMS) to examine the reaction products of the carbamylation and acetylation of bovine γII-crystallin which has a free N-terminus, two lysines and seven cysteines. Differences in the products of the reactions might explain the effects of carbamylation and acetylation in cataractogenesis.

Bovine lenses from 2-yr-old cows were homogenized in a buffer of 0.5M NaCl, 0.05M TRIS, 0.001M EDTA, pH 7.4 for 1 hour, and centrifuged. The γ-crystallins were separated by gel filtration chromatograghy (Sephadex G-200). The γII-crystallin was further purified by ion exchange chromatograghy. γII-crystallin was either carbamylated by incubation in 0.1M KOCN or acetylated by incubation in 0.1M aspirin for up to 24 hours at 37 ^{0}C.

The crystallin was digested with pepsin for 7 hours at 37 ^{0}C. The peptides were separated by reversed phase HPLC, and their identities were determined by FABMS. Modified residues were easily recognized by the +43 mu increase of carbamylation and the +42 mu increase of acetylation. The rate constants of the modifications at each amino group were calculated from the intensities of the modified and unmodified peaks, averaged over at least 10 scans (Fig. 1). In addition to the modifications at the amino groups, some of the cysteines were found S-carbamylated and S-acetylated. Confirmation of the identity of the cysteine containing peptides was obtained by reducing the peptides with thioglycerol and oxidation with performic acid. The MS/MS fragment patterns of the S-carbamylated and S-acetylated peptides established that the modifications were at cysteine residues (Fig. 2).

The rate constants for carbamylation and acetylation at each amino group of γII-crystallin have been determined. Because the effects of carbamylation and acetylation of the lysines of γII-crystallin are so similar, it appears unlikely that the diverse effects of carbamylation and acetylation in cataractogenesis can be attributed to these reactions. Our observation that cysteines in γII-crystallin could be acetylated led to speculation that this modification might be responsible for the inhibitory action of aspirin on disulfide bonding and cataract. However, subsequent observation of carbamylated cysteines indicated that cysteines as well as lysines react similarly to aspirin and cyanate. The study of the stability of the S-carbamylated and S-acetylated peptides is underway.

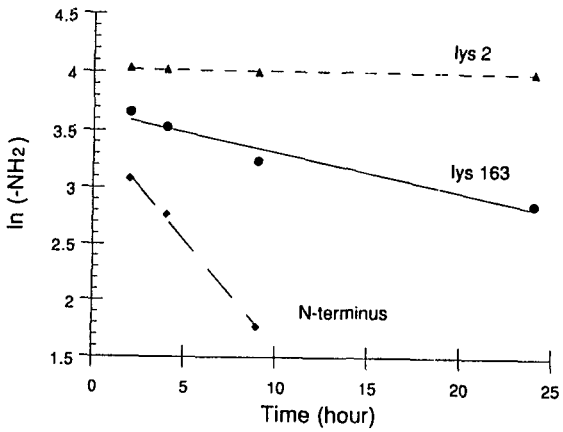

Fig. 1 Plot of ln [-NH_2] vs time used to calculate the rate constants for acetylation at each amino group of γII-crystallin

Mass Spectrometric Analysis of Human α-Crystallins

Laura R. Miesbauer, Jean B. Smith and David L. Smith
Department of Medicinal Chemistry and Pharmacognosy
Purdue University, West Lafayette, IN 47907

Post-translational modification due to aging or disease states may disrupt the three dimensional structure of the lens crystallins, leading to lens opacity and cataract, To identify age and disease related modifications of lens proteins, it is important to confirm the amino acid sequence and to identify covalent modifications characteristic of the normal lens proteins. Electrospray ionization (ESI) and fast atom bombardment (FAB) mass spectrometry have played a major role in our investigation of the primary structures of normal as well as modified proteins.

Research into the structure of lens crystallins has been largely done using lens from bovine or other animal species. Although very high sequence identity between species exists in α-crystallins, there are a few differences that may be critical in the formation of human cataract. Two Cys residues in human αA compared with one in bovine make intramolecular disulfide bonding possible in human α-crystallins.

Human lenses were obtained from G. Adrien Shun-Shin of Clinical Cataract Research Unit, Nuffield Laboratory of Ophthalmology, Oxford. The water soluble portion was separated into α, β and γ-crystallins by Sephadex G-200 gel filtration using a 2.5 x 86 cm column and a buffer of 0.05M Tris-HCl, 0.5M NaCl, 0.001M EDTA, pH 7.4 at 4°C. Fractions containing α-crystallin were further separated into αA and αB by C_4 reversed phase HPLC using a gradient of 30-55% CH_3CN in H_2O (0.1% TFA) over 60 minutes with uv detection at 280 nm. Aliquots of the HPLC fractions were analyzed by ESI mass spectrometry by Dr. Yiping Sun of Procter and Gamble, Miami Valley Laboratories. The proposed primary sequences of human αA and αB were verified or corrected by enzymatic digestion of the proteins, primarily with trypsin and endoproteinase Asp-N (1:50 enzyme-to-substrate ratio, 0 1M Tris-HCl, pH 8.2, 37°C, 4 hrs), C_{18} HPLC separation (1-40% CH_3CN in H_2O with 0.1% TFA over 60 min), followed by FAB mass spectrometric analysis. Post-translational modifications, such as phosphorylation, disulfide bonding, glutathione adducts, and deamidations were identified and sequence confirmations were made by enzymatic subdigestion and FAB mass spectrometry.

The primary sequence of human αB crystallin was confirmed by a combination of ESI and FAB mass spectrometry. There were no corrections to the primary sequence, except for partial deamidation of Asn-146. N-terminal acetylation and phosphorylation at Ser-45 were observed, analogous to bovine αB. Loss of the C-terminal Lys residue was also seen.

Analysis of human αA by ESI mass spectrometry showed several forms of αA. The amino acid sequence of αA is shown in Fig. 1. αA, αA-Ser (loss of the C-terminal residue), αA+1PO_4, αA+2PO_4 and αA+glutathione were identified. Glutathione is present in the lens and its binding to lens proteins has been postulated. This work clearly shows its presence as a disulfide bond with Cys 131 (See Fig. 2). Additionally, a modified αA component was seen by ESI mass spectrometry, but full identification of the modification has not been completed.

FIGURE 1: *Amino acid sequence of human αA crystallin derived from the gene sequence.*

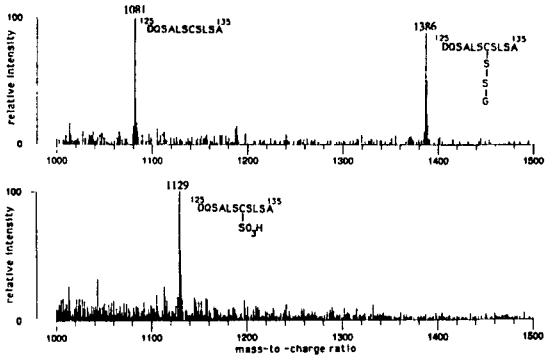

Figure 2: FAB mass spectrum of αA (125-135), and αA (125-135) disulfide bonded to glutathione. After performic acid oxidation, the glutathione adduct peak disappears and the peptide (125-135) shifts by 48 mass units

Modifications of αA that were indicated by ESI mass spectrometry were confirmed by enzymatic digestions and FAB mass spectrometry. One phosphorylation was assigned to Ser-122, where it is also seen in bovine and rabbit. The other phosphorylation is likely at Ser-45. Phosphorylation at Ser-45 appears to be unique to human, as it has not been reported in other species. A correction at (153-156) confirmed the sequence as -THAE- and not -HT(del)E-.

Disulfide bonding between Cys-131 and Cys 142 was seen. It is not clear whether this disulfide bond is in native αA, or if it the result of enzymatic digestion at high pH (8.2). Disulfide bonds were confirmed by performic acid oxidation of Cys in which the peak of the disulfide bonded peptide disappeared and the constituent peptides shifted by 48 mass units (Fig. 3).

Deamidation, or partial deamidation, of Asn was apparent at residues 136 and 101. Deamidation at 136 had been previously proposed. Deamidation at Asn-101 was likely because 4 peptides corresponding to (92-100), (91-100), (84-100) and (76-100) were seen in the endoproteinase Asp-N digest of human αA. Asp-N is specific for cleavage N-terminally to Asp. All 4 peptides could be generated in the event of deamidation at Asn-101 to Asp, but are not likely to be made if Asn is at 101. Carboxypeptidase B and Y subdigestion of the peptides showed loss of the C-terminal residues His and Lys, and confirmed at least partial deamidation of Asn-101.

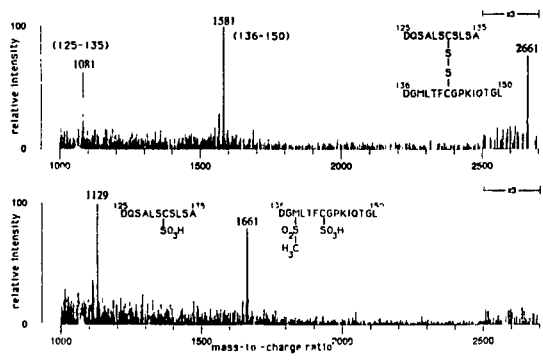

Figure 3: FAB mass spectrum of a disulfide bond in human αA between Cys 131 and Cys 142. The disulfide bonded peptide and its constituent peptides are shown (top). Following performic acid oxidation (bottom), the constituent peptides shift by 48 mass units (oxidation of Cys) and an additional 32 mass units upon oxidation of Met-138 in peptide (136-150).

HPLC CF FABMS Facilitates use of Hydrogen Exchange as a Probe of Conformational Changes in Proteins

Zhongqi Zhang and David L. Smith, Department of Medicinal Chemistry and Pharmacognosy, Purdue University, West Lafayette, IN 47907.

Isotopic exchange of protein backbone amide hydrogens has been used extensively as a sensitive probe of protein structure. The principal method for determining rates of hydrogen exchange in peptides and small proteins has been one and two-dimensional NMR. This approach has been used to investigate protein folding, enzyme-inhibitor complexes, and antibody-antigen complexes. However, the use of NMR is restricted to investigations of relatively small and highly soluble proteins. Here we describe a new method, based on microbore HPLC CF FABMS, that will facilitate application of hydrogen exchange studies to large proteins. In addition, the isotope patterns of peptide molecular ions provide a new type of information that may lead to better understanding of the hydrogen exchange processes in proteins.

Cytochrome c was partially deuterated by incubating the protein in phosphate buffer in D_2O (pD 7.2). Exchange-in was quenched using slow exchange conditions (pH 2.2, 0 °C). The protein was then digested with pepsin for 10 minutes under the same slow exchange conditions. Pepsin is an aggressive protease, giving good yields at 0 °C after 10 minutes. The isotope pattern and deuterium content of each peptide in the digest was determined by HPLC FABMS. To minimize the hydrogen exchange during peptide analysis, the HPLC injector, column, and most of the transfer line were cooled to 0 °C. Adjusting for the extent of back exchange occuring during proteolysis and analysis gave the corrected value of the deuterium content of each peptide. For the experimental conditions used in this study, the corrected deuterium content of the peptides was a direct measure of the number of deuteriums located at peptide amide linkages.

According to the structure unfolding model of protein hydrogen exchange, the protein first locally unfolds exposing the amide hydrogens to the solvent. Amide hydrogens within the unfolded segment have an opportunity to undergo isotopic exchange before the protein folds back to its natural state. The relative magnitudes of the rate constants for hydrogen exchange and folding of the protein determine the isotopic patterns of the molecular ions of peptides derived from the unfolded region. If the back folding rate constant dominates, the isotope pattern will be binomial; if the exchange rate constant dominates, the isotope pattern will be different. The observed isotope patterns of peptides from cytochrome c resemble the binomial distribution, indicating that protein folding occurs much faster than isotopic exchange.

From the time courses of deuterium incorporation in different segments of cytochrome c (Fig. 1), it is evident that segment 95-104 is much more resistant to hydrogen exchange than segment 67-82. This observation is consistent with the structure of cytochrome c. Residues 87-102 form a stable α-helix in which the amide hydrogens undergo strong intramolecular hydrogen bonding, which is indicated by a low rate of hydrogen exchange. For segment 67-82, residues 67-70 and 75-78 occur as two β-turns in which hydrogen exchange proceeds readily. Upon adding acetonitrile to the incubation, the deuterium incorporation increases, indicating that acetonitrile causes partial denaturation of the protein.

From the thermal denaturation curves (Fig. 2), it can be seen that segment 95-104 has a sharp increase in deuterium incorporation at 61 °C, which indicates the conformational transition is cooperative in this region. This result is consistent with the fact that most of this region is in a very stable α-helix. As for segment 81-96, part of the region is in an α-helix, which gives rise to the major increase at 60-65 °C, and part of the region is in loops, which gives rise to the minor increase at 40-50 °C. The results are consistent with the literature results. With increasing temperature, cytochrome c has a denaturation event at 50-60 °C as measured by CD (Meyer *et al.*, *Biochemistry*, **1980**, 19, 199), 64 °C as measured by differential scanning calorimetry, and 60-62 °C as measured by Fourier-transform infrared spectroscopy (Muga *et al.*, *Biochemistry*, **1991**, 30, 7219).

A new method, based on HPLC FABMS to quantify the deuterium exchange of protein amide hydrogens, has been developed. This technique is a sensitive probe for conformational changes induced by an organic solvent or elevated temperature. This approach is attractive because it can be used to study large proteins, and because it requires much less time and sample than methods based on NMR. The present results suggest that the combination of amide hydrogen exchange and HPLC FABMS could be used to investigate a variety of protein structure problems, including ligand-receptor binding sites, protein-protein interactions, and conformational changes resulting from post-translational modifications.

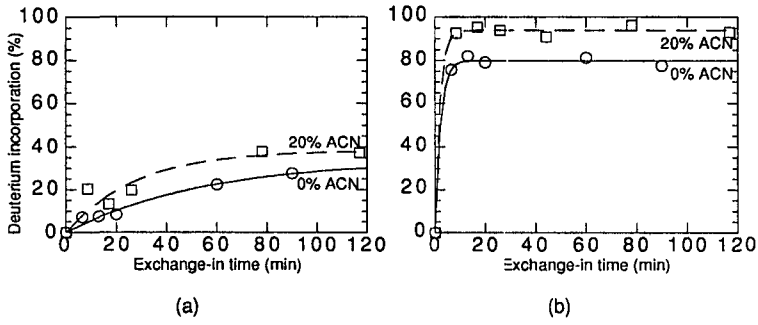

Fig. 1 Deuterium incorporation (percent of amide positions deuterated) into different segments of cytochrome c in 0% and 20% acetonitrile as a function of exchange-in time. (a) peptide 95-104; (b) peptide 67-82. The results have been corrected for the effect of acetonitrile on the [OD^-], as determined from pD.

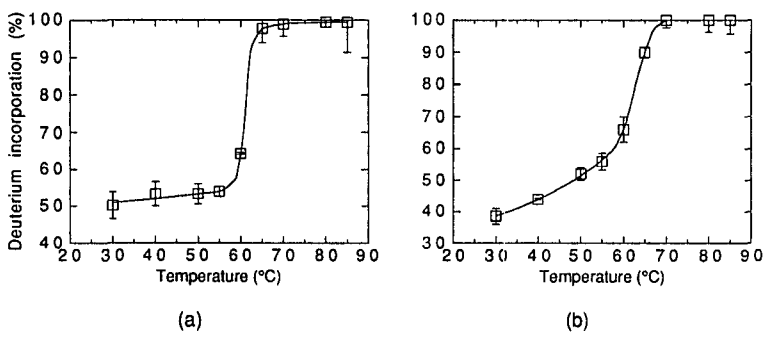

Fig. 2 Effect of temperature on the deuterium incorporation in different segments of cytochrome c. (a) segment 95-104; (b) segment 81-96. The exchange-in time was varied from 1.4 to 118 minutes to compensate for the effect of temperature on the intrinsic rates of exchange.

Carboxy-Terminal Protein Sequencing by Carboxypeptidase Digestion and Electrospray Mass Spectrometry

Kevin L. Duffin and Christine E. Smith, Monsanto Corporate Research, Monsanto Company, St. Louis, MO 63198.

The determination of the C-terminal sequence of a protein, although not automated like N-terminal sequence analysis, is desirable for characterization of the protein termination site. Within a cloned DNA sequence, this is usually accomplished through the location of stop codons. However, post-translational processing or stop codon suppression can lead to an unexpected C-terminal sequence. Additionally, C-terminal sequence information can assist in establishing the integrity of recombinant proteins. Also for cloning purposes, the C-terminal sequence can be used in the generation of an oligonucleotide probe. This probe, used in conjunction with a probe designed against the N-terminal sequence, affords the possibility of obtaining the entire gene using PCR technology.

Classical methods of C-terminal sequencing involve the digestion of single amino acids from the C-terminus of a protein using carboxypeptidases. Analysis of the released amino acid is usually performed at several predescribed time intervals using ion-exchange chromatography or RP-HPLC. When monitoring for the released amino acid only, problems in data interpretation are common. The presence of double residues is often missed or misinterpreted. Additionally, free amino acid background can contribute to the complexity of interpretation. Since the kinetics of the digestion reaction are dependent on the protein sequence, variation in the temporal release of amino acids commonly occurs. Therefore, the enzymatic reaction must be monitored at frequent time intervals so the true sequence of amino acids can be determined. These problems associated with the analysis of released amino acids from a carboxypeptidase digestion can be circumvented if the analysis is performed on the degraded protein.

Several groups have reported success at the analysis of carboxypeptidase digested peptides using Fast Atom Bombardment-Mass Spectrometry (FAB-MS) and Thermospray LC/MS (Self and Parente, *Biomedical Mass Spectrometry*, 1983; Caprioli and Fan, *Analytical Biochemistry*, 1985; and Kim,et al, *J.Am.Chem.Soc*, 1984). Accurate mass analysis of peptides was shown using this technology. The level of sensitivity was generally 0.5-5 nmoles. Additionally, Plasma Desorption Mass Spectrometry (PDMS) has also been used to monitor carboxypeptidase digestions (Klarskov, et al, *Analytical Biochemistry*, 1989). More recent advances in mass spectrometry include electrospray ionization (ESMS). This type of ionization allows mass spectrometric analysis of large molecular weight molecules (eg. proteins) by producing multiple charge states of the compound during ionization. This decreases the effective mass-to-charge ratio so that it falls within the limits of the mass range of the mass analyzer. This allows the capability for mass analysis of carboxypeptidase-digested proteins.

Since electrospray analysis of proteins yields optimal data under low ionic strength and volative buffer conditions, a carboxypeptidase that functions under these conditions is required. Carboxypeptidase P (CPP) (Takara Biochemicals) has been reported to be a non-specific carboxypeptidase, capable of cleaving all amino acids from the C-terminus, although slow release of serine and glycine residues has been observed. The literature has suggested activity of CPP at pH 4.0 in a low molarity of sodium acetate (Lu, et al, *J. Chrom.*, 1988). In this study, peptides or proteins were dissolved in 15 mM ammonium acetate adjusted to pH 4.0 with trifluoroacetic acid and CPP was added at a enzyme to substrate ratio of 1:100. At various timepoints, aliquots from the digestion reaction were acidified with methanol:formic acid:water (50:50:1) and mass-analysed.

As a peptide model, Neurotensin (13mer) was digested at an enzyme-to-substrate ratio of 1:100 in 100ul of 15 mM ammonium acetate, pH 4.0 at room temperature. Aliquots of 10ul were removed at 1 min, 15 min, 30 min, 35 min, and 60 min, diluted 1:10 with formic acid:methanol:H2O and analyzed by ESMS. The approximate quantity analyzed at each time point was 200 pmoles. Results indicated that CPP digested prolines much more slowly than other amino acids. The activity of CPP also declined over time and nearly inactive at 60 min. However, compilation of mass spectra obtained at several timepoints yielded the C-terminal sequence of R-R-P-Y-I/L-I/L-OH, which corresponds to the known sequence of neurotensin.

In order to test the applicability of the ESMS analysis method for the CPP digestion of proteins, recombinant *E. coli* derived IL-3 was chosen as a model. The same digestion conditions

were used to digest 2.7 nmoles of IL-3. At several time points, 10 min, 20 min, and 50 min, 500 pmole aliquots were removed and analyzed by ESMS. At the 10 minute time point, the appearance of multiple new mass ions representing five C-terminally degraded IL-3 species were observed. Figures 1 and 2 show the presence of these mass ions at the $(M+9H)^{+9}$ charge state. The ions can be identified at several charge states and an average mass calculation of each species is possible through deconvolution of the mass spectrum. Again the mass shift of these species reflects the sequential loss of amino acids. The mass spectrum obtained from the 10 minute time point alone provided enough information to establish the C-terminal sequence as ...S-I/L-A-I/L-F-OH. Additional time points yielded another mass ion representing the loss of the next residue, either leucine or isoleucine. Further degradation was not observed. The sequence data obtained was consistent with the expected C-terminal sequence of IL-3.

The results obtained to date indicate that ESMS is an effective tool for the analysis of carboxypeptidase-degraded proteins and peptides. It compliments the analytical techniques currently used for obtaining C-terminal sequence information. However, the method is not capable of differentiating isobaric amino acids (ie. leucine/isoleucine, lysine/glutamine) and careful mass analysis is necessary to differentiate amino acids that differ by 1 amu. Protein samples must be fairly homogeneous to eliminate spectral overlap and complicated data interpretation. Glycine and Serine, which have been reportedly difficult to digest with CPP, cleaved without problem in our experiments. However, proline digested very slowly. Some proteins were not digested by CPP under the conditions used in this study. Steric hindrance of the C-terminus of these proteins to the active site of CPP is suspected a probable cause for this lack of CPP activity. Current experiments include the use of other carboxypeptidases and different buffer conditions for generalizing this approach to C-terminal sequencing. Reduction and alkylation of some proteins will be necessary for the C-terminus to be accessable to carboxypeptidase digestion.

Use of Mass Spectrometric Molecular Weight Information to Identify Proteins Relative to Protein and Sequence Databases

Mann, M.*, Højrup, P. and Roepstorff, P.
Odense University, Campusvej 55, 5230 Odense M, Denmark
Present address: European Molecular Biology Laboratory,Heidelberg, Germany

During the last decade new ionization techniques have made it possible to measure the molecular weight of many intact proteins by mass spectrometry. Concomitantly, it has become much easier to obtain a mass spectrometric (MS) peptide map of a protein. At the same time advances in protein and DNA sequencing technology are resulting in an exponential increase in the number of sequences deposited in databases. Here we investigate the possibility to use MS data to identify proteins in databases.

Methods:
Release 27 of the Protein Information Resource (PIR) database was used in these studies. The General Protein Mass Analysis (GPMA) program (Peter Højrup) was modified to transform the database into a number indicating the total molecular weight and a series of molecular weights corresponding to the predicted peptides resulting from a chosen cleavage agent. These data sets where scanned in various ways on a Macintosh IIcx computer with a program written in THINK C (Symantec, Cupertino, CA). The search program accepts as input the following parameters: (i) the measured total molecular weight or a series of measured peptide masses (ii) the experimentally achieved mass accuracy (iii) the required number of peptide matches to count as a protein match (iv) the mass range of proteins to be considered for a match (v) various options such as a search which considers incomplete digestion or a search of a subdigest of a single peptide.
Search times on the Macintosh computer were below 1 second for the total molecular weight and below 10 seconds for the search by partial MS peptide map.

Searching by the total molecular weight of a protein:
In this search a list of proteins within a mass range given by the experimentally determined mass and the obtained mass accuracy is obtained. There are usually several candidates for a match but they can often be distinguished by the source organism. In our experience the search by total molecular weight was a useful tool especially for small and unmodified proteins. Larger proteins are often modified so the predicted and actual molecular weights do not coincide. This

feature and the difficulty to obtain precise molecular weight information on many large molecules limit the generality of the method.

Searching by the Molecular Weights of Selected Peptides:
For more specificity and for error tolerance in both the MS data and the database information we search by the partial mass spectrometric peptide map of the protein. In this approach, a series of peptide masses - derived from the MS spectrum of a mixture or separated fractions of a digest of a protein - is searched. A protein match is counted when a certain number of the measured peptide set matches the predicted peptides for a given protein. In general, just four to six proteolytic peptides measured with a mass accuracy between 0.2 and 0.02 % allow a useful search of databases such as the Protein Identification Resource (PIR). For example, at a mass accuracy of 0.02% four of the 14 predicted tryptic peptides of bovine cardiac acid-binding protein are sufficient to uniquely identify the protein in the database. At a lower mass accuracy of 0.2% unique identification can be achieved by placing an upper limit of 200 kDa on the proteins considered in the search.
Several refined modes of searching were developed such as the search by a subdigest of a single peptide and a search which considers the possibility of incomplete digestion. These specialized searches together with appropriate protein chemical procedures can increase the specificity of the search in difficult cases.

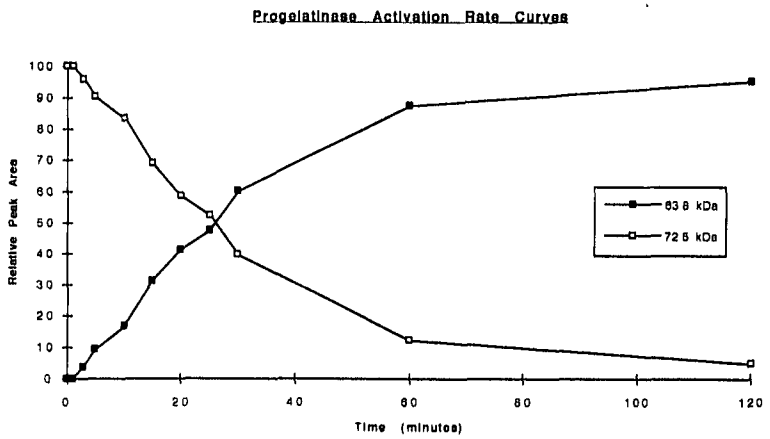
Conclusion and Prospects:
To the degree that the size of DNA and protein sequence databases increases, identification by partial MS peptide maps should become increasingly powerful and may become a general method to identify and characterize proteins. In particular, it may become possible to use the above approach to identify large numbers of proteins from two dimensional SDS PAGE gels.

FIBROBLAST GELATINASE ACTIVATION MONITORED BY MATRIX ASSISTED LASER DESORPTION MASS SPECTROMETRY

C. W. Sutton, A. C. Poole, and J. S. Cottrell, Finnigan MAT Ltd.,
Hemel Hempstead HP2 4TG, UK.
T. Crabbe and A. J. P. Docherty, Celltech Ltd., Slough SL1 4EN, UK

Tissue metalloproteinases, (collagenase, stromelysin, gelatinase, etc.), are an important group of enzymes implicated in a number of connective tissue disorders such as rheumatoid arthritis, gingivitis, and formation of metastases in cancer. The regulation of these enzymes is the focus for development of new drugs. Each metalloproteinase occurs in a latent form which can be activated by a number of mechanisms, (organomercurials, heat, and proteases), leading to the removal of a propeptide from the N-terminus.

Matrix assisted laser desorption mass spectrometry (LDMS) was used to observe activation of progelatinase by 4-amino phenyl mercuric acetate. The change in molecular weight of the protein from the latent form (72.5 kDa) to the active form (63.8 kDa) was monitored over a 24 hour time course. In addition, the molecular weights of peptides cleaved from the pro-region were correlated with the known sequence to identify the cleavage sites leading to activation.



Summary

* This study revealed that the activation process proceeded via the removal of a number of small peptides from the amino terminus, rather than a single 8.7 kDa peptide.
* In addition to monitoring the molecular weight change of gelatinase, LDMS makes it possible to observe the peptides lost from the pro region. 11 such fragments were identified by correlating their measured molecular weights with the known amino acid sequence of gelatinase.
* This approach is directly applicable to a number of similar reactions: e.g. activation of other metalloproteinases, transglutaminase cross linking of plasma proteins, removal of signal peptides from secreted proteins, activation of constituents of the blood clotting cascade, etc.

Characterization of Snake Venoms using Nanoscale Separation Techniques in Combination with Electrospray Mass Spectrometry.

John R. Perkins, Carol E. Parker, Steven R. Mc Gown and Kenneth B. Tomer,
Laboratory of Molecular Biophysics, NIEHS, Research Triangle Park, NC 27709.

Introduction

Mambas (*Dendroaspis*), cobras (*Naja*, *Hemachatus*) and coral snakes (*Micrurus*) are all members of the Elapidae family of snakes. These snakes all possess venomous bites where the venoms exist as a complex mixture. Dried snake venoms contain 90-95% protein components which are mainly responsible for the pharmacology and lethal action of the venoms. Elapidae snake venoms from the genera *Naja* and *Hemachatus* contain toxins that can be divided into α-neurotoxins and cardiotoxins of the molecular weight range 6000-9000 together with the phospholipases A_2 which have molecular weights of around 13000 . *Dendroaspis augusticeps* (Eastern Green Mamba) venom does not contain phospholipase A_2 and it has been postulated that this is true of the other mambas. Consequently the mambas have developed many neurotoxins that differ pharmacologically from those of other snakes.

We have been interested in the applications of CZE/ESI/MS for a variety of problems. The experimental method was developed for the snake venoms using those containing known toxins and applied to the uncharacterized venom of *Micrurus fulvius* (Eastern Coral Snake). It is possible to gain some idea of the molecular weight of some proteins from the ESI spectrum but the use of CZE/ESI/MS greatly simplifies the task of relating masses to each other. It also helps overcome ion suppression which occurs during flow injection analysis. A further advantage of CZE/ESI/MS is that it readily reveals multiple ions of the same mass. Due to the fact that many of the toxins are basic and likely to yield tailing peaks using fused silica capillaries with basic buffers, CZE of the snake venoms was performed on a 3-aminopropyltrimethoxysilane derivatized column with acetic acid (pH 3.5) as the buffer.

Our major limitation was the limited mass range of the VG 12-250 mass spectrometer (m/z=1200). For the snake venoms of interest the phospholipases A2 and other toxins of Mr~13000 proved to be beyond the range of our quadrupole instrument. Electrospray spectra acquired on a magnetic instrument (Kratos Concept 1-SQ) provided some molecular weight data concerning these species.

Results and Discussion

We initially acquired full scan electrospray spectra of the snake venoms with the instrument at unit resolution for mass accuracy. We found no ions of importance below m/z=880. The CZE/ESI/SIM/MS runs were based solely on these spectra to prevent bias. We only compared our results with proteins sequenced in the literature once the CZE/ESI/MS experiments had been performed. For the majority of those toxins sequenced our experimental molecular weight confirmed the described sequence. However, we could find no match for some toxins listed in the literature. For some this seemed to result from multiple charged ions which fell outside the range of the mass spectrometer. For other toxins we noted similar species of a similar molecular weight, most notably Toxin FS2 from *Dendroaspis polylepis polylepis* (Black Mamba), which is the third most abundant toxin in the venom. The theoretical molecular weight based on the amino acid sequence was 7018.25[1] whereas we identified a major component with the experimental molecular weight of 7035. We have been able to confirm sequences where ambiguity has existed previously. Toxin I, the most abundant toxin in the venom of Dendroaspis polylepis polylepis has been reported with the N-terminal amino acid being postulated as pyroglutamic acid or glutamine. Our experimental molecular weight of 7133 confirms that pyroglutamic acid is the correct N-terminal group.

We have acquired a full scan CZE/ESI/MS run for *Dendroaspis polylepis polylepis* where we have obtained full scan spectra from 200fmole of proteins. We typically employ single ion monitoring for maximum sensitivity to aid detection of minor components. During CZE/ESI/SIM/MS experiments the maximum amount of any toxin injected is about 200 fmole (Toxin I, *Dendroaspis polylepis polylepis*). To further increase sensitivity we reduced resolution. Under these conditions we noted that some channels for adjacent masses showed peaks which co-migrated. At first we thought this resulted from overlapping masses due to the decreased resolution. However, full scan spectra acquired at reduced resolution show separation of the masses. This indicates that these

peaks result from homologs where the simple substitution of a non polar residue has occurred. The results obtained from CZE/ESI/MS of selected masses of *Hemachatus haemachatus* (Ringhals Cobra) venom at unit resolution support this hypothesis where the channels for m/z=1132 and m/z=1134.5 show peaks with identical migration times yet the channel due to m/z=1133 shows a single peak with a much longer migration time (Figure 1).

In our opinion CZE/ESI/MS provides a rapid means of interpreting the complex spectra arising from the snake venoms. The runs were routinely reproducible though column deactivation occurred with time. We believe that this indicates that CZE/ESI/MS can provide useful support to more traditional methods for approaching this type of problem.

ENHANCED DETECTION OF GLYCOPEPTIDES CONTAINING N-LINKED COMPLEX-TYPE GLYCANS

Zamas Lam and Barbara S. Larsen
The Du Pont Company, CR&D Experimental Station, Wilmington, DE 19880-0228.

Under ESI conditions, tryptic peptides can acquire +2 and +3 charge states, which are adequate for nominal mass measurement. For glycosylated peptides, however, the carbohydrate moiety increases the molecular weight significantly without providing additional charge sites, thus, moving the multiply charged ion envelope to a higher mass range and out of the most sensitive mass range of detection for quadrupole instruments. It is advantageous to chemically modify the glycopeptide with compounds containing tertiary amino group in order to move the multiply charged ion envelope to a lower and more sensitive mass range.

For a complete proteolytic digest, the glycoprotein needs to be denatured, reduced, and alkylated. This is achieved by reduction of the disulfide bridges followed by either carboxyl-methylation or pyridinyl-ethylation of the cysteine residues. Here, we demonstrate that

- vinylpyridine treatment (VP) of the reduced glycoprotein has significant advantages over the traditional carboxyl-methylation procedure (RCM).
- in order to get an accurate profile of the carbohydrate micro-heterogeneity on glycopeptides, an extra HPLC fractionation step is required to eliminate possible sample suppression of the glycopeptides.

Reduced carboxyl-methylated and pyridinyl-ethylated fetuin was digested with trypsin and individual glycopeptides were identified and isolated by comparing the HPLC chromatograms of the N-glycanase treated and the non-N-glycanase treated tryptic digests. The intact tryptic digest and the individual fractions (around 40 pmoles total injected) were analyzed separately. LC-ESI-MS was performed on a Finnigan TSQ 700 triple quadrupole with 5 second/scan from 200 to 1800 amu. A capillary C-18 reverse-phase column was used for the separation with an elution gradient from 0% B to 80% B in 20 minutes at 2μL/min and hold for 20 minutes. (Solvent A: 0.5% acetic acid. Solvent B: 20% water, 80% acetonitrile, 0.5% acetic acid).

The results indicate that VP treatment has three main advantages over the traditional RCM procedure. i) VP tryptic glycopeptides give higher charge states. ii) VP tryptic glycopeptides give more intense ion currents. iii) VP tryptic glycopeptides show a more complete profile of glycan micro-heterogeneity. The individual tryptic glycopeptide fractions also show a more complete profile than the total tryptic digest. This is probably due to sample suppression by the other peptides and glycopeptides. Furthermore, a tetra-antennary structure which has not been previously reported was observed in the LC-ESI-MS analysis of the individual tryptic glycopeptide fractions.

MATRIX-ASSISTED LASER DESORPTION MASS SPECTROMETRY AS AN INTEGRATED TECHNIQUE FOR BIOPOLYMER STRUCTURAL ANALYSIS

Ling Chen, Robert Mattaliano, Henrik Rahbek Nielsen*, Agneta Nylund*, Jacek Bielawski*
Applied Biosystems, Inc., 850 Lincoln Centre Drive, Foster City, CA 94404, USA
*Applied Biosystems AB, Box 150 45, 750 15 Uppsala, Sweden

INTRODUCTION

Matrix-assisted laser desorption (MALD)[1] mass spectrometry has rapidly evolved as a promising method for the biopolymer structural analysis laboratory. This technique is of particular interest due to the high sensitivity, extended mass range, high tolerance to contaminants commonly present in biological samples and accuracy exceeding more conventional high mass measurement methods, e.g., PAGE. The availability of molecular weight data is often the key element for the solution of biopolymer analysis problems when using structural information obtained by complementary methods. We have used MALD-MS in conjunction with a variety of separation methods, protein sequencing, peptide synthesis and amino acid analysis. This presentation includes MALD-MS data developed during routine analysis of proteins/glycoproteins, verification of synthetic MAP peptides (not shown), identification of N- and O-linked glycopeptides, and time-course monitoring of partial hydrolysis for C-terminal peptide sequencing.

EXPERIMENTAL

Mass spectrometry The mass spectrometer was a linear time-of-flight analyzer with a pulsed nitrogen laser (337 nm). Sample preparation for MALD-MS was as described by Beavis and Chait[2] using either sinapinic acid[2] or 2,5-dihydroxybenzoic acid (DHB)[3] as a matrix. Spectra shown in this poster were acquired at 20 to 28 kV acceleration potential in positive-ion mode from multiple laser shots.

Microbatch affinity binding for isolation of glycopeptides A 0.1 ml of Jacalin-Sapharose resin suspension was washed with binding buffer (175 mM tris-HCl, pH 7.5). The resin was resuspended in 200 µl of IgA digest mixture in binding buffer for 15 min and washed again with binding buffer. The bounded peptides were released from the resin using the extraction buffer (0.5M of Galactose). The glycopeptides were separated by HPLC.

Tsugita Chemistry for C-terminal sequencing of peptides Approximately 500 pmol of sample reacted with Pentafluoropropionic acid (Aldrich) 10% water, 5% Dithiothreitol (Sigma) in vapor phase[4]. The reaction was carried out at 90°C for 3 time points of 1, 2 and 4.5 hours.

RESULTS AND DISCUSSIONS

Identification of N- and O- linked glycopeptides

In our attempt to develop complete structural analysis of glycopeptides, MALD-MS was used as a key technique in combination with HPLC, CE, protein sequencing, chemical-derivatization and enzymatic methods. The following example shows a general approach to isolate and characterize N- or O- linked glycopeptides from proteins bearing complex type of carbohydrate chains.

The protein of interest, human IgA, was subjected to tryptic digest. The glycopeptide was isolated from the digest mixture using microbatch affinity binding and elution method using Jacalin-Sapharose. MALD-MS was employed to rapidly identify the fraction, and establish the heterogeneity of the CHO moiety (Fig. 1a). The detail CHO structure of this O-linked glycopeptide was not well-characterized at this time. Sequence analysis indicated five Serine glycosylation sites. N-linked high mannose glycopeptide can be isolated using the same approach with ConA-Sapharose. In the case of a glycopeptide from Rnase B, the CHO structure can be deduced from the mass of the glycopeptide using the sequence information and known high mannose structures (Figure 1b).[5]

Time-course monitoring for C-terminal sequencing using Tsugita Chemistry

MALD-MS is an ideal technique for peptide mapping, reaction monitoring due to its nature of high sensitivity, short analysis time, and relative low selectivity. We have applied this technique to monitor partial hydrolysis reaction suggested by Tsugita for C-terminal sequencing of peptides and proteins[4]. General observations from 6 peptides in our preliminary study can be summarized as follows.

- Fragments resulted from sequential loss of C-terminal amino acids were observed in most peptides tested. The fragments can provide useful C-terminal sequence information (Fig. 2a)
- Side reactions: N-terminus of Ser is the most fragile linkage (Fig. 2b). C-terminus of Asp fragments were reported by Tsugita Further C-terminal fragments from the side products may cause major complications in sequence deduction

The Analysis of Pentraxin Proteins by Electrospray Mass Spectrometry.

T. Hutton and M.A. McDowall, Fisons Instruments, VG BioTech, Tudor Road, Altrincham, WA14 5RZ, UK.M.B. Pepys, G. Noble and R Gallimore, RPGMS, Hammersmith Hospital, London, UK.

Introduction

The pentraxins are a family of plasma proteins conserved among all vertebrates. In man the two members are C-reactive protein (CRP) and serum amyloid P component (SAP).
CRP is present in low concentrations in normal healthy individuals, but is the classical acute phase protein with increased production in response to most types of infection, inflammation and tissue damage. CRP consists of five identical, 206 amino acid residue, non glycosylated polypeptide chains, which are non-covalently associated with cyclic pentameric symmetry.
SAP is not an acute phase protein but although it is present at rather stable levels its synthesis is highly regulated. Each molecule consists of 10 glycosylated polypeptide subunits arranged in two pentameric discs interacting face to face. Each subunit bears a single typical complex n-linked bi-antennary oligosaccharide chain, which is uniquely homogenous and invariant. SAP is the precursor of Amyloid P component (AP) which is deposited together with amyloid fibrils in all forms of amyloidosis.
The amino acid sequences of SAP and CRP and the glyco structure of SAP have been established by conventional techniques. However, there is some conflict as to whether residue 82 is a serine or a proline. This investigation using electrospray mass spectrometry (ESMS) was carried out to confirm the sequences by MW determination and to establish whether any modifications to SAP are associated with the development of amyloidosis.

Methods

CRP SAP and AP were isolated and purified by affinity and gel filtration chromatography. SAP was isolated from pooled normal human serum and malignant effusion fluid. AP was extracted from tissues of individual patients with amyloidosis. The purified samples were then analysed by Electrospray Mass Spectrometry on a Fisons Quattro-BQ in positive ion mode. The lyophilised samples were diluted to a concentration of 10-20pmol/µl with aqueous acetonitrile (50:50) with 1% acetic acid. A 5µl aliquot was introduced into the ionisation source at 5µl/min. Data was accumulated at 10 seconds/scan over the m/z range 1000-1900amu. The multiply charged ions produced were transformed by the MassLynx data system onto a true molecular mass scale. The mass scale was calibrated using the multiply charged ions from a separate introduction of a 20pmol/µl solution of bovine trypsinogen.

Results

The transformed spectra obtained from human CRP is presented in Figure 1. The major component has a MW of 23027Da.

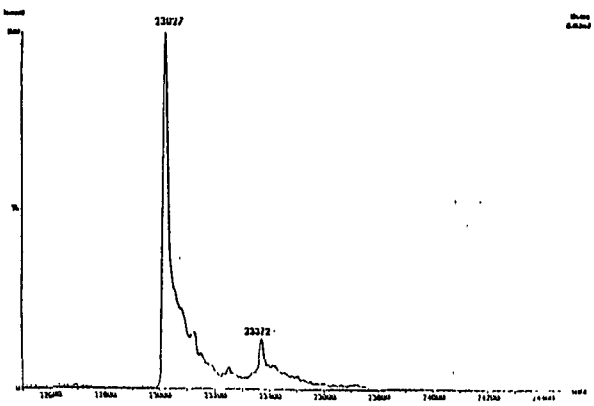

Figure 1.
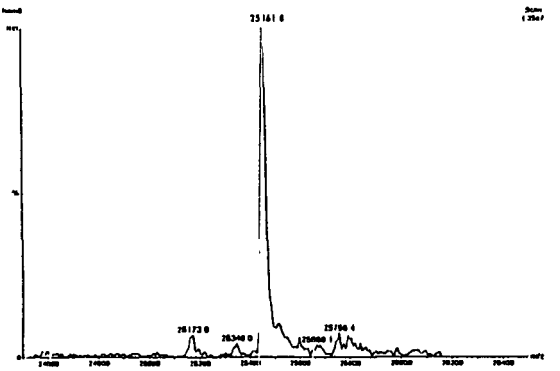
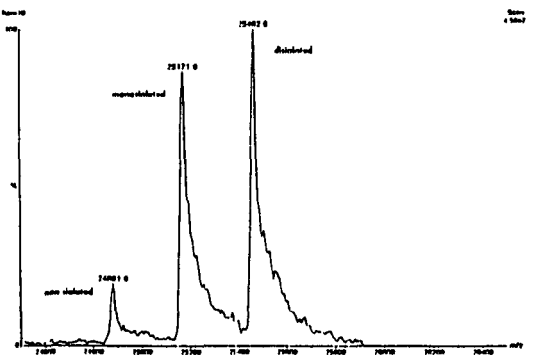
Human CRP

Figure 2 shows a comparison of data from SAP obtained from pooled normal serum and SAP purified from malignant effusion fluid. The major component observed in normal SAP had a MW of 25461 consistent with the disialated form of the glycoprotein. This particular SAP preparation from malignant effusion fluid however contained monosialated and disialated forms of the protein together with a non sialated form confirming earlier biochemical results. Other preparations from fluid closely resembled normal SAP.

Figure 2.
Normal serum SAP



Malignant effusion fluid SAP



The molecular weight of the major component of the AP isolated from amyloid deposits in tissues of three different patients was also consistent with the disialated form of the glycoprotein.

Conclusion

The results confirm the amino acid sequence of the subunit of human CRP and the presence of pyroglutamic acid at the n terminus.

The molecular weight determination of SAP from normal pooled serum confirmed the homogeneity in both protein composition and glycan structure. This data suggests that residue 82 is in fact a serine. One preparation of SAP obtained from malignant effusion fluid was found to differ in the extent of sialation of the biantennary glycan. Finally the AP isolated from amyloidosis patients contained the same major component as that purified from serum.

Mass spectral characterization of a bacterial prolyl endopeptidase by combined LC-MS and MS-MS#

S. Chevalier[1], P. Goeltz[1], *P.Thibault[2], D. Banville[3], J. Gagnon[1]

[1]:*Laboratoire de biologie structurale*, CEA and CNRS, URA 1333, DSV/DBMS, CEN-G 85 X, 38041 Grenoble, Cédex, France, [2]: Institute for Marine Biosciences, NRC, 1411 Oxford St. Halifax Canada B3H 3Z1, [3]: Biotechnology Research Institute, NRC, 6100 Royalmount, Montréal, Canada, H4P 2R2

Intracellular prolyl endopeptidases are ubiquitous proteases present in various vertebrate tissues such as human uterus, lamb kidney, porcine muscle as well as in the cells of mushrooms and bacteria. Prolyl endopeptidase cleaves specifically at the C-terminal side of proline residues irrespective of the composition of adjacent amino acids. A novel prolyl endopeptidase was recently purified from cultures of *Flavobacterium meningosepticum* [1]. Based on the sequence of tryptic fragments, two oligonucleotide probes were synthetised and used to select the gene encoding for this enzyme. This gene comprises a reading frame of 2115 base pairs, encoding the complete protein sequence of 705 amino acids. The ionspray mass spectrum of a purified extract of this enzyme is shown in Figure 1A. Using the multiply-charged ions observed in this spectrum, the calculated molecular weight of the native enzyme is 76784±7 Da. This molecular weight is about 2056 Da below the mass deduced from the nucleotide sequence and suggests that a signal peptide is cleaved to generate the mature enzyme. As for most serine proteases this prolyl endopeptidase can be inhibited by diisopropylfluorophosphate (DFP). The molecular weight of the inhibited enzyme is 76944± 7 Da (Figure 1B), and is consistent with the covalent binding of only one molecule of DFP per molecule of protein.

In order to confirm the sequence assignment determined by the cDNA cloning experiments, cleavage of the enzyme was conducted with cyanogen bromide (CNBr) and the resulting peptides were analysed by Liquid Chromatography coupled to ionspray Mass Spectrometry (LC-ISP-MS). The total ion chromatogram (m/z 700-1300) for this analysis is presented in Figure 2A along with the two-dimensional (time and m/z) contour map of ion intensity. As observed, abundant signals were obtained for all CNBr peptides including the largest fragment (1-201) having a molecular weight of 22982 Da. The observed masses were in good agreement with those expected from the proposed sequence. Similar analyses were conducted on the DFP-inhibited enzyme and permitted identification of the inhibitor binding site. Consistent with previous experiments using radiolabelled DFP, the active serine was found at position 536. The LC-ISP-MS analysis of the CNBr cleavage products also permitted confirmation of a disulfide bond between cysteine 608 and 641, as evidenced by peptides at mass 8257 and 8273 corresponding to the serine lactone and homoserine forms of peptide 591-666. Confirmation of the N-terminal amino acid sequence was obtained by the LC-ISP-MS analysis of the tryptic digest of the prolyl endopeptidase using selected ion monitoring. These experiments indicated the presence of both a pyroglutamate and free glutamine forms of tryptic peptide 1-7. The fact that these two forms were observed in the tryptic digest suggests that deamidation of the glutamine might have occured during storage in acidic conditions (0.1% TFA in water). In view of the mass accuracy achieved with ionspray mass spectrometry (typically 0.01%), the possibility of having glutamine at position 1 is further substantiated by the good agreement of the measured molecular weight (76784 Da).

The specificity of the native enzyme and the recombinant enzyme expressed in *E. coli* was investigated by monitoring the digestion of an octadecapeptide substrate using Capillary Electrophoresis coupled to ionspray Mass Spectrometry (CE-ISP-MS). The digestion was monitored every 25 minutes using each time only ≈ 20nL from a total sample volume of 30 µL. Identification of preferential sites of cleavage could be unambiguously identified for both the native and expressed proteases using the combined CE-ISP-MS analysis.

CAPILLARY CHROMATOGRAPHY/IONSPRAY TANDEM MASS SPECTROMETRY FOR THE CHARACTERIZATION OF PEPTIDES AND PROTEIN DIGESTS

Kevin J. Volk, J. Liu, M.S. Lee, S.E. Klohr, E. Kerns, and Ira E. Rosenberg,
Bristol-Myers Squibb Company, 5 Research Parkway, Wallingford, CT 06492-7660

The separation, analysis, and characterization of peptide mixtures such as those produced from protease digestions are a major focus in the bio-pharmaceutical industry. Peptide mapping techniques such as micro-column chromatography (micro-LC) and capillary zone electrophoresis can be used to quickly and efficiently separate complex biological mixtures. The high separation efficiency of micro-LC combined with tandem mass spectrometry is an extremely powerful approach for the structural characterization of peptides and protein in complex mixtures.

We have interfaced a modified micro-LC system to a SCIEX API III triple quadrupole mass spectrometer for the analysis and characterization of protein and glycoprotein digests. The utility of capillary (250μm i.d.) packed LC columns coupled with Ionspray tandem mass spectrometry is demonstrated with specific examples of protein digests. Here we demonstrate that the products of microscale enzymatic reactions with proteins and glycoproteins can be characterized by direct infusion, micro-LC/MS and micro-LC/MS/MS. Using a coordinated approach, this strategy provides information about proteins and glycoproteins such as molecular weight, amount of heterogeneity, carbohydrate content, sequence information, and sites of glycosylation.

The methodology is illustrated with a model glycoprotein, Ribonuclease B, shown in Figure 1. A comparison of the deconvoluted Ionspray mass spectra of the native protein and the product of peptide-N-glycosidase F (PNGase F)[1] treatment shown in Figure 1 illustrates the molecular weight, heterogeneity, and carbohydrate content information obtained in these studies. Some non-glycosylated form of the protein was present before enzymatic treatment. Since not all intact glycoproteins yield interpretable mass spectra without deglycosylation, a coordinated approach using a combination of enzymes such as trypsin and PNGase F followed by micro-LC/MS and micro-LC/MS/MS analysis provides complementary information such as carbohydrate composition, sites of N-linked carbohydrates, and sequence information. Figure 2 illustrates the full scan mass spectrum of a glycosylated tryptic fragment of Ribonuclease B. The spectrum has been averaged to include closely eluting glycoforms. As shown in Figure 3, treatment of this protein with PNGase F followed by trypsin digestion produces a deglycosylated tryptic fragment at m/z 476. Enzymatic treatment with PNGase F produces a mixture of deglycosylated protein as well as protein which contains a single N-acetylglucosamine residue attached to the asparagine. Therefore, a tryptic digest of this material will produce a deglycosylated tryptic fragment as well as a tryptic fragment with a single N-acetylglucosamine residue attached to the asparagine. These two products can be chromatographically separated since complete cleavage of the carbohydrate results in a conversion of the asparagine residue to aspartic acid.

In summary, these approaches can be used to obtain detailed peptide maps of proteins and glycoproteins providing molecular weight confirmation of tryptic fragments as well as partial sequence information. Methodologies were developed to characterize glycoproteins and sites of glycosylation and are applicable for the characterization other post-translational modifications as well as binding sites of monoclonal antibodies and their immunoconjugates.

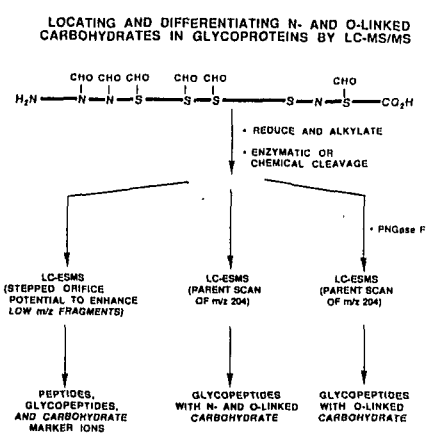
Selective Identification and Differentiation of N- and O-Linked Oligosaccharides in Glycoproteins by Liquid Chromatography-Tandem Mass Spectrometry

Steven A. Carr, Michael J. Huddleston, and Mark F. Bean
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

A tandem mass spectrometry-based method has been developed for selective detection at the low picomole level of glycopeptides in digests of glycoproteins. The technique involves collision-induced fragmentation of glycopeptides during liquid chromatography-mass spectrometry analysis to yield the $HexNAc^+$ fragment at m/z 204 (Huddleston et al., Proceedings of the 39th ASMS Conference on Mass Spectrometry and Allied Topics, pp. 280-281). This fragment derives from the GlcNAc or GalNAc sugar linked to the Asn, Ser, or Thr of the peptide chain, and it is produced by oligosaccharides of all commonly occurring structural classes. Glycopeptides may be selectively located in complex mixtures by detecting only those parent ions that fragment in Q2, the second collision region of the triple quadrupole, to produce an ion at m/z 204. This parent-ion scanning procedure has the advantage that only the $(M+H)^+$ ions of the glycopeptides are observed in the spectra, thereby removing interference from co-eluting peptides which often obscure the presence of the glycopeptides during normal LC-ESMS. Glycopeptides eluting during LC-ESMS analysis may, alternatively, be collisionally excited in the region between the sampling orifice and first quadrupole mass analyzer, to enhance formation of carbohydrate-related fragment ions (including m/z 204) in the otherwise normal mass spectra. The collisional excitation potential is increased to a level sufficient to induce fragmentation only during that portion of each scan in which the low mass, carbohydrate-related ions are being monitored. In this way carbohydrate-related fragment ions are produced with minimal distortion of the observed distribution of glycopeptide and peptide MW-related peaks. In addition to identifying glycopeptides in complex mixtures, these techniques enable the heterogeneity of the glycoforms at specific attachment sites, and the specific sequence context of the attachment site, to be directly assessed. N-linked carbohydrates are differentiated from O-linked by LC-ESMS/MS analysis of the digested glycoprotein prior to, and after selective removal of N-linked carbohydrates by PNGase F. Glycopeptide signals that disappear following PNGase F digestion correspond to peptides containing N-linked carbohydrates. Those glycopeptide peaks in the LCMS/MS data that are not affected correspond to O-linked glycopeptides.



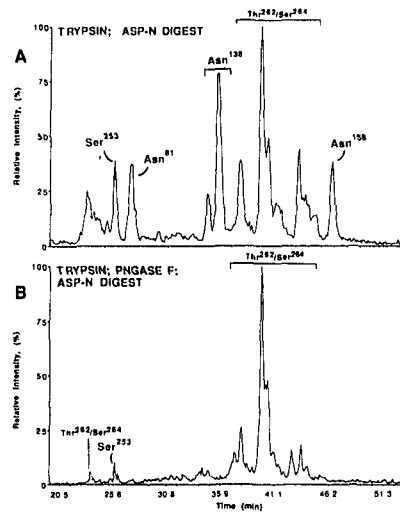


Figure 1 (left). Overview of strategy for locating and differentiating N- and O-linked carbohydrates.

Figure 2 (right). Comparison of the TIC traces from two separate LC-ESMS/MS parent ion scan experiments (parents of m/z 204) on 25 pmol injections of enzymatic digests of fetuin. Both N- and O-linked glycopeptides are detected in (A), whereas only the O-linked glycopeptides are observed after digestion with PNGase F (B).

The strategy is demonstrated for bovine fetuin, a 42 kDa glycoprotein containing three N-linked, and three O-linked carbohydrates. Triantennary Asn-linked carbohydrates with the general structure $(NeuAc)_3(HexHexNAc)_3Hex_3HexNAc_2$ were identified at Asn-81, 138, and 158. Some biantennary structures were also observed, primarily at Asn-138. The O-linked carbohydrates attached to Ser-253 have the general composition $(NeuAc)_l(HexHexNAc)_m$ with l,m = 1 (major) and 2 (minor). A glycopeptide spanning the region containing both Thr-262 and Ser-264 contains carbohydrate of aggregate composition $(NeuAc)_l(HexHexNAc)_m$ where l,m = 2 (major) or 3 (minor). Over 90% of the protein sequence was also corroborated by these LC-ESMS studies of fetuin at the low (≤ 25) picomole level.

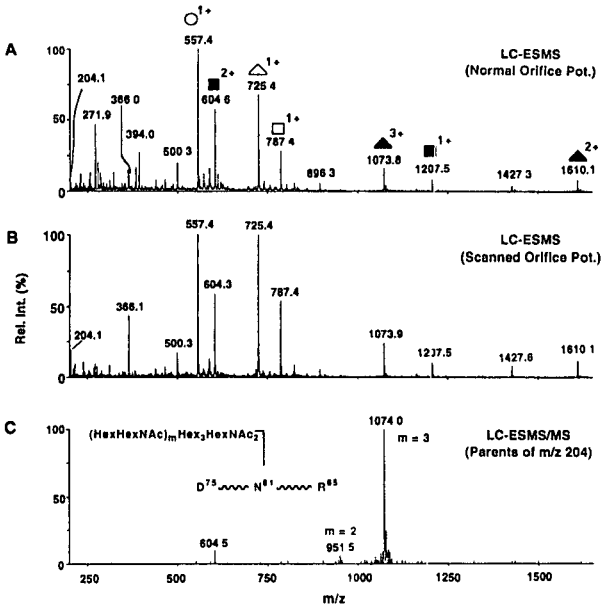

Figure 3. Electrospray mass spectra of the glycopeptide eluting at ca. 26 min. in the TIC traces shown in Figure 2. A) LC-ESMS using normal orifice voltage (65 V). Symbols identify a number of the parent species present. B) LC-ESMS performed with the orifice voltage ramped from 120 V at m/z 150 to 65 V at m/z 500; from m/z 500 to m/z 2000 the orifice voltage was held constant at 65 V. C) LC-ESMS/MS, scanning for parents of m/z 204 ($HexNAc^+$). All experiments were done under data system control.

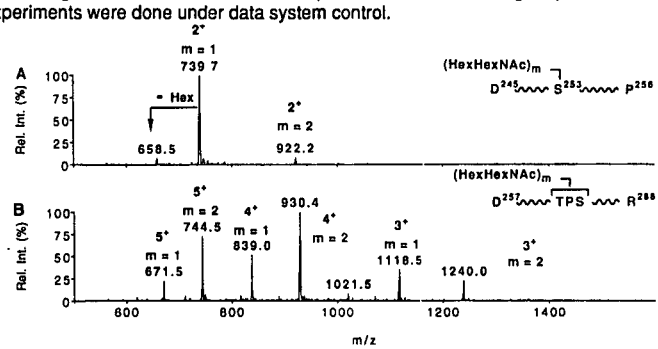

Figure 4. Parent ion scan electrospray mass spectra of the O-linked glycopeptides eluting at ca. (A) 25.6 min. and (B) 39.8 min in the TIC traces shown in Figure 2.

Intramolecular Disulfide Bond Formation and Stable Mixed Disulfides in a Zinc-finger Peptide Detected by Matrix-assisted UV Laser Desorption Time-of-flight and Electrospray Ionization Mass Spectrometry

T. William Hutchens, Mark H. Allen*+, Chee Ming Li, Gary L. Cook, Tai-Tung Yip

Protein Structure Laboratory, USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, 1100 Bates St., Houston, Texas 77030 and *Vestec Corporation, 9299 Kirby Dr., Houston, Texas 77054
+(present address: PE SCIEX, 55 Glen Cameron Rd., Thornhill, Ontario, Canada)

SUMMARY

Mass spectrometry of intact peptides and proteins now allows certain alterations in structure to be evaluated in minutes. We have evaluated mass spectrometric techniques to monitor the formation of *intra*molecular disulfide bonds within peptides and proteins. The 71-residue "zinc-finger" metal-binding sequence from the DNA-binding domain of the human estrogen receptor protein (ERDBD) contains nine cysteine residues. The formation of up to four intramolecular disulfide bonds within the ERDBD could be demonstrated by matrix-assisted UV laser desorption/ionization (MALDI) time-of-flight (TOF) and electrospray ionization (ESI) mass spectrometry (MS). Subsequent addition of either 2-mercaptoethanol or dithiothreitol resulted in the formation of stable peptide-reducing agent mixed disulfide bonds that were readily detected by either MALDI-TOF or ESI. Finally, by ESI, alterations in peptide conformation resulting from disulfide bond formation were detected as discrete alterations in the charge envelope.

INTRODUCTION

Knowledge of the rate and extent of intramolecular disulfide bond formation is important for our understanding of protein structure/function relationships. Rapid (min) and sensitive (<pmol) methods for the direct observation of *intra*molecular disulfide bond formation have not been available before now. Particularly, in the case of peptides and proteins capable of forming multiple intramolecular disulfide bonds, it has not been possible by chemical and spectroscopic methods alone to evaluate the specific distribution of a given peptide or protein with different numbers of disulfide bonds. Such information is important for the interpretation of protein structure and biochemical reactivity (e.g., metal binding).

We have demonstrated previously that peptide-metal ion complexes involving one or more N-ligands (His residues) are stable to the volatilization and ionization processes associated with both MALDI and ESI (1-6). Metal ion binding to "zinc-finger" sequences, however, involves cysteine residues. Although we have shown that peptide-metal ion complexes involving multiple S-ligands (Cys residues) are also stable to the ESI process (7-9), the correct metal binding stoichiometry depends on the redox state of each Cys residue involved (see ASMS abstract FOB 12:15). Thus, we have used MALDI-TOF and ESI to determine the redox state of the eight Cys residues which *define* the two C_2-C_2 type zinc-finger sequences within the DNA-binding domain of the human estrogen receptor protein (ERDBD).

EXPERIMENTAL

The 71-residue estrogen receptor DNA-binding domain (K180-M250) was prepared by solid phase chemical synthesis, purified, and characterized as described previously (7,8). MALDI was performed on a Vestec Model 2000 linear TOF mass spectrometer as described previously (1,5); sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) was used as a matrix for MALDI-TOF. ESI of the ERDBD in aqueous solutions was performed on a Vestec Model 201 single quadrupole mass spectrometer as described previously (7,8). The formation of intramolecular disulfide bonds within the ERDBD was followed by titration with Ellman's reagent (5,5-dithionitrobenzoic acid); the thiol-dependent production of nitrothiobenzoate anions was followed by absorbance at 412 nm.

RESULTS

The molecular mass observed for the ERDBD apopeptide in its fully reduced state (8248.4 ± 0.4 Da), determined by both MALDI-TOF and ESI, agreed with the calculated mass (8248.5 Da). To verify the reduced status of the ERDBD by MALDI-TOF, subsequent in situ oxidation of the ERDBD could be induced by the addition of Cu(II) ions directly to the dried sample on the probe tip. The formation of four intramolecular disulfide bonds was indicated by a reduction in mass to 8240.5 Da (2 Da per disulfide bond); as reported previously (5), peptide-bound Cu(II) ions are not observed with sinapinic acid as the matrix. Unfortunately, our attempts to use 2,5-dihydroxybenzoic acid as a matrix to evaluate the the fully reduced ERDBD by MALDI-TOF resulted in the formation of *multiple* covalent adducts, probably due to reactivity with reduced Cys residues.

Formation of intramolecular disulfide bonds within the ERDBD was routinely monitored by titration with 5,5'-dithio-bis-(2-nitrobenzoic acid) and by ESI. At neutral pH in aqueous buffers (purged with N_2), up to 3

intramolecular disulfide bonds were formed within 24 to 48 h. Formation of the fourth intramolecular disulfide bond was only observed after exposure of the ERDBD to elevated temperatures (37°C) or oxidant. Addition of excess reducing agent, either 2-mercaptoethanol or dithiothreitol, to the oxidized ERDBD resulted in the formation of multiple peptide-reducing agent mixed disulfide bonds (e.g., Figure 1). These mixed disulfide bonds were observed regardless of reaction time (up to 24 h) or temperature (24° to 37°C).

CONCLUSIONS

MALDI-TOF and ESI represent rapid (min) and sensitive (<pmol) new methods for determining the rate and extent of intramolecular disulfide bond formation within intact peptides and small proteins. In the case of the ERDBD, where bioactivity is closely related to Cys residue stability, we found MALDI-TOF and ESI particularly useful to monitor experimental variables affecting the kinetics and extent of intramolecular disulfide bond formation. This is the first demonstration of intramolecular disulfide bond formation within the ERDBD.

Detailed Structural Characterization of Glycoprotein N- and O-Linked Glycans by ESI and CID

S.H. Stephen Chan, Bruce B. Reinhold and Vernon N. Reinhold
Department of Nutrition, Harvard University School of Public Health, Boston, MA 02115

Biofunctional relationships of selected glycoproteins have been directly attributed to their attached glycan structures. In part, these residues have been shown to stabilize the conformation of proteins to the extremes of pH and temperature, serve as protectors to enzymatic degradation, direct folding during biosynthesis and serve as directing entities during trafficking. Several recent studies have reported that these glycan attributed activities can be related to a specific carbohydrate glycotype and glycoform. In the recent years, the important roles of carbohydrates to our physiological systems have been recognized by the intense interest in the development of carbohydrate-based drugs. Because of the complexity of many glycan structures, detailed structural analyses of glycans derived from biological samples can be an enormous challenge. In this work, chemical derivatization coupled with electrospray ionization (ESI) and collisionally induced dissociation (CID) were used to obtain detailed structural information for both N- and O- linked glycans. This technique is applicable to lipophilic as well as hydrophilic samples.

The N-linked glycans studied in this research are high-mannose types derived from protein of soybean. The enzymatic method used for de-glycosylation produces glycans with only one N-acetylglucosamine structure at the reducing terminals. The structural analysis of O-linked glycan is based on samples of digested fragments of glycopeptides derived from Erythropoietin (EPO). For the N-linked glycans, two different schemes of chemical derivatization were used in this study. The first scheme involves permethylation which allows the elimination of hydrophilic residues, such as salt and protein fragments, through solvent extraction. The second scheme involves sequential steps of periodate oxidation, sodium borohydride reduction and permethylation (1). It is primarily used to enhance the molecular specificity available for mass measurement.

Solution of methanol / water (7:3 by volume) containing 1 mM of sodium acetate was used as buffer for the analysis of all the N-linked glycans using ESI. Molecules adducted with two Na^+ are found to be the predominant ions for all the high-mannose glycans studied. The ESI/MS spectrum indicates that our N-linked sample contains high-mannose glycans with the number of mannose residues ranging from four to nine. Under our experimental ESI/MS conditions, the detection limited for the permethylated N-linked glycans is at the low femtomole level. Detailed structural information for each glycoform is then obtained from CID of the doubly charged ions using a Finnigan TSQ-700 triple stages quadrupole mass spectrometer. Figure 1 shows the daughter spectrum derived from the glycoforms containing eight mannose residues. On the bases of the CID fragment ions derived from the natriated parent cations (m/z = 985.1), different isomeric structures are identified. The structural assignments are further confirmed by our CID study using deuterium-labelled analogs.

Mass spectrum derived from ESI/MS of the periodate oxidized, borohydride reduced and permethylated N-linked glycans are shown in figure 2. The derivatized samples clearly allow two types of isomers to be distinguished for the glycoforms containing five and six mannose residues. For the O-linked glycopeptide, the fragment daughter ions (figure 3) derived from the CID of the quadruply protonated parent cations allow the glycan structure to be identified.

In summary, we have found that permethylation coupled with ESI/MS allows N-linked high-mannose glycans to be detected at a detection limit well below other traditional techniques. The combined mass spectrometric information derived from CID study of the permethylated samples and ESI/MS study of the periodate oxidized, borohydride reduced and permethylated samples allows detailed glycosidic structural information to be obtained from only a trace quantity of analyte.

CHARACTERIZATION OF WATER SOLUBLE ORGANIC COMPOUNDS BY MASS SPECTROMETRY

*Tanya M. Lewis and David Russell
Department of Chemistry, Texas A&M, College Station, TX

Water quality remains a primary concern for industry, municipalities and government regulatory agencies. Water soluble organics pose one of the most important risk factors; however, because of the extreme complexity of the sample and low level concentrations, identification of water soluble organics compounds is a challenging analytical task.

The primary target of the current work is on the identification of naphthenic acids and related compounds. The analysis of naphthenic acids is of interest as a source of geochemical correlations and biodegradation mechanisms in crude oils.

Research is needed to devise techniques for identifying ppm and ppb levels of complex water soluble organic compounds. In this laboratory we are developing GC/MS, tandem mass spectrometry, high resolution mass spectrometry, positive and negative FAB methodologies for structural characterization and identification of aqueous organic materials.

The present emphasis of this work is to develop a synergistic approach using multiple methodologies. Each of the discussed methodologies provides a different perspective. The results produced using data from GC/MS and High resolution mass spectrometry together with a powerful probability based matching program, BenchTop/PBM, will be presented.

Figure 1 depicts a total ion chromatogram of water soluble organics used in this study. The complexity of the sample and high background interference as shown in this graph present major problems for elemental and structural identification based on GC/MS data alone.

Unknown mass spectral data from the GC/MS were tabulated and entered into a computer algorithm for matching unknown spectrum against reference spectral files. BenchTop/PBM was the software program used to reverse research the GC/MS output against the Wiley Registry. Probability based matching reports generate "hits", or best spectral matches for the unknown. The feasibility of the hits was confirmed by high resolution mass spectrometry.

Figure 1

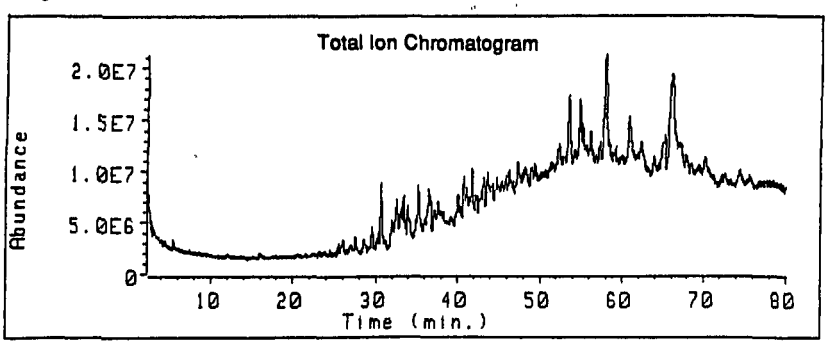

Figure 2 depicts the unknown spectrum and the best spectral match generated through PBM. Visually the peaks from m/z 149 down, compare very well. 149 is the fragment ion produced from the loss of methyl from the reference compound. The unknown spectrum contains a peak at m/z 180. The 31 mass unit difference could be attributed to presence of a methoxy group. The conclusion from this data is that the unknown spectrum is produced from a compound very similar to the reference compound, differing in the loss of methyl and the addition of a methoxy group. High resolution Mass spectrometry was used to confirm this finding.

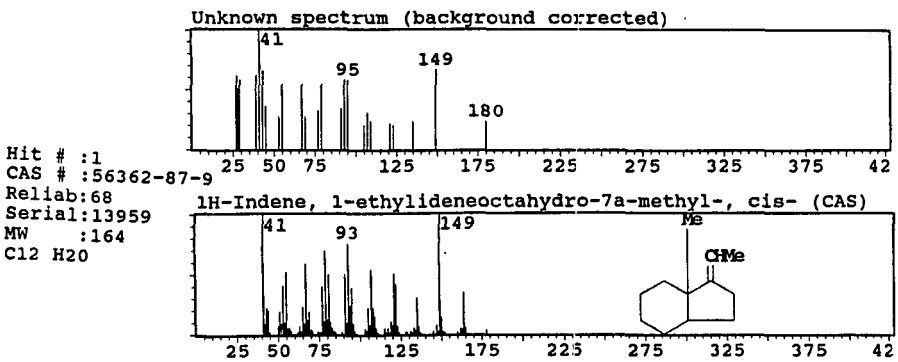
Determination of molecular composition by accurate mass measurements was accomplished with the double focusing magnetic sector mass spectrometer operated at high resolution, (10,000). A computer algorithm assigned empirical formula to sample peaks. The error in mass measurement and chemical valence requirements assisted in final elemental assignment. The high resolution results confirmed the presence of an ion at m/z 149 of the elemental composition $C_{11}H_{17}$. The elemental composition of the peak at m/z 180 was found to be $C_{12}H_{20}O$. These findings increase confidence levels in identifying unknown spectra.

The two mass spectrometry methodologies coupled with the BenchTop/PBM comprise a logic triangle. Spectra from the GC/MS are entered into the probability based matching program. PBM hits are confirmed with high resolution. Each of the three sides of the triangle is capable of analyzing the unknown from a different perspective. The triangular approach increases the inherent power of these instruments and methodologies.



OPTIMIZATION OF A PCB ANALYSIS USING AN ION TRAP MASS SPECTROMETER

Karen Salomon and Sidney E. Buttrill, Jr., Edward L. Ginzton Research Laboratories, Varian Associates, 3075 Hansen Way, Palo Alto, CA 94304-1025.

We have improved the analysis of dilute samples in the presence of an interfering matrix by optimizing the operating parameters of an ion trap. The sensitivity of a GC-ion trap system is reduced when too many matrix ions are trapped together with sample ions. We have achieved better detection limits by adjusting the parameters of the ion trap mass spectrometer to reduce the number of trapped ions arising from the co-eluting matrix. Our procedure has been applied to the analysis of five PCBs (dichlorobiphenyl, tetrachlorobiphenyl, hexachlorobiphenyl, octachlorobiphenyl and decachlorobiphenyl) in a 1.0% transformer oil solution.

Two strategies were employed to improve the performance of the system. In the first, the range of masses scanned is reduced so that more microscans per scan are performed. By increasing the number of microscans per scan, the ion trap is emptied and filled more frequently, leading to an increase in the total number of ions measured. A full mass range (FMR) scan typically covers 50 to 650 daltons with 3 microscans per scan. A narrow mass range (NMR) scan covers a mass range of at least 60 daltons that includes the parent PCB ion; the number of microscans per scan increases to eight. By using NMR, measured signal-to-noise ratios for the five PCBs are improved by a factor of two over those measured for the same sample run under FMR.

The second method used for maximizing the sensitivity of the PCB analysis was to raise the rf storage level. Typically, the ion trap stores all ions from 20 to 650 daltons. For the PCB sample studied, most of the ions generated are low mass ions from the hydrocarbon transformer oil. The sample ions are a small fraction of the total number of ions in the trap. It is possible to raise rf storage level so that the lower molecular weight ions are not trapped. By not storing low mass ions, the ionization time as set by the automatic gain control increases to fill the trap with higher mass ions. More sample ions relative to transformer oil ions are created and trapped. As a result of raising the rf storage levels from 20 to 145 daltons, the signal-to-noise ratios for the PCBs increase because of the extended ionization time (Figure 1).

The rf storage level cannot be increased indefinitely, because the trapping efficiency decreases at high rf values. In Figure 2, the signal intensities of five ions from perfluorotributylamine (a compound used for mass calibration) are plotted as a function of rf storage level. The signal intensities of the m/z = 69 and m/z = 131 ions drop to zero at rf levels greater than 64 and 128 respectively. For the higher mass ions, a slight decrease in signal intensity is observed as the rf storage level is increased beyond 64 daltons. Optimum sensitivity should occur when the rf storage level is set between 64 to 145 daltons, a region where the decrease in trapping efficiency is compensated by the increased ionization times.

Detection limits were determined using the EPA-suggested method (1) for all five PCBs in a 1% transformer oil solution. Samples were injected onto the GC without prior clean-up. Best detection limits were obtained at storage levels of 74 daltons or greater, where the majority of oil ions were no longer stored. The following values were obtained: 8 pg/µl for 2,6-dichlorobiphenyl (at 102 daltons); 5 pg/µl for 2,2',6,6'-tetrachlorobiphenyl (at 145 daltons); 3 pg/µl for 2,2',4,4',6,6'-hexachlorobiphenyl (at 74 daltons); 1 pg/µl for 2,2',3,3'5,5'6,6'-octachlorobiphenyl (at 74 daltons); and 7 pg/µl for decachlorobiphenyl at (102 daltons). These detection limits are comparable with those obtained using a GC-ECD system where detection limits of 2 to 8 pg/µl have been reported using clean samples in hexane solutions (1). A benefit of using GC-MS analysis over GC-ECD is that analytes may be positively identified. Even under the conditions of a narrow mass range scan of 60 daltons, it is possible to perform library searches and obtain correct identification of these compounds as PCBs.

Sensitive Detection of Targeted Volatile Organics by Direct-Sampling Ion Trap Mass Spectrometry*

G.B. Hurst, R.L. Hettich, M.B. Wise, R.N. Nodine*, M.V. Buchanan, and M.R. Guerin
Analytical Chemistry Division and *Instrumentation and Controls Division
Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge TN 37831

The need for rapid and sensitive analytical methods to measure volatile organic pollutants in environmental samples, such as water and soil, is growing as remediation progresses at numerous waste sites. Current regulatory methods include a lengthy gas chromatographic step. Rapid screening methods are being developed using direct-sampling ion trap mass spectrometry (DS-ITMS), which involves no GC step, taking advantage instead of selective ITMS operating modes to identify specific components of a sample.

The two-dimensional nature of the GC-MS measurement (retention time and m/z) provides selectivity enhancement over either technique used alone. For DS-ITMS methods, the retention time variable is eliminated, so mixture components can interfere with one another by yielding ions at common m/z values. However, reasonable selectivity can be maintained by cycling through different ITMS operating conditions, each set of which is sensitive only to a selected class of compounds. In practice, for site remediation, a limited number of volatile contaminants is present, so the full resolution of GC-MS methods is not necessary.

The experimental apparatus consists of a Finnigan ITMS interfaced directly to a water purge device. The sample, contained in a standard 40 mL VOA vial attached to the purge device, is sparged with helium at a flow rate of 100-150 mL/min. A portion of the helium purge gas, containing purged volatiles and water vapor, flows into the ITMS through a restricting capillary. Because no hardware modifications are necessary, mass spectra can be obtained under a variety of EI and CI conditions for a single sample. Spectra are obtained by cycling through a set of scan functions, each of which acquires a mass spectrum under different conditions. The time to cycle through, for example, a dual EI-CI scan function is approximately three to four seconds. Data acquisition for a given sample continues until the signal due to the volatiles decreases below the noise level, indicating exhaustive purge of the volatiles from the sample.

Figure 1 shows mass spectra obtained from a single water sample by alternating between proton transfer CI (using water as the reagent gas) and EI conditions. This sample was a mixture of three halogenated hydrocarbons (vinyl chloride, trichloroethene, and tetrachloroethene) and three aromatics (benzene, toluene and xylene). The CI spectrum shows prominent $(M+H)^+$ ions due to the aromatics, with minor contributions from the halogenated compounds. The EI spectrum shows mostly molecular ions for trichloroethene and tetrachloroethene, and fragment ions from the aromatics. The CI spectrum is thus selective for the aromatics because it discriminates against the chlorinated aliphatics, and, because there is virtually no fragmentation of the aromatics, more confident identification of the species present is possible. The EI spectrum provides good sensitivity, as well as specificity due to Cl isotope distributions, for the chlorinated compounds.

A second application of multiple-scan-function data acquisition uses three scan functions: a short-ionization-time (low sensitivity) EI function, a long-ionization-time (high sensitivity) EI function, and a charge exchange (CE) CI function. The CE CI ionization mechanism exploits the presence of atmospheric oxygen in the headspace of the purge apparatus when a new sample vial is placed on the inlet. Calibration curves for the high-sensitivity EI and CE CI scan functions are nonlinear above 150 ng/mL. At low concentrations, however, these two scan functions provide enhanced sensitivity relative to the low-sensitivity EI scan function. Figure 2 compares purge profiles for CE CI and low-sensitivity EI conditions obtained from a sample containing tetrachloroethene. Note the higher signal-to-noise ratio for the CE CI scan function. The sharper purge profile for the CE CI scan function is due to dilution of the oxygen reagent gas in the purge device headspace by helium as the purge proceeds. Work is in progress to mix oxygen with the helium purge gas so the CE reagent will be present during the entire time the analyte is being purged.

Finally, proton transfer CI and CI MS-MS spectra were obtained for samples containing benzene and alkylbenzenes. The CI scan function identifies the alkylbenzenes present, while distinct progeny ion spectra resulting from MS-MS of m/z 107 allow one to distinguish ethylbenzene from the xylenes.

DS-ITMS is potentially very useful for rapid, accurate and sensitive determination of volatile organic contaminants in water. Eliminating the GC step prior to the mass spectrometric analysis yields a considerable time savings, and the selectivity thus sacrificed can be compensated for by using ITMS scan functions that are selective for target analyte classes.

MASS SPECTROMETRY OF NOVEL METABOLITES OBSERVED FOR TRANSFORMATION OF DICLOFOP-METHYL IN A MODEL AQUIFER

J.V. Headley[a], P.W. Brooks[b], J.R. Lawrence[a] and B.N. Zanyk[a]. [a]National Hydrology Research Institute, 11 Innovation Boulevard, Saskatoon, Saskatchewan S7N 3H5. [b]Institute of Sedimentary and Petroleum Geology, Geological Survey of Canada, 3303 - 33rd Street, Calgary, Alberta, Canada T2L 2A7.

Diclofop-methyl, the common name for the herbicide 2-[4-(2,4-dichlorophenoxy)phenoxy]propionate, is used to control graminaceous annual weeds such as wild oats, green foxtail, and witch grass primarily in wheat, barley and soybeans. Environmental assessment of this herbicide has concentrated on the parent compounds, however there is increasing evidence for the importance of metabolites. For example several non-identified metabolites of diclofop-methyl were reported in earlier field studies[1,2]. It is not known whether the identification of these metabolites would indicate important pathways essential for understanding the degradation process. Thus, in this study, the degradation of diclofop-methyl was re-examined under isothermal steady state conditions in a laboratory aquifer model[3], using GC/MS broad spectrum analysis[4].

Experimental

A full description of the design and evaluation of the meso-scale model vadose zone and ground water system is given elsewhere[3]. Soil samples were extracted using a solution consisting of acetonitrile+water+acetic acid (70+28+2 by volume) as in the procedure described by Smith[1]. Off-line GC/ECD conditions were established for quantification of diclofop-methyl. Electron impact GC/MS analysis was used for identification of metabolites, MS/MS studies of which were performed to elucidate possible degradation pathways. The GC/MS/ECD conditions utilized a Hewlett Packard 5970 GC/MSD equipped with TARGET software and a UNIX Chem Station. All identifications were based on (a) retention time data and electron impact data obtained for commercial standards, (b) mass spectral library searches and (c) fundamental principles of interpretation of mass spectra. GC/MS conditions utilized a Supelco 30 m DB-5 column, internal diameter 0.33 mm, film thickness 0.25 μm, helium carrier gas 1 ml/min, injector 280°C, transfer line 300°C, temperature program 150°C/5 min at 10°C/ min - 280°C/7 min. Off-line GC/ECD conditions utilized a Hewlett Packard 5980 gas chromatograph equipped with a Supelco 15 m fused silica DB-5 column, internal diameter 0.534 mm, film thickness 0.5 μm, helium carrier gas 4.5 ml/min, with the column profile: 60° C for 1 min, temperature program 15° C/min to 280° C, and final temperature hold for 4.0 min. GC/MS/MS experiments were conducted using a hybrid VG 70S mass spectrometer with EBQQ geometry.

Results and Discussion

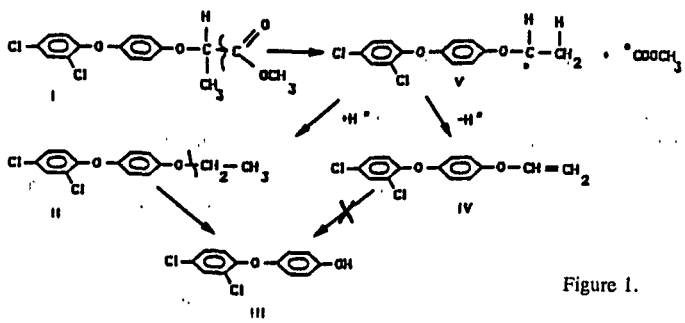

Figure 1.

Apart from diclofop acid (detected as the methyl ester) the degradation products were observed at trace levels. Although this is consistent with earlier field experiments[1,2], the metabolites identified for the laboratory experiments were significantly different from those reported[1,2]. The major differences were:

(a) preferential formation of a dichlorodehydrophenetole (IV) metabolite instead of the corresponding dichlorophenetole (II) and a phenolic degradation product (III), and
(b) formation of chlorinated metabolites of benzoic acid (VI).

The daughter-ion scan of the molecular ion of diclofop-methyl indicated that predominant cleavage of the side chain of diclofop-methyl in the ion-source occurred via neutral losses of free radicals with 59 and 87 a.m.u.

Daughter-ion scan of diclofop-methyl molecular ion m/z 340.

Ion	M/Z
M	340 (100)
M - CO_2CH_3	281 (15)
M - $CH(CH_3).CO_2CH_3$	253 (27)

M is the molecular-ion; ion-abundance (%) given in parenthesis.

Assuming that the degradation of diclofop-methyl in soil is likewise dependent on bond energies, reaction kinetics and thermodynamic properties of the transformation products, metabolites may also occur via similar free radical intermediates. For example, the GC/MS and MS/MS data are consistent with the mechanism given in Figure 1. As indicated, the formation of the phenetole and dehydrophenetole may occur via a common intermediate (V) involving transformation by hydrogen atom abstraction or transformation by hydrogen atom elimination. Based on the observed relative abundances of the metabolites in the GC/MS total-ion profiles, the dehydrophenetole is resistant to transformation to the more polar metabolite 4-(2,4-dichlorophenoxy)phenol. This is in marked contrast to the phenetole which is susceptible to this transformation (Figure 1). The observed transformation of diclofop-methyl to the chlorinated metabolites of benzoic acid, do not appear to occur by simple unimolecular dissociations as evidenced by the results of the daughter-ion scan. These transformations may involve complex rearrangements and /or reactions with other contaminants present in the soil. If the formation of the chlorinated benzoic acids occurred via free radical intermediates, contaminants present in the soil could participate as free radical scavengers as indicated in Figure 2. In the mechanism proposed, plasticizers (phthalate esters present as ubiquitous contaminants), compete for radical intermediates to form chlorinated metabolites of benzoic acid. Preliminary data indicated that in the absence of phthalate esters, chlorinated metabolites of benzoic acid were not observed.

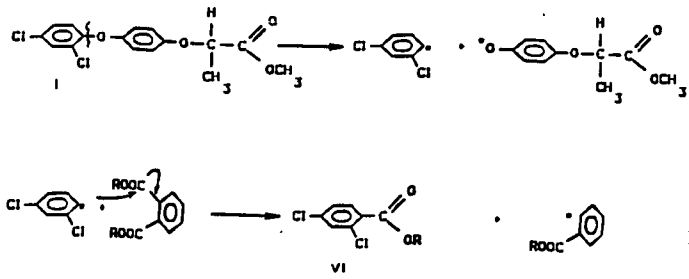

Figure 2.

Conclusion

The novel metabolites observed for laboratory experiments indicated that free radical intermediates may play an important role in the degradation of the herbicide. The formation of chlorinated metabolites of benzoic acid has major implications for remediation of the parent compound. It appears that chlorinated intermediates can undergo transformations via reaction with free radical scavengers present in soil. It is therefore critical to (a) establish the identity of metabolites and (b) develop models to predict the conditions under which transformations occur.

CE/MS DETERMINATION OF INORGANIC ANIONS AND CATIONS USING ION SPRAY WITH A SHEATH FLOW INTERFACE

Jack Henion and Thomas Huggins, Drug Testing and Toxicology, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Introduction

The determination of inorganic anions and cations is important in many environmental, biological and industrial arenas. Historically ion chromatography (IC) has been the separation technique of choice to separate small inorganic species. Recently, however capillary electrophoresis (CE) coupled with indirect UV detection has shown impressive speed and separation efficiency for many inorganic ionic species [1,2]. Although CE with indirect UV detection would be adequate for many applications there are times that the sensitivity and selectivity of a mass spectrometer would be beneficial for the identification of unknowns and/or co-migrating peaks. In the present study we have investigated the utility of CE/MS using a sheath flow ion spray interface coupled to an atmospheric pressure ionization MS in the determination of inorganic ions.

Experimental

A Sciex TAGA 6000E triple quadropole mass spectrometer upgraded to an API III was operated in either the positive or negative ion detection mode with unit mass resolution (10% valley definition). The mass spectrometer was coupled to a Beckman P/ACE 2050 capillary electrophoresis instrument fitted with a 50mm I.D. x 100 cm separation capillary. A sheath flow interface was utilized for coupling the CE to the mass spectrometer. The sheath buffer was composed of 2 mM ammonium acetate in methanol (pH 6.7) and was delivered at 8ml/min. The CE buffer used for the analysis of cations was a solution of 30 mM creatinine and 8 mM 2-hydroxyisobutyric acid (HIBA), pH 4.8. The analysis of anions required a buffer composed of 5 mM Cr_2O_7, 10 mM ammonium acetate and 20 mM diethylenetriamine (DETA), pH 9.7. Normal polarity was used for cation analyses while reversed polarity was used for the separation of anions.

Results and Discussion

A synthetic mixture containing 12 different cations was separated in 12 min and detected in the full scan positive ion mode. Figure 1 shows the total ion current profile (upper panel) and total extracted ion current profile (lower panel) for 300 pg of each cation. The detection of as little as 30 pg/cation has also been accomplished when operating the MS in the full scan mode. The usefulness of CE/MS for detection of metal ions in real samples was tested by analyzing used aircraft engine oil. The results shown in Figure 2 indicate that Pb, Ni and Cr are present in used aircraft oil. These same metals were absent from new aircraft engine oil. The ability of CE/MS to separate and detect anions from a synthetic mixture is also illustrated. Currently,our ability to detect anions lags behind that of cations. The culprit appears to be the CE buffer (Cr_2O_7) which gives rise to an extremely high chemical background. This background has inhibited full scan negative ion detection and has hampered detection of various inorganic anions when operating in SIM mode.

Real-Time Detection of Airborne PCP by Mobile APCI MS/MS

Nicholas S. Karellas, Gary B. De Brou and Andy C. Ng
Air Resources Branch, Ontario Ministry of the Environment
880 Bay Street, Fourth Floor Toronto, Ontario M5S 1Z8, Canada

Pentachlorophenol (PCP), which is widely used as a wood preservative, is known to cause lung, liver and kidney damage. At elevated temperatures, PCP has a very pungent odour. In 1989 while monitoring emissions from a wood treatment facility using a mobile single quadrupole MS system, trace amounts of PCP were detected. Since that incident, a technique of measuring ppt levels of airborne PCP on-site was developed. This monitoring technique combines a preconcentrator and a mobile triple quadrupole mass spectrometer, the TAGA 6000 MS/MS, which is capable of detecting PCP in real-time. The technique was recently used to monitor PCP emissions from a wood treatment plant.

The TAGA is remarkably sensitive to most chemical compounds, however its response to PCP at ppt levels is not sufficient for real-time detection. Thus, a simple sampling device is used to concentrate PCP for immediate analysis by the mobile TAGA. This device, an automated short term adsorber (ASTA), consists of two nichrome probes which are coated with a chromatographic stationary phase. The probes can be rotated to place them alternatively in the adsoption or desorption position. PCP molecules adsorbed to the probe are thermally desorbed into the TAGA's ionization chamber where positive and negative PCP ions are formed. These ions are mass-analyzed by the TAGA's quadrupoles. The time required to complete one full adsorption/desorption cycle, or analysis, is 2 minutes.

The basic operation of the TAGA is governed by the principles of APCI (atmospheric pressure chemical ionization) tandem mass spectrometry. Parent ions, formed in the APCI region, pass through an orifice into the vacuum chamber where they are separated by the first quadrupole and fragmented under collision activated dissociation (CAD) with argon gas in the RF only second quadrupole. The resultant fragments, or daughter ions, are analyzed by the third quadrupole and detected by a channel electron multiplier.

The ion chemistry of PCP under APCI conditions is relatively simple: PCP molecules, M, undergo charge transfer reactions with benzene to yield M^+ positive ions; H-abstraction reactions yield $(M-1)^-$ negative ions and rearrangement reactions produce $(M-HCl+O)^-$ negative ions. Owing to the ^{35}Cl and ^{37}Cl isotopes and the five Cl atoms in the PCP molecule, positive ions at 264, 266, 268, 270, 272 and negative ions at 263, 265, 267, 269, 271, 244, 246, 248, 250, 252 amu are observed. Ion signals corresponding to all five Cl atoms being ^{37}Cl, are negligible. The relative signals of the positive PCP ions are shown in Figure 1. Similar MS spectra are also obtained for the negative ions. Under CAD conditions, daughter ions are formed via loss of CO, Cl, HCl and Cl_2. The CAD spectra of the parent positive ion at 266 amu corresponding to one of the five Cl atoms being ^{37}Cl is shown in Figure 2. Unlike positive ions, fragmentation of negative ions under CAD conditions is not significant. When PCP levels are so low that signals are not sufficient for MS/MS analysis, only MS is employed to monitor the negative ions $(M-1)^-$ and $(M-HCl+O)^-$.

Identification of PCP is achieved by comparing daughter ion spectra of ambient air samples to a standard TAGA CAD library spectrum of PCP. In this work both MS and MS/MS were used to monitor negative and positive PCP ions respectively. When single MS is used, identification is based on the chlorine isotopic ratios.

Quantitation of PCP is accomplished by injecting aqueous standards upstream of the adsorbing probe via a heated nebulizer at 300 °C. Vapourized PCP is mixed with the ambient airflow then trapped

by the ASTA's adsorption probe for subsequent desorption and analysis. Nebulizer injection flow rates from 0 to 20 μL/min generated a PCP concentrations range of 0 to 5 ppb in the APCI source. Five-point calibrations are performed for determining the response factors of selected PCP ions. The lowest TAGA detection limit for PCP was 20 ng/m^3 (2 ppt).

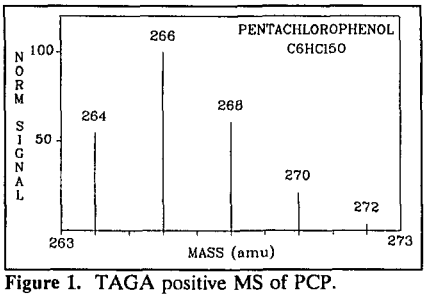

Figure 1. TAGA positive MS of PCP.

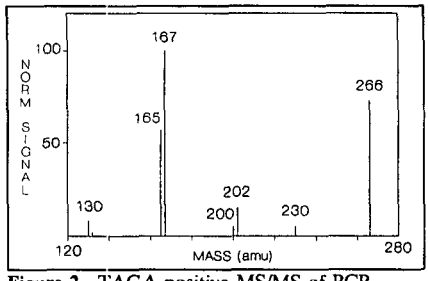

Figure 2. TAGA positive MS/MS of PCP.

MS analysis was used in the determination of ambient PCP levels near a wood treatment plant. Utility poles are immersed in a hot bath of PCP and oil mixture for several hours. Treated poles are removed for drying on-site in an open area. Odours are emitted mainly from freshly treated poles. Mobile air monitoring was conducted to assure compliance of the Ministry's PCP guidelines for allowable ambient levels. PCP was measured by the TAGA at several locations of various distances from the plant. Elevation in PCP levels was observed near freshly treated poles. PCP was also detected as far as 1 km from the plant. A half-hour average concentration of PCP based on 15 consecutive 2-minute real-time measurements is shown in Figure 3. A plot of several half-hour average concentrations as a function of distance from the plant is shown in Figure 4. Modellers can use such information to predict the effects of emission rates and meteorology on ambient downwind concentrations. The mobile TAGA real-time data can be used to validate theoretical models. For ground level emissions theoretical curves do in fact exhibit similar characteristics to curves synthesized from the TAGA data.

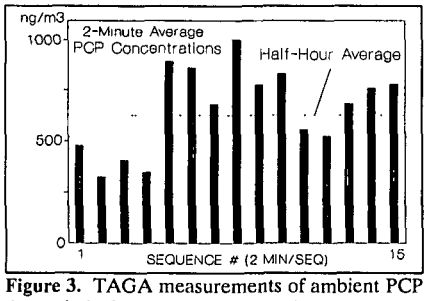

Figure 3. TAGA measurements of ambient PCP downwind of a wood treatment plant.

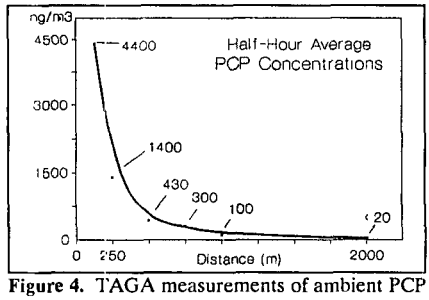

Figure 4. TAGA measurements of ambient PCP versus distance from a wood treatment plant.

PCP can be measured by the TAGA under APCI conditions either in positive or negative mode. In positive mode, both MS and MS/MS may be used. The MS/MS spectrum of PCP is unique in that daughter ions are produced from the molecular positive ions via loss of CO, Cl, HCl and Cl_2. In negative mode, fragmentation of PCP is negligible so only MS may be used. The ASTA/TAGA technique was successfully applied to monitoring airborne PCP from a wood treatment plant where levels between 20 to 4400 ng/m^3 were recorded. The TAGA real-time PCP data are in agreement with theoretical models.

Some Quantitative Aspects of Spray-and-Trap Sampling for Gas Chromatography / Mass Spectrometry

G. Baykut, H.-P. Vetters, A. Schiller
Bruker-Franzen Analytik GmbH, Fahrenheit Str. 4, 2800 Bremen 33, Germany

Spray extraction (SPEX) is a method for sampling volatile organic compounds in aqueous systems. Tiny droplets of a water sample are generated by spraying water samples through special nozzles. One way of producing the water spray is pressurizing the aqueous sample[1-3] (pressure chamber, water pump). Aqueous solutions can also be sprayed by using a fast flowing gas to generate a dynamic vacuum in the gas/liquid nozzle, where the sample gets nebulized[3] (gas-driven nebulizer). Forming very small droplets helps increase the total interfacial area between the liquid and the gas phase enormously and thus accelerates the partitioning of the volatile organic compounds between them. Compounds extracted from water are transferred to the sorption tube of an automatic preconcentrating injector unit and finally to the GCMS for separation and analysis. In the spray chamber of a gear pump-driven spray extractor, droplets fly against the carrier gas, where a countercurrent extraction takes place. The efficiency of SPEX depends on the size of the gas/liquid interface area. Thus, the way of generating droplets is the main instrumental contribution to the extraction efficiency of a compound. Nozzles that generate smaller droplets increase the efficiencies. Vapor pressure and solubility in water affect the efficiency of SPEX for a particular compound. High solubilities in water complicate the extraction of polar compounds into the gas phase.

Using a gear pump-driven spray extractor with the solid-cone spray nozzle, various compounds were spray extracted, collected and analyzed with GCMS. The experiments were performed with the gear-pump driven spray extractor of a 150 ml cylindrical spray chamber. The water flow rate was 420ml/min, the carrier gas flow rate was 100ml/min. In the regular "simple flow" mode the water sample is extracted only once. The first method used to determine the efficiency of the spray extraction is based on the repetitive spray extractions of the same water sample. A solution, which is already used for extraction once, is sprayed over and over again under the same conditions. During the ith spray cycle:

Extracted mass : $m_{ei} = m_{w0}\, E\, (1-E)^{i-1}$ (1)
Remaining mass: $m_{wi} = m_{w0}\, (1-E)^{i}$

m_{w0} is the initial mass of the compound in water and E ($m_{e1} = E\, m_{w0}$) is the efficiency for the simple flow mode. E is a function of the type of the nebulization and of the compound. Using the logarithmic form of (1) and working in the linear range of the sorption sampler (short sampling time, large breakthrough volumes), where the GC peak area N_e is proportional to the sampled mass $m_e = N_e/k_j$, following equation can be written:

$$\ln (N_{ei}) = i \ln (1-E) + \ln [m_{w0} E k_j/(1-E)] \qquad (2)$$

If $\ln(N_{ei})$ is plotted against i, E can be calculated from the slope of the curve: $E = 1 - e^{\tan \alpha}$. Total extracted mass from n-times repetitive sampling is $\Sigma m_{ei} = m_{w0}[1-(1-E)^n]$. Thus, the total efficiency $E_T(R)$ is

$$E_T(R) = \Sigma m_{ei}/m_{w0} = [1-(1-E)^n]. \qquad (3)$$

The decrease in the observed signal in repeated extractions is due to the extracted amount in the previous extraction step plus all possible losses during the operation. Losses in the system can be determined by repeating the experiments, where the sample goes through all the steps except the spray process. A different version of the method of repetitive extractions is circulating the sample from a sample container. Small amounts of water samples can be handled easier using the circulated-flow spray extraction. At constant flow of carrier gas, the extracted total amount

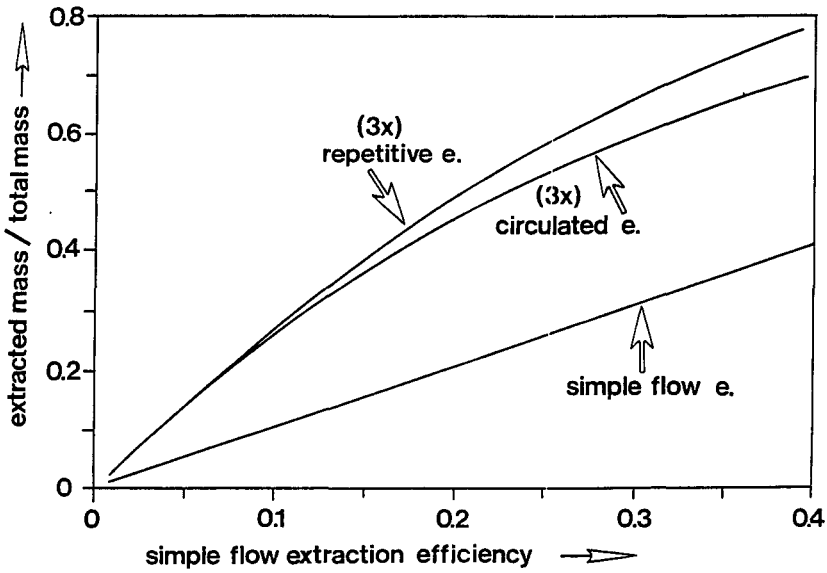

Fig. 1: Sampling in simple, repetitive and circulated flow SPEX

from a water sample of the volume V_s during a time period t using a water flow rate of f_w, is given as $m_e(t) = m_{w0}\,[1-\exp\{-f_w\,E\,t/V_s\}]$, which leads to a total efficiency of

$$E_T(C) = 1 - \exp\{-f_w\,E\,t/V_s\}\ . \qquad (4)$$

Since the concentration of the sample in the container continuously drops due to the extraction in the spray chamber, the efficiency curve is a little below the curve of repetitive extractions (Fig. 1). The second method used for efficiency calculations is based on a comparison of the analysis results of spray extracted compounds with the results from direct gas sampling. The gaseous solution (in nitrogen) containing the compounds is sampled and preconcentrated in the sorption injector (gas sampler) and analyzed by GCMS. A calibration curve is plotted using different concentrations. The same mixture of compounds is sampled from water by spray extraction. Calibration curves were obtained by analyzing different concentrations in water. These curves were then compared to determine those concentrations in water and in the gas sample. At concentrations, where both calibration curves show the same number of counts (GC peak area), the extracted concentration in the spray experiment corresponds to the concentration in the gas sampling experiment. From these data efficiencies were calculated.

Spray extraction efficiencies E for 2min simple flow experiments, gear-pump driven extractor, solid cone nozzle, water flow: 420ml/min, N_2 flow: 100ml/min, are for benzene 4.8%, trichloroethene 7.6%, toluene 5.3%, n-octane 21%, tetrachloroethene 12.1%, p-xylene 4.9%, and naphthalene 0.8%. Repetitive or circulated flow extractions increase the extracted amount (Fig. 1) and recommended for samples of small volume.

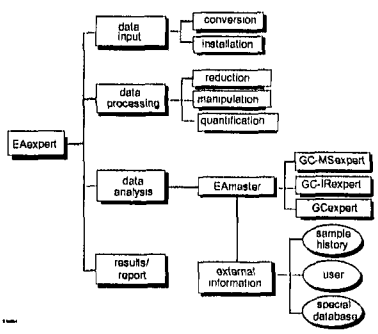
GC-MSexpert: The Design of an Expert System for use in the Analysis of Environmental Contaminants using Gas Chromatography-Mass Spectrometry

Devon A. Cancilla, Guosheng Huang, Shengping Ma and Martin J. Stillman
Department of Chemistry, University of Western Ontario, London, Ontario N6A 5B7
Phone: 519-661-3821, FAX: 519-661-3022

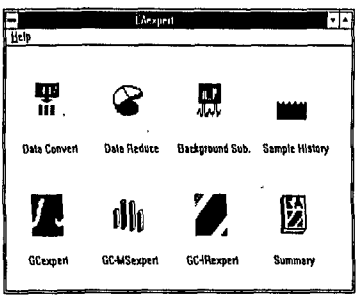
Introduction- GC-MSexpert is one module of a multimodule Environmental Analytical expert system (**EAexpert**) currently under development in our laboratory. Modules within EAexpert are designed to aid the analyst with the management and interpretation of data acquired from environmental samples, in the case of GC-MSexpert, data acquired from gas chromatography mass spectrometry.

Novel aspects of GC-MSexpert are (i) its ability to import mass spectral data from a variety of instruments into a format usable in programs written as Windows™ applications, (ii) its use of an expert system shell within Windows to provide a user-friendly and intuitive environment for the identification and quantitation of environmental contaminants using mass spectral data, and (iii) its ability to search and use historical sample information to aid in the identification of chemical unknowns. GC-MSexpert is also capable of searching NIST and user supplied libraries and performing standard chromatographic and spectral manipulations within Windows.

Design- The figure below shows the outline of the multimodule expert system, **EAexpert**, which combines information from a variety of sources (GC, GC-MS, Sample history, and User). Each module, such as GC-MSexpert, acts independently of the others in interpreting specific data. Each can access historical, user-defined and sample history databases. **EAmaster** is capable of querying individual modules to obtain further information for resolving interpretive conflicts between modules. Modules within EAexpert can be accessed by clicking specific icons. Standard spectral and chromatographic manipulation can be carried out within the **Data Processing** modules.

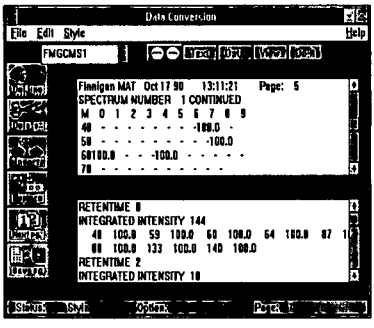


EAexpert includes a number of modules which can be accessed by clicking the appropriate icon.

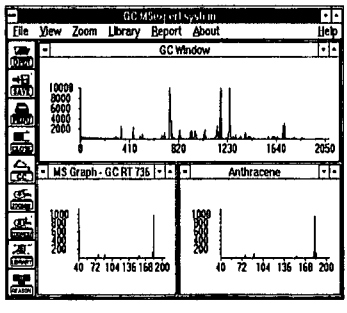


Data Conversion- Data from different instrument types can be imported and translated into **EAexpert** standard or user-defined formats.

The Data Conversion module converts spectral data in different formats into standard or user defined formats.

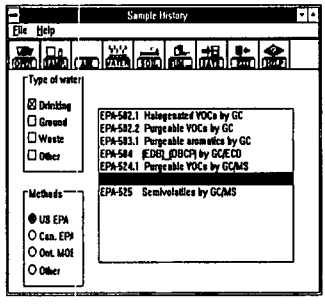


Manipulating Data- The **GC-MSexpert** module contains functions which allow the user to manipulate chromatographic and spectral data imported from a variety of instrument types. Spectra can be searched against NIST standard and user-defined libraries.



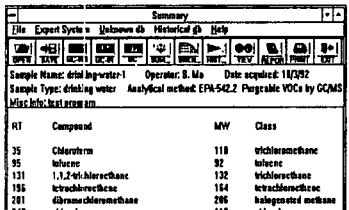
Sample History- Sample history information is incorporated into the interpretive process. Information on sample type, method work-up and analytical conditions are used to narrow search conditions for unknown compounds.

The Sample History module is used to input sample history information.



Summary module- The summary module provides a summary of the results obtained through individual modules and condensed through **EAmaster**. Clicking various icons brings up specific information. For example, how many times a compound has been detected, from what samples and under what conditions.

The Summary module summarizes the results from individual expert system modules and can access unknown and historical databases.



Summary- Prototype testing has included the development of a novel expert system shell (**EAshell**) which allows expert system development within the Windows environment. Knowledge within each module is represented in a tabular form and can easily be transported, audited and expanded by individual groups using the systems.

Dry CI - The Use of Monoenergetic Electrons for Analysis of Explosives, Pesticides and Environmental Chemicals.

J.A. Laramée and M.L. Deinzer, Department of Agricultural Chemistry and the Environmental Health Sciences Center, Oregon State University, Corvallis, OR 97331

Discrete energy electrons are produced by an electron monochromator/mass spectrometer system (1). The goal of this project is to apply monoenergetic electron capture methodology to the analysis of environmental compounds and explosives, to investigate fundamental processes governing energy deposition by electron capture in the negative ion mode (2), and to seek ultra low-level (10^{-15} g) detection. No reagent gas is used to moderate the electron's kinetic energy (dry CI) and the mass spectra are free of the usual artifact peaks (1).

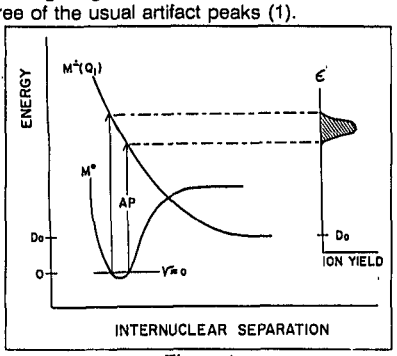


Figure 1

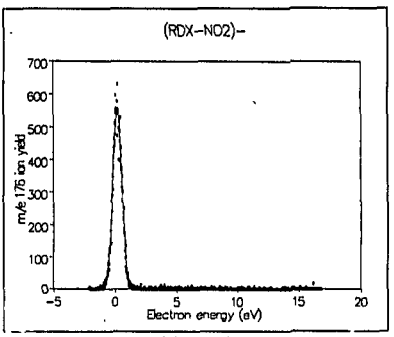

Figure 2

One hypothesis being tested is that reflection of the neutral molecules (M^o) wavefunction off an anionic dissociative surface ($M^{\cdot-}$) contains enough information about its history to allow for identification of the original explosive at very low-levels of detection and that the resulting ion yield curve measurement is describable in terms of the Franck-Condon factors as a function of electron energy (ϵ). This embodiment of the reflection principle (3) can be described within the Born-Oppenheimer formalism (Figure 1). This approach has been applied to six energetic materials, for instance $(M\text{-}NO_2)^-$ formation can occur from any one of the three equivalent nitro groups of RDX (1,3,5-trinitro-1,3,5-triazacyclohexane), and a single peak with ϵ_{max} = 0.22 eV is found at m/e 176 (Figure 2). But $(M\text{-}NO_2)^-$ formation from TNT (2,4,6-trinitrotoluene) at m/e 181 shows three separate processes are involved with ϵ_{max} of 0.32 eV, 1.88 eV, and 4.54 eV (Figure 3). Molecular orbital calculations reveal three distinct nitro moieties. Spectra were deconvoluted by non-linear least-squares analysis to obtain accurate ϵ_{max} values.

Another hypothesis being tested is that polychlorodibenzo-p-dioxins, polychlorodibenzofurans, and polychlorobiphenyls undergo chloride loss in a regiospecific fashion. Using chlorine-37 labeled compounds, polychlorodioxins lose their epi-chlorines first to preferentially form the toxic 2,3,7,8-tetrachlorodibenzodioxin isomer (4), while polychlorodibenzofurans lose chlorines at positions 2,3,7 and 8 to form less toxic intermediates (5). Now regiospecific chloride loss as a function of internal energy has been measured for 1(^{37}Cl),3-dichlorodibenzo-p-dioxin at electron energies of 0.03 eV (Figure 4) and 1.8 eV (Figure 5). Arrhenius rate theory and adiabatic mapping have been successfully applied to *quantitatively* explain the observed chemical dynamics. Another successful approach has been to relate the regiospecific bond dissociation energy, i.e. BDE (C-Cl) = $\Delta H_f(M\text{-}Cl)^{\cdot} + \Delta H_f(Cl^{\cdot}) - \Delta H_f(M)$ to the experimentally

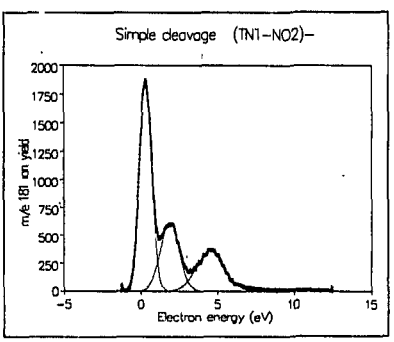

Figure 3

measured appearance potential by AP(Cl^-) + EA($Cl^\cdot$) - E_{excess} = BDE(C-Cl) for polychlorobiphenyl isomers. Chloride ion loss from 2,4,6-trichlorobiphenyl shows three resonances with appearance potentials of 0.08 eV, 2.9 eV and 4.1 eV (Figure 6). Loss of either ortho chlorine gives a predicted AP = 0.07 eV in excellent agreement with the measured value, while loss of chlorine 4 would yield a peak with AP = 0.14 eV which is not observed. Further fragmentation to give loss of chlorine atom and anion occurs at 4.1 eV cf. 4.0 eV for the predicted value. The peak with AP = 2.9 eV could be a core-exited resonance.

The Non-linear Resonance Quadrupole Ion Traps (QUISTOR) — Intensity and Frenquenc-shift Characteristics of the Different Resonance Lines

Y. Wang and J. Franzen
Bruker-Franzen Analytik GmbH, Fahrenheistr. 4,
D-2800 Bremen 33, Germany.

D-2800 Bremen 33, Germany

The non-linear resonance, caused by certain multipole fields superimposed on a three-dimensional rotationally symmetric quadrupole field, can be employed for mass analysis in the corresponding quadrupole ion trap.

In general, each kind of multipole fields (for example, hexapole and octapole) results in several different resonance lines in the first stability diagram. A general expression for the non-linear resonance conditions is derived from basic Hamilton and Fourier transform principoles, and some additional rules are presented. The resonance intensity with superposition of hexapole field is studied theoretically.

The computer simulation study is carried out to aim at the main octapole resonance $\beta_z + \beta_r = 1$. The intnesity and frequency shift by changing the ion trap shape parameter θ is investigated by ejection analysis, and by Fourier transform analysis of the sumulated movements of the ions. The analysis is important for proper selection of the principle resonance line in the mass analysis and the quantitative selection of the corresponding multipole field and additional technique, which are important factors directly influence resulution, sensitivity and mass scanning speed.

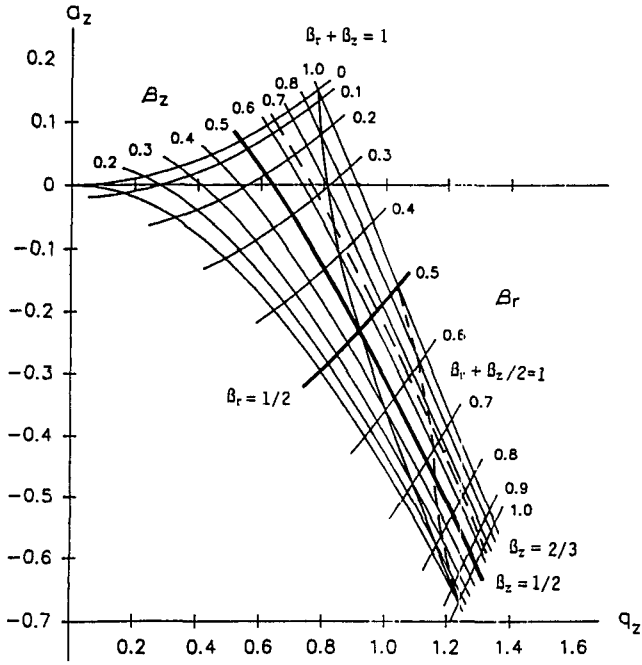

Fig. The complete set of nonlinear resonances for an ion trap with rotationally symmetric superpositions of hexapole and octapole fields. There are only two resonance types for hexapoles (third order), and three types for octapoles (fourth order).

Other types of resonances (e.g. the hexapole resonance $\beta_r/2 + \beta_z = 1$, or $\beta_r = 2/3$) appear only in rotationally non-symmetric arrangements.

THEORETICAL BASIS OF RESOLUTION ENHANCEMENT IN THE QUADRUPOLE ION TRAP

D.E. Goeringer, W.B. Whitten, J.M. Ramsey, S.A. McLuckey, G.L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831

The evolution of quadrupole ion trap as a modern analytical mass spectrometer has been quite rapid following the development of the mass-selective instability technique[1] for acquiring mass spectra for trapped ions. Despite many other recent performance advances mass spectrometers based on the device have not been viewed as high mass resolution instruments. However, recent results in which resonance excitation was combined with retarded scan rates have yielded a mass resolution of up to 1,000,000 in the device[2,3,4,5]. This paper presents a theoretical basis for resolution enhancement in the quadrupole ion trap when operated in the resonance ejection mode.

Analytical expressions for the resonance excitation line shape in the ion trap can be derived from the pseudopotential well approximation[6] for ion motion with additional terms included to account for the effects of ion-molecule collisions and finite sweep rates. The expression obtained for the line shape is

$$Z(t) = \frac{-ieV_s}{4mz_0\omega_0}\left[\frac{\tau - i\Delta_\omega\tau^2}{1+(\Delta_\omega\tau)^2} - B\exp\left(-\frac{x}{\sqrt{a}\tau} - \frac{ix^2}{2}\right)\right] \quad (1)$$

$$B = \int_{-\infty}^{x}\left[\exp\left(\frac{x'}{\sqrt{a}\tau} + \frac{ix'^2}{2}\right)\frac{a}{\left(\frac{1}{\tau} + i\sqrt{a}x'\right)^2}\right]dx' \qquad x = \sqrt{a}t \qquad \tau = 2/c$$

where Z is the amplitude of the slowly varying envelope of rapid ion oscillations in the axial (z) direction, m is mass, e is charge, z_0 is one-half the endcap-to-endcap distance, V_s is the supplementary voltage (pk) applied to the endcaps, a is the scan rate (rad s^{-1}), and Δ_ω is the difference between the supplementary frequency and the secular frequency, ω_0. The reduced collision frequency, c, represents the rate of ion momentum relaxation due only to collision processes which are nonreactive and does not include ion loss at the electrodes during passage through resonance. When the ionic mass is taken to be much greater than the neutral mass (the normal case as helium is typically the buffer gas), the ion collisional relaxation time, τ, can be expressed as a function of the mass-to-charge/neutral number density, n.

$$\tau \propto \frac{m/e}{n} \quad (2)$$

The first term in eqn. 1 is a Lorentzian function that is dependent on the instantaneous value of $\Delta_\omega(t)$, and the exponential term represents a damped oscillation; its amplitude and phase are contained in the coefficient B which is a function of the explicit time dependence of Δ_ω. Numerical integration of eqn. 1 reveals that the FWHM line width for the magnitude-mode peak shape, $\Delta\omega_0$, can be approximated as the sum of the low and high scan rate limits.

$$\Delta\omega_0(rad\ s^{-1}) \approx \frac{2\sqrt{3}}{\tau} + a\tau \quad (3)$$

Eqn. 4 relates frequency linewidth and mass resolution, $m/\Delta m$, in the ion trap.

$$\frac{m}{\Delta m} = \frac{q_z\Omega}{2\sqrt{2}(\Delta\omega_0)} \quad (4)$$

Substitution of eqn. 3 into eqn. 4 allows the normalized mass resolution, $(m/\Delta m)(1/[q_z\Omega])$, vs scan rate for selected τ values to be plotted (Fig. 1; the scan rate, dm/dt [mass units s^{-1}], can be determined by multiplying the displayed abscissa values by $[2\sqrt{2}m]/[q_z\Omega]$). It is clear from the figure that an increase in ultimate mass resolution results from decreased damping (lower neutral pressure, higher m/e) but requires lower scan rates to attain. For relatively high scan rates the mass resolution will be inversely related to scan rate and proportional to damping. (This is consistent with the observation of increased resolution using the helium buffer gas with axial modulation in the normal operation of the ion trap.) At some sufficiently low scan rate the mass resolution should become independent of scan rate and inversely proportional to damping. However, for any non-zero scan rate an optimum damping value should exist which corresponds to a resolution maximum, indicated by the solid line in Fig. 1.

While this model adequately explains the observed qualitative dependence of mass resolution on experimental variables and parameters, a comparison with quantitative results indicates that the calculated values appear (within experimental error) to underestimate experimental resolutions by a factor of 3-5. The FWHM of the entire line shape, calculated from the model for resonantly excited ion motion, was arbitrarily used as an indication of resolution. However, because the optimum resolution would be realized when $|Z_e|$ becomes exactly equal to z_0, the ejected ion line shape under near optimum resolution conditions would correspond to only a portion of the calculated line profile near the apex. It is important to realize that even under such conditions the entire ion population can be ejected, provided that enough cycles of the excitation signal are experienced during passage through the apex. The FWHM for any such truncated apex is some fraction of that for the complete line profile, with the fraction dependent on the ratio Z_e/z_0. The overall effect is to reduce the observed linewidth compared with the calculated value, thus increasing the corresponding experimental mass resolution.

Laser Desorption - Ion Trap Studies of Low Volatility Components in Complex Matrices.

*P.H. Hemberger, M.L. Alexander, M.E. Cisper, and N.S. Nogar. Chemical and Laser Sciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545.

We describe the application of combined excimer laser/ion trap mass spectrometer technology to the characterization of complex mixtures. The sample is introduced to the ion trap with a direct insertion probe through a 2 mm hole drilled through the ring electrode in a configuration described by Cotter et al.[1] Photons for sample desorption were generated by a XeCl excimer laser (Questek 2200). The laser produced output pulses with a duration of ca. 15 ns at 308 nm. Laser energy at the probe tip was about 1 mJ/pulse, corresponding to a power density of nearly 1×10^6 watt/cm^2. The electron multiplier was configured with a conversion dynode for the detection of both positive and negative ions. The laser energy dependence for the production of negative ions from a mixture of 16 polyaromatic hydrocarbons (PAHs) shows a threshold at about 0.5 mJ/pulse. Discontinuities in ion production at 1 mJ/pulse and 1.7 mJ/pulse were also observed indicating either different desorption processes or changes in desorption cross-section.

The chemical characterization of soots from the detonated explosives can show differences due to both the explosive and the manner in which it was detonated. Soots from the detonation of 300 grams of pure TNT and 300 grams of a 50/50 mixture of TNT and nitroguanidine (NIGU) were examined. Analysis of the TNT/NIGU soot shows intact NIGU and urea, which was formed during detonation (Figure 1). The TNT mixture contains mostly PAHs as shown in Figure 2. With the exception of the C3 - C6 carbon clusters shown in Figure 2, the observed products in both soots agreed with those found by direct insertion probe mass spectrometry. The small carbon clusters arise during the laser desorption of PAHs at the laser energies (> 1 mJ/pulse) used in these experiments.

Laser Sampling of TNT/NIGU Detonation Soot

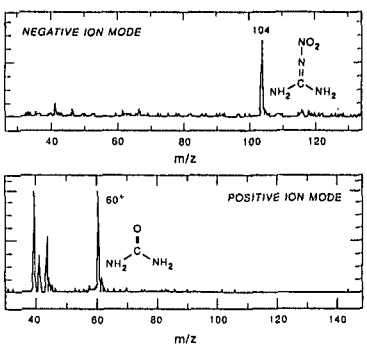

Figure 1

Laser Sampling of TNT Detonation Soot

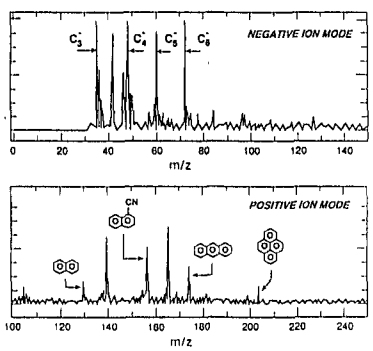

Figure 2

Laser sampling ion trap techniques can also be used to characterize metal complexes and could be used for speciation of metals in soil for environmental screening. The positive ion mass spectrum of chromium acetyl acetonate at 0.5 mJ/pulse laser energy shows primarily molecular ion; at 1.5 mJ/pulse the complex decomposes and elemental information can be obtained (Figure 3). Structural information for the ligand can be obtained by switching to negative ion mode and performing MS/MS on the intact acetyl acetonate negative ion (Figure 4).

We have also demonstrated the detection of PAHs and other semi-volatile compounds in soils. Preliminary results of the analysis of Peruvian Soil (NIST SRM 4355) indicate that trace metals at the part-per-million level can be detected in very small samples (10 - 100 μg) with this technique. Improvements in sampling technique and data acquisition are currently in progress.

The Paul Ion Trap Mass Selective Instability Scan: Trap Geometry and Resolution

J. Louris, J. Schwartz, G. Stafford, J. Syka, and D. Taylor
Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95134-1991

Not only does the Paul ion trap not need to be built to exacting tolerances when used as a mass spectrometer in the mass-selective instability mode, we have found that performance is actually enhanced if the geometry of the trap is grossly distorted. Although it is not widely recognized, all of the commercially produced traps have had a distorted geometry. In particular, the resolution is consistently better in traps with a distorted geometry. Since a number of groups are now studying the details of ion motion in the trap, it is important that the actual geometry of the commercially-produced trap be widely known: the Finnigan trap has electrodes whose shape is the "theoretical" shape determined by r_0 = 10.00 mm and z_0 = 7.07 mm. However, the three electrodes are not held in the relative position of a "theoretical" trap. Instead, the end electrodes are spaced such that the distance of each to the center of the trap is 7.83 mm (instead of the theoretical 7.07 mm). This "stretched" geometry is shown schematically in Figure 1.

Recently, a "black hole" has been reported by Guidulgli and Traldi in which daughter ions in ms/ms experiments are not trapped if their q (at creation) is 0.78. This is just a special case of the poor trapping of ions close to the non-linear resonance line of β_z = 2/3. Figure 2 shows the abundance of m/z 176 from dissociation of m/z 264 from FC43 for three a_z values, and Figure 3 shows the same data plotted as a function of β_z. These results were obtained with the stretched geometry. Interestingly, we find that the effect is more pronounced in a trap with theoretical geometry, and the hole is actually somewhat deeper (Figure 4). We suspect this is due to the interior of the stretched trap being somewhat more shielded from external field penetration.

We have also been studying anomalous peaks in resonance ejection mass spectra in which peaks are present because of ejection at more than one place on the stability diagram. The simplest cause of these anomalous peaks is applying the resonance ejection voltage at a time when ions are present with a q_z between the edge of the stability diagram and the q_z associated with the resonance ejection frequency. Also, occasionally only part of the ion population is ejected during the scan through the frequency of the resonance ejection voltage. The highest m/z resolution is attained with a lower ejection voltage, but a lower voltage also leads to a decreased ejection efficiency. Any ions that are not ejected remain in the trap until the RF voltage is increased to the point that the ions encounter the edge of the stability diagram. Ejection at the edge of the stability diagram is very efficient, and the mass spectrum will therefore show two different peaks arising from ions of the same m/z value. In such a case, we refer to the second peak (arising at the edge of the stability diagram) as a "ghost peak".

In a mass spectrum acquired using the mass selective instability mode with resonance ejection, those peaks arising from resonance ejection must be distinguished from those arising from ejection at the edge of the stability diagram, or at non-linear resonance lines, before the m/z value can be determined with complete confidence. We have discovered that the fine structure of the two different types of peaks may be used to distinguish them from one another.

Figure 5 shows an example of a mass spectrum obtained in a typical mass selective instability scan with resonance ejection in which the RF is scanned upward. The resonance ejection frequency was 146761 Hz. The base peak is a doubly charged ion of m/z 649.2, but ions of this m/z also produce a ghost peak as they are ejected at the edge of the stability diagram.

Figure 6 shows the fine structure of the peak at m/z 649.2 as well as the peak at m/z 660.2. The comb-like appearance of the mass peak is due to the coherent nature of the ion motion during resonance ejection; the individual peaks or "ion packets" emerge from the trap at a period equal to the period of the resonance ejection signal.

Figure 7 shows a comparison of the fine structure of the resonance ejection peaks with the fine structure of the ghost peak (which is ejected at the edge of the stability diagram). The difference in the frequency spectrum of the two types of peaks allows the ghost peak to be removed by digital signal processing. Figure 8 shows the result of such signal processing, in which the ghost peak has been eliminated by digital "demodulation" in which the spectrum is point-wise multiplied by $\sin(2\pi ft)$, where f is the resonance ejection frequency and t is the time at which a point in the spectrum was acquired. The resulting product was then subjected to a 15 kHz low-pass filter. This procedure is the digital analogue of using a lock-in amplifier at the frequency of the resonance ejection voltage.

HIGH PRESSURE, HIGH MAGNETIC FIELD SOURCE FOR FTICR MASS SPECTROMETRY

S. A. Hofstadler, E. Schmidt, D. A. Laude, Jr., Department of Chemistry and Biochemistry,
The University of Texas at Austin, Austin, TX, 78712

In an effort to simplify the ion transfer process for external source FTICR, we have undertaken a new approach to vacuum chamber design. As an alternative to the serial concatenation of pumping stages, a network of concentric tubes which are separated at conductance limits in the bore of the superconducting magnet is used [1]. The concentric network design spatially consolidates differential pumping so that high pressure ionization occurs in the magnet bore within a few cm of the analyzer cell which is still maintained at low pressure for FTICR detection. Advantages include confinement of ions with substantial radial kinetic energies to small cyclotron orbits so that near-unit transfer of ions to the analyzer cell is possible, efficient trapping of ions because axial kinetic energies of a few eV are compatible with the applied trapping potential, elimination of expensive focusing optics necessary to overcome the magnetic mirror, and reduced spectrometer size. An added benefit is that whereas the dual cell design can only reach source pressures of 10^{-5} torr and retain optimum conditions for FTICR detection, the concentric tube assembly houses probe-mounted sources operating at atmospheric pressure yet achieves analyzer pressures in the 10^{-8} torr range.

The most recent configuration of the concentric tube external source shown in Figure 1 was designed with the goal of reducing ultimate pressures achieved at the analyzer cell, improving ion optical alignment at conductance limits along the path to the cell, and permitting rapid change between probe mounted ionization sources. The new system satisfies these design criteria. Atmospheric pressure ionization still occurs in the source positioned in a 3 T magnetic field about 20 cm from the trapped ion cell but pressures under electrospray flow conditions are now maintained below 2×10^{-8} torr. Ion current reaching the final pumping stage where FTICR detection is accomplished is increased from below 5 pA to greater than 100 pA by improving alignment optics. Finally, a rapid conversion from electrospray ionization to other probe mounted high pressure sources is possible; the example to be demonstrated here is a pulsed supersonic beam laser ablation [2].

High Performance Electrospray/FTICR. The primary purpose in coupling electrospray to a high performance mass spectrometer is to realize improved high m/z performance, mass resolution and mass accuracy compared to quadrupole mass analyzers. Presented in Figure 2 are examples of electrospray mass spectra accomplished that cannot be achieved on a quadrupole instrument. Shown in Figure 2a is a low resolution spectrum of bovine albumin following a proton transfer reaction; ions are observed out to $(M + 13H)^{13+}$ ion at m/z 5098. Presented in Figure 2b is a high

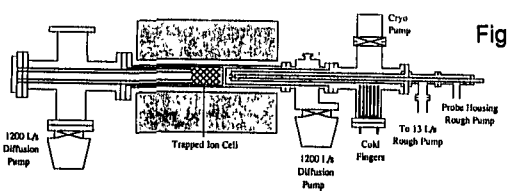

Figure 1

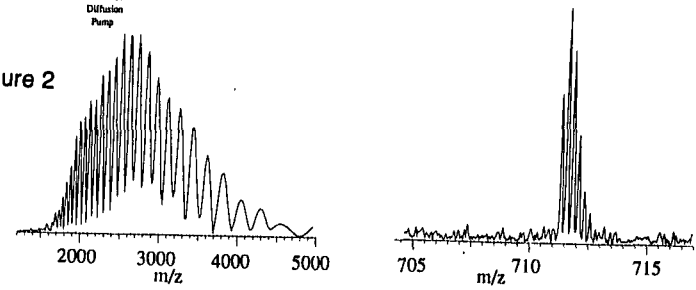
Figure 2



mass resolution spectrum of the $(M + 4H)^{4+}$ ion of melittin. The resolution of 20,000 is sufficient to resolve the individual isotopes within a single charge state at a pressure of 2x10-8 torr.

ESI /FTICR Remeasurement. McLafferty and coworkers [3] demonstrated that the ion packets for large mass compounds may be remeasured by FTICR because collisional cooling of ions to the center of the cell is favored over entropic processes. We evaluated this possibility for electrospray ions and found that remeasurement is extermely rapid and efficient under appropriate conditions. Relaxation delay times range from about 200 ms at 10^{-7} torr to 2 s at 10^{-8} torr. Efficienices for large ions are essentially 100% as spectral S/N is found to increase proportionally with the square root of the number of remeasurements even up to 250 scans. For example, a 30 femtomole sample of bovine albumin dimer was analyzed by ESI/FTICR. Presented in Figure 3 are comparison spectra following a single scan and after 250 remeasurements of the same ion population. A 2 s delay between remeasurements was used.

Pulsed High Pressure Cluster Source. Extending the idea advanced by Smalley for miniaturizing the pulsed cluster source and moving it closer to the trapped ion cell [1], we evaluated the feasibility of probe mounting the source and mating it with the concentric tube pumping system. The source region included a target positioned in a waiting room adjacent to a fiber optic which delivered the pulsed laser light. A carrier gas was pulsed into the waiting room to deliver cluster ions through the skimmer to the cell. Shown in Figure 4 are FTICR spectra derived from a gold target. The spectrum in Figure 4a results when laser plasma ignition occurs at the gold target but the pulsed valve is not triggered. A single intense monatomic ion signal is observed. When a pulsed valve is used to create a directed gas flow which carries cluster ions from the waiting room through the skimmer cone, cluster ions are observed in the FTICR spectrum. Figure 4b is a spectrum acquired under identical conditions to that in Figure 4a except that a burst of N_2 gas was timed to arrive at the waiting room at the appropriate time relative to the laser firing to maximize cluster formation. Gold cluster ions extending to n = 4 are observed in positive ion mode.

Tailored Excitation Based on Sine Wave Modulation

Zhenmin Liang
EXTREL FTMS (*Now Part of Millipore*)
6416 Schroeder Road, Madison, WI 53711-2424.

In Fourier Transform Ion Cyclotron Resonance mass spectrometry (FT/ICR) and Ion Trap Mass Spectrometry (ITMS), highly selective radiofrequency (RF) excitation is often desirable. The first tailored excitation scheme was developed for FT/NMR in 1973 [1]. The tailored excitation for FT/ICR, called Stored Waveform Inverse Fourier Transform (SWIFT) excitation, was developed in 1985 [2]. In this presentation, a new tailored excitation based on the modulation of sine waves is described.

I. Theory

For two functions, A and B, their Fourier transform counterparts are FT (A) and FT (B). The Fourier transform convolution theorem is expressed as

$$FT(A \cdot B) = FT(A) * FT(B)$$

It states that the Fourier transform of the product of two functions, A and B, equals the convolution of the function FT (A) and the function FT (B).

In tailored excitation, the major concern is that the frequency spectrum of the excitation (time domain) consists a well-defined boxcar function or multiple well-defined boxcar functions.

According to the convolution theorem, the modulation (multiplication) of a sine wave by a sinc function results in a frequency spectrum that is a boxcar function. The center of the boxcar function is at the frequency of the sine wave. The width of the boxcar function relates to the width of the sinc function. Therefore, a component of a tailored waveform can be expressed as

$$E(t) = A_0 \sin 2Pi\, v\, [\sin 2Pi(t-t_0)\, W / 2Pi(t-t_0)\, W]$$

in which Pi = 3.14159, t is a time variable, t_0 is the time at which the sinc function has a maximum value. 2W is the width of the boxcar function from the FFT of the sinc function. The magnitude spectrum of the modulated sine wave E(t) is a boxcar function centered at frequency v and spanning over $\pm$W.

Sinc-modulated sine waves of different boxcar function can be co-added to form an excite waveform. Its the magnitude spectrum of the waveform is equivalent to the sum of each individual boxcar function from each modulated sine wave, providing that the boxcar functions do not overlap with each other. This is the basis of obtaining a waveform of an arbitrary multiple boxcar function spectrum.

II. Results and Discussions

A) Notch ejection

A waveform consisting of two sinc-modulated sine waves was downloaded to an EXTREL SWIFT module. The power spectrum of this waveform has a notch at m/z 220 $\pm$ 0.5. The use of this waveform effectively ejected m/z 219 in a PFTBA mass spectrum and left m/z 220 unexcited, as shown in Figure 1.

B) Uniform Broadband excitation

Because the output of a broad-band RF amplifier is usually limited to a few hundred volts, the maximum value of an excite waveform must be within that of the excite amplifier. In a simultaneous excitation method, when the excite bandwidth exceeds a certain value, for example, 100 KHz, the excite amplifier can not satisfy the power requirement. In SWIFT, this is solved by "phase-scrambling" [2-4]. In this method, shifting the modulation maximum by using a different value of t_0 in the equation of E(t) for each modulated sine wave achieves amplitude reduction.

For example, if an excitation amplifier provides an excitation field strength of 1200 volts/meter, the adequate excitation bandwidth in a 3 Tesla magnet is about 50 kHz with a single sinc-modulated sine wave. To uniformly excite a 360 kHz bandwidth, a waveform consisting of 9 sinc-modulated sine waves can be used. Each of the 9 modulated sine wave has a 40 kHz wide boxcar function spectrum and the frequency of the sine waves are different by 40 kHz from each

other. The maximum of each modulated sine wave is different from one another by 30 us; therefore, it prevents the overlap of excite voltages of each modulated sine waves in the large amplitude regions. This excite waveform will effectively excite the 360 kHz uniformly. Fine adjustments of the sinc maximum positions are necessary for smooth connection of excite bands. The best way for the fine adjustments is by try-and-error, since the delays need to be determined once for subsequent uses. A waveform that excites ions spanned over 360 kHz is shown in Figure 2, along with its magnitude spectrum.

III. Conclusion

The method discussed above provides an alternative to SWIFT excitation. The method provides a mean for broadand uniform excitation, notch-ejection, selective ion excitation, etc.. The ion selection performance of the proposed method is the same as that of SWIFT. This method requires minimum computation, which can be the basis for real-time tailored excitation.

Long-Time Storage in Ion Traps

J. Franzen and R.-H. Gabling, Bruker-Franzen Analytik GmbH,
Fahrenheitstraße 4, W-2800 Bremen 33, Germany

Ion traps have seen a dramatic development during the last years: high sensitivity, high-yield MS/MS, high mass, and high resolution are only some examples.

This presentation opens another field for investigations with ion traps. Superimposed weak octapole fields stabilize the storage of ions in quadrupole fields ion traps. The storage of ions over many hours without any measurable ion losses even in the presence of medium-weight damping gases allows to study slow ion/molecule reactions, fragmentation energy thresholds, photochemical ion reactions, high atmosphere ion chemistry under effect of uv radiation, or interactions of ions in the ion cloud.

If a weak octapole field is superimposed on the basic quadrupole field, the storage stability is greatly enhanced because the secular frequency of the ions becomes dependent on the secular amplitude[1]. This non-linear behaviour of the field prevents losses by all kinds of linear perturbances. The trap can even be operated in harsher environments, e. g. with pure argon or air as cooling gases, which is not possible in purely quadrupolar fields.

In such a trap ions can be stored for periods of hours even in gases like air. This opens the examination of the reactions of high molecular weight ions in air with trace amounts of other molecules.

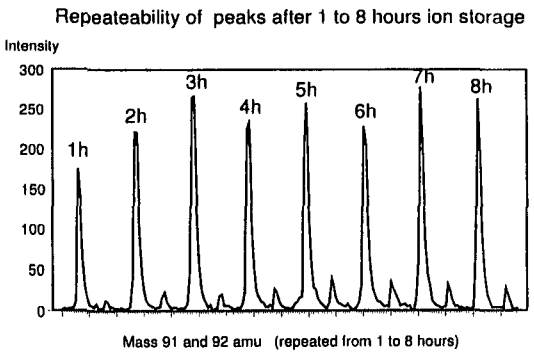
Experiments have been performed (a) to store isolated ions of mass 91 amu from toluene in pure nitrogen for periods up to ten hours, and (b) to investigate the long-time behavior of ions in normal lab air.

(a) Experimental conditions: About 10 resp. 1 ppm of toluene in pure nitrogen was enclosed in a 50 liter tetlar bag, and connected to the membrane inlet system of the $2r_0 = 2$ cm ion trap with roughly 2% octapole field (the exact field is a hyperboidal quistor[2,3]). The nitrogen pressure within the trap amounted to $2*10^{-4}$ mbar. Using the high-level control language SIMPL, the following measurement procedure was set up: ionization of the toluene with ion cut-off at mass 50 amu, 5 msec damping time, isolation of mass 91 amu ions (leaving a small amount of mass 92 ions in the trap), switching off electron gun filament and multiplier, storing period for the ions, switching on the multiplier voltage, and scanning the spectrum from mass 50 amu to 450 amu in exactly 14.6 msec. The exiting ions were measured in time periods of 3 μsec each, corresponding to the ion pulses exiting the trap under the effect of the non-linear octapole resonance.

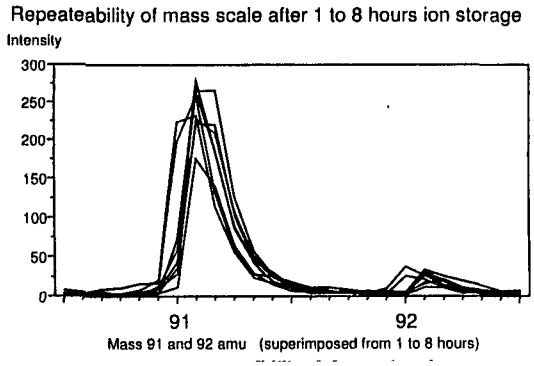
The 1 ppm toluene experiments were performed with reference measurements of 1 sec storage periods between all long-time storage experiments. The long-time experiments started with 1 hour periods, progressing in 1 hour steps to 10 hours of storage. Such an experiment needed a total time of about 55 hours, and was performed automatically during a weekend.

Results: (i) Experiments with 10 ppm of toluene over 1 to 8 hours exhibited no measurable decrease of the ion intensities (see figures). The repeateability of the ion signals was 8 % relative standard deviation. The repeateability of the mass scan (exit of the ions after scan start) was outstanding: the peak maximum was found in 6 cases at the same 3 μsec measurement interval, and in two cases in the neighboring next interval.

(ii) Experiments with 1 ppm toluene demonstrated a decrease of the ion signals by a factor of 2 in about 8 hours. If the ion signals are related to the reference measurements, no significant decrease could be seen: the decrease was probably due to a decrease of the toluene concentration in the tetlar bag. Again, the repeateability of the mass scale was outstanding.



However, the relation of the ion intensities to the reference measurements revealed a severe loss of ions in the first hour: Only about one third of the ions could be found after one hour of storage. A closer investigation brought to light that the ion losses occur within the first five to ten minutes, mainly via decay to mass 65 amu, and by ion-molecule processes resulting in mass 105 amu ions. Both mass 65 and mass 105 amu ions disappear quickly. This result has to be confirmed by more investigations.



(b) In the experiments with normal lab air, the steadily progressing formation of series of heavier ions is shown, starting from the mass 91 ion of toluene in air. Depending on the purity of the air, the mass 91 ions itselves disappear within minutes, forming adduct ions. Within the precision of the measurements, the total ion charge ejected from the trap does not decrease, even after storage periods of 12 hours.

Conclusions: Quadrupole ion traps with superimposed octapole fields form an excellent tool for the study of long-time behavior of ions. As was shown earlier, this type of traps already has proven to be superior in many other respects: superfast scanning, excellent isolation methods, and high-gain fragmentation.

Charged Disk and Charged Cylinder Models for Coulomb Effects in FT-ICR

Shu-Ping Chen and *Melvin B. Comisarow
Department of Chemistry, University of British Columbia
Vancouver, B. C., Canada V6T 1Z1

Almost all treatments of ICR and FT-ICR motion treat the ionic system as single particles whose motion is affected only by external electric and magnetic forces. It has also been long known that the cyclotron frequency of any given ion is shifted to lower frequency by the presence of other ions. Recently[1,2] ,we have developed some simple physical models which account for these effects. The first model treated the excited cyclotron motion of two different ions as two charged points which were undergoing excited cyclotron motion. By looking in a rotating coordinate frame which rotated at the frequency of the test ion, we were able to show that this ion was subjected to an average radial force arising from the second, perturbing ion. The magnitude of the perturbing radial force was a function of an "apparent Coulomb distance", D_c, which was the distance, that from the viewpoint of the test ion, the perturbing ion appeared to be. Similarly, we developed a charged line model which in addition to accounting for Coulomb frequency shifting, also predicted inhomogeneous Coulomb broadening[1].

We have extended our charged point and charged line models to charged disk and charged cylinder models for Coulomb effects in FT-ICR[2]. Figure 1 shows the instantaneous force on the test disk 1 as a function of the position angle, ϕ, of the perturbing disk 2. Note that the radial force on disk 1 is a minimum at $\phi = \pi$, reaches a maximum when the disks touch and is zero when the disks overlap. Note that for the smaller disk radius, the touching angle decreases, the maximum force increases and the average force increases. In the limit that the disk radius, $r' \rightarrow 0$, the average and maximum forces $\rightarrow \infty$, as the disk model reduces to the point model. The average force can be used to calculate an "apparent Coulomb distance", D_c. D_c is a function of r/r', the ratio of the cyclotron radius to the disk(cylinder) radius. Figure 2 gives D_c as a function of r/r'. The following SI formula

$$\Delta\omega_i = \sum_{j=1}^{j_{max}} \frac{k\, N_j\, q_j}{r\, B\, D_c \sqrt{(l/2)^2 + D_c^2}} \qquad [1]$$

where $\Delta\omega_i$ is Coulomb frequency shift for the ith ion , k is the Coulomb constant, Nj is the number of the jth perturbing ions, q is the electronic charge, r is the cyclotron radius, B is the magnetic field strength, l is the length of the ICR cell and D_c is the apparent Coulomb distance, should permit accurate calibration of FT-ICR spectra obtained with ICR cells that are designed to have negligible trapping fields[2].

A feature of our model is that it accounts the heretofore unexplained dependence of ICR frequency upon the number of like ions (j = i in Eq. [1]). For ICR cells with negligible trapping fields, the summation in Equation [1] should *not* include the number of the ith ions. For ICR cells which do have a trapping field, a term for the ith ion should be included in the summation of Equation [1]. This term will though be somewhat less that for an ion of differing mass.

UNIVERSAL COLLISIONAL ACTIVATION IN ION TRAP MASS SPECTROMETRY

Scott A. McLuckey, Douglas E. Goeringer, and Gary L. Glish

Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

A major difference between collisional activation in an ion trapping instrument and a beam instrument is that in the former collision activation is m/z dependent. In beam instruments all ions are accelerated as they are extracted from the ion source and this is the source of the kinetic energy needed for collisional activation. In trapping instruments, however, each m/z has a characteristic frequency of motion and kinetic excitation is obtained by applying an appropriate resonant excitation voltage. For the quadrupole ion trap MS/MS experiment, the resonant frequency of motion typically falls somewhere in the range of 50-300 kHz. From the operating parameters, an approximate resonant frequency can be determined but the actual frequency is also dependent upon the number of ions in the trap and can vary by several hundred Hz. Thus, the conventional MS/MS experiment in the quadrupole ion trap requires *a priori* knowledge of the parent ion mass and "frequency tuning" of the resonant excitation frequency. In this paper we present a new resonant excitation method that overcomes the need for tuning to obtain an MS/MS spectrum in an ion trapping instrument.

Instead of applying a single frequency to the endcaps for resonant excitation, a noise signal, which contains all frequencies, is applied. Figure 1 is a schematic of the experimental setup. An appropriate trigger pulse is used from the ion trap electronics to trigger a pulse generator which then turns on the noise generator. The output of the noise generator is input into a differential amplifier, as is the normal single frequency output from the ion trap electronics. This allows either the noise signal or the single frequency signal (used for axial modulation during data acquisition) to be applied to the endcaps. The rf amplifier is used to obtain sufficient amplitude on the noise signal and the Balun box phase shifts the output to one of the endcaps 180° to make the resonant excitation signal dipolar.

Figure 2 shows the MS/MS spectrum of the TNT molecular anion obtained by using noise excitation. Typical product ions are observed although the ions below m/z 190 are usually very minor in the single frequency MS/MS spectrum. The intensity of these lower mass product ions results from the fact that the product ions are also resonantly excited when using noise. In a single frequency MS/MS experiment, product ions are not resonantly excited and thus do not dissociate further. Thus, using noise for resonant excitation can generate spectra which have more product ions, which usually means more information.

Figure 3 shows an example of this, comparing the noise MS/MS spectrum with the single frequency MS/MS and MS^3 spectra of N,N-dimethylaniline. This figure shows that for a single frequency experiment an MS^3 experiment is required (with two tuning steps), to obtain useful information, while noise excitation gives similar information in a single MS/MS experiment. Differences are observed in the relative intensity of the second generation product ions from the single frequency experiment and the noise experiment and this is a result of continued dissociation of these second generation product ions in the noise MS/MS experiment. In this particular example, the MS/MS efficiency is about the same for both excitation methods. In general, however, the noise excitation is only 25 - 50% as efficient as single frequency excitation. This is due in part to multiple dissociation steps which form low mass ions below the trapping level.

In summary, noise excitation for collisional activation offers several attractive features: it is insensitive to space charge; does not require *a priori* knowledge of the parent ion; and provides more extensive fragmentation. The trade-off for these advantages is a loss of MS/MS efficiency of up to a factor of four. Some of the expected uses of the technique are: real-time MS/MS monitoring; on-line chromatography/MS/MS; declustering of ions injected from atmospheric pressure sources; resonant ejection during ionization/ion injection; and elimination of weakly bound adducts formed in elemental ionization techniques.

Selected Ion Trapping to Increase Sensitivity for Low Level Samples in Complex Matrices

S. E. Buttrill, Jr., Barrie Shaffer, Joe Karnicky, and James T. Arnold
The Edward L. Ginzton Research Center
Varian Associates, 3075 Hansen Way K-407, Palo Alto, CA 94304-1025

The very high sensitivity of ion-trap mass spectrometers is well known. It results from the ability of the ion trap to accumulate ions for a relatively long time and then scan them out rapidly to the detector. The effect is to integrate a weak ion current and then detect it as a short burst of ion current over 100 times larger than the current which would be measured if all of the ions at a single mass were continuously detected. However, the total capacity of the ion trap to store ions is limited by space charge effects. Very often, the storage capacity of the trap is taken up by ions formed from substances bleeding off of the gas chromatograph (GC) column and from uninteresting components of the sample matrix.

Trapped ions follow complex trajectories which are the superposition of several different oscillatory motions. It has been known since Paul's original disclosure that ion masses which were otherwise stably confined could be selectively ejected from the trap by a supplementary RF waveform at the fundamental frequency of the ion motion. This so-called secular frequency is given by $\omega_z = \beta\,\Omega/2$ where β is a function of $q=4eV/mr^2\,\Omega^2$ and so depends on the ion mass. We calculate a waveform which contains a frequency component at the secular frequency of each of the undesired ion masses. By applying this waveform across the end cap electrodes, all undesired ions are ejected simultaneously from the ion trap.

The timing diagram below shows how selected ion monitoring (SIM) works on the ion trap. Because the unwanted ions are ejected during all of the ionization and cooldown periods in a microscan, including the automatic gain control (AGC) prescan, they are removed from the reconstructed total ion current chromatogram without loss of any quantitative information. The AGC function continues to operate normally, so the dynamic range of the trap is actually extended.

RESULTS: In complex mixtures, the chemical background at the mass of interest will determine the detection limit using SIM. Figure 1 shows the result of using two SIM ranges to monitor dichloro- and trichloro- PCBs. The signal-to-noise for the low pg level PCBs is limited by the fluctuations in the baseline due to the m/z 222 and m/z 256 peaks from the many coeluting hydrocarbons in the transformer oil. In contrast, the SIM background is much lower for a clean hexachlorobenzene sample (Figure 2). 25 femtograms injected onto the GC column is easily detected with the correct isotope ratio for the chlorine isotope peaks.

Timing Diagram for Selected Ion Monitoring

Matrix-Assisted Laser Desorption Quadrupole Ion Trap Mass Spectrometry.

*Mark E. Bier, Jae C. Schwartz, Ian Jardine, and George Stafford
Finnigan Corp, 355 River Oaks Parkway, San Jose, CA 94025

Matrix-assisted laser desorption (MALD) of large biomolecules, such as peptides, has become routine using time-of-flight (TOF) mass spectrometers. With the advent of external ionization/ion injection, mass range extension, and improved resolution capabilities, the ion trap mass spectrometer may also be used to analyze large biomolecules by the MALD technique.

A pulsed nitrogen laser beam at 337.1 nm (Laser Science) was focused onto a 200 μm core fiber optic (Newport). The fiber transmits the 3 ns pulse of photons at 10^6-10^7 W/cm^2 to the external source where a stainless steel probe tip holds a matrix:sample (1000:1) mixture. We used a 2,5-dihydroxybenzoic acid matrix for molecular weights below 20,000 amu and a sinnapinic acid matrix for molecular weights above 20,000 amu. The exposed spot was 0.1-0.4 mm^2 in diameter. The power density and the spot size were adjusted by moving the probe along the ion axis and were chosen for optimum performance. The probe was also rotated to expose fresh sample matrix (see Figure **1**).

The desorbed ions were extracted from the external source and transmitted at relatively low kinetic energy into the ion trap for analysis. The main rf was increased in amplitude to trap the higher mass peptides or proteins during the "ionization" period. Both the main rf and the resonance frequency were decreased as the mass range was extended eventually reaching 130,000 amu (β_{eject}= 0.013, Rf= 550,300 Hz). Under these conditions it was possible to scan the analyzer at a rate of 880,000 amu/s. For high resolution work the Rf amplitude scan rate was decreased and the appropriate resonance amplitude was applied to the end caps.

In Figure **2** the mass spectrum from one laser shot shows the $(M+H)^+$ ions for angiotensin I and 10 pmoles of renin substrate. The renin substrate isotope cluster was further isolated and resolved into the isotopes as shown in Figure **3**. Isotopes were also resolved for mellitin having an average molecular weight of 2847.3 amu shown in Figure **4**. MS/MS is shown for bovine insulin (M.W.=5733.6) in Figure **5**. Fragments of bovine insulin are seen throughout the mass range. A three pmole sample of α-lactalbumin (M.W.=14175) is shown in Figure **6** along with its doubly charged ion. Egg albumin having a molecular weight of 43300 amu can be observed and is shown in Figure **7**.

By controlling space charge, increasing the number of data points per amu, and improving the ion trap electronics, the performance of this mass spectrometer at high mass and high resolution should greatly improve. These experiments show MALD/ion trap feasibility to 50,000 amu with a resolution of 6000 at m/z 3000. The encouraging MS/MS data for bovine insulin suggests that even at high mass, CAD is still possible in an ion trap.

Oak Ridge National Laboratory
Oak Ridge, TN 37831-6142

The electrodynamic trap has achieved widespread use in the mass spectrometry community in the form of the ion trap mass spectrometer or quadrupole ion trap (1). We are developing a novel technique for the chemical characterization of single microparticles that is based upon the use of the electrodynamic trap. Small macroscopic particles with diameters less than 100 μm can be confined or levitated within the electrode structure of the three-dimensional quadrupole electrodynamic trap in the same way as fundamental charges or molecular ions (2). By using a combination of ac and dc potentials the microparticle can be made to reside motionless at the center of the trap after appropriate damping.

In our concept the microparticle will first be trapped and spatially stabilized within the trap for characterization by optical probes, i.e., absorption, fluorescence, or Raman spectroscopy. (We have previously shown that such spectroscopic probes can be extremely sensitive, e.g., a detection limit of one molecule of Rhodamine-6G has been determined in the case of fluorescence spectroscopy (3,4)). After the particle has been optically characterized, it will be further characterized by mass analyzing the ions generated from the particle surface using laser ablation or desorption. When the laser pulse strikes the particle the voltages applied to the trap are changed from a particle levitation mode to an ion trapping mode and the ions formed are subsequently mass analyzed in the normal manner of operation of the trap. Laser desorption has previously been demonstrated in ion trap devices by applying the sample to a probe which is inserted so as to place the sample at the surface of the ring electrode (5,6). We have demonstrated proof-of-principle experiments by dropping microparticles along the rotational symmetry axis of the trap. The laser was triggered such that the particle was illuminated as it falls through the center of the trap. A detection limit of ~ 1 femtomole was obtained for tetraphenylphosphonium bromide on the surface of a 125-um diameter silicon carbide particle. This sensitivity was achieved using one laser pulse on a single particle. The work described here focuses on the ability to perform laser desorption experiments on a single microparticle levitated at the center of the ion trap.

The ion trapping device that is used for these experiments is a modified Finnigan MAT Model 800 Ion Trap Detector (ITD). The trapping electrodes were removed from the ITD vacuum chamber and placed in a 6-inch vacuum cube with the rotational symmetry axis of the trap oriented vertically. The rf voltage from the ITD was reattached to the ring electrode through a high-voltage vacuum feed through and the transformer was retuned for resonance. Three millimeter holes were drilled in the ring electrode for laser access.

Figure 1 shows a schematic diagram of the circuitry that is used for particle levitation and ion mass analysis. The charged particle to be analyzed is dropped into the trap at atmospheric pressure with the appropriate 60 Hz ac and dc potentials applied to the end caps for trapping the particle. The trapped particle is illuminated with a 5-mW HeNe laser and observed with a telescope. The trapping potentials are adjusted if necessary to keep the particle stabilized at the center of the trap while the cube is evacuated and then maintained at nominally 1 mtorr of He buffer gas as usual. At this point the ITD electronics are activated to start the normal ion trapping and mass scanning sequence. In order to

PARTICLE LEVITATION/ION TRAP MS

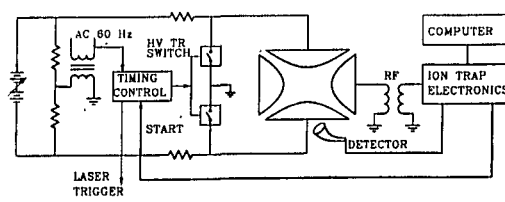

Figure 1

measure the mass spectra of ions desorbed from the particle, the applied ac and dc potentials must be turned off and the end caps grounded at the time of ionization. This is accomplished by the timing control electronics as shown in Figure 1. The switching sequence and time behavior of the applied voltages are illustrated in Figure 2. When a trigger pulse is initiated by the ion trap electronics (Fig.2B), the timing control electronics waits for a preset phase angle of the 60 Hz ac (Fig. 2C). When this phase angle is reached the HV transistor switches are closed and the end caps are grounded (Fig. 2D). The laser pulse for the desorption/ionization is triggered at this time (Fig. 2F) and the ITD scans the rf voltage to record the mass spectrum (Fig. 2E). The fourth harmonic laser radiation from a pulsed Nd:YAG laser (Quanta-Ray DCR-2A) is being used for desorption/ionization.

Figure 3 shows a mass spectrum that was obtained for a 50 um levitated nickel particle with adsorbed tetraphenylphosphonium bromide (TPPB). The particle loading was estimated to be about 3 ng of TPPB. The spectrum represents the analysis of a single particle with one laser pulse. We have demonstrated that a microparticle can be restabilized at the center of the trap after the levitating ac and dc potentials have been momentarily turned off. This depends upon how far the particle has dropped and the phase angle of the ac when the potentials were turned off. We hope to be able to use this capability for signal averaging from multiple desorption experiments on a single particle.

Laser Desorption and Selective Ion-Molecule Reactions in a Quadrupole Ion Trap Mass Spectrometer

Jennifer S. Brodbelt, Chien-Chung Liou and Aubrey McIntosh
Department of Chemistry, University of Texas, Austin, TX 78712-1167.

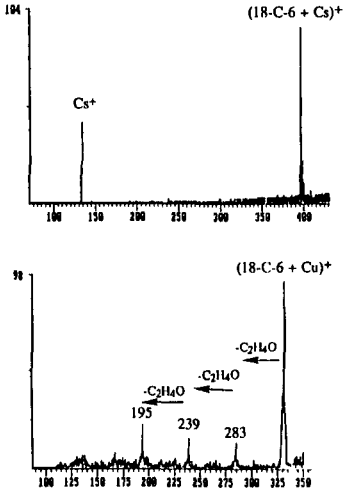
The implementation of a versatile new fiber optic laser desorption interface and a probe-mounted electron ionization source have recently been completed in our lab. Combined with our continuing interest in selective ion-molecule reactions for analytical applications, these developments open many new frontiers for the types of investigations that can be undertaken with a quadrupole ion trap. For example, laser desorption can be used to generate various metal ions for subsequent reactions with organic substrates. Such reactions are important for our ongoing studies of host-guest chemistry in the gas phase. Ultimately, metal ion reactions with polyfunctional organic substrates may prove useful for modelling some of the types of selective chemistry that occur for antibiotics and metabolic products.

Crown ether macrocycles are suitable models for hosts because they consist of an array of repeating structural units that define a cavity size. Due to the electrostatic nature of the oxygen atoms, crown ethers form complexes with a variety of atomic and polyatomic substrates (guests). The binding selectivity is determined by the cavity size of the crown ether and the thermodynamic properties of the host and guest substrates. Simple guests which have been examined to date included the alkali metal cations which form a size-ordered array of spherical guests. These alkali metal cations are bound through weak multiple electrostatic interactions to the oxygen atoms of the macrocycles. Other types of guests, such as transition metal ions or ammonium ions, provide insight into other types of binding interactions. For example, transition metal ions bind with more covalent character than alkali metal cations, and in fact may insert into polar C-O ether bonds. Alternately, ammonium ions may promote formation of multiple strong hydrogen bonds to the macrocyclic host. Such structural changes are manifested in the different types of dissociation processes that the host-guest complexes undergo after collisional activation.

Several techniques are used to investigate host-guest complexation in the gas phase. Complexes may be formed by simple ion-molecule association reactions between a crown ether and a selected guest. Depending on the nature of the guest, it is initially formed by laser desorption of an alkali metal salt or a metal foil. Orders of binding affinities of the crown ethers are determined by application of the kinetic method, in which an adduct consisting of two different hosts bound to a single guest is energized to induce de-complexation. The host having the higher affinity for the guest preferentially retains the guest to a larger extent, and this appears as a more abundant ion in the CAD spectrum. Host-guest binding energies can also be estimated by measurement of thresholds for decomplexation from energy-resolved collisional activation experiments, and the structures of the complexes are evaluated by comparison of collision-activated dissociation spectra.

In order to obtain a detailed understanding of the factors which influence the formation, stabilization and structures of gas-phase host-guest complexes, the binding characteristics of macrocyclic building blocks were examined. For example, dimethyl ether is the simplest ether building block and 1,2-dimethoxyethane is the simplest acyclic diether unit of a crown ether and both are expected to reflect some of the binding properties of the larger macrocycles without the strong influence of multiple binding interactions. The ether models form loosely-bound complexes and dimers by

association reactions with alkali metal cations. However, these substrates form different types of clusters with transition metal ions, including ones in which the ether sub-units have undergone covalent bond cleavages during the complexation processes. The electronic nature of the guest model is also an important factor in the complexation process. For example, alkali metal cations form multiple weak electrostatic bonds with the oxygen atoms of the crown ether host, whereas transition metal cations undergo insertion into the C-O bonds of the macrocycle. These different behaviors are indicated by the distinctive types of CAD spectra generated from each metal/crown ether complex (Figure 1).



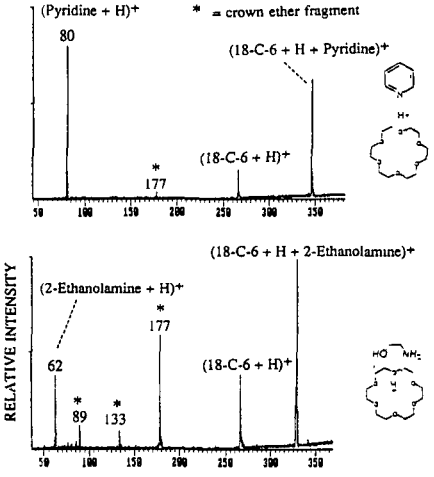


Figure 1. CAD spectra for (18-crown-6 + Cs)+ and (18-crown-6 + Cu)+

Figure 2. CAD spectra for complexes of 18-crown-6 with pyridine and 2-aminoethanol.

The opportunity for formation of multiple hydrogen-bonds exists in complexation of an ammonium ion with a crown ether. Depending on the cavity size of the crown ether (an entropic factor which influences the capability for formation of near-linear hydrogen bonds), and the number of possible hydrogen-bond donating or accepting sites in the host and guest substrates (all OH and NH groups), the resulting complexes may be loosely or strongly bound. These differences are manifested in the CAD spectra as simple cleavage of the host-guest complex into intact constituents or as fragmentation of the macrocyclic skeleton. Illustrated in Figure 2 are the dissociation spectra of two types of hydrogen-bonded complexes involving 18-crown-6, a flexible host with many hydrogen-bond accepting sites. The complex with pyridine dissociates by simple decomplexation processes, whereas the complex involving 2-aminoethanol shows extensive covalent bond cleavages within the crown ether. The latter behavior is indicative of a strongly-bound complex. Acyclic ethers are more flexible and thus are better able to adapt a suitable conformation for involvement in multiple hydrogen-bonding interactions to an ammonium ion. For example, 12-crown-4 has four binding sites but because of its rigid cyclic nature, it is unable to form strongly-bound complexes with any ammonium ion. In contrast, diethylene glycol dimethyl ether has only three binding sites but it forms strongly bound complexes with the ammonium ion.

THE EFFECT OF ALTERNATIVE GASES ON RELATIVE SENSITIVITY FACTOR VALUES USING PULSED GDMS

S. K. Ohorodnik* and W. W. Harrison
Department of Chemistry
University of Florida
Gainesville, Fl 23611-2046 USA

INTRODUCTION

Pulsed glow discharge mass spectrometry (GDMS) is a recently developed technique for trace elemental analysis of solid materials. The pulsed discharge produces higher sputter yields and ion signals than its dc counterpart as well as exhibits time-dependent anomalies on individual ion signals. It is these anomalies that are of particular interest since they might provide information on the fundamental processes occurring in the glow discharge.

The applied voltage is turned on and off following the square wave input of a pulse generator. An increase in ion signal is observed at different times in the pulse period for sputtered and contaminant gaseous species. A rapid increase in ion signal at the beginning of the pulse (prepeak) is observed for the gaseous species before dropping to a plateau value for the remainder of the on time of the pulse period. The sputtered species ion signal increases to a plateau value, then upon termination of the pulse a rapid rise in the signal is observed (afterpeak). It is possible that different ionization mechanisms are responsible for these signal anomalies. Electron ionization (EI) probably dominates during the prepeak, while Penning ionization (PI) probably dominates during the afterpeak region. The dc discharge and the plateau of the pulsed discharge are both assumed to be a combination of electron and Penning ionizations. If different ionization mechanisms dominate during the pulse period, differences in the relative sensitivity factor (RSF) values obtained for the plateau and afterpeak regions of the ion signal.

The RSF value is a ratio of the sensitivity (signal intensity/concentration) of an analyte element to the sensitivity of a reference element.

$$RSF = \frac{signal\ intensity_{anal}}{conc_{anal}} \times \frac{conc_{ref}}{signal\ intensity_{ref}}$$

RSF values correct for reproducible variations due to the physical, chemical, and instrumental effects in the observed sensitivities. The RSF values obtained from a standard material similar in composition to the unknown sample can be used for the analysis of the unknown as long as constant analysis conditions are maintained.

Previous studies using argon showed no significant differences in RSF values for the plateau and afterpeak regions of the pulse and the equivalent dc discharge. This presentation will report results obtained when neon was added to the argon discharge. Neon has higher metastable energy levels of 16.6 and 16.7 eV compared to 11.5 and 11.7 eV for argon allowing comparison of RSF values between EI and differing levels of PI.

EXPERIMENTAL

The glow discharge serves as the ion source of a quadrupole mass spectrometer. The discharge can be operated in a dc or pulsed dc mode. When operating in the pulsed mode, a pulse generator controls the discharge power supply amplitude (0-4000V) and frequency (20-100Hz) and triggers the data collection system. The trigger from the pulse generator is sent to a delay box that produces the data acquisition gate that can be placed on the afterpeak, plateau, or dc ion signal. All experiments were performed with a pulse rate of 100Hz, a 50% duty cycle, and an absolute pressure of 1 Torr for the various argon/neon gas mixtures. The sample was a low-alloy steel standard, NIST SRM 1264. The discharge voltage was held constant at 1250 or 1500V.

RESULTS AND DISCUSSIONS

As the gas mixture was varied from 100% argon to a mixture of 20% argon and 80% neon, the RSF values were found to be similar for the dc discharge and the plateau and afterpeak regions of the pulsed discharge. Figure 1 illustrates the results obtained for the 60% argon and 40% neon gas mixture. Initially, it might be assumed that there is no difference between the ionization mechanisms for plateau and afterpeak regions of the ion signal, but this is not correct since the afterpeak appears after the discharge voltage has turned off, resulting in the elimination of electrons and EI. It is possible that the afterpeak is due to an increase in metastable atoms caused by the elimination of the recombination processes with electrons.

It was observed that when neon was added to the argon, the afterpeak decreased in size compared to the plateau. The results are shown in Figure 2 where the ratio of the afterpeak height compared to the plateau height is plotted for the $^{56}Fe^{+}$ signal using a discharge voltage of 1500V. The results were obtained for two cases: (1) tuning the ion optics using 100% argon and (2) tuning the ion optics for 100% neon. When using a mixture of neon and argon, the afterpeak to plateau ratio is smaller than for the 100% argon or neon discharge. It appears that the afterpeak formation is being quenched. Correspondingly, as the amount of neon is increased, there is a corresponding increase in the Ar^{+} signal because the neon metastable has sufficient energy to ionize the argon atom. This results in fewer argon and neon metastable atoms to ionize the sputtered species.

Initial results appear to indicate that the metastable atoms are responsible for the afterpeak formation in the pulsed discharge. This will be further examined by using a discharge gas with lower metastable energy levels (such as xenon with 8.3 and 9.4 eV). An element having a larger ionization potential (such as carbon with 11.3 eV) should not produce an afterpeak when xenon is used as the discharge gas. In addition, the effect of quenching the afterpeak formation by introducing water or methane into the discharge will be investigated.

THE ROLE OF TRACE WATER VAPOR IN GLOW DISCHARGE MASS SPECTROMETRY

*P.H. Ratliff and W.W. Harrison
Department of Chemistry
University of Florida
Gainesville, FL 32611-2046 USA.

The glow discharge (GD) is a versatile ion source for mass spectrometric studies of a solid sample, producing ion signals that are representative of the sputtered bulk sample. However, the processes occurring in this source are susceptible to impurities (especially water) coming from the discharge gas, vacuum leaks, or sample introduction. This presentation focuses on the effects of trace water vapor on plasma processes and discusses possible methods (e.g., getter elements and liquid nitrogen cooling) for controlling the water vapor content.

Dramatically different mass spectra are obtained as the water vapor content varies in a GD ion source. Using a "clean" source, the spectrum is dominated by the sputtered sample and support gas ion signals, while a "contaminated" source results in a spectrum dominated by water species ion signals (i.e., H_2O^+ and H_3O^+). These results may become more apparent when equations that involve water are considered. Some of the pertinent reactions are shown below:

$$Ar^+ + H_2O \rightarrow ArH^+ + OH$$
$$ArH^+ + H_2O \rightarrow H_3O^+ + Ar$$
$$H_2O^+ + H_2O \rightarrow H_3O^+ + OH$$
$$Ar^+ + H_2O \rightarrow H_2O^+ + Ar$$

As can be seen from these equations, the addition of water into the ion source will shift the equilibrium of each reaction to the right. Thus a mass spectrum taken at this time would reveal large amounts of H_2O^+ and H_3O^+. This is illustrated in Figure 1. The top half of the figure was taken after approximately 20 minutes of sputtering, which is sufficient time for the plasma to stabilize and produce a spectrum that is fairly free of contaminant species. The bottom spectrum was taken about 5 minutes after bleeding in a steady amount of water equivalent to 0.05 Torr pressure, or about 5% of the total chamber pressure. These results may be from the effects water vapor has on the atomization step, the ionization step, or a combination of the two. These effects may be countered by three water removal methods: 1) the MS vacuum system , 2) plasma reactions of sputtered species with water, and 3) use of a liquid nitrogen cooled coil to freeze out the water vapor.

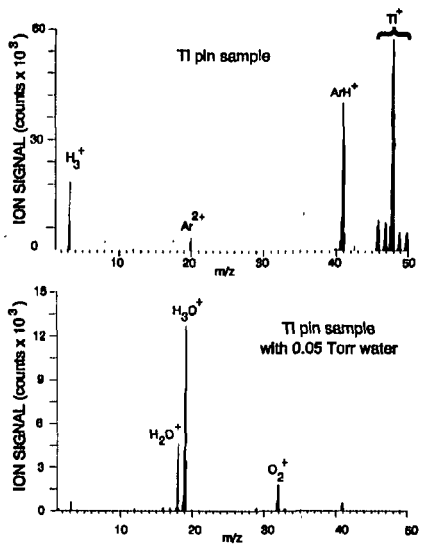

Figure 1. Comparison of titanium spectra taken under different plasma conditions.

Mass spectra have been taken as water vapor is removed to compare these three methods. Water removal by pumping alone is slow and does not produce a water-free spectrum. Various degrees of water removal are achieved by sputtering different cathode materials. For titanium (a getter) the $^{48}Ti^+/H_2O^+$ ratio is about 25 after 20-30 minutes of sputtering; for copper, the $^{63}Cu^+/H_2O^+$ ratio is only about 1.3. Time profiles were obtained for the species involved in the possible plasma reactions of water to study the equilibrium shifts with changing

water content. These results are shown in Figures 2 and 3 below. Figure 2 is a plot of how the water content in the plasma is changing over the time frame of the experiment. Figure 3 illustrates how three different matrix ion signals (Cu^+ in copper pin, Ti^+ in titanium pin, and Fe^+ in NBS SRM 1265 low alloy stainless steel pin) behave over this same time frame.

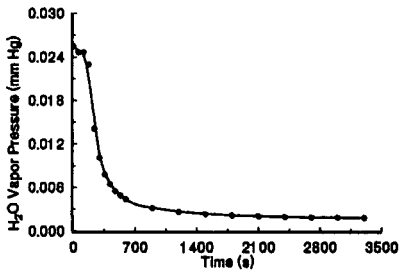

Figure 2. Water vapor pressure in the mass spectrometer ion source. The water inlet valve was closed at t=166 s.

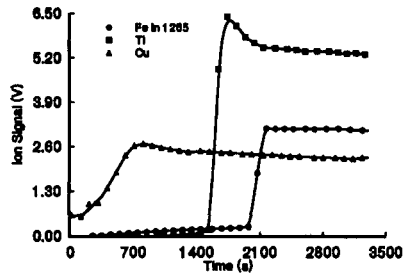

Figure 3. Behavior of three matrix ion signals as water is removed from the ion source. Water vapor turned off at t=166 s.

These three elements are of interest since they exhibit a range of differing oxide bond strengths (Ti-O, 159.3±1.5 kcal/mol; Fe-O, 97.7±3 kcal/mol; Cu-O, 65.2 kcal/mol). Figure 3 contains three different stages with respect to time: 1) the initial stage before and just after the water valve is closed, 2) the middle stage where ion signal transitions occur, and 3) the final stage after the transitions, where the ion signals again reach a steady state intensity. The initial stage exhibits ion signals that are at or very close to zero intensity. The only observable signal at this point is from copper. During this period, the surface of the cathode should be essentially oxidized due to the presence of the water vapor. The copper exhibits a small ion signal probably because its surface is not as readily oxidized as the other two cathodes due to its lower reactivity toward oxygen. After the water is turned off, the copper signal begins to increase more quickly than the other two suggesting that the relatively thinner oxide layer is being removed more readily and the copper atoms in the sample may begin to sputter sufficiently and produce an ion signal. In the middle stage, a "titration-like" curve is seen for the titanium sample at about 1500 s. The iron signal shows a similar behavior, but its "transition point" occurs later, at about 2100 s. This demonstrates the ability that iron and titanium cathodes have to produce a "clean" discharge environment, although it takes longer to achieve these conditions for iron since its ability for chemical removal of water is less sufficient than titanium, as evidenced by the lower oxide bond strength of iron. At the times where titanium and iron are quickly increasing, the copper ion signal is maintaining its plateau value and shows no "transition point."

A liquid nitrogen cooling coil was constructed to fit inside the mass spectrometer ion source. The coil was made from 1/8" stainless steel and surrounded end of the direct insertion probe where the sample and plasma are located. The liquid nitrogen cooling source was the most effective method studied for removing water and maintaining a "clean" ion source. After about five minutes of using liquid nitrogen the $^{48}Ti^+/H_2O^+$ ratio was >4000 while the $^{63}Cu^+/H_2O^+$ ratio was only about 50. Thus coupling liquid nitrogen cooling with a gettering element cathode to react with the water molecules in the plasma resulted in a very efficient removal of water. One disadvantage of this method may occur if the analysis takes a long time. Depending on the discharge conditions, the coil may become saturated and the water might reach an equilibrium between the gas phase in the ion source and the solid phase on the coil. The time at which this might occur will vary with the discharge conditions.

RF-GLOW DISCHARGE COMBINED WITH A QUADRUPOLE ION TRAP FOR ELEMENTAL ANALYSIS

Gary L. Glish[1], Scott A. McLuckey[1], Douglas C. Duckworth[1,2], and R. Kenneth Marcus[2]

[1]Analytical Chemistry Division

Clemson University
Clemson, SC 29634

The quadrupole ion trap has developed from a very sensitive GC detector into a multipurpose mass spectrometer. Some of the capabilities that have spurred this development are high efficiency MS/MS, high resolution, controlled ion/molecule reactions, and coupling with external ionization sources. A wide variety of ionization techniques have now been demonstrated with the quadrupole ion trap, mostly for organic or biological samples. However, the same capabilities that make the ion trap useful for organic mass spectrometry suggest that it should also have a role in inorganic mass spectrometry. In this paper we present some preliminary results of using the quadrupole ion trap for elemental analysis by combining it with an rf-glow discharge ionization source.

Most experiments were performed with a brass sample (NIST 1103) which contains the following elements (Cu, 59.27%; Zn, 35,72%; Pb, 3.37%; Sn, 0.88%; Fe, 0.26%; Ni, 0.15%). Figure 1 compares the mass spectrum obtained on the quadrupole ion trap (bottom) with a mass spectrum from the literature (Jakubowski et al. Int J. Mass Spectrom. Ion Processes, 71, 183 (1986)) of an unknown brass sample obtained on a quadrupole instrument*. The relative intensity of the peaks in the ion trap spectrum will be discussed below. The purpose of this figure is to show the lack of matrix (Ar) related ions in the ion trap spectrum. The absence of these potential interferents can be attributed to either the "warm" or the "reactive" environment of the quadrupole ion trap. The metal argides are weakly bound species and most likely dissociate in the ion trap experiment, either upon ion injection or during the milliseconds that they are trapped prior to ejection during the mass scan. The more stable species, such as $Ar^{+\cdot}$, ArH^+ and $Ar_2^{+\cdot}$, react by charge exchange or proton transfer with residual H_2O. The ions formed (m/z 18 and 19) are typically below the low mass cut-off and thus are not trapped. This leaves the metal ions as the dominate species in the mass spectrum.

Figure 2 shows the scan function that was used to obtain the ion trap mass spectrum shown in Figure 1. One of the capabilities of the ion trap is that specific ranges of masses can be selective enhanced or discriminated against during ion injection. Additionally, the ion injection time can be varied allowing long ion injection times to be used for minor components to increase the number of ions in the mass spectrum. Thus, the ion trap mass spectrum shown in Fig. 1 was obtained in segments with differing ion injection times to compensate for the variation in composition of the sample. The Fe and Ni ions were injected for 100 ms. A dc voltage was applied to the ring electrode during injection to keep higher mass ions from being trapped. After scanning over the Fe and Ni range of the mass spectrum, all the ions were ejected out of the ion trap and a 1 ms ion injection time was used to obtain the portion of the mass spectrum with the major components, Cu and Zn. Following this segment, a 100 ms ion injection time was used to inject the Sn ions. During the injection period a dc voltage was applied to the ring electrode and a resonant excitation voltage was applied to the endcaps. The combination of these two voltages ejects the lower mass ions that would otherwise space charge limit the number of Sn ions which could be injected into the ion trap. Finally, for the fourth segment of the mass spectrum, Pb ions are injected for 20 ms with a dc used to eject low mass ions to avoid space charge limitations.

In the initial experiments contamination in the ion source lead to a relatively large number of oxide species being formed. However, in the ion trap, predominately hydroxides were observed, due to reaction of the oxides with residual water. The MS/MS capability of the ion trap to dissociate polyatomic species is shown in Figure 3 for $BaOH^+$, formed by the above mentioned mechanism. It is seen in this figure that essentially 100% MS/MS efficiency is obtained, with unit mass selectivity.

*(The literature spectrum was obtained with a dc glow discharge but we find no difference in the spectra of this sample on the ion trap using either an rf or dc discharge.)

These preliminary results suggest that the quadrupole ion trap may be able to make a significant contribution to elemental analysis. A major advantage of the ion trap over other mass spectrometers appears to be it ability to deal with polyatomic interferences. In addition to the techniques demonstrated here, other new ion trap capabilities, such as high resolution and universal CID, should add even more to the potential of the ion trap for elemental analysis.

SAMPLING RADIO FREQUENCY GLOW DISCHARGES WITH A FOURIER TRANSFORM/ ION CYCLOTRON RESONANCE MASS SPECTROMETER

R. Kenneth Marcus,[1] Paul R. Cable,[1] Douglas C. Duckworth,[1,2] Michelle Buchanan,[2] Joseph M. Pochkowski,[3] and Robert R. Weller,[3]

[1]Department of Chemistry, Howard L. Hunter Chemical Laboratories, Clemson University, Clemson, SC 29634. [2]Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN, 37831. [3] Environmental Technology Section, Westinghouse Savannah River Company, Aiken, SC 29802.

Plasma source mass spectrometry has proven over the last ten years to be a powerful means of providing complete, high sensitivity elemental analysis. As such, the techniques of ICP-MS and GDMS are approaching a relatively mature state. Two of the areas in which advances in the field may be made are in minimization/elimination of spectral (isobaric) interferences and in the improvement of short term stability (i.e., precision). Minimization of isobaric interferences has been achieved in commercial instrumentation through judicious choice of discharge conditions and the use of high resolution (6,000-10,000) sector-based mass spectrometers. Such instruments alleviate many "simple" isobaric overlaps, but may not be suitable for many applications. I terms of improved precision, multi-collector sector instrumentation is now available for use over limited mass ranges. We present here an approach for still higher mass resolving powers and pseudo-simultaneous monitoring capabilities by the use of Fourier transform/ion cyclotron resonance (FT/ICR) mass spectrometry. In this demonstration project at the Oak Ridge National Laboratory, a radio frequency (rf) powered glow discharge device is employed as the atomization/ionization source. As has been described previously [1], this source allows for the direct elemental analysis of solid samples ranging from metals and alloys to glasses and ceramics.

EXPERIMENTAL

The instrumentation employed in the rf -GD/FTMS experiments described here is shown in Figure 1. The radio frequency glow discharge source relies on a direct insertion probe for sample introduction into a stainless steel six-way cross (2.75" conflat) which acts as the anode ion volume. Samples are mounted to the end of the probe with the rf potential applied directly through an isolated feedthrough. The plasma operating parameters were a pressure of 0.15 torr Ar and a power of 45 watts. The six-way cross source housing was mounted to a five-way cross (6" conflat) which was in turn coupled to the end flange on the analyzer side of an FTMS 2000 (Extrel FTMS, Madison, WI) by way of a 8.5" long nipple. Addition pumping capacity was provided by a 1200 l/sec diffusion pump also attached to the five-way cross. The GD source had a 0.01" ion exit aperture to the differential pumping region which in turn had a 0.375" conductance limit to the nipple and the main chamber. The resultant pressures in the "analyzer" cell of the FTMS 2000 were on the order of 1-5 X 10^{-7} torr. In the work presented here, the analyzer cell was used for spectra acquisition as ion transfer efficiencies to the lower pressure "source" cell were low, possibly due to misalignment of the vacuum system caused by the addition of the auxiliary pumping stage. In spite of the less than ideal vacuum conditions, mass resolving powers ($m/\Delta m$) on the order of 75,000 have been achieved with this instrumentation. It must be stressed that no ion optics are employed in the current system.

RESULTS AND DISCUSSION

The well defined, relatively low energy rf-GD ion beam (KE = 15+/-2 eV) is easily accepted into the ICR cell. The initial kinetic energy of the ions, travelling in a collinear fashion, serves to inject the ion along the magnetic field axis and are likely focussed into the analyzer cell by those fields. In general, trapping potentials of the order on 8-10 volts are sufficient to trap large populations of GD-produced ions. Shown in Figure 2 is a broadband rf-GD/FTMS spectrum of NIST 1103 brass. The spectrum is a 256k-point transform of the transients of 100, one-second ion accumulations. Seen clearly are the Cu^+ and Zn^+ matrix species ($m/\Delta m$ = ~12,000) along with the common Ar^+ and ArH^+ discharge gas ions. Scale expansion reveals the minor analyte species such as Pb (3.72% in the sample). Figure 3 shows narrow

bandwidth (1 MHz) detection of the major species in this sample. The spectrum is a 256k- point transform of the transients of 1000, one-second ion accumulations The mass resolving power observed in this spectrum is ~40,000. The types of resolving powers seen to date are more than adequate for alleviating the vast majority of isobaric interferences encountered in all forms of plasma source mass spectrometry. Relatively simple instrumentation alterations should allow for attainment of resolving powers of >100,000 The instrumentation is relatively straightforward and appears to be viable alternative for high resolution, pseudo-simultaneous elemental analysis.

An Improved Ion Guide for External Injection Glow Discharge-Fourier Transform Ion Cyclotron Resonance (GD-FTICR) Mass Spectrometry

C.M. Barshick
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN, 37831-6375, USA

J.R. Eyler

Gainesville, FL 32611-2046, USA

Ion generation external to the analyzer cell in FTMS has proven to be a powerful means of obtaining mass spectral information for ionization sources that operate above the relatively low conventional pressure requirements (10^{-6} - 10^{-8} Torr) necessary for high resolution and good signal-to-noise ratios. Previously we described how external injection of glow discharge (GD) generated ions was facilitated by a relatively simple four element electrostatic lens. Quantitative analysis at the 0.1% and above level was demonstrated, along with mass resolution ($m/\Delta m_{1/2}$) in excess of 40,000. Based on the sensitivity demonstrated for other GDMS instruments, however, we believe that factors such as the "magnetic mirror effect" or collisional scattering of ions by the relatively high gas pressures they encounter during transport from the source are playing a role in determining the total ion population in the analyzer.

For this study several modifications were implemented to improve ion transport. One simple improvement was the addition of an electrically isolated conductance limiting (CL) orifice, which previously had been maintained at ground potential and used only to facilitate pumping between the source and analyzer. Additionally, an electrically isolated ion flight tube was positioned behind the conductance limiting orifice along the injection (z) axis, and an ion decelerator, consisting of an electrically isolated ring electrode and a grounded housing, was positioned behind the flight tube and in front of the entrance trapping plate of the analyzer cell.

A nonconventional total ion detection scheme was facilitated by the use of a Faraday cup/probe built at the University of Florida. The probe was constructed from a 5 kV high voltage feedthrough welded into a 97.5" long stainless steel tube. This probe was inserted through a 0.5" diameter solids insertion probe vacuum interlock to permit manipulation along the z-axis in the vacuum chamber. The probe passed through the icr analyzer cell (trapping plates open) and could be extended to within a few millimeters of the cell side of the conductance limit. In this manner, the ion beam intensity could be measured from the conductance limit to the analyzer cell without breaking vacuum.

For the initial measurements, the ion signal was monitored by standard FTICR detection in the analyzer cell as a function of the CL voltage. A 2 - 5 x increase in signal intensity was observed as a 75 V negative bias was applied to the previously grounded CL. This increase in signal intensity is believed to result from the more efficient transport of ions through the CL and not any additional source of ionization.

Even though the signal level improved with the addition of a voltage to the conductance limit, no steps had been taken yet to overcome the effects of the fringing magnetic fields. Figure 1 illustrates the variation in magnetic field strength along the primary injection axis (z-axis) for the 2.0 Tesla superconducting magnetic used in our FTICR-MS system (filled squares). As the field is measured from the GD source to the analyzer cell, an increase from 95 G to 20,000 G is observed. It is reasonable to assume that the transport of ions over this region is tenuous, and that our prior success can be attributed to the abundant population and small energy spread of ions exiting the GD source. In order to gauge the effects of the magnetic field, the ion beam current was measured along the injection axis under conditions for a grounded CL/grounded flight tube (A), a -75 V CL/grounded flight tube (B), and a -75 V CL/-175 V flight tube (C). These results are also illustrated in Figure 1 (open squares). The signal intensity directly behind the CL is increased ca. 7 times in applying -75 volts to the CL; this agrees surprisingly well with the results discussed in the previous paragraph obtained from ion signals detected by FTICR methods in the analyzer cell. As the ion beam is monitored closer to the analyzer cell a decrease in signal is observed (Figure 1A and 1B); this decrease occurs over the same region in which the magnetic field is sharply increasing, a fact that is not surprising. In fact, with the grounded flight tube there is a 2 - 3 fold loss in ion current arriving at the analyzer cell compared to that at the CL, due solely to the fringing fields of the magnet. However, with a potential applied to both the CL and the flight tube (C), a virtually constant ion beam is present from the conductance limit through the fringing magnetic field and into the icr cell. Thus the combination of a floating conductance limit, flight tube, and decelerator increased the number of glow discharge generated ions reaching the analyzer cell by almost a factor of 20, with no apparent ion loss in the fringing magnetic field.

Analysis of Isotope Ratios in Single Particles Using Particle-Inlet Mass Spectrometry

John F. Wacker
Pacific Northwest Laboratory[1], P.O. Box 999, Richland, WA 99352

Introduction: The chemical analysis of individual particles is an emerging field that encompasses a wide range of topics, from tracing pollutants in the environment [1–4] to analyzing dust from comets [5]. Several mass spectrometric methods have been developed for particle analysis, including secondary ion microscopy (SIMS) [6], laser microprobe mass spectrometry (LAMMA) [7], and direct-inlet mass spectrometric methods [8-9], such as Particle-Inlet Mass Spectrometry (PIMS) [10]. With the exception of the direct inlet methods, all of these techniques require locating the particles of interest — a time consuming process that severely limits the speed of analyzing samples.

In contrast to other mass spectrometric techniques, PIMS analyzes particles by directly admitting them in aerosol form into the ion source of a mass spectrometer. PIMS is rapid: particulate samples, such as soils, can be measured in minutes, and airborne particles, such as dusts and aerosols, can be measured in real-time. PIMS is also highly sensitive: sub-micron particles ($\leq 10^{-12}$ g), are easily measured. Simultaneous measurement of multiple isotopes provides good background rejection as well as providing information on chemical speciation. With real-time capabilities, PIMS can be used to correlate the chemical or isotopic compositions of the particles with the particle generation conditions. We have developed PIMS for analyzing uranium in particles for applications such as monitoring environmental contamination and radiation detection.

Mass spectrometry: The PIMS instrument is a single-focusing, 60°, 15-cm-radius, magnetic sector mass spectrometer, with a thermal ionization source, and a multi-mass ion detector. A differentially-pumped nozzle-skimmer inlet forms the basis of the PIMS technique. Aerosol particles are drawn into the inlet, focused into a beam, and directed into an oven in the ion source. The oven, which consists of rhenium foil and can be resistively heated to 2400°C, vaporizes the particles and thermally ionizes the vapor.

Ion detection: The ion detector uses a microchannel plate (MCP) and has four pairs of slits and anodes. Each slit/anode pair measures a different ion mass, using ion counting The detector features high sensitivity and low interchannel crosstalk (better than 3000:1) and was required since particles produce bursts of ions with intensities that vary faster than the mass spectrum can be scanned. The slit spacing is set for detection of ^{235}UO and ^{238}UO ions.

Data Acquisition: Data are acquired with a custom-designed data acquisition system. Output pulses from the detector are amplified by a pre-amplifier/discriminator (PAD; Amptek model A-111)[2] that detects pulses with >500,000 electrons and at count rates up to 2.5 MHz. Ion counts are collected over a series of 200 msec count integrations (count times from 5 msec to 6 sec are possible). Mass spectra, reflecting the average composition of a population of particles, are obtained by scanning the magnetic field, whereas U isotope ratios in particles are measured by continuously monitoring ^{235}UO and ^{238}UO ions at a constant magnetic field setting.

Aerosol generation: To generate aerosols from powders or collected particulates, an automated sample inlet system was developed. Particulate samples are loaded onto 47 mm-diameter filters by ultrasonic suspension and dispersion in Freon-TF, followed by filtration. A particle-laden filter is mounted on a computer-controlled X-Y stage that scans the filter beneath a teflon tube that is

2 The use of tradenames is for information and identification purposes only and does not constitute any endorsement or recommendation by the authors.

connected to the PIMS inlet. The airflow entering the inlet is sufficient to dislodge μm-sized particles from the filter surface and draw them up through the tube and into the inlet. Up to 90% of the particulate mass is removed from the filter in this manner.

Results: Results obtained with PIMS show that uranium isotope ratios ($^{235}U/^{238}U$) are easily measured in particles from heterogeneous particulate samples. For example, uranium-bearing mineral grains, such as zircons, are easily detected in an airborne dust sample (National Institute of Standards and Technology, SRM 1648 — urban particulates, containing 5.5 ppm U) Figure 1 shows the results of simultaneously measuring ^{235}UO and ^{238}UO ions in a mixture of pure TiO_2 and 0.1% natural UO_2 particles. Ion bursts occur simultaneously for both ^{235}UO and ^{238}UO, with individual bursts having $^{235}U/^{238}U$ ratios that were, to within ~10% uncertainties, consistent with the natural value of 0 0072. Count rates from a background channel (with no isotope peak) were much lower than either of the U isotope channels. In general, measurements on various heterogeneous particulate samples show that U-bearing particles typically produce ion bursts with intensities that exceed the background signals from other sources such isobaric interferences or scattered ions from other masses. Backgrounds are highly variable but corrections can be made by monitoring mass channels near U and by using the U-channel signals before and after the U-isotope bursts. These results clearly demonstrate the capability of using PIMS to measure isotope ratios in single particles from particulate samples without isolating individual particles from the sample

Calcium Isotopic Analysis Using Autoionization-Mediated LAser Photoionization

X. Xiong†, H. Si, and L. J. Moore

In the human body, calcium homeostasis is maintained by a number of inter-related regulatory processes, such as skeletal bone building and resorption which are related to osteoporosis. Radioactive isotope tracers used with adults are not appropriate with infants, children, pregnant or lactating women because of the hazards of radioactivity. The development of calcium stable isotope ratio measurement methodology a few years ago using thermal ionization mass spectrometry (TIMS) has permitted the use of safe stable calcium isotope tracers in the study of calcium dynamics in infants and children[1,2]. Therefore, it serves as an important experimental tool to study calcium in humans during all stages of the life cycle. Conventional resonance ionization mass spectrometry (RIMS) combines the advantages offered by both the conventional mass spectrometry techniques and the laser technology. It has proved to be an effective method for the study of isotope tracer analysis with added sensitivity and selectivity. The Autoionization-Mediated LAser Photoionization (A-MLAP) technique to be discussed here represents a 'next generation' set of photoionization processes. Through the use of autoionizing states above the ionization limit, it provides additional photoionization enhancement.

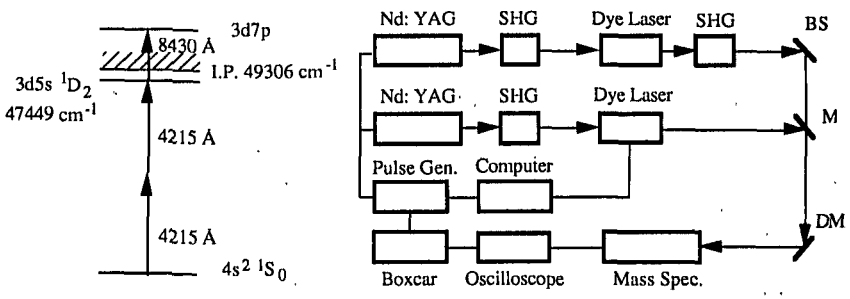

Fig. 1 Calcium A-MLAP scheme and the experimental arrangement.

Figure 1 shows a 2 + 1 (two-photon resonant three photon ionization) A-MLAP process and the experimental arrangement. Two tunable dye lasers pumped by the second harmonic of Nd:YAG lasers provided the radiation with desired frequencies or wavelengths. Photoionization and mass analysis were conducted in a time-of-flight mass spectrometer (TOF-MS) for the study of calcium autoionization states and in a magnetic sector mass spectrometer for calcium isotopic ratio measurements. Atomic calcium was prepared by heating the metallic calcium on a rhenium filament for spectroscopy, and by volatilization of

calcium salts for isotope ratio quantification measurements. The data acquisition system consisted of an oscilloscope, a boxcar integrator, and a microcomputer. The whole system was triggered either by the laser pulse or by a digital delay/pulse generator. The blue radiation near 4215 Å produced by frequency doubling of the radiation from one of the dye lasers was fixed for the Ca $4s^2$ -> 3d5s two-photon resonant transition. The tunable IR radiation from the second dye laser was used to reach the 3d7p autoionizing states. A 1 + 2 process using Ca 4s4p resonance was also used in the study of autoionization states in different regions.

Several autoionization states in the region from 55890 cm^{-1} to 56020 cm^{-1} for 3d4f manifold and in the region from 58820 cm^{-1} to 58830 cm^{-1} for the 3d7p manifold were investigated. Excepting the new lines, our experimental results are in good agreement with existing data. Because all the schemes used are three-photon processes starting from the Ca ground state $4s^2\ ^1S$, all the autoionizing states with J = 1, 2, and 3 can be reached. When the input laser energies were kept at 500 μJ for IR and 50 μJ for the blue radiation, the peak signal corresponding to the autoionization ion yields has approximately an order of magnitude enhancement compared with nearby resonant values.

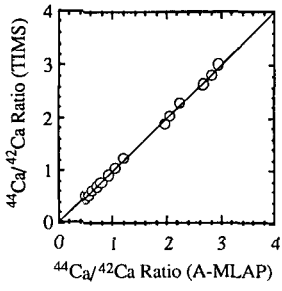

Fig.2 Comparison of $^{44}Ca/^{42}Ca$ ratio measurement results using TIMS and A-MLAP methods.

Using the scheme of Fig. 1, we have studied calcium stable isotope analysis. Our measurement result of the natural $^{44}Ca/^{42}Ca$ isotope ratio is 3.287, which agrees with the accepted value of 3.219 within an error of 2%. In addition we have conducted isotope ratio measurements for a set of urine and serum samples with metabolically altered Ca isotopic ratios. Results from a thermal ionization mass spectrometer were used to compare the performance of the A-MLAP technique. Figure 2 shows the comparison of $^{44}Ca/^{42}Ca$ ratio measurements using both methods. The average TIMS/A-MLAP for the measured isotopic ratio is 1.0135 (± 0.0213) which indicates the results from both TIMS and A-MLAP methods agree well within the experimental limits. The A-MLAP technique has demonstrated the feasibility of using a solid state cw laser system which has the advantage of higher working efficiency. It is also suitable for ultrasensitive calcium metabolism studies.

ICP/MS determination of Pb and Pb isotope ratios in bones and artifacts of a Native American tribe: a Pb poisoning and Pb source study.

***Ghazi, A. Mohamad and Durrance, Eric M., Dept. of Geology, Univ. of Nebraska, Lincoln, NE 68588; Sandness, Karlin L. and Reinhard, Karl J., Dept. of Anthropology, Univ. of Nebraska, Lincoln, NE 68588**

The determination of Pb concentrations and Pb isotope ratios in skeletal (human and animal) remains, and artifacts can provide new insights into understanding the cultural impact of Pb exposure and environmental contamination by Pb. Here we report a simple method for obtaining these measurements that only involves acid digestion of samples and use of an ICP/MS. In this example human and animal bones and their associated artifacts, excavated from a Omaha Indian village (1780-1820), were analyzed.

Semiquantitative analysis of the artifacts reveals that, except in one sample which is an alloy, the artifacts are almost pure Pb. Unusual for such artifacts, Hg is essentially absent. Figure 1 shows the mass spectrum of the alloy artifact, showing the presence of Sn and Pb. Results have also been obtained from pigments used for body ornament. These again indicate high Pb content, but they also contain Hg. (Fig. 2).

Pb concentrations in some of the human bone samples are unusually high with values of up to 2567 $ug.g^{-1}$. There is no correlation between Pb concentration and the age of the individual at death. However, on a broad scale the data indicate that Pb is greater in the sub-adult than in the adult individuals and animals. Pb concentrations in soils collected from the same burial sites are low compared to those found in most of the bones. This suggests that metabolic uptake of Pb in the human bones during life is more important than post-burial addition of Pb.

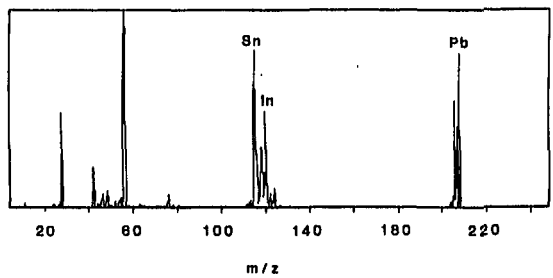

Figure 1. Mass spectrum of the Sn-Pb alloy artifact.

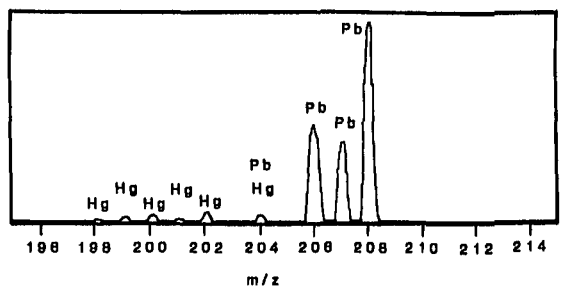

Figure 2. Mass spectrum of a pigment used for body ornament.

Isotope ratios of a reagent grade $Pb(NO_3)_2$ solution were measured by TIMS, as well as by ICP/MS, to establish short-term and long-term accuracy and precision, and linearity of the ICP/MS. The ICP/MS measurements were found to be within 0.03%-0.2% for $^{206}Pb/^{204}Pb$, 0.1%-0.3% for $^{207}Pb/^{204}Pb$ and 0.2%-0.6% for $^{208}Pb/^{204}Pb$ of the ratios obtained by TIMS. The short-term precision (RSD%) of Pb isotope ratio measurements for four sets of analyses (N=7) obtained in 9 days are 0.11%-0.28%, 0.13%-0.36% and 0.1%-0.43% for $^{206}Pb/^{204}Pb$, $^{207}Pb/^{204}Pb$ and $^{208}Pb/^{204}Pb$, respectively.

On a Pb isotope correlation diagram (Fig. 3), the Pb isotope ratios of three of the artifacts are sufficiently close to those of Pb from Tri-State (Joplin, MO) area that is possible to identify the source of the Pb. The isotope signatures are characteristic of Mississippi Valley-Type deposits (J-Type), which are enriched in radiogenic Pb. In contrast the Pb isotope ratios of the pigments show a non-Mississippi Valley Type signature. Pb isotope ratios in the bones are different from those of the artifacts and the pigments, showing more scatter. This suggests possible mixing of Pb from different regions.

Considering the ubiquitous presence of Pb in various forms among the Omaha tribe, it is possible that Pb poisoning was a cause of mortality of some of the individuals.

In the fields of archaeology and anthropology the use of ICP/MS for the measurement of both trace element concentrations and isotope ratios, is in its infancy. However, despite the advantages of ICP/MS, a number of important aspects of this technique, particularly isotope ratio measurements, require further studies.

Performance comparison of laser ablation ICP and glow discharge sources for mass spectrometric analysis of glasses

*R C Hutton, D Milton, A Kingston, J E Cantle

VG Elemental, Winsford, Cheshire, CW7 3BX, UK

High resolution mass spectrometry with either ICP or DC glow discharge sources is used in semiconductor applications for the analysis of high purity reagents (ICP) and sputter target metals (GD). However, one area not currently addressed by such techniques is the analysis of high purity glasses. Each technique as currently configured has limitations for such analysis.

1. The ICP source is designed to accommodate liquid samples. Hence glasses would have to be reduced to an aqueous solution prior to analysis. Despite the high sensitivity of the technique, use of such dissolution would negate this advantage.

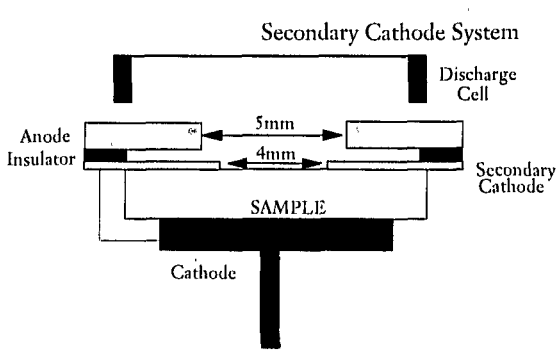
2. The DC glow discharge requires that the sample be the cathode hence must be electrically conducting. Since glasses are insulators then this analysis would in theory be impractical.

It is possible to make a sample conducting by mixing with a conducting binder, however, such procedures have been found to be limited to certain applications.

Solutions to these problems exist however, firstly the use of a laser as an ablation source for the ICP. In this configuration a glass sample can be ablated to a micro-particulate aerosol which can then be transported in an argon stream to the ICP.

In this work we will describe however, modifications to a commercial D.C. glow discharge cell which allows non conducting samples such as glasses to be analysed.

In this modified source, a secondary Ta cathode is used to initiate and sustain the discharge. A schematic of the modified source is given in Figure 1.



The principles behind this method rely on the processes occurring within the glow discharge. Argon ions are attracted to the metal (secondary) cathode and atoms are sputtered in the normal manner. These diffuse into the discharge and eventually are redeposited on the surface of the sample (insulator), this backdiffusion accounting for 50% of sputtered material at 150m Torr. This deposited material renders the sample conducting and insulator atoms will be removed in the normal manner.

Once the conditions are optimised with respect to discharge pressure, cathode material and geometry, then good analytical precision is obtained in the equilibrated system.

Table 1 - Precision on NIST 610 over 150 minutes (n=10)

Element	Mean (ppm)	S. Dev (ppm) n=10
Rb	117	13
Sr	152	10
Ag	312	17
Tl	13	0.8
Pb	456	8
Th	13	0.8
U	33	0.8

Table 1 illustrates typical precision data on NIST 610 glass. This data compares favourably with conventional conducting sample data and it is interesting that R.S.F. values obtained for elements in this study are also comparable to literature values.

Limits of detection for this technique depend on the purity of the secondary cathode, however values of 10-100ppb at a resolution of 5000 were found to be typical whilst for elements which could be determined in low resolution (500) i.e. Th and U, values of <0.5ppb were obtained.

The technique provides a useful alternative method for certain types of insulators which cannot be compacted to powders, or which are of high purity.

A GC/MS Tracer Method for the Measurement of Cysteine and Methionine Kinetics in Man

T. E. Chapman, A.I. Zijlstra and V.R. Young

Laboratory of Human Nutrition,
Clinical Research Center
MIT, Cambridge and
Shriners Burns Institute, Boston, MA.

The method uses [3,3-^{2}H]cysteine and [1-^{13}C; $^2H_3$-methyl]methionine which are given by the primed constant intravenous isotope infusion technique to healthy adults.The two tracers were infused for eight hours.[3,3-^{2}H] cysteine and [1-^{13}C;^{2}H3-methyl] methionine were infused at 1.0 and 1.5umol $kg^{-1}\cdot h^{-1}$,respectively .

Following ion exchange extraction of the sulfur amino acids from 200 µl plasma tertiary butyl-dimethylsilyl ether derivatives were prepared. Ethanethiol was included in the derivatization step, as it converted cystine to cysteine and greatly increased the yield of derivatization. Measurement of the plasma amino acid enrichments was carried out on a Hewlett Packard 5988A system equipped with a HP 5890 Series II gas chromatograph. Chromatography was carried out on a Durabond DB1301 fused silica capillary column Quantification of the isotope enrichment in plasma of [3,3-^{2}H]cysteine was carried out by selective ion monitoring (SIM) of the fragment ions at m/z 378.2 [M-85] and m/z 406.2 [M-57] for endogenous cysteine, and m/z 380.2 and m/z 408 2 for labelled cysteine (Figure 1a and b). A high energy dynode (HED) from Phrasor Scientific was used to multiply the amount of ions collected at the electron multiplier detector Without the HED precise and accurate isotope measurements of cysteine enrichment in plasma were impossible. Isotope enrichments of labelled methionine in plasma were carried out at m/z 320.2 [M-57],m/z 321.2 and m/z 324.2 for endogenous, [1-^{13}C] and [1-^{13}C, $^2H_3$-methyl]methionine, respectively (Figure 2a, b and c) Isotope enrichments of labelled methionine in plasma were also carried out at m/z 290.2 [M-85] and m/z 295 2 for endogenous and [$^2H_3$-methyl]methionine, respectively (Figure 2a,b and c). All ion ratios were converted to isotope enrichments using calibration graphs. These were all linear with correlation coefficients of $\geq$ 0.98 The slopes and y-intercepts were close to the theoretically predicted values. The intra- and inter-assay coefficients of variation of the complete extraction, derivatization and GC/MS SIM method ranged from 1 to 3 and from 3 to 5%, respectively,for metionine and cysteine. The accuracy of the GC/MS selective ion monitoring measurement of all the enrichments was within 6% of the true values

The whole body methionine-methyl flux rate (Q_m) could be calculated from two independent sets of ion ratio pairs in derivatized methionine, namely m/z 295.2 /m/z /292.2 and m/z324.2 / m/z320.2 for [$^2H_3$ methyl]- and [1-^{13}C;$^2H_3$-methyl] methinine, respectively These isotope enrichments showed an excellent agreement The whole body methionine methyl and carboxyl flux rates of 16.2+1.4 and 18 3$\pm$2.8 µmol $kg^{-1}.h^{-1}$ in the fasted state were similar to those previously reported by us The cysteine flux rates could also be calculated from two independent sets of ion pair ratios, namely, m/z 380.2 / m/z 378.2 and m/z 408.2 / m/z 406 2, and these too showed excellent

agreement. The whole body cysteine flux rates of 35.6± 5.6 μmol.kg^{-1}.h^{-1}, in the fasted state are the first to be directed estimated from a stable isotope infusion study. The measurement of cysteine and methionine fluxes simultaneously, represents an improvement of our previously published model.

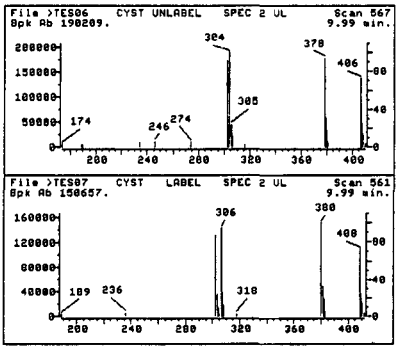


Figure 1(a) natural cysteine tBDMS ether (b) [3,3-^{2}H] cysteine tBDMS ether

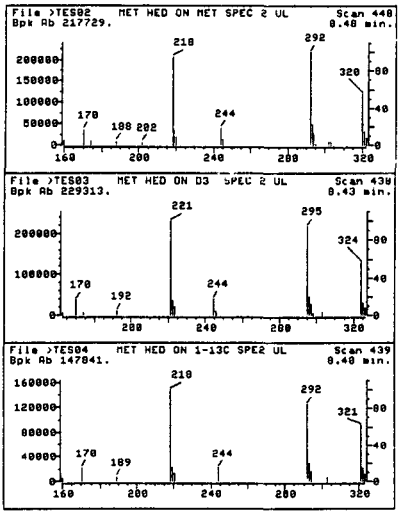

Figure 2(a)natural methionine tBDMS ether (b) [1-^{13}C;^{2}H$_3$-methyl] methionine tBDMS ether (c) [1-^{13}C] methionine tBDMS ether.

Low Energy Ion/molecule Charge Exchange Reactions of Singly and Doubly Ionized Rare-gas Atoms with n-propylbenzene

E. Ghelichkhani, R. G. Cooks

Chemistry Department
Purdue University
West Lafayette, IN 47906

For a given deposited energy above the ionization limit of a molecule characteristic patterns of fragment ions and intensities are observed. The intensities and the distribution of the fragment ions correlates with the internal energy of the molecular ion[1]. In this work, we have studied the low energy ion/molecule charge exchange reactions of singly and doubly ionized rare-gas atoms with n-propylbenzene. The charge exchange mass spectrum displaying the unimolecular fragmentation of the internally excited molecular ions was collected from near zero eV to 10 eV in the center-of-mass frame. Figure 1 displays the charge exchange mass spectra of Xe^+, and Kr^+, with n-propylbenzene. The importance of the charge exchange reaction of the singly ionized rare-gas atoms with n-propylbenzene is that the single electron capture neutral atoms are formed in their ground states. This means that the recombination energy is used in ionizing the neutral molecule (IE= 8.72 eV) and in internally exciting the molecular ion. The single electron transfer charge exchange reactions of doubly ionized rare-gas atoms with n-propylbenzene are more complicated. Not only can such reactions produce internally excited molecular ions but also this may form excited state single electron captured atomic ions. For example, the availability of excited states in singly ionized krypton is such that the reactions:

$$Kr^{2+}\ 3\ \ Kr^{+}\ \{(5s,^{2,4}P_J),\ (4d,\ ^4D_J),\ (4d,\ ^4F_J)\}$$

can occur along with the formation of internally excited molecular ions when charge exchange of Kr^{2+} takes place with n-propylbenzene. The charge exchange mass spectra of Xe^{2+}, and Kr^{2+} with n-propylbenzene, corresponding to near zero eV collision energy, are shown in Fig. 2. Distinct differences are seen between the spectra shown in this figure and those of Fig.1.

Detailed investigations of selected major fragment ions resulting from the unimolecular reaction of the internally excited n-propylbenzene radical cation have allowed the characterization of the charge exchange reactions under investigation. For example, from the charge exchange reactions of the doubly ionized rare-gas atoms with n-propylbenzene we have learned that the overall reaction energetics does not control the extent of the molecular excitation. It is found that the availability of appropriate Rydberg states of the atomic ions is a determining factor.

The thermochemistry for the formation of major fragments are evaluated using fully optimized semi-empirical molecular orbital calculations of the AM1 (MNDO/3) hamiltonian[2] for the minimum geometries. The energy barrier for the transition between the trans and gauche conformers of n-propylbenzene were calculated for both the neutral molecule and the molecular ion. Computation was carried out by changing a suitable dihedral angle and optimizing the molecular geometry at each point in the parameter space.

The high energy barrier between these two conformers (3.1 Kcal/mole for the neutral molecule and 3.84 Kcal/mole for the molecular cation) is not overcome by the room temperature thermal energy k_bT, this is consistent with the formation of a low and relatively constant intensity of $C_7H_8^+(92)$ fragment ion. Formation of $C_7H_8^+(92)$ ion is mostly controlled by the availability of the gauche conformer. Nevertheless, the ratio of these two fragment ions, $C_7H_7^+(91)$/ $C_7H_8^+(92)$, changes as a function of the internal energy because of the considerable change in the intensity of $C_7H_7^+(91)$ ion. In Figure 3 the ratio of $C_7H_7^+(91)/C_7H_8^+(92)$ fragments is plotted against the total available energy for the reactions of $Xe^{+, 2+, 3+, 4+, 5+}$, and $Kr^{+, 2+, 3+, 4+, 5+}$ with n-propylbenzene. The available energy is the reaction exothermicity corresponding to single electron capture. The ratio increases in going from singly to doubly charged ions and decreases for the higher charge states with the exception of a small increase for the reactions of Xe^{5+} and Kr^{5+} with n-propylbenzene.

[b] University Pierre and Marie Curie, Pl. Jussieu 4, 75252 Paris cedex 05, France

Anion-molecule reactions in the gas phase have been studied using ICR and FTICR, ITMS or Flowing-Afterglow, but never by Collision Activated Reaction (CAR) in the collision cell of either magnetic, triple quadrupole or hybrid instruments [1]. We report here the first observation in a triple quadrupole (Finnigan TSQ70) of the reactions of dithiole anions produced in a chemical ionisation source with CS_2 as an electrophile in the collision cell. Previous FTICR studies [2] on dithioacetals groups demonstrated cyclo-reversion and elimination rather than anion reaction with an electrophile.

Figure 1 displays the spectrum obtained when the benzo-1,3-dithiole anion is selected with the first quadrupole and reacted with CS2 in the collision cell. The fragments displayed in the daughter spectra contains ions resulting from CID fragmentation as well as from ion/molecule reaction. By a comparison with the spectra obtained when CS_2 is replaced by Xe, one can attribute the CID fragments. Furthermore, by focusing the $(M+2)^-$ ion, which contain one ^{34}S atom, and combining this with the natural abundances in CS_2, it is possible to count the number of sulfur atoms from both origins in each ion.

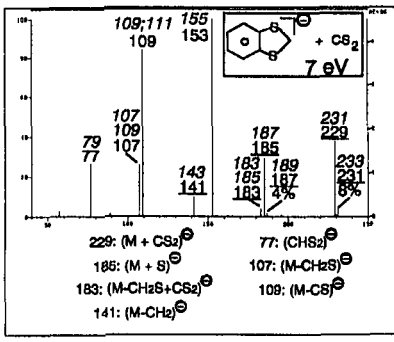

Figure 1: Products after collision of the dithiole anion with CS_2. Standard figures indicate fragmentation ions, underlined are products of the reaction between the anion and CS_2, and in italic, the shifted masses observed when the selected anion contains one ^{34}S: if unshifted, the ion thus not contain sulfur from the dithiole. Dedoubled, it contains one of those atoms, and when shifted the two sulfur atoms from the dithiole are included [3]. The (M+2) percentage indicate the number of sulfur atoms from CS_2.

These result show that ion-molecule reactions with formation of covalent bonds has indeed occurred, as ions are observed that contain part of both reactants. The ion at mass 185 corresponds to the addition of one sulfur atom of CS_2 to the anion. This is a strong indication that a thiophilic attack occurred, as already proposed by other authors [1]. Since, from other observations in our laboratories, this is uncommon for a dithioacetal type anion, we

have compared the spectra obtained when the 2,2-dideutero-1,3-dithiole is used. Figure 2 diplays the CAR (collision activated reaction) spectra obtained when either a deuterium or a hydrogen is abstracted to yield the dithiole anion.

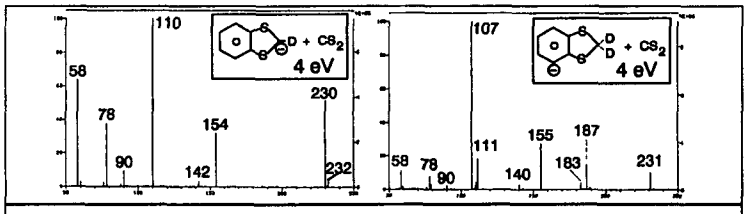

Figure 2: Comparison of the CAD spectra obtained from both anions with CS_2. The typical ion of a thiophilic attack is not observed from the dithioacetal type ion (left), but well from the phenylic one (on the right).

From these spectra, it is clear that two different anions are formed: one of dithioacetal type, the other of penylic type. The first one does not yield the product from the thiophilic attack, that should appear now at 186 amu.

Furthermore, these ions do not interconvert as demonstrated by the complete absence of thiophilic product in the spectrum from the dithioacetal type anion. The 107 amu fragment ion is also present in one spectrum, and completely absent in the other. This same behaviour is observed in the fragmentation daughter spectrum with xenon.

Such a phenylic anion has already been observed by Ingemann and Niebering [4] from the methyl-phenyl thioether. Theses authors have shown by isotope labelling that the ionisation occurs ortho to the sulfur atom.

In conclusion, we have shown that benzo-1,3-dithiole yield two different anions. These anions do not interconvert. They display different reactivities with CS_2 as an elctrophile: one, of dithioacetal type, reacts on the carbon atom of CS_2 (carbophile), while the other, of phenylic type, leads to a thiophile attack.

REACTIVE COLLISIONS IN QUADRUPOLE CELLS

A.G. Harrison, J. Ni, L.L. Usypchuk and J.-Y. Wang
Department of Chemistry
University of Toronto
Toronto, Canada M5S 1A1

Tandem mass spectrometry is well-established as a technique for the analysis of complex mixtures and for structure elucidation of gaseous ions. The majority of these studies have involved collision-induced dissociation of mass-selcted ions. With the advent of r.f.-only quadrupole collision cells, as part of either triple quadrupole instruments or hybrid sector/quadrupole instruments, it is possible to decrease the energy of the incident ion to levels such that chemical reactions occur between the ion and a reactive collision gas. The present paper explores the use of such reactive collisions to distinguish among the C_5H_{10} olefins. In addition, preliminary results obtained in studies of H/D exchange reactions in the quadrupole cell are presented.

Figure 1 shows, in bar graph form, the spectra resulting from reaction of mass-selected $CH_3NH_2^{+\cdot}$ ions with the isomeric olefins at an indicated pressure of 1×10^{-6} torr of the olefin in the quadrupole collision cell of a hybrid BEqQ mass spectrometer [1]. Distinctive spectra are obtained in each case. The methyl amine ion reacts with 1-pentene and 3-methyl-1-butene almost exclusively by addition to the double bond [2] followed by fragmentation (in some cases after rearrangement) to form a series of imminium ions at m/z 44, 58, 72 and 86. With the remaining olefins the major reaction channel is charge exchange to give the olefin molecular ion (m/z 70); this reaction is modestly endothermic, except for the case of 3-methyl-2-butene, indicating that the internal energy and/or the kinetic energy of the incident ion is effectively used to overcome this endothermicity. The molecular ion formed from 2-pentene reacts readily with the olefin to form $C_7H_{14}^{+\cdot}$ (m/z 98) and $C_8H_{15}^{+}$ (m/z 111), both known[3] to be products of ion/molecule reactions in 2-pentene. A significant reaction channel of $CH_3NH_2^{+\cdot}$ with 2-methyl-1-butene is proton transfer to form the tertiary pentyl ion, a reaction which also is mildly endothermic for ground state reactants.

We also have begun a study of the H/D exchange reactions of a variety of deprotonated and protonated species with CH_3OD and C_2H_5OD in the quadrupole cell. Figure 2 shows, in bar graph form, the results obtained for reaction of a variety of enolate ions with C_2H_5OD. Clearly, the number of enolizable hydrogens present in the molecule can be counted by this method, except for the case of the enolate ion of 2,4-pentanedione. Figure 3 shows the results obtained in the reaction of the MH^+ ion of a number of alkylbenzenes with CH_3OD. Exchange of the added hydrogen and all aromatic hydrogens is observed. By contrast, the $[M - H]^-$ ions of the alkylbenzenes exchange the hydrogens in benzylic positions as shown in Figure 4.

A full report of the reaction of the methyl amine molecular ion with olefins will appear in Org. Mass Spectrom. Some of the H/D echange work has been submitted to J. Am. Soc. Mass Spectrom.

THE ENERGY DEPENDENCE OF THE DISSOCIATION OF PEPTIDE IONS

J. Paul Speir and I. Jonathan Amster
Department of Chemistry, University of Georgia, Athens, Georgia 30602

INTRODUCTION

Recent studies in our laboratory have been directed toward the measurement of fundamental properties of peptides and amino acids with the technique of laser desorption/chemical ionization (LD/CI). Here, LD/CI is used to probe the energy dependence of the dissociation pathways of peptides. Proton transfer chemical ionization, equation 1 (R=reagent, P=peptide), allows a discrete amount of energy to be placed into a peptide ion. Using different reagent species, the exothermicity of the proton transfer reaction can be changed, allowing the product ion distribution to be measured as a function of the internal energy of the peptide protonated molecule (internal energy is equal to the enthalpy of the protonation reaction). The enthalpy of the proton transfer reaction is equal to the difference in the proton affinities (P.A.'s) of the reagent species and the peptide molecule, as in equation 2. We determine the P.A. of a peptide molecule with a bracketing measurement, which allows the enthalpy of the proton transfer reaction to be calculated.

$$RH^+ + P \text{ ----> } PH^+ + R \qquad (1)$$

$$\Delta H = P.A.(R) - P.A.(P) \qquad (2)$$

EXPERIMENTAL

The experiments are performed using a Fourier transform mass spectrometer equipped with a 1-3/4" cubic analyzer cell, a 1 Tesla electromagnet, and an IonSpec data system. The main vacuum chamber is pumped with a 330 l/s turbomolecular pump to a base pressure of $2x10^{-10}$ Torr. The introduction of reagent gases is controlled by the use of two pulsed valves and a sapphire sealed leak valve.

Proton transfer reagent ions are generated by electron ionization of a reagent gas which is admitted through a pulsed valve. The reagent ions are trapped in the cubic analyzer cell, and allowed to react with the neutrals desorbed from the sample stub which is supported 5 mm outside of an opening in one of the analyzer cell detection plates. Intact peptide molecules are desorbed using the technique of substrate-assisted laser desorption (SALD), which we describe elsewhere in these proceedings. Intact neutral molecules of the peptide are desorbed from the sample probe using either the 248 nm (KrF) or 337 nm (N_2) output from an excimer laser with a typical irradiance of 1-10 MW/cm^2.

RESULTS

The P.A. of the pentapeptide amide, FFGLM-NH_2, was bracketed between that of diethylamine and diisopropylamine, 10.1±0.1 eV. LD/CI mass spectra of this peptide were obtained with a series of eight reagent ions. The enthalpies of the protonation reactions ranged from -0.2 eV to -5.4 eV. Figure 1 is a breakdown curve that summarizes the results. The molecular ion abundance drops dramatically when the reaction is exothermic by more than 3.5 eV. The loss of H_2NCO from the protonated molecule is the dominant fragmentation channel for exothermicities between -3.5 eV and -4.5 eV. The formation of small fragment ions becomes important when the reaction is exothermic by more than 5.0 eV. Similar measurements have yielded a breakdown curve for the pentapeptide, RKDVY, shown in Figure 2. The presence of arginine and lysine at the N-terminus of this peptide favors the formation of N-terminal

fragment ions. Accordingly, b and c Roepstorff ions are prominent in the LD/CI mass spectra of this peptide. The dominant reaction channel at low protonation enthalpy is the formation of the b_1 fragment. The formation of the larger fragment ion, b_3, becomes more important with more exothermic reactions. The reaction channel for the formation of b_4 begins to open at protonation energies of 3.0 eV. We are currently studying the dissociations of this peptide with more exothermic protonation reactions to extend the breakdown curve to higher energies.

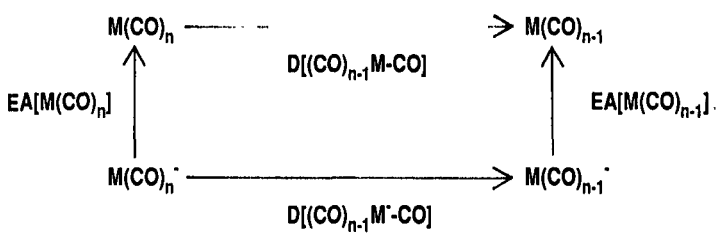
Metal-Ligand Bond Strengths in First Row Metal Carbonyls

*Lee S. Sunderlin, Dingneng Wang, and Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette IN 47907

Activation energies for loss one or two carbonyl ligands from metal carbonyl anions have been measured using energy-resolved collision-induced dissociation in a flowing afterglow-triple quadrupole instrument. The flowing afterglow was used to produce highly unsaturated metal carbonyl fragment ions that were thermalized to room temperature by *ca.* 10^5 collisions with the He buffer gas. The activation energies for ligand loss are equated with the metal-ligand bond energies. The data derived are given in the table below. All of the measured values lie in the 33-46 kcal/mol range. There is an odd-even alternation to the bond strengths such that almost all 14-, 16-, and 18-electron metal-carbonyl anions have weaker bond strengths than 15- and 17-electron metal carbonyl anions.

The metal-carbonyl anion bond strengths can be combined with electron affinities of the neutral metal carbonyl fragments (where known) in the thermochemical cycle below to give the neutral metal-carbonyl



bond strengths shown in the table. These values vary more widely, with D(Fe-CO) = 8.1 ± 3.5 kcal/mol being a striking standout.

The present results can be combined with information from ligand substitution studies to derive lower limits on bond strengths to other ligands. The bond strengths can also be used to derive heats of formation for metal carbonyl fragments, which can be combined with heats of formation measured using calorimetry to give other metal-ligand bond strengths, such as $D[(CO)_4Fe\text{-}C_2H_4]$ = 36 ± 4 kcal/mol, $D[(CO)_4Fe\text{-}C_4H_6]$ = 62 ± 9 kcal/mol, and $D[(CO)_4Fe\text{-}2C_4H_6]$ = 111 ± 9 kcal/mol.

Automated Confirmation of Drugs of Abuse by GC/MS.

*D. Swain, Fisons Instruments, Manchester, UK.
R. Rutter, MedExpress National Laboratory Center Inc., Memphis, TN 38175-2110 USA.

Urine drug testing is an important tool in efforts to combat drug abuse and in the proper context, can be used to deter drug abuse in general. Reliable discrimination between the presence or absence of specific drugs is critical. To ensure reliable results, laboratory quality control procedures must be designed to monitor the system at each step in the process. NIDA certified laboratories are required to have quality control samples comprise 10% of each analytical batch. Quality control measures include validation of limits of detection (LOD) and limits of quantitation (LOQ), determination of linearity, extraction of 'blank' samples, extraction of conjugated samples to determine efficiency of hydrolysis, determination of possible carry-over from sample to sample and validation of a linear calibration curve for multi-point calibrations.

In a high volume, high throughput laboratory, most samples are injected by an autosampler and the analytical runs are often left unattended with the data being reviewed after the analytical run is completed. Failed calibration, failed QC and extraction problems may.require that the run be reinjected or repeated. In laboratories where manual injection of calibrators and controls is performed, the operator involved in the analysis can make real time decisions regarding the goodness of the fit of the calibration curve, acceptability of the QC samples and efficiency of the extraction.

This paper describes a software package which permits automated injection of calibrators, controls, blanks and unknown samples and makes decisions similar to those one would make if the injections where done manually. Some of the decisions made by the system are reinjection of individual calibration standards should the correlation coefficient not exceed a predetermined value and reinjection of controls which violate QC rules. Blank samples are examined for the possibility of carry over and flagged if an analyte is found above a user defined level. Other parameters which an operator must be aware of in reviewing sample data are quantitative values which exceed the linearity of the assay, quantitative values which are above a level at which carry over might be suspected, incomplete hydrolysis as shown by poor recovery of a hydrolysis control and quantitative values less than the predetermined LOQ or LOD. For each of these situations the operator can allow sample data to be flagged by the system. The operator has the flexibility to set each of these flags individually as well as set the levels at which the samples will be flagged.

The decision making capability of the system as well as the flagging of suspect data allows for more thorough review by the certifying scientist. The determination of goodness of fit of calibration and real time review of quality control samples provides for faster turn around time of positives. In the event the calibration fails or QC is unacceptable, the run can be aborted and the next method started rather than wasting valuable instrument time. Again, the operator has great flexibility in making these determinations. With respect to QC samples, Westgard rules[1] can be invoked by the operator making it easier to recognise shifts, trends and biases in QC results. Random and systematic errors become more apparent.

The system also allows for flexibility in calibration. Historical calibrations can be used as well as single point and multi-point calibration (up to 6 calibrators). The origin can be included or excluded from multi-point calibrations. Ion ratios for qualifier ions in SIR can be determined as a weighted average, a straight average or determined by a single calibrator. The advantage to the operator is that the analysis and data manipulation can be custom tailored to the method and analyte.

The Dynamics of S_N2 Reactions in the Gas Phase

*Susan T. Graul and Michael T. Bowers
Department of Chemistry, University of California
Santa Barbara, CA 93106

Introduction

Dynamics of thermal energy ion–molecule reactions are usually assumed to be well-described by statistical theories, so exceptional cases often provoke intense interest. This is certainly true for the bimolecular nucleophilic substitution (S_N2) reactions of halide ions with methylhalides (eq 1).

$$X^- + CH_3Y \rightleftharpoons [X^-(CH_3Y)]^* \longrightarrow Y^- + CH_3X \qquad (1)$$

Results of several theoretical studies point to nonstatistical dynamics for S_N2 reactions,[1] while some recent experimental investigations have begun to address questions of randomization of energy within the intermediate complex[2] and to examine the kinetic energy releases associated with exoergic substitution reactions.[3,4] In the present study, a combination of experiment and theory has been applied to the analysis of kinetic energy releases for dissociations of metastable $Cl^-(CH_3Br)$, $Cl^-(CH_3I)$, and $Br^-(CH_3I)$, which are treated as models for the intermediates of the corresponding substitution reactions.

Experiment and Theory

The metastable $X^-(CH_3Y)$ adducts were generated by association reactions under low-pressure conditions, such that most of the adducts exited the ion source without experiencing a stabilizing collision. Collision-induced dissociation (8 keV, helium) demonstrated that the $X^-(CH_3Y)$ and $Y^-(CH_3X)$ species were distinct isomers that did not interconvert. Energy-analyzed product ion peak shapes were measured by means of mass-analyzed ion kinetic energy mass spectrometry in a reverse-geometry sector mass spectrometer (V.G. Analytical ZAB-2F), and kinetic energy release distributions were derived from the peak shapes in the manner described previously.[5]

The experimental results were modeled using statistical phase space theory. The model incorporated the well-known double-well S_N2 reaction coordinate (Figure 1), with four configurations entering explicitly into the calculations: the orbiting transition states at the reactant and product channel, the "pre-reaction" ion–molecule complex, and the S_N2 transition state at the central barrier. Relative energies for the first three configurations were taken from literature data.[6] Estimates for the S_N2 transition state energies were obtained by modeling experimental rate constants.[7] These estimated transition state energies, an ion internal energy distribution that accounts for the possibility of partial collisional stabilization, and the adduct lifetime selection enforced by the experimental timescale are all included in the model to calculate the kinetic energy release distribution that would be expected for statistical partitioning of the released energy into internal and translational modes of the product species.

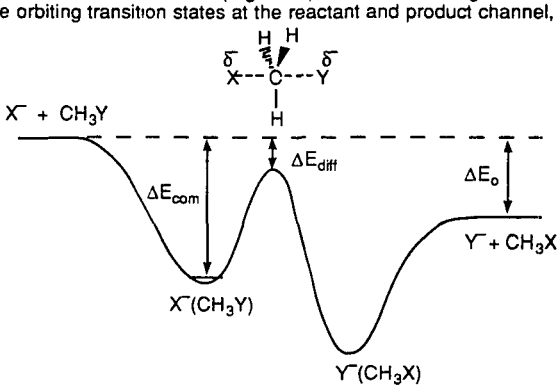

Figure 1. Schematic diagram of S_N2 reaction coordinate

Results and Discussion

In Table 1 are listed the experimental rate constants, the calculated transition state energy relative to reactants (where a negative number indicates that the transition state is lower in energy than the reactants), and the experimental and predicted average kinetic energy releases. The estimated barrier height for the Cl^-/CH_3Cl reaction is shown primarily for comparison with the corresponding values of 3–6 kcal/mol (0.13–0.25 eV) from ab initio calculations.[8,9]

Table 1. Experimental and calculated average kinetic energy releases.

Reaction	Rate constant (eff)[a]	ΔE_{diff}, eV	$\langle KE \rangle_{expt}$, eV	$\langle KE \rangle_{calc}$, eV
$Cl^- + CH_3Br$	2.72×10^{-11} (0.016)[b]	−0.07 ± 0.02	0.028 ± 0.03	0.063
$Cl^- + CH_3I$	1.66×10^{-10} (0.095)[b]	−0.17 ± 0.04	0.025 ± 0.03	0.092
$Br^- + CH_3I$	2.89×10^{-11} (0.022)[b]	−0.08 ± 0.02	0.023 ± 0.03	0.074
$Cl^- + CH_3Cl$	3.5×10^{-14} (2×10^{-5})[c]	0.12 ± 0.01	–	–

[a] Rate constants in units of cm^3/sec; eff = k_{expt}/k_{coll}, where $k_{coll} = k_{ADO}$. [b] Ref. 2. [c] Ref. 3.

For each system, the energy that is actually partitioned to relative translation of the products is much less than predicted by statistical theory. Conservation of energy dictates that the balance of the energy released in these dissociations must be partitioned to internal energy of the methylhalide products. In order to model a dissociation process that produces internally excited products, the kinetic energy release distributions were calculated assuming that certain amounts of the released energy are not available for randomization in the exit channel. Shown in Figure 2 are the experimental and calculated kinetic energy release distributions for the metastable dissociation of $Cl^-(CH_3Br)$. If all of the energy released in this dissociation partitions statistically among relative translational and internal modes, the calculated curve (shown by the filled circles) is much broader than the experimental result. When about 0.2 eV of the released energy is assumed unavailable, the theoretical curve shows much improved agreement with experiment. This indicates that most of the energy released does not randomize in the post-reaction complex. Similar results were obtained for metastable dissociation of $Cl^-(CH_3I)$, for which about 0.53 eV was found to be unavailable for randomization (ΔE_o = 0.59 eV), and for $Br^-(CH_3I)$, with about 0.26 eV unavailable (ΔE_o = 0.36 eV). We interpret this as evidence that the CH_3X products are formed with significant vibrational excitation. This is consistent with theoretical predictions of vibrational excitation in the products of the S_N2 reactions of H^-, F^-, and OH^- with CH_3F, and with inefficient energy transfer within the post-reaction complex.[1,2]

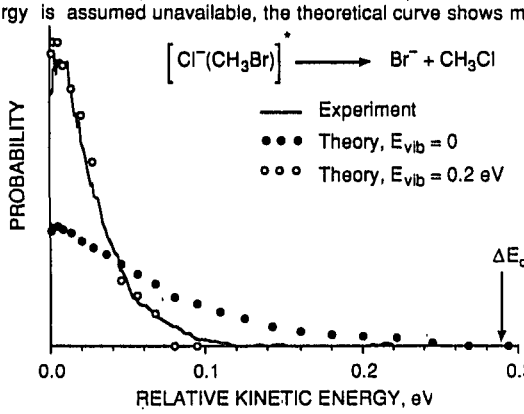

Figure 2. Kinetic energy release distributions for metastable dissociation of $Cl^-(CH_3Br)$.

Gas-Phase Ion Chemistry of Distonic Radical Cations

H.I. Kenttämaa
Department of Chemistry, Purdue University
West Lafayette, IN 47907

Characterization of the structure of a gaseous radical cation is a difficult and time-consuming task. Various experimental strategies, usually based on a combination of different types of data, have been developed just for the determination of the connectivity in polyatomic ions. The recent recognition of the stability and generality of *distonic ions*, ions with spatially separated charge and radical sites, has created a need for new approaches of ion structure verification. We report here a novel bimolecular reaction that allows the positive identification of distonic radical cations.

It was recently demonstrated in our laboratory that the ionization of cyclobutanone in a Fourier transform ion cyclotron resonance instrument (Extrel FTMS-2001) yields a stable γ-distonic ion: $^{\bullet}CH_2CH_2CH_2C^+=O$. The ion undergoes interesting bimolecular reactions, many of which entail homolytic bond cleavages. One of these involves the abstraction of $CH_3S^{\bullet}$ from dimethyl disulfide. This novel reaction has no well-known precedent in the gas phase or in solution. Hence, we decided to examine the generality of this reaction.

Conventional radical cations with oxygen-containing functionalities were found *not* to abstract $CH_3S^{\bullet}$ from CH_3SSCH_3. Exothermic charge exchange occurs at every collision, and it is the only reaction observed for example for the molecular ions of simple organic ethers (ethyl vinyl ether, oxetane), ketones (acetone, cyclopentanone, cyclohexanone) and lactones (γ-butyrolactone, δ-valerolactone). Enol radical cations ($CH_2=C(OH)_2^{+\bullet}$, $CH_2=C(OH)OCH_3^{+\bullet}$) also undergo predominant electron transfer with CH_3SSCH_3. However, strikingly different results were obtained when distonic ions with well characterized structures (see below) were studied (Table 1): abstraction of $CH_3S^{\bullet}$ *was found to be common for distonic ions*. The reaction is often accompanied by dissociative charge exchange. For the ion $^{\bullet}CH_2OCH_2^+$, abstraction of $CH_3S^{\bullet}$ is followed by spontaneous loss of CH_2O to yield $CH_3SCH_2^+$. The higher homolog, $^{\bullet}CH_2CH_2OCH_2^+$, shows product ions from $CH_3S^{\bullet}$ abstraction as well as from $CH_3S^{\bullet}$ abstraction accompanied by CH_2O loss.

The data obtained for homologous ion pairs ($^{\bullet}CH_2OCH_2^+$, $^{\bullet}CH_2CH_2OCH_2^+$; $^{\bullet}CH_2CH_2C^+=O$, $^{\bullet}CH_2CH_2CH_2C^+=O$) indicate that CH_3S-abstraction does not require a specific distance between the charge and radical sites in the reactant ion. The only distonic ion shown in Table 1 that does *not* abstract $CH_3S^{\bullet}$ is $HC^+(OH)OCH_2^{\bullet}$. This ion is a strong Brönsted acid, and proton transfer dominates over all other reaction channels. It is concluded that the absence of CH_3S-abstraction, especially if a fast proton transfer (or possibly charge exchange) is observed, does not allow one to *rule out* a distonic structure for the reacting ion. CH_3S-abstraction is expected only for those distonic ions whose conjugate base has a proton affinity lower than that of CH_3SSCH_3 (196 kcal/mol).

Even-electron ions were found to be unreactive toward CH_3SSCH_3. This is true for example for $CH_3CH_2CH_2C^+=O$ and $CH_3CH_2OCH_2^+$ which are the even-electron analogs of $^{\bullet}CH_2CH_2CH_2C^+=O$ and $^{\bullet}CH_2CH_2OCH_2^+$, respectively. This finding, together with the fact that the distonic radical cations abstract $CH_3S^{\bullet}$ from CH_3SSCH_3 while the related conventional radical cations (e.g., ionized cyclopentanone, ionized oxetane) react only by charge exchange, strongly suggests that the prerequisite for the CH_3S-abstraction is the presence of a radical site remote from the charge site in the reactant ion. The mechanism of the reaction is currently under investigation.

Ion	Efficiency (k/k_{ADO})	Reaction	%	ΔH (kcal/mol)
$^{\bullet}CH_2OCH_2^+$	1.0	CH_3S-abstraction, loss of CH_2O	100	-8
$^{\bullet}CH_2CH_2OCH_2^+$	0.8	CH_3S-abstraction, loss of CH_2O	25	
		e^--transfer	40	-41
		CH_3S-abstraction	35	
$^{\bullet}CH_2CH_2C^+=O$	0.8	e^--transfer	93	-24
		CH_3S-abstraction	7	
$^{\bullet}CH_2CH_2CH_2C^+=O$	0.6	e^--transfer	50	-3
		H^+-transfer	5	
		CH_3S-abstraction	45	
$HC^+(OH)OCH_2^{\bullet}$	0.9	H^+-transfer	100	-18
$(CD_3)_2C^+\text{-}OCH_2^{\bullet}$	0.3	e^--transfer	81	-26
		CH_3S-abstraction	19	
$(CH_3)_2S^+\text{-}CH_2^{\bullet}$	0.5	CH_3S-abstraction	100	
$(CH_3O)_2P^+(OH)OCH_2^{\bullet}$	very slow	CH_3S-abstraction

ION-MOLECULE REACTIONS OF IONIZED BUTENES IN A TRIPLE-QUADRUPOLE MASS SPECTROMETER

Dingneng Wang and Bahman Rejai

Chemical Technologies Research Branch
National Renewable Energy Laboratory (formerly SERI)
1617 Cole Boulevard, Golden, CO 80401

Introduction

The differentiation of isomeric compounds by mass spectrometry has attracted much attention in recent years. The electron impact (EI) ionization mass spectra of isomeric butenes (1-butene, *cis*-2-butene, *trans*-2-butene, and isobutene) are almost identical, while molecular ions of butene isomers also give very similar daughter ion patterns upon collision-induced dissociation (CID). Partial to complete randomization of both carbon and hydrogen atoms occurs prior to fragmentation of $C_4H_8^+$ to form $C_3H_5^+$ and $C_2H_4^+$, and the extent of this randomization depends on the internal energy (or ionization energy) of the $C_4H_8^+$ ions and their lifetimes. However, the CID patterns do not have such dependence. Prior to fragmentation, the $C_4H_8^+$ molecular ions isomerize to a mixture of rapidly interconverting structures and such isomerization is thought to be extensive even for nondecomposing ions after 10^{-5} seconds.[1] Low energy ion-molecule reactions have proven successful in distinguishing isomeric alkenes, most based on a neutral rather that on an ionized alkene, a close relative of chemical ionization.

Isomeric $C_4H_8^+$ ions formed by 10.0 eV photoionization (PI) and by low energy EI have been shown to behave differently in ion-molecule reactions. Sieck *et al* observed dramatic differences in the kinetics of charge transfer reactions between $C_4H_8^+$ ions (10.0 eV PI) and NO, and the measured bimolecular rate constants reflected well differences in the ionization potentials (IP) of C_4H_8 isomers.[2] The isomeric $C_4H_8^+$ ions also showed different reactivities toward cyclic alkanes. In an FT-ICR,[3] 1-butene and 2-butene radical cations generated by low energy EI underwent up to 6 H/D exchanges with MeOD or EtOD, while up to 8 H/D exchanges occurred for isobutene$^+$ with MeOD (only 6 with EtOD). Recently, Kenttämaa *et al* reported methylene addition reactions between an ionized alkene and a neutral alkene that were characteristic of the location of double bonds in both reagents (straight chain alkenes larger than pentenes), with the exception of terminal alkenes.[4] These results strongly suggest that low energy ion-molecule reactions in a TQMS may be a useful tool for distinguishing the isomeric butene ions. We report here the possibility of distinguishing ionized butene isomers by their ion-molecule reactions with certain neutral reagents in a triple quadrupole mass spectrometer (TQMS). This study has potential applications to the analysis of catalytically upgraded products formed in one of the biomass-to-energy conversion processes currently under investigation at NREL.

Experimental

All experiments were carried out in a molecular beam-triple quadrupole mass spectrometer, which has been previously described.[5] Low flows of butenes (5-50 cm^3/min) were diluted in helium (5 dm^3/min). The gas stream undergoes a free-jet supersonic expansion to form a molecular beam, producing internally cooled molecules that were ionized by EI (25 eV). This combination limits the internal energy available in the molecular ion for further rearrangement and fragmentation, hopefully still preserving some of its structural identity.

Except for otherwise stated, the ion-molecule reaction conditions were room temperature, collision energies of about 1-2 eV (lab frame), and reactive gas pressure of approximately 10^{-4} torr (multiple collision conditions). N_2^+ or Ar^+ was used as the CI reagent to assay the purity of reactive gases and to determine secondary product ions formed from simple charge transfer reactions (ionized reactive gas with itself). All gases and liquid samples were obtained from commercial sources and used without further purification except for a few freeze-and-thaw cycles of liquids to remove air and other volatile impurities.

Results and Discussion

Shown in Table 1 is a list of thermochemical data for all four butene isomers. It is obvious from these data that the *trans*- and *cis*-butenes are indistinguishable using the ion-molecule reaction approach. Reagents with a proton affinity of 757 (a medium value between 738 and 777, see Table 1), or 785 kJ/mol, or with an R-H bond energy of 350 or 388 kJ/mol, may give different results with the isomeric $C_4H_8^{+\cdot}$ ions *via* proton transfer or hydrogen atom abstraction reactions. Alternatively, charge transfer reactions with reagents such as NO (IP=9.264 eV) may also show enough difference.

Table 1. Thermochemical Data for Butene Isomers

C_4H_8 isomer	IP(C_4H_8) eV	PA(C_4H_7) kJ/mol	IP(C_4H_9) eV	D°($C_4H_8^+$-H^-) kcal/mol	D°($C_4H_8^+$-H) kcal/mol
1-	9.58	738	7.25	999	377
iso-	9.239	777	6.70	974	399
cis-2-	9.108	792	7.25	944	322
trans-2-	9.100	797	7.25	940	318

All data taken from *J. Phys. Chem. Ref. Data* Vol. 17, Suppl. 1, 1988.

Results of reactions with dimethyl ether clearly indicate that the butene ions have not completely lost their identities under our conditions. While all $C_4H_8^+$ ions (*m/z* 56) form ample $MeOCH_2^+$ and Me_2OH^+ product ions, only isobutene$^+$ abstracts an H atom from Me_2O to form *t*-butyl cation as a significant minor reaction pathway (exothermic by 9 kJ/mol). Relative abundances of *m/z* 57 (normalized to the reactant ion, whose abundance is set at 100) were 15.2, 4.3, 1.7 and 1.6 from molecular ions of iso-, 1-, *trans*- and *cis*-butenes, respectively. This can be attributed to the thermochemistry of the isomeric $C_4H_8^+$ ions. It is thus concluded that the $C_4H_8^+$ ion from isobutene still contains largely isobutene ion. This was again evident when 1-butene was used as the reactive gas. More abundant $C_4H_9^+$ signal was detected in the case of isobutene$^+$ than the other isomers.

However, no significant difference was observed in reactions with other reagents studied: methyl vinyl ether, methanol, acetonitrile, propene, 1,3-butadiene, isoprene, and methyl formate. The following overall trends were observed: rates of H^+ transfer from butene ions (to the reactive gases) in the order of 1-butene$^+$ > 2-butene$^+$ > isobutene and rates of H-abstraction by the butene ions in the order of isobutene$^+$ > 1-butene$^+$ > 2-butene$^+$. Studies with more reagents, including D-labeled compounds, are planned and even more prominent differences may be revealed.

ION-MOLECULE REACTIONS OF tert-BUTYL CATION WITH TERTIARY ALCOHOLS.

Henri E. Audier[1], Dorothée Berthomieu[2], Danielle Leblanc[1], T.B. McMahon[3], and T.H. Morton[4]

Tert-Butyl cation (tBu^+) is widely used as a chemical ionization reagent ion, for which simple proton transfer to neutral substrates is the dominant reaction. As the proton transfer becomes endothermic, the predominance of this reaction channel diminishes, and it becomes possible to examine other reactions that take place in competition with proton transfer. For the reaction of tBu^+ with tert-butanol (tBuOH), net proton transfer is approximately 10 kJ/mol endothermic.

If one considers the approach of tBu^+ to tBuOH theoretically, one may envisage a preliminary stage of engagement. Theoretical calculations confirm that expectation. Semiempirical calculations (AM1) show a hydrogen-bonded complex of tBu^+ with tBuOH that appears energetically more favorable than the Lewis acid-base adduct, protonated di-tert-butyl ether (tBu_2OH^+). *Ab initio* calculations show a hydrogen-bonded structure of similar geometry, but with vastly different energetics: tBu_2OH^+ has an SCF electronic energy (3-21G//3-21G) that is 94 kJ/mol lower than that of the hydrogen-bonded structure. While the zero-point energy of the latter is 14 kJ/mol (unscaled) lower than that of the former, the net calculated enthalpy difference between the two isomeric structures is >80 kJ/mol at 300 K. This is comparable to the C-O bond dissociation energy for tBu_2OH^+ that can be extracted from published experimental data. Therefore the hydrogen bond is not calculated to be very strong.

The hydrogen-bonded structure is calculated to have C-O bond lengths of 1.48 Å and 3.18 Å, as opposed to two equal bond lengths of 1.57 Å in tBu_2OH^+. In the harmonic oscillator approximation the entropy of the hydrogen-bonded structure is calculated to be 55 J/mol·K greater than that of tBu_2OH^+. Since the harmonic oscillator approximation underestimates vibrational entropy, it is appropriate to view the hydrogen-bonded structure as a complex in which large amplitude motions take place. Very likely these motions are of sufficiently large amplitude to satisfy the "Reorientation Criterion"[1], in which case this species is appropriately portrayed as being an ion-neutral complex.

The hydrogen-bonded structure represents the potential energy minimum of a 2-body complex, in which the charged partner enjoys rotations about axes perpendicular to the interfragment axis. This is not the only type of ion-neutral complex that is accessible when tBu^+ reacts with tBuOH. Terbody complexes (*i.e.* species in which an ion is electrostatically bound to at least two neutrals) are also possible. Experimental data on metastable decompositions of tBu_2OH^+ and its deuterated analogues (prepared both by CI of tBu_2O and by ion-molecule reactions in the ZAB source when high pressures of tBuOH are introduced) and the reactions of tBu^+ (injected from an external source) with tertiary alcohols[2] provide useful comparisons with theory.

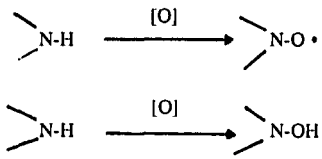
DIFFERENTIATION OF ORGANIC NITROXYL AND HYDROXYLAMINE ANALOGUES BY AMMONIA CHEMICAL IONIZATION

K. Ng, C. Shimanskas, B. Piatek, A. Smith, Analytical Research Department, Ciba-Geigy Corporation, 444 Saw Mill River Rd., Ardsley, NY 10502

Nitroxyl and hydroxylamine analogues are oxidation products of secondary amines and their molecular weights differ only by one.



When chromatography fails to separate the two types of derivatives due to either thermal instability or high polarity by GC and no suitable column conditions by LC, it becomes very critical to have a method to differentiate the two species.

Soft ionization techniques can be used by enhancing the molecular ion information. Desorptive Chemical Ionization with ammonia was used to demonstrate its effectiveness. Ammonia as the reagent gas was found to be far more superior than either methane or isobutane. This was based on the difference in proton affinity (PA) between the two derivatives in forming the protonation product, $M+H^+$ and the association product, $M+NH_4^+$. These ions characteristic of the intact molecule (M) depend upon the proton affinity of the molecule. When 787 kJ/mol < PA(M) < $PA(NH_3)$, $M+NH_4^+$ will be observed. When PA(M) > PA(NH3), both $M+NH_4^+$ & $M+H^+$ will be formed with $M+NH_4^+/M+H^+$ ratio decreases as PA(M) increases.(1) When ND_3 analogue is used instead of natural ammonia, the molecular ion information can be further verified as shown in spectrum (1) and (2) for the nitroxyl derivative of (I).

Three series of compounds, represented by Structures (I), (II) and (III) which are all 2,2,6,6 tetramethylpiperidine based, were evaluated. All of the experimental data confirmed the expectations, as shown by the results of Structure (I) in Table 1. The pK_a values listed reflect that they are not in the same order as the actual proton affinity. All the effects such as temperature, competition from other functional groups, stereochemistry and difference in molecular size have been considered but not included in the data obtained.

Selective Ion-Molecule Reactions of Biologically Active Lactones in a Quadrupole Ion Trap

Tracy Donovan and Jennifer Brodbelt
Department of Chemistry and Biochemistry
University of Texas
Austin, TX 78712-1167.

The design ion-molecule reactions that are specific and structurally diagnostic for increasingly complex molecules offers new avenues in analytical mass spectrometry. Our chosen method is to characterize the bimolecular and dissociation reactions of subunits of larger molecules, and then use this information to determine sites of reactions, understand the influence of neighboring functional groups, and evaluate structural factors which mediate reaction pathways of the larger molecules which consist of multiple subunits. We have examined the ion-molecule reactions of a bicyclic substrate, 2,5-dimethylpyrrole-γ-butyrolactone, which is an analog to a potent plant growth stimulator. It is useful for testing this method since it consists of two component rings that can be represented easily by model compounds: γ-butyrolactone and 2,5-dimethylpyrrole.

Experiments were performed in a Finnigan Ion Trap Mass Spectrometer with helium as a buffer gas at 1 mtorr and dimethyl ether reagent gas at 1×10^{-5} torr. Samples were introduced by a leak valve or solids probe at nominally $0.8\text{-}2.0 \times 10^{-6}$ torr. The reactive ions of dimethyl ether are $CH_3OCH_2^+$, at m/z 45, and $(CH_3OCH_3)H^+$, at m/z 47. Under these chemical ionization conditions, $(M + H)^+$ and $(M + 13)^+$ or $(M + 15)^+$ were formed from the organic substrate, M, during a 100 msec reaction period. A dc potential was applied to isolate the protonated molecules or adducts of interest, and a supplementary ac voltage was used to excite ions for collisional activation experiments.

Bimolecular Reactions. 2,5-Dimethylpyrrole-γ-butyrolactone forms $(M + H)^+$ and $(M + 13)^+$ ions upon reactions with dimethyl ether ions in the ion trap mass spectrometer. Isolation of indvidual reagent ions prior to the reaction period revealed that the protonated dimethyl ether ion is responsible for formation of the $(M + H)^+$ ion, whereas the methoxymethylene cation produces the $(M + 13)^+$ adduct.

Previous studies of the reactions of dimethyl ether ions with organic substrates have indicated that the $(M + 13)^+$ adduct is formed by methylene substitution, which occurs by attachment of $CH_3OCH_2^+$ to the organic molecule, followed by elimination of methanol. This mechanism was tested for 2,5-dimethylpyrrole-γ-butyrolactone by experiments in a triple quadrupole mass spectrometer. For these experiments, 2,5-dimethylpyrrole-γ-butyrolactone was introduced into a conventional chemical ionization source with 1.4 torr dimethyl ether. Under these conditions, an $(M + 45)^+$ adduct (likely $(M + CH_3OCH_2)^+$) was formed in addition to the $(M + H)^+$ and $(M + 13)^+$ ions that were observed in the quadrupole ion trap. Upon subsequent collisional activation, the $(M + 45)^+$ adduct dissociated predominantly by loss of methanol, to produce $(M + 13)^+$ directly. This supports the proposal that the $(M + 13)^+$ ions are produced by spontaneous elimination of methanol from $(M + 45)^+$ adducts in the ion trap.

In order to determine the site of methylene substitution in the formation of $(M + 13)^+$ ions, experiments in which ion-molecule reactions with model compounds representative of each half of the pyrrole lactone were performed in the ion trap mass spectrometer and compared (Fig. 1). Upon dimethyl ether chemical ionization, both model compounds are protonated, but 2,5-dimethylpyrrole forms an $(M + 13)^+$ adduct, whereas γ-butyrolactone forms an $(M + 15)^+$ adduct.

The 2,5-dimethylpyrrole-γ-butyrolactone and 2,5-dimethylpyrrole exhibit similar bimolecular reaction chemistry, so the pyrrole ring, rather than the lactone ring, is presumably the director and substrate for formation of $(M + 13)^+$ ions.

To elucidate the specific site on the pyrrole ring of 2,5-dimethylpyrrole-γ-butyrolactone which attacks the methoxymethylene cation and to determine the atoms involved in the loss of methanol from the $(M + CH_3OCH_2)^+$ complex, various saturated and substituted analogs of 2,5-dimethylpyrrole were allowed to react with dimethyl ether ions in the ion trap. Methylene substitution products at $(M + 13)^+$ are formed *only* for compounds containing a double bond or a secondary amine. On the basis of this evaluation of model compounds, it is apparent that the only structural feature of 2,5-dimethylpyrrole-γ-butyrolactone that is capable of promoting the methylene substitution reaction is one of the double bonds. Methylene substitution is *not* initiated by attack by the tertiary amine site.

Dissociation Reactions. The collisionally activated dissociation pathways of protonated 2,5-dimethylpyrrole-γ-butyrolactone were compared to those of protonated γ-butyrolactone and protonated 2,5-dimethylpyrrole. Upon collisional activation of protonated 2,5-dimethylpyrrole-γ-butyrolactone, the predominant fragment ion produced is observed at m/z 134, presumably from sequential decarbonylation and dehydration (Fig. 2). Other observed pathways that are characteristic of the lactone ring are loss of CO and H2O. Protonated 2,5-dimethylpyrrole (m/z 96) predominantly dissociates upon collisional activation to form ions of m/z 79, 80 ($-CH_4$), and 81 ($-CH_3$). However, none of these neutral losses are observed for the dissociation of protonated 2,5-dimethylpyrrole-γ-butyrolactone.

In summary, ion-molecule reactions may target specific sites in a molecule, as illustrated for 2,5-dimethylpyrrole-γ-butyrolactone. The bimolecular reactions were mediated by the pyrrole ring, whereas the dissociation reactions were mediated by the lactone ring. The strategic use of model compounds has provided a systematic method for evaluating the site of reaction, determining a mechanism, and characterizing the product structures of $(M + 13)^+$ ions generated from methylene substitution.

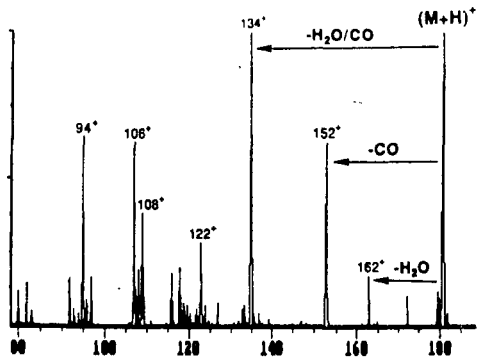
CAD of Protonated Pyrrole Lactone



Isomers of $C_3H_6N^+$ and the Interstellar Synthesis of C_2H_5CN

Murray J. McEwan, Paul F. Wilson and Colin G. Freeman
Department of Chemistry, University of Canterbury, Christchurch, New Zealand.

Propionitrile (ethyl cyanide) was first observed in the interstellar medium in the Orion Nebula (OMC-1) and SgrB2.[1] Among the mechanisms considered as possibly being responsible for its formation are the ion molecule reactions[2,3]

$$CH_3^+ + CH_3CN \longrightarrow C_2H_5CNH^+ (?) \qquad (1)$$

$$H_2CN^+ + C_2H_4 \longrightarrow C_2H_5CNH^+ (?) \qquad (2)$$

followed by dissociative recombination.

Although in each reaction, the production of $C_2H_5CNH^+$ is energetically favourable, the structural identities of the $C_3H_6N^+$ products of reactions (1) and (2) have not been determined. The purpose of this study is to identify the products of reactions (1) and (2).

We have carried out a selected ion flow tube investigation of several $C_3H_6N^+$ isomers and have utilized the known proton affinities (PA's) of the corresponding C_3H_5N neutrals in order to characterise the isomer reactivities. The proton transfer reactions of the isomers $C_2H_5CNH^+$ ($PA_{C_2H_5CN}$ = 806 kJ mol^{-1}), $C_2H_5NCH^+$ ($PA_{C_2H_5NC}$ = 852 kJ mol^{-1}) and $CH_3CNCH_3^+$ (PA unknown) were examined with a number of bases selected because of their PA's. The bases chosen include (units in kJ mol^{-1}) 1,4-dioxane (811), acetone (823), ammonia (854), methylamine (896) and ethylamine (908). Proton transfer was observed to occur from $C_2H_5CNH^+$ to 1,4 dioxane and acetone and from $C_2H_5NCH^+$ to NH_3 but not to acetone in accordance with the listed PA's.

The ion products of reactions (1) and (2) were also examined. For reaction (1), no proton transfer occurred from $C_3H_6N^+$ to any base B with a PA up to and including ethylamine (908 kJ mol^{-1}). The structure of this $C_3H_6N^+$ ion was designated $CH_3CNCH_3^+$ on the basis of ab initio

investigations of the CH_3^+/CH_3CN potential energy surface.[4,5] The high PA observed for this ion is consistent with the anticipated low stability of the CH_2CNCH_3 neutral molecule.

$$C_3H_6N^+_{(R1)} + B \not\longrightarrow BH^+ + C_3H_5N \qquad (3)$$

The $C_3H_6N^+$ product of reaction (2) was found to proton transfer to ammonia but not to acetone and the structure of this ion was assigned to protonated

$$C_3H_6N^+_{(R2)} + NH_3 \xrightarrow{0.95} NH_4^+ + C_3H_5N \qquad (4)$$

$$\xrightarrow{0.05} C_3H_6N^+.NH_3$$

$$k = 1.1 \times 10^{-9}\ cm^3\ s^{-1}$$

$$C_3H_6N^+_{(R2)} + (CH_3)_2CO \longrightarrow C_3H_6N^+\ (CH_3)_2CO \qquad (5)$$

$$k_5 = 7.2 \times 10^{-10}\ cm^3\ s^{-1}\ (P = 0.3\ Torr)$$

ethyl isocyanide, $C_2H_5NCH^+$. This experimental result supports the conclusions of an earlier study on reaction (2) in which a theoretical model based on the formation of $C_2H_5CNH^+$ as the reaction product, could not predict the observed termolculear rate coefficient.[3]

Conclusion. Neither of the $C_3H_6N^+$ ion products of reactions (1) and (2) correspond to $C_2H_5CNH^+$ and these reactions are therefore unlikely to be important sources of interstellar ethyl cyanide.

Structures and Stabilities of Carbon Cluster Ions

Gert von Helden, Ming-Teh Hsu, Paul R. Kemper and Michael T. Bowers
Department of Chemistry, University of California, Santa Barbara, CA 93106

Introduction:

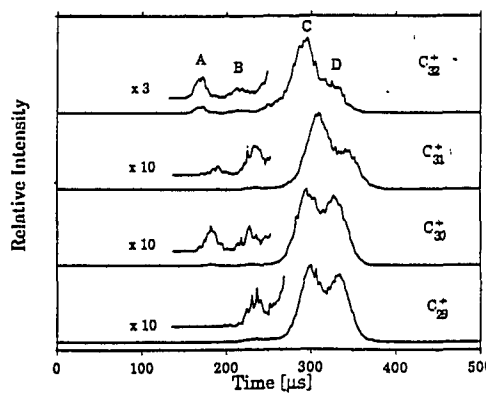
During the last ten years, the structures and properties of metal and semiconductor clusters have been subject to an intense research effort. Most of the cluster chemical and physical properties are dramatically different from either the isolated atom or the bulk. Due to the directional bonding of carbon, carbon clusters are expected to exhibit complex structures and structural isomers are likely. Little is known about the structures of carbon clusters other than some recently isolated fullerenes like C_{60}, C_{70} and others.

Experimental setup:

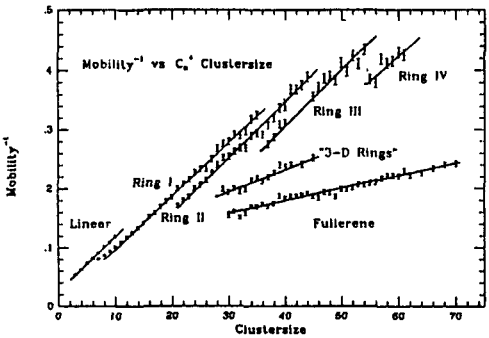
The experimental setup is described in previous publications[1] Clusters are generated by laser vaporization of graphite in a Smalley type laser vaporization/supersonic expansion source. The cluster beam generated consists of positively charged, negatively charged and neutral clusters. After passing a skimmer, the positively charged clusters are accelerated to 5 keV and focussed on the entrance slit of a reverse geometry, double focusing mass spectrometer. A 5 - 8 μs packet of mass selected carbon cluster ions is then decelerated and injected into a high pressure drift cell. The cell is 4 cm long, with 0.5 mm entrance and exit orifices. Helium at 2 - 5 torr is used as a buffer gas and injection energies are typically 4 - 9 eV Drift voltages are, depending on the pressure, between 2 and 10 V/cm. Under these conditions, collisions between helium and the clusters are entirely thermal, except very near the entrance orifice. Ions exiting the cell are passed through a quadrupole mass filter and their appearance is recorded as a function of time. Different cluster isomers can have different drift times through the cell and therefore show up as different peaks in the collected arrival time distribution (ATD).

Results and Discussion:

This figure shows ATD's for C_{29}^+, C_{30}^+, C_{31}^+ and C_{32}^+. The peak at shortest time, labeled A, corresponds to the fullerene structure. Note that it is totally absent in the C_{29}^+ trace. Hence, the first fullerene appears at C_{30}^+. The peak labeled B is assigned as a 3 dimensional ring structure. Peak C is assigned to bicyclic planar rings and peak D to a monocyclic ring.



For each peak, a mobility can be determined. A *plot of the mobility*$^{-1}$ *vs cluster* size for the clusters examined so far is shown in this figure. The inverse mobility is proportional the the cross-section of the cluster averaged over all orientations. The error bars are the relative errors in the measurements (± 3%). The lines are drawn only to guide the eye. Clearly, different "families" of carbon clusters can be identified



Note that all clusters from n = 29 to 41 have at least three resolved peaks in their arrival time distributions corresponding to different structural isomers. Structural assignments are unambiguess for for the families labeled "linear", "Ring I" (a monocyclic ring) and the "Fullerenes".

In order to get structural information on the families "Ring II" and "3-D Rings", extensive geometry searches, using semi-empirical and/or ab-initio methods, have been undertaken. The mobilities of the calculated structures can be simulated using Monte-Carlo methods and can then be compared with experimental values. Results of these simulations for linear and monocyclic (Ring I) clusters are consistent with experimental findings. Deviations between calculated and experimental mobilities are usually less then 3%.

This approach can be used as a tool for structural analysis on larger systems also, where, as yet, no definite structural assignment is possible. Details will be given in the talk and in a forthcoming publication(2).

AROMATIC ADDUCTS OF FULLERENES CHARACTERIZED BY MASS SPECTROMETRY

Steven H. Hoke II, Dominique Dilettato, Jay Molstad,
Mary Jennifer Jay, Bart Kahr, and R. Graham Cooks,
Purdue University, West Lafayette, IN 47907-1393, U.S.A.

Reactions of buckminsterfullerene with various aromatic compounds in solution and in the gas phase are described. Production of aromatic derivatives in solution with $FeCl_3$ or $AlCl_3$ as the catalyst occurs with many aromatic compounds including benzene, toluene, and *p*-xylene[1,2]. Collision induced dissociation (CID) of the mass selected monotoluene adduct in a Finnigan TSQ 700 requires vigorous conditions providing evidence that the toluene molecules are covalently bound to C_{60}[1].

Of several aromatic addends studied, mass spectrometry showed that the simplest reaction mixture was that containing the C_{60}-toluene species. Isolation and further spectroscopic characterization was attempted. However, the chromatography of this reaction mixture proved to be difficult because of the large number of adducts (up to 20) and dehydrogenation products associated with each adduct. Benzyne was subsequently added to C_{60} in an attempt to obviate some of these problems. Benzyne was generated by the reaction of anthranilic acid with *iso*-amylnitrite. Figure 1 shows a negative ion desorption chemical ionization mass spectrum of this reaction mixture with up to 4 benzyne molecules bonded to a single C_{60} molecule (m/z 1024). CID of the monobenzyne adduct at m/z 796 generates a single product ion, C_{60}, with the onset of fragmentation at approximately 50 eV with a krypton target at 0.6 mTorr. These results are similar to CID of the monotoluene adduct. CID of the tribenzyne adduct produces sequential C_6H_4 loss, ultimately restoring C_{60}.

HPLC of the benzyne reaction mixture with a C_{18} reversed phase column shows that the elution of the dibenzyne adduct occurs before the elution of the monobenzyne adduct; C_{60} elutes last. Milligram quantities of the mono- and dibenzyne adducts were isolated. The ^{1}H-NMR spectrum of the isolated monobenzyne adduct shows an AA'BB' spin system in the aromatic region which is characteristic of a mirror symmetric product (Figure 2). The ^{1}H-NMR spectrum of the dibenzyne adducts shows multiple peaks between 7.5 and 8.2 ppm indicating regio-nonspecificity for the addition of the second benzyne molecule to $[C_{60}+C_6H_4]$.

Production of aromatic adducts of C_{60} in the gas phase has also been achieved. In the positive ion mode with benzene as the CI reagent gas, no significant reaction is observed with $C_6H_6^+$ (m/z 78), the benzene radical cation. However, the use of chlorobenzene as the reagent gas allows the generation of the closed shell species $C_6H_5^+$ (m/z 77). Under these conditions, a phenyl adduct of C_{60} is observed at m/z 797. With toluene as the CI gas, a C_{60} adduct at m/z 811, which corresponds to the addition of the closed shell $C_7H_7^+$ species, is observed. Production of this adduct in an API source has been previously reported[3]. The reaction of benzyl chloride with C_{60} under CI conditions shows the addition of both $C_7H_7^+$ and $C_7H_6Cl^+$ (m/z 845) to C_{60} (Figure 3).

Other reactions which occur in the source of a TSQ 700 in negative ion mode under desorption chemical ionization conditions are hydrogenation and halogenation of C_{60} with appropriate reagent gases.

Gas chromatographic-mass spectrometric (GCMS) assay of tissue malondialdehyde (MDA) and other aldehydes after reduction to stable alcohols.

C. Des Rosiers, M.-J. Rivest, M.-J. Boily, M. Jetté and A. Carrobé-Cohen.
Department of Nutrition, University of Montréal, Québec, Canada H3C 3J7.

Free radical induced lipid peroxidation is associated with numerous pathological conditions, including cancer, inflammatory diseases, post ischemic injury., etc. However, to date, our understanding of the role of lipid peroxidation in human diseases has been considerably impaired by methodological problems in measuring the process. More specifically, the thiobarbituric acid (TBARS) method which is most frequently used because of its simplicity, has often been criticized for its lack of selectivity (1). Interest in the development of reliable quantitative methods to measure the various aldehydic lipid peroxidation by-products, mainly malondialdehyde (MDA), hexanal and 4-hydroxynonenal (HNE), stems not only from their potential usefulness as indicators of the peroxidative processes, but also from their toxicity to biological systems (2). Among available methods to determine aldehydes, those involving GCMS (3-5), offer the advantage of selectivity and sensitivity. However, none of these GCMS methods measure simultaneously all aldehydes. We present a quantitative GCMS assay which offers this possibility.

The strategy of our method is to reduce aldehydes into stable alcohols. Reduction of all tested aldehydes is complete with sodium borodeuteride (NaB^2H_4) in neutral conditions at 4°C or room temperature, except MDA which requires a more powerful reducing agent, borane trimethylamine (BTM). After extraction and evaporation, alcohols are converted to *t*-butyldimethylsilyl (TBDMS) esters and analyzed by selected ion monitoring (SIM) GCMS of the $[M+H]^+$ and $[M\text{-}OTBDMS]^+$ ion in the positive chemical ionization (CI) mode using NH_3 as a gas for diols derived from MDA and HNE, respectively, and of the $[M\text{-}57]^{+\cdot}$ ion using electron impact (EI) for alcohols derived from hexanal and other aldehydes. Quantitation is achieved using internal standards of $[^2H_6]$-1,3-propanediol for MDA, of $[2\text{-}^2H]$HNE for HNE, and of the corresponding saturated per-deuterated alcohols for all saturated aldehydes, for example $[^2H_{13}]$hexanol for hexanal. These deuterated alcohols also serve as external standards for their unsaturated aldehydes with same chain length. Detection limit for individual aldehydes is 0.5 nmol in a given sample before extraction.

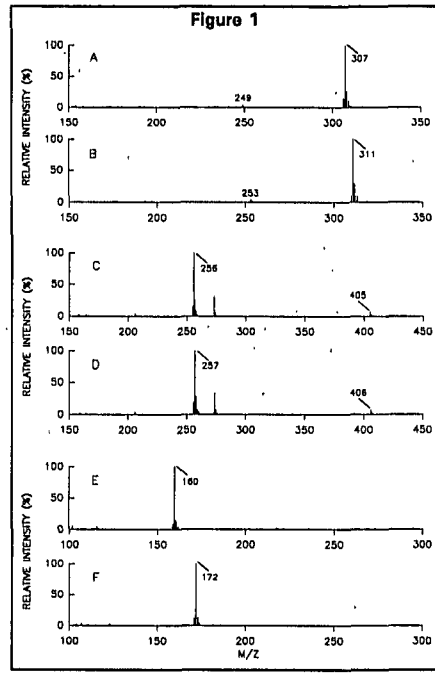

Figure 1 shows the CI or EI mass spectra of the TBDMS derivatives of deuterated diols and alcohols obtained after the NaB^2H_4 reduction of **MDA** ($[1,3\text{-}^2H_2]$-1,3-propanediol; ***A***), **HNE** ($[1\text{-}^2H_2]$-4-hydroxynonenol; ***C***) and **hexanal** ($[1\text{-}^2H]$hexanol; ***E***) and of their corresponding internal standards, $[^2H_6]$-1,3-propanediol (***B***), $[1,2\text{-}^2H_2]$-4-hydroxynonenol (***D***), and $[^2H_{13}]$hexanol (F), respectively.

Table 1 lists the $[M\text{-}57]^+$ ions for all TBDMS-alcohols obtained by reduction of various aldehydes along with their corresponding retention time on a 25 m HP-5 capillary GC column with the following temperature program: 115 °C for 5 min, increased by 4 °C/min until 165 °C, and then by 50 °C/min until 250 °C.

Our GCMS method was used to measure aldehydes accumulating in autoxidized arachidonic acid (AA) solution and in heart homogenates before and after induction of lipid peroxidation by a 2h incubation at 37°C ± $FeSO_4$/ascorbate (Fe/Asc. 0.1/0.4 mM). In agreement with others (2), aldehydes detected in autoxidized AA are: MDA 8.5±0.5, HNE 0.84±0.05 and hexanal 4.3±0.1 mol% AA. Results from heart homogenates are shown in *Table 2*. Recovery from heart tissue of added MDA, HNE and hexanal is > 95%. The identity of each aldehyde was confirmed by observing a mass shift when sample was reduced with NaB^2H_4 or BTM: e.g. reduction of hexanal with NaB^2H_4 forms [1-^{2}H]hexanol (ion at m/z 160), whereas reduction with either BTM or $NaBH_4$ forms hexanol (ion at m/z 159). MDA concentrations assayed by GCMS and by TBARS were similar in autoxidized AA solutions. In heart homogenates, values agreed only if samples had been deproteinized before the TBARS assay, suggesting an important contribution by non-lipid components to color development in the TBARS assay (1).

TABLE 1

20.7	HNE	[1-^{2}H]-4-hydroxynonenol	330

* Internal or external standard.

Compared to other GCMS assays for aldehydes (3-5), our method combines the following features: (i) Quantitation using isotope dilution of a wide spectrum of aldehydic lipid peroxidation products, including MDA, hexanal and HNE; (ii) verification of compound identification by referring to the elution time of the corresponding internal standard and by observing a mass shift when aldehydes are reduced with $NaBD_4$ and BTM; (iii) mild conditions for sample processing minimizing lipid peroxidation during sample preparation; (iv) measurement of free MDA and other aldehydes and additional possibility of measuring total MDA after acid or alkaline hydrolysis of the sample; (v) comparable limit of detection. Conditions described can be used to assay aldehydes in any biological system. (Supported by the Medical Research Council of Canada).

Structural Analysis of Epoxy, Hydroxy Fatty Acids by Thermospray LC/MS/MS.

H.Y. Kim and S. Sawazaki
Section of Mass Spectrometry, LMBB, DICBR, NIAAA
Building 10, Room 3C-102, 9000 Rockville Pike, Bethesda, MD 20892

Polyunsaturated fatty acids can be oxygenated to hydroperoxy compounds by lipoxygenation or peroxydation. Hydroperoxy derivatives are primarily reduced to hydroxy compounds by peroxidase activity, however, some hydroperoxy compounds can undergo transformation to hepoxilin (epoxy, hydroxy compounds)- or leukotriene-like compounds. Many of these oxygenated products are reported to possess important biological activities. Docosahexaenoic acid (22:6n3), which is the major polyunsaturate in neuronal cells, can also be oxygenated to hydroperoxy derivatives, as we have reported for the rat brain tissues. In the present study, we have examined further transformation of hydroperoxy-22:6n3 formed by leukocyte 12-lipoxygenase and soybean 15-lipoxygenase using thermospray LC/MS/MS as pentafluorobenzyl (PFB) derivatives. In order to establish the fragmentation pattern, PFB derivatives of various oxygenated fatty acid standards were analyzed either before or after hydrogenation.

Experimental

Preparation of 12- and 15-lipoxygenase (LO) products of 22:6n3

Either ^{14}C-22:6n3 or non-labeled 22:6n3 was incubated with partially purified porcine 12-LO in tris buffer (pH 7.4) at 37°C for 20 min. Separately, 22:6n3 was incubated with soybean 15-LO in borate buffer (pH 9.0) on ice for 15 min. Reaction was terminated by acidification to pH 3.0 with formic acid and the products were extracted with dichloromethane 3 times. After drying under the nitrogen stream, the products were redissolved in methanol for the subsequent reversed-phase HPLC or thermospray LC/MS analysis.

HPLC analysis of oxygenated metabolites

The separation of oxygenated products were achieved using an Axxiom-ODS (4.6 mm x 25 cm, 5u) and a solvent gradient of 0.1M ammonium acetate:methanol changing from 40:60 to 15:85 in 50 min and then to 0:100 in 5 min. The flow rate was 0.8 mL/min. The separated compounds were detected by UV/radioactivity detector or by thermospray LC/MS (Finnigan TSQ 70). For further analysis by LC/MS/MS, metabolites were collected from the reversed phase column and derivatized to PFB derivatives.

Derivatization of oxygenated fatty acids

Pentafluorobenzyl derivatization was carried out by reacting oxygenated fatty acids with 1% pentafluorobenzyl bromide and 10% diisopropylethylamine in acetonitrile at 40°C for 15 min. Hydrogenation was achieved by bubbling hydrogen through the methanol solution containing PFB derivatives on the dry ice for 3 min in the presence of platinum oxide (PtO_2) as a catalyst.

Thermospray LC/MS/MS analysis

Derivatized hydroxy fatty acids were redissolved in acetonitrile and injected into the Finnigan TSQ mass spectrometer via an C-18 column (Ultrasphere-ODS, 4.6 mm x 7.5 cm, 3u) using 100% methanol as the mobile phase with the flow rate of 0.8 mL/min. The vaporizer control temperature was 75°C and the source temperature was 250°C. Filament or discharge electrode was kept on throughout the analysis.

Results and Discussion

Upon incubation of 22:6n3 with porcine leukocyte enzyme or soybean LO, 14- or 17-hydroperoxy derivatives were formed as the major products, respectively. Further transformation of these products to hepoxilin-like compounds was also observed. Positive ion thermospray spectra provided information concerning molecular weight and the site of peroxidation or epoxidation. However, the position of hydroxylation could not be determined solely by the fragmentation observed in the positive ion spectra. Thermospray LC/MS analysis of PFB derivatives in the negative ion mode provided a sensitive method for detecting $(M-H)^-$ ions. Detailed structural information could be obtained using MS/MS analysis of these $(M-H)^-$ ions using argon as a collision gas. Collision-induced dissociation (CID) spectra of the $(M-H)^-$ ions of various deuterated and non-deuterated hydroxy-20:4n6 (HETE) and hepoxilin standards as well as their hydrogenated forms indicated that characteristic cleavage occurs at the C-C bond adjacent to the hydroxylated carbon (Figure 1). Using this method, it was found that 12-hydroxy-13,14-epoxy-22:5n3 (hepoxilin B_3 type) was the major hepoxilin-like compound formed from 14-hydroperoxy-22:6n3 by leukocyte 12-LO (Figure 2). However, 17-hydroperoxy-22:6n3 formed by 15-LO appeared to transform to both 13- (hepoxilin A_3 type) and 15-hydroxy-16,17-epoxy-22:5n3 (hepoxilin B_3 type).

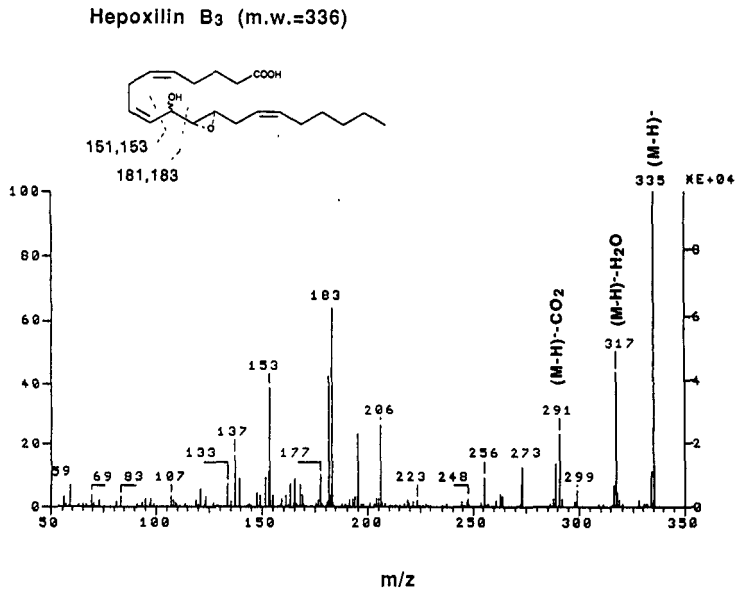

Figure 1. Negative ion thermospray LC/MS/MS spectrum obtained from 10 ng of hepoxilin B_3 standard after PFB derivatization. The collision energy was 8 eV.

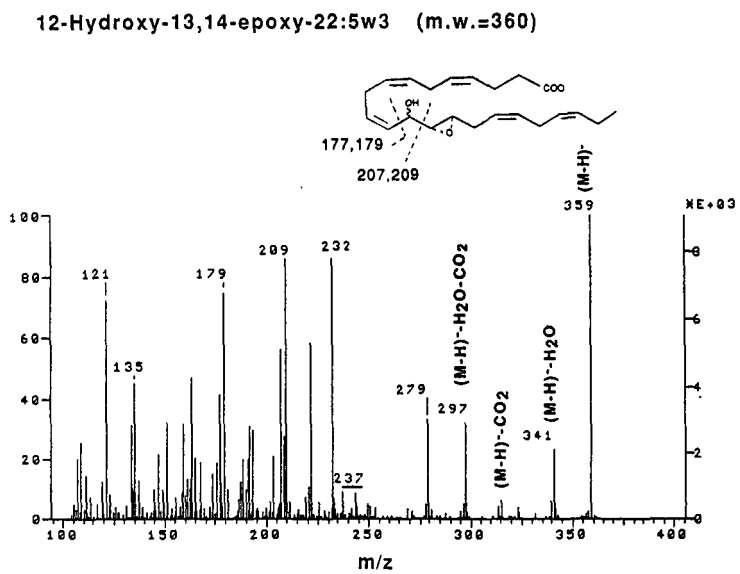

Figure 2. Negative ion thermospray LC/MS/MS spectrum of the hepoxilin-like compound obtained from the incubation of 22:6n3 with leukocyte 12-LO. The collision energy was 8 eV.

Quantitative Analysis of Vitamin K_1 and Vitamin K_1-epoxide from Biological Samples by GC-NCI/MS,

Y.-C. Huang, J. A. Sadowski, *G. G. Dolnikowski,
USDA Human Nutrition Research Center on Aging at Tufts University,
Boston, MA 02111.

Introduction

Vitamin K_1 and a metabolite, vitamin K_1-epoxide are found in small quantities in both plants and animals that are commonly used as food. After the vitamin K_1 and its epoxide are extracted and preconcentrated, reversed-phase HPLC with ultraviolet detection is typically employed for separation and quantification of these two compounds. For many applications, the concentrations of these compounds are below the detection limit of the HPLC detector, therefore, we have developed a gas chromatography - electron capture negative ion chemical ionization mass spectrometry technique for trace detection of Vitamin K_1 and its epoxide.

GC-MS Instrumentation

The mass spectrometer is a HP 5988A quadrupole with an EI/CI source and a conversion dynode electron multiplier for negative ion detection. The gas chromatograph is an HP 5890 Series II with an autosampler, and a cool on-column injection port with temperature and pressure programming. The GC column is an SGE 15 meter, 0.1 mm i.d., aluminum clad fused silica column. It is coated with HT-5, a high temperature (400° C max.) low bleed bonded stationary phase. The computers are an HP 1000 and an HP Vectra 486 PC. An RTE data system on the HP 1000 runs the GC/MS automation software, Aquarius. Data are transferred via RS-232 cable using the Advancelink program to the Vectra. Data analysis are performed and presentation graphics are generated using Microsoft Windows, Excel, and Powerpoint.

Sample Extraction and Clean-up

Homogenize food in food processor with twice the weight of the food in anhydrous sodium sulfate, then homogenize with hexane in blender for 5 min. Filter the homogenate through a sintered glass funnel and evaporate. Dissolve residue in 15% benzene/hexane. Elute the Vitamin K1 fraction from a silicic acid column with a gradient of 15% to 37% benzene and evaporate the solvents. Isolate Vitamin K_1 fraction by reverse phase HPLC using a C-18 column and isocratic elution with 10% dichloromethane/methanol.

GC-NCI/MS Expermental Conditions

Helium was the GC carrier gas. The helium pressure at the beginning of the run was 8 psi, and was automatically programmed along with the oven temperature to maintain a constant flow rate of 0.79 ml/min. The gas chromatograph oven temperature was programmed from 50°C to 350°C at 20°C/min. The injection port temperature was linked to the oven temperature but 3°C higher. The GC/MS interface temperature was 300°C. The ion source temperature was 150°C. Methane was the moderator gas for EC-NCI and the ion source pressure was 0.5 torr.

GC-NCI/MS Results

The structures of Vitamin K_1 and its epoxide, as well as their respective selected ion monitoring GC-NCI/MS profiles, are shown in Figure 1. The cool on-column injector is responsible for the good chromatographic performance indicated in Figure 1. With a vaporizing injector, the compounds degrade thermally or adsorb onto the injection port liner. The NCI spectra of Vitamin K_1 and its epoxide show only the M^- ions at m/z 450 and m/z 466, respectively. The detection limit of Vitamin K_1 by this method is 2 pg and the detection limit of the epoxide is 4 pg. Calibration curves for GC-NCI/MS of Vitamin K_1 and its epoxide are linear over 5 orders of magnitude from 1 pg to 10 ng injected, but the relative standard deviations at the very lowest end of the curves are about 30%. Therefore, we are currently engaged in synthesizing D_4-Vitamin K_1, so that it can be used as an isotope dilution standard to increase the precision of the quantitative analysis. We are also investigating and hope to eliminate a small but noticable memory effect for Vitamin K_1 in the injection port of the GC.

Conclusions

Electron capture negative ion chemical ionization is an ideal ionization technique for quantification of Vitamin K_1 and its epoxide. GC-NCI/MS yields low picogram detection limits for Vitamin K_1 and its epoxide. On-column injection and a high temperature, low bleed capillary column are required for high sensitivity GC-MS analyses of Vitamin K_1 and its epoxide. Calibration curves for both comounds are linear throughout the pg and ng range, but a deuterium-labelled standard will be necessary to increase the precision of the assay.

Evaluation of Pentafluorobenzyl Esters of Substituted Fatty Acids in Structural Analysis.

Pat Wheelan, Joseph A. Zirrolli and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
Denver, Colorado 80206

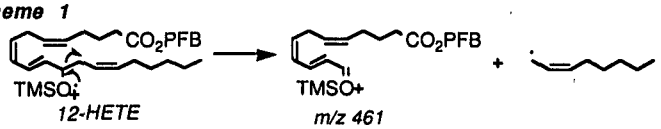
Introduction The pentafluorobenzyl esters of hydroxy substituted fatty acids typically have been used in electron capture ionization GC/MS where a high level of sensitivity is achieved in the detection of the molecular anion. Because little or no additional fragmentation occurs under these conditions, the methyl ester derivative is traditionally analyzed by EI GC/MS to obtain structural information. This approach requires the preparation of two derivatives with differing gas chromatographic retention times. The present study evaluates the pentafluorobenzyl ester (PFB) derivative under EI GC/MS conditions as suitable derivatives for structural elucidation of eicosanoids and other hydroxy substituted fatty acids.

Methods Hydroxy substituted fatty acids were obtained from Cayman Chemical Co. (Ann Arbor, MI). Methyl esters (1-5 ug) were prepared by treatment with diazomethane. Pentafluorobenzyl esters (PFB) were prepared by treating the dried fatty acids (1-5 ug) for 15 minutes at room temperature with 10% diisopropylethylamine in acetonitrile (50 uL) followed by 10% pentafluorobenzyl bromide in acetonitrile (50 uL). Trimethylsilyl ethers were formed by treating the fatty acid esters with bis(trimethylsilyl)trifluoroacetamide (50% BSTFA in acetonitrile) and heating for 10 - 15 minutes at 60 °C. Derivatized fatty acids were analyzed on a Finnigan SSQ 70 interfaced with a Varian 3300 gas chromatograph equipped with a 10 m x 0.25mm DB-1 capillary column programmed from 150 °C to 300 °C at 15 °C/min. The quadrupole mass spectrometer was operated in the EI mode with an electron energy of 70 V and a source temperature of 180 °C. Full scans were acquired over the mass range of 50-700 u at 1 scan/sec.

Results Monohydroxy unsaturated fatty acids as the PFB/TMS derivatives give total ionization comparable to that obtained with methyl ester/TMS derivatives with molecular ions and $(M-15)^+$ ions present in low abundance for both derivatives. The mass spectra contain abundant fragment ions formed by α cleavage around the hydroxy substituent. When the derivative contains unsaturation β,γ to the hydroxy substituent (e.g. 12-HETE), the most abundant fragment ion results from α cleavage to give a neutral allylic radical and the charged R-OTMS fragment (indicated in bold in Table 1 and shown in Scheme 1). When the hydroxy substituted derivative does not contain unsaturation in this position (e.g. 5-HETE), fragment ions are generally observed that result from rearrangement processes analogous to those reported for the methyl ester derivatives (Hill, E. and Murphy, R.C., *J. Brit. Pharmacol. in press*) and shown in Scheme 2. This rearrangement also results in the loss of a neutral allylic radical.

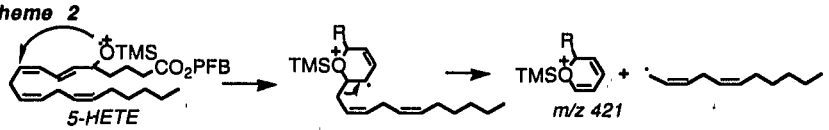
Saturated monohydroxy fatty acids give two abundant fragment ions resulting from the two possible fragmentations α to the hydroxy substituent.

Scheme 1



12-HETE *m/z 461*

Scheme 2



5-HETE *m/z 421*

EI GC/MS mass spectra of PFB/TMS derivatives of dihydroxy fatty acids contain structural information comparable to that obtained with the methyl ester derivatives. Generally, more rearrangement ions are observed corresponding to apparent vinylic α cleavage than were observed for monohydroxy derivatives.

The mass spectra of saturated dihydroxy derivatives also provide structural information on the hydroxy substituent position where all four possible α cleavage fragment ions were generally observed.

A possible disadvantage in the use of PFB derivatives for EI GC/MS structural analysis is the resulting decrease in volatility relative to the methyl ester derivatives. PFB esters have an equivalent carbon number 4.5 greater than the corresponding methyl esters.

*α cleavage positions are assigned as in the following diagram.

[1] This results from both α2 cleavage as well as α4 cleavage minus two TMSOH groups. This was verified by the use of d9-TMS where the fragment ion resulting from m/z 567-d9TMSOH-d9TMSOH is m/z 369 but α2 cleavage is observed at m/z 378.

Facile Determination of Alkyl-Branched Fatty Acid Methyl Esters by Tandem Mass Spectrometry

Joseph A. Zirrolli and Robert C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson Street, Denver, CO 80206

The assignment of alkyl substituent positions on fatty acids traditionally has been a difficult task. However several mass spectrometric approaches have been developed toward that purpose. Jensen and Gross (1) have employed FAB and tandem MS in their studies of free fatty acids. High energy collision-induced dissociation of carboxylate anions yielded product ions characteristic of the fatty acyl carbon skeleton via remote site fragmentation processes. This technique successfully analyzed iso- and anteiso- methyl substituted fatty acids, as the iso-isomer showed losses of methane and propane without any loss of ethane - confirming the methyl substitution on the w-1 carbon.

Other approaches have used special ester derivatives of fatty acids to obtain similar results with electron ionization. Ayanoglu et al. (2) studied pyrolidide esters of fatty acids, while Harvey (3) made picolinyl esters. The EI spectra of these derivatives are characterized by a regular series of ions from high to low mass corresponding to cleavage at each carbon atom. When an ion of low abundance is observed in the series, a methyl substituent is suggested at that carbon.

Simple methyl esters of fatty acids (FAMES) have been extensively studied by Ryhage and Stenhagen (4). Their studies indicated that, with electron ionization, alkyl-substituted FAMES produced variable results dependent upon the position of the substitution. Thus while substitution at C-6 produced abundant diagnostic ions, alkyl substitution at sites more than nine carbons removed from the carbomethoxy group were very difficult to identify.

We have studied the low energy CID of molecular ions from saturated FAMES. These product ion spectra are characteristic of the fatty acyl skeleton and also diagnostic of methyl-branching sites.

Method

Methyl esters of fatty acids were obtained by treatment with diazomethane. FAMES were introduced into a triple-sector quadrupole mass spectrometer (TSQ70, Finnigan Corporation) by solid probe or via a gas chromatograph (Varian 3300) under electron ionization conditions. Collision-induced dissociation of molecular ions of FAMES was performed with varying offset potentials on the second quadrupole (1-100 eV) and argon gas pressures (0.1-0.5 mTorr). Product ion spectra were obtained by scanning the third quadrupole from m/z 50 to the molecular ion in two seconds.

Results

Structurally significant ions are produced from the low energy collision-induced dissociation of molecular ions of fatty acid methyl esters. These product ion spectra, as demonstrated with methyl stearate (Fig 1), were characterized by simple sequential alkyl losses from the omega terminus (M-15, M-29, M-43, etc.) This ion series of alkyl losses was observed under low energy CID conditions, 1-5 eV offset potentials. Under more energetic CID conditions, 20-50 eV offset potentials, the abundance of these ions was proportionately decreased and the abundance of hydrocarbon-type ions and the carbomethoxy rearrangement ions (m/z 101, 143, 199, 255, etc.) increased.

Surprisingly, the CID of molecular ions of FAMES did not yield the McLafferty rearrangement ion at m/z 74 under all conditions studied. This ion is normally the base peak ion in the spectra of these compounds under EI conditions.

A useful application of this technique is the identification of alkyl-branching points in saturated FAMES. This is demonstrated with methyl branched iso- and anteiso pentadecanoate and most strikingly with methyl 3,7,11,15-tetramethyl-hexadecanoate (Fig 2). With this compound the only product ions observed corresponded to losses from alpha cleavage of the carbon skeleton on either side of the methyl-substituted carbon. This is in contrast to the complex mass spectrum obtained under EI conditions

Collision Induced Dissociation of LTB_4 and Metabolites Derived from the Pentafluorobenzyl Ester Trimethylsilyl Ether Derivative.

B. Fruteau de Laclos, J.A. Zirrolli, and R.C. Murphy
National Jewish Center for Immunology and Respiratory Medicine
1400 Jackson St., Denver, CO 80206

The 5-lipoxygenase pathway arachidonic acid metabolism is present in various inflammatory cells (1). This pathway gives rise to several products, including leukotriene B_4 (LTB_4) and the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4). The metabolite LTB_4 acts as a potent chemotactic agent on the human neutrophil (2). Measurement of LTB_4 and its metabolites in physiological fluids has therefore been an important goal to follow biosynthesis *in vivo*. Electron capture negative ion mass spectrometry has been used widely for the analysis of pentafluorobenzyl derivatives of eicosanoids because of the production of abundant carboxylate anions and the favorable gas chromatographic properties of the PFB ester, trimethylsilyl ether derivative (3). However, little has appeared concerning the collision induced dissociation (CID) of these carboxylate anions during GC/MS analysis. The low energy CID of several compounds related to LTB_4 has been studied in a tandem quadrupole instrument. Several stable isotopically labeled species had been synthesized to further elucidate the mechanisms of decomposition following collisional activation. PFB ester formation was carried out using previously published methods (3) and trimethylsilylation was performed using bis(trimethylsilyl)trifluoroacetamide and acetonitrile. GC/MS/MS was carried out on a 7m DB-1 capillary column with injector at 280° and transfer line at 340°. The column was temperature programmed from 150° to 320° in 15 min using helium as carrier gas. The ion source of the Finnigan TSQ70 was set at 150° and source pressure at 5,000 mTorr using helium as moderating gas. The collision gas (Ar) was adjusted to obtain a manifold pressure of approximately 10^{-5} torr and collision energy was set at 50 eV.

The $[^{18}O_2]LTB_4$ was obtained through exchange of the carboxylic acid oxygen atoms with $H_2{}^{18}O$ catalyzed by porcine liver esterase (4). $[6,7,14,15\text{-}^2H_4]LTB_4$ was purchased from Biomol Research Laboratory (Philadelphia, PA).

The collision induced dissociation of the LTB_4 carboxylate anion (m/z 479) and its two labeled isotope labeled analogs are shown in Figures 1, 2, and 3. The most abundant ions from decomposition of the carboxylate anion corresponded to [A-90] and [A-90-90] suggesting the sequential loss of one and two trimethylsilanol moieties. The resulting ions at m/z 389 and 299 respectively were initially thought to result from remote site loss of TMSOH with formation of the corresponding conjugated pentane (loss of the C(12-OTMS) and conjugated hexaene. However, the stable isotope labeled species revealed a more complex mechanism. The ion corresponding to the loss of one trimethylsilanol clearly involved the loss of one of the carboxylate oxygen atoms at m/z 391 in Figure 2 suggesting a charge driven mechanism which would transfer this site of ionization to possibly the C(5) oxygen atom. Even more surprising was that the deuterium labeled species indicated a loss of one of the olefinic deuterons as the proton in trimethylsilanol. This is shown as the $[A\text{-}91]^-$ ion at m/z 392 in Figure 3. A mechanism which could account for the loss of such a deuterium atom as well as an oxygen 18 atom from the carboxylic acid group is shown in Scheme 1.

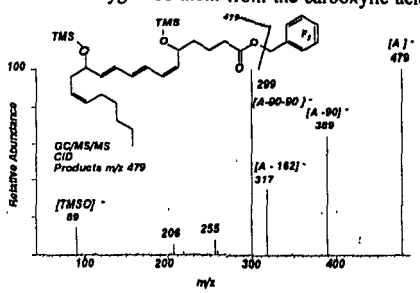

Figure 1: LTB_4

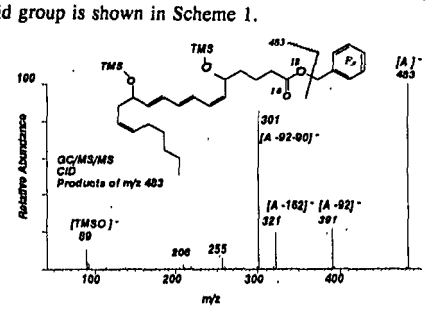

Figure 2: $[^{18}O_2]$-LTB_4

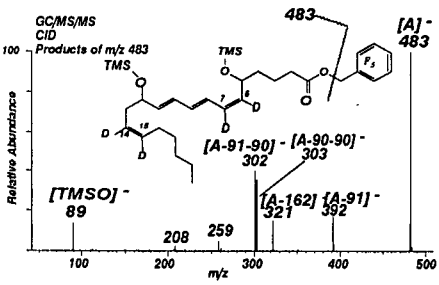

Figure 3: [$^2H_4$]-LTB_4

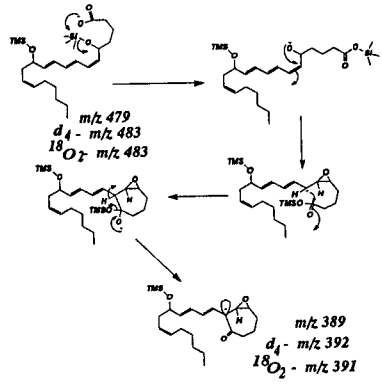

Scheme 1

The ion at m/z 317 corresponds to [A-161]⁻ which shifted to [A-180]⁻ when a d_9-TMS derivatizing agent was used. This ion is likely the loss of trimethylsilyl ether following the charge driven mechanism shown in Scheme 2.

The ion observed for all of the 5-lipoxygenase metabolites studied thus far occurs at m/z 89 corresponding to [TMSO]⁻ which may also result following the charge driven mechanism shown in Scheme 3.

The collision induced dissociation of LTB_4 was revealed to be somewhat more complex than anticipated when stable isotope labeled analogs were studied. The results suggest that possibly charge driven decomposition of these anionic species are more important than remote site fragmentations under these low energy activation conditions in the complex hydroxy acids.

NOVEL FRAGMENTATION OF BISPENTAFLUOROBENZOYL ESTERS $(PFB)_2$ OF 1-0-ALKYL- AND 1-ACYL-2-LYSO-SN-GLYCERO-3-PHOSPHOCHOLINES AND 1-MONOGLYCERIDES.

Walter C. Hubbard, The Johns Hopkins University School of Medicine, JHMI Asthma and Allergy Center, Baltimore, MD 21224

Capillary gas chromatography-mass spectrometry (GC-MS) and GC-MS/MS analysis were investigated for selectivity and sensitivity for identification of 1-0-alkyl- and 1-acyl-2-lyso-sn-glycero-3-phosphocholines in biological samples. Commercially available 1-0-alkyl- and 1-acyl-2-lyso-sn-glycero-3-phosphocholine standards were converted to 1-monoglyceride (1-MG) residues via HF hydrolysis of phosphoryl esters. The 1-MG residue of the lysophosphotidylcholines and commercially available 1-MG standards were treated with excess pentafluorobenzoyl chloride (PFB-Cl) in the presence of 4-dimethylaminopyridine (4-DMAP) as a catalyst for synthesis of bispentafluorobenzoyl esters $(PFB)_2$ of the 1-radyl moieties. GC analysis resulted in resolution of the 1-radyl-$(PFB)_2$ in relation to chain length, degree of unsaturation and 1-radyl functionality.

Methane negative ion chemical ionization (NICI) mass spectra of 1-radyl-$(PFB)_2$ are characterized by the presence of an intense molecular anion ($M^{-\bullet}$) either as the base peak or > 80% of the base peak and fragment ions at $M^{-\bullet}$ -18, $M^{-\bullet}$ -44 and $M^{-\bullet}$ -210. Other fragment ions common to the NICI mass spectra of the 1-radyl-$(PFB)_2$ include: m/z 464, m/z 446, m/z 420, m/z 402, m/z 270, m/z 268, m/z 254, m/z 252, m/z 240, m/z 211, m/z 196, m/z 193, m/z 174 and m/z 167. The NICI mass spectra of 1-acyl-(PFB)2 are characterized by the presence of a fragment ion at $M^{-\bullet}$ -212 not present in the NICI mass spectra of 1-0-alkyl-$(PFB)_2$. In addition, the ions at m/z 464, m/z 446, m/z 420 and m/z 402 are more intense in the NICI mass spectra of 1-acyl-$(PFB)_2$. The ion at m/z 464 is the base peak in the NICI mass spectra of 1-acyl-$(PFB)_2$ with stearoyl, arachidonoyl and arachidoyl substituents at the sn-1 position.

Negative product ion experiments indicate distinct features in ion generation from 1-acyl-$(PFB)_2$ and 1-0-alkyl-$(PFB)_2$. Features of the product ion spectra from $M^{-\bullet}$ of isotonic 1-acyl-$(PFB)_2$ and 1-0-alkyl-$(PFB)_2$ are depicted in Figure 1.

Two distinct features of negative product ion spectra of the molecular anion of 1-pentadecanoyl-$(PFB)_2$ are evident in Figure 1. Characteristic features of the negative product ion spectra of the 1-acyl-$(PFB)_2$ include: (1) an ion at $M^{-\bullet}$ -212 (loss of C_6F_5C00H) and (2) an ion at m/z 241 representative of the pentadecanoyl anion (Panel A). The negative product ion spectra of 1-0-hexadecyl-$(PFB)_2$ and other 1-0-alkyl-$(PFB)_2$ are devoid of ions at $M^{-\bullet}$ -212 and at a m/z ratio representative of the 1-0-alkyl moiety.

Negative product ions mass spectra from $M^{-\bullet}$ of 1-0-alkyl- and 1-acyl-$(PFB)_2$ indicate that two characteristic ions in the NICI mass spectra of these compounds ($M^{-\bullet}$ -210 and m/z 464) do not directly originate from the molecular anion. Additional MS/MS experiments indicate that the formation of ions at $M^{-\bullet}$ -210 and at m/z 464 present in the NICI mass spectra of 1-radyl-$(PFB)_2$ may result via two different mechanisms. Postulated mechanisms for the formation of the ions at $M^{-\bullet}$ -210 and at m/z 464 include proton transfer subsequent to cleavage of either pentafluorobenzoate or the 1-radyl-substituent.

The studies summarized above demonstrate that GC-MS and GC-MS/MS analysis of $(PFB)_2$ derivatives of 1-0-alkyl- and 1-acyl-2-lyso-sn-glycero-3-phosphocholines provide a selective and sensitive technique for the identification of lysophosphatidylcholines isolated from biological samples. The 1-radyl-$(PFB)_2$ derivatives are baseline resolved during gas chromatographic analysis and can be identified by their characteristic NICI mass spectra and their negative product ion mass spectra derived from $M^{-\bullet}$ of the individual 1-radyl-$(PFB)_2$ species.

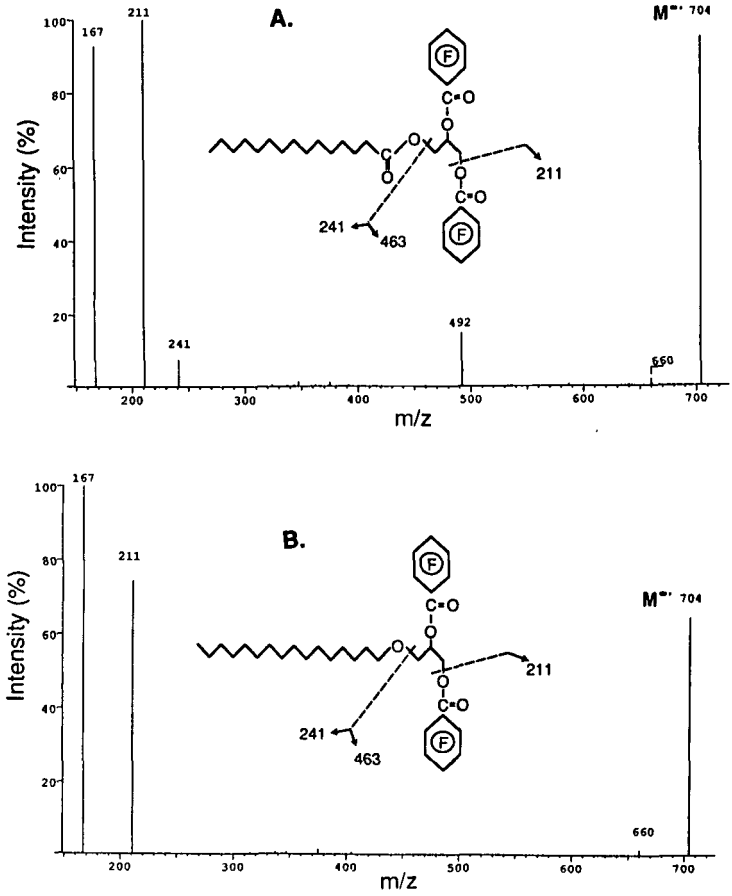

Figure 1: Negative product ion spectra of $M^{-\cdot}$ (m/z 704) from 1-pentadecanoyl-$(PFB)_2$, Panel A, and from 1-0-hexadecyl-$(PFB)_2$, Panel B.

A SENSITIVE ASSAY FOR ESTROGENS IN HUMAN PLASMA USING GAS CHROMATOGRAPHY-ELECTRON CAPTURE NEGATIVE ION CHEMICAL IONIZATION-MASS SPECTROMETRY (GC-ECNICI-MS).

J. Carlson, D. Watson, H. Yamashita and KDR Setchell. Childrens Hospital Research Foundation, Cincinnati, OH 45229

INTRODUCTION: We have developed a new stable isotope dilution method based on electron capture negative ion chemical ionization (ECNICI) of bis-trifluoromethyl benzoyl (TFMBO) derivatives for the measurement of estrone (E_1), estradiol (E_2) and estriol (E_3) in biological fluids. Selected ion monitoring (SIM) methods for quantifying E_2 in biological fluids have been previously developed, mainly for use in validation of less specific assay techniques, such as radioimmunoassays (RIA). Previous mass spectrometric methods have been based on electron ionization (EI) of silyl ethers of E_2, but have limited sensitivity, thereby requiring large volumes (2ml) of plasma for analysis. Utilizing TFMBO derivatives and GC-ECNICI-MS, the three derivatized estrogens yielded intense M^- signals of mass to charge (da/e) 510, 752 and 1008 for E_1, E_2 and E_3 respectively. In SIM mode the detection limit for E_2 is <1 pg (S/N=8 for 1pg injected [1], which is below the normal physiological range for free circulating estrogens in serum (E_1=40-80pg/ml, E_2=20-60pg/ml). We therefore explored the possibility of using this method for the measurement of estrogens in physiological fluids.

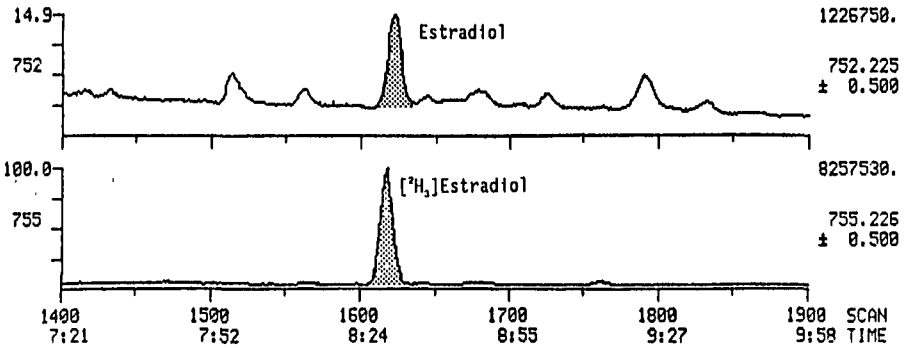
METHODS: Quantitative assays of the E1, E2 and E3 were developed using deuterated internal standards and SIM of the characteristic M^- signals of the TFMBO derivatives. The internal standards ($[^2H_3]E_2$ and $[^2H_4]E_1$) were obtained from MSD Isotopes.

Extraction of estrogens from biological samples:

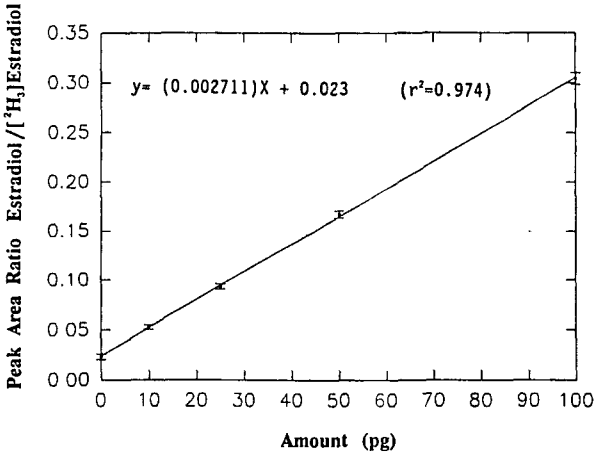
- 5vols of 0.45% NaCl added to 1ml of serum and deuterated standards; heat 64°C, 15 minutes
- C_{18}/C_8 solid phase extraction; elute with 6ml of methanol
- Triethylaminohydroxypropyl Sephadex LH-20 (TEAP LH-20) column chromatography
- elute with 9ml of CO_2 saturated methanol
- Sephadex LH-20 column chromatography
- elute with 11ml of 100:80:15:1 (dichloromethane:cyclohexane:methanol:water)

The extracts from Sephadex LH-20 were converted to their TFMBO derivatives as described previously [1]. An increase in molecular weight of 240 daltons occurs for each derivatized hydroxyl group, and intense high mass ions result from the ionization of the molecule. GC-MS was performed on a Finnigan 4635 quadrupole mass spectrometer housing a 10 meter x 0.25mm i.d. DB-1 (J&W Scientific) capillary column operated with temperature programming between 265°C - 315°C with increments of 10°C/min. Helium was used as carrier gas with a flow-rate of 1.5 ml/min. Samples were introduced using an all glass solid injection system. The mass spectrometer was operated in the negative ion chemical ionization mode with an electron energy of 100eV. Ammonia was used as the reagant gas with an ion source pressure of 0.35 Torr. The ion source temperature was 150°C.

RESULTS: Ion current chromatograms showing detection of TFMBO derivatives of E_2 and $[^2H_3]E_2$ extracted from human serum.



Calibration: Estradiol standard curve measured against [$^2H_3$]estradiol



This curve represents 20 measurements of estradiol at each point analyzed over a 5 month period. The error bars represent the 95% confidence level for the standard deviation.

Serum Estrogen Concentrations: Table indicating the molecular ion (M^+), the signal-to-noise ratio at 1pg concentration of standard and the normal range (± SD) for estrone, estradiol and estriol determined from the measurement of 35 serum samples from normal adult males. Estriol concentrations were below the detection limit of the method.

		M^+ (da/e)	S/N at 1pg	Normal Range Adult Males (n=35)
a)	Estrone	510	13:1	70.2±14.3 pg/ml
b)	[$^2H_4$]Estrone	514	--	------
c)	Estradiol	752	25:1	50.0±5.3 pg/ml
d)	[$^2H_3$]Estradiol	755	--	------
e)	Estriol	1008	8:1	<10 pg/ml

SUMMARY:

- A new highly sensitive method has been developed for measuring circulating E_1, E_2 and E_3 concentrations in relatively small volumes (1.0ml) of serum under normal physiological conditions.
- This method is a useful candidate reference method to establish the accuracy of routine assays for plasma estrogens

Enantioselective metabolism of 14,15-epoxyeicosatrienoic acid by human platelets

*Ji Y. Zhang, Chandra Prakash, Kouwa Yamashita and Ian A. Blair.
Department of Pharmacology, Vanderbilt University, Nashville, TN 37232.

14,15-Epoxyeicosatrienoic acid (14,15-EET) is a cytochrome P-450 epoxygenase metabolite of arachidonic acid produced by the liver, kidney and blood vessels. 14,15-EET has potent biological activities including its ability to inhibit arachidonate-induced human platelet aggregation. It has been reported that different enantiomers of 14,15-EET have different biological activities. For example, 14(R),15(S)-EET is a cyclooxygenase inhibitor whereas the 14(S),15(R)-enantiomer is ineffective. During recent studies on the inhibition of human platelet aggregation by 14,15-EET enantiomers, we observed that they were rapidly metabolized. The structure of the products have now been established.

Human platelets were obtained from the Vanderbilt Clinical Blood Bank. The platelets were centrifuged at 500 x g for 15 min, pellets were collected and suspended in buffer (145 mM NaCl, 5 mM KCl, 5.5 mM Dextrose, 1 mM $MgCl_2$, 0.2 mg/ml BSA, 100 mM HEPES, pH 7.4) and adjusted to a suspension of 1 x 10^9 platelets/ml. Aliquots of platelet suspensions (5 ml) were incubated with [1-^{14}C]14,15-EET or its enantiomers (5 mCi/mmol, 3 uM) at 37 °C for different time periods (5 to 60 min). Incubations were stopped by addition of 5 ml of ice-colded methanol. Lipids were extracted into chloroform/methanol (2/1; v/v). and were separated by TLC. The free fatty acid fractions were isolated and converted to their corresponding methyl ester (ME) derivatives, then separated by normal phase HPLC. The metabolites were isolated and converted to their trimethylsilyl (TMS) derivatives. Structure elucidation was carried out by using electron ionization (EI), positive chemical ionization (PCI) and electron capture negative ion chemical ionization (EC) mass spectrometry. Phospholipid fractions were isolated and then separated by normal phase HPLC. Individual molecular species of phosphatidylcoline were further separated by reverse phase HPLC on ultrasphere ODS column. The two major peaks were isolated and identified by negative FAB mass spectrometry.

EI and GC/PCI-MS were performed on a Finnigan-MAT INCOS 50 quadropole mass spectrometer interfaced with a Hewlett Packard 5890 gas chromatograph. GC/EC-MS was carried out on a Nermag R-1010C quadropole instrument equipped with a Varian Vista 6000 gas chromatograph. Chromatography was carried out on a SPB-1 (15 m x 0.32 mm ID., Supelco) fused silica capillary column. The temperature of injector, transfer line and ion source was kept at 260 °C. Helium and methane were used as a carrier and reagent gas, respectively. The GC oven temperature was held at 190 °C for 0.5 min, then programmed to 320 °C at 20 °C/min, then held for 5 min at this temperature. Fast atom bombardment (FAB) mass spectra were obtained on a VG 70/250 double focusing mass spectrometer at a resolution of 1000. Fast atoms were generated with a xenon Saddle-field gun operating at 8 kV and 20% 3-nitrobenzyl alcohol (3-NBA) in dimethyl sulfoxide (DMSO) was used as the matrix. Lipid samples were dissolved in 10 µl of DMSO solvent.

HPLC analysis of the products from incubations of [1-^{14}C]14S,15R-EET with human platelets revealed the presence of two metabolites [Figure 1a]. The EI mass spectrum of metabolite 1 as its ME, TMS derivative showed a base peak at m/z 295, suggesting a hydroxyl group at C-12. When the compound was hydrogenated the characteristic peak m/z 295 was shifted to m/z 301 due to hydrogenation of three double bonds at 5,6; 8,9 and 10,11 positions, which was consistent with a hydroxyl group at C-12. The EC mass spectrum of its pentafluorobenzyl (PFB), TMS derivative was dominated by the ion of m/z 407 corresponding to (M-PFB). These data suggested that metabolite 1 was 12-OH-14(S),15(R)-EET. The stereochemistry of the hydroxyl group at C-12 was confirmed as (S)-configuration by comparison with authentic synthetic materials. The EI mass spectrum of the ME-TMS derivative of metabolite 2 exhibited significant fragment ions at m/z 173, 275, 323 indicating two hydroxyl groups at C-14 and C-15. The EC mass spectrum of its PFB, TMS derivative gave a base peak at 481 (M-PFB). This

suggested that metabolite 2 was 14,15-dihydroxyeicosatrienoic acid (DHET). When [1-^{14}C]14R,15S-EET was incubated with human platelets, only one metabolite was formed [Figure 1b]. The metabolite 3 had same HPLC retention time and mass spectra as metabolite 2, so it was identified as 14,15-DHET. It was found that 14,15-EET was incorporated into platelet phospholipids at the *sn*-2 position. The major class of esterified phospholipid (PL) was phosphatidylcholine (PC). Individual molecular species of PC were further separated. The structure of two major species of PC was confirmed as 1-palmitoyl-2-14,15-EET-PC and 1-stearoyl-2-14,15-EET-PC [Figure 2] by FAB mass spectrometry. In addition, it was found that the incorporation of 14,15-EET into platelet membranes was enantioselective The ratio of 14(R),15(S)-EET to 14(S),15(R)-EET was approximately 3 to 1.

In summary, 14,15-EET was metabolized to 12-OH-14,15-EET and 14,15-DHET by 12-lipoxygenase and epoxide hydrolase, respectively, in human platelets. Further enantioselective analysis showed that 14(R),15(S)-EET was a good substrate for epoxide hydrolase and was incorporated into PLs. In contrast, 14(S),15(R)-EET was an excellent substrate for 12-lipoxygenase and was poorly incorporated into PLs.

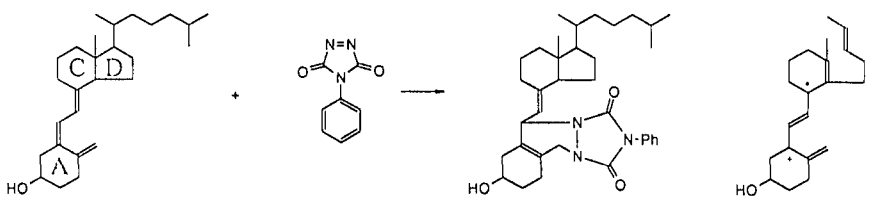
Northeastern University, Boston, MA 02115
[2]Department of Pediatrics, Women & Infants Hospital of Rhode Island,
Providence, RI 02905

Introduction Vitamin D is a group of secosteroid hormones involved in the regulation of vitamin D-binding protein, which is responsible for the transport of calcium in the body. Vitamin D_3 (I) is the most physiologically important one in the group, and it is first metabolized in the liver to $25(OH)D_3$, then in the kidney to $24,25(OH)_2D_3$ and $1,25(OH)_2D_3$. However, the detection of these metabolites in plasma has been proven to be a difficult task, due to their structural and chemical similarities, the presence of other interferences such as lipids and sterols and, most importantly, their low concentrations in plasma[1]. Current techniques used for detecting these metabolites in plasma include HPLC, GC-MS, and saturation analysis. As an alternative, we describe here a MS technique which involves a simple pre-column derivatization using 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD, II). PTAD forms stable adducts with vitamin D metabolites which are highly UV sensitive. The FAB spectra of the adducts have identified a common and intense fragment, which allows the use of multiple reaction monitoring (MRM) as a sensitive detection scheme.

SCHEME I



I II III

Experimental

Chemicals: Vitamin D_3 and PTAD were purchased from Aldrich (Milwaukee, WI). The other vitamin D metabolites were synthesized by Dr. M.R. Uskokovic of Hoffmann LaRoche (Nutley, NJ).

MS conditions: All MS data were obtained on a VG Quattro (VG Biotech, UK). For dynamic FAB, matrix solution (1% tetramethylene sulfone, 5% ACN and 19% EtOH in H_2O) was delivered by a pump (Isco μLC-500) at a flow rate of 5 μL/min to the probe tip through a 50 μm (i.d.) fused silica capillary (Polymicro, Phoenix, AZ). A stainless steel wire mesh (5 μm pore size, 0.003" thick, ~2 mm in diameter) was placed at the tip to stabilize the solution flow. Samples were introduced by flow injection via a Rheodyne injector (#7520) with a 0.5 μL internal sample loop. Source temperature was maintained at 35 ^{0}C. The CID (static probe) and MRM data were obtained with a collision energy set at 70 eV. Peak intensity was attenuated by 75% using Ar gas.

Results Besides the MH^+ ions of the adducts, an intense and common fragment ion (m/z 298, III) is also found in the normal FAB spectra. For the A ring-hydroxylated metabolites, this ion is shifted by 16 mass units to m/z 314. Their proposed structures are consistent with their CID data. MRM transitions of $MH^+ \rightarrow$ ions 298/314 have been used as a detection scheme with dynamic FAB. Profiles for different injection quantities are shown below for vitamin D_3- and $1,25(OH)_2D_3$-PTAD adducts.

Conclusions The pre-column derivatization of vitamin D metabolites with PTAD is an effective labelling technique for improving their UV responses in HPLC separation. When used in conjunction with MS with MRM detection, their determination will be more definitive. For most commonly occurring vitamin D_3 metabolites, the LC/MS combination will be complementary to the current techniques. The detection limits achieved in this work were through flow injection mode; they are expected to improve once HPLC is coupled on-line with the MS. Future directions of our work will include such on-line coupling, the use of other dienophiles with high UV or fluorescence responses as derivatizing reagents[2,3], and analysis of the metabolites in plasma samples using the developed technique.

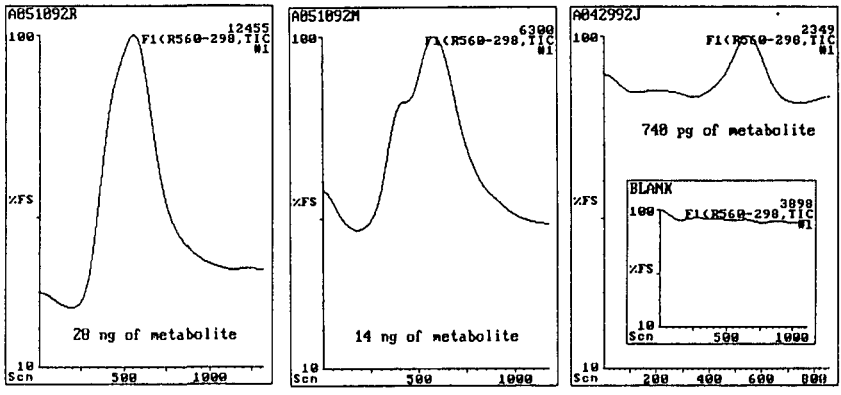
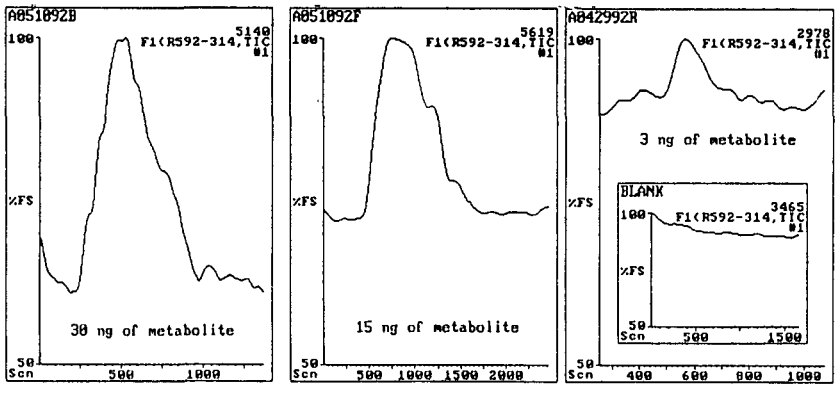
Vitamin D_3-PTAD



1,25$(OH)_2D_3$-PTAD

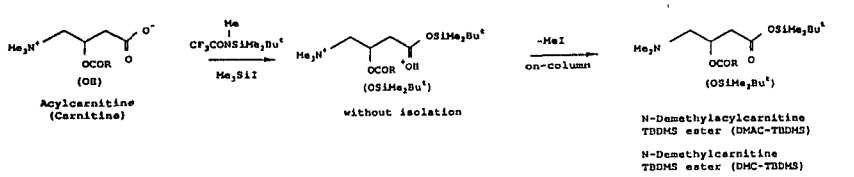


A GENERAL METHOD FOR THE SIMULTANEOUS ANALYSIS OF FREE CARNITINE AND ACYLCARNITINES BY GC-MS OF THEIR N-DEMETHYLATED SILYLATED DERIVATIVES

Z.-H. Huang[1], C.C. Sweeley[1], L.L. Bieber[1], C. Tallarico[2]
G. Bruno[2], A. Marzo[2], and D.A. Gage[1]
[1]Department of Biochemistry, Michigan State University, East Lansing, MI 48824
[2]Drug Metabolism and Pharmacokinetic Department, Sigma-tau S.p.A., Pomezia-Roma, Italy

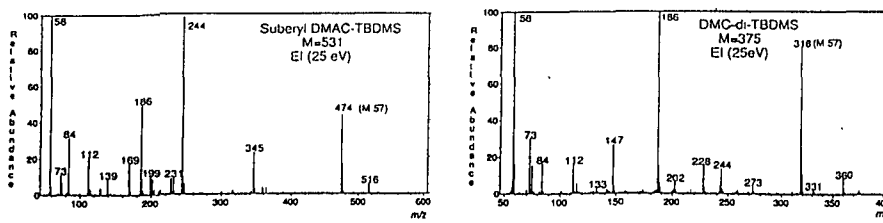
To date, two GC-MS techniques have been adopted for analysis of acylcarnitines (AC) which are based on the base-catalyzed cyclization to butyrolactone derivatives (1), or on-column dequaternization of the corresponding acylcarnitine esters (2). While these methods have proved to be suitable for the profiling of urinary acylcarnitines with medium chain-length (C_4-C_{14} acyl groups) at ng levels, they exhibit some degree of discrimination against the lower homologues (< C_4). Moreover, neither of these methods can be extended to the analysis of free carnitines (FC).

To overcome these limitations, we report here a new protocol by which FC and ACs are analyzed as the corresponding N-demethylcarnitine TBDMS esters by a single-step derivatization followed by GC or GC-MS.



Derivatization

Method 1. To the starting material (5-50 µg, dried over P_2O_5) added an excess (50-100 fold) of "silylation cocktail" composed of N-(*tert*-butyldimethylsilyl)-N-methyltrifluoroacetamide (MTBSTFA), trimethyliodosilane (TMIS), 2,4,6-trimethyl-pyridine (TMP), and 2,2-dimethoxypropane (DMP) (20:0.2:0.4:0.2, v/v) in CH_2Cl_2. The mixture, after standing at r.t. for 5 min, is ready for GC-MS analysis.



Method 2. Method 1 is slightly modified for mixtures containing ACs with longer chains (>C_{10}). In such case, an additional portion of MSTFA (10-20% of the amount of MTBSTFA) is added to the silylation cocktail to promote complete conversion.

An aliquot of the above silyl derivative is directly injected onto the GC system to effect N-demethylation. The mass spectra of the dequaternized products are recorded as corresponding N-demethyl acylcarnitine TBDMS esters (DMAC-TBDMS) or N-demethylcarnitine TBDMS ester (DMC-TBDMS). Alternatively, TMS derivatives are obtained when N-methyl-N-(trimethylsilyl)-trifluoroacetamide (MSTFA) is used in place of MTBSTFA as the silylating agent. For clinical samples, the derivatization is preceded by purification through a column of AG 1X8 anion exchanger followed by enrichment using a C-18 cartridge.

Instrument

Spectra were acquired on an JEOL AX 505H double focusing mass spectrometer coupled with a HP 5890J gas chromatograph. GC: DB-1 or DB-5MS (J. & W. Scientific), 15 m x 0.25 mm id, 250 mμ film thickness, programmed at a rate of 20°C/min between 100-300°C. Injection port temperature 260°C. He gas flow 1 ml/min. Detection: CI(methane or NH_3) or EI(25 eV).

Results

The dequaternized derivatives exhibit excellent resolution to allow isomeric compounds to be separated and identified. Prominent [M+H] (CI) or [M-57] (25 eV EI) and characteristic fragments at *m/z* 58 and 186 are found in all cases that makes spectral interpretation easy. The gas chromatograms of FC and ACs from different sources (synthetic mixture and the urine of a patient suffering from medium-chain acyl-CoA dehydrogenase (MCAD) deficiency) and typical mass spectra are presented below.

Conclusion

In summary, TMIS-catalyzed silylation and subsequent thermolytic dequaternization provides a general method for the complete profile analysis of carnitine related compounds in plasma and urine samples. The advantages include: (i) one-step derivatization; (ii) simultaneous analysis of ACs and their polar congeners (FC, ACs derived from dibasic and hydroxy-acids); (iii) choice of different detection modes: CI(CH_4 or NH_3) or EI(25 eV); (iv) good separation for isomeric compounds; (v) low ng (GC-MS) - <100 pg (SIM) detection.

MASS SPECTRAL CHARACTERIZATION OF A PRIMARY HYDROPEROXY CHOLESTEROL ESTER FROM OXIDIZED LDL

Paul Toren and Vicki Chlanda, Monsanto Corporate Research, St. Louis, MO 63167 and Paul DiCorleto, David Schmidt and Margaret Van Heek, Cleveland Clinic Foundation, Cleveland OH 44195

Abstract

The oxidation of low density lipoproteins (LDL) results in enormous modifications in biological activities including the stimulation of adhesion of monocytes, platelet aggregation, tissue factor expression and inhibition of the expression of platelet derived growth factor (PDGF). Since LDL's are the major carriers of cholesterol, it's important to understand and characterize how oxidation processes affect cholesterol related structures. A variety of analytical techniques including FTIR, LC, GCMS, and FABMS were used to isolate and identify the major cholesterol ester components from the oxidation of LDL's. Isolation of the molecule of interest using reverse phase HPLC resulted in one major peak. Further separation using normal phase HPLC resulted in 3 distinct peaks of variable intensity. The structures were identified as isomers of hydroperoxy cholesteryl octadecadieneoate.

Experimental:

Oxidation of the LDL's or cholesterol esters was accomplished by air oxidation of a thin film of the material for 1-3 days.

Both the reverse phase and normal phase LC work was done using a Perkin-Elmer 410 LC system equipped with a PE LC-95 variable wavelength detector. Mass spectral analyses were carried out on either a VG ZAB-SE double-focussing sector instrument or a VG 40-250T triple quadrupole instrument. Both instruments used FABMS with a nitrobenzyl alcohol matrix which was either acidified or saturated with LiCl. For the FTIR work, a Spectra-Tech IR plan microscope coupled with a Nicolet 800 series FTIR spectrometer was used.

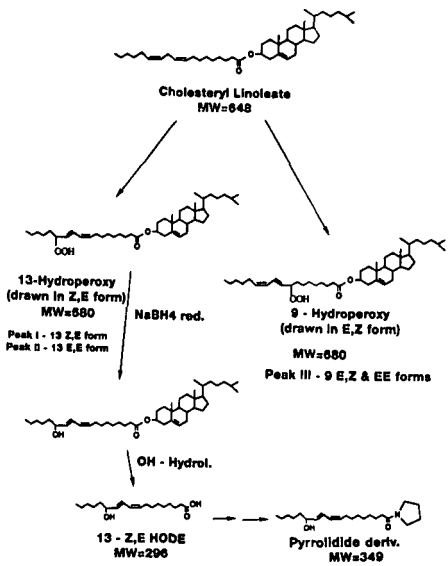
	indicative of 13 – HODE		indicative of 9 – HODE	



Conclusions:

Analyses of the biologically active oxidized LDL material was done using reverse phase and normal phase HPLC, FAB mass spectrometry and FTIR spectrometry. The active compounds were shown to correspond to cis/trans and trans/trans isomers of 9- and 13- hydroperoxides of cholesteryl octadecadieneoate. The 9-isomers were not separated intact using the normal phase LC systems giving the appearance of 3 peaks.

IMMUNOAFFINITY EXTRACTION/GC-MS TO IDENTIFY CROSS-REACTING COMPOUNDS IN IMMUNOASSAYS: EVALUATION OF ANTIBODIES AGAINST THROMBOXANE METABOLITES

Chiara Chiabrando, Luigi Rivoltella, Renè Djurup* and Roberto Fanelli
Istituto di Ricerche Farmacologiche Mario Negri, Via Eritrea 62, 20157 MILANO, Italy
* Novo Nordisk, Copenhagen, Denmark

INTRODUCTION

The potential interactions between IMMUNOTECHNOLOGY and MASS SPECTROMETRY for describing biological systems are still poorly explored.
A recent successful application of such interaction is IMMUNOAFFINITY CHROMATOGRAPHY/ GC-MS, a breakthrough technique for measuring trace compounds in complex biological matrices [1].
We addressed the possibility of using IMMUNOAFFINITY/GC-MS to better define antibody specificity in immunoassays, by identifying unknown or unexpected compounds binding to the antibody.

THE PROBLEM
Known (and available) endogenous compounds chemically related to antigen (or hapten) are normally tested in immunoassays, to define their ability to cross-react with the antibody

THE QUESTION
How to recognize unknown cross-reacting compounds?

A POSSIBLE ANSWER
Immunoaffinity/GC-MS

PROPOSED STRATEGY

1. IMMOBILIZE ANTIBODY
2. PREPARE IMMUNOAFFINITY COLUMNS (IAC)
3. EXTRACT BIOLOGICAL MATRIX ON IAC
4. DERIVATIZE
5. ANALYZE BY GC-MS
6. ASSIGN PUTATIVE STRUCTURES TO UNKNOWN COMPOUNDS
7. PREPARE STANDARDS
8. IDENTIFY IMMUNOEXTRACTED COMPOUNDS
9. DEFINE CROSS-REACTIVITY OF ANTIBODY WITH NEWLY IDENTIFIED COMPOUNDS

IN THIS STUDY

1. Antibodies (Protein A purified IgG fraction) were coupled to CNBr-activated Sepharose 4B (10 mg/g or 3mg/ml gel).We studied four different antibodies, raised respectively against TXB2 (Antibody #1), 2,3-dinor-TXB2 (Antibody #2), 11-dehydro-TXB2 (Antibody #3), 11-dehydro-TXB2 (Antibody #4)

2. Immunoaffinity columns (IAC) were prepared with 0.25 ml gel for each antibody.

3. Pooled urine (from man and rat) was extracted on IAC [1] by:
   -slowly percolating diluted urine (in 50 mM phosphate buffer pH 7.4)
   -washing IAC with water to remove material not bound to antibody
   -eluting antibody-bound material with acetone-water (95:5)

4. Dried eluates were derivatized to:
   -pentafluorobenzyl ester, methyloxime,trimethylsilyl ether

5. Samples were analyzed by GC-NICI MS [1] with:
   -Dani 6500 gas chromatograph (25 m CP SIL 5 CB column);Finnigan 4000 mass spectrometer; TEKNIVENT VECTOR ONE data system

6. GC-NICIMS of urine extracts showed the presence of expected TXB2 metabolites (according to antibody known cross-reactivity) plus some other major compounds, tentatively identified as 2,3-dinor-TXB1 (rat urine), 2,3,4,5-tetranor-TXB1 (rat urine), 11-dehydro-2,3-dinor-TXB2 (human urine). These compounds are not normally measured in urine nor are tested for cross-reactivity in immunoassays for thromboxane metabolites..

7. 2,3-Dinor-TXB1 and 2,3,4,5-tetranor-TXB1 were prepared biosynthetically by:
   -infusion of TXB2 into an isolated perfused rat liver system
   -collection of biliary TXB2 metabolites
   -extraction by IAC
   -separation by TLC

   11-Dehydro-2,3-dinor-TXB2 was prepared chemically by:
   -treating 2,3-dinor-TXB2 with silver oxide
   -solvent extraction
   -purification by TLC

8. NICI spectra and GC behaviour of synthesized compounds were in accordance with those of authentic closely related metabolites (TXB2, 2,3-dinor-TXB2 and 11-dehydro-TXB2). NICI spectra and GC behaviour of urinary metabolites were identical to those of synthesized compounds.

9. Antibodies showing significant binding of unexpected urinary metabolites (when immobilized on IAC) revealed also a significant cross-reactivity with the respective immunoextracted compounds (when tested in the respective immunoassay).

CONCLUSIONS

We present here a novel approach for isolating and identifying unknown endogenous compounds binding to antibodies. Using immobilized antibodies and GC-MS we collected and identified compounds specifically bound to each antibody. For each antibody, immunoextracted compounds showed also significant cross-reactivity in the respective immunoassay. By this technique, we could demonstrate the presence in urine of relevant amounts of some thromboxane metabolites never reported before as abundant endogenous products.
This new approach might serve in future studies as a basis for characterizing immunological reactions and products *in vivo*.

UNUSUAL ORTHO EFFECTS IN THE FAST ATOM BOMBARDMENT MASS SPECTRA OF PLATELET ACTIVATING FACTOR ANTAGONISTS CONTAINING BIS-ARYL PHOSPHATE MOIETIES

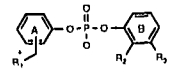
Marshall M. Siegel*, Russ Tsao, Allan Wissner

American Cyanamid Company, Medical Research Division, Lederle Laboratories, Pearl River, New York 10965

INTRODUCTION

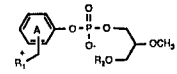
Synthetically produced platelet activating factor (PAF) antagonists which contain substituted bis-aryl phosphate groups (I) are potential therapeutic agents for the treatment of spetic shock. These materials when studied by low resolution FAB mass spectrometry (MS) exhibited unusual fragment ions when the aryl group A was substituted in the ortho and meta positions relative to the phosphate oxygen atom. Additional FAB/MS experiments were performed in order to elucidate the structures of these ions and for proposing mechanisms for their formation. High-resolution exact-mass FAB/MS experiments were performed to verify the elemental composition of the fragment ions. Tandem FAB/MS/MS experiments were performed to determine the origin and structures of the ions and hydrogen-deuterium exchange experiments were performed to determine the number of labile hydrogens in the fragment ions.

Bis - Aryl Phosphate



I

Glyceryl Mono - Aryl Phosphate



II

RESULTS AND DISCUSSION

A) FAB/MS and Deuterium Exchange Reactions for Structures 1, 2 and 3

The FAB/MS spectra were obtained from three pairs of bis-aryl phosphate PAF antagonists, structures **1**, **2** and **3**, listed in Table I. Each pair differed only in the position of the benzyl CH_2 group relative to the phosphate oxygen on aryl ring A, viz., either ortho or meta substituted. The generated mass spectra contained a very abundant proton adduct molecular ion and a number of abundant fragment ions. For each pair of compounds, the spectra were nearly identical since all the intense fragment ions had the same masses. An exception to this observation were the most abundant fragment ions listed in Table I. Each ortho substituted compound produced a fragment ion which was consistently two mass units lower than the corresponding ion observed with the meta substituted compound. Exact-mass FAB data indicated that this mass difference corresponded to the mass of two hydrogen atoms. The FAB/MS experiments when performed with glycerine-d_8 to exchange all labile hydrogen atoms for deuterium atoms indicated that only the proton adduct was exchanged for a deuteron adduct in the molecular and fragment ions but no labile hydrogens were exchanged in the PAF antagonist structures.

B) Fragment Ion Structures of the Ortho and Meta Isomers of Structure 1

The FAB/MS high-resolution exact-mass measurements for the m/z 309 and 311 fragment ions of the ortho and meta isomers were consistent with the elemental compositions $C_{14}H_{14}O_6P$ and $C_{14}H_{16}O_6P$, respectively. The FAB/MS/MS experiments on the proton adduct molecular ions for the ortho and meta isomers produced abundant fragment ions at m/z 309 and 311, respectively. These tandem MS results confirm the deuterium exchange experiments in that the fragment ions are products of unimolecular decompositions of the parent ions and that the two additional hydrogens observed in the meta fragment ion arise from an intramolecular rearrangement process.

Table I

Abundant Fragment Ions Found in FAB/MS of Bis-Aryl Phosphate Aryl Ring A Isomers of Platelet Activating Factor Antagonists

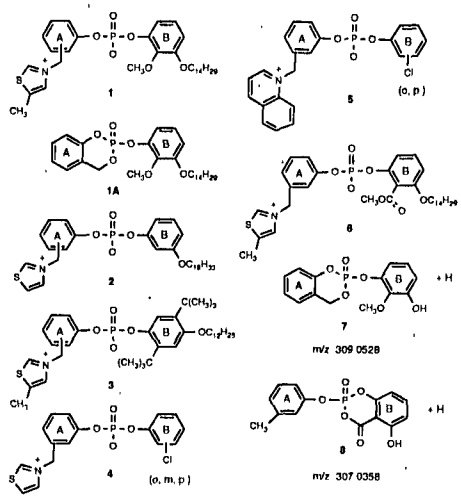
6	631	-	307.0358 (1.4)

( ) - Values in parenthesis are the differences between the theoretical and experimental masses in millimass units.



Structure 7 is the proposed structure for the m/z 309 fragment ion derived from the ortho isomer of structure 1. This structure is based upon the elemental composition derived from the FAB/MS exact mass data, the FAB/MS/MS spectra and the deuterium exchange data. This protonated fragment ion was formed by replacement of the hydrocarbon chain on aryl ring B by a hydrogen atom and by an intramolecular displacement reaction of the substituted thiazole moiety on aryl ring A by the negatively charged oxygen of the phosphate group. This intramolecular displacement reaction results in the formation of a very stable six member ring. This reaction appears to be facile since it procedes through a positively charged benzylium ion which readily reacts with the negatively charged oxide group of the phosphate moiety. The proposed structure for the m/z 309 fragment ion, 7, was confirmed in the following way. The ortho cyclized structure of 1 was synthesized, 1A. The FAB/MS and FAB/MS/MS spectra were obtained. A prominant fragment ion in the FAB mass spectrum and an abundant daughter ion in the FAB/MS/MS spectrum were observed at m/z 309. The FAB/MS/MS spectra for the m/z 309 ion from structures 1 and 1A were identical demonstrating that in both cases the m/z 309 ion most likely had a cyclic structure. This most unusual ion arose in the FAB spectrum as a result of an ORTHO EFFECT reaction.

The m/z 311 fragment ion for the meta isomer of 1 should be related to that of the ortho fragment ion at m/z 309 but was reduced by two additional hydrogen atoms. A cyclized ring system cannot easily form with the meta isomer due to geometrical constraints, therefore, one hydrogen atom was assumed to be bound to the phosphate oxide and one hydrogen atom bound to the benzyl CH_2 carbon forming a tolyl group. These hydrogen atoms were transferred via intramolecular rearrangements either from the substituents on aryl rings A and/or B. A large number of analogs of the meta isomer of structure 1 were synthesized and used to probe the origin of the intramolecularly transferred hydrogen atoms. A series of compounds contained substituents on the aryl B ring that were identical with a variety of moieties attached to the CH_2 of the benzyl group, including a large number of substituted thiazoles, triethylamine and pyridine. In all cases, the most abundant fragment ion had a mass of m/z 311. Likewise, when the hydrocarbon chain on aryl ring B was substituted with other hydrocarbon chains, or when the position of the OCH_3 group on aryl ring B was changed, the most abundant fragment ion was still m/z 311. When the OC_nH_{2n+1} group on aryl ring B was substituted by chlorine (Cl) in either the ortho, meta or para positions and the benzyl group in the meta position of ring A was bound to either a thiazole or quinoline, structures 4 or 5, a prominant fragment ion with m/z 297 (1 Cl) was observed consistent with the loss of thiazole or quinoline wihout any reduction occurring. These results demonstrate that the two additional hydrogen atoms in the meta isomers of structures 1, 2 and 3 originate from the hydrocarbon chain on aryl ring B and not from the substituents on aryl ring A.

C) *Fragment Ion Structures for Ortho and Meta Isomers of Structures 2 and 3*
Similar FAB/MS and FAB/MS/MS observations were made with structures 2 and 3 as was with structure 1. Unusual features of the FAB spectra of the ortho and meta isomers of structure 3 are that the most abundant fragment ions listed in Table I have the same masses as those of strucutre 2. These fragment ions produced identical FAB/MS/MS spectra and arose from the displacement of each tertiary butyl group by a hydrogen atom.

D) *Fragment Ion Structures for the Meta Isomer of Structure 6*
The FAB mass spectra of structure 6 produced an abundant fragment ion at m/z 307 with an exact-mass consistent with the elemental composition of $C_{14}H_{12}O_6P$. Deuterium exchange experiments were consistent with one exchangeable hydrogen atom which arose as the proton adduct of the fragment ion. This fragment ion was also a prominent daughter ion in the FAB/MS/MS of the parent proton adduct molecular ion. The FAB/MS/MS spectra and the above data were consistent with proposed structure 8, viz., the displacement of the methoxy group of the methyl ester on aryl ring B by the phosphate oxide to form a six member ring system, the replacement of the $C_{14}H_{29}$ hydrocarbon moiety by a hydrogen atom, the reduction by a hydrogen atom of the benzyl CH_2 group on aryl ring A with the loss of the methyl thiazole ring and the addition of a labile proton for generating the charge on the fragment ion. The intramolecular cyclization on the aryl ring B is an illustration of an ORTHO EFFECT reaction.

E) *FAB/MS of Substituted Glyceryl Mono-Aryl Phosphate Derivatives (II)*
FAB/MS was used to analyze a large number of substituted glyceryl mono-aryl phosphate compounds (II) where a variety of substituents were bound to the aryl benzyl ring A in the ortho, meta and para positions. In nearly all cases, no abundant fragment ions were observed corresponding to the reduction of the benzyl CH_2 group as in the bis-aryl phosphate compounds (I) described above. These results demonstrate the importance of the aryl ring B in the bis-aryl phosphate molecules in the formation of the unusual fragment ions reported above.

CONCLUSIONS
1. Intramolecular cyclization reactions in bis-aryl phosphate molecules have been observed between the phosphate oxide and substituents at the ortho positions of the A and B aryl rings in FAB mass spectra
2. Intramolecular reduction reactions have been observed in bis-aryl phosphate molecules substituted in the meta position of aryl ring A with a CH_2R_1 group and with an OC_nH_{2n+1} group on the aryl ring B. Three hydrogen atoms are transferred to one of the most prominant fragment ions from the hydrocarbon chain. These hydrogen atoms are most likely found in the following positions of the molecule: one hydrogen atom displaces the hydrocarbon group of aryl ring B, a second hydrogen atom is bound to the phosphate oxide and a third hydrogen atom displaces the R_1 group and is bound to the benzyl CH_2 group of aryl ring A.

Liquid Secondary Ionization Mass Spectrometric Analysis of Novel *In Vivo* Prostaglandin-containing Glycerophospholipids

Hollis J. Boss, Jason D. Morrow, Brian J. Nobes,
L. Jackson Roberts II, Ian A. Blair

Department of Pharmacology and Chemistry, Vanderbilt University, Nashville, Tennessee 37232-6602

Previous studies of glycerylphospholipids[1] have demonstrated that liquid secondary ionization (LSI) mass spectrometric analysis can be used to characterize the fatty acid side chains at the *sn*-1 and *sn*-2 positions of phosphotidylcholines. Positive and negative ion LSI/MS mass analysis of 1-stearyol-2-arachidonyl-*sn*-glycero-3-phosphotidylcholine (PC) are reported. The negative ion spectra provide significantly more structural information for this class of compound, whereas the positive ion spectra give molecular weight information and supporting fragment data. Negative ion LSI/MS/MS analysis of the fatty acid side chains of m/z 283 (stearoyl) and m/z 303 (arachidonyl) confirmed the structure of PC and are shown in Figure 1.

Using LSI/MS and LSI/MS/MS, we investigated the possibility that prostaglandin $(PG)F_2$-like compounds may be formed *in vivo* by a free radical catalyzed peroxidation of arachidonic acid, rather than by a cyclooxygenase mechanism. In as much as phospholipids readily undergo peroxidation, we examined the possibility that these prostanoids may be formed *in situ* on phospholipids. This hypothesis was supported by the finding that levels of free PGF_2-like compounds measured following alkaline hydrolysis of liver phospholipids extracted from rats treated with CCl_4 to induce lipid peroxidation were more than 100-fold higher in the induced rats as compared to the uninduced rats. Additionally, increased levels of PGF_2-like compounds in livers of CCl_4 induced rats preceded the associated increase in the circulation of PGF_2-like compounds, suggesting that the free PGF_2-like compounds arose secondarily from hydrolysis of peroxidized phospholipids. Normal phase HPLC of liver phospholipids from CCl_4 treated rats resulted in the elution of phospholipids which yielded PGF_2-like compounds upon hydrolysis at a much more polar retention time than non-oxidized phosphotidylcholine.

The positive and negative ion LSI/MS analysis of the more polar HPLC fraction confirmed it as a mixture of PGF_2-containing species of phosphotidylcholines 1-palmitoyl-2-PGF_2-L-α-phosphotidylcholine and 1-stearoyl-2-PGF_2-L-α-phosphotidylcholine. LSI/MS/MS of the fatty acid side chain at sn-2 (m/z 353) further supported the structural characterization.

NEW APPROACHES TO QUANTITIATIVE MASS SPECTROMETRIC ANALYSES OF LIPID MEDIATORS

Ulla Justesen, Ralph S. Orkiszewski, Hartmut Jaeschke and Simon J. Gaskell.
Baylor College of Medicine, Houston, TX 77030.

The cysteine-containing leukotrienes (LTC_4, LTD_4, LTE_4 and N-acetyl LTE_4) and platelet-activating factor (PAF; acyl glyceryl ether phosphocholine, AGEPC) are lipid mediators important in a number of inflammatory processes. The two mediator types share the common structural feature of incorporating both hydrophilic and hydrophobic moieties. Analogous strategies may therefore be applied to their quantitative mass spectrometric analysis:

1) Controlled degradation and derivatization to yield products amenable to gas phase analysis[1-3].

2) Analysis of the intact lipid using fast atom bombardment or electrospray techniques, ideally in combination with tandem MS[4,5].

Here we describe an application of the first approach to the study of endotoxemia in the rat, and developments related to the second approach. An isotope dilution procedure for the determination of LTC_4 and N-acetyl LTE_4 in rat bile has been established and validated[2]. The method uses [$^{13}C_4$]-analogues[6] and incorporates HPLC fractionation, hydrogenation to 5-hydroxyeicosanoic acid, and conversion to the pentafluorobenzyl ester, trimethylsilyl ether derivatives[1]. Detection is by selected ion monitoring during GC-electron capture MS. Application of this procedure established that biliary excretions of LTC_4 and N-acetyl LTE_4 in the rat were increased by 190% and 1000%, respectively, following endotoxin injection. Depletion of serum complement (by prior administration of cobra venom factor) almost completely abolished the increase in LT excretion (Figure 1A). Intravenous injection of activated complement factors (in the form of zymosan activated serum) elevated LT excretion in a manner similar to endotoxin administration (Figure 1B). It is concluded that endotoxin-induced cysteinyl leukotriene generation in vivo in the rat is mediated exclusively through activation of complement.

Preliminary evaluation of electrospray MS (in the positive ion mode) has established its utility for the detection of both leukotrienes and PAF. Figure 2 shows the electrospray spectrum (molecular ion region) of 1 ng C18-PAF, indicating a useful sensitivity of detection. LTC_4 is readily detected at the 100 fmol level during electrospray MS/selected ion monitoring. With a view to the development of an extremely rapid analytical method based on electrospray MS detection of LTC_4, we have evaluated immunoadsorption extraction as a simple and rapid isolation procedure. Our preliminary data suggest that satisfactory extraction of LTC_4 from rat bile may be achieved using antibodies coupled to activated Sepharose.

Pitfalls in Quantitative Analysis of PAF

Susan T. Weintraub and R. Neal Pinckard
Department of Pathology
The University of Texas Health Science Center at San Antonio
San Antonio, Texas 78284-7750

Platelet-Activating Factor (PAF) is the term used to denote a class of extremely potent lipid mediators that have been implicated in a wide variety of inflammatory processes. The first molecular species of PAF to be identified by mass spectrometry were found to be the 16- and 18-carbon alkyl chain homologs of 1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine (AGEPC). The existence of multiple forms of PAF dictated that methods be developed for quantitative analysis of the various species. In the course of our studies on PAF, we have become aware of two distinct types of problems that can occur during quantification of molecular species. One involves a differential response of various molecular species during electron capture mass spectrometry (ECMS) with negative ion detection of the pentafluorobenzoyl (PFB) derivative (part I), and the other relates to significant side product formation which results from currently used direct derivatization procedures (part II).

Results, Part I

Differential GC/ECMS response of AGEPC/PFB homologs - When equimolar quantities of 16:0-, 18:0- and 18:1-AGEPC were derivatized with PFBCl either by the direct method or following phospholipase C (PLC) treatment, it was consistently observed that the GC peak areas for the 18-carbon homologs were significantly less than for the 16-carbon species. It was then discovered that the 14:0-homolog produced a greater response than the 16:0-AGEPC/PFB. The relative areas for $[M]^-$ were: 14:0, 1.61; 16:0, 1.00; 18:0, 0.49. In order to verify that equal amounts of each homolog were being analyzed, separate experiments using 16:0-, 18:0- and 18:1-[^{14}C-acetate]-AGEPC were carried out in parallel, after careful purification of each radiolabelled homolog and assessment of phosphorus content. The recoveries of 16:0- and 18:0-AGEPC/PFB were found to be essentially the same, while some loss of the 18:1 homolog was observed

In view of the fact that the analyses described above utilized the GC, it was necessary to rule out chromatographic artifacts in the differential response of the homologs. Microgram quantities of homolog mixtures were prepared by both methods and the resulting products analyzed by ECMS, with sample introduction by means of a direct insertion probe. Once again, the response of both 18-carbon homologs was significantly less than that of 16:0-AGEPC/PFB. During these experiments it was quite surprising to find that on heating the sample in the probe tube in the presence of methane, at least 50% of 18:1-AGEPC/PFB was reduced to form the 18:0 species. GC/ECMS analysis of another aliquot of the same sample indicated that only 18:1-AGEPC/PFB was actually present along with the 16:0 homolog.

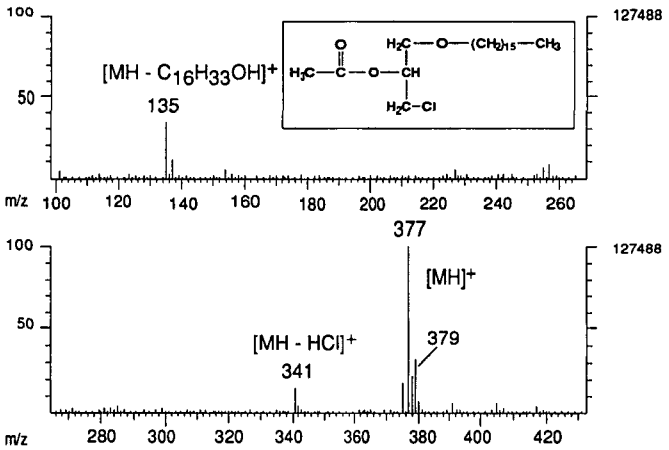
Relative response of [^{13}C-acetate]-AGEPC/PFB as compared to unlabelled homologs - Equimolar mixtures of AGEPC/PFB homologs were prepared by both methods in the presence of corresponding ^{13}C-labelled analogs. The resulting spectra for 16:0- and 18:1-AGEPC/PFB revealed that approximately the same response was observed for each pair of labelled and unlabelled species.

Relative response of fatty alcohol/PFB - Derivatization of a mixture of fatty alcohols was accomplished with PFBCl in the presence of pyridine. Analysis by GC/ECMS revealed that the mass spectral responses for homologs from 14:0 to 20:0 decreased uniformly, although to a much lesser extent than observed for AGEPC/PFB derivatives. The relative areas for $[M]^-$ ranged from 1.17 to 0.76. For comparison, the trimethylsilyl ethers of the alcohols were prepared and analyzed by electron ionization mass spectrometry with positive ion detection. Similar results were obtained for both derivatives. In order to determine if the response factor for one homolog could be deduced by extrapolation, a mixture which included 17:0-alcohol/PFB was analyzed by GC/ECMS. This homolog was selected as a model for components with odd-numbered hydrocarbon chains which are less common in mammalian systems and, therefore, less likely to be available as standards. A

plot of response factor (relative to the 16:0-alcohol) versus carbon number was constructed for the 14:0, 16:0, 18:0 and 20:0 homologs. An excellent fit was found for the observed value for the 17:0-homolog; therefore, it is anticipated that similar extrapolation will be possible as needed for molecular species of AGEPC.

The results of the current study show that there is a substantial effect of chain length on the ECMS response of AGEPC/PFB homologs. This can lead to profound consequences for quantification of these compounds. There is universal agreement that precise quantitative analysis requires the use of appropriate internal standards. However, in numerous instances, it is assumed that a uniform response will be obtained for all homologs of a particular analyte, and only one "representative" standard curve is prepared. It is clear from the results presented above that without a series of standard curves, the use of labelled 16:0-AGEPC as the only internal standard can result in serious underassessment of the quantities of higher order homologs, and overassessment of the amounts of the smaller molecules.

Results - Part II - In our previous reports on direct derivatization with heptafluorobutyric anhydride (HFB) or PFBCl, the percent recovery of product was assessed by measuring the amount of hexane-soluble radioactivity. In the case of the HFB derivatives, only the desired product was found in the hexane extract. However, a comparison of AGEPC/direct PFB and AGEPC/PLC/PFB prepared from the same quantities of lipid revealed that the GC peaks from the PLC sample were substantially larger than those from the direct reaction, even though there were significant losses associated with the PLC procedure. Parallel samples of [^{14}C-acetate]-AGEPC were then carried through the two procedures, and the final products fractionated by TLC. The results suggested that the major radioactive product from the direct reaction was different from the one produced by PLC/PFB. But, neither the EC nor the EI spectrum of the major product was sufficiently informative to permit its identification. Using chemical ionization with positive ion detection, however, it was possible to determine that 1-*O*-hexadecyl-2-acetyl-3-chloro-1,2-propanediol had been formed during the direct reaction.



The poor reaction efficiency which results from the direct PFB reaction was not initially detected because of the extraordinary sensitivity afforded by GC/ECMS analysis of these derivatives. Only by comparison with the product obtained after PLC treatment was it apparent that a serious loss of lipid had occurred. Efforts are currently underway to modify the conditions for the direct reaction so that improved yields of the PFB derivative can be obtained.

Supported in part by NIH grants HL-22555 and AI-21818. The excellent technical assistance of Cynthia Lear is gratefully acknowledged.

PHARMACOKINETICS OF PHOSPHOLIPIDS BY HIGH DYNAMIC RANGE, HIGH RESOLUTION MASS SPECTROMETRY

M. Orlando, M.L. Gross - *Midwest Center for Mass Spectrometry, Dept. of Chemistry, University of Nebraska, Lincoln, NE 68588-0304*
L. Binaglia - *Biochemistry Ististute, University of Perugia, Perugia, Italy*
G. Kirshner - *FIDIA Research Laboratories, 35031 Abano Terme, Italy*

Phospholipids are the principal components of cell membranes and are used as precursors in the synthesis of novel antiviral and antitumor drugs. In current pharmacokinetics studies of phospholipids, ^{14}C and ^{3}H radioactive isotope labelling is used[1]. This application has disadvantages due to radioactive waste problems, the impossibility to do experiments in humans and the limited shelf-life of the labeled molecules. A method involving the use of stable isotopes is therefore needed.

During the last several years, the use of stable isotopes in tracer methodologies has increased. This is due to the technical improvements in the field of mass spectrometry. Such advancements open the door for this analytical technique to play an important role in qualitative and quantitative assays; the detection limit can be lower than the one attainable with the use of one molecule labeled with one ^{14}C atom (picomole level) and is comparable to that achievable by using a system containing one tritium atom marker (femtomole level). However, the use of stable isotopes in pharmacokinetics studies of natural compounds is complicated by the problems encountered in detecting and differentiating between endogenous and exogenous molecules. These difficulties occur in the analysis of phospholipids, which are a class of compounds with variable molecular weights depending upon substituent acids and/or head groups. In addition, portions of phospholipids can undergo exchange during in vivo experiments.

OBJECTIVES

1) Synthesize (glycerol-D_5) phosphatidylserine

2) Develop a micro-method for phospholipid hydrolysis and glycerol purification

3) Develop and evaluate a method for trace analysis.

Because the glycerol moiety is a common and stable part of all phospholipids, we have decided to label the glycerol with five deuterium atoms. A method that makes use of the analysis of glycerol-D_5 in a final step allows one to follow the different metabolic steps occurring in the in-vivo experiment while avoiding the interference of endogenous phospholipid and the occurrence of transacylation and base exchange reactions in animal tissues.

At the end of the in vivo experiment, the lipids are to be extracted from biological samples and completely hydrolyzed to give the glycerol. Mass spectrometry will be used to detect with high sensitivity and precision the labelled glycerol. This procedure can incorporate the separation of the phospholipid into various classes.

METHODS

Objective 1: synthesis

An enzymatic-chemical synthesis of glycerol labeled phosphatidylserine that was already reported for radioactive labeling was used[2].

Prepare standard compounds by mixing natural PS and (glycerol-D_5) PS.

objective 2: hydrolysis

Hydrolyze by enzymatic and chemical means to obtain a mixture of glycerol and D_5-glycerol.

According to the goal of our research, the total amount of phospholipid has to be related to the endogenous amount present in various tissues. Because the most unfavorable PS exogenous/PS endogenous ratio has been found in the brain, we have decided to investigate cerebral tissue.

In the brain, the main amount of the PS is approximately 5 umol/g. After 20 min. the exogenous PS in mouse brain reaches the concentration of 3 nmol/g. To apply the method, 200 mg of tissue samples,

containing 1.3 umole (1 mg) of PS were taken. Finally standard samples were prepared each containing 1.3 umole of PS, and scalar quantities of deuterated PS were added.

To verify the analytical data obtained from PS hydrolysis, a standard containing 14C-labelled PS was also included. The samples were hydrolyzed by using an enzymatic procedure followed by chemical procedure to obtain the two isotopomers of glycerol.

MASS SPECTROMETRY

The chemical-physical properties of glycerol do not allow quantitative GC-MS analysis without derivatization. Previous work[3,4] showed that this procedure is sensitive and reproducible but it adds a further step to the analysis, and it is slow. Our goal is to analyze a wider number of samples in a short time period. The soft ionization technique named FAB (fast atom bombardment) allows molecular ions to be detected without prior sample derivatization, and it is ideal for the identification and quantitation of the samples that we have prepared.

Experimental details

Kratos MS50 triple analyzer; Kratos Mach3 data system
Resolving power 10,000 (10% valley definition)
Selected Ion Monitoring (m/z 94.058524, m/z 96.065234, m/z 98.086554)

- Peak at m/z 98.0865 = $(M+H)^+$ of D_5-glycerol
- Peak at m/z 96.0652 ≈ $(M+H)^+$ of $^{13}C_3$-glycerol (internal standard)
- Peak at m/z 94.0585 ≈ $(M+H)^+$ of glycerol (^{13}C isotope)*

*The ^{13}C isotope of native glycerol was monitored to reduce demands on instrument dynamic range. By monitoring this ion, glycerol from the endogenous PS could also be quantified.

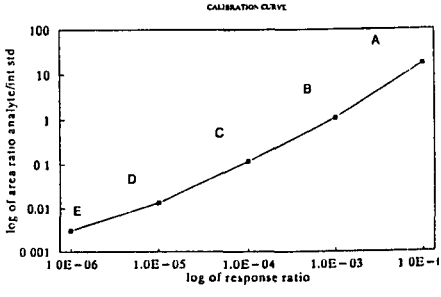
Five standard solutions have been prepared mixing 1mg of natural glycerol and scalar amounts of D_5-glycerol. We have added to each solution 1 ug of $^{13}C_3$-glycerol as internal standard.

A calibration curve has been obtained by plotting the logarithm of the areas (y axis) versus the logarithm of the ratios of the analyzed solutions (x axis).

The calibration is linear over the range of 3 ng to 10 ug of D_5-glycerol in 1 mg of native glycerol.

By using FAB-MS, it is expected that D5-glycerol could be quantified in the presence of million-fold excess of unlabeled glycerol, and the minimun amount detected was 1 ng (10 picomoles).

Solutions	Glycerol	D5-glycerol	Ratio
A	1 mg	10 ug	1.0E-02
B	1 mg	1 ug	1.0E-03
C	1 mg	100 ng	1.0E-04
D	1 mg	10ng	1.0E-05
E	1 mg	1 ng	1.0E-06



Method evaluation

The analytical data obtained by the use of high resolution FAB-MS exceeded our expectation. The real possibility now is to couple the three objectives of the project.

This method could be used to study the pharmacokinetics and the metabolism of phospholipids in tissues that contain the low levels.

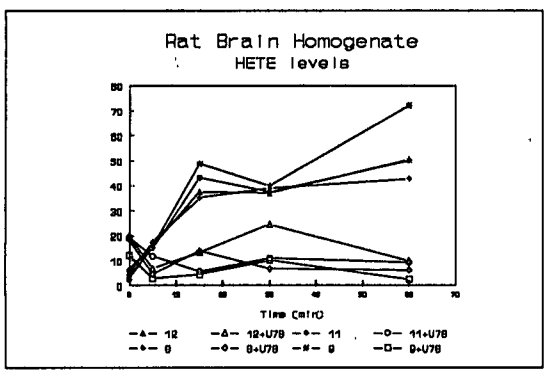
A GAS CHROMATOGRAPHY-MASS SPECTROMETRY ASSAY FOR LIPID PEROXIDATION

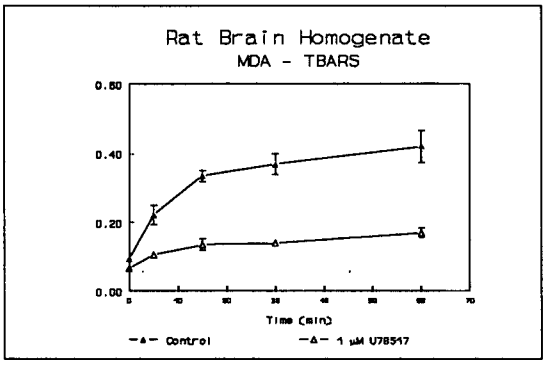
W.R. Mathews, R. McKenna, and D.M. Guido
Biochemistry, The Upjohn Company, Kalamazoo, MI 49001

Peroxidation of cellular membrane lipids has been implicated in a wide variety of pathologies including chronic degenerative disorders such as atherosclerosis, cancer, and Parkinson's disease; hepatotoxicity induced by chemicals such as CCL_4 and diquat; and acute disorders such as ischemia/reperfusion injury. We have developed a method for quantifying lipid peroxidation products using gas chromatography/mass spectrometry in order to elucidate the role of lipid peroxidation in such disorders and to assess the ability of selected antioxidants to inhibit lipid peroxidation. The method involves analysis of the methyl ester, trimethylsilyl ether derivatives of various hydroxy-arachidonic acids (HETES). HETES were chosen as markers for lipid peroxidation since arachidonic acid is an abundant unsaturated fatty acid in most biological membranes and thus a likely target for lipid peroxidation. In addition several HETES and hydroperoxy- arachidonic acids (HPETES) are commercially available.

Selection of an appropriate internal standard posed several problems. Th ideal internal standard would be an isotopically labeled HPETE or HETE. Deuterated HETEs are commercially available however the deuterium label is lost during derivatization. ^{18}O-labeled 12-HETE was prepared but was also found to be inppropriate due to back-exchange during sample work-up. Finally, 6-hydroxy-9,12,14-heneicosatrienoic acid was synthesized for use as an internal standard by G.L. Bundy, The Upjohn Company. The assay procedure involves the following steps: The internal standard is added to the sample and cellular lipids are extracted and transesterified. Next, any hydroperoxides are reduced with triphenylphosphine and the samples are subjected to two steps of solid phase extraction. The samples are then hydrogenated and the trimethylsilyl ether derivative of the hydroxyls formed. The derivatized HETES are analyzed by electron impact GC/MS. 12-HETE, 11-HETE, 9-HETE and 8-HETE are assayed by monitoring ions at m/z 301, 287, 259, and 271 respectively. Standard curves were constructed for each HETE and were linear over the range 1 to 250 ng with typical correlation coefficients of greater than 0.99.

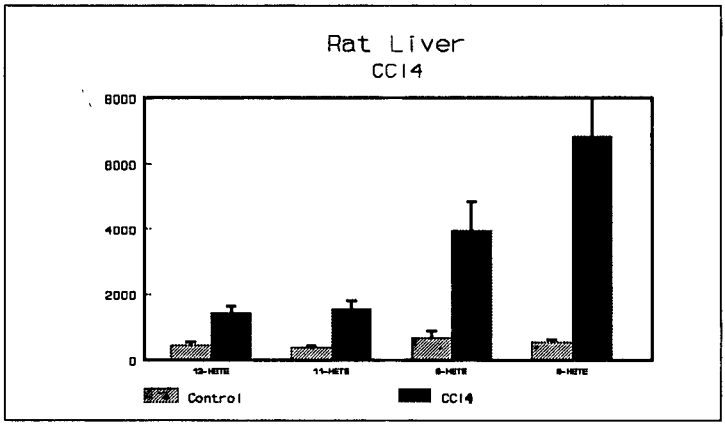


The assay has been applied to the study of autooxidation of lipids in both *in vitro* and *in vivo* systems. Figure 1 shows the formation of HETEs as a function of time in rat brain homogenates treated with 200 μM ferrous ammonium sulfate. HETE formation is inhibited by the antioxidant U78517.



Lipid peroxidation was also measured in this system using the MDA assay, a commonly used assay for lipid peroxidation that measures malondialdehyde (MDA) formation spectrophotometrically following reaction with thiobarbituric acid (Figure 2). Both assays gave similar results.

The HETE assay has also been used to measure lipid peroxidation *in vivo*. Male Sprague-Dawley rats were treated with CCl_4 (600 µl/kg, i.p.) or vehicle. Three hours later the livers were removed, homogenized and assayed for HETES. As shown in figure 3, CCl_4 treatment significantly elevated HETE levels.



The analysis of HETES formed by oxidation of arachidonic acid (and possibly other 20 carbon unsaturated fatty acids) appears to be a useful index of lipid peroxidation that can be used for both *in vitro* and *in vivo* experiments.

Membrane Probe for Quantitation of Nitric Oxide in Liquid Systems

Randy S. Lewis[1], William M. Deen[1], Steven R. Tannenbaum[2,3], and John S. Wishnok[3], Division of Toxicology[3], Department of Chemistry[2], and Department of Chemical Engineering[1], Massachusetts Institute of Technology, Cambridge, MA 02139 USA.

Nitric oxide (NO) is an important physiological and biochemical messenger that may be involved in endogenous carcinogenesis and cell toxicity. This cytotoxicity and genotoxicity may occur via formation of N-nitroso compounds and via direct DNA damage by nitrosating agents arising from the reaction of NO with O_2.

To study the kinetics of the reaction of NO with O_2 in model systems and the formation and disappearance of NO in more physiological systems such as macrophage and other cell cultures, we have designed a "probe" consisting of a silastic membrane mass spectrometer inlet.

Membrane Probe Apparatus and Design. The membrane probe, used for aqueous phase measurements, consists of a 15 cm length of silastic tubing (0.058" I.D., 0.077" O.D.) attached to teflon tubing (0.052" I.D., 0.076" O.D.) at both ends by heat shrink tubing. The heat shrink tubing covers all but 2.9 cm of the silastic tubing. The tubing is inserted into a swagelok "tee" fitting and tightened after centering the exposed section of the silastic. The "tee" is attached to the mass spectrometer. The membrane probe unit is attached in line to a loop in which liquid flow is facilitated by a peristaltic pump.

The membrane probe, used for gas phase measurements, consists of silastic tubing (0.058" I.D., 0.077" O.D.) sealed at one end and attached to teflon tubing at the other end with silicone rubber. The exposed portion of silastic is 2 mm and is supported inside against collapse with a stainless steel coil. The teflon is attached directly to the mass spectrometer with a swagelok fitting.

A 3-neck, 100 ml volumetric flask is used for gas and aqueous phase NO measurements. One neck contains an injection port for NO. A second neck contains 1/16" stainless steel tubing in which one tube is connected to a differential pressure transducer and the other two tubes are used for purging the flask with argon. The gas membrane probe or the external flow loop containing the aqueous membrane probe is inserted into the last neck (Figure 1).

Methods. NO samples were obtained using gas-tight syringes. The NO flowed through two vials in series. After the second vial was clear (displaying the lack of NO_2), the syringe was used to withdraw NO from the first vial.

The gas membrane probe was connected to the flask and amounts ranging from 100-1000 µl were injected into the flask after purging with argon. The NO abundance versus time was monitored by the mass spectrometer. NO_2 was also injected into the flask to monitor the affect of NO_2 on the NO abundance. The signal-to-noise ratio at the pseudo steady-state abundance was calculated for several runs.

The flask was filled with deionized water for aqueous phase NO measurements. The water was stirred and purged with argon. The aqueous membrane probe was connected to the flask and a flow rate of 8 ml/min was established through the external flow loop. NO was injected into the gas phase and the abundance versus time was monitored by the mass spectrometer. O_2 was also injected into the gas phase to facilitate a reaction between NO and O_2. A 4-way valve was inserted approximately 10 cm upstream of the membrane probe to introduce a NO-free water step change to the probe for evaluating the probe response.

The mass spectrometer was run at a source temperature between 200 and 250 C. The multiplier voltage ranged from 1700 to 2200 V, depending upon the condition of the mass spectrometer.

Results and Discussion. Gas phase measurements showed that NO_2 affected the NO abundance when NO_2 was at least the same concentration as NO. A probe response time of 5.6 ± 1.4 seconds was measured for the gas membrane probe. The probe response time was evaluated by fitting the data to the solution of:

$$\frac{dC_{measured}}{dt} = \frac{C_{actual} - C_{measured}}{\tau}$$

where C is the concentration and τ is the response time. Preliminary results have also shown a NO throughput of 1 pmol/s with a signal-to-noise ratio (SNR) of 100. This throughput versus SNR varies with instruments and the life of the multiplier.

Aqueous phase measurements showed that NO_2 did not affect the NO abundance since NO_2 was not detected. A probe response time of 10 ± 1.3 seconds was measured for the aqueous membrane probe when the flow rate was approximately 11 ml/min. A NO volumetric mass transfer coefficient describing mass transfer across the gas-liquid interface was measured as 0.018 s^{-1}. The inverse of the coefficient, 55 seconds, is the characteristic time for mass transfer. The coefficient is dependent upon the stir rate and the liquid volume. A reaction of NO with O_2 was observed when O_2 was injected into the gas phase of a system in which NO equilibrium was initially maintained between the gas and liquid phase (Figure 2).

Conclusions. The characteristic times (inverse mass transfer rate and inverse "pseudo" first order reaction rate for the NO-O_2 reaction) can be manipulated to enable the probe response time to be faster than these characteristic times. When this condition is met, the influence of the probe is diminished when evaluating the mass transfer rate and the depletion of NO in a solution. The aqueous membrane probe will be useful for monitoring NO disappearance in the presence of O_2 since NO_2 does not affect the NO abundance readings. The design of the aqueous membrane probe allows for ease of sterilization and fabrication. Also, the probe tube design allows for the theoretical analysis of the probe mass transfer and response characteristics.

Structure Confirmation of Alfalfa Saponins By LSIMS and B/E LSIMS/MS

*Paul R. West[1], Paul W. Geno[2], George R. Waller[3], Wieslaw Oleszek[4] and Marian Jurzysta[4]
[1]Department of Chemistry, Oklahoma State Univ., Stillwater OK 74078
[2]Southwest Research Institute, San Antonio TX 78228
[3]Department of Biochemistry, Oklahoma State Univ., Stillwater OK 74078
[4]Institute of Soil Science and Plant Cultivation, Pulawy 24-100, Poland

Alfalfa *(Medicago Sativa)* seeds, aerial parts and roots contain high concentrations of saponins. Many of these saponins are triterpene glycosides which have shown a wide range of biological activities such as animal growth depression, and antifungal activity. They have also been shown to be antiviral, hemolytic and have great potential as pharmaceutical synthons. Saponin glycosides of medicagenic acid are effective for the reduction of serum cholesterol in primates, and may be equally as effective in treatment of hypercholesteremia in humans.

LSIMS and B/E LSIMS/MS analyses have been used to confirm the structure of several of these compounds, isolated and purified using the methods recently developed by Oleszek and Jurzysta. Results obtained clearly show that this method provides spectra containing peaks of significant structure elucidating importance. Information about the identity of the aglycone, the sequence and type of sugars (hexose, deoxyhexose, hexuronic acid, pentose etc.) and their linkage positions can be determined.

LSIMS studies were performed on a VG ZAB2-SE by bombarding a 50:50 glycerol / thioglycerol matrix containing sample with a 35 keV Cs+ ion beam. In one series of experiments, 0.1 N NaCl was added to the matrix to increase the intensity of the sodium adduct ions for portions of the saponin molecule containing sugar(s). B/E linked scan LSIMS/MS spectra were obtained for both metastable daughter ions and daughter ions produced by CAD (Collisionally Activated Dissociation) of the parent ion. For comparison purposes, positive EI spectra were also obtained for the two aglycones (sapogenins) in the samples (medicagenic acid and soyasapogenol B).

Positive LSIMS spectral peaks were generally more significant than negative only when sodium was added to the matrix. The predominant pseudomolecular ion for the aglycones in postive mode without sodium added was $[M-H]^+$, somewhat unusual for LSIMS. As the number of sugars attached to the aglycone increased, $[M+H]^+$ became more prominent. Surprisingly, positive and negative LSIMS spectra of the two aglycones present show reverse Diels-Alder fragmentation of the sapogenin triterpenoid rings (similar to EI), thus giving excellent structural information.

In many cases, the addition of 0.1 N NaCl to the matrix provided enhanced spectra due to the vast difference in affinities for Na^+ demonstrated by the aglycone and sugar portions of the saponin molecules.This affinity increases proportionally to the number of sugars present, as shown by some compounds with pseudomolecular ions containing as many as 4 sodium adducts ($[M+4Na-3H]^+$). Comparing the positive LSIMS spectra with and without sodium added leads to structurally informative conclusions due to this difference in Na^+ affinity, since adding sodium causes a large increase in the intensities of the sodium adduct peaks for the sugar portions of the molecule, whereas the aglycone ion intensity is much less affected.

CAD B/E LSIMS daughter ion spectra consistently provided more stuctural information than metastables, particularly for daughters of lower mass. Daughter ion spectra of the $[M+Na]^+$ parents showed ring fragmentations for various sugars linked to the aglycone.

GC/MS Analysis of Low Molecular Weight Organic Acids and Di-acids in Aqueous Matrices

(*David E. McKenzie and B. Mason Hughes, ESC, Monsanto Company, St. Louis Missouri 63167.)

Introduction: Low Molecular weight (< 150 AMU) acids and di-acids in aqueous matrices are an important class of compounds which present a difficult analytical problem. Although mono-acids are gas chromatographable on various GC columns, it is difficult to extract them into a suitable matrix for gas chromatographic analysis. Underivatized low molecular weight di-acids are not gas chromatographable. Low level analyses of these compounds in a real matrix using liquid chromatography is difficult because these compounds contain no chromophores. Ion chromatography, capillary zone electrophoresis and liquid chromatography are not suitable to interface easily with a mass spectrometer for unambiguous identification of unknowns.

Experimental: Water Sample aliquots (3mL) were added to 40mL amber Pierce vials. Base (250µL) 15% NaOH, KOH, or CsOH was added to each sample. Samples were vortexed for approximately 10 seconds. Acetonitrile (35mL) was added to each sample and the samples were reduced to dryness under a nitrogen stream in a warm (65°C) sand bath. Hexamethylphosphoramide (HMPA) and methyl iodide (250µL of each) were then added to each sample. The samples were capped with Teflon faced septa and vortexed for approximately 30 seconds. Samples were placed in a vial rack and allowed to stand in a hood at room temperature overnight. The following day ethyl ether (10mL) containing 10 ppm toluene was added to each sample. Deionized water (5mL) was added to each sample and the samples were shaken. After the phases had separated an aliquot of organic phase was removed and analyzed on a Hewlett Packard GC/MS 5989A (MS engine) system. This data was collected scanning from 36 to 500 AMU from 1.8 minutes to 16 minutes. The oven temperature was programmed at a higher rate after data collection was halted to allow the elution of HMPA. The chromatographic conditions were as follows:

Column:	J&W DB-5, 30m X 0.32mm I.D. with 0.25µ film thickness.
Carrier:	Helium
Injection:	Splitless
Oven Program:	18°C (4 minutes) to 120°C (@8°C /minute)/ (20°C /minute) to 300°C

Discussion: Total ion chromatograms resulting from this derivatization techniques are unusually "clean" (i.e. they have few if any extraneous peaks). Figure 1 is an example of a chromatogram obtained using this derivatization technique with CsOH as the base. This technique also offers another advantage in that the methyl esters of most common organic acids are present in the Wiley NBS mass spectral library allowing easy identification. As with any derivatization method, the completeness of reaction is highly dependent upon the specific analyte and the use of isotopically labeled surrogate compounds would be preferred. Figure 2 is an example of a mass spectra obtained and a mass spectral library search result.

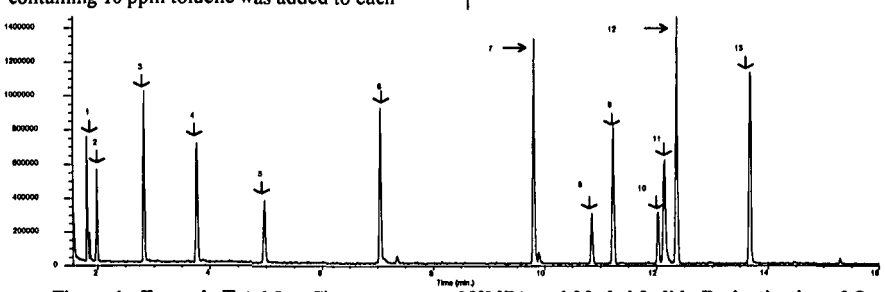

Figure 1. Example Total Ion Chromatogram of HMPA and Methyl Iodide Derivatization of Organic Acids. (1=propenoic acid methyl ester, 2=propanoic acid methyl ester, 3=isobutanoic acid methyl ester, 4=butanoic acid methyl ester, 5=toluene, 6=pentanoic acid methyl ester, 7=hexanoic acid methyl ester, 8=methyl propanedioic acid dimethyl ester, 9=propanedioc acid methyl ester, 10=p-cresol methyl ester, 11=butenedioic acid dimethyl ester, 12=cyclopentenoic acid methyl ester, 13=benzoic acid methyl ester)

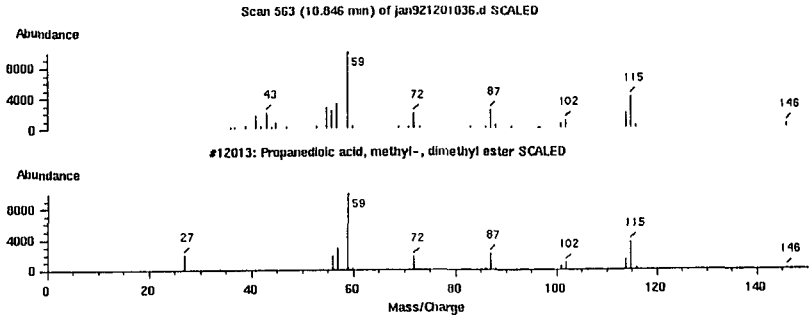

Figure 2. Example of Derivatized Propanedioic Acid Dimethyl Ester (Top) and Library Search Result (Bottom)

Conclusions: Total ion chromatograms resulting from this derivatization method are unusually "clean" (i.e. they contain few if any extraneous peaks). Investigation of which salt facilitates the esterification reaction clearly indicates that the order of reactivity is Cs > K >> Na for reactions with low molecular weight acids. The methodology used in this derivatization technique is inherently simple, however because sample preparation takes approximately 24 hours rapid sample turn around times are not possible. Because of this constraint and the expense involved in acquiring isotopically labeled surrogates for all of the organic acids it is recommended that this technique be used as a qualitative tool for unambiguous identification of components, and other techniques such as ion chromatography, or capillary electrophoresis be used for quantitative information. Levels of detection for these analyses was on the order of 4 ppm and could have easily been decreased to below 1 part-per million by increasing the sample size and the use of selected ion monitoring.

Fundamentals of Short-Column GC/MS/MS and Applications to Anabolic Steroid Screening

Stacy-Ann Rossi Oak Ridge National Laboratory, Oak Ridge, TN 37831
Jodie V. Johnson and Richard A. Yost University of Florida, Gainesville, FL 32611

Anabolic steroids are a biologically significant class of steroids believed to improve athletic performance through their anabolic action. Because the long-term health effects of these drugs are not well known and also on the basis of sports ethics, analytical methods have been established to detect their use. The goal of steroid screening methodologies is a single profile where all components of interest are determined in a non-discriminatory way. This, however, has yet to be achieved by any of the current screening methods. An assay based on short-column GC separation in combination with tandem mass spectrometric detection for the determination of six underivatized anabolic steroids was evaluated. The method described here demonstrates the ability to rapidly and quantitatively analyze underivatized anabolic steroids in spiked urine matrices.

Experimental:

Experiments were performed on a Finnigan MAT TSQ45 triple quadrupole mass spectrometer equipped with a 9610 gas chromatograph and a Finnigan MAT TSQ70 triple quadrupole mass spectrometer equipped with a Varian 3400 GC. Gas chromatographic separation was performed on a 3.5 m, 0.25mm i.d. DB-5 capillary column. Helium carrier gas was adjusted from subambient to low pressure regulation (2 psig). A temperature program from 150 to 250 °C was used. Instrumental conditions were electron energy of 40 eV (EI) and 100 eV (CI) and ionizer temperature of 190 °C (EI) and 150 °C (CI). Methane was used as the CI reagent gas at a pressure of 0.2 torr (TSQ45) and 1.5 torr (TSQ70). Argon was used as the collision gas in the PCI MS/MS studies at a pressure of 2.5 mtorr (TSQ45) and 1.5 mtorr (TSQ70). Collision energy varied from 14 to 27 eV depending on the individual steroid.

Results and Discussion:

The short-column GC/MS/MS assay was designed to accomplish the following goals: to reduce and simplify sample preparation procedures, to reduce analysis times, and to improve the sensitivity and selectivity of present screening methods. Chemical ionization and tandem mass spectrometric detection methods were investigated as methods of increasing sensitivity and selectivity and as alternatives to lengthy sample preparation procedures and gas chromatographic separation times.

Electron ionization and chemical ionization methods were compared for each of the steroids. It was shown that PCI resulted in 4 to 40 times greater sensitivity (as measured by the peak area of the base peak ion) than both EI and NCI. In addition, the extent of fragmentation for PCI was much less than for EI. For trace and quantitative analyses, CI is preferred since it produces a highly abundant molecular ion, a minimum number of fragment ions, and reduces potential matrix interferences.

Mass spectrometric detection methods were also compared. SIM was shown to be the most sensitive of the three methods. The lower sensitivity for SRM was presumably due to the less than 100% CAD efficiency of the steroids. Under optimum chromatographic conditions rapid sample introduction of thermally-labile and involatile compounds can be achieved, but with some loss in chromatographic resolution. Tandem mass spectrometry can be used to overcome this problem. The selectivity of SRM was much greater than that for either full scan or SIM detection methods due to the addition of a second mass analyzer. The selectivity obtained with MS/MS is illustrated in Figures 1 & 2.

Table 1 shows the results for limits of detection and precision studies for spiked urine samples. Oxymetholone and stanozolol were not detected in the spiked urine sample and may have been lost in the sample preparation procedure. Limits of detection for selected reaction monitoring of these compounds have not been reported in the literature, however, the IUPAC LODs (determined from a calibration curve) obtained in this study (2 to 40 ng/mL) are comparable to the low end of suggested physiological levels (5 to 500 ng/mL) in urine.

Conclusions:

The analytical method of choice, short-column GC/MS/MS using selected reaction monitoring and positive ion chemical ionization permits positive identification of underivatized anabolic steroids based on retention time and production of characteristic daughter ions, as well as offering quantitative capabilities. Detection limits in spiked urine samples are promising for four of the six compounds studied. The main advantages of this method compared to conventional-length column GC/MS screening methods is its rapidity and selectivity. Positive identification of the six steroids studied can be performed with a short-column GC/MS/MS run of less than 6 minutes and a reduction in sample preparation time of at least 1-2 hours.

Table 1: PCI SRM LODs

limit of	Spiked Urine Samples[a]

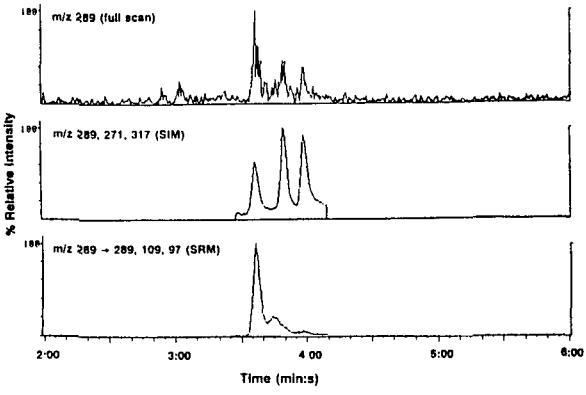

Figure 1: PCI full scan, SIM and SRM mass chromatograms for testosterone illustrating the selectivity of MS/MS. Three chromatograms are shown for testosterone spiked into urine samples at 5000 ng steroid/mL of urine. Note the two additional peaks in the full scan and SIM chromatograms presumably due to endogenous testosterone metabolites. The first peak corresponds to the correct retention time for testosterone and is the only peak present in the SRM chromatogram.

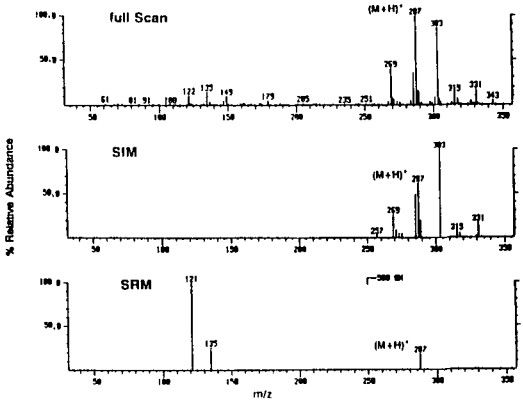

Figure 2: PCI full scan, SIM, and SRM mass spectra for the steroid dehydrotestosterone. This steroid (m/z 287) is typically chromatographically unresolved from methyltestosterone on the short GC column. The limited chromatographic resolution is problematic when using full scan and SIM detection methods; note the m/z 303 and 331 ions of methyltestosterone in the full scan and SIM spectra. The selectivity of MS/MS detection is shown in the bottom spectra where only the daughter ions for dehydrotestosterone are observed.

Tracheal Eicosanoid Measurements Using Microdialysis Sampling and GC/MS Detection..

***James A. Yergey, Dean Callaghan, Pascale Rousseau, Paul Masson. Merck Frosst Centre for Therapeutic Research, P.O. Box 1005, Pointe Claire-Dorval, Quebec, H9R 4P8.**

INTRODUCTION: Eicosanoids are important mediators in many physiological and pathophysiological conditions. RIA, EIA, and GC/MS can all be effectively utilized for detection of eicosanoids, however, GC/MS remains the detection method of broadest scope when investigating new systems. Sampling the eicosanoids remains a challenge, particularly in the respiratory tract. Lavage sampling can be problematic when multiple time points are required from a given animal, while urinary measurement would be difficult to relate back to respiratory production. In contrast, microdialysis offers a means for sampling the large airways which may provide profiles of local eicosanoid levels before and after challenge. Experiments were conducted to assess the ability to sample and quantify prostaglandins E_2, D_2, $F_{2\alpha}$ and 6-keto-$F_{1\alpha}$ and thromboxane B_2 produced in the guinea pig trachea, before, during, and after i.v. challenge with leukotriene D_4 (LTD_4), a potent respiratory immflamatory agent, or with its precursor fatty acid, arachidonic acid.

EXPERIMENTAL: Commercially available microdialysis probes (CMA/10), of radial design with 4 mm of exposed dialysis membrane, were perfused at 3.8 µL/min with a PBS buffer solution. *In vitro* probe recoveries were determined using ^3H-PGE_2 before and after guinea pig experiments. Male albino guinea pigs (Charles River, 350-550 g) were anesthetized by i.p. injection of urethane and a tracheotomy performed. Microdialysis probes were inserted 2-3 cm into the trachea. A plastic cannula was then inserted, maintaining a seal around the microdialysis probe. Spontaneous breathing was inhibited and artificial respiration started. The carotid artery was cannulated and a pressure transducer connected, enabling blood pressure and heart rate monitoring. The jugular vein was cannulated for administration of drugs. Microdialysis sampling began after a 30 min recovery period, and continued for six one hour intervals. Dialyzate was collected in polypropylene tubes. All challenges were given i.v. following two hours of baseline sampling. Arachidonic acid was given as 3 bolus doses of 5, 4 & 3 mg/kg, separated by 15 min between doses. LTD_4 was given as a single dose of 0.2 µg/kg at the start of the third hour. Each challenge dose was followed by a 0.5 mL of saline. Matched saline control animals received similar injections without drug. Internal standard solution, containing 100 pg each of $^2H_4$-$PGF_{2\alpha}$, $^2H_4$-PGE_2, $^2H_4$-6-keto-$PGF_{1\alpha}$, was added to samples and the standard curve (3-300 pg each of PGE_2, PGD_2, $PGF_{2\alpha}$, 6-keto-$PGF_{1\alpha}$ and TXB_2 in PBS). Samples were treated (1% MOX-HCL, pH 5) overnight to produce the N-methoxime, extracted with C_{18} SPE, derivatized to the PFB ester (0.1% PFBBr, 10% DIEA in CH_3CN, 60°C for 15 min), TMS ether (CH_3CN:BSTFA, 60°C for 15 min), and dissolved in 25 µL dodecane. Derivatized samples were injected on-column into a 1 m retention gap and separated on a 15 m, 0.25 mm i.d. Rt_x-1 column housed in an HP5890 gas chromatograph. The HP5988A mass spectrometer was operated in resonance electron-capture ionization mode, with SIM switching between the predominant $[M\text{-}PFB]^-$ ion for each eicosanoid.

RESULTS & DISCUSSION: Consistent microdialysis probe recoveries were observed over several months of experimentation for several different probes (mean recovery 6.5 ± 0.6%). The microdialyzate was a relatively clean fluid, necessitating only a single solid-phase extraction step. The gas chromatographic conditions outlined allowed complete separation of the five measured eicosanoids in under 3.5 min (See example for PGE_2 & PGD_2 in Figure 3). These factors, coupled with the resonance electron-capture ionization, selected-ion monitoring mass spectrometric determinations, allow over fifty samples to be processed and analyzed in a 36-hour period. Consistent eicosanoid levels were observed during the predose period of two hours, and for all time points in the saline controls (Tables 1 & 2; range 5-20 pg / one hour sample). Upon challenge with LTD_4, significant elevations in microdialysis sampled tracheal eicosanoids were observed (Figure 1). Greater than 2-fold elevations were observed for PGD_2 ($p<0.05$), 6-keto-$PGF_{1\alpha}$ ($p<0.05$), PGE_2 ($p<0.025$) and $PGF_{2\alpha}$ ($p<0.025$). No significant change was seen for TXB_2. Blood pressure was observed to increase 5-10 mm Hg immediately upon challenge, decrease slowly to a value below baseline over the next 25 minutes, and finally to recover to baseline about one hour post-challenge. Upon challenge with arachidonic acid, significant changes were observed for all five measured eicosanoids (Figure 2). The greatest change observed was an 8-fold elevation for PGE_2 ($p<0.01$), while the smallest change was a 3-fold increase for TXB_2($p<0.05$). Significant elevations were also observed for $PGF_{2\alpha}$ ($p<0.005$), PGD_2 ($p<0.05$) and 6-keto-$PGF_{1\alpha}$ ($p<0.05$). Trends in blood pressure were similar to those observed for the LTD_4 challenge experiments, however the changes occurred more rapidly, recovering to baseline within 15-20 minutes post-challenge.

CONCLUSIONS: These data demonstrate that microdialysis sampling, coupled with GC/MS determination, is a unique methodology for measuring the profile of endogenously produced eicosanoids in the trachea of the guinea pig. Significant elevations in eicosanoid levels, relative to predose levels, were observed following challenge with the potent respiratory mediator, LTD_4, as well as following challenge with the precursor fatty acid of LTD_4, arachidonic acid. The methodology might be particularly amenable to larger animals, where the relative size of the microdialysis probe in the airway would be much less than is the case for the guinea pig.

TABLE 1: Predose Eicosanoid Levels

Eicosanoid	Mean ± SE (pg/ sample)	n
PGD_2	10.6 ± 1.9	17*
PGE_2	11.3 ± 1.8	36
$PGF_{2\alpha}$	21.3 ± 2.7	34
TXB_2	12.0 ± 1 5	34
6-keto-$PGF_{1\alpha}$	7.0 ± 1.4	37

* PGD_2 not quantifiable in many cases

Characterization of Angiotensin II Receptor Subtypes in Isolated Perfused Rat Kidney by Quantitative Analysis of Prostanoids.

P.Haroldsen, S.Murakami, I.Massey, D.Clarke, Syntex Research, Palo Alto CA 94304.

Interest in the renin-angiotensin system has increased dramatically with the advent of nonpeptide angiotensin receptor antagonists. Two angiotensin II (AII) receptor subtypes, AT1 and AT2, have recently been identified based on their relative affinities for selective peptide and nonpeptide antagonists. A major challenge in this field is to identify, characterize and classify subtypes of angiotensin receptors that would allow for selective drug targeting and therapeutic intervention in hypertension and congestive heart failure. In this regard, preliminary evidence exists linking angiotensin-induced prostaglandin (PG) release to a putative novel receptor type in rabbit vas deferens (1) and rat glioma cells (2). The object of the present study was to investigate this putative receptor further by studying angiotensin-induced prostanoid release in the rat kidney using a quantitative pharmacologic-analytical approach based on isotope dilution mass spectrometry(MS).

PHARMACOLOGIC METHODS: Kidneys were prepared as previously described(3).Perfusate samples,12ml,were collected on ice and deuterated (D4) PG standards were added:PGE2(10ng), PGF2alpha(5ng) and 6keto-PGF1alpha(5ng).

ANALYTICAL METHODS: Prostaglandins were isolated with C18 solid phase cartridges(4). The pentafluorobenzylester-methoxime-TMS ethers were prepared as described(5,6).GC was performed with a 14m x 0.25mm ID DB-5 column programmed 150°C (0.3min) ramped to 280°C @ 30deg/min, injector at 265°C.Negative ion electron capture MS employed an HP-5987a quadrupole with CH4 @ 3torr and source T @ 150°C. Carboxylate anions monitored @ m/z=524 (PGE2 & PGD2), 569 (PGF2alpha) and 614 (6keto-PGF1alpha).

Initial experiments to screen for prostanoid types indicated the presence of PGE2, PGD2, PGF2a and 6keto-PGF1a which were quantitated in subsequent experiments over the range 80-1250 pg/ml. Perfusion of kidneys with a buffered solution containing 10nM AII resulted in a rise in perfusion pressure and a transient increase in perfusate levels of PGE2, PGD2, PGF2a and 6ketoPGF1a (Fig 1A, 2A). PGE2 levels increased 4.5-10.8 fold, PGD2 increased 3.7 - 4.3 fold, PGF2a increased 2.2-3.2 fold and 6keto-PGF1a increased 2.3-2.7 fold. Perfusion of kidneys with DUP-753 (1uM) a non-peptide AII receptor (AT1) antagonist 20 minutes prior to AII abolished or attenuated the AII induced elevation in perfusion pressure and prostanoid release (Fig 1B,2B). The elevation of PGE2 levels was completely abolished in 1/3 kidneys and attenuated to only a 2 fold increase in the remaining 2/3 kidneys. These data suggest the involvement of an AT1 receptor in mediating PGE2 release but do not rule out the possibility of additional Angiotensin receptor subtype involvement. As DUP-753 is a competitive antagonist it is also possible that inhibition at the AT1 site was partially surmounted. The AII induced increases in PGD2, PGF2a and 6-ketoPGF1a (Fig 2B) were abolished by DUP-753.

Perfusion of kidneys with the agonist desPhe AII(100nM) did not evoke an increase in prostanoid levels nor a vasoconstrictor response (Fig 1C,2C). This initial result is of interest since desPhe AII is claimed to be of equal or greater potency with AII in the rat vas deferens(1) and brain glioma cells(2) for eliciting PGE2 and PGI2 production.

20-HYDROXYEICOSATETRAENOIC ACID IS EXCRETED AS A GLUCURONIDE CONJUGATE IN HUMAN URINE

Chandra Prakash*[1], Ji Y. Zhang[1], J. R. Falck[3] and Ian A. Blair[1,2]
Departments of Pharmacology[1] and Chemistry2 and Center in Molecular Toxicology[2]
Vanderbilt University, Nashville, TN 37232

Department of Molecular Genetics[3] University of Texas
Southwestern Medical Center, Dallas, TX 75235

20-Hydroxyeicosatetraenoic acid (20-HETE) is a major metabolite of arachidonic acid (AA) formed by cytochrome P-450 ω-hydroxylase in human kidney and also in other tissue. It is a potent vasoconstrictor, promotes sodium excretion and causes natruresis when administered to anesthetized euvolemic rats. 20-HETE inhibits $[^{86}Rb]^+$ uptake in isolated medullary thick ascending limb cells from the rabbit. The *in vitro* biosynthesis of 20-HETE from exogenous AA by renal microsomes was increased during the development of hypertension in the SHR rat. These findings suggested that 20-HETE may play an important role in renal function and in the pathogenesis of hypertension. A recent study showed that 20-HETE was present in the urine of SHR and WKY rats. We have developed a highly sensitive and specific assay, based on gas chromatography/electron capture negative ion chemical ionization mass spectrometry (GC/ECMS) for the quantification of 20-HETE in human urine. as its pentafluorobenzyl bromide (PFB), t-butyldimethylsilyl (BDMS) derivative. A dideuterated analog was used as an internal standard. PFB derivatives of 16-, 17- and 18-HETE were readily separated from 20-HETE-PFB on silica HPLC. 20-HETE-PFB and 19-HETE-PFB were readily separated from each other as their BDMS derivatives on capillary GC. Unlike conjugated diene-HETEs, the PFB, BDMS derivatives of 20-HETE and 19-HETE had excellent GC properties. Synthetic 19-HETE-PFB-BDMS eluted at 10.42 min on capillary GC while 20-HETE-PFB-BDMS eluted at 11.22 min. The PFB-BDMS derivative of $[^2H_2]$20-HETE eluted 1.5 sec ahead of the corresponding protium derivative, in accordance with the expected isotope effect. Intense [M PFB] negative ions were observed at m/z 433 in the mass spectra of PFB-BDMS derivatives of 19-HETE and 20-HETE. An intense [M-PFB] negative ion was observed at m/z 435 for $[^2H_2]$20-HETE-PFB-BDMS. Quantitative analyses were carried out using SIM analysis of ions m/z 433 and m/z 435.

The recovery of 20-HETE through the entire assay was 30.1 ± 0.4 %. Intra- and inter-assay variability at 30 pg/mL were 10 % and 15 % respectively (n=6). The assay was applied to the analysis of 20-HETE in human urine from four normal volunteers. A typical selected ion current profile obtained for the analysis of 20-HETE in human urine is shown in Figure 1a. In contrast to the previous rat study, only trace amounts of 20-HETE could be detected. The urinary concentrations for the four subjects were in the range 22-30 pg/mL. It was found that β-glucuronidase treatment of the urine for 2 hr resulted in a dramatic increase of the signal in channel m/z 433 corresponding to 20-HETE-PFB-BDMS (Figure 1b). When the urine was incubated with β-glucuronidase for longer periods (up to 15 hr) no further increase in 20-HETE concentrations was observed. A full scan mass spectrum from GC/ECMS analysis of the same urine sample, to which no internal standard had been added, was identical with that of an authentic standard of 20-HETE-PFB-BDMS (Figure 2). This suggested that the 20-HETE was present in the urine primarily as a conjugate. Three other human urine samples were analyzed after β-glucuronidase treatment and the signal from 20-HETE was found to increase from 13- to 28-fold when compared with no β-glucuronidase treatment. No increase in 20-HETE was observed when the urine was incubated at pH 5 for 2 hr at 37 °C indicating that the conjugate was not a sulfate. The sensitivity of the conjugate to β-glucuronidase suggests that it was a glucuronide derivative. Further studies will be required to establish whether glucuronidation had occurred on the carboxyl or hydroxyl moieties.

This is the first report that an eicosanoid is present in human urine primarily as a glucuronide conjugate. In summary, we have established that 20-HETE is formed *in vivo* in humans. In contrast to other eicosanoids, it is conjugated before being excreted in the urine. Further studies can now be carried out in different patient populations to help explore a possible pathophysiological role for 20-HETE.

This work was supported by NIH grants DK38226 and ES00267.

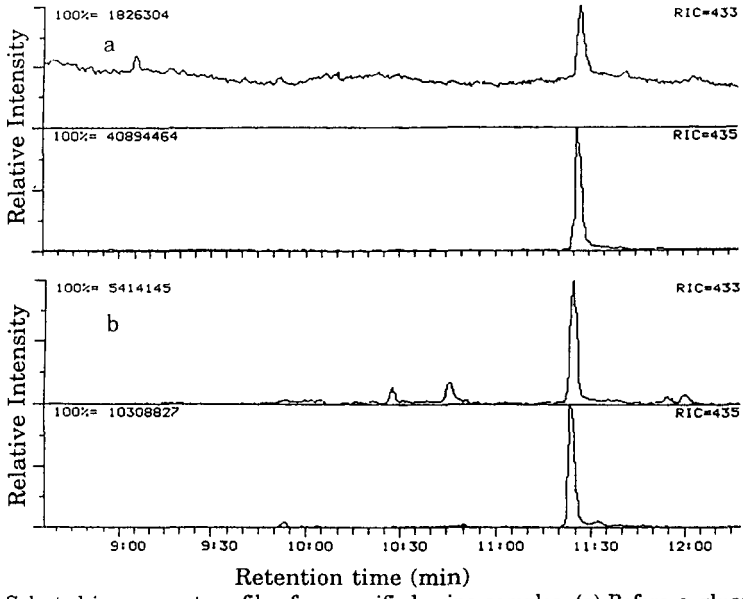

Fig. 1. Selected ion current profiles from purified urine samples. (a) Before β-glucuronidase treatment: (upper) 20-HETE-PFB-BDMS (lower) [$^2H_2$]20-HETE-PFB-BDMS internal standard. (b) After β-glucuronidase treatment: (upper) 20-HETE-PFB-BDMS (lower) [$^2H_2$]20-HETE-PFB-BDMS internal standard. Chromatograms are normalized to the most intense peak. The concentration of 20-HETE before β-glucuronidase treatment corresponds to 22.0 pg/mL and after treatment to 447.9 pg/mL.

Introduction

The use of HPLC (UV) for the quantitative analysis of selected urinary nucleosides has been proposed as a method for diagnosing HIV infection and staging of AIDS [1,2]. GC/MS of HPLC purified fractions containing urinary nucleosides indicates the presence of numerous other components which suggests that the use of UV absorbance for quantitation may not accurately reflect the actual concentration of the "nucleoside biomarkers" [2]. EI-GC/MS methods have, therefore, been developed and applied to the quantitation of nucleosides in human urine. These quantitative methods are, however, time consuming. Screening techniques using nucleoside profiles , which are more rapid, have also been developed and are the subject of this report. Where indicated, confirmation of infection/staging is obtained using the more extensive quantitative GC/MS techniques.

Experimental

Sample preparation involves addition of an internal standard (3-deazaadenosine) to one ml. of urine. The sample is then placed on a solid phase extraction (SPE) C-18 column, washed and eluted with methanol. This mixture is then added to a phenyl-boronic acid (PBA) column, washed and eluted with acetic acid/methanol. The final solution is taken to dryness and derivatized at 110° for one hour using BSTFA/pyridine.

Gas chromatographic conditions include: injection, splittless at 260°; column, 30m DB-5 (J&W Scientific) temperature programmed (150° for 3 min. - ramped at 6°/min. to 300° - held at 300° for 10 min.); and direct interface to the MS ion source, 250°.

Mass spectrometer (Finnigan MAT90, Finnigan Corp., Palo Alto, CA) conditions: source, electron ionization (70eV) at 250°; analyzer, scanned from 70 to 1000 (at 0.4 sec./decades with 0.1 sec. inter-scan delay) and a mass resolution of 1000 (10% valley definition).

Profile information for both known and unidentified nucleosides is generated by normalizing the total RIC of each nucleoside to the total RIC from the internal standard. and adjusting for sample volume.

Results and Discussion

A comparison of known and unknown urinary modified nucleoside profiles from a pool of non-infected subjects, three HIV-infected but asymptomatic patients and five AIDS patients is shown in Figures 1 and 2.

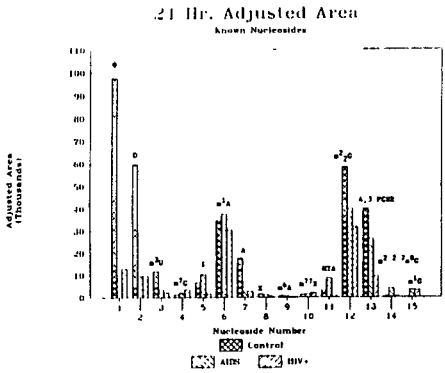

Figure 1

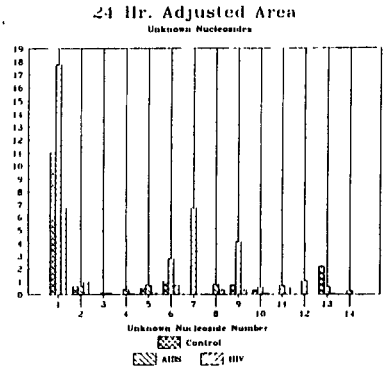

Figure 2

Conclusions

A comparison of the nucleoside profiles for the HIV+ and AIDS with the control urine samples show significant differences in the relative amounts of both known and unknown nucleosides. In addition, all three sample types (AIDS, HIV+ and control) contain nucleosides of unknown structure and origin that may serve as unique biomarkers of HIV infection. Further work on the identification and quantitation of the compounds is in progress.

HPLC methods for quantifying modified urinary nucleosides may not have sufficient sensitivity or selectivity to be useful for the diagnosis of HIV infection or staging of AIDS. Alternatively, the GC-MS methods described here-in do not suffer these limitations and provide structural information on nucleosides of unknown structure.

FAB/MS ANALYSIS OF NUCLEOSIDE DERIVATIVES USED TO INCORPORATE OXIDATIVE LESIONS INTO SYNTHETIC OLIGODEOXYNUCLEOTIDES

Robert A. Rieger, Veeraiah Bodepudi, and Charles R. Iden

Department of Pharmacological Sciences, School of Medicine
Health Sciences Center, SUNY at Stony Brook, Stony Brook, NY 11794-8651

INTRODUCTION

Oxidative damage to genetic material is known to form modifications to purine and pyrimidine nucleotides which may be important in mutagenesis, carcinogenesis, and the aging process. Moreover, many of the same species are formed in DNA exposed to high energy radiation. A careful examination of the biological implications of DNA containing oxidative lesions requires synthetic oligodeoxynucleotides in which one or more of these lesions are incorporated. Three important oxidative lesions that have been identified are 8-oxo-2′-deoxyguanosine, 8-oxo-2′-deoxyadenosine, and 5-hydroxymethyl-2′-deoxyuridine, and we have incorporated all of these modified nucleosides into synthetic oligodeoxynucleotides using automated DNA synthesis technology. FAB/MS has been used to characterize synthetic intermediates, modified nucleoside phosphoramidites, and oligomers containing these lesions. Positive ion FAB/MS is used to analyze modified nucleosides and modified nucleosides with standard protecting groups. However, negative ion FAB/MS is used in the analysis of 5′-dimethoxytrityl-protected nucleosides, modified nucleoside phosphoramidites, and oligodeoxynucleotides. Fragmentation in these spectra is sufficient to characterize the protected monomers and provide information on the sequence of the oligomer and the position and molecular weight of the lesion in the oligomer.

EXPERIMENTAL

FAB mass spectra were acquired on a Kratos MS890 Mass Spectrometer with a DS90 Data System. An saddle field ion source (Ion Tech) provided fast xenon atoms (7 kV) for sample bombardment. Samples were dissolved in either glycerine or thioglycerine on a stainless steel probe and introduced into the mass spectrometer. Several small oligomers were synthesized on a Dupont Coder 300 DNA Synthesizer using conventional nucleoside phosphoramidite chemistry. Modified nucleoside phosphoramidites were introduced via the X-port at the same concentrations as commercial reagents. After release from the solid support, oligomers were purified on a Waters HPLC system equipped with a Hamilton PRP-1 semi-preparative column. The dimethoxytrityl protecting group was removed after HPLC purification, and lyophilized DNA was used directly for FAB/MS analysis.

RESULTS AND DISCUSSION

We have used FAB/MS extensively to characterize modified and protected nucleosides, synthetic intermediates, and small oligodeoxynucleotides. In many cases the base portion of the modified deoxynucleoside must be protected to prevent reaction during the automated synthesis procedure. This includes the amino groups at C-6 of deoxyadenosine, C-2 of deoxyguanosine, and C-4 of deoxycytidine. Figure 1 shows the positive ion FAB mass spectrum of such a substance, N^6-benzoyl-8-oxo-2′-deoxyadenosine. Present in the mass spectrum is an intense MH^+ at m/z 372 and a BH_2^+ ion at m/z 256 indicating the loss of the deoxyribose moiety. The positive ion spectrum is less valuable once the 5′-hydroxyl is protected by dimethoxytrityl (DMT) moiety because the dimethoxytrityl cation (m/z 303) dominates the mass spectrum and only a weak molecular ion is present. More informative, however, is the negative ion FAB mass spectrum of these compounds in which the $(M-H)^-$ ion is intense and a confirming $(M+Cl)^-$ is often present. Figure 2 shows the negative ion mass spectrum of the fully protected phosphoramidite of 8-oxo-2′-deoxyguanosine (MW 855). Important structural fragment ions also exist in this spectrum, i.e., cleavage of the phosphorus oxygen bond with subsequent loss of the phosphoramidite moiety (m/z 654) and loss of the fully substituted deoxyribose (m/z 235). A weak ion at m/z 702 indicates the presence of the hydrolysis product of the nucleoside phosphoramidite.

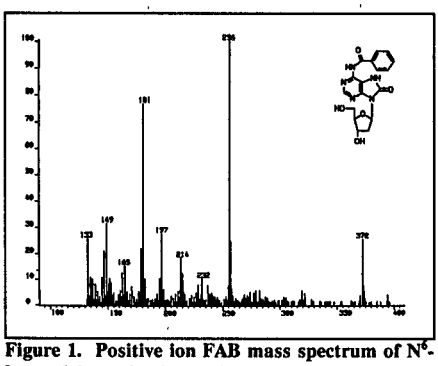

Figure 1. Positive ion FAB mass spectrum of N^6-benzoyl-8-oxo-2′-deoxyadenosine.

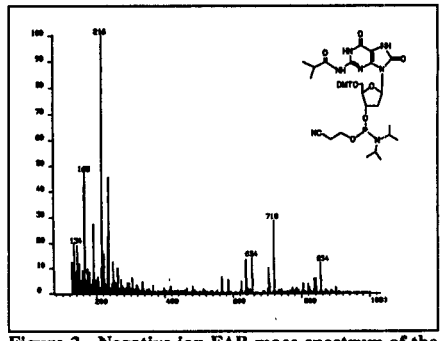

Figure 2. Negative ion FAB mass spectrum of the phosphoramidite of 5′-dimethoxytrityl-8-oxo-2′-deoxyguanosine

The negative ion FAB mass spectrum is also essential for characterization of the oligodeoxynucleotide containing the modified base.[1,2] Figure 3 shows a pentadeoxynucleotide with 8-oxo-2′-deoxyadenosine included at center position. A strong $(M - H)^-$ exists revealing the molecular weight of the oligomer, and all the necessary fragment ions are present so that the base sequence and the molecular weight of the modified base may be deduced. This spectrum also contains a doubly negative charged molecular ion at m/z 750.

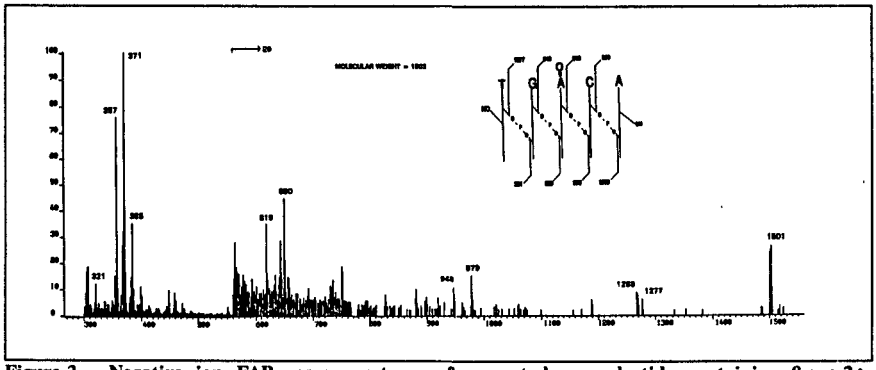

Figure 3. Negative ion FAB mass spectrum of a pentadeoxynucleotide containing 8-oxo-2′-deoxyadenosine, 5′-TG(8-oxo-dA)CA-3′.

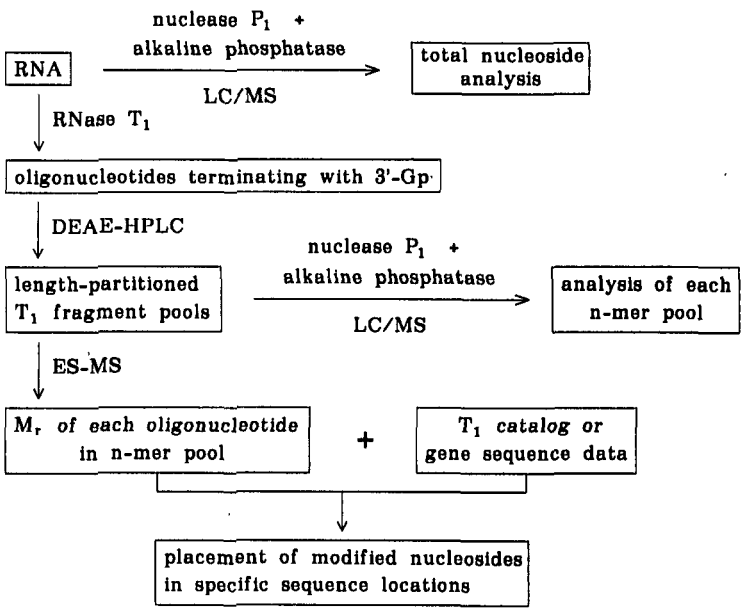
New Strategies for RNA Structure Analysis by Mass Spectrometry

Jeffrey A. Kowalak, Steven C. Pomerantz, and James A. McCloskey
Departments of Biochemistry and Medicinal Chemistry,
University of Utah, Salt Lake City, Utah 84112

Posttranscriptional modification of nucleosides plays an important, yet incompletely defined role in the structure and function of large ribosomal RNAs. We report on new experimental approaches (see below) for the structural characterization and sequence location of posttranscriptionally modified nucleosides in 16S rRNA. Our method takes advantage of previously unrecognized correlations between oligonucleotide composition and molecular mass. We demonstrate that oligonucleotide composition can be *uniquely* established through the 14-mer level by constraining the identity of one terminus of an oligonucleotide using site-specific RNases.

Methodological Scheme for RNA Structure Analysis



Using *E. coli* 5S rRNA (M_r 38,855) as a model, we have verified the exact nucleotide composition of all 41 RNase T_1 fragments ranging in size up to one 10-mer (M_r 3137). The method is applied to *E. coli* 16S rRNA (M_r 499,759) in which six different modified nucleosides are located at 10 sequence positions (see Fig.1). Recognition and analysis of modification-containing T_1 fragments by directly combined HPLC-mass spectrometry of total hydrolysates, used in conjunction with T_1 oligonucleotide mass values predicted from gene sequence data, is used for characterization and sequence placement of individual residues.

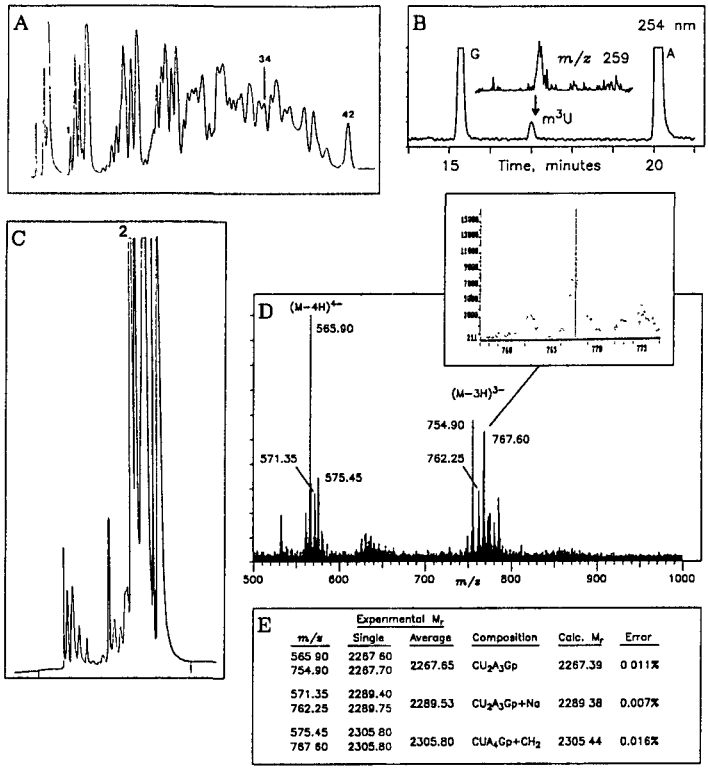


Fig. 1 Detection of 3-methyluridine (m^3U) in *E. coli* 16S rRNA, using ES-MS (A) Separation of T_1 oligonucleotides into 42 fractions by DEAE HPLC. (B) Detection of m^3U in a nuclease P_1/alkaline phosphatase total digest of peak 34 by thermospray LC/MS. *m/z* 259, MH^+. (C) Re-chromatography of DEAE peak 34 by C18-RP-HPLC. (D) ES mass spectrum of RP-HPLC-isolated peak 2 (Instrument: Vestec 201). Inset. centroid of $(M-3H)^{3-}$ from single scan, *m/z* 767.60, equivalent to M_r 2305.80 (Teknivent Vector/1 data system). (E) Mass composition correlations from panel D. Examination of the gene sequence reveals that CUA_4Gp is the composition of an expected T_1 fragment corresponding to nucleotides 1498-1504. The location of the single m^3U residue is therefore confined to nucleotides 1498-1504, which in the present case establishes U1498 as the site of methylation.

The *E. coli* 5S rRNA model allows us to conclude that (1) we can selectively and completely hydrolyze RNA without significant under- or over-cutting, (2) we can resolve the resultant oligonucleotide mixture into manageable fractions by various chromatographies, and (3) we can mass measure all expected T_1 fragments and assign their correct nucleotide compositions.

The *E. coli* 16S rRNA model allows us to conclude that (1) our experimental approach for the identification and sequence location of modified nucleotides in large RNAs is feasible, and (2) alternate strategies are required to place modified residues found in short T_1 oligonucleotides (n<5), in which compositional redundancies tend to occur.

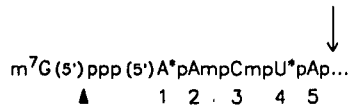
CHARACTERIZATION OF TWO NOVEL NUCLEOSIDES FROM TRYPANOSOMAL mRNA CAP 4 OLIGONUCLEOTIDE

P. F. Crain, T. Hashizume and J. A. McCloskey, Department of Medicinal Chemistry, University of Utah, Salt Lake City, UT 84112; and J. D. Bangs and J. C. Boothroyd, Department of Microbiology and Immunology, Stanford School of Medicine, Stanford, CA 94305

The 5'-end of trypanosomal messenger RNA contains a highly modified structure (called a cap 4) consisting of four ribonucleosides, which in the case of *Trypanosoma brucei* was partially characterized:



The arrow denotes the RNase cleavage site that cleaves the cap structure from the remainder of the RNA. Previous work showed the presence of two unknown nucleosides A* and U* (1-4). We have completed a definitive structural analysis of the cap 4 oligonucleotide from two organisms, *Crithidia fasciculata* and *T. brucei*, and have determined the identities of these nucleosides (5). Because less than one microgram of material was available, characterization was achieved by LC/MS and GC/MS and were confirmed by rigorous comparison with synthetic standards.

The initial measurement was an LC/MS screen of completely digested *Crithidia* cap (Fig. 1; Table 1). The thermospray mass spectra (6) permitted identification of four known nucleosides (Cm,G, m^7G, A and Am. Retention times and spectra of two of the nucleosides (U* and A*) do not correspond to any known nucleoside. The indicated molecular weight of U* was 272, and it contains a methylated sugar. The residual mass, therefore, is consistent with a singly-methylated uracil species as the base. The indicated molecular weight of A* was 309 (6), and it likewise contains a methylated sugar. The residual mass is consistent with an adenine moiety with 28 Da substituent(s). The peaks for m^7G and A* are not seen in the partial digest, and a new peak is produced, showing that A* is nucleoside 1 (structure above).

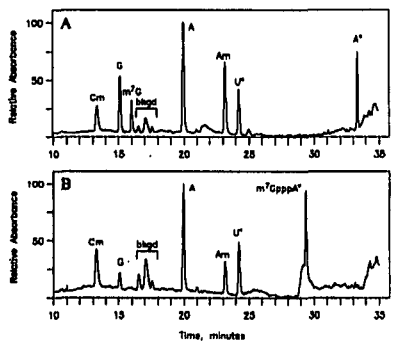


Figure 1. C18 reversed phase HPLC of nucleosides from *C. fasciculata* mRNA cap4. Detection by UV absorbance at 254 nm. A. Total digest from treatment with nuclease P1 (P1), tobacco acid pyrophosphatase, and alkaline phosphatase (AP). B. Partial digest from treatment with P1 and AP only.

Based on biological precedent and on inferences from UV spectroscopic (254/280 ratio) and chromatographic data, we judged the most likely structures to be 3,2'-*O*-dimethyluridine (U*) and N^6,N^6,2'-*O*-trimethyladenosine (A*), and these nucleosides were synthesized for rigorous comparison with the *Crithidia* cap 4 nucleosides by GC/MS (6).

A silylated digest of cap 4 oligonucleotide was analyzed by GC/MS (Figs. 3 & 4, panel A), and a silylated mixture of the synthetic standards was run immediately afterward (Figs 3 & 4, panel B). It is apparent that the spectra for each cap 4 component are identical to those of the synthetic standards. The retention times between natural and synthetic nucleosides agreed within 0.5 sec, based on reconstructed ion chromatograms of the respective M — CH3 ions (6).

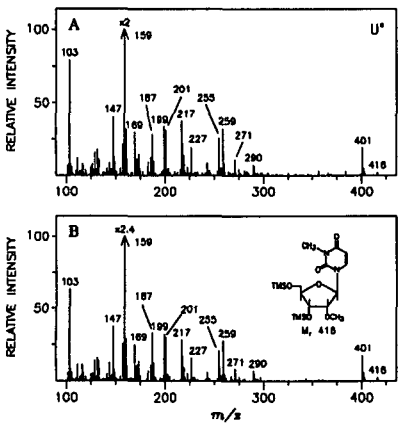

Figure 3. EI mass spectra of U* (panel A) from silylated cap 4 total digest (panel A) and synthetic 3,2'-*O*-dimethyluridine (panel B).

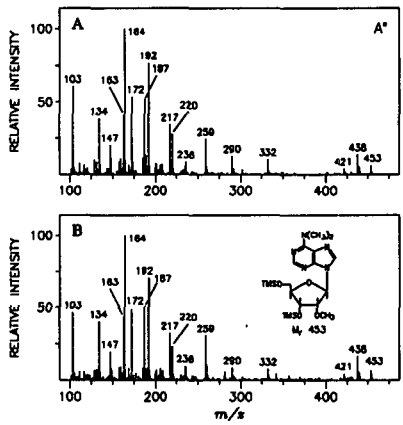

Figure 4. EI mass spectra of A* from silylated cap 4 total digest (panel A) and synthetic N^6,N^6,2'-*O*-trimethyladenosine (panel B).

The cap 4 oligonucleotide from *T. brucei* was compared with the synthetic models using LC/MS and was found to contain U* and A* (6). In summary, two nucleosides not known naturally or synthetically have been characterized in the trypanosomal mRNA cap structure. The structure determinations were accomplished from sub-microgram amounts of cap 4 oligonucleotide without isolation of the unknown nucleosides. Knowledge of the cap 4 structure will facilitate studies directed toward chemotherapy of trypanosomal-borne diseases.

Acknowledgments: This work was supported in part by NIH grants AI21025 and GM29812 and by the Burroughs Wellcome fund.

Comparison of Assays on Thymine Glycol in Genomic DNA by EI vs PCI/MS/MS GC/MS

S.P. Markey, C.J. Markey and T.-C. L. Wang
Section on Analytical Biochemistry, Laboratory of Clinical Science,
National Institute of Mental Health, Bethesda, MD 20892.

Introduction

Accumulated oxidative damage to neuronal DNA bases has been implicated in disorders of aging such as Parkinson's and Alzheimer's diseases(1). In order to directly detect DNA damage, we have been developing GC/MS methods for measuring thymine glycol(2,3), a well characterized result of hydroxyl radical attack on DNA. We previously reported that thymine glycol can be converted to 2-methylglyceric methyl ester di-(tertiarybutyldimethylsilyl) ether for quantification(4). This derivative which appears to be satisfactory for GC/MS studies is a structurally specific product of base hydrolysis, sodium borodeuteride reduction, anhydrous acidic methanolysis and silylation of thymine glycol within intact double stranded genomic DNA.

As reported before, 0.5 mg DNA is required for electron ionization (GC/EI/MS) analysis. In search for a method to decrease this detection limit as well as to increase analysis specificity, ammonia positive chemical ionization followed by collision induced dissociation (GC/PCI/MS/MS) was performed and the results of both analytical methods compared.

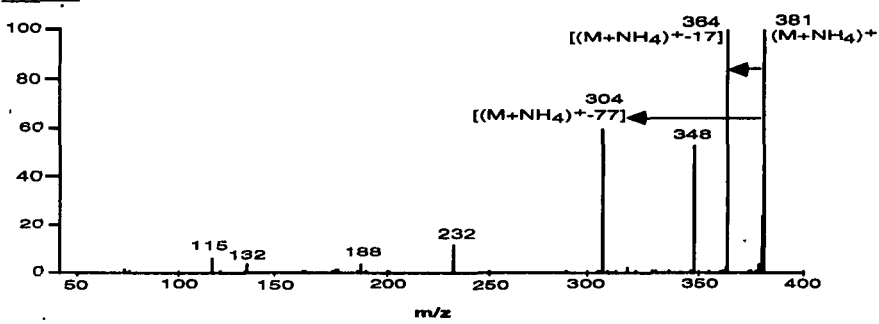
Experimental Methods

Procedure: A solution of the internal standard (d_4-thymine glycol, 16 ng/10 μL) is added to each tube. Then DNA (0.5-2 mg in 50-100 μL water) or thymine glycol quantitative standards (0.1-to-25 ng) are added, and 100 μL of $NaBD_4$ (10mM) in 0.2 M NaOH (prewashed with CH_2Cl_2 and stored in non-glass containers) is added next, and the mixture is heated for 1 hour at 37°C. All solutions are prepared fresh prior to use. The reaction is quenched with 100 μL of 6M HCl and dried in a vacuum desiccator. Anhydrous methanolic/HCl (200 μL, 0.5M) is added, vortexed, and heated for 30 minutes at 70°C. For the sperm DNA samples, the methanolic/HCl containing the 2-methylglyceric methyl ester was separated from the solid residue and transferred to new tubes. The samples are dried in a vacuum desiccator, and 100 μL of t-butyldimethylsilyl imidazole reagent (prepared from 150 mg t-butyldimethylsilyl chloride, 170 mg imidazole in 1 mL acetonitrile, washed five times with equal volumes of heptane) is added and heated at 70°C for 30 minutes.

The products are partitioned between 100 μL heptane/decane (90/10) and 100 μL water, and the organic phase is removed after freezing the tube with dry ice. The organic extracts in autosampler vial inserts are concentrated in vacuo to approximately 20-25 μL.

GC/MS: Comparisons of mass spectrometric response between GC/PCI/MS/MS and EI/MS/MS were performed on a Finnigan TSQ70 mass spectrometer equipped with a Varian 3400 gas chromatograph. A 15 meter, 0.25 mm i.d., 0.25 μ DB-225 column was programmed from 110°C (1 minute) to 220°C (1minute) at 35°C/minute, followed by a 40°C ramp to 240°C. The 2-methylglyceric methyl ester di-(tBDMS) ether elutes at 2 minutes 45 seconds, and is characterized by intense M-57 ions at m/z 306 (d_1), or 310 (d_5). For ammonia PCI/MS/MS analyses, ions with m/z 381 $[(d_1\text{-M})+NH_4]^+$ and 385 $[(d_5\text{-M})+NH_4]^+$ were selected as precursor ions and their product ions with m/z 364, and 368 $[(M+NH_4)^+\text{-}17]$ or m/z 304 and 308 $[(M+NH_4)^+\text{-}77]$ were measured.

Results



Ammonia GC/PCI/MS/MS of d_1-2-methylglyceric methyl ester-di-tBDMS ether ions chosen for selected reaction monitoring were losses of 17 or 77 daltons from $(M+NH_4)^+$.

Using $^2H_4$-thymine glycol as an internal standard, the linearity of standard curves was excellent over the range of 0.1-100 ng/tube with 100 pg/tube being the lower limit of detection for both modes of analysis. With EI, the measured thymine glycol in native (undamaged) salmon sperm and herring sperm DNAs were found to be indistinguishable (0.35 ng ± 0.07 SD and 0.38 ng ± 0.07 SD, respectively). By PCI/MS/MS the comparable values were 0.37 ng ± 0.12 and 0.41 ng ± 0.08. Linear responses with increasing quantities of salmon or herring sperm DNA from 0.5 to 2 mg have been obtained by both EI and PCI/MS/MS methods.

Conclusions

The similar results from EI and PCI/MS/MS indicate that there is no sensitivity or selectivity advantage to tandem mass analysis for this assay. We have observed that further sensitivity enhancements are possible through changes in derivatization procedures (less reagent, transfer of product with ethyl acetate). We are applying these analytical techniques to DNA from cell culture experiments with agents causing oxidative damage where increased thymine glycol concentrations are anticipated. DNA isolated from the brains of patients with neurodegenerative disorders such as Alzheimer's and Parkinson's diseases will be used to test whether unrepaired DNA damage is linked to disease progression.

Acknowledgments

We wish to thank the Alzheimer's Association for providing grant support (CJM).

Interface of a Commercial Visual Data Analysis Software Package to Mass Spectral Data Files

Sanford Shew, EXTREL FTMS, Inc., 6416 Schroeder Road, Madison, WI 53719

The contents of data files from scientific instruments are often inaccessible to users. Compounding this problem, it is difficult for the designer of an instrument data station to anticipate all future analysis needs of all users. Interfacing a powerful visual data analysis (VDA) software package with the data files of a commercial Fourier Transform Mass Spectrometry (FT/MS®) system greatly expands the mass spectrometrist's data analysis options.

The VDA and the data files interface run on a single Sun SPARCstation or on a network. Communication between the VDA and the data files is seamless and immediate, requiring no file conversion or intermediate temporary files. Control over access to the data files is entirely from within the VDA. Figure 1 illustrates the access the VDA has to data files; data and associated parameters can be both read from and written to files.

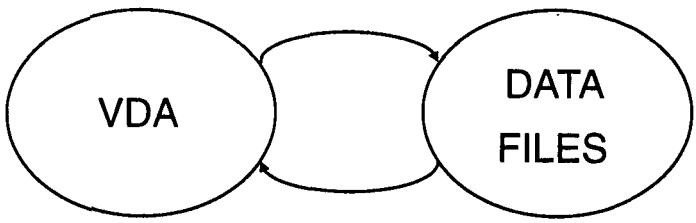

Figure 1. Schematic representation of VDA-data file interface.

The interface provides low-level, basic functions that directly interact with the data files, as well as higher-level functions that combine the basic functions and the VDA's own functions. The VDA offers extensive mathematical and graphical capabilities. In addition to standard mathematical functions, arrays and matrices are easily manipulated. Custom 2-D and 3-D plots can be conveniently constructed, and can be displayed in color on the workstation's monitor or written to PostScript® files and printed or included in a word processor document.

Since data and parameters can also be written to data files, intermediate processing steps can be done in the VDA and the results written to a data file that can be further processed by the FT/MS data station. For example, one may read a time-domain data file from the VDA, apply a novel apodization function, and write the apodized transient signal back to the data file. Processing may then proceed in the data station.

Data files from the FT/MS data station can also be post-processed. An example of this is display of ion abundances as a function of reaction time in kinetic studies. The results from such an experiment are shown in Figure 2, which shows the dependence on reaction time of the abundances of three ionic

species involved in ion/molecule reactions of methane. Mass spectra corresponding to different reaction times were processed in the FT/MS data station, and the various ion abundances were read and plotted within the VDA. Such specialized applications can be written quite efficiently, while also remaining reasonably general. For example, the abscissa in Figure 2 can correspond to any parameter that is varied by the spectrometrist, not just reaction time.

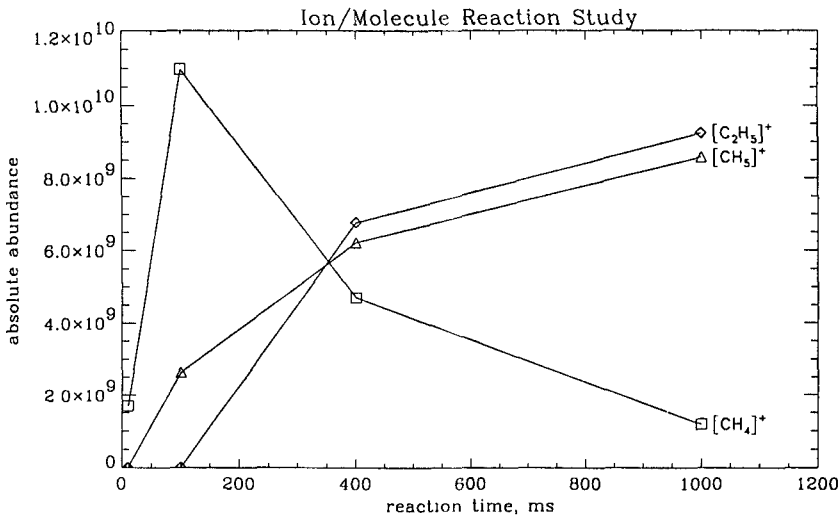

Figure 2. Example of co-processing by the FT/MS data station and the VDA.

Not only is the interface package useful for building user-defined processing tasks, but it also serves as a convenient test platform for determining if, for example, a new analysis algorithm shows sufficient promise for further development.

The Use of the Generalized Rank Annihilation Method for Mixture Analysis by Neutralization-Reionization Mass Spectrometry

Scott A. Shaffer, Karl Booksh, Ming Gu*, Yongdong Wang, Bruce R. Kowalski and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

Quantitative analysis of ion mixtures by tandem mass spectrometry using collisionally activated dissociation (CAD) *(1,2)* is based on linear superposition of the ion peaks formed from the individual components (eq 1a),

$$\mathbf{M}_{1D} = \mathbf{C}_M\mathbf{Y}^T \quad (1a)$$

$$\mathbf{M}_{2D} = \mathbf{X}\mathbf{C}_M\mathbf{Y}^T \quad (1b)$$

where $\mathbf{M}_{1D}$ is the matrix of normalized peak intensities (analyte responses) in the MS-2 spectra, $\mathbf{Y}^T$ is the transposed matrix of pure component MS-2 responses and $\mathbf{C}_M$ is a diagonal matrix of component molar fractions. For mixture analysis including isomeric ions and isobaric overlaps eq 1b holds, where $\mathbf{M}_{2D}$ is the response matrix, and $\mathbf{X}$ is the matrix of pure component responses in the MS-1 spectrum. Typically, a complete knowledge of $\mathbf{X}$ and $\mathbf{Y}^T$ is necessary to solve eq 1b for $\mathbf{C}_M$ unequivocally. However, the analysis of second order bilinear data (e.g., GCMS) can be accomplished by using the title method (GRAM) *(3)* to yield concentration estimates and pure spectra of a common component without the necessity of calibrating for spectral interferences, i.e. those from unidentified contaminants. With non-bilinear data (e.g. MSMS) GRAM analysis can provide component concentration ratios and thus be useful for mixture analysis. GRAM applications depend critically on the quality of information provided by the second-dimension (MS-2) technique. In this work we utilize the high information content of neutralization-reionization ('NR') mass spectra for model GRAM applications to quantitative mixture analysis. The spectra were measured on the Tandem Quadrupole Acceleration Deceleration (QADQ) mass spectrometer described previously *(4)*.

As model mixtures we used (i) 2-hexanone (component) and 1,4-bis-(dimethylamino)butane (contaminant) that give an EI mass spectrum with isobaric overlaps at *m/z* 100, 71, 58, 43, and 29 and (ii) 5-hexen-1-ol (component) and cyclohexane (contaminant) with fragment ions at *m/z* 29, 31, 39, 41, 54, 57, 67, and 82. 'NR' mass spectra (Xe/O_2, 70% transmittance) were taken of ions from one pure component and the mixture, while the contaminants were taken as unknowns. Due to the annihilation procedure, NR conversion efficiencies, component partial pressures, and ionization cross sections need not be known.

With mixture (i) response matrices were constructed from 25 channels (daughter ion relative intensities) in each 'NR' spectrum with zero filling for the spectra of *m/z* 29, 43, and 58. GRAM analysis of the NR data overestimated the 2-hexanone molar fraction in the mixture by 4-36% depending on the channels used for data evaluation. For mixture (ii) the Nonbilinear Rank Annihilation (NBRA) procedure *(5)* was used to evaluate the 'NR' spectra (Figure 1). The net analyte rank for 5-hexenol was estimated from singular value decomposition of the NRMS data for the pure analyte and mixture (ii). The concentration estimates can be narrowed down by the target factor analysis test yielding a 5-hexenol molar fraction in (ii) as 0.9-0.91, close to the true value (0.89). This estimate is consistent with the net analyte signal obtained from data analysis that essentially consisted of the NR spectrum of CH_2OH^+ which is unique for 5-hexenol. The presence of such a unique ion in the MS-1 spectrum of the target component appears to be necessary for obtaining reasonable concentration estimates. Analytical figures of merit (selectivity, sensitivity and limit of determination) were also calculated based on the estimated S/N ratio (76).

Computer-Assisted Interpretation of Copolymer Mass Spectra

Paul O. Danis and Francois J. Huby
Rohm and Haas Company, Spring House, PA 19477

With soft ionization techniques such as fast atom bombardment and field and laser desorption, mass spectra can be obtained showing the distribution of polymer molecular ions. There is a wealth of information available in these spectra, and it is usually difficult for the analyst to extract all the useful information. When the separate molecular ions can be resolved, the composition of the polymer can be proposed. For a homopolymer the interpretation is usually straight forward: any molecular ion is composed of *n* monomer units plus the end groups. However, when more than one monomer is used in the preparation of the polymer then the interpretation is not simple. For a copolymer molecular ion the quantities that must be determined are the mass of the monomers, the number of each monomer, and the end groups.

Though several approaches have been taken for the interpretation of copolymer mass spectra(1,2) ours is unique in that we make no assumptions about the mass or number of the monomers and end groups. The program we have developed will determine the most likely masses of the monomers and from these values then determine the most likely masses for the end groups. It is written in basic and runs on IBM PC or Macintosh systems.

The FAB mass spectrum of poly(N-vinylpyrrolidone/vinylacetate) is complicated and contains many species of varying composition and mass. The program can reduce this information to give the most likely monomer masses shown which are 86 and 111. The 112 is also large because of isotopic contributions, and most other possibilities are combinations of these values. There are several possible end groups values meaning that several end groups are present or there are merely some mathematical coincidences.

The possibilities can be greatly reduced by then considering chemical information such as logical compositions and possible end groups from known initiators and chain transfer agents. Often a single unambiguous result is not obtained. However, the greatest asset of this approach is that all possibilities are examined in contrast to the manual approach in which the analyst is often satisfied when a fit is found, and further inquiry is halted.

Future work includes the expansion of the data bases to include most reasonably common monomers, initiators, and chain transfer agents and their product end groups. The output will contain this information. Further refinement of the isotopic contribution correction is also underway. Finally monomer ratios and compositions for each peak in the spectrum will be determined.

UTILIZING AN APPLE MACINTOSH COMPUTER FOR TRANSFER, DISPLAY AND INTERPRETATION OF MASS SPECTRAL DATA

*Paul R. West[1], Paul W. Geno[2] and Andrew Mort[3]
[1]Department of Chemistry, Oklahoma State Univ., Stillwater OK 74078
[2]Southwest Research Institute, San Antonio TX 78228
[3]Department of Biochemistry, Oklahoma State Univ., Stillwater OK 74078

As rapid communication in chemistry becomes increasingly important, the need has arisen for better interfaces between various computer data systems. We have interfaced a VG ZAB2-SE mass spectrometer data system and a VG TS-250 mass spectrometer data system with a Macintosh Classic personal computer at a cost of less than $300. The computers are interfaced by connecting the serial output of the mass spectrometer DEC PDP-11/73 computers by way of an RS-232 cable to an A-B switch box which are connected to the modem port of the Macintosh with an RS-232 to mini-DIN8 modem adapter cable.

Data transfer is accomplished by using a DEC terminal emulator program, "Mac 240" by White Pine Software, run on the Macintosh in conjunction with Kermit file transfer on both systems. While running the Mac 240 program, the Macintosh acts as an auxiliary terminal for the DEC, thereby allowing mass spectra (and all other displays from the DEC) to be viewed on the Mac. This software allows both text and graphics to be cut and pasted into other Mac programs. The VG software is capable of generating an ASCII mass spectrum list file which can be transferred directly to the Mac using Kermit, thereby allowing processing and storage of the data on the Mac hard disk or floppy disk.

Two original programs have been written for the Macintosh which allow display, graphical enhancement and data interpretation of a mass spectrum list.

SpectraGraph

This HyperCard program allows graphical display and manipulation of an input mass spectrum list on a Macintosh. The mass spectrum list may be entered manually or input automatically to SpectraGraph using the transferred ASCII file as described above. Some of the mass spectral display features of SpectraGraph include variable display mass range, normalization of the mass spectrum display, multiplication of a defined mass range of the display, manual and automatic peak annotation with 0 to 4 decimal places and the ability to save any particular display for later recall.

A complete set of drawing tools is available, enabling the user to draw and rearrange graphics (such as structures, labels etc.) directly on the spectral display. The entire display may be copied and pasted into other application documents or graphics and/or text may be copied from other application documents and pasted onto the display. The mass spectrum list may also be output automatically to SpectraSort for further interpretation.

SpectraSort

Another original HyperCard program, "SpectraSort", has been developed to aid in the interpretation of mass spectra. SpectraSort uses a simple "mass loss" algorithm to find mass differences between peaks in the spectrum. Determining these mass differences can be very helpful for chemical structure elucidation. The mass spectrum may be entered manually or input automatically as described above. SpectraSort then calculates mass differences between peaks in the spectrum according to parameters defined by the user. Once these mass differences are calculated, the user has the option of matching them with expected mass losses of known fragments stored in several user-definable look-up tables. Included with the program are several residue tables containing masses of common amino acids, saccharides and EI common losses.

Both programs include user manuals and help stacks. These programs are both available as shareware for a small fee to cover expenses.

Determining Congener-Specific Polychlorinated Biphenyls In Human Serum by using Isotope Dilution Mass Spectrometry: A Proposed Data Acquisition and Management Scheme

*Cynthia C. Alley, Barnett F. Smith, Jr., Margaret P. Korver, and Virlyn W. Burse

National Center for Environmental Health and Injury Control, Centers for Disease Control, Public Health Service, U.S. Dept. Health and Human Services, Atlanta, GA 30333

The number of PCB congeners that might be found as residues in human matrices (at least 53 out of 209 have been reported) and the complex nature of the matrices themselves coupled with the presence of other environmental contaminants (e.g. pesticides) makes the use of high resolution gas chromatography with selective detection (HRGC/MID) necessary to discriminate PCBs from other components of the sample matrix. We recognized early, during the development of an analytical method to determine polychlorinated biphenyls (PCBs) in human serum by using isotope dilution mass spectrometry (IDMS), that the voluminous amount of data generated by such an approach precluded the use of manual data handling techniques from a practical perspective. Because of the unwieldy data handling problems an automated approach to management of this type of data was investigated and is the subject of this report.

We propose the use of an semi-automated data handling system consisting of the following software:

- **Finnigan MAT 4500 GC/MS with Incos™ Data System**

  A procedure (ASRPCB) operates a CTC A200S autosampler and the GC/MS at night. Data are acquired in Negative Chemical Ionization (NCI) mode in 4 MID windows containing 3 chlorine groups each. A minimum of 25 specific PCB congeners and their corresponding ^{13}C-labelled isotopes have been targeted. After acquisition a procedure MAKEPA converts .TI and .TX files to .EP files (44 min/datafile).

- **XFER**

  A program designed to exchange files between MS-DOS systems and Incos™ data systems via an RS-232 link allows the use of a batch process to transfer the .EP files (~26 min/datafile).

- **PKZIP**

  The .EP files (~1.2 Mbytes each) are compressed prior to being archived on diskettes.

- **DataMaster™**

  ACON is used to convert the .EP files to .DAT files for PCDS. Analytes are identified by retention time (RT), automatically integrated and written into a quantitation list, and hardcopies made. The integration report consisting of the compound name, quantitation mass, scan #, RT, area, and height is captured into a file. All processed files are also archived on diskettes.

- **RBase 3.1**

  An ASCII text editor is used to remove the printer control language (PCL) and reformat the files for loading into the Rbase 3.1 database. The data is imported into a temporary table in the database and then loaded into the storage table. Isotope ratios are calculated upon loading. After verification of data, various data sets are exported to an ASCII file for statistical analysis.

- **PC-SAS**

  Standard curves are generated. Slopes, intercepts, and amounts of each congener are calculated in SAS. Quality Control/Quality Assurance Charts are constructed.

- **Advantages**

  Using an MS-DOS based PC for data processing releases the GC/MS for data acquisition. There are more archival options. The data is easier to retrieve. PCs are less expensive and more versatile than stand-alone Incos data systems. Larger volumes of data can be handled in RBase and PC-SAS.

- **Disadvantages**

  Data conversion and transfer are very time consuming. With the current version of PCDS, the types of printers supported are extremely limited and the data processing is not as flexible with Incos™.

Automated Writing of Selected Ion Recording (SIR) Descriptors and Plotting of Mass Peak Profiles from SIR Data

Andrew H. Grange, Lockheed ESC, 1050 E. Flamingo Rd., Las Vegas, NV 89119
William C. Brumley, EMSL, USEPA, P.O. Box 93478, Las Vegas, NV 89193-3478

Introduction. Accurate mass determinations often permit the elemental composition of ions to be discerned. When multiple ions could be present at the same nominal mass, high mass resolution can be used to prove their absence or, when present, to document or correct for interferences. However, with high resolution the scan time for full scan modes is too long to follow the contours of chromatographic peaks in GC/MS and ions with low abundance do not provide an adequate signal. Both cycle time and sensitivity limitations are mitigated when mass peak profiles are constructed from selected ion recording (SIR) data. But alas, the VG 250 data system cannot plot the profiles. This abstract illustrates automated procedures for writing a SIR descriptor and for plotting mass peak profiles from the data acquired with it.

A mass peak profile. In Figure 1 the plotting of a mass peak profile is demonstrated for a compound that elutes from a chromatograph. The areas under 21 ion chromatograms, corresponding to the expected mass and 10 progressively smaller and larger masses, are integrated and plotted to provide the mass peak profile. The mass increment depends on the resolution used, but is limited to ~5 ppm before repeated points appear on the mass peak profile due to digitization limitations of the data system.

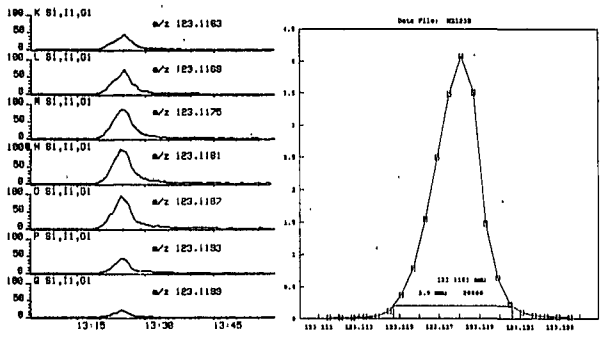

FIGURE 1. The areas under the 7 ion chromatograms were used to plot the mass peak profile.

Writing the SIR descriptor. Entering 21 m/z ratios for the analyte and 2 for the reference mass is a tedious and error prone task. A DOS batch file performs this task automatically in 2 minutes using R4 software to link the VG data system and an IBM PC (286 16 MHz). The batch file runs LOTUS, WP and R4 programs, successively. The operator enters the center mass, the mass increment and the reference mass into the LOTUS spreadsheet shown in Figure 2. The LOTUS program writes R4 code, which is saved as an ASCII file. The ASCII file is then run as an R4 program to enter the m/z ratios into the menu of the SIR descriptor. The program ends with the menu on the PC's video display to permit review or change of entries.

123.1235	0.0006	21000

Enter the estimated mass: **123.1181**

Enter the mass increment: **0.0006**

Enter the Reference mass: **118.9920**

Resolution of peak with 10 points: **20520**

FIGURE 2.

After the center mass is entered, the mass increment for each resolution that will provide 10 points across the ion profile is listed. In this example the first 2 m/z ratios are the lock mass.

Plotting the mass peak profile. After data is acquired with the SIR descriptor, a DOS batch file invokes an R4 program, which in turn invokes a VG RUN program to determine peak areas. The R4 program copies the peak areas into the LOTUS directory of the PC, after which, a LOTUS program plots the mass peak profile. Finally, a WP program imports the plot into a document. The operator enters only **P XX:XX YY:YY**, where XX:XX and YY:YY are the start and end times of the chromatographic peak, to obtain the mass peak profile at the end of the WordPerfect document chosen beforehand by the user. 3 minutes is required. The portion of the spreadsheet containing the information that yields the plot in Figure 1 is shown in Figure 3. The x and y coordinates for each point are in the first and second columns, respectively. The data labels option is used to add the labels in the third column to the XY plot.

FIGURE 3. The m/z ratios, areas and labels used to plot the mass peak profile.

Multiple mass peak profile processing. One can plot the SIR data acquired for a prior run and prepare a new SIR descriptor while data is being acquired. However, it is often convenient to process batches of mass peak profiles. A LOTUS program was written to write a DOS batch file to run the software outlined above for multiple data files or for peaks within a data file.

Software description. A detailed description of the DOS 3.30, LOTUS 123 v2.2, WordPerfect 5.1, Reflection 4.1 and VG B2.2 software used to perform these tasks is available from the author upon request.

Application. Mass peak profiles plotted from SIR data can be used to:

- determine the accurate mass of ions
- document the mass resolution at a mass as a compound elutes
- determine the relative abundance of two ions
- correct for interference between a quantification and an interfering ion, and
- document the resolution necessary to discriminate against an interference.

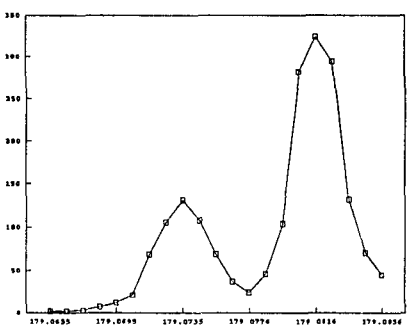

FIGURE 4. Ion profiles for 2 molecular ions that have similar masses.

Several of these applications are illustrated by Figure 4. The accurate masses of the two ions are 179.0735 amu and 179.0816 amu, the resolution is about 22,000, the area under the larger peak is about 2.5 times the area of the smaller peak, and a resolution of at least 20,000 is necessary before one can monitor either peak without interference from the other in this sample. The reference further describes the utility of mass peak profiles obtained from SIR data.

Interfacing Spreadsheet and Word Processing Software to the VG 250 Data System

Andrew H. Grange, Lockheed ESC, 1050 E. Flamingo Rd., Las Vegas, NV 89119

Introduction. The software of the VG 250 data system is less versatile and user friendly than common spreadsheet and word processing programs. The manufacturer has incorporated such software into the Opus 2000 data system to improve efficiency. There are, however, many 250 data systems in use. Described herein is a software suite composed of DOS 3.30, LOTUS 123 v2.2, WordPerfect 5.1 (WP), Reflection 4.1 (R4), VG B2.2 and RSX, which provides access to a spreadsheet and word processor on an IBM personal computer (PC). In addition, the software used to link the computers enables the user to write fully automated procedures to acquire data, process the data on either computer, plot data and incorporate results into a final document or form.

Role of each Software

Director. DOS batch files are executed on the PC to direct a procedure through the programs written in the other softwares. At the end of each program, an exit instruction returns execution to the next statement in the DOS batch file. In Figure 1, the emboldened commands invoke programs written in LOTUS, WP and R4.

```
CD \REFLECT
R4,PROF.RCL %1 %2 %3
CD \123
123 -wPROF
CD \WP51
WP /m-TMP
```

FIGURE 1. A DOS batch file that invokes programs in other softwares. Global variables from the DOS call-up command can be used by Reflection 4 programs.

Thinker & Writer. LOTUS serves as the brains of the software suite. Calculations, decisions and the writing of software are done by LOTUS commands. These commands can be executed sequentially as a program or stored within individual cells, where they are executed immediately, when data is input into other cells from which the commands extract values or labels. In addition, LOTUS provides string manipulation operators, sorts data bases, allows linkage of spreadsheets and stores results as ASCII files. The versatility, execution speed and the ease of writing and debugging code in LOTUS relative to the other softwares, makes it the preferred language to perform many tasks.

Reporter. WP is the document preparation software and can import plots directly from LOTUS spreadsheets. WP programs to produce attractive forms with shadow boxes and emboldened or underlined entries have also been written.

The Great Communicator. Reflection 4 links the two computers; files can be transferred in either direction, which facilitates integration of software on the two computers into one package by using DOS batch files. VG and RSX programs are invoked from R4 and the ASCII files generated by them are transferred and saved in any directory chosen by the user on the hard drive of the PC. As a terminal emulation program, R4 also provides a second terminal for the VG data system. It costs less than $250.

Data Acquisition and Minimal Processing. The VG software is used to acquire data and to generate ASCII report files in the normal manner. Lists of m/z ratios, retention times and peak areas are transferred to the PC for further processing in LOTUS. RUN procedures are invoked from the ancillary computer by R4.

File manipulation. RSX is used for file manipulation on the PDP 11/73 computer. RSX commands are issued from the ancillary computer through R4 or by MCR commands within VG RUN programs.

Complexity. At first glance, the use of 5 softwares might appear complex. However, operators already know VG and RSX and many are also proficient with LOTUS and WP. R4 is straightforward

and required less than two weeks to install and learn well enough to utilize its terminal emulation, data transfer and command transmission capabilities. Proficiency with LOTUS and VG is essential, while less thorough knowledge of the other softwares is required. Soon, the software suite is viewed as a package, with DOS, LOTUS, R4, WP, VG and RSX accepted as parts of the whole, just as CHR, SPE, LIS, PKD, PKS, and other programs are accepted as parts of the VG package, with each serving specific functions. The advantages of using this software suite are considerable.

Advantages of the Software Package

Speed. Code preparation is at least 10 times faster and execution is at least 5 times faster in LOTUS on a 286 12 MHz PC than in VG on a PDP 11/73 computer.

Simplicity of use. For batches of samples, a LOTUS program can write the DOS and R4 programs necessary to acquire and process the data. Any operator need enter only the samples' names, weights and other information specific to each set of samples. The operator's skill level can be low and detailed recall of a method, which has not been done recently, is not required.

Modified easily. Code can be added to perform additional tasks or to include new criteria as they are specified and lessons learned by the operator can be added to the program. Labs with specific needs, unforeseen by the manufacturer's programmers, can address them in their own procedures.

Independence. The code that processes data is no longer a mystery known only to the manufacturer. Numerous in-house people can access and modify the code for minimal cost.

More instrument time. Because most of the software is written in LOTUS, several procedures can be developed at a time on PCs at other locations. Meanwhile the instrument is not tied up by the writing and debugging of VG code. Academics with few machines and with many students might benefit, and their students would graduate with programming experience having wider applicability.

Non-obsolescence. Software written to perform analyses remains usable when a new data system is purchased, as long as the new system provides ASCII files.

Rapid hardware updating. Faster PCs are available each year. One need not wait for the next generation of a data system to gain speed for most of the data processing.

Broad Applicability. With the substitution of Reflection 7 for R4, the software suite has been used to automate low resolution dioxin analyses on an HP RTE-A data system. The softwares on the PC can be interfaced in similar fashion with other cumbersome data systems that provide ASCII files and are not limited to instruments used for mass spectrometry.

Criteria checking as data is acquired. Data quality can be checked as it is acquired. For example, when multiple SIR descriptors are used, the data for one group can be checked as the next group is being acquired. For GC/MS analyses of multiple samples, the column temperature can be maximized to flush out the column more rapidly when a fatal criterion violation is found. The time saved might be enough to run another sample before the next quality assurance run is required.

Criteria checking during data processing. Criteria violations can be noted on output forms. A "V" next to an entry indicates that a criterion was violated. The absence of "V"'s means that all criteria that apply to a form were met.

Automated decisions for data acquisition. When an autosampler that can be controlled by the data system is used, a GC/MS run with a fatal criterion violation can be evaluated and repeated before additional injections are made. Instructions to repeat the injection are written in LOTUS, stored as a Reflection file and executed before continuing with later samples. By using LOTUS to monitor time (@NOW), continuing calibrations are run as required.

Calculation of Pharmacokinetic Parameters Using PC Spreadsheet Macros

*S. Carlsen, M. J. Hayes and M. L. Powell,
Clinical Pharmacokinetics and Disposition, Pharmaceutical Div.,
Ciba-Geigy Corp., Ardsley NY, 10502.

A macro package has been developed that provides an easy, dependable and efficient method for calculating various pharmacokinetic parameters in Microsoft® Excel (Version 3.0 or later). Raw data from quantitation programs utilized on Nermag R10-10C systems equipped with Digital PDP-11/73 computers are easily stored in ASCII files, which can be transferred to a PC and converted into spreadsheets for further computations by the macro package. It is not necessary for the user to be well versed in all Microsoft® Excel functions. Once the macro package is installed, the user can access its utilities directly from the Excel menu bar as shown in Figure 1.

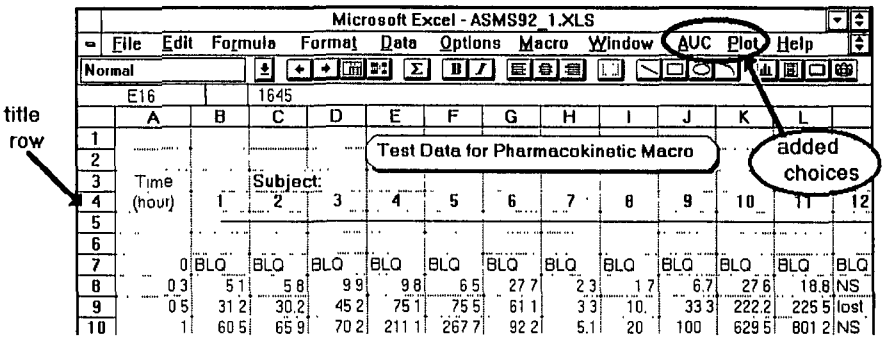

Figure 1: The Excel enverionment utilizing the pharmacokinetic macro package.

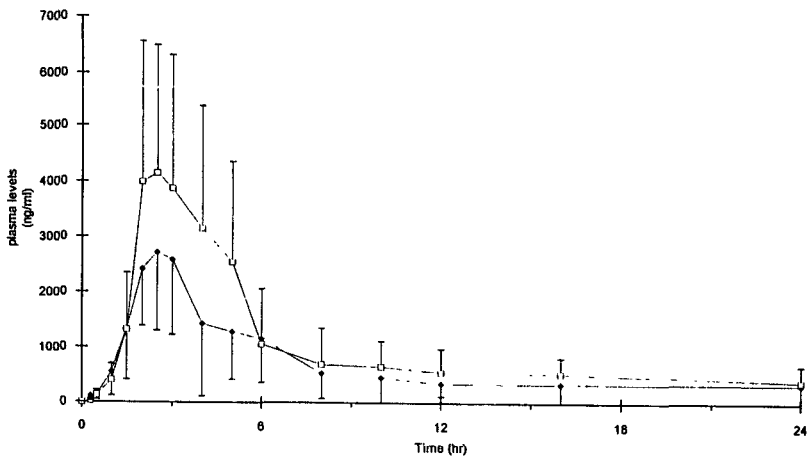
Cmax (maximum concentration), Tmax (the time corresponding to Cmax), AUC(0-T) (area-under-the-curve from time 0 to time "T"), AUC(0-inf) (extended area-under-the-curve), and t1/2(terminal elimination half-life) are among the calculable parameters. The user can obtain incremental and cumulative area data and include subject plots automatically. The macro package can handle multiple sets of subject data simultaneously. Alphanumerics present among the concentration data (such as "NS" for "no sample", or "BLQ" for "below the limit of quantification") are adequatley handled by the macro package When multiple sets of concentrations are used, statistics (average, standard deviation, standard error, coefficient of variation, minimum, maximum, and count) are produced for concentrations and all calculated parameters. When t1/2 and/or AUC(0-inf) are calculated, the associated correlation coefficients are produced.

Whenever the macro package is used to calculate AUC's and other parameters, two resultant spreadsheets are produced. One spreadsheet contains all data, both input and output; the purpose of this spreadsheet is to show precisely which input data is associated with which output data. The second spreadsheet contains a summary of the output data.

The macro package can also be utilized for calculating and recalculating multiple elimination half-lives for a single set of subject data. It can be used for examining various types of regression calculations (linear, weighted linear, non-parametric, log-log, and log-log with correction) on a single set of data, producing all the regression parameters. It can be used to generate a plot containing one or more curves from multiple spreadsheets. It can be used to generate a plot containing one or two curves with associated error bars (see Figure 2 below).

Figure 2: A plot with user-defined error bars generated by the Pharmacokinetic Macro Package.



Flexible File Format and Library for Storage of Mass Spectral Data

*R. Kent Wenger, EXTREL FTMS, Inc., Madison, WI 53711

Introduction

A new, highly flexible, file format, supported by a powerful programming library, provides many benefits for the storage of mass spectral data The file format accommodates spectral data of any size, as well as an unlimited number of parameters, text, and hypermedia (audio and/or video) data

The spectral data can be 16-or 32-bit integers or 32- or 64-bit IEEE floating point numbers The data type and number of elements stored can be changed at any time, and any portion of the data can be read or written without disturbing the rest of the data.

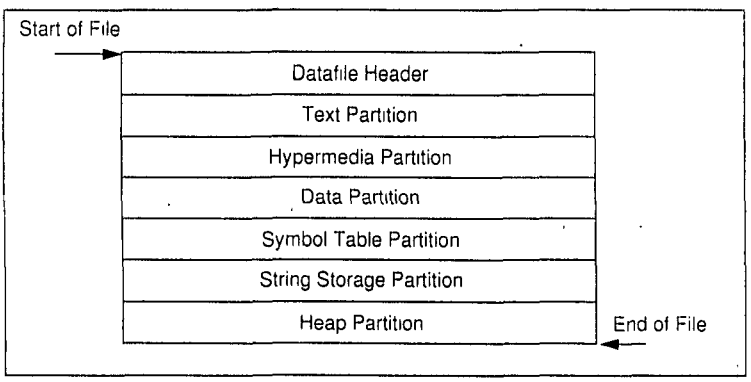
The datafile parameters are stored in a symbol table, with the following advantages. the number of parameters is unlimited, and parameters can be added or deleted at any time, parameters are accessed by name, not by a fixed address or offset; parameters can be scalars or arrays of characters, strings, booleans, integers, or floating point numbers, and the type and size of a parameter can be changed at any time Any unused parameters do not exist in the file, thus saving space Because the file format and library place no constraints on parameter names, these files can be used to store any type of data

The programming library is provided to users, allowing them to write custom applications that access the data, including adding their own parameters. The library also has provision for transparent access to other file formats, allowing easy data interchange for both commercial software and user-written software The files also maintain information such as byte order and processor type, aiding access on various system architectures.

The library is designed to allow large data sets (for example, a data set of 1M 32-bit floating-point numbers can easily be accommodated). To the greatest degree possible, the library has been implemented without fixed limits to allow data size and library performance to increase with continuing progress in the development of storage media.

File Structure

FIGURE 1 Datafile Layout.



Each partition contains a certain portion of the data within the file The contents of each partition can be accessed separately (other than the symbol table, string, and heap partitions, which are tied together)

The size of any of the partitions can be changed at any time, without regard to the data contained in other partitions For example, if the user enlarges the hypermedia partition, all of the following partitions are moved back in the file automatically by the library The application program never has to know the exact location of each partition within the datafile.

Use of the Datafiles Library

The following are examples of calls to the datafiles library All calls to the library use a *filehandle* (an opaque data type) to identify the datafile. Most datafiles library calls return OK or FAILED to indicate the result of the operation. If an operation fails, the program can retrieve detailed information on the error from the library.

All constants used by the library (for example, OK, FAILED, PARM_TYPE_INT32, etc) are defined in header files that are included by the program using the library.

Parameters are always accessed by name, not by a fixed location in the file

- Read a parameter value.

```
param_name = "Data_Count";
if (Df_ReadParameter(fhandle, param_name,
    &value_buffer) != OK)
{
    (handle error condition)
}
```

- Create a new parameter.

```
param_tag = PARM_TAG_USER;
param_type = PARM_TYPE_INT32_ARRAY;
param_size = sizeof(param_array);

if (Df_CreateParameter(fhandle, param_name,
    param_tag, param_type, param_size) != OK)
{
    (handle error condition)
}
```

- Write a parameter value:

```
if (Df_WriteParameter(fhandle, param_name,
    param_array) != OK)
{
    (handle error condition)
}
```

Conclusions

- The library was originally designed for mass spectral data, but could be used for any kind of data, since parameter names, types, etc. and the type of data are not constrained by the datafile structure or library.
- Parameters can easily be added without having to worry about obsoleting already-existing datafiles, since parameters are always accessed by name.
- The library has provisions for accessing other file formats with the same function calls by defining other file types. This allows future use of other formats without any change to application programs.
- Parameters don't exist unless they are created, so there is no penalty for having a very large set of possible parameters.
- The flexibility of the file format and library mean that future changes to data storage requirements can be accommodated with a minimum amount of effort

Expanded Data Base of 220,000 mass spectra of 190,000 compounds

Millions of unknown mass spectra are generated annually from literally thousands of mass spectrometers worldwide for routine analytical problems. Computer identification by matching unknown mass spectra against a reference file is an absolute necessity for which the quality and diversity of the reference mass spectra obviously are crucial factors. The Wiley Registry of Mass Spectra Data, the most comprehensive reference file of electron-ionization mass spectra, has now been expanded from 140,00 spectra of 118,000 compounds (1989 Edition)[1] to 220,000 spectra of 190,000 compounds. Our data entry program provides the ability to check the errors from manual entry, such as formulas and spectral data. A sophisticated program assigns Chemical Abstracts (CAS) Registry numbers to these compounds using their literature references, elemental compositions, and names, searching against CAS Online. A single answer was returned for about 75% of compounds searched; for multiple answers, the correct compound was selected manually. This process also provided a further check of the entered names and formulas of spectra. Multiple spectra of the same compound in the expanded database were identified using their CAS Registry numbers. For those compounds with no CAS numbers, the identifications were made by using either the compound name or the Probability Based Matching (PBM) algorithm. Multiple spectra of the same compound obtained under different experimental conditions are retained in the database to increase the matching probability.[2] For further error detection, all spectra are examined manually and cross-compared using the PBM algorithm.[2] This expansion of the data base has mainly involved new areas of mass spectral information, thus improving the capability for identifying a broader range of unknown compounds.

A set of 5459 mass spectra were obtained from a third party source and used as unknowns to test the ability of the Wiley Registry, 5th Ed, and the NIST/EPA/NIH library to give good matches. As with true unknowns, there was no assurance that a correct answer for any of the unknowns was in either reference library. Using BenchTop/PBM, a mass spectral search system running under Microsoft Windows, the Wiley Registry gave high reliability matches for a much larger fraction of the unknowns than did the NIST/EPA/NIH library. For example, the Wiley gave a hit of at least 90% predicted reliability for about 50% of the unknown spectra, while the NIST/EPA/NIH gave such a high match quality for only 31% of the unknowns.

A second test was done to compare the ability of the two databases to return correct answers as the best reported matches. Of this set, the 3532 spectra that were in both libraries were used to generate

statistics on the ability of each database to retrieve correct answers. As Table 1 shows, the Wiley retrieves about half the number of incorrect answers as does the NIST database. This is probably due to the inclusion of multiple spectra of the same compound in the Wiley, which gives a much better chance of having a spectrum similar to the unknown. In addition, extensive corrections have been made to the Wiley spectra over the years.

Table 1. Position in Hit List of Best Correct Answer for 3532 Unknowns

Hit List Rank of Correct Answer	Wiley #Retrieved	Wiley Cumulative%	NIST #Retrieved	NIST Cumulative%
1	2859	81	2156	61
2	114	84	199	67
3	28	85	62	68
no correct answer	485	14	1012	29

TESTING AND OPTIMIZATION OF MASS SPECTRAL SEARCH ALGORITHMS

S.E. Stein, NIST, Gaithersburg, MD 20899

A file of 12,600 good quality replicate spectra taken from the NIST mass spectral archive file was used to measure the performance of a variety of mass spectral comparison functions. Searches were done against the 62,200 spectra in the NIST/EPA/NIH collection using a modified version of the NIST PC database software. In addition to obtaining quantitative measures of search performance, the present analysis led to the development of a highly discriminating means of estimating the likelihood that a retrieval is correct.

SEARCH PERFORMANCE

A variety of simple comparison functions have been tested for their ability to correctly identify unknown compounds. Table I shows results for six different functions, with several variations. A comparison with published results for PBM against the Wiley Registry is also given.

TABLE I Percent of Unknowns Retrieved at Top Hit List Positions

Function	% Correct At Position			Scaling
	1	1-2	1-3	
Dot Product[a]	71.3	83.7	88 4	m1,a1
Dot Product[a,b]	71 6	84.1	88.6	m1,a1
Dot Product[a,c]	71.2	83.7	88.4	m1,a1

The "dot product" of the reference and unknown spectra gave the best results. Effects on performance of various mass and abundance scaling factors are given in Table II.

TABLE II. Percent Correct Top Hits for Different Scaling Factors

MASS^m

m							
0	.5	1	2	3	4	5	6
68.9	70.1	71.3	**71.9**	71.8	71.0	69.9	68.3

ABUNDANCE^n

n						
.9	1	1.1	1.2	1.3	1.5	2.0
69.8	71.3	71.7	72.0	**72.2**	71.7	68.5

PROBABILITY THAT A HIT IS CORRECT

Analysis of results led to a new method for reporting search results. This involved factoring the probability of a hit being correct into two probabilities: 1) that a retrieval is correct **assuming the unknown compound is in the database**, and 2) that the unknown compound actually is in the database. The first probability can be extracted directly from search results using DIFFERENCES in similarity values reported in hit lists. A relative measure of the latter was obtained by comparing results with the test compound in the database with results in which is was (logically) removed. The similarity value of the best hit and the largest difference in similarity value in the hit list correlated strongly with the latter probability. The resulting probabilities for a hit being correct are highly discriminating and considerable better than would be obtained without the use of relative similarity values.

CONCLUSIONS

1) The "Dot Product" function is uniquely effective for identifying compounds.
2) A simple adjacent peak ratio function improves "Dot Product" function performance.
3) Commonly used scaling, $Mass^1 * Ab_{library}^{1/2} * Ab_{unknown}^{1/2}$, is near optimal, but may be slightly improved.
4) Spectrum "normalization" does not improve performance.
5) Separation of the probability that a hit is correct in two more fundamental factors along with use of differences in similarity values leads to a powerful new way of reporting results of library searches.

EFFICIENT MASS SPECTRA LIBRARY PRESEARCH

Brahim El Abbassi, Hélène Mestdagh, Christian Rolando

Ecole Normale Supérieure, Département de Chimie,
Laboratoire de l'Activation Moléculaire, URA 1110 du CNRS,
Laboratoire associé à l'Université Pierre et Marie Curie,
75231 Paris Cedex 05, France

Library search of mass spectra involves a presearch step selecting rapidly a subset of spectra to be matched with the unknown. This subset must at the same time : (i) include the 'right' library spectrum, which may be substantially different from the experimental spectrum; (ii) contain a limited number of spectra.

The existing methods, generally based on the similarity of the highest peaks of the spectrum, are unsatisfying concerning these points : (i) elimination of the 'right' spectrum may occur when the experimental and library spectra have been recorded under different conditions (e.g. unknown from GC/MS); (ii) the number of preselected spectra is too large for compounds whose highest peaks correspond to very common ions, e.g. alkanes.

Description of the method

All the library spectra are characterized by a few parameters which are stored in presearch files. The presearch program uses these files to select the spectra whose parameters are in agreement with those of the unknown.

In order to reflect the whole pattern of a spectrum, various kinds of parameters have been chosen for its characterization, as human recognition would proceed.

To take in account the variability of the spectrum obtained from a given compound, distortion of the experimental spectrum allows to define an acceptable range for each of these parameters.

The mass range is divided in two parts : low mass from 50 to 119, high mass above 120. Parameters defined separately on each mass range are much less sensitive to instrumental variability than if taken on the full mass range.

Each library spectrum is defined by four parameters :

1 - Mass barycenter for the low mass range (rounded to integer).

2 - Mass barycenter for the high mass range (rounded to integer).

3 - Mass of the most significant peak : this peak is the highest in the high mass range if its intensity is > 50%; in the opposite case, the base peak is retained as most significant.

4 - General intensity pattern : in each mass range the intensity of the highest peak may be zero, small (< 10%), medium (10-50%) or large (>50%). This results in 7 possible combinations, coded by a character.

The presearch for an unknown proceeds by the following steps :

1 - Determination of parameter range

- Identification of general intensity pattern
- Labelling of all the significant peaks (> 70% in the low mass range, >40% in the high mass range)

- For each mass range : determination of mass barycenter Mb, then distortion of the spectrum : for each peak (mass M, relative intensity in % I) : if M > Mb, I_{lb} = I/F, I_{hb} = I*F; if M < Mb, I_{lb} = I*F, I_{hb} = I/F; The factor F increases with decreasing peak height : F = 1.1+10/(I+10).
The mass barycenters of the distorted spectra corresponding to intensities I_{lb} and I_{hb} give respectively the lower and upper limit for the barycenter acceptable range.

2 - Search of the appropriate presearch files and selection of library spectra fulfilling the criteria : (i) general pattern not too different from the unknown, (ii) both barycenters in the acceptable range; (iii) significant mass included in the labelled set

Results

1 - Presearch on library spectra

The library used for filling presearch files was the EPA/NIH Mass Spectral Data base from NSRDS, containing 42000 spectra.

The presearch procedure was run on 1000 spectra sampling this library. As expected the initial spectrum was always retrieved among the selection. The number of selected spectra varied from 1 to 472, with an average value of 48. The average presearch time was 5 seconds per spectrum.

2 - Presearch on experimental spectra from GC/MS

Experimental spectra were obtained from GC/MS of Chrompack column test mixture on a Nermag R10/10 quadrupole mass spectrometer fitted with a Girdel capillary column. The raw GC/MS data have been analyzed using our GC/MS data treatment program (1).

Compound	Number of selected spectra	Retrieval ?
1-Octanol	297	Yes
2,6-Dimethylphenol	27	Yes
Undecane	54	Yes
Methyl octanoate	54	Yes
2,6-Dimethylaniline	18	Yes
Naphtalene	49	Yes
Dodecane	115	Yes
1-Decanol	279	No
Tridecane	292	Yes
Methyl decanoate	10	Yes

Conclusion

Although several of the experimental spectra had intensity distributions fairly different from the corresponding library spectra, the correct spectra were always retrieved except in one case (with 1-decanol the presearch failed because the experimental spectrum had no peak at all in the high mass range, whereas the (M-18) ion at m/z 140 appeared in the library spectrum). The number of selected spectra is often very low, leading to a quick subsequent recognition, and remains reasonable even in the case of alkanes.

A USER-CONFIGURABLE PLOTTING ENVIRONMENT FOR MASS SPECTRAL DATA

Tracy L. Snyder Walder
EXTREL FTMS, Inc., 6416 Schroeder Road, Madison, WI 53711-2424

Over the past several years, the availability of computers with improved graphics capabilities has increased dramatically. The scientific community now demands a higher quality user interface and graphics output from analytical applications software than ever before. With the large number of word processing and desktop publishing programs now available that can import graphics directly into a document, the ability to easily configure and generate these high-resolution graphical figures becomes paramount to data analysis and visualization software. It remains difficult, however, for a designer of such a software package to anticipate all of the needs and desires of its eventual users [1].

The software presented is used for visualization and analysis of data acquired from the powerful Fourier Transform Mass Spectrometer (FT/MS®). The primary objectives of the software design were:

1. Compliance with the OPEN LOOK™ graphical user interface (GUI) standard [2].
2. High degree of flexibility for user configuration of the layout.
3. Graphical output in a standardized format (PostScript®). This is necessary so that the graphics can be imported into a word processing program for producing technical papers.
4. Generating WYSIWYG (What You See Is What You Get) output.

A novel facility of this software is the ability of the user to configure reusable page layouts to his or her own taste, analogous to creating document templates within a word processor. These page templates can be set up to contain one or more plots of any size on a page. Plots on a page can overlap one another if desired. The page layout can be changed by modifying properties of each specific plot as desired from a plot properties window. There are a number of categories for the plot properties, including colors, axes, fonts, drawing options, and size and location. These properties can be changed at any time, even when the plot contains active data. An example of the properties window for drawing the X and Y axes is shown in Figure 1.

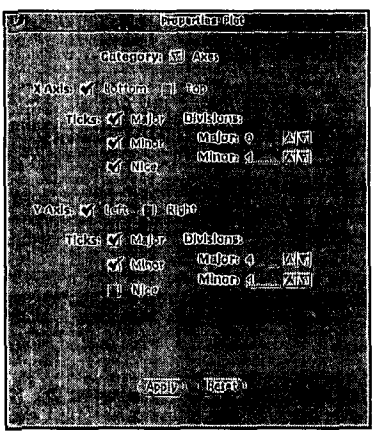

Figure 1. Plot Axes Properties Window

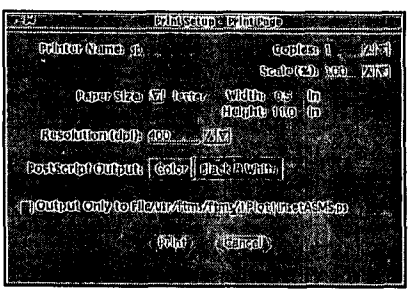

Figure 2. Print Window

Arbitrary text strings can also be placed on a page, which can be used for sample and personnel identification, figure captions, annotating data features, etc. The text string, font, angle, color, etc. can be modified from a text properties window.

After data has been loaded into a plot, additional data display parameters such as the X-axis start and end limits can be set from a plot information window. This window also displays relevant information about the data in the currently selected plot, such as the data file name and mouse pointer location (if the pointer is currently in the data region of a selected plot). If peaks are present, the threshold and number of decimal places used for labeling the peaks can be set and applied to the selected plot.

When it is desired to print the contents of a page, a print popup window as shown in Figure 2 is displayed. The output is generated in PostScript format and can be directed either to a designated printer or to a file on disk. This output can be scaled to any desired size. The printer resolution is needed in order to minimize the number of vectors required to plot the data (an FT/MS spectrum can contain a million data points or more). The PostScript output is Document Structuring Convention (DSC) 2.0 compliant so that it can be imported into word-processing software.

An example of the output from the software package is shown in Figure 3. This manuscript was prepared by using FrameMaker®, a desktop publishing software package (Frame Technology Corporation).

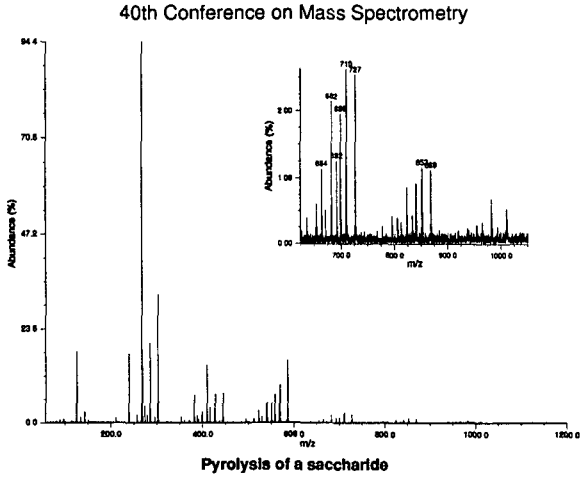

Figure 3. Example output. Page set to letter size, landscape mode, scaled to 50%. PostScript file was rotated 270 degrees when imported into FrameMaker.

The Calculation of Fringing Fields of Quadrupoles

*R.Becker, H.Wollnik, B.Pfreundtner, B.Hartmann and H.Irnich
II. Physikalisches Institut der Universität Gießen, 6300 Gießen, Germany

Only for ideal quadrupoles with infinitely long electrodes or polepieces of hyperbolical geometry (Fig. 1a) the field increases linearly with the distance from the optic axis. However, usually such hyperbolas are approximated by cylinders which give rise to an additional twelve-pole component in the multipole expansion of the field. Moreover, there are fringing fields at the entrance and exit face of the quadrupole in which the main field gradient $g_0 = dE/dx$ or $g_0 = dB/dx$ falls from the main field value to zero. Estimating the impact of these field perturbations on particle trajectories requires a truly three-dimensional calculation of the electrostatic or scalar magnetic potential. To this end we adopted the Integral Equation Method (IEM) which calculates the potential $V(\vec{r})$ from the surface charge density $\sigma(\vec{r}')$ on the surface F' of the quadrupole's electrodes or polefaces [1]:

$$V(\vec{r}) = \int_{F'} \frac{\sigma(\vec{r}')}{|\vec{r} - \vec{r}'|} d^2r'. \tag{1}$$

To calculate this charge distribution a triangular mesh is created on all faces of the quadrupole's electrodes or polepieces (Fig. 1b). Then it is assumed that at each of the N mesh points "i" charges "q_i" are placed. Using eq. (1) one furthermore determines the potential at a point "j" from N charges q_i which yield N linear equations with N unknowns that can be solved to determine all q_i. Using these charges then the potential at an arbitrary point in space can be determined from eq. (1). By this method a three-dimensional quadrupole fringing field was investigated both theoretically and experimentally. As can be seen from Fig. 2 the calculated and the measured fringing-field distributions agree quite well.

In a second step the calculated fringing-field distributions must be related to the ion optics of a particle beam passing through several quadrupoles. This can be achieved by time-consuming ray-tracing methods or by computer codes like TRIO [3] or GIOS [4] in which fringing field integrals [5] describe small shifts and bends the trajectories experience at the effective field boundaries. Once calculated for a known fringing-field distribution they allow for a quick and accurate computation of the fringing-field effects which has been done in ref.[6] for which however we find different results for the position of the effective field boundary.
As an example the optical properties of a stigmatic focusing quadrupole quadruplet have been determined once neglecting and once including the fringing-field effects (see Figs. 3).

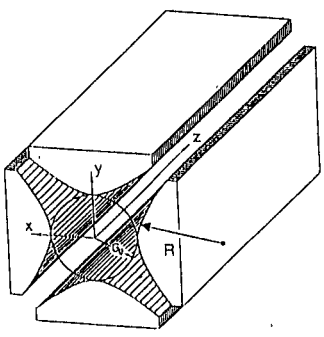

Fig.1a: Standard quadrupole with apperture diameter $2G_0$ and radius of curvature R of the electrodes or the polepieces

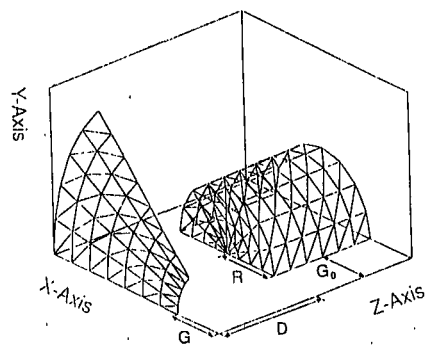

Fig.1b: Triangular mesh for a quadrupole with a field clamp of diameter $2G$ at a distance D from the polefaces

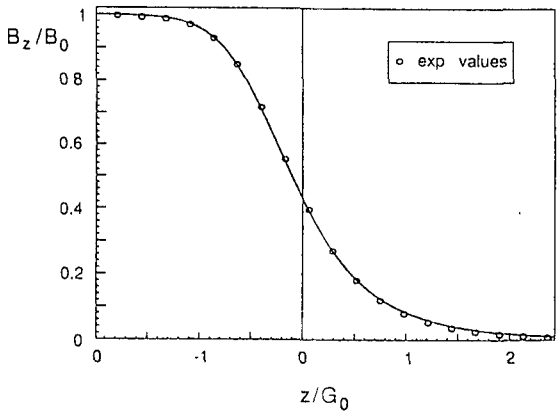

Fig.2: Calculated (*shown curve*) and *measured* (*circles*) *distribution of* the axial magnetic flux density B_z at the physical field boundary $z = 0$ with the main field value B_0 normalized to unity

Artificial Intelligence and Mass Spectrometry for Life Support Systems Monitoring

P.T. Palmer and C.M. Wong
NASA - Ames Research Center, MS 239-20
Moffett Field, CA 94035-1000

R.A. Yost, J.V. Johnson, and N.A. Yates
Department of Chemistry, University of Florida
Gainesville, FL 32611

Monitoring air quality for life support on long term, manned space missions presents a formidable set of challenges. Analytical requirements include monitoring major or critically important constituents as well as suspected contaminants present at trace levels. Given the potential hazards of toxic compounds accumulating in such systems over long periods of time, the capability to identify the presence and elucidate the structures of unknown compounds is also desirable. These requirements imply the need for instrumentation with exceptional sensitivity and chemical selectivity. Ion trap mass spectrometry (ITMS) is clearly the most suitable technology given its excellent sensitivity, experimental diversity, and small size.

Additional requirements for this application include artificial intelligence and advanced automation, which are essential to enable intelligent feedback for decision making, real-time instrument control and optimization, processing large quantities of multidimensional data, combining data from different experiments, and interacting with users in a facile manner. The complexity and heuristic nature of these tasks implies the need for an expert system to control the chemical analysis.

An expert system / ITMS system has been developed for life support system monitoring applications. A diagram of this system is shown in Figure 1. A Finnigan ITMS instrument is used to generate EI, CI, and MS/MS data and is controlled from a Compaq PC, which includes specialized software for instrument control and optimization. A DECstation 2100 computer is used to satisfy the computational requirements for this application and runs the expert system and conventional software tools for data processing and display. The expert system was developed in CLIPS, an expert system shell developed at NASA Johnson Space Center. CLIPS includes an inference engine and provides mechanisms for developing data structures, knowledge bases, and rule bases. The expert system currently includes over 100 rules for mass spectral analysis and a variety of knowledge bases for storing MS and application-specific information.

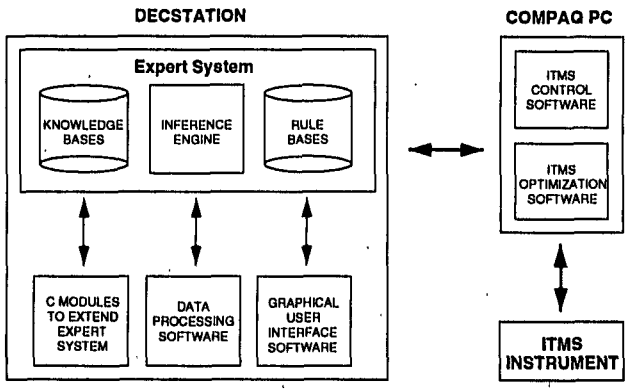

Figure 1. Diagram of system architecture

The expert system is organized along the lines of the analysis cycle shown in Figure 2. It performs each phase of the analysis internally. The data processing, acquisition, and display tasks are accomplished by conventional software tools. Where necessary, these have been developed and/or integrated to the expert system. ICIS, a commercial software package developed by Finnigan, is employed for many of the data processing and display functions.

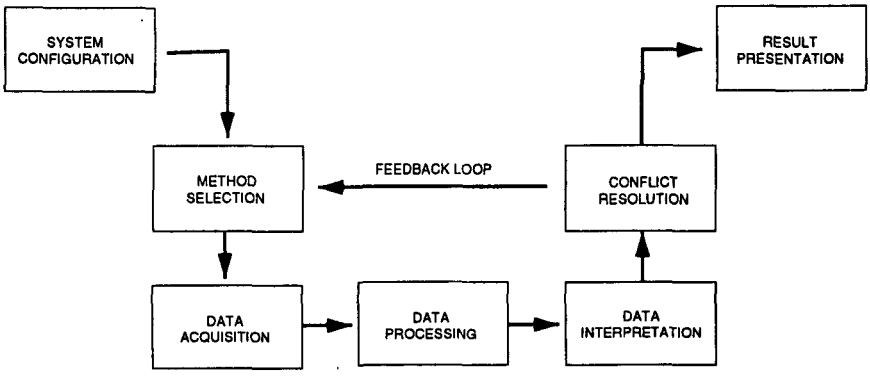

Figure 2. Operational phases in the expert system's analysis cycle

A 100 ppm mixture of five compounds was spiked into an air sample from a bioregenerative life support testbed to test the capability of the system for trace contaminant analysis, and in particular, the expert system's capability for autonomous chemical analysis. The results of the analysis are shown in Table 1.

Table 1. Results from expert system analysis of five-component mixture

Retention Time	Tentative Assignment	Computed Score	Identification Criteria
1:19	**acetone**	732	rt, mw, sm
1:19	2-butanone	326	sm
1:48	**2-butanone**	841	rt, mw, sm
1:48	tetrahydrofuran	100	mw
2:06	**tetrahydrofuran**	400	rt, mw
2:06	2-butanone	100	mw
2:18	**dichloroethane**	701	rt, sm
2:18	**benzene**	857	rt, mw, sm

KEY: Retention times are given in minutes:seconds
The correct identification of each peak is highlighted in bold text
Maximum possible score is 1000, which is computed from the following identification criteria: retention time match (rt), molecular weight match (mw), and spectral matching results (sm)

The expert system unambiguously identified all five components and performed the analysis without any human intervention with the exception of sample introduction. By combining data from different experiments, it distinguishes between competing hypotheses and achieves more reliable results. This research represents an excellent means for encoding the knowledge of human experts in mass spectrometry into a more active, usable form and represents the next logical step in the development of intelligent instrumentation.

This research was jointly sponsored by NASA, Finnigan, and the University of Florida through the *American Technology Initiative for Aerospace Research and Technology Transfer (AmTech-8801).*

Networking Mass Spectrometer Data Systems for Improved Productivity and Electronic Archival of Data

*Mark J. Hayward, Paul V. Robandt, Jon T. Meek,
Dale H. Chidester, Richard S. Wayne and Michael L. Thomson
American Cyanamid Company - Agricultural Research Division
P.O. Box 400 - Princeton, NJ 08543-0400

The following mass spectrometer and data system combinations are in use in the Process and Analytical Research Department of the Agricultural Research Division of American Cyanamid Company and have been networked together: (1) a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer with an Interactive Chemical Information System (ICIS) data system based on a Digital Equipment Corporation (DEC) DECstation 2100 workstation, (2) a Finnigan MAT TSQ 46 triple quadrupole mass spectrometer with an INCOS data system based on a Data General Nova 4X minicomputer, (3) a Finnigan MAT TSQ 45 triple quadrupole mass spectrometer with an INCOS data system based on a Data General Nova 4X minicomputer, and (4) a Finnigan MAT ITS 40 Magnum ion trap detector with an Ion Trap data system based on a Gateway-2000 486/33C IBM PC/AT compatible computer.

UNIX workstations, IBM PC/AT compatible computers and Data General Nova mini-computers have been connected via Ethernet interfaces in order allow rapid data transfer between all systems and X-Windows access to UNIX based systems. Bridging techniques have been employed to isolate possible high traffic areas of the network and to enable security measures for adequate protection of files. Additionally, serial connections have been made through a Northern Telecom phone system in order to provide multiplexed remote terminal access to the Data General Nova based systems. Use of these connectivity techniques has significantly improved productivity by allowing retrieval, processing and printing of data from remote locations such as office areas without affecting the usual data acquisition, processing and printing performed simultaneously at the instruments.

For archival purposes, data files are electronically stored on high capacity magneto-optical disks for rapid retrieval. A high capacity fixed disk is also available for centralized temporary data file storage. A Digital DECstation 2100 UNIX workstation has been used as the file server for centralized data storage while being simultaneously utilized as the data system computer for one of the mass spectrometers. Utilization of this UNIX based file server system in conjunction with Ethernet connectivity techniques provides a centralized, rapid access, high capacity, cost and space efficient method for electronic archival of mass spectrometric raw data recorded at all of the instruments.

The application of computer connectivity techniques to mass spectrometer data systems has facilitated the achievement of the following two important objectives: (i) to electronically archive mass spectrometric data at a central location on a high capacity, fast access device that allows rapid retrieval of archived data from any computer on the network and (ii) to allow access to mass spectrometric data and data processing and printing functions from remote locations without affecting simultaneous data acquisition at the instruments. The result of successfully completing these links has been a substantial increase in productivity through greatly increased access to the needed information when and where it is needed.

While the techniques applied here have worked well, there is still considerable work left to be done in the area of standardization. The completion of the work presented here depended heavily on the standardization of communication hardware. Before similar work can be successfully implemented in a multi-vendor environment, standardization of a data format must be agreed upon. Similarly, the widespread successful use of laboratory information management systems (LIMS), where both multiple vendors and multiple analysis types are integrated, depends on standardization of data formats and computer platforms.

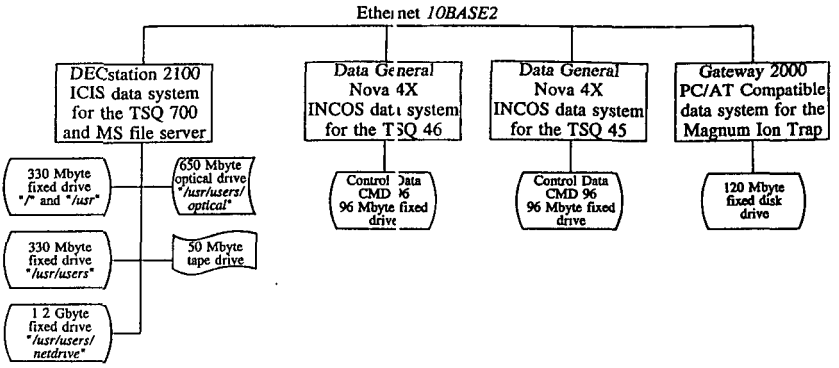

Figure 1. A schematic illustrating the Ethernet connection of four mass spectrometer data systems each shown with their respective file systems. The DECstation 2100 workstation is utilized as both a mass spectrometer data system and the file server for the storage of data files from all of the mass spectrometers.

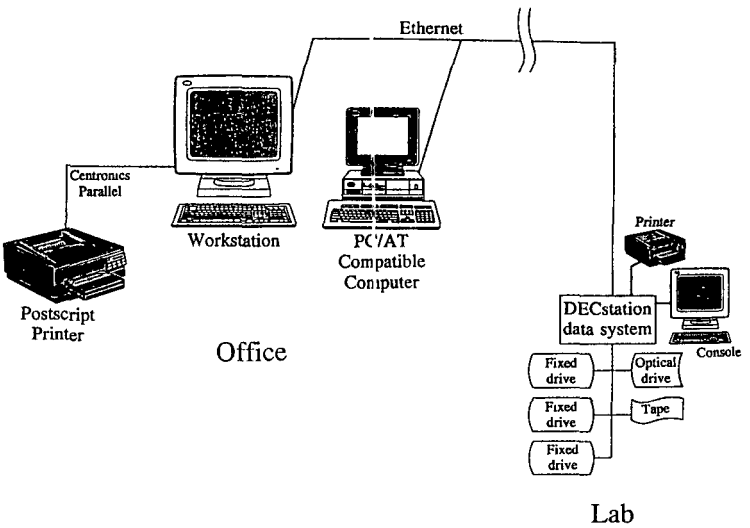

Figure 2. A schematic showing the Ethernet connection of the DECstation 2100 based ICIS data system to remote PC's, workstations and printers. This link makes all of the capabilities of the data system available at remote locations.

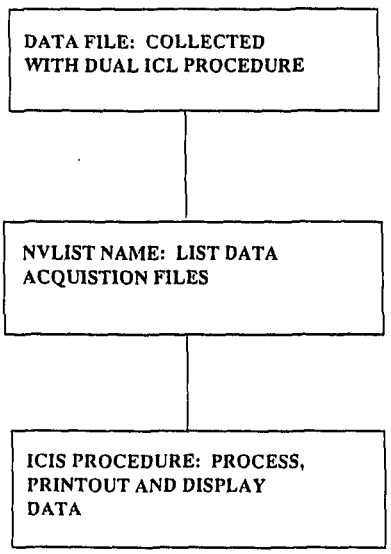
Automated Alternating Positive Ion/Negative Ion FAB MS Data Acquisition for Routine FAB MS Samples and Automated Data File Processing/Data File Printouts Using a Finnigan MAT TSQ70 Mass Spectrometer/Data System. * Mark A. Olsen, H. Craig Snyder, Sterling Winthrop Pharmaceuticals Research Division, 9 Great Valley Parkway, Malvern, PA 19355. C. Bruce Lutz, Finnigan MAT, Frederick, MD 21701.

The authors have integrated data acquisition and data processing features available on the Finnigan MAT TSQ70 Mass Spectrometer and ICIS data system, thereby providing rapid and efficient analysis of routine FAB MS samples. This process simplifies and automates both data acquisition and post-acquisition data processing routines. A simple Instrument Control Language (ICL) procedure for changing quadrupole rod polarities, tuning parameters and detector dynode polarity allows for alternating positive ion/negative ion FAB (PINIFAB) data acquisition. Routine FAB data is acquired using two different FAB matrices (glycerol/thioglycerol 1:1 and 3-Nitrobenzyl alcohol) utilizing one file name with the version number extensions 1 and 2 for each matrix, respectively. Post-acquisition, a modified version of the Finnigan provided Name List (NLIST) program, designated Name Version List (NVLIST), allowing for the processing of data files inclusive of version numbers is run in conjunction with a NAMELIST and an ICIS data processing procedure. This procedure automatically filters positive ion and negative ion data, sums scans and produces hard copies of the resultant data.

FLOW CHART



A procedure for automated data analysis/printouts has been prestented. The inherent advantage to utilizing these procedures is to liberate the analyst from repetitive data processing thus allowing the analyst additional sample data analysis time. Based on a 40 hour work week, approximately 15 hours are saved by utilizing these procedures thereby achieving a 37.5% increase in efficiency. However, a caveat exists in that increased sample throughput is associated with increased instrument maintenance, time required for data interpretation, and report generation. The final phase in this ongoing automation process will be report generation via electronic mail.

Automated Data File Transfer from a Finnigan MAT TSQ70 Mass Spectrometer PDP1173 to a Central Vax Computer for Routine Data Archiving. H. Craig Snyder and * Mark A. Olsen, Sterling Winthrop Pharmaceuticals Research Division, 9 Great Valley Parkway, Malvern, PA 19355.

The authors have developed a system for the transfer of files from the Finnigan MAT TSQ70 Mass Spectrometer's DEC PDP1173 computer to the central VAX computers for the primary purpose of archiving critical mass spectral data sets. The system moves targeted files from the TSQ70 DEC PDP1173 computer to the central VAX on an automated basis with no manual intervention. This archiving system was required to maintain all version extension numbers during file transfers.

Additional benefits include: the facile manipulation of project related data sets to and from the VAX, the rapid retrieval of archived data files, and minimal service time for the mass spectrometer's computer system. The system allows for convenient organization of data sets according to several variables such as notebook number, researcher, project name or project number. Files moved to the central VAX are then targeted by the VAX archive system for removal from the central VAX storage area to long term storage on a regular basis, thus providing GLP/GMP compliance as well as maintaining PDP1173/VAX disk space usage to a minimum.

Introduction:

Mass Spectrometery produces large data files, anywhere from one to forty megabytes in size. This requires the researcher to backup and remove files from the system on a regular basis. The researcher must maintain and store a large numbers of tapes for GLP purposes.

The maintenance and physical storage of tapes was becoming an increasing problem. Other drawbacks of the existing tape system included slow tape processing speed, execessive times to recover a data set from tape, difficulty in maintaining project related data sets, and down time due to the backup process.

The researcher requested that the Laboratory & Robotics group investigate the possibility of utilizing the VAX based Research Cluster to store Mass Spectral data. The goal was to achieve an automatic system for the regular archiving of general Mass Spectral data with no visable affect on the daily operation of the instrument.

Menu Hierchy

Main Menu

5) Delete a directory from the Archive list
6) Return to the Main Menu

Summary:

This system has been archiving data since April, 1990. All errors where files were not transferred were related to illegal characters or incomplete information in the file header information. The system has since been modified to handle most illegal characters which caused errors. As lab personnel became more consistent in entering the file information, file transfer errors became virtually non-existent. We are now seeing a file transfer rate of 99.9%.

The system has freed the lab personnel from tedious and non-productive backup procedures, saving a minimum of eight hours a month for the mass spectrometrists. Down time due to data disk errors has been eliminated.

This system has freed the mass spectrometrists from computer maintenance and allows them to concentrate on sample analysis. To date this system has archived over 3000 data sets consisting of over 15,150 files reprsenting over 3,200 megabytes of data.

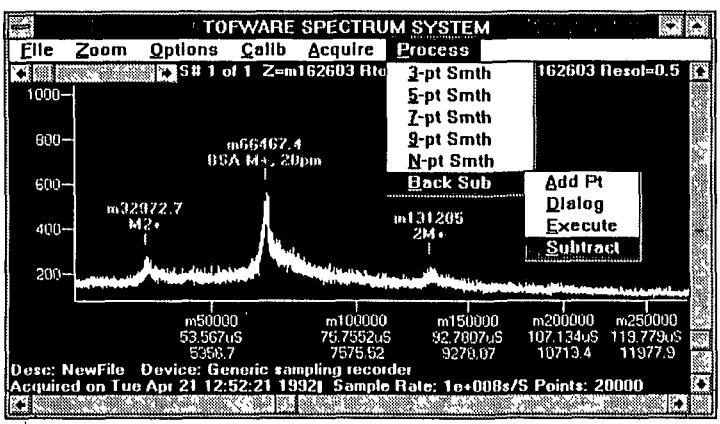
TOFWARE: A Windows(R)-based Data Acquisition System for Time-of-Flight Mass Spectrometry.

Marc R. Chevrier*[1], Ihor Lys[2] and Robert J. Cotter[1]

[1]Department of Pharmacology and Molecular Sciences, The Johns Hopkins University School of Medicine, Baltimore, Maryland 21205
[2]Department of Electrical Engineering, Carnegie Mellon University, Pittsburgh, Pennylvania 15217

A new data system running under the Microsoft Windows(R) operating environment acquires and processes data from commercially availible transient recorders allowing display, manipulation and output of mass spectra. The software, written by Ihor Lys, was specified, initially tested and optimized at the Middle Atlantic Mass Spectrometry Laboratory at Johns Hopkins. The system runs optimally on 386/486 series PC compatibles, which are GPIB linked to the transient recorders. Several transient recorders are supported, including LeCroy and Tektronix models.

The data system supports single, multiple and integrated multiple spectrum acquisition. Processing procedures include automatic inversion, point smoothing and background subtraction. Multiple display windows allow for numerous spectra to be displayed simultaneously, permitting comparison of spectra currently being acquired with past runs. Cursor-based measurements calculate resolution and mass shifts of selected peaks. Protein/peptide mapping experiments and matix/salt adduct identification are thus simplified. Spectral display and output is very flexible, including customized labelling and axes definitions. Calibrations can be checked using statistical analyses.



TOFWARE has been utilized to acquire a variety of UVLD spectra of biomolecules, such as small peptides, large proteins and their glycoconjugates. Spectral acquisition of 25K channels on a 486-33 with 256KB cache makes the speed of the transient recorder rate-limiting. Rapid analysis of multiple samples is possible. Calibration yields mass accuracies of >0.1% and is highly instrument-dependent. On a high resolution instrument in our laboratory, mass accuracy >0.003% for peptides has been achieved using a single calibration point under TOFWARE.

TOFWARE has been tested on both high sensitivity linear TOF's using matrix-assisted laser desorption as well as higher resolution reflectron instruments. TOFWARE adjusts easily to account for the variability of instruments and transient recorders, insuring optimum performance under most situations.

The flexibility and intuitive operation of the software emerges from the familiar mouse-based environment of Windows(R). Multi-user systems are easily installed, allowing each person to configure the software as they prefer, with their own defaults. The use of common AT compatibles permits analysis off-line, thereby minimizing user demand for the computer dedicated to the TOF instrument. Tofware thus provides a flexible and widely applicable data analysis system suitable for TOF/MS.

Deconvolution of Gas Chromatography/Time-of-Flight Mass Spectrometric Data: A Potential Alternative to Two-Dimensional Gas Chromatography/Mass Spectrometry

R. D. MCLANE, P. R. VLASAK and C. G. ENKE, *Department of Chemistry, Michigan State University, East Lansing MI 48824*

G. E. YEFCHAK, *Meridian Instruments, Inc., 2310 Science Parkway, Okemos MI 48864*

P. A. RODRIGUEZ, C. L. EDDY, M. A. MAZZONE and J. D. PINKSTON, *The Procter and Gamble Company, Miami Valley Laboratories, P.O. Box 398707, Cincinnati, OH 45239*

Resolving the components of complex mixtures is a major challenge for high-resolution gas chromatography/mass spectrometry (GC/MS). These mixtures often contain hundreds of compounds whose concentrations may differ by several orders of magnitude. When a large number of components are present in a mixture, the likelihood of two or more of these components coeluting from the chromatographic column is high. Davis and Giddings [1] estimated the probability that a single peak contains only one compound is less than 50% for a chromatogram filled to only 35% of the peak capacity.

One approach to resolving chromatographic coelutions is to use two-dimensional GC with mass spectral detection (2-D GC/MS). In this method, regions containing coeluting species are separated on a second chromatographic column of a different polarity and the separated components are then detected using a mass spectrometer. This process is time consuming. The sample must first be analyzed using GC to determine regions of interest. Each selected region is then isolated onto the second column where the components are separated and detected. Frequently, only one region can be analyzed during each chromatographic run necessitating multiple runs to examine all possible coelutions.

An alternative approach is to use the combination of GC/high-speed MS and data deconvolution to resolve coeluting species. Time-of-flight mass spectrometry with time-array detection can generate 25 or more unskewed mass spectra per second with high sensitivity [2]. When the elution profile for each m/z value is described accurately across a chromatographic peak, deconvolution techniques [3] can use the temporal differences in the elution profiles of the mass chromatograms to locate coeluting compounds and extract mass spectra for each compound. In our deconvolution approach, we assume that each coeluting compound has at least one m/z value that is unique to that compound.

These two techniques were compared using a test perfume mixture whose composition was unknown to the analysts. This mixture was expected to have many regions where components would not be chromatographically resolved by capillary GC. Results obtained by sniff-port detection of the sample were used to select two regions for further analysis.

Region 1 The elution profile of this region was not symmetric. Figure 1 shows the total ion current chromatogram from the high-speed MS analysis for Region 1. The mass chromatogram peak position plot (MCPPP) is overlaid to show the times when mass chromatograms reached their maximum intensities. Since all m/z values in the spectrum of a compound rise and fall synchronously, the pattern of responses in the MCPPP indicates the presence of at least two compounds (2 and 3) late in the elution profile. The shoulder on the leading edge of the peak indicates the presence of at least one more component. Since no m/z

1. J. M. Davis and J. C. Giddings, *Anal. Chem.* **1983**, *55*, 418.
2. R. E. Tecklenburg, Jr., et al., Proceedings of the 38th ASMS Conference on Mass Spectrometry and Allied Topics, Tucson, AZ, June 3-8, 1990.
3. *For example*, G. E. Yefchak, et al., Proceedings of the 39th ASMS Conference onm Mass Spectrometry and Allied Topics, Nashville, TN, May 19-24, 1991.

value reaches its maximum intensity during this shoulder, the additional component(s) shares all m/z with component 2.

Figure 1

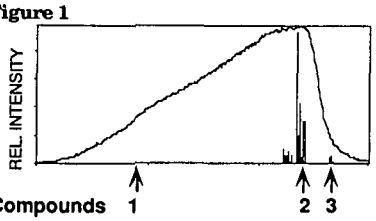

Figure 2

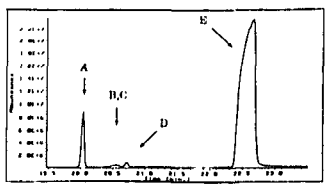

Figure 2 shows the TIC obtained for for the 2-D GC/MS analysis of Region 1. Five compounds were detected in this region. Three of these compounds (B,C,D) comprise less than 0.6% of the total mass in Region 1 while the third component contributes about 7% of the ion intensity. The m/z values in the largest response did not change relative intensities across the assymmetrical peak. There is no indication of the presence of coeluting compounds in this response.

A total of six compounds were located in this region. The three most abundant compounds, including the isomeric pair, were found using the deconvolution approach. 2-D GC located five of the six compounds, but failed to resolve the two most abundant compounds. When the presence of the isomers was known, no discernable mass spectral differences were observed across the peak. The spectra of the ionone isomer resolved by both techniques agreed favorably.

Region 2 Figure 3 shows an expanded portion of the TIC from Region 2 with the MCPPP overlaid. The intriguing feature of this region is the small fluctuation in the baseline and the MCPPP response in the same area. These two features indicate the presence of one or more component(s) with low intensity in an area of the TIC with a large background signal. The deconvoluted mass spectrum (A) from the area shown in Figure 3 and a spectrum obtained from the 2-D GC/MS approach (B) for the same compound are shown in Figure 4. The high quality of spectrum B was achieved by increasing the concentration of the compound and reducing the background via the chromatographic separation. All of the major m/z values in the 2-D GC/MS spectrum are also present in the deconvoluted spectrum.

Figure 3

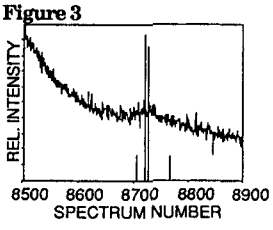

Figure 4

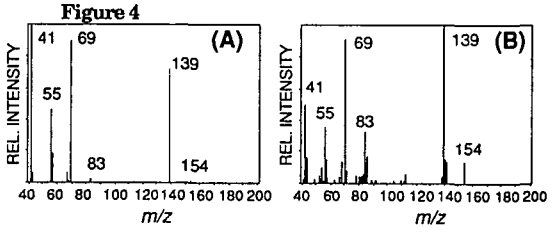


Conclusions Deconvolution data generated by GC/high-speed MS and 2-D GC/MS are complementary techniques. A large fraction of coeluting compounds can be resolved in a single chromatographic run by using the information available from high-speed MS for data deconvolution. This approach can minimize the number of GC runs for all regions resolved by deconvolution. Where the MCPPP, elution profiles and sniff-port results indicate further resolution is necessary, 2-D GC/MS can be employed.

Gas - Phase Ion Chemistry of Cycloheptatriene Chromium Tricarbonyl $\{\eta^6\text{-}C_7H_8Cr(CO)_3\}$ by FT - ICR

Ziyi Kan and Melvin B. Comisarow
Department of Chemistry, University of British Columbia
Vancouver, B. C., Canada, V6T 1Z1

Although the very first examination of ion-molecule chemistry by FT-ICR was on hydrocarbon-metal carbonyls[1], most subsequent FT-ICR studies of organometallic molecules have been on metal carbonyls[2]. In this work we examine the ion-molecule chemistry of Cycloheptatriene Chromium Tricarbonyl $\{\eta^6\text{-}C_7H_8Cr(CO)_3\}$ (the title compound) - a hydrocarbon-metal carbonyl with a *reactive* organic ligand.

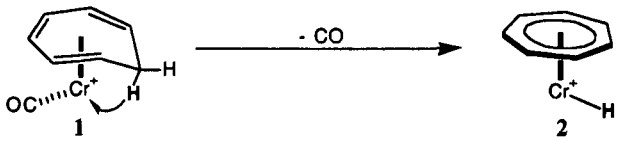
At a pressure of 1.0×10^{-7} Torr, 25 eV electron impact (EI) on $\eta^6\text{-}C_7H_8Cr(CO)_3$ generates five major primary fragment ions : Cr^+ (90%), $C_7H_8Cr^+$(100%), $C_7H_8Cr(CO)^+$(38%), $C_7H_8Cr(CO)_2^+$(23%) and $C_7H_8Cr(CO)_3^+$(63%). Except for the molecular ion, all the primary ions react with the neutral parent molecule in the gas phase, and the self-condensation ionic products are typically of the form $(C_7H_8)_nCr_{n+1}(CO)_m^+$ (n = 1-3; m = 0-3) and $(C_7H_8)_2Cr_2(CO)_m^+$ (m = 0 or 3).

Rate constants for the pseudo-first order reactions between reactive ions and neutral parent molecules are determined by following the variations of ion intensities with reaction times.

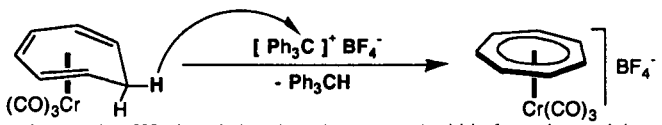
Table I.

Species	ED	ED*	Rate Constants (10^{-9} cm^3 mole^{-1}.s^{-1})
Cr^+	13	13	4.6
$C_7H_8Cr^+$	7	5 (2)	3.2
$C_7H_8Cr(CO)^+$	5 (1)	5	3.4
$C_7H_8Cr(CO)_2^+$	3	3	2.3
$C_7H_8Cr(CO)_3^+$	1	1	0.00
$C_7H_8Cr_2(CO)^+$	7.5	4.5	2.6
$C_7H_8Cr_2(CO)_2^+$	6.5	3.5	1.5
$(C_7H_8Cr)_2^+$	5.5	1.5 (4)	0.079
$(C_7H_8Cr)_2(CO)^+$	4.5	2.5	0.42
$(C_7H_8Cr)_2(CO)_2^+$	3.5	1.5	0.19
$(C_7H_8Cr)_2(CO)_3^+$	2.5	0.5 (3)	0.00

The ED column in the **Table I** gives calculated electron deficiencies, assuming single metal - metal bonds and C_7H_8 as a 6 electron donor as it is in the neutral parent molecule. The ED* column gives calculated electron deficiencies consistant with the rate constant trends, using ($\eta^7 + \eta^1$) and triple metal - metal bond structures as appropriate. We can see that the rate constant for $C_7H_8Cr^+$(ED=7) is not larger than that of $C_7H_8Cr(CO)^+$(ED=5), even though the former is more electron deficient. This is contradictory to the "normal" electron deficiency model[3][4]. Another exceptional case is that of $(C_7H_8Cr)_2^+$ and $(C_7H_8Cr)_2(CO)_3^+$, which are the only two dominant products of the reaction between $C_7H_8Cr^+$ and the neutral molecule, and both products are basically unreactive. Reaction **[1]** provides an explanation for above observations. Reaction **[1]** has a well known literature counterpart, reaction **[2]**[5].



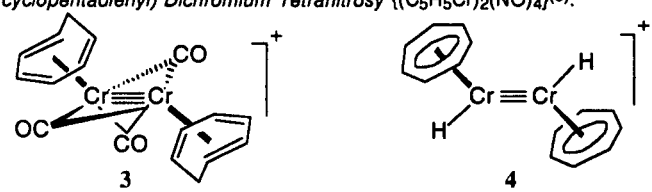
[1]



[2]

In reaction [2], the trityl cation abstracts a hydride from the cycloheptatriene ligand to form a stable tropylium cation. In reaction [1], when the third CO is ejected, hydride is intramolecularly transferred from the organic ring to the Cr atom. The coordination hapticity to Cr is converted from η^6 to $\eta^7 + \eta^1$ and the electron deficiency of Cr in $C_7H_7CrH^+$ drops by two. Thus Cr in both η^7 - $C_7H_7CrH^+$ and η^6 - $C_7H_8Cr(CO)^+$ has same electron deficiency(ED*, Table I), which explains why the two species have similar rate constant.

This study and previous studies on gas phase ion molecule reactions of organometallic molecules have revealed that molecular ions are generally unreactive[6]. This is because molecular ions are only short of one electron from their neutral molecules. Here we suggest that $(C_7H_8Cr)_2(CO)_3^+$ has structure 3, and is the molecular ion of an as-yet-unprepared 18 electron compound *bis(cycloheptatriene) dichromium tricarbonyl*. 3 would have a triple metal - metal bond by comparison to the two known 18 electron compounds *Bis(η^5 - cyclopentadienyl) Dichromium Tetracarbonyl* $\{(C_5H_5Cr)_2(CO)_4\}$[7] and *Bis(η^5 - cyclopentadienyl) Dichromium Tetranitrosy* $\{(C_5H_5Cr)_2(NO)_4\}$[8].



$(C_7H_8Cr)_2^+$, in structure 4, is formed by double hydride transfer from the two organic rings. This triple metal - metal bond and hydride-tropylium structure is much less electron deficient(ED*, table I), which acounts for the low rate constant shown in Table I.

Competing Reactions in the Source of a Corona Discharge Atmospheric Pressure Ionization Mass Spectrometer

S.N.Ketkar, R.G. Ridgeway and J.V. Martinez de Pinillos
Air Products and Chemicals, Inc.
7201 Hamilton Boulevard, Allentown, PA 18195

Atmospheric pressure ionization mass spectrometry (APIMS) is a very sensitive technique which is used for detecting trace constituents . The semiconductor industry has seen an increasing use of APIMS because of the need of this industry to use ultra clean bulk gases with impurity levels below 1 ppb . The ability of APIMS to detect less than 100 ppt of contaminants in gases has been demonstrated . However, this is the result of performing single component calibrations i.e. one impurity is added to the gas stream and the APIMS response is measured. In a real world situation, where APIMS might be used for process control the situation that is likely to occur is the simultaneous presence of many impurities. For such cases the understanding of the ion chemistry in the corona discharge source of APIMS is essential. A rate equation analysis is used together with a model for a corona discharge to calculate the loss in sensitivity of APIMS to an analyte, in the presence of another analyte of lower ionization potential. These results agree with a recently published steady state analysis.

In a corona discharge APIMS source, a corona discharge is struck between a sharp needle and an aperture plate. The separation between the needle and the plate is typically a few mm and the aperture is usually between 100 to 400 μm. The typical discharge parameters are a voltage of a few kV and a current of a few μA. Such a source is a unipolar space charge dominated source in which the ion molecule interactions take place over an ion residence time, determined by the needle to plate separation and the discharge current. The ions that are produced in such a source enter the mass spectrometer through the aperture with a rate governed by the viscous flow rate of the gas through this orifice. Thus the total ion current that enters the mass spectrometer is given by $I = \rho(\tau).S$, where $\rho(\tau)$ is the ion density at time t which equals the ion residence time, i.e. in close proximity to the aperture through which the ions are sampled by the mass spectrometer and S is the flow rate through the aperture.

Consider the case of a bulk gas X with trace level impurities Y and Z of differing ionization potentials (IP). Let IP(X) > IP(Y) > IP(Z). In the corona discharge the primary ionizing events will ionize the bulk constituent X, to produce X^+, which will be the primary ion. The primary ions will then react with the trace impurities Y and Z via the following reactions.

$$X^+ + Y \rightarrow X + Y^+ \quad (\kappa_1) \qquad (1)$$
$$X^+ + Z \rightarrow X + Z^+ \quad (\kappa_2) \qquad (2)$$
$$Y^+ + Z \rightarrow Y + Z^+ \quad (\kappa_3) \qquad (3)$$

where κ_1, κ_2 and κ_3 are the reaction rate constants. Let X, Y and Z be the density of the different components and let X^+, Y^+ and Z^+ be the density of their respective ions. The rate of change of the density of the different ions is given by the following equations

$$\frac{dX^+}{dt} = -(\kappa_1 Y + \kappa_2 Z)X^+$$

$$\frac{dY^+}{dt} = \kappa_1 YX^+ - \kappa_3 ZY^+$$

$$\frac{dZ^+}{dt} = \kappa_2 ZX^+ + \kappa_3 ZY^+$$

These equations can be solved, by integrating over the interaction time, τ, to yield the ion densities at time equal to the ion residence time, τ.:

$$X^+(\tau) = \rho_0 \exp\{-(\kappa_1 Y + \kappa_2 Z)\tau\}$$

$$Y^+(\tau) = \frac{\kappa_1 Y \rho_0}{(\kappa_1 Y + \kappa_2 Z - \kappa_3 Z)}\{\exp\{-(\kappa_3 Z)\tau\} - \exp\{-(\kappa_1 Y + \kappa_2 Z)\tau\}\}$$

where ρ_0 is the ion density at time t = 0. Since the total ion density must be conserved, we have

$$\rho(\tau) = Z^+(\tau) + -X^+(\tau) + Y^+(\tau).$$

where $\rho(\tau)$ is the ion density at time t = the ion residence time, i.e. in close proximity to the aperture.

Moreover, in a corona discharge source the time dependence of the ion density is given by [7]

$$\frac{1}{\rho(\tau)} = \frac{1}{\rho_0} + \frac{\kappa\tau}{\varepsilon}$$

where $\rho(\tau)$ is the ion density after an interaction time, τ, κ is the mobility of the ions and ε is the permittivity. The typical two body ion molecule reaction rate constants are about 10^{-9} cm^3/sec, and we will assume that $\kappa_1 = 10^{-9}$ cm^3/sec. A mobility of 10^{-4} $m^2/(V.s)$ is used in the calculations. The space charge dominated ion density, in typical corona discharges used in APIMS is about 10^{10} ions/cc.

The above equations can be solved to calculate the effect of the presence of the two impurities on the signal detected by the mass spectrometer. The effect of Z on the intensity of Y^+ is critically dependent upon the interaction time. As the interaction time decrease, the influence of Z on Y^+ diminishes.. For the case of $\kappa_2 > \kappa_3$, the increase in Y is accompanied by a decrease in Z^+. On the other hand for the case of $\kappa_2 < \kappa_3$ the increase in Y results in an increase in Z^+.

Gas Phase Cl^+ Affinities of Pyridines Determined by the Kinetic Method and MS^3 Experiments in a Pentaquadrupole Mass Spectrometer

Marcos N. Eberlin Universidade Estadual de Campinas, Instituto de Química C.P.6154, 13081 Campinas, SP Brazil
Tapio Kotiaho and R.Graham Cooks Purdue University, Department of Chemistry, West Lafayette, IN 47907 USA

The kinetic method [1] has been employed with success to compare and to determine the gas phase affinities of neutral molecules toward several ionic species. The method is based on the postulation that when a loosely bound dimer of two different molecules dissociates under appropriate conditions, the difference in their ionic (X) affinities is given by: $\ln [AX]/[BX] = \Delta(X \text{ affinity})/RT_{eff}$.

Recently we have observed that $Cl{-}C{\equiv}O^+$ (m/z 63) is an efficient gas phase Cl^+ transfer agent [2]. By using a mixture of two different pyridines, unsymmetrical Cl^+-bound dimers are produced. For example, a mixture of pyridine and 3-methyl pyridine shows the Cl^+ dimer at m/z 207. The pentaquadrupole mass spectrometer employed in this study allows selection of this dimer and its further dissociation by collision, yielding a MS^3 spectrum from which the relative values of Cl^+ affinities of both pyridines can be estimated (Figure 1). Therefore it was possible for the first time to order a series of compounds (here pyridines) in term of their gas phase Cl^+ affinities. When the relative Cl^+ affinities values are plotted versus the proton affinities (PA) of these pyridines (Figure 2), it is clearly seem that most of the *ortho*-substituted compounds display lower values than expected. This can be best understood by the result of the steric effect caused by the *ortho* groups.

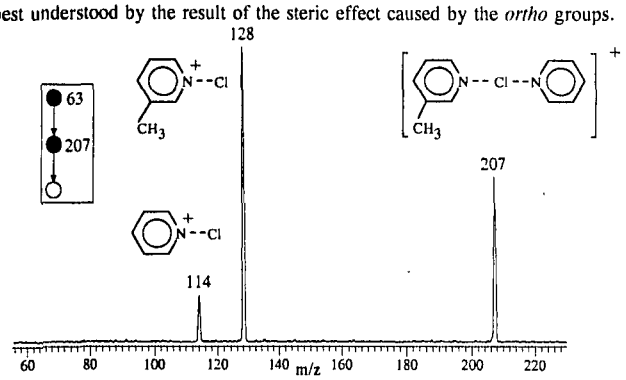

Figure 1- *MS^3 Sequential product spectrum showing the CID fragmentation of $[Py{-}{-}Cl{-}{-}3MePy]^+$.*

For pairs of non-crowded pyridines, the ratios of the two fragments obtained by CID of the H^+- and Cl^+-dimers are very similar. Given this and since both H^+- and Cl^+-bound dimers fragment under very similar experimental conditions, one can consider that for a dimer comprised of an *ortho*-substituted pyridine (*o*-Py) and a pyridine without a 2-group (2H-Py), the decrease observed in the relative abundance of the $[o\text{-PyCl}]^+$ fragment is due mainly to the steric effect of the *ortho*-substituent. It is therefore possible to estimate the magnitude of the steric effects of these substituents (Table 1). One interesting result seen in Table 1 is that the higher the Cl^+ affinity of the compound, the greater the steric effect of the *ortho* group. The increase in the ionic affinity causes a decrease in the length of the molecule-Cl^+ bond, which intensifies the steric effect. This methodology can also be used to directly compare the steric effects of two *ortho*-substituents (Table 2). The relative steric factors are in very good agreement with the non relative values shown in Table 1.

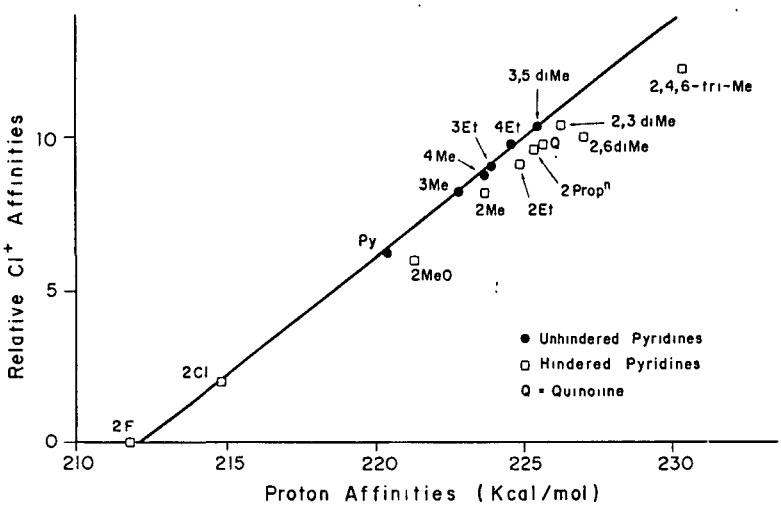

Figure 2- *Plot of the Relative Cl^+ Affinities Versus PA's of Several Pyridines*

Table 1. Steric Effects of 2-Substituents on the Cl^+ Affinities of Pyridines.

Py_1	Py_2	Steric Factor
2-Me	2-H (Py)	1.5
2-Et	4-Me	2.8
2-Prop^n	pyridine	3.0
2-MeO	pyridine	2.3
2,6-diMe	4-Me	4.9
quinoline	pyridine	1.2
2,3-diMe	4-Me	1.9

Table 2- Relative Steric Effects of *ortho*-Substituents on the Cl^+ Affinities of Pyridines.

Py_1	Py_2	Relative Steric factors
2-Et	2-Me	1.9
2-Prop^n	2-Et	1.2
2-Cl	2-F	2.0

Reaction of a mixture of pyridine and 2-methoxy pyridine with $^{79}Br\text{-}C{\equiv}O^+$ leads to formation of the Br^+-dimer. The MS^3 spectrum of the dimer indicates the steric factor of the 2-methoxy group to be 4.7 when Br^+ is involved. This shows that the steric effect is greater for the larger ion, i.e. $H^+ << Cl^+ < Br^+$.

Since Cl^+ affinities have not been measured in either the gas or solution phase and the kinetic method is a comparative method, it is not possible to obtain absolute values of Cl^+ affinities from the experimental results. Therefore, the AM1 method was used to estimate these values and to compare the relative Cl^+ affinity order to that obtained in this work. The Cl^+ affinity values obtained by the AM1 method show a good correlation with the experimental values for the unhindered pyridines. However, with the exception of 2-methoxy pyridine, the AM1 values for all the *ortho*-substituted pyridines are higher than those observed experimentally which shows that the AM1 method overestimates the Cl^+ affinities for hindered pyridines.

Reactions of $C_2H_4N^+$ and Substituted Analogues with Isoprene. Applications of MS/MS and MS/MS/MS in a Pentaquadrupole Mass Spectrometer.

Brian J. Shay*, Marcos N. Eberlin and R. Graham Cooks, Department of Chemistry
Purdue University, W. Lafayette, IN 47907

Following their discovery in the stratosphere as the part of an important cluster series, $C_2H_4N^+$ ions have been studied by MIKES-CID [1,2], NRMS [1], and by proton exchange reactions [1-3]. Six reasonable structures, shown below, have been identified by calculation [4a] although only the first two have been experimentally verified [1-3].

	$\Delta H_f°$(MNDO) [4a]	Relative energy (ab initio) [4a]	$\Delta H_f°$(experimental) [3]
1. $H_3C\text{-}C{\equiv}N\text{-}H^+$	207.39 kcal/mol	-18.07 kcal/mol	195 kcal/mol
2. $H_3C\text{-}N{\equiv}C\text{-}H^+$	212.56	-9.44	205
3. $H_2C{=}N{=}CH_2^+$	212.29	0.00	
4. $H_2C{=}C{=}NH_2^+$	216.99	2.37	
5. $H\text{-}C{\equiv}C\text{-}NH_3^+$	232.02	22.57	
6. 	244.80	23.89	

This work seeks to utilize the ion source and the two reaction/collision quadrupoles available in the pentaquadrupole instrument to create specific $C_2H_4N^+$ isomers, identify them via ion/molecule reactions with the diene isoprene, and explore their gas-phase chemistry. Once the reactivity patterns were established we proceeded to select $C_2H_4N^+$ fragments from larger organics to determine their structure using ion/molecule reactions. A final goal is to examine the effects of alkyl- and aryl- substitution on reactivity.

Two populations of $C_2H_4N^+$ ions of reasonably well known structures, isomers **1** and **2** above, are examined for their reactivity with isoprene. Both **1** and **2** undergo charge exchange with isoprene but only isomer **2** forms a stable adduct. Isomer **1** is generated by methane chemical ionization (CI) of CH_3CN. Isomer **2** is generated by a number of methods including mass selecting the phenyl loss product from ionized $CH_3N{=}CHC_6H_5$, by methylating HCN in the ion source with $CH_3I^{+\cdot}$, and by methylating HCN in the first collision quadrupole using mass selected CH_3OCO^+ ions from methylacetate. The latter method exemplifies the MS/MS/MS capabilities (Figure 1) by the sequence 59→42→o: Q1 mass selects CH_3OCO^+, m/z 59, for reaction with HCN in Q2 (1st reaction) and $C_2H_4N^+$, m/z 42, is mass selected with Q3. Reaction with isoprene occurs in Q4 (2nd reaction) and Q5 is scanned (o) to record the products. A separate scan, 42→110→o, shown in Figure 2, is used to examine the dissociation characteristics of the mass selected adduct (m/z 110) of **2** and isoprene (68 amu). The mass selected $C_2H_4N^+$ ion, m/z 42, in this case formed in the source, is reacted with isoprene in Q2. The adduct, m/z 110, is selected for dissociation in Q4 while scanning Q5 (o) to record the products. Dissociation yields the reversion product, m/z 42, as well as m/z 41 and 69 (protonated isoprene). The occurrence of the latter product ions support covalent bond formation by a [2^+ + 4] Diels-Alder cycloaddition mechanism, but could also be attributed to a hydrogen bound dimer structure. With the above clear distinction between **1** and **2**, other molecular sources were examined to ascertain the type of $C_2H_4N^+$ ion formed on fragmentation following electron ionization. $CH_3N{=}CHC_6H_5$, 1-methylpyrrolidine, 1-methylpiperazine, trimethylamine, and N,N-dimethylamine all gave m/z 42 ions that formed adducts with isoprene while the isobar $C_3H_6^{+\cdot}$ from n-hexane and $(CH_3)_3CCN$ did not. This indicates that isomer **1** is not formed from these compounds although it is 10 kcal/mol more stable than **2** [3].

Substituted analogues of **1** and **2** were prepared to assess their reactivity. $CH_3CNCH_3^+$, m/z 56, $C_2H_5CNCH_3^+$, and $C_6H_5CNCH_3^+$ were formed by methylating acetonitrile, propionitrile, and benzonitrile, respectively, with $CH_3I^{+\cdot}$ in the ion source. $C_6H_5CNCH_3^+$ was also generated by H atom loss from ionized $CH_3N{=}CHC_6H_5$. None of the above ions formed adducts with isoprene. Interestingly, adducts were found for the m/z 56 fragments of 1-methylpiperazine and trimethylamine indicating a different structure than $CH_3CNCH_3^+$ formed from these compounds. Additional precursors to m/z 56 are being sought to shed light on the possible structures of this ion.

Electrophilic Aromatic Chlorination in the Gas Phase

*Tapio Kotiaho, Marcos N. Eberlin, Brian J. Shay, and R. Graham Cooks

Purdue University, Department of Chemistry, West Lafayette, IN 47907, U.S.A.

Chlorine cation addition to benzene, aniline, anisole, styrene, chlorobenzene, and nitrobenzene was studied using NH_3Cl^+, $Cl\text{-}C{\equiv}O^+$, and Cl^+ as reagent ions (Table 1). The gas-phase reactions of protonated monochloramine were followed using a direct insertion membrane probe for sample introduction and a pentaquadrupole mass spectrometer for product characterization. The other reagent ions, $Cl\text{-}C{\equiv}O^+$, and Cl^+ were generated by electron ionization of acetyl chloride and carbon tetrachloride, respectively. The main reactions of the NH_3Cl^+ reagent ion with aromatic compounds are electrophilic Cl^+ and H^+ addition, and charge exchange to form the aromatic radical cation (Equation 1). Reactions of $Cl\text{-}C{\equiv}O^+$ with aromatic compounds results in (i) Cl^+ addition, (ii) $CO^{+\bullet}$ substitution of a ring hydrogen atom, and (iii) formation of the molecular radical cation of the substrate (Equation 2). The naked Cl^+ ion does not chlorinate aromatic compounds but does undergo charge exchange (Equation 3).

Ion/molecule reaction products were characterized by comparing sequential product ion mass spectra (MS/MS/MS) to the MS/MS product ion mass spectra of reference ions, generated by chemical ionization of appropriate chlorine-substituted compounds. The sequential product spectra collected with the pentaquadrupole instrument show that electrophilic aromatic substitution occurs, both the Cl^+ addition products and the $CO^{+\bullet}$ substitution products are σ-bonded to the aromatic compound. Comparisons with the MS/MS spectra of model ions show that both Cl^+ and $CO^{+\bullet}$ add principally to the para position in aniline and anisole while $CO^{+\bullet}$ substitution onto anisole also proceeds primarily at the para position. For aniline an observable $CO^{+\bullet}$ substitution product bonded at the nitrogen is also seen. Addition of Cl^+ to the β-carbon in styrene and to the ring in chlorobenzene is also observed. Nitrobenzene, the least reactive compound gave only traces of Cl^+ addition and did not substitute $CO^{+\bullet}$ for hydrogen. However, nitrobenzene did display one unique reaction, the substitution of $NO_2^\bullet$ by Cl^+. The evidence provided by the MS^3 experiments for the site of Cl^+ addition was tested against and found to be consistent with the reaction sites predicted to have the highest Cl^+ affinity by semi-empirical AM1 molecular orbital calculations.

Table 1 Summary of electrophilic aromatic chlorination and other reactions.*

Analyte	Reagent			
	NH_3Cl^+		$Cl\text{-}C{\equiv}O^+$	
	$(M+Cl)^+$	$(M+H)^+$	$(M+Cl)^+$	$(M-H+CO)^+$
Benzene	Y	Y	Y	Y
Aniline	Y	Y	Y	Y
Anisole	Y	Y	Y	Y
Styrene	Y	Y	Y	NR
Chlorobenzene	Y	Y	Y	Y
Nitrobenzene	NR	Y	Y≠	NR

* - The bare Cl^+ ion does not add to any of these compounds.
Y - Reaction occurs
NR - No addition reaction product formed
≠ - very little addition reaction product formed

ION/SURFACE REACTIVE COLLISIONS AT FUNCTIONALIZED ALKYL-MONOLAYER SURFACES

One of the phenomena observed when ions collide with surfaces is the abstraction of surface species by the incident projectile, as has been observed previously [1]. The use of stainless steel surfaces is often accompanied by the addition of a hydrogen, or C1 and higher alkyl chains (with, or without, subsequent fragmentation) resulting from hydrocarbon deposits that aggregate on metal surfaces, even under high vacuum conditions. Recent work [2,3] has concentrated on the use of well characterized surfaces, self-assembled monolayers of (functionalized) alkanethiols on a gold substrate, and as well as the differences observed in the dissociation process, the possibility now exists for specific ion/surface reactions to be detected and investigated.

We have used a custom-built BEEQ instrument [4] to examine the ion-surface reactive collisions. The target surfaces examined were functionalized self-assembled monolayers [5] on a gold substrate. In particular, $CF_3(CF_2)_{11}(CH_2)_2$-S-Au, $CD_3(CD_2)_{15}$-S-Au, $NC(CH_2)_{10}$-S-Au, $HO(CH_2)_{11}$-S-Au and $HOOC(CH_2)_{10}$-S-Au, and untreated stainless steel were used and are denoted by F, D CN, OH, COOH and S/S surfaces, respectively.

Adduct formation as a function of surface

We have used the molecular ions of pyrazine (m/z 80) at 25eV collision energy and pyrene (m/z 202) at 70eV collision energy and incidence and extraction angles of 55° and 90°, respectively, in order to examine the surface dependence of these processes.

Pyrazine: Reactions of the molecular ion of pyrazine with surfaces appear to have an onset at approximately 15eV. As the collision energy is raised, adduct formation increases, but is also accompanied by an increase in the extent of fragmentation of the molecular and adduct ions.

When the molecular ion of pyrazine (m/z=80) is incident on S/S, the dominant feature of the product ion spectrum is the hydrogen adduct ion, $(M+H)^+$, at m/z=81. This is borne out by the presence of the $(M+D)^+$ ion when identical conditions are used with a D surface.

On collision with OH and COOH surfaces, protonated pyrazine (m/z=81) is the dominant peak in the spectrum, with a slight amount of $(M+CH_3)^+$ (m/z=95) and $(M+C_2H_3)^+$ (m/z=107) also being observed. This raises some questions, since the abstraction of alkyl groups from OH and COOH terminated species was not expected. While the mechanism of the C_nH_m groups abstraction is not fully understood, it appears that the reactive collisions involve the hydrocarbon chain below the terminal functional groups. One of the striking observations when the COOH surface is used is the severe (two orders of magnitude) reduction in ion beam transmission between the surface and the final collector when compared to other surfaces, and is thought to be attributable to extensive naturalization taking place on the target surface.

When pyrazine is incident upon a CN surface, the hydrogen adduct is less intense than the molecular ion, and no higher alkyl adducts are observed. The use of an F surface results in a clean SID spectrum with no evidence of adduct formation.

Pyrene: Under the conditions specified, the abstraction of deuterium from a D surface by the pyrene molecular ion appears to be followed by an immediate loss of H, as shown by the peaks at m/z=203 and m/z=204 (Figure 1b). (There is a likelihood that the D will also be lost.) A comparison with the reactions of pyrene on S/S (Figure 1a) shows that a minimal hydrogen abstraction occurs (m/z=203) - even when alkyl adducts are formed - suggesting that hydrogen abstraction is followed by immediate elimination of one and two hydrogen atoms. In addition to the hydrogen/deuterium pick-up, peaks are observed in the spectra that are attributable to the abstraction of alkyl species from the surface. In these experiments, C_1 and C_2 alkyl adducts were seen to form at both surfaces with adequate resolution for the individula ions to be specified.

The 70eV collisions of pyrene molecular ion on the F surface showed reactive collisions with the

abstraction of fluoro species from the target surface. Peaks were observed in the adduct region at m/z=220 $(M+F-H)^+$, 219 $(M+F-H_2)^+$ and 218 $(M+F-H_3)^+$.

Adduct formation as a function of angle

The roles of the incidence and scattering angles on the formation and observation of adduct ions in ion/surface collision processes has not previously been studied, and we have examined the effect on changing these parameters on the adduct formation when the molecular ion of benzene (m/z=78) interacts with an F surface at 40eV. In the mass spectra of the adduct region of the benzene molecular ion incident upon an F surface, peaks are observed at m/z=95 $(M+F-2H)^+$, 96 $(M+F-H)^+$ and 97 $(M+F)^+$, for the adducts and m/z=100 $(C_2F_4)^+$ for species sputtered from the surface when the incidence angle is 55° and the scattering angle is 90° (Figure 2b). Varying the incidence and scattering angles show differences in that at more normal incidence (incidence angle 35°, scattering angle 93°) adduct formation dominates with an absence of sputtering (Figure 2a). When more grazing angles are used (Figures 2c and 2d) (incidence/scattering angles 65°/70° and 70°/80°, respectively), sputtering is increased relative to the adduct formation, with a dominance of sputtered species when the incidence and scattering angles are 70° and 80°, respectively.

MOLECULAR RECOGNITION IN THE GAS PHASE

Marco Vincenti
Dipartimento di Chimica Analitica, Università di Torino,

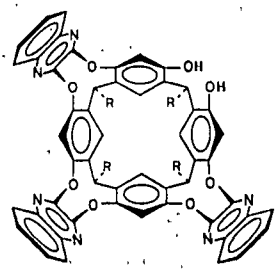
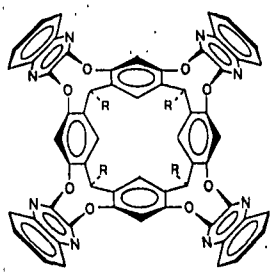
Enrico Dalcanale
Istituto di Chimica Organica, Università di Parma,
Viale delle Scienze, 43100 Parma, ITALY

Molecular recognition has been defined as a process involving both binding and selection of substrate by a given receptor molecule. When the substrate is a neutral organic molecule, the design of the receptor requires, in addition to shape complementarity, the modulation of weak attractive forces. Solvent effects occurring in the condensed phase frequently hinder the formation or the comprehension of these supramolecular interactions; therefore, the study in the gas-phase should provide a completely new tool to uncover hidden aspects of supramolecular interactions.

We focused our study on cavitands 1 and 2, whose limited structural differences (two adjacent phenolic hydrogens on the rim of the cleft in 1, a rigid concave surface in 2) involve functional groups with extremely different interaction capabilities. Vessel-like cavitand 2 selectively forms host-guest complexes with aromatic compounds in organic solvents (i.e. acetone), that are precipitated when the aromatic substrate concentration reaches a critical value [1]. Precipitates are not formed when an aromatic compound is added to a solution of cleft-shaped cavitand 1. Our preliminary study on host-guest complexation in the gas-phase confirmed that aromatic substrates are much more strongly bound by 2 than by 1 [2].



1



2

R=C_6H_{13}

Equivalent amounts of 1 and 2 were placed on a rhenium wire, which was introduced into the mass spectrometer ion source kept cold and filled (0.5 mBar) with an atmosphere containing two candidate guests and an excess (99%) of methane, acting as bathing gas. Then, the two cavitands were vaporized simultaneously from the wire heated by a fast-raising current.

Under such conditions, the two cavitands undergo complexation reactions with the guests, under thermodynamic control. Moreover, the two guests compete for each receptor (the hosts are in defect), and the relative complexation constants (Ka) for the two hosts can be measured. Identical conditions are established for the two hosts and the two guests, so that their behavior can be compared. The excess of methane is responsible for the ionization and the thermal deexcitation of reaction products, while the guests act uniquely as reactants in the complexation; stable and reproducible conditions are achieved, when the guests or their partial pressures are modified.

An example is shown in Figure 1, reporting the electron capture mass spectrum obtained in an experiment where benzene and n-butylamine (3:2, as measured by headspace GC) were selected as guests. Although the molecular ion of the free cavitands can be detected, most part of both hosts have interacted with the guests, forming the four possible supramolecular complexes. It is evident

that 1 interacts preferentially with n-butylamine (Ka=0.13), while 2 forms complexes more extensively with benzene than with n-butylamine (Ka=3.6); neither interacts with methane, despite its high concentration (99%). This double selectivity exhibited by the cavitands toward the complexation of different guests represents the first example of molecular recognition in the gas-phase [3].

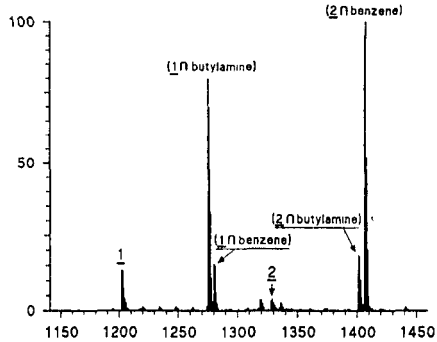


Figure 1

Face-to-face and edge-to-face interactions explain why 2 forms complexes with aromatic (benzene, toluene) and unsaturated cyclic (cyclohexene) compounds selectively. In contrast, a pure hydrogen bonding on phenolic hydroxyls does not explain entirely the complexation properties exhibited by 1. In fact, 1 interacts strongly with n-butanol and ethyl acetate (Ka=0.02 and Ka=0.5, as referred to benzene), but does not form complexes either with ethanol or methyl acetate (Ka>5). A rough estimation of the selectivity exhibited by 1 in the complexation of n-butanol versus ethanol exceeds 250; the striking example of methyl- and ethyl acetates is presented in Figure 2. We believe that a stable complex can be formed only if the guest can establish a double interaction with 1, possibly an hydrogen bond on phenolic hydroxyls and a CH_3-π interaction on the quinoxaline ring facing the hydroxyls. Ethanol and methyl acetate likely have too short structures to undergo both these interactions and consequently their complexes with 1 are much more labile. This example demonstrates that very subtle interaction effects can be distinguished in the gas phase, that can not be observed in solution chemistry.

Determination of Product Ion Structures Derived from the Reaction of Phenylium and Substituted Phenylium Ions with Neutral Reagent Ions

K.J. Hart, S.A. McLuckey and G.L. Glish
Oak Ridge National Laboratory, P.O. Box 2008
Oak Ridge, TN 37831-6365

The reaction of phenylium and substituted phenylium ions with methane has been investigated using quadrupole ion trap mass spectrometry. The structures of the $C_7H_7^+$ product ions were determined by selective ion molecule reactions for the benzyl and tolyl ions. In the case of the phenylium/methane reaction, we have identified a different structure than that reported in a previous study using an ICR mass spectrometer. Other product ions of the chloro-phenylium ion with methane were also observed. These ions were identified as consecutive reaction products of the tolyl ions formed during the initial reaction of the chloro-phenylium ions with methane. While characterizing the reactivity of tolyl ions with methane, evidence of isomerization of the tolyl ions during the isolation step was obtained. Isomerization of ions stored in the trap results from collisional "heating" of the ions with the helium buffer gas as the ions increase kinetic energy near the edges of the stability diagram.

Phenylium ions were generated by EI of chlorobenzene and isolated by applying appropriate rf and dc voltages to the ring electrode of the ion trap. Reaction of $C_6H_5^+$ ions with methane yields two product ions at m/z 91 ($C_7H_7^+$) and m/z 93 ($C_7H_9^+$). The ions at m/z 93 arise from collisional stabilization of the phenylium-methane complex by the helium buffer gas. Helium is used in the ion trap to collisionally damp the kinetic energies of the ions stored in the trap to improve detection efficiency and ion resolution.

The rate constant k_1 depends on a number of instrumental conditions including helium pressure and trap temperature and to a lesser extent on the number of stored ions and the Mathieu q value for m/z 77 during the reaction period. These results are presented elsewhere [1]. Using conditions commonly employed on the ion trap (1 mtorr of He, 100 °C, relatively low ion density and a q of 0.472), k_1 was determined to be 1.6 +/- 0.1 x 10^{-10} $cm^3molecule^{-1}s^{-1}$. The neutral number density of methane was determined by calibrating an ion gauge using the methane proton transfer reaction and assuming a rate constant of 1.1 x 10^{-9} $cm^3molecule^{-1}s^{-1}$.

The structure of the $C_7H_7^+$ ions was identified as the benzyl ion in contrast to a study performed on an ICR [2]. This determination was made by observing a characteristic CH_2^+ transfer reaction with m-xylene ($C_6H_5CH_2^+ + C_6H_4(CH_3)_2 \rightarrow C_6H_3(CH_3)_2CH_2^+ + C_6H_6$) [3]. When perdeuterated methane was used as the neutral reagent gas, a CD_2^+ transfer was observed. The rate constant for the CH_2^+ transfer reaction was determined to be 4.7 x 10^{-10} compared to a literature value of 6.5 x 10^{-10} [3]. The neutral number density of m-xylene was determined in this case by correcting the ionization gauge reading using an ionization probability correction factor (S/S_{N_2}) of 7.8. and may account for some this discrepancy.

The reactivity of chloro-phenylium ions ($C_6H_4Cl^+$) with methane was also investigated. These ions were generated by CID of the molecular ion of p-dichlorobenzene. This reaction yielded a number of product ions at m/z 79, m/z 91, m/z 105, m/z 107 and m/z 125. The abundance of these ions vs. reaction time is provided in Figure 1. It is clear from this plot that there are at least two $C_7H_7^+$ product ions formed during this reaction, one or more that are reactive with methane to form the m/z 79, m/z 105 and m/z 107 ions and one or more that are not reactive with methane. The presence of tolyl ions was confirmed by observation of the characteristic m/z 122 ion [4] when dimethylether was added to the system. Ions can be selectively ejected from the ion trap by applying an ac "tickle" voltage with the appropriate frequency and magnitude to the endcap electrodes in analogy with the "double resonance" experiment in the ICR. Selective ejection of m/z 91 eliminates all ions except the precursor ion and m/z 125 indicating that m/z 125 is $C_7H_8Cl^+$. There is a residual signal due to m/z 91

"The submitted manuscript has been authored by a contractor of the U S Government under contract No DE-AC05-84OR21400 Accordingly, the U S Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U S Government purposes."

observed in this experiment because the precursor ion continues to react with methane until it is ejected from the trap during the detection rf ramp.

A "pure" population of tolyl ions was reported by McLafferty et. al. using methane CI of 3-fluorotoluene [5]. A similar determination was made using the ion trap by allowing the tolyl ions to react with methane to completion. When m/z 91 was isolated using several isolation methods, a substantial unreactive component to the m/z 91 ion current was observed as shown in Figure 2. The relative degrees of isomerization caused by each isolation method should be interpreted from the data in Figure 2 with caution. The extent of isomerization depends on the duration and resolution of the isolation step. The duration of the isolation step determines the length of time that the ions are kinetically excited. The resolution of the isolation determines the magnitude of the excitation (e.g. an isolation step that ejects an ion 10 m/z units from the ion of interest will not excite that ion to the same extent as an isolation step that ejects an ion 1 m/z from the ion of interest). Exciting the m/z 91 ions with a small ac tickle voltage has the same effect. This effect is important to consider in ion trap applications involving ion species with activation barriers for isomerization lower than the activation barriers for dissociation.

The Gas Phase Reaction of HO^- and DO^- with Acrolein

*Marin S. Robinson, Fred W. Breitbeil, III and C.H. DePuy
University of Colorado, Boulder, CO. 80309

I. Introduction

In a recent work[1] we showed that the acrolein anion ($CH_2{=}\bar{C}CHO$) reacts with CS_2 to give 85% *m/z* 85, 11% *m/z* 87 and 4% *m/z* 103. In this study, we use this branching ratio as a probe to determine the amount of the $CH_2{=}\bar{C}CHO$ isomer formed when HO^- or DO^- is allowed to react with acrolein, $CH_2{=}CHCHO$.

The gas phase acidity of acrolein is 375.0 kcal/mol,[2] assuming that the neutral loses its most acidic proton to form the $CH_2{=}\bar{C}CHO$ isomer. The gas phase acidity of water is 390.8 kcal/mol,[3] hence HO^- can easily abstract this proton. The exothermicity of this reaction is the difference between the gas phase acidities of acrolein and water, or -15.8 kcal/mol. Calculations predict, however, that HO^- can also abstract any one of the other 3 protons in acrolein: removal of the proton on the β-carbon to form the cis-isomer is calculated to be 8.8 kcal/mol exothermic; abstraction of the proton on the β-carbon to form the trans-isomer is calculated to be 7.4 kcal/mol exothermic; and abstraction of the proton on the carbonyl carbon is calculated to be 1.6 kcal/mol exothermic.[4]

The purpose of this study is to determine how often HO^- abstracts the most acidic proton in acrolein to form the $CH_2{=}\bar{C}CHO$ isomer, rather than a proton from one of acrolein's less acidic cites. The reaction of DO^- with acrolein is also studied to gain mechanistic insight into this reaction.

All experiments were performed in a tandem flowing afterglow-selected ion flow tube (FA-SIFT) described previously.[5] HO^- was prepared by electron impact ionization of a mixture of N_2O and CH_4. DO^- was prepared by electron ionization of a mixture of N_2O and cyclohexane-d_{12}.

II. HO^- with Acrolein

The isomeric composition present when HO^- is allowed to react with acrolein was determined by allowing HO^- to react with acrolein in the first flow tube, injecting the mass selected $C_3H_3O^-$ ions that formed into the second flow tube, then probing their isomeric composition with CS_2. A different product distribution is obtained when the $C_3H_3O^-$ ions from HO^- and acrolein are allowed to react with CS_2, then when $CH_2{=}\bar{C}CHO$ alone is allowed to react with CS_2. Quantifying these differences allows us to conclude that the $CH_2{=}\bar{C}CHO$ isomer is formed 59% of the time, while the other $C_3H_3O^-$ isomers are formed 41% of the time.

III. DO^- with Acrolein

Mechanistic insight is gained by allowing DO^- to react with acrolein. When DO^- is injected into the reaction flow tube and allowed to react with acrolein, $C_3H_3O^-$ is formed 72% of the time, while $C_3H_2DO^-$ is formed 28% of the time. For $C_3H_2DO^-$ to form, the ion-molecule complex must undergo a minimum of 2 proton and 1 deuteron transfers before separation to products. We investigated the isomeric composition of these $C_3H_2DO^-$ ions by forming them in the first flow tube, injecting them into the second flow tube, then allowing them to react with CS_2. Their isomeric composition is enriched in the most stable isomer: 77% is now the $CH_2{=}\bar{C}CHO$ (d_1) isomer. These results indicate that as the number of proton and/or deuteron transfers within the ion-molecule complex increases, so does the probability that the most acidic proton will be abstracted. If this proton is abstracted, the greatest energy is released, thereby increasing the likelihood that the complex will separate to products rather than undergo further proton/deuteron transfers.

The isomeric composition of the 72% that formed the undeuterated $C_3H_3O^-$ ions was also probed. The $CH_2{=}\bar{C}CHO$ isomer makes up 50% of these ions. We assume, however, that 28% of these ions also underwent multiple proton/deuteron exchanges within the ion-molecule complex (as described above), but that a proton rather than a deuteron was transfered before separation to products, resulting in the formation of $C_3H_3O^-$ rather than $C_3H_2DO^-$. We therefore

subtract 28% from this 72%, and conclude that 44% of the collisions between DO^- and acrolein result in an ion-molecule complex that separates after only a single proton abstraction to form HOD and a $C_3H_3O^-$ isomer. To determine the isomeric composition of this 44%, we correct the branching ratio data obtained with CS_2 for the 28% that formed $CH_2{=}\bar{C}CHO$ 77% of the time, and find that when only a single proton transfer abstraction takes place, the $CH_2{=}\bar{C}CHO$ isomer is formed 33% of the time.

IV. Conclusions

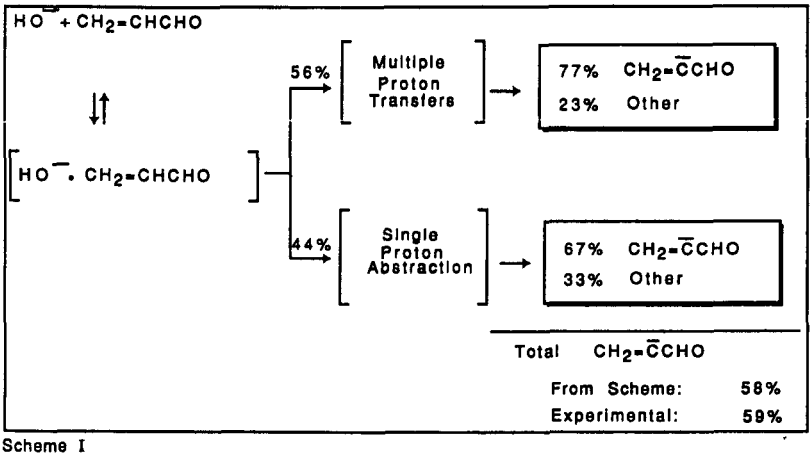
Scheme I summarizes the results discussed above. In general, we propose the following model for the reaction between HO^- and acrolein:

(1)The ion-molecule complex formed between HO^- and acrolein varies in lifetime: 56% of the time it survives long enough to undergo multiple proton transfers before separation to products, while 44% of the time it separates after the initial proton abstraction.

(2) When the ion-molecule complex undergoes multiple proton transfers, the $CH_2{=}\bar{C}CHO$ isomer is formed 77% of the time.

(3) When the ion-molecule complex separates after the initial proton abstraction, the $CH_2{=}\bar{C}CHO$ isomer is formed 33% of the time.

(4) When both processes are included, the $CH_2{=}\bar{C}CHO$ isomer is formed 58% of the time. This is in good agreement with the 59% observed experimentally.



Scheme I

NEGATIVE ION CHEMICAL IONIZATION OF ESTERS AND RELATED COMPOUNDS

M. Cheung, A.B. Young and A.G. Harrison

Department of Chemistry
University of Toronto
Toronto, Ontario, CANADA M5S 1A1

The use of $O^{\cdot-}$ and OH^- as reagent ions for identification of esters and related compounds using a double-focussing mass spectrometer has been explored. Compounds studied include methyl esters of simple (C_1-C_9) carboxylic acids, methyl esters of C_{18} fatty acids with varying degree of unsaturation, methyl esters of C_{18} monounsaturated positional isomers, triacylglycerols (TAG's) of the form:

$$\begin{matrix} -A \\ -A \\ -A \end{matrix} \;,\; \begin{matrix} -A \\ -A \\ -B \end{matrix} \;,\; \begin{matrix} -A \\ -B \\ -A \end{matrix} \;,\; \begin{matrix} -B \\ -B \\ -A \end{matrix} \;\text{and}\; \begin{matrix} -B \\ -A \\ -B \end{matrix}$$

(A and B are acyl portions attached to the glycerol backbone; chain length of A is shorter than that of B), and structural isomers of TAG's with different combinations of stearoyl/oleoyl portions. Analyses of methyl esters were performed using a VG ZAB-2FQ spectrometer, whereas those of tricaylglycerols were conducted with a VG 70-250S instrument that was linked to a VG 11-250J data system. The ion chamber pressure was 0.1 - 0.3 torr and the source temperature was 250°C.

Negative ion chemical ionization[1] (NICI) of the sample molecules resulted in only a few structurally significant species: the deprotonated ion, $[M-H]^-$, and the appropriate carboxylate ions. Fatty acid methyl esters also gave rise to the $[M-H-CH_3OH]^-$ species. $[M-H]^-$ was formed by proton abstraction of the most acidic proton of the molecule, which was the proton located α to the carbonyl[1]. Loss of methanol from $[M-H]^-$ occurred via elimination of the remaining α proton and the methoxy group, as shown in Equation (1).

$$R'\text{-}\underline{C}H\text{-}\overset{O}{C}\text{-}OCH_3 \;\text{---}\; R'\text{-}\overset{H\text{--}O\text{-}CH_3}{C}\text{=}C\text{=}O \;\text{---}\; R'\text{-}C\text{≡}C\text{-}O^- + CH_3OH \qquad (1)$$

The carboxylate ions resulted from the competing nucleophilic reactions[8] indicated in Equations (2) and (3).

$$R\text{-}\overset{O}{C}\text{-}OCH_3 + O(H)^- \;\text{---}\; R\text{-}\overset{O}{C}\text{-}\underset{H}{\overset{H}{C}}\text{-}O(H) \;\text{---}\; R\text{-}\overset{O}{C}\text{-}O^- + CH_3O(H) \qquad (2)$$

$$R\text{-}\overset{O}{C}\text{-}O\text{-}CH_3 + O(H)^- \;\text{---}\; R\text{-}\underset{O(H)}{\overset{O}{C}}\text{-}O\text{-}CH_3 \;\text{---}\; R\text{-}\overset{O}{C}\text{-}O^- + CH_3O(H) \qquad (3)$$

$O^{\cdot-}$ and OH^- generated the same type of ionic species, but in different abuundances. $O^{\cdot-}$ *produced a higher proportion of the carboxylate ion,* whereas OH^- produced more of the $[M-H]^-$ species. These results suggest that $O^{\cdot-}$ is both a good nucleophile and a strong Brønsted base, but that OH^- reacts as a stronger Bronsted base and a weaker nucleophile. $O^{\cdot-}$ was not observed to react with the esters or triacylglycerols as a radical.

The m/z of the $[M-H]^-$ species of a C_{18} fatty acid methyl ester gave an indication of the number of double bonds present for a homologous series since each double bond reduced the m/z of the deprotonated ion by 2. Although $O^{\cdot-}$ and OH^- NICI provided no information regarding the site of unsaturation, collision-activated decomposition (CAD) spectra of the carboxylate ions generated from monounsaturated fatty acid methyl esters have been shown to display sequential losses of C_2H_{4+2} units from the alkyl terminus that can be used to locate the position of the double bond[4,5,6]. $O^{\cdot-}$ would be more useful than OH^- for these experiments since it yields more carboxylate ion.

The structural composition of a triacylglycerol was reflected in the m/z of its $[M-H]^-$ ion and the carboxylate ions derived from the acyl portions. $[M-H]^-$ was the minor species formed, but its abundance increased as the acyl chains decreased in length. Since triacylglycerols of the form:

- A/A/B and A/B/A
- B/B/A and B/A/B
- structural isomers of TAG's with different C_{18} acyl groups

generated similar abundances of $[M-H]^-$ and carboxylate ions (A and B), the mechanism of fragmentation of a triacylglycerol is independent of the chain length and the degree of unsaturation present in its acyl portions.

Thus, although $O^{\cdot-}$ and OH^- NICI permits rapid structural characterization of a variety of fatty acid methyl esters and triacylglycerols, the technique is not capable of distinguishing structural isomers of these species.

SIFT Studies of Reactions of SiH^+.

Arnold Fox, Gholamreza Javahery, Stanislaw Wlodek and Diethard K. Bohme
Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, Ontario, Canada M3J 1P3.

Atomic silicon, Si, is among the top ten most abundant elements in the universe. It has an unusually high proton affinity, PA(Si) = 200.5 kcal mol^{-1}, so that the formation of SiH^+ is favoured on thermodynamic grounds. In interstellar environments formation of SiH^+ is expected from the protonation of Si by the ions H_2^+, H_3^+, CH^+, HCO^+, H_3O^+ and many other protonated atoms and molecules. Consequently the chemistry of SiH^+ is important in these environments. Of particular interest are reactions with H_2, because of the detection of SiH_4 in circumstellar clouds, and reactions with oxygen-containing compounds, given the importance of the Si-O bond.

In this study the Selected-Ion Flow Tube (SIFT) technique[1] has been used to investigate the chemical reactions of SiH^+ with the molecules H_2, CO, O_2, H_2O, HCN, CO_2, NO_2, SO_2, N_2O, NH_3 and C_2H_2 at 296 ± 2K in helium buffer gas at 0.35 Torr. SiH^+ was produced by electron impact at 80 to 100 eV from $HSiCl_3$ in a low-pressure ion source. The selected SiH^+ was predominantly in its ground $^1\Sigma^+$ state. There was no evidence for proton transfer with SO_2 which is exothermic with the first excited $^3\Pi$ state. Once thermalized by collisions with the buffer gas, SiH^+ ($^1\Sigma^+$) exhibited a range in reactivity.

No reactions were observed with H_2 and CO. A slow addition reaction was seen with O_2 to form $HSiO_2^+$ which appeared to transfer a proton to O_2. The structures and energies of isomers of $[H,Si,O_2]^+$ were investigated theoretically with ab initio molecular orbital calculations at the full MP2 level with a 6-311g** basis set using Gaussian 90. SiO_2 protonated at an oxygen atom was found to be the most stable isomer. However, the cyclic C_{2v} structure protonated at Si is also characterized by a well-defined minimum on the potential energy surface. Proton affinities were computed for protonation at both the oxygen and silicon sites. The affinity at the Si site was found to be less than the proton affinity of O_2.

Formation of $SiOH^+$ was observed in the reactions of SiH^+ with CO_2, N_2O and SO_2 and explained in terms of a proton-shuttle mechanism.[2] Also, the high-energy $HSiO^+$ isomer was shown to be produced by the reaction of SiH^+ with N_2O.[2] SiC_2H^+ was the predominant product in the reaction with acetylene and can result from C-H bond insertion. Adduct formation was observed with HCN. Proton transfer was observed only with ammonia which is consistent with the high proton affinity of Si, PA(Si) = 200.5 kcal mol^{-1}.

The results have relevance in the interstellar chemistry of silicon. The failure of SiH^+ to react with the abundant interstellar gases hydrogen and carbon monoxide makes SiH^+ available for reactions with minor constituents.

THE PROTON AFFINITIES OF SOME DIOLS DETERMINED BY HIGH PRESSURE MASS SPECTROMETRY

QingFeng Chen and John A. Stone
Department of Chemistry, Queen's University
Kingston, Ontario, Canada, K7L 3N6

The literature values for the proton affinities of linear alkanediols are lower than expected by analogy with those of diamines. Hydrogen bond formation following protonation should lead to cyclic structures for both diamines and diols. The maximum proton affinity increase if the ring is strain free is 22 kcal mol^{-1} for diamines and 31 kcal mol^{-1} for diols. These are respectively the values for H bonding in symmetrical proton bound dimers of amines[1] and alcohols.[2] α,ω-diamines, $H_2N(CH_2)_nNH_2$, almost attain the expected value for n≥3[1] but α,ω-diols do not. Since $PA(C_nH_{2n+1}OH)$ tends to a maximum value of 191 kcal mol^{-1} for n≥3, the maximum value expected for $PA(HO(CH_2)_nOH)$ is 222 kcal mol^{-1}, i.e. 191 + 31 kcal mol^{-1}. The only reported proton affinity values for α,ω-diols[3] yield hydrogen hydrogen bond energies which are 22 (n=2), 17 (n=3) and 10 (n=4) kcal mol^{-1} less than this maximum value. These results were obtained by the kinetic method involving the metastable dissociation or collision assisted dissociation of proton bound dimers, $H_3N{\cdot}H^+{\cdot}DIOL$. In order to assess the reliability of these unexpectedly low PA(DIOL) values we have used high pressure mass spectrometry with pulsed electron beam (PHPMS) to measure the proton affinities of α,ω-alkanediols (n=2,3,4). Equilibrium constants were measured as functions of temperature for proton transfer between the diols and suitable reference bases, B. The thermodynamic data obtained are shown in Table I. Thermodynamic data for the further solvation of the protonated diols by a second diol or by an ethanol molecule are shown in Table II.

The very large entropy changes for proton transfer to 1,3-propanediol and 1,4-butanediol show that cyclization occurs by internal hydrogen bond formation. The much smaller entropy change for proton transfer to 1,2-ethanediol demonstrates that a much less constrained structure is formed by protonation. The internal hydrogen bond in this protonated molecule is much weaker than those for the diols which form larger cyclic structures. The entropy changes due to cyclization may be calculated by subtracting the contributions from translational and rotational changes. The $\Delta S^\circ_{cyclization}$ values obtained are shown in Table I and are almost identical to those obtained for the analogous α,ω-diamines[1]

The proton affinity values for 1,3-propanediol and 1,4-butanediol are about 5 kcal mol^{-1} greater than those obtained by CAD[3]. The latter were obtained from ΔG° values using estimated entropy changes with the $\Delta S^\circ_{cyclization}$ values taken being identical to those for the analogous diamines. This could account for only 1 kcal mol^{-1} difference between the two sets of proton affinity values. The lower CAD results may be due to problems associated with using a proton bound dimer, $H_3N{\cdot}H^+{\cdot}DIOL$, with a different functional group on each of the two bases since it has been reported that in order to obtain accurate results using CAD, the proton bound bases should be as similar as possible.[4]

Further solvation of DIOL·H^+ by another diol is considerably more exothermic than solvation by ethanol and also the decreases in entropy are far greater. This is consistent with the second diol molecule in the cluster ion also acting as a bidentate ligand, although the exact structures of the cluster ions is not available from these PHPMS experiments.

Basic and Applied Studies with a Trace Atmospheric Gas Analyzer TAGA 3000

*R.J.Hughes and R.E.March, Department of Chemistry,
Trent University, Peterborough, ON, CANADA, K9J 7B8
J.M.Goodings and D.K.Bohme, Department of Chemistry,
York University, Downsview, ON, CANADA, M3J 1P3

Our objectives have been to establish a collaborative research facility, using the SCIEX TAGA 3000, at Trent University and to study the gas-phase chemical reactions which occur in the API source and which may improve the sensitivity of the instrument to a variety of compounds. This work was carried out in association with the Ontario Ministry of the Environment, Air Resources Branch.

The SCIEX TAGA series of mass spectrometers utilize an atmospheric pressure ionization (API) source. The ionization of trace analytes is accomplished by the transfer of protons from the ionizing species (generally water clusters) to the target analyte. The subsequent relative intensities of target analyte signals is determined not only by the relative proton affinities (PA) of the two compounds, a thermodynamic factor, but also by the rate of proton transfer, a kinetic factor. Furthermore, the process is affected by the distribution of higher-mass water clusters, which have higher proton affinities than the naked hydronium ion.

Under favourable conditions, API-source mass spectrometers display a remarkable sensitivity towards certain classes of compounds such as nitrogen-containing bases [1]. For these compounds proton and proton hydrate transfer is rapid, and the production of ionized target analytes is limited only by the collision rate.

For other compounds, generally oxygen-containing bases, the production of analyte ions is controlled by the equilibrium distribution of protonated water clusters $H^+(H_2O)_n$. Sensitivity falls off as the proton affinity of the analyte approaches that of water. Ethanal is an example of such a compound.

Certain compounds form hydrates of very low stability; at equilibrium there are much fewer hydrates of the analyte than of water. Furan is such a compound and has a much lower sensitivity than acetone even though their proton affinities are similar.

A new source arrangement has been designed based on the results of our initial experiments. The new source is depicted below and incorporates the following modifications:

1) The sample is injected through a hypodermic needle directly into the corona discharge region; only small amounts of sample are required.

2) The ion/molecule reaction area is contained in a glass tube which is flooded constantly with high-purity dry air; the equilibrium distribution of water clusters is shifted towards the lower-mass clusters which transfer their protons more readily.

3) Samples may be reacted in the gas phase with reagent gases during passage through the heated reactor tube in order to produce derivatives with higher proton affinities and/or more stable hydrates.

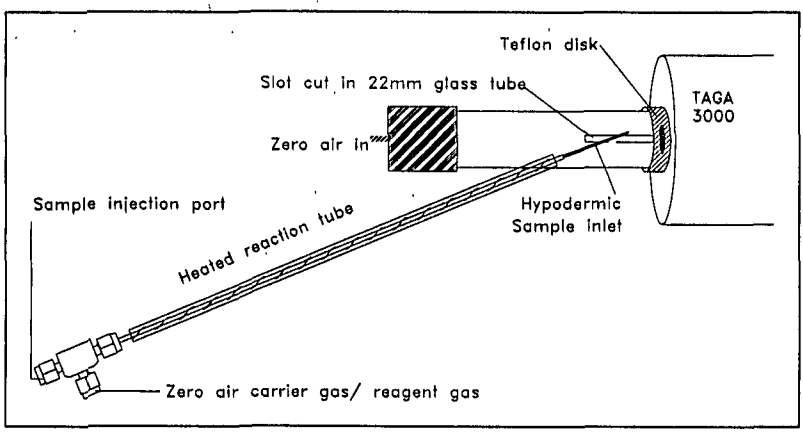

Figure 1 Schematic of the modified TAGA 3000 source showing the heated reactor with hypodermic inlet needle and the low-volume source area.

Our recent experiments have included an examination of the gas-phase reaction of ethanal and hydrazine molecules to form the ethanal hydrazone product: preliminary results indicate that the hydrazone product gives rise to a protonated ion signal intensity that is some 70 times more intense than the ethanal signal alone (*i.e.* unreacted with hydrazine).

Ion/Molecule Reactions of $Si_xD_y^+$ with Disilane

W. D. Reents, Jr., M. L. Mandich, and C. R. C. Wang
AT&T Bell Laboratories, Murray Hill, NJ 07974

Gas phase particle formation in silane plasmas degrade the materials grown from the plasma. Thin silicon films can be grown quicker and at lower temperatures than using other processes. These films have many useful applications in the optoelectronics industry. However, micron-sized particles formed within the plasma will deposit onto the film's surface. This roughened surface has degraded properties making it unsuitable for many applications.

The source of particles in a silane plasma is unknown. Ion/molecule reactions have been invoked because of their potentially rapid rates and because the observed particles are charged.[1]

Disilane, present at percent levels in silane plasmas, may be the source of particles. Ion/molecule reactions in neat silane do not lead to particles formation; reactions terminate with ions containing less than 7 silicon atoms.[2-8] Disilane, with its weaker bonds, could overcome the kinetic roadblocks present with silane and exhibit continued growth of ions. Our objective is to map out the ion chemistry in the disilane system to determine if kinetic roadblocks exist or if unlimited growth of ions to micron-sized particles occurs.

The ion chemistry in disilane exhibits kinetic roadblocks which stop growth of ions. The sequential reactions of ions with disilane produces larger ions than for the silane system as shown in TABLE I. However, the size of these ions, containing less than 9 silicon atoms, is still insignificant compared with micron-sized particles.

In conclusion, neither silane nor disilane alone are responsible for production of gas phase particles. However, the presence of percent levels of water overcomes the kinetic roadblocks present in the pure silane or disilane system.[9] Ions are then present with over twice the number of atoms as found in the pure silane or disilane system. The extended reactions show no signs of abating.

TABLE I

LARGEST ION FORMED
FOR SILANE AND DISILANE SYSTEM
AS A FUNCTION OF REACTANT ION

Thermal Energy Reactions of H_3^+ and H_3O^+ with a Series of Small Organic Molecules.

Mark Drucker, Hack Sung Lee and Nigel G. Adams
Department of Chemistry, University of Georgia,
Athens, Georgia 30602.

Rate coefficients and ion product distributions have been determined for the reactions of H_3^+ and H_3O^+ with CH_3OH, CH_3CHO, C_2H_5OH, $(CH_3)_2O$, $(CH_3)_2CO$ and $(C_2H_5)_2O$ using a flowing afterglow. These ions are implicated in interstellar molecular synthesis, their reactions with the above neutral molecules (coupled with electron-ion recombination) being a destruction mechanism for the molecules. The ions were created by operating in the afterglow of a microwave discharge at high pressure (1.3 Torr) with slow flows such that He_2^+, together with helium metastable atoms, He^m, were the dominant species upstream in the plasma. By sequential addition of Ar and H_2, H_3^+ was created as the dominant ion via the reactions: $He^m(He_2^+) + Ar \rightarrow Ar^+ + He + e(He)$, $Ar^+ + H_2 \rightarrow ArH^+ + H$ and $ArH^+ + H_2 \rightarrow H_3^+ + Ar$. H_3O^+ was generated as the dominant ion by replacing H_2 by H_2O. Reaction rate coefficients and product distributions were then determined in the usual way by adding reactant vapors and gases to the flow and monitoring the reactant and product ions with the downstream mass spectrometer.[1] In the case of the H_3^+ reactions, some H_3O^+ ions were also present due to the large rate coefficient for the proton transfer from H_3^+ to small H_2O impurities. Stringent efforts were made to minimize these impurities and the effect of the remaining impurity ions were accounted for using the data for the H_3O^+ reactions (given in Table 2).

H_3^+ is readily vibrationally excited in its production and this excitation can persist in the flow tube. For example, excitation of vibrational levels up to $v''=6$ in the ground state is possible in the production scheme given above if all of the available energy is channelled into that excitation. Evidence for some vibrational excitation was obtained from the reactions of H_3^+ with CH_3CHO and C_2H_5OH in which two slopes were observed on the decay plots. Additional H_2 was used to completely quench vibrational excitation in the H_3^+. For H_3O^+, there was no evidence for vibrational excitation, a consequence of the addition of sufficient H_2O to quench any vibrational excitation (this is certainly true if the quenching rate coefficient is similar to that for H/D exchange in the H_3O^+/H_2O system).

TABLE 1. Rate coefficients for the H_3^+ and H_3O^+ reactions.

	Rate Coefficient (10^{-9} cm^3s^{-1})					
	H_3^+			H_3O^+		
Reactant Molecule	Present	Theory[2]	Previous[3]	Present	Theory[2]	Previous[3]
CH_3OH	7.0	4.54	2.9	3.8	2.18	2.8, 2.2
CH_3CHO	6.9	6.44	-	3.7	2.96	3.6
C_2H_5OH	5.0	5.02	-	3.8	2.30	2.8
$(CH_3)_2O$	4.7	4.40	8.6	2.4	2.01	2.7
$(CH_3)_2CO$	7.7	7.13	-	3.9	3.18	3.9
$(C_2H_5)_2O$	4.2	5.20	-	3.1	2.27	-

The data in Table 1 for the rate coefficients show that in all cases these exothermic proton transfer reactions occur at the collisional rate and that the data are in general agreement with the previous data where available.

The ion product distributions for the H_3O^+ and H_3^+ reactions are, however, very different (see Table 2).

TABLE 2. Product Distributions (%) for the H_3^+ Reactions.

Reactant Molecule	Product Distribution (**Present**), <{[Previous]}>[3]
CH_3OH	CH_3^+(**53**)[23]{70}<46>; HCO^+(**18**); H_3CO^+(**17**)[19]{30}<28>; $CH_3OH_2^+$(**12**)[58]{0}<26>
CH_3CHO	CH_3^+(**21**); CH_5^+(**12**); H_3O^+(**15**)[25]; $C_2H_3^+$(**13**)[16]; HCO^+ \ $C_2H_5^+$(**11**)[57]; $C_2H_3O^+$(**6**)[9]; CH_3CHOH^+(**22**)

$(C_2H_5)_2O$	CH_3^+(**8**); $C_2H_3^+$(**29**); HCO^+ \ $C_2H_5^+$(**34**); H_3CO^+(**12**); $C_2H_5O^+$(**8**); $C_2H_7O^+$(**5**); $C_3H_7O^+$(**3**)

The H_3O^+ reactions proceed by direct proton transfer (except in the case of the C_2H_5OH reaction where the association product (10%) and some $CH_3OH_2^+$ production were also observed), whereas in the H_3^+ reactions there is a great deal of fragmentation with direct proton transfer not being the dominant channel. There is a measure of agreement between the products detected in this study and those reported previously, although in this study additional products are seen. For the CH_3OH reaction, for which most of the previous measurements have been made, there are some variations between measurements but within these variations there are no inconsistencies with our data (except that we observe the additional product HCO^+). CH_3^+ is an important product in all but the $(C_2H_5)_2O$ reaction for which mass 29 (presumably $C_2H_5^+$) is dominant together with an almost equally important $C_2H_3^+$ product. For the other species containing the ethyl grouping (C_2H_5OH), mass 29 is also dominant but $C_2H_3^+$ is not very important, consistent with the slight endothermicity of this channel (1 kcal mol^{-1}). Mass 29 is also an important product in the other H_3^+ reactions, except $(CH_3)_2CO$ for which its production would require significant rearrangement. Comparison between the results for the isomeric species $(CH_3)_2O$ and C_2H_5OH is also interesting. CH_3^+ is an equally important product in both cases (~30%) resulting from the breaking of a C-O and a C-C bond for $(CH_3)_2O$ and C_2H_5OH respectively. The other fragment ions resulting from the fracture of these bonds are possibly different forms of H_3CO^+ (i.e., H_3CO^+ and H_2COH^+). These data are discussed in more detail in Ref. 4.

A High Pressure Mass Spectrometric Re-evaluation of Proton Affinities of Fluorinated Benzenes

J.E. Szulejko and T.B. McMahon,
Dept. of Chemistry, University of Waterloo, Waterloo, Ontario, N2L 3G1, **CANADA.**

A High Pressure Mass Spectrometric investigation of the low Proton Affinity regime[1] from N_2 to H_2S by proton transfer equilibria between pairs of bases A and B [$AH^+ + B \leftrightharpoons BH^+ + A$] was examined as a function of temperature on a modified VG 70-70 HPMS[2]. The van't Hoff plots' data required that the PA of H_2O and H_2S (referenced to CO PA taken as 141.4 kcal mol^{-1}) to be reduced by c 2 kcal mol-1 from that cited in the NIST PA database[3]. In view of this observation, the study was extended upwards to include C_3H_6 as an additional reference PA. A search of the NIST tables, suggested C_6F_6 would have been an excellent base of PA intermediate between that of H_2S and C_6H_6. However, when proton exchange equilibrium experiments were attempted between C_6H_6 and C_6F_6, no protonated C_6F_6 (if any) could be observed except during the ionization pulse! Bases of decreasing PA were tried. It was only then with SO_2 that equilibrium could be established and studied. The PA of C_6F_6 is now concluded to be some 24 kcal mol^{-1} lower than the NIST entry. Upon further investigation with other fluorinated benzenes, led to the startling conclusion that major revisions were needed to the NIST PA database. A new PA scale from N_2 to $C_6H_5CH_3$ is presented in the Table. With the notable exceptions of the fluorobenzenes, most of the PA's differ only slightly (less than 2 kcal mol^{-1}) from the NIST PA values.

It was also observed that the exothermic direction proton transfer rate constant between non isomeric fluorinated benzenes was considerably slower than the collision rate, ($C_6F_6 \rightarrow C_6HF_5$ $k = 6.5 \times 10^{-11}$ cm^3 s^{-1} at 500K). This could have been a factor in the original ICR PA *equilibrium* data[4] in which only a quasi non reacting steady state would have been observed in the ICR timeframe. Another problem encountered in the ICR work, is that rather large ^{13}C isotope carryover corrections due to radical molecular cation, M^+, had to be made to $(M+1)^+$ signal of interest. This was much less of a problem in the present HPMS study.

For some of the fluorinated benzenes, the half reaction ($A \rightarrow AH^+$) entropy changes $\Delta S_{1/2}$ are larger than expected from symmetry considerations alone (see Table). This would implied the concepts of; (i) *dynamic proton*, (ii) protonation on a F atom to create a new free rotor or (iii) bending of F atom(s) out of the plane of the aromatic ring. The main factors for this to happen are twofold; (i) 3 or more neighbouring Fluorine atoms or (ii) 2 Fluorine atoms disposed in a 1,4 fashion. This phenomenon of excess entropy has been reported, especially for the protonated 1,4 halotoluenes[5]. Carbon disulphide, for such a small simple molecule also has an extremely large $\Delta S_{1/2}$ of 10.5 cal mol^{-1} K^{-1} and is only possible if the S-C-S heavy atom chain is significantly non-linear. Ab initio calculations do not support this conjecture or protonation on carbon.

DETAILS OF THE CHARGE TRANSFER REACTION BETWEEN $FeCp^+$ AND ETHYLENE OXIDE†

Cheryl A. Turner, Li Lin, Charles R. Kutal, I. J. Amster
Department of Chemistry, University of Georgia, Athens Georgia, 30602

INTRODUCTION

We have been studying the gas phase ion chemistry of $FeCp^+$ with ethylene oxide in order to gain a better understanding of its role in the cationic polymerization of epoxides. We previously reported evidence of two reaction channels: oxygen abstraction and electron transfer. The two competing reactions can be individually enhanced by changing the internal energy of the $FeCp^+$ ion. A larger amount of internal energy favors oxygen abstraction and yields the major metal-containing product, $FeCpO^+$. However, a reduction in internal energy favors electron transfer which produces the radical cation, $C_2H_4O^{+\cdot}$. This cation rapidly abstracts a hydrogen from neutral ethylene oxide in a subsequent step to give the observed product $C_2H_5O^+$. The rate constants for these reactions have been measured and are reported here.

EXPERIMENTAL

A Fourier transform mass spectrometer that is equipped with a 1-3/4" cubic cell, a 1 Tesla electromagnet, and an IonSpec Omega data system is used in these studies. The gas/liquid inlet system is equipped with two pulsed valves and a sapphire sealed leak valve which are used for introducing volatile samples into the main vacuum chamber. The gas/liquid inlet system is pumped with a diffusion pump and the main vacuum chamber is pumped with a 330 L/s turbomolecular pump to a base pressure of 2×10^{-10} Torr.

The $FeCp^+$ used in these experiments is formed either by electron ionization of ferrocene or by charge exchange ionization of ferrocene. For electron ionization, ferrocene is leaked into the main chamber at a pressure of 1.0×10^{-8} Torr. For charge exchange ionization, the reactant gas CO_2 is pulsed into the cell where it is ionized by electron impact to form the reactant ion, $CO_2^{+\cdot}$. The reactant ion then interacts with the neutral ferrocene molecules that are introduced by the leak valve according to the reaction shown below.

$$R^{+\cdot} + FeCp_2 \text{ ---> } R + FeCp_2^+ \text{ ---> } FeCp^+ + Cp^\cdot$$

RESULTS

The timeplot of the intensities of the precursor and product ions for the reaction between ethylene oxide and $FeCp^+$, which is generated at 70 eV, is shown below in Figure 1. The data produced from this experiment allows one to derive the rate constants for the various reaction channels. Electron transfer is measured to have a rate constant equal to 4.4×10^{-11} $cm^3molecule^{-1}s^{-1}$. The formation of $C_2H_5O^+$ has a rate constant of 1.2×10^{-9} $cm^3molecule^{-1}s^{-1}$. Oxygen abstraction has a rate constant equal to 1.0×10^{-9} $cm^3molecule^{-1}s^{-1}$.

The effects of the internal energy of $FeCp^+$ on the rate of reaction have also been studied. The same experiment that is shown in Figure 1 has been repeated, however, the electron beam energy is decreased to 30 eV. In this experiment, the rate constant of electron transfer is equal to 5.0×10^{-10} $cm^3molecule^{-1}s^{-1}$, while the rate constant for oxygen abstraction is 2.5×10^{-10} $cm^3molecule^{-1}s^{-1}$, consistent with the results that we observe for the ratio of $FeCpO^+$ to $C_2H_5O^+$ in the studies above.

Our data supports the argument that the formation of the radical cation, $C_2H_4O^{+\cdot}$, by electron transfer is the rate determining step in the formation of $C_2H_5O^+$. Thus the $C_2H_4O^{+\cdot}$ generated from the reaction of $FeCp^+$ with ethylene oxide quickly reacts away to form $C_2H_5O^+$. The low abundance that we observe for the intermediate in the mass spectra is consistenet with this explanation. Continuous double-resonance ejection experiments of $C_2H_4O^{+\cdot}$ show that the production of $C_2H_5O^+$ is drastically reduced (Figure 2), thereby establishing the parent-daughter relationship of the two species.

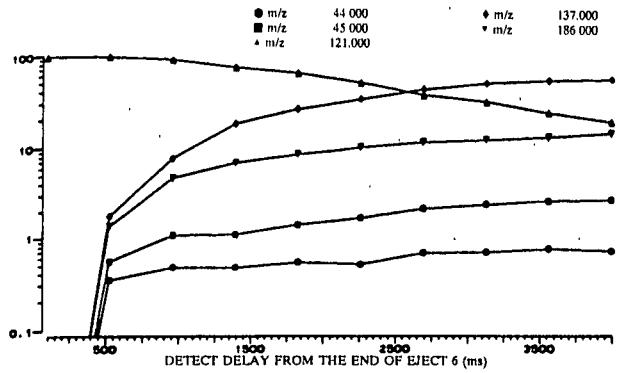

Figure 1: Timeplot of the relative intensities of the precursor and product ions produced during the reaction of ethylene oxide and $FeCp^+$ at 70 eV.

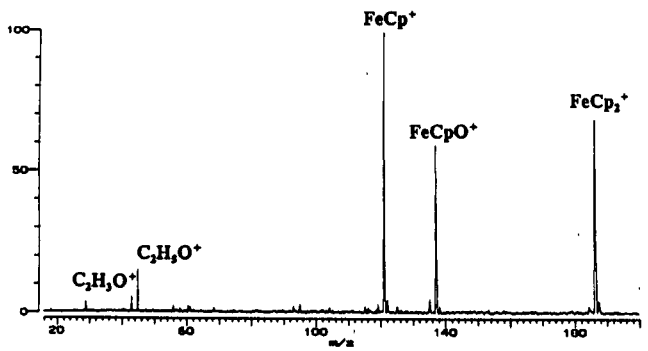

Figure 2: Continuous double-resonance ejection experiment of $C_2H_4O^{+\cdot}$ which shows the drastic decrease in the abundance of $C_2H_5O^+$.

Low Pressure Glow Discharge Ionization MS/MS Analysis of Benzene and Toluene in Automobile Exhaust.

*Mark A. Dearth, T.J. Korniski, E. Chladek, J.E. Weir, R.H. Hammerle
Ford Motor Co. Scientific Research Labs, Dearborn, MI 48128

Introduction. There is an intense interest in the automotive emissions measurement community to develop techniques that can generate species concentration data in real-time, thus eliminating long delays between vehicle testing and data reporting. Such a technique, based on low pressure glow discharge ionization coupled with tandem mass spectrometry, is reported here. The technique titled above addresses two concerns; it produces real-time data for select species in vehicle emissions, and it reduces potential interferences from unmeasured compounds by enhancing sensitivity and selectivity for the species of interest (benzene and toluene). Other techniques do not have the sensitivity or selectivity to quantify trace species in the complex matrix of auto exhaust. The success of this method hinges on the use of nitric oxide (NO) as a charge attachment reagent gas. Previous work (1-3) using NO in classical CI, suggested NO might be a useful reagent gas in glow discharge CI. Low pressure glow discharge ionization generates predominately NO^+ from dry air at higher discharge currents.

In this work, the adduct ion formation of NO^+ with benzene and toluene, and subsequent tandem mass spectrometric analysis of these adducts, are used to quantify these two species in auto exhaust. For the first time, the intermittent nature of these emissions and their correlation with changes in the operation of the vehicle can be examined under dynamic operating conditions and with a variety of fuels.

Experimental. Measurements were made with an API-III tandem mass spectrometer (Sciex, Thornhill, Ont.) equipped with a low pressure glow discharge ion source. The ion source was operated at 100°C, with ion source pressure (1.1 torr) and discharge current (0.75-1.5 mA) optimized (daily) by adjusting the various ion source parameters to produce the maximum response and resolution for benzene and toluene. The sample delivery system and other experimental parameters have been described in greater detail elsewhere (4).

For quantitation, the NO adducts of benzene (m/z 108) and toluene (m/z 122) were selected by Q1, were fragmented in Q2, and the molecular cations (m/z 78 and 92) were selected by Q3 for detection. Instrument response was typically 2000-3500 ion counts per second per part per billion (icps/ppb).

Results and Discussion. We have found the adduct formation with benzene and toluene to be a linear process across a useful concentration range. A typical calibration curve is shown in Figure 1, along with the MS/MS spectrum of the benzene+NO^+ adduct.

To test the utility of this method, benzene and toluene are quantified in auto exhaust, both before and after the catalytic convertor while the vehicle is operated according to the Federal Test Procedure Urban Dynamometer Driving Cycle. Three different fuels were used in the vehicle, with each producing different quantities of benzene and toluene as combustion byproducts or unburnt fuel, as can be seen in Figure 2. Small amounts of benzene and

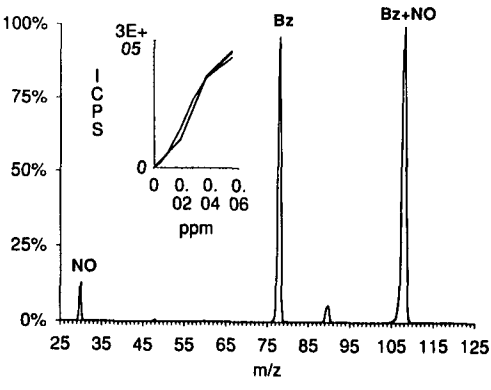

FIGURE 1

toluene are produced, even from a vehicle operated on a fuel containing no aromatic compounds. Adding aromatic compounds to the fuel can be seen to elevate the emissions of these two species dramatically.

For the first time, the transient nature of these emissions has been determined. One useful result of this experiment is that loading of the catalytic convertor can be discerned by the difference in the pre- and postcatalyst elution time for the initial concentration spike of benzene and toluene. In Figure 2, the precatalyst concentration maximizes in 10-15 seconds, while the postcatalyst concentration maximizes at 16-20 seconds.

Gas-Phase Thermochemical Properties and Reactivity of the Bicarbonate and Bisulfite Negative Ions.

Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN 47907.

A combined experimental and theoretical study of the gas-phase thermochemical properties of bicarbonate ion $HOCO_2^-$, bisulfite ion $HOSO_2^-$, and their conjugate acids is presented.[1] The formation and qualitative identification of the sulfonate ion HSO_3^- is also reported. Threshold energies for collision-induced dissociation of OH^- ion from $HOCO_2^-$ and $HOSO_2^-$ have been determined to be 50.3 ± 2.5 and 61.3 ± 2.5 kcal/mol, respectively, from which the standard heats of formation $\Delta H^o_{f,298}[HOCO_2^-,g] = -177.8 \pm 2.5$ kcal/mol and $\Delta H^o_{f,298}[HOSO_2^-] = -165.6 \pm 2.5$ kcal/mol are derived by means of simple thermochemical cycles. The measured HO^- binding energies of CO_2 and SO_2 are in good agreement with *ab initio* calculations and with the expected values based on empirical correlations between Bronsted and Lewis basicities of negative ions. Reactions between bicarbonate ion and a series of neutral acids in the flowing afterglow indicate an *apparent* proton affinity of 356 ± 2 kcal/mol. Bicarbonate ion reacts with H_2S to produce both HS^- and $HS^-(H_2O)$, and the deuterium labelled ion, $DOCO_2^-$, reacts by H/D exchange as well. Bisulfite ion is found to have an *apparent* proton affinity of 337 ± 3 kcal/mol from its behavior in proton transfer reactions with a series of reference acids. The reaction between $HOSO_2^-$ and HCl yields $Cl^-(SO_2)$ as the major ionic product, along with a small amount of Cl^-. $DOSO_2^-$ does not exhibit any H/D exchange with HCl or carboxylic acids. Sulfonate ion can be formed at room temperature in the flowing afterglow either by oxygen atom transfer from NO_2 to HSO_2^-, or by hydride transfer from CH_3O^- to SO_3. High-level *ab initio* calculations predict gas-phase acidities (ΔH_{acid}) for carbonic acid $(HO)_2CO$ and sulfurous acid $(HO)_2SO$ of 339 and 330 kcal/mol, respectively, and enthalpy changes for their dehydration of -5 and -2 kcal/mol, respectively. The origin of the large differences between the calculated and apparent basicities of $HOCO_2^-$ and $HOSO_2^-$ is proposed to be due, in part, to a dissociative neutralization mechanism wherein dehydration of the nascent carbonic acid and sulfurous acid molecules accompanies proton transfer.

Development of a Stereochemical Protocol. Reactions and Competitive Dissociations of Pentacoordinate Silicon Ions

Yeunghaw Ho and Robert R. Squires
Department of Chemistry, Purdue University
West Lafayette, IN 47907.

Some time ago we reported the generation of pentacoordinate silicon hydride ions in a flowing afterglow apparatus by adding a bare hydride ion to an alkylsilane (eq 1). These

$$H^- + RSiH_3 \rightarrow RSiH_4^- \qquad \text{(eq 1)}$$

species were found to be reactive reducing agents, transferring hydride to CO_2, transition metal carbonyls, boranes, and even to SiH_4[1,2]. The $RSiH_4^-$ ions reduce simple organic carbonyl compounds such as aldehydes and ketones by the net addition of an Si-H bond across the carbonyl group to produce an alkoxysiliconate ion product (eq. 2). Comparison of

$$BuSiH_4^- + Me_2C{=}O \rightarrow [^iPrOSiH_3Bu]^- \leftarrow {}^iPrO^- + BuSiH_3 \qquad \text{(eq. 2)}$$

the collision-induced dissociation (CID) spectrum of the adduct obtained from reduction of acetone with $BuSiH_4^-$ with that of an authentic $(^iPrO)BuSiH_3^-$ ion produced by direct addition of $^iPrO^-$ to $BuSiH_3$ verifies the structural assignment for the alkoxysiliconate ion product of eq. 2. Analogous experiments with other alkoxide/carbonyl compound pairs and different mono-, di-, and trialkylsilanes show this reduction behavior to be general.

Direct addition of a pre-formed alkoxide ion to an alkylsilane provides an alternative approach to pentacoordinate silicon ion reducing agents. Reduction of an aldehyde or ketone with an alkoxysiliconate ion produces a pentacoordinate silicon ion bearing two alkoxy groups (eq 3). The dialkoxysiliconate ions formed in this way provide the keys to

$$ROSiH_3Bu^- + Me_2C{=}O \longrightarrow (RO)(^iPrO)SiH_2Bu^- \qquad \text{(eq. 3)}$$

determining the <u>diastereoselectivity</u> of the gas-phase reduction reactions. The dialkoxysiliconate ions undergo CID by loss of either alkoxide ion (eq 4), and the relative

$$(RO)(R'O)SiH_2Bu^- \xrightarrow{CID} RO^- + BuSiH_2OR' \text{ or } R'O^- + BuSiH_2OR \qquad \text{(eq. 4)}$$

yield of the two alkoxides appears to be an extremely sensitive function of their structures and relative basicities. For example, addition of $^iPrO^-$ to $BuSiH_3$ followed by reaction of the adduct with butanal produces the dialkoxysiliconate ion $BuSiH_2(^iPrO)(BuO)^-$. CID of this ion with argon target at 18 eV (lab frame) yields the alkoxide fragments in a measured ratio $^iPrO^-/BuO^- = 1.51 \pm 0.15$. For comparison, CID under similar conditions of the corresponding proton-bound dimer $(^iPrO^-)(BuO^-)H^+$ gives the alkoxides in essentially identical yields: $^iPrO^-/BuO^- = 1.00 \pm 0.01$. Thus, the secondary alkoxide is preferentially cleaved from the siliconate ion, presumably due to steric repulsion effects that weaken the Si-O^{i}Pr bond.

The alkoxy ligands in dialkoxysiliconate ions undergo positional exchange, either in the long-lived ions or during their decomposition in the collision chamber, and become chemically and structurally equivalent. This is shown by the equivalence of the CID spectra obtained from the dialkoxysiliconate ions produced either from addition of cyclohexylalkoxide ion to $C_6H_{13}SiH_3$ followed by reduction of 3-pentanone, or by addition of 3-pentoxide ion to $C_6H_{13}SiH_3$ followed by reduction of cyclohexanone.

On the basis of these general characteristics of pentacoordinate silicon hydride ions, we designed a strategy for determeining the stereochemical outcome of the gas-phase reduction of 2-methylcyclohexanone. The alkoxysiliconates were generated from the attachment of diastereomerically-pure cis- and trans-2-methylcyclohexylalkoxide ions to $C_6H_{13}SiH_3$ in the flow tube. Subsequent reduction of 3-pentanone yields the dialkoxysiliconate ions **C** and **T**. CID of these ions gives the two alkoxide fragments in yield ratios ($C_5H_{10}O^-/C_7H_{13}O^-$) of 0.31 ± 0.01 for **C** and 0.69 ± 0.02 for **T** (Fig. 1). Addition of 3-pentoxide to $C_6H_{13}SiH_3$ followed by reduction of 2-methylcyclohexanone with the adduct produces dialkoxysiliconate ions with an unknown diastereomeric composition. CID of this mixture yields the two alkoxides in a ratio ($C_5H_{10}O^-/C_7H_{13}O^-$) = 0.55 ± 0.04 (Fig. 2). The composition of the diastereomeric mixture then can be derived from these data by using simple algebraic expressions. The final percentages are 32 ± 6% cis and 68 ± 6% trans.

Thus, the reduction of 2-methylcyclohexanone with an alkoxysiliconate ion in the gas phase occurs predominately by axial attack forming the more stable trans product.

Biradical Thermochemistry from CID Threshold Measurements in a Flowing Afterglow-Triple Quadrupole Instrument

*Paul G. Wenthold, Kirk Arvidson, and Robert R. Squires, Department of Chemistry
Purdue University, West Lafayette, IN 47907

We have recently shown how collision-induced dissociation (CID) of α-chlorocarbanions can be used to obtain carbene thermochemistry.[1] The basic procedure involves the generation of a chlorocarbanion which loses Cl^- upon collisional activation to give a carbene. The threshold for chloride loss, E_T, can be measured and combined directly with the anion proton affinity and other auxiliary data from the literature in a simple thermochemical cycle to give the heat of formation for the neutral carbene. We have now extended this approach to more remote "(α,ω)" Cl^- eliminations to give unsaturated and diradical products. We report here the results of our studies of a variety of aromatic biradicals, including benzynes, dehydrotoluenes, and dehydrophenols. These studies clearly demonstrate the versatility of the CID method for determining accurate thermochemistry for highly reactive biradical species.

Benzynes

Initial studies focused on the thermochemical properties of the dehydrobenzenes (ortho-, meta-, and para-benzyne).[2] These were prepared by CID of o-, m-, and p-chlorophenyl anions, respectively, which were generated by the reaction of the corresponding chlorophenyltrimethylsilanes with fluoride ion. The thresholds for Cl^- loss from o-, m-, and p-chlorophenyl anions are 15.7 ± 3.0, 24.2 ± 3.0, and 35.3 ± 3.0 kcal/mol, respectively. These thresholds, when combined with the anion proton affinities (obtained by standard bracketing techniques) and auxiliary data, give heats of formations of 106 ± 3, 116 ± 3, and 128 ± 3 kcal/mol for ortho-, meta-, and para-benzyne, respectively.

Dehydrotoluenes

We have measured the heats of formation for the isomeric dehydrotoluene[3] biradicals as an extension of the benzynes. Here the procedure simply entails preparation of o-, m-, and p-chlorobenzyl anions which lose Cl^- upon CID to give α,2-, α,3-, and α,4-dehydrotoluene. Surprisingly, the threshold for chloride loss from m-chlorobenzyl anion is significantly lower then that for the ortho or para isomers. Using the experimental heats of formation, it is possible to calculate the C-H bond strengths in benzyl radical. While the ortho and para C-H bonds are comparable to that in benzene, the meta C-H bond is ca. 7 kcal/mol weaker. This is attributed to a previously unrecognized singlet ground state for this biradical.

In principle, CID of (halomethyl)phenyl anions would give the same biradicals as above. Measuring the threshold for halide loss from these ions provides an alternate approach to the heats of formation for the dehydrotoluenes. However, certain of the (halomethyl)phenyl anions were found to undergo an unprecedented 1,4 halide shift to give the halobenzyl anions. Although this limits their utility for thermochemical studies, it demonstrates a new class of gas-phase, biradical rearrangements.

Dehydrophenols

Finally, we have investigated the thermochemical properties of the dehydrophenols, a system analogous to the dehydrotoluenes. These are prepared by deprotonating o-, m-, and p-chlorophenol and subjecting the resulting ions to CID. As before, the α,3 isomer is found to be unusually stable as a result of a singlet ground state. While deprotonation of the phenols is readily accomplished with F^-, a different result is obtained when o-chlorophenol is deprotonated with hydroxide. In this case, the Cl^- appearance curve has two distinct onsets. It is shown by deuterium labeling that the deprotonated o-chlorophenol is actually a mixture of O- and ring-deprotonated species. By measuring the threshold for chloride loss from the latter, we have estimated the heat of formation for hydroxybenzyne.

Thermochemical results are summarized in table 1.

MEASUREMENT OF S_N2 RATE CONSTANTS AT ATMOSPHERIC PRESSURE USING THE PHOTODETACHMENT-MODULATED ELECTRON CAPTURE DETECTOR

Kyle S. Strode and Eric P. Grimsrud
Department of Chemistry, Montana State University, Bozeman, MT 59717

In this study, we report measurements of rate constants for the S_N2 reactions of chloride ions with methyl,

$$Cl^- + RBr \rightarrow Br^- + RCl \qquad (S_N2 \text{ reaction})$$

ethyl, *n*-propyl, isopropyl, cyclopropyl, allyl, *n*-butyl, *sec*-butyl, and isobutyl bromides. These measurements were made in a specialized photodetachment-modulated electron capture detector (PDM-ECD) at atmospheric pressure. In the PDM-ECD, electron photodetachment from Br^-, reaction 2, was monitored. Any Br^- detected

$$Br^- + h\nu \rightarrow Br\cdot + e^- \qquad (\text{reaction } 2)$$

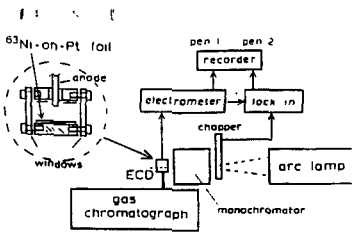
was attributed to reaction of RBr with Cl^-, because the brominated compounds have extremely low electron capture rates. A gas chromatograph (GC) was used for sample introduction to the PDM-ECD. GC introduction provided complete separation of the brominated compound of interest from potentially interfering impurities, and made it possible for unambiguous measurements of their S_N2 rate constants.

The apparatus is shown in Figure 1. The stainless steel ECD has a cylindrical ionization volume of 2.65 cm^3. A ^{63}Ni-on-Pt foil forms the cylindrical walls of the cell, and the ends of the cell are formed by fused silica windows. The reaction volume is maintained at atmospheric pressure, which is about 640 torr in Bozeman. A 1000-Watt Hg-Xe arc lamp, an IR filter, an optical chopper operated at 23 Hz and a high throughput monochromator are used to focus chopped light of a selected wavelength into the PDM-ECD cavity. The PDM-ECD current is processed by an electrometer and is sent to pen 1 of a 2-pen recorder and also to a lock-in amplifier, as shown. The lock-in amplifier mixes the electrometer signal with the square waveform coming from the chopper and the resulting product is sent to pen 2 of the recorder. Pen 1 records the response due to electron capture, while pen 2 records the modulated photodetachment response.

The compound of interest is diluted in nitrogen gas, injected into a 2-mL sample loop of a GC and passed through a 10-ft × ⅛-in stainless steel column packed with 10% SF-96 on Chromosorb W. Upon elution, the effluent from the GC mixes with a make-up gas and is introduced into the PDM-ECD. The total gas flow rate is between 60 and 100 mL min^{-1}. Both carrier and make-up gases consist of a mixture of 10% methane in argon and are passed through water- and oxygen-removing traps. Using this method, we obtain complete separation of the brominated compounds from potential impurities, including structural isomers. The chromatographic retention times of all compounds studied were determined from parallel GC studies with flame ionization detection and/or mass spectrometric detection.

The Cl^- reactant ion is generated from dissociative electron capture by CF_2Cl_2, which flows continually into the make-up gas through a needle valve. The introduction of CF_2Cl_2 is controlled so that the Cl^- concentration is approximately equal to that of electrons in the ECD.

The threshold for photodetachment (PD) from Br^- is 371 nm, while the PD threshold for Cl^- is 342 nm. In order to provide a selective response to Br^- without interference from Cl^-, the intense emission at 365 nm of the Hg-Xe lamp was selected with the monochromator. In figure 2, the PD and EC responses are monitored simultaneously for ethyl bromide (EtBr). As expected, no EC response is observed for EtBr, since the EC rate constant is extremely low. A PD response is observed, however, which is due to conversion of Cl^- to Br^- by reaction 1. The magnitude of the PD response is proportional to the concentration of Br^-, and approaches a saturation level as the concentration of EtBr is increased, as shown in figure 3. This saturation level is proportional to the Cl^- concentration in the PDM-ECD when RBr is not present, and is independent of the identity of RBr.



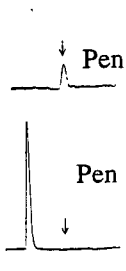


Figure 3 Plot of the magnitudes of the photodetachment responses due to Br^- as a function of [EtBr]

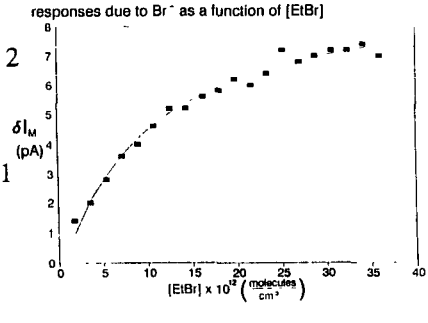

Recombination of Br^- with positive ions is shown in reaction 3. The rates of reactions 1 and 3 govern the

$$Br^- + P^+ \rightarrow \text{neutrals} \qquad \text{(reaction 3)}$$

steady-state concentration of Br^- in the ECD. From these two reactions, equation 1 can be derived. The value for $[Br^-]/[Cl^-]$ is determined for each measurement from $\delta I_M/(S-\delta I_M)$ where S is the saturation level and δI_M is the

$$[Br^-]/[Cl^-] = k[RBr]/(R[P^+]) \qquad \text{(equation 1)}$$

PD response. A plot of $[Br^-]/[Cl^-]$ over a range of concentrations of RBr yields a straight line with a slope of $k/R[P^+]$. Although the pseudo first-order rate constant, $R[P^+]$, for reaction 3 cannot be directly measured in an ECD, it has been previously estimated to be about 100 s^{-1} for this system. A graph of $[Cl^-]/[Br^-]$ versus concentration of EtBr is shown in figure 4. From the slope of the line in this graph, k for the reaction of EtBr with Cl^- is determined to be 9.3×10^{-12} cm^3s^{-1}.

The reactions of ten brominated compounds with Cl^- were studied at 125°C in the PDM-ECD, and the S_N2 rate constants are listed in Table 1. Also listed in table 1 are comparisons of some of these data with measurements by IMS at 640 torr and PHPMS at 4 torr. The temperature dependencies of the S_N2 rate constants for MeBr and i-PrBr were also studied. Arrhenius plots are shown in figure 5 and are compared with results obtained for these two compounds by PHPMS. Table 2 lists the activation energies and preexponential factors obtained from Figure 5. For comparison, data from PHPMS are also included for these compounds.

It is apparent from Table 1 that good agreement is obtained between the k determinations for MeBr, EtBr, i-PrBr and n-BuBr at 640 Torr by the PDM-ECD and by IMS. The rate constants obtained by the PDM-ECD for EtBr, i-PrBr and n-BuBr are also similar to those obtained by PHPMS at 4 Torr. k is therefore independent of pressure from 4 to 640 Torr for these compounds. However, for MeBr, the value for k is about four times greater at 640 Torr than at 4 Torr. These results are explained by Giles and Grimsrud (Wednesday Poster 94).

The measured k values from Table 1 are higher for MeBr and the primary alkyl bromides, EtBr, n-PrBr, n-BuBr and i-BuBr, than for the other alkyl bromides, i-PrBr, cycPrBr and s-BuBr. This agrees with the theoretical prediction that bimolecular nucleophilic substitution should occur more readily at less sterically hindered carbon centers. Allyl bromide (3-bromopropene) exhibited the highest S_N2 rate constant of all compounds studied. Two important factors contribute to the increased reactivity of allylBr over the alkyl bromides. First, the reaction is thought to proceed through a transition state which resembles a highly stabilized allylic cation. Second, allylBr can react with Cl^- by the S_N2' reaction, shown below, and undergo rearrangement of the double bond.

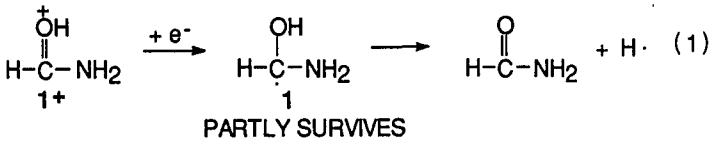
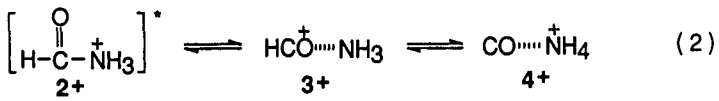
THE UNIMOLECULAR CHEMISTRY OF THE PROTONATED PEPTIDE BOND

Jinnan Cai, Michael J. Polce, Thomas L. Selby, and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron OH 44325-3601

This study concerns the site of protonation of formamide, $HC(=O)-NH_2$, which represents the simplest molecule with a peptide bond. The structures and reactions of the CH_4NO^+ cation, generated by protonating formamide, are investigated with the objective to obtain information relevant to the dissociation mechanisms of protonated peptides.





Combined collisionally activated dissociation (CAD) and neutralization–reionization (NR) experiments, including labeled isotopomers, reveal that protonation with CH_5^+ takes place at both heteroatoms of the amide group. The ion formed by O–protonation (1^+) produces upon CAD diagnostic $HCOH^{+\cdot}$ and $HCNH^+$ fragments via specific $\cdot NH_2$ and H_2O eliminations, respectively (no scrambling) (Fig.1a). This is confirmed by the spectrum of the deuterated isomer (Fig. 1b) which now loses HDO (forming m/z 28) and $\cdot NH_2$ (forming m/z 31). Upon neutralization, a stable radical (1, eq 1) is generated giving rise to a recovered parent cation. The recovered parent cation is very weak; moveover, the NR spectrum of Figure 2a resembles that of formamide (Fig. 2b), particularly, in peak shapes, documenting extensive dissociation of 1 into $HCONH_2$ and H·.

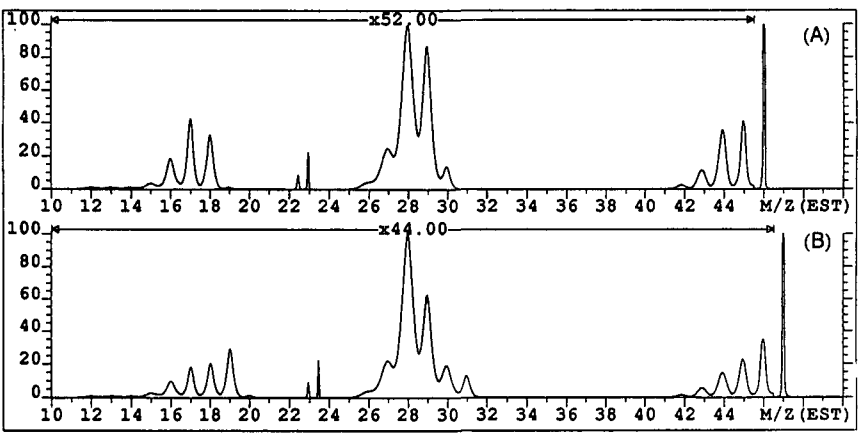


Figure 1. CAD,O_2 spectra of protonated formamide produced by (A) CH_5^+ and (B) CD_5^+ chemical ionization

Several additional features of the CAD and NR spectra further suggest that the N-protonated species is also formed, albeit as an intermediate to the ion/molecule complexes 3^+ and 4^+. 4^+ makes all hydrogens atoms of protonated formamide equivalent and must be sampled before ammonia loss because this process is associated with complete scrambling ($[29^+]$: $[30^+]$ in Fig. 1b is 3:1).

3^+ and 4^+ could be formed upon CAD or be already present in the parent ion beam before it undergoes dissociating collisions. In the latter case the most likely origin of 3^+ and 4^+ is the N-protonated species 2^+. The NR spectra support this latter case: more HCO^+, $CO^{+\cdot}$, and $NH_3^{+\cdot}$ are observed in Figure 2a than expected from $HCONH_2$, the major neutral product from neutralization of the O-protonated species (vide supra). Presence of 3^+ and 4^+ in the parent ion beam would explain the additional HCO^+, $CO^{+\cdot}$, and $NH_3^{+\cdot}$, as neutralized 3^+ and 4^+ are expected to yield extra $HCO^\cdot$, CO, and NH_3.

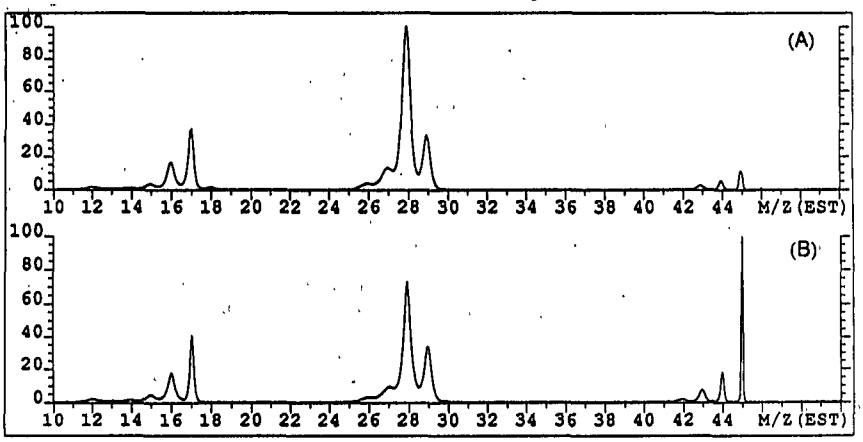

Figure 2. +NR+ Xe/O_2 spectra of (A) protonated formamide and (B) formamide radical cations, produced by CH_5^+ chemical ionization and 70 eV electron impact, respectively.

Application of a Sputtering Glow Discharge Ion Source to a Flowing Afterglow Study of Transition Metal Ion Chemistry

W.S. Taylor, and W.R. Everett
Department of Chemistry, University of Central Arkansas, Conway, AR 72035
L.M. Babcock and T.L. McNeal
Department of Chemistry, Louisiana State University, Baton Rouge, LA 70803

The reactions of metal ions in the gas phase have been the recent subject of much interest.[1] Examination of these processes in the absence of complicating solvent effects can yield fundamental kinetic and mechanistic information. The conditions under which these processes have been examined range from "single-encounter" environments to those in which collisions with a third body predominate. Methods used for the production of metal ions have included: EI, surface ionization, laser ablation, sparks, and arcs, each of which can suffer from one or more disadvantages. These include: inconsistent ion production, low ion currents, mechanical complexity, high cost, and production of ions in undefined electronic states. Many of these disadvantages can be overcome with the use of a dc glow discharge ion source (GDIS). This simple device is capable of providing large, stable metal ion signals over long periods for a variety of metals. Here, we present an example where a GDIS is coupled to a flowing afterglow reactor.

In the dc glow discharge, the substance to be ionized serves as the cathode, and the anode is the discharge cell housing, which is at ground potential. The discharge volume is filled with He at ~1 torr. When ~1KV is placed across the cathode and the anode, the He is ionized. These ions bombard the surface of the cathode, thereby sputtering material off the surface. Atoms sputtered from the cathode diffuse away from the cathode and into the negative glow region of the discharge where they are ionized primarily by Penning ionization. Sampling of the ionized species is accomplished via a small orifice immersed in the negative glow.

A schematic of the GDIS interfaced to the flowing afterglow is given in Figure 1, where only the ion source and the extreme upstream end of the flowtube are shown. This particular source was developed for use in glow discharge mass spectrometry,[2] and its fundamental operating parameters have been well characterized.[3] In operation, reactant ions are injected into the flowtube via a 3 mm orifice concentric with a venturi inlet through which the carrier gas is introduced into the flowtube. In order to reduce noise levels arising from helium metastables formed in the discharge, it was necessary to inject a small amount of argon downstream from the discharge as a quenching reagent. This argon flow was on the order of 40 sccm.

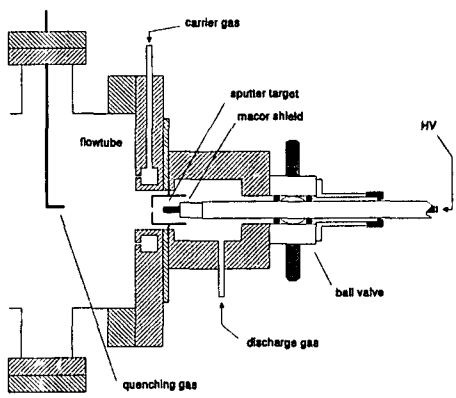

Figure 1: *The glow discharge ion source*

The stability of the ion signal produced by the GDIS is demonstrated in Figure 2. Here, copper ions were generated by sputtering a brass sample, and the $^{63}Cu^+$ signal was monitored as a function of time. The ion signal stabilizes within approximately 10 minutes subsequent to the initiation of the discharge, after which it remains constant to within ±1% for the remainder of the time over which data was accumulated. Similar results were obtained for other metals.

With the flowing afterglow technique, it is possible to obtain second-order rate constants for ion-molecule reactions. These rate constants are obtained from the pseudo

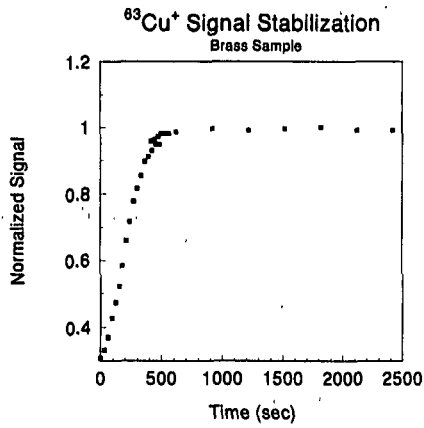

Figure 2: *$^{63}Cu^+$ signal stabilization*

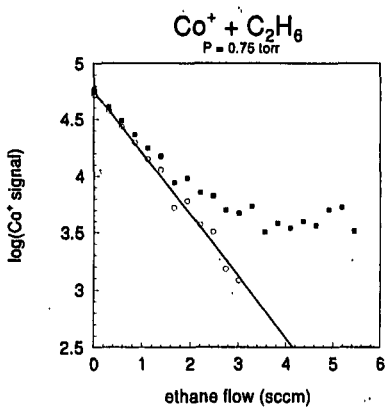

Figure 3

first-order decay of the reactant ion signal with respect to the concentration of the neutral. For the purposes of comparison with reported values for ground state ions, the rate constants for the reactions of Co^+, Ni^+, Cu^+, and Zn^+ with ethane were measured.[4] This data is given in Table I. In all of these processes, one primary product was observed of the general form $[M{\cdot}C_2H_6]^+$, which is believed to involve some degree of C-H bond insertion. The decay lines for Cu^+, Ni^+, and Zn^+, exhibited no curvature, but the decay line for Co^+ (Figure 3) approaches a constant non-zero value which, if not the result of an interfering species, is indicative of a nonreactive electronic state. The rate constant for Co^+ was obtained by subtracting out the constant component. This behavior would be consistent with the presence of the ^5F ($3d^74s$) state which should be less

Table I

Metal Ion	k^*_{lit} (x 10^{-10})	k_{exp} (x 10^{-10})
Co^+	3.2 ± 0.9	2.6 ± 0.4
Ni^+	3.6 ± 1.1	4.06 ± 0.01
Cu^+	2.9 ± 0.9	2.66 ± 0.09
Zn^+	0.15 ± 0.05	0.160 ± 0.005

* units of cm^3 $molec^{-1}$ sec^{-1}

reactive with respect to C-H bond insertion than the ground state ($3d^8$). Further evidence of the presence of the ^5F state is provided by the fact that in the reaction of Co^+ with CH_3I, $CoCH_3^+$ is observed as a product. This reaction is thought to be state-specific with respect to the ^5F state of Co^+.[5]

The GDIS is a simple, inexpensive, and versatile method for the production of metal ions for study under the conditions presented by the flowing afterglow. Large, steady-state ion signals can be obtained from any substance which can be obtained as a conductive solid. Kinetic data obtained here agree well with published values; however, our results indicate that the GDIS can produce electronically-excited ions when low-lying excited states are available.

GAS-PHASE PROTON AFFINITIES OF SMALL PEPTIDES

Barry D. Sperling and Carolyn J. Cassady
Department of Chemistry
Miami University
Oxford, OH 45056

Protonation is a major pathway in the ionization of peptides by mass spectrometry, but few fundamental gas-phase ion chemistry studies have been performed to probe the thermodynamic aspects of this process. This information is important because it can be used to design experiments which enhance the detection limits, selectivity, and structural data obtained during peptide analysis. Therefore, we are presently undertaking a systemic study of the effects of chain length and amino acid composition of the basicities and protonation sites of peptides. The present work focuses on determining the gas-phase basicities (GBs) of the simplest peptides: peptides composed entirely of glycine units, $(GLY)_x$, x = 1-6.

All experiments were performed in a Fourier transform ion cyclotron resonance mass spectrometry (FTMS) equipped with an external fast atom bombardment (FAB) source. In the general experimental sequence, protonated molecular ions, $(GLY)_xH^+$, were produced by FAB, transferred into the FTMS cell via electrostatic focusing, collisionally-cooled with a pulsed pressure of argon, mass-selected by frequency sweeps/shots, and allowed to react with a reference compound maintained at a static pressure on the order of (1-5) x 10^{-8} Torr.

Deprotonation reactions of $(GLY)_xH^+$ with reference compounds of known gas-phase basicity were used to bracket the basicities of the polyglycines.[1] These compounds were generally alkylamines, anilines, and pyridines. A representative series of spectra from the peptide deprotonation reactions are shown in Figure 1. In general, no reaction should be observed if the peptide has the higher basicity, while reaction should occur if the reference compound is the most basic. However, slightly endothermic reactions also occur but are generally slow relative to exothermic reactions. Therefore, experimental reaction rates were measured and compared to the collision rates in order to allow determination of the "break point" between exothermic and endothermic protonation.

During the reaction studies, proton-bound dimers containing the peptide and the reference compound often formed when the gas-phase basicities of the two reactants differed by only a few kilocalories. Low-energy collision-induced dissociation (CID) of this dimer was employed to determine the basicities of the peptides. This kinetic method was first developed by Cooks and coworkers.[2] In these experiments, the species with the highest basicity should retain the proton at low CID energies. However, this method is most accurate if the two species attached to the proton have similar structures. This is not the case in the present study; therefore, this kinetic method was only used to provide confirmation of the deprotonation reaction studies.

The basicities obtained for the glycine-containing peptides are:

$GB[GLY] = 204.3 \pm 2$ kcal/mol
$GB[(GLY)_2] = 208.0 \pm 2$ kcal/mol
$GB[(GLY)_3] = 213.2 \pm 2$ kcal/mol
$GB[(GLY)_4] = 217.5 \pm 2$ kcal/mol
$GB[(GLY)_5] = 220.0 \pm 2$ kcal/mol
$GB[(GLY)_6] = 223.2 \pm 3$ kcal/mol.

The values determined by deprotonation reactions and by the kinetic method are in agreement for all peptides studied. In addition, our value for glycine is consistent with two previous studies[3,4]. As the results above show, the basicities increase steadily as the peptide chain length increases. This may indicate that coordination of the proton to multiple basic sites on the peptides (intramolecular bonding) is occurring for the larger peptides. The break between slow and facile deprotonation reactions becomes less clear as the peptide chain length increases. This is consistent with larger peptides having more sites for proton attachment, with various sites

having slightly different basicities.

These results also suggest that the combination of FAB-FTMS has a bright future in studies of fundamental and analytical properties of biomolecules.

BRACKETING STUDIES OF THE GAS PHASE BASICITY OF THE 20 COMMON α-AMINO ACID USING FOURIER TRANSFORM MASS SPECTROMETRY.†

G. S. Gorman, J. P. Speir, I. J. Amster
Department of Chemistry, University of Georgia, Athens Georgia, 30602

INTRODUCTION

We have recently completed measurements of the gas-phase basicity (-ΔG of protonation) of the 20 common α-amino acids from which the proton affinities (-ΔH of protonation) can be derived. Using a technique known as laser desorption/chemical ionization (LD/CI),[1] the gas-phase basicity is determined by monitoring the occurrence or nonoccurrence of a proton transfer reaction between an amino acid A, and a protonated reference base BH^+.

$$A + BH^+ \rightarrow AH^+ + B \quad (1)$$

$$AH^+ + B \rightarrow BH^+ + A \quad (2)$$

The observation of proton transfer between the protonated reference base and an amino acid implies a negative free energy for reaction 1 and establishes a lower limit of the gas-phase basicity of an amino acid. Experiments in which protonated amino acids, formed by matrix assisted laser desorption (MALD) are reacted with reference base neutrals have been studied for the occurrence or nonoccurrence of reaction 2 and establishes an upper limit of the gas-phase basicity of the amino acids. The assignment of the gas-phase basicity of an amino acid is determined by the spacings between the basicities of the reference bases, and has an uncertainty of ±2.5 kcal/mol on average. The proton affinity values were derived from the gas-phase basicities by estimating the entropies of the reactions.

EXPERIMENTAL

The experiments were performed with a Fourier transform mass spectrometer equipped with a 4.4 cm cubic analyzer cell, IonSpec Omega data system, and electromagnet operating at 1 Tesla. Using LD/CI, amino acids are desorbed as intact neutral species which take part in proton transfer reactions with protonated reference bases. Desorption of amino acid neutral molecules is accomplished by focusing 248 nm light (KrF) from an excimer laser onto the sample prepared using the substrate assisted method.[2] The reference base is introduced into the vacuum system using a pulsed valve (General Valve, Series 9) where it undergoes proton transfer with NH_4^+ formed by electron ionization. After a 1 s delay, an eject pulse is applied to the analyzer cell to remove any unreacted NH_4^+. A second pulse of NH_3 is admitted to collisionally thermalize the protonated reference base ions prior to firing the laser beam for neutral desorption. In the MALD experiments, protonated amino acid ions are collisionally thermalized with Ar admitted through a pulsed valve before they react with neutral reference bases.

RESULTS

For most of the amino acids, the entropy of the proton transfer reaction can be calculated based on changes in the rotational symmetry numbers of the reactants and products.

$$\Delta S_{ROT} = R\ln[\sigma_A \, \sigma_{BH+} \, / \, \sigma_{AH+} \, \sigma_B]$$

The amino acids and reference bases used in this study have low symmetry, producing rotational entropy values of approximately ±2 cal/mol-K. At an estimated operating temperature of 350 K, the contribution of entropy to the free energy of the proton transfer reaction (±0.7 kcal/mol), is much less than the average uncertainty associated with gas-phase basicity assignment, therefore ΔH = ΔG for a proton transfer reaction. An exception

to this approximation is observed when intramolecular hydrogen bonded cyclization occurs. Geometric requirements for such a cyclization are fulfilled by lysine (2-carboxy-1,5-pentanediamine). The formation of a intramolecular hydrogen bond in diamines results in a substantial increase in the gas-phase basicity and proton affinity compared to the corresponding monoamine.[3] Leucine, a structurally related monoamine, has a gas-phase basicity that is 11.2±3.2 kcal/mol smaller than that of lysine. This difference is approximately equal to that between the gas-phase basicities of n-pentylamine and 1,5-pentanediamine (10.7±1.5 kcal/mol) suggesting the intramolecular cyclization for protonated lysine. The entropy of proton transfer for lysine is expected to be the same as for 1,5-pentanediamine (ΔS= -20.7 cal/mol-K).

The relative ordering of the proton affinities values of the amino acids agrees well with previously reported results,[4,5] although there are a few exceptions with others.[6] Histidine, methionine and threonine were found to be more basic than suggested by Bojensen. We find glutamic acid to be more basic than glutamine, opposite to Bojensen's findings. The disagreement between our measurements and Bojensen's may be a limitation of the kinetic method when applied to polyfunctional, structurally different compounds such as amino acids.[7]

Extent of Hydrogen Reduction in the Chemical Ionization Mass Spectra of a Series of Octaethylporphyrins and Tetraphenylporphyrins

Helen H. Schurz, Centers for Disease Control, Environmental Health Laboratory Sciences, Toxicology Branch, Atlanta, GA 30312
Kenneth L. Busch, Georgia Institute of Technology, School of Chemistry and Biochemistry Atlanta, GA 30339

Early applications of mass spectrometry to porphyrin analysis was met with difficulty due to the inability of the ionization method to fragment the porphyrin macrocycle. Electron ionization could not provide sufficient fragmentation of the porphyrin macrocycle, nor could fast atom bombardment (FAB) mass spectrometry. Chemical ionization (CI) provided the needed fragmentation, but products of oxidation and reduction present in the mass spectra and coupled with the complexity of the fragmentation patterns made porphyrin identification from these spectra non-trivial.

It is generally agreed that reduction of the porphyrin structure is required to provide the mechanism by which the usual fragmentation of the porphyin macrocycle occurs. Sequential reduction of the porphyrin in the gas phase forms the porphyrinogen $(M+6H)^+$ (meso-hexahydroporphyrin), which then fragments at the meso positions of the porphyrin macrocycle. Van Berkel, et al.[1] show conclusively that this reduction occurs as a surface-assisted reaction in chemical ionization, as had been suggested by other authors. Hydrogen reduction (defined as the addition of hydrogen atoms to an ion **without** a change in charge) of the porphyrin structure occurs in FAB, as well as CI. However, fragmentation of the porphyrin ring is only achieved by CI. For a series of porphyrins, the FAB mass spectra have been acquired and the extents of hydrogen reduction determined. Similar experiments for the FAB mass spectra of dyes have shown that the extents of reduction could be correlated to electrochemical reduction potentials.[2] The appearance of the hydrogen chemical ionization mass spectra and the extents of reduction present in the molecular ion region are discussed in this presentation for the same series of porphyrins as have been studied by FAB. In particular, a correlation between the extent of reduction of species and their electrochemical reduction potentials was sought.

The mass spectra of metalloporphyrins measured with fast atom bombardment (FAB) or chemical ionization (CI) often exhibit substantial signals corresponding to reduction products formed by hydrogen addition.[3,4] The ions corresponding to the products of this reduction take on the form of $(M+nH)^+$, where "n" is usually a number that ranges from two to six. A time-dependence of the production of reduced species is noted for several porphyrins. For example, the increased production of the $(M+6H)^+$ ions of TPP H_2 is clearly indicated. Initially, the M^+ ions of TPP H_2 is observed. As time and temperature increase, the relative intensity of the reduction products with the form $(M+6H)^+$ increases. These ions, produced over the lifetime of the sample in the ion source, can seriously hinder identification of an unknown porphyrin structure. Thus it is imperative that identification and calculation of mathematical quantities, such as extents of hydrogen reduction, be determined from data taken early in the scan before reactions in the source can build up to complicate the results.

The extents of hydrogen reduction were calculated for each of the TPP and OEP porphyrins. The equations used to calculate the extents of reduction are available from the authors. The appearance of the spectra and degree of reduction are extremely dependent upon source conditions. In each set of runs for the data, a different extent of reduction was noted. Given this lack of reproducibility, but clear evidence that reduction processes are occurring, measurement of a definitive extent of reduction in hydrogen chemical ionization has been impossible. This is in clear contrast to some of our earlier FAB results, in which a well-behaved ionization method led to reproducible, time- and concentration-independent parameters. Spectra selected to establish the extent of reduction were chosen from those early in the run so that reduction products that accumulate with time would not predominate.

Hydrogen CI mass spectra of porphyrins are extremely dependent upon source conditions. Additionally, for the case of the FAB mass spectra, a mechanism based upon the correlation of the porphyrins to electrochemical ring reduction potentials could be made (Figure 1, TPP porphyrins analyzed by FAB-MS in m-NBA matrix). Such is not the case for the hydrogen CI mass spectra, which do not correlate with electrochemical values (Figure 2, TPP porphyrins analyzed by hydrogen CI-MS). However, in hydrogen CI, the reduction of porphyrins is not limited to the addition of a few hydrogen atoms. The presence of reduced ions like the $(M+6H)^+$ ion (meso-hexahydroporphyrin molecular ion) or the $(M+14H)^+$ ion (extensively reduced porphyrin macrocycle) produce complex mass spectra with groups of fragment ions that mask the true instrumental resolution.

An extraordinary dependence upon source conditions is displayed by the hydrogen chemical ionization mass spectra of porphyrins. The mechanism of surface-assisted reduction promoted by hydrogen radicals from the chemical ionization plasma is supported by a desorption profile. The profile displays three humps; the first represents the molecular species desorbed directly from the DCI probe and, the second and third humps represent evaporation of the reduced molecular ion desorbed from the source surfaces.

From the data that has been obtained for the porphyrins, it is difficult to state that chemical ionization of these compounds is reliable for unknown compound identification. Although CI has proven itself to be an excellent method for fragmenting the porphyrin macrocycle, that same process for which it is hailed destroys its usefulness in obtaining accurate molecular weight measurements. For porphyrins, the "well-behaved" chemical ionization process is elusive.

Gas-Phase Ambident Reactivity of N-Deprotonated Amides[1].

Ivo L. Freriks, Leo J. de Koning and Nico M.M. Nibbering.
Institute of Mass Spectrometry, University of Amsterdam,
Nieuwe Achtergracht 129, 1018 WS, Amsterdam, The Netherlands.

Ambident N-deprotonated amides $^{-}NR_1(CO)R_2$ have two reactive centra which are connected through mesomerism. This allows competition between the reaction channels involving reaction via the nitrogen and oxygen end of the anions. As a typical example, the reaction of N-deprotonated acetamide with hexafluoropropene via the nitrogen and oxygen nucleophilic centers is shown in figures 1 and 2.

Fig. 1: Reaction via the O-nucleophilic center of N-deprotonated acetamide.

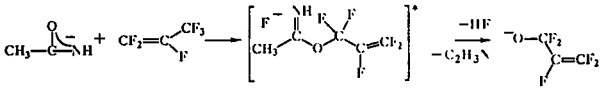

Fig. 2: Reaction via the N-nucleophilic center of N-deprotonated acetamide.

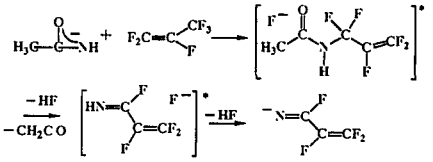

Using FT-ICR mass spectrometry it is observed that several N-deprotonated amides exhibit an ambident chemical behavior in their gas-phase reactions with unsaturated perfluorocarbon compounds (see Table 1). The reaction selectivity of the studied imidate anion reactions can be interpreted in terms of electrostatic and specific orbital interactions in the reaction complex. The increasing preference for O-alkylation in the series C_6F_6, C_4F_8, C_7F_8, C_3F_6 may be explained with increasing dipole-moment, and thus increasing electrostatic interaction. Competition between reaction via the N and O nucleophilic centers of imidate anions may be interpreted in terms of simple perturbation theory: As for their enolate analogs[2,3] it seems reasonable to assume that the HOMO-energies of N-deprotonated formamide, acetamide, and N-methylformamide are very close, whereas N-deprotonated trifluoracetamide has a lower HOMO-energy. Figures 3 and 4 visualize the frontier orbital interactions which rationalize the observed reaction selectivities of the studied anions.

Chemical behavior of the gas-phase pentacoordinated carbonium ion $C_2H_7^+$

Albert J. R. Heck, Leo J. de Koning and Nico M. M. Nibbering,
Institute of Mass Spectrometry, University of Amsterdam,
Nieuwe Achtergracht 129, 1018 WS Amsterdam, The Netherlands.

Results are presented of a study on the uni- and bimolecular chemistry of $C_2H_7^+$ ions in the gas phase combining the methods of sector and Fourier transform ion cyclotron resonance mass spectrometry [1].

Unimolecular decomposition of metastable $C_2H_7^+$ ions proceeds via elimination of a hydrogen molecule, a process which takes place without significant kinetic energy release. Yet, the elimination of a hydrogen molecule is found to display a very large isotope effect, which is rationalized by the difference in Gibbs free energy change for H_2, HD and D_2 loss from the various isotopomers of protonated ethane.

It is shown that long-lived $C_2H_7^+$ ions can be generated via gas phase ion / molecule reactions, either by proton transfer to ethane, methyl cation transfer to methane or by association of $C_2H_5^+$ and H_2. Conversely, $C_2H_7^+$ ions can react as a proton or a methyl cation donor, or eliminate a H_2 molecule (see Table).

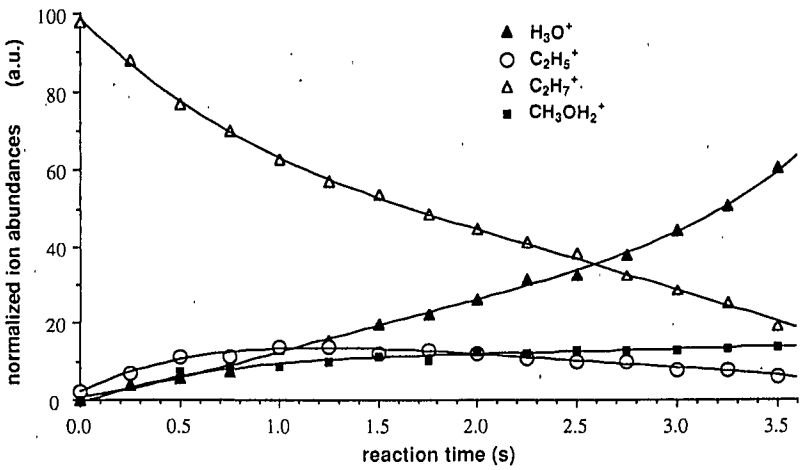
Methyl cation and proton transfer product ions in the reaction of $C_2H_7^+$ with compounds M.

compound M	CH_3^+ transfer	ΔH	H^+ transfer	ΔH
H_2	NR	- 17	NR	+ 178
N_2	NR	- 29	NR	+ 109
Xe	Y (slow)	- 42	NR	+ 105
CD_4	NR	0	NR	+ 50
HCl	Y	- 63	NR	+ 63
HBr	85 %	- 84	15 %	+ 19
CO	50 %	- 156	50 %	+ 13
H_2O	40 %	- 105	60 %	- 94

ΔH are given in kJ/mol. NR = no reaction observed, Y = reaction observed.

In the ion / molecule reactions with water $C_2H_7^+$ displays an ambident chemical behavior, which shows a balanced competition between a proton and a methyl cation transfer (see Figure), in contrast with CH_5^+, which reacts only via proton transfer. These observations may be explained by assuming that rearrangement of $C_2H_7^+$ to a reactive intermediate resembling a loosely bound complex between a methyl cation and methane requires substantially less energy than rearrangement of CH_5^+ to a reactive intermediate resembling a complex between a methyl cation and a hydrogen molecule.

Kinetics of the reaction of $C_2H_7^+$ with water.



The study on both the uni- and bimolecular reactivity of $C_2H_7^+$ reveals that the proton accepted in an exothermic protonation of ethane randomizes with the original hydrogen atoms of ethane. This intramolecular randomization is found to be a very fast process which precedes decomposition of the metastable $C_2H_7^+$ ions as well as the bimolecular processes of the long-lived $C_2H_7^+$ ions.

Characterization of PAHs and Aromatic Substrates by Laser Desorption and Ion-Molecule Reactions in a Quadrupole Ion Trap.

Niloo Asgharian and Jennifer Brodbelt, Department of Chemistry, University of Texas, Austin, TX 78712.

Polyaromatic hydrocarbons (PAHs) are one of the largest classes of environmental carcinogens. They are formed during the pyrolysis or incomplete combustion of almost all organic materials, making them widespread contaminants. The planar structure of these compounds makes it possible for them to intercalate between specific basic sites in DNA to form PAH-DNA adducts, which cause cells to metabolize and induce tumors. Isomer differentiation and diagnosis of PAHs by conventional mass spectrometry is extremely difficult since fragmentation is often minimal due to the nature of the aromatics. Moreover isomeric compounds tend to follow the same dissociation pathways.

In order to develop alternate methods to distinguish PAHs, ion-molecule reactions of aromatic substrates containing different substituent groups as well as PAHs have been examined in a quadrupole ion trap mass spectrometer (ITMS). Preliminary studies were conducted using dimethyl ether as the reagent gas. Depending on the electron donating or electron withdrawing capabilities of the substituent groups, distinctive types of adducts were formed. Substrates with electron-donating substituents formed $(M + 13)^+$ ions whereas those with electron-withdrawing substituents formed $(M + 15)^+$ products. In a series of kinetic studies, these adducts were monitored in time in order to observe how the rates of adduct formation varied with substituent effects. These studies were further advanced by using another technique, laser desorption ionization (LDI). This novel technique in our ion trap has allowed gas phase organometallic chemistry to be scrutinized in the ITMS for the first time, since previously most work in this field had been carried out in the FTICR. In particular, these results serve as a springboard for PAH distinction.

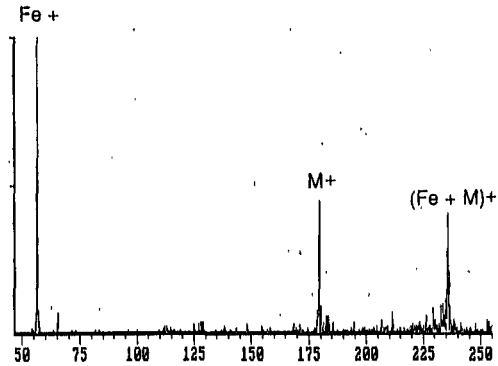
A beam of a Nd:YAG laser of 10^7 W/cm^2 with pulse of duration of 10 ns is focussed on a pure metal foil, which causes a plume of material to be ejected from the surface. The beam is introduced into the ion trap vacuum chamber by a fiber optic interface. The PAHs were coated on a metal foil that was moistened with methanol so that the particles would adhere to the surface. The disubstituted benzenes were introduced through a leak valve at a pressure of 1.0×10^{-6} Torr. For kinetic studies dimethyl ether was used as the reagent gas at a pressure of 1.0×10^{-6} Torr. The products $(M+H)^+$, $(M+13)^+$, and $(M+15)^+$ were isolated individually and monitored by varying the reaction time.

The results of laser ionization/ quadrupole ion trap experiments using metal foils onto which PAHs were adsorbed will be described first. The metal foils that were used were the transition metals iron and copper. The PAHs used were anthracene, pyrene, and pentacene. In all cases the PAH molecular ion M^+ is observed, likely by charge exchange with the metal cations. Anthracene and pyrene undergo metal attachment and also may form metal-bound dimers. In contrast, pentacene does not form any metal-attachment products. An example of the metal ion attachment to the PAHs is shown in Figure 1 and summarized in Table 1.

	Fe+	Cu+
Anthracene	M+ (Fe + M)+	M+ (Cu + 2M)+
Pyrene	M+ (Fe + M)+	M+ (Cu + M)+ (Cu + 2M)+
Pentacene	M+	M+

Selective ion-molecule reactions of Fe^+ were used to distinguish between isomers of disubstituted benzene derivatives, as has been shown previously in an FTICR study (1). Two classes of isomers, methoxyphenols and flouroacetophenones, were probed. The key point here relies upon the bridging ability of Fe^+, the formation of Fe^+-complexes and their subsequent fragmentation to produce characteristic peaks for each isomer. The results of the reactions are summarized in Table 2. These isomers have two electron-donating substituents. The ortho isomer forms $(Fe + M - CH_4)^+$, whereas the meta isomer forms $(Fe + M - H_2)^+$ and $(Fe + M - CH_2O)^+$. In contrast, the para isomer does not undergo metal attachment, but only forms its molecular ion by charge exchange.

Figure 1 Anthracene



The meta and para isomers of flouroacetophenone lead to very similar reactions, but the ortho isomer can readily be distinguished. Both meta and para isomers result in complexes at m/z 166 brought about by the loss of a carbonyl unit, m/z 194 which is the $(M + Fe)^+$ complex , and m/z 212 a metal-bound dimer after loss of an iron carbonyl unit. The ortho isomer results in ions at m/z 91 which is the benzyl cation, m/z 152 from the loss of $COCH_2$ from the $(M + Fe)^+$ ion, and m/z 166 from the loss of a carbonyl unit.

In order to distinguish the isomers, kinetic studies were also performed on these disubstituted benzenes. The neutral aromatics were allowed to react with dimethyl ether ions, and the products due to proton transfer $(M+H)^+$ and methyne addition $(M+13)^+$ were monitored. As Figure 2 shows for methoxyphenol, the adducts $(M+H)^+$ and $(M+13)+$ are distinct for each isomer. For the flouroaceto- phenones, $(M+15)^+$ is distinct for the ortho isomer, as shown by the kinetics..

Proton and Ammonium Ion Affinities of Macrocycles: Effects of Multiple Binding Interactions

Chien-Chung Liou and Jennifer S. Brodbelt
Department of Chemistry, University of Texas
Austin, TX 78712

The ability to examine host-guest chemistry without the influence of solvent effects opens up new avenues for understanding some of the fundamental details of molecular recognition. For example, intermolecular and intramolecular hydrogen-bonds are arguably the most important interactions in molecular self assembly and molecular recognition in solution chemistry. In order to examine the intrinsic interactions involved in the host-guest chemistry of these systems, we have undertaken an investigation of crown ether complexation with the proton or ammonium ions in the gas phase. In the present work, a systematic evaluation of the intermolecular binding forces responsible for the association of crown ethers (hosts) with amines (guests) is presented. The relative strengths of hydrogen-bonding interactions of crown ether/amine ion-complexes are examined with respect to macrocyclic size effects, the gas-phase basicities of thirteen different amines and three crown ethers, and the number of possible binding interactions.

All measurements were performed in a Finnigan triple stage quadrupole mass spectrometer (TSQ-70) equipped with a chemical ionization source. The samples were introduced by a direct insertion probe, and typical sample pressure was 1-3 x 10^{-6} torr. Ammonia was admitted into the source to 2 torr as a chemical ionization agent. The kinetic method was used to determine the orders of relative proton affinities and ammonium ion affinities of the various ethers. To evaluate the strengths of the hydrogen-bonding interactions involved in stabilization of each host-guest complex, CAD experiments were performed. The hydrogen-bonded complex was mass-selected with the first quadrupole, then accelerated into the collision quadrupole filled with 0.2 - 1.5 mtorr argon. The kinetic energy of the ion was varied from 0 - 25 eV in the lab frame, which corresponded to approximately 0 - 3 eV relative kinetic energy (i.e. collision energy).

The trends for relative proton affinities and ammonium ion affinities as measured by the kinetic method are strikingly different. For the proton affinities, there is a fairly uniform correlation of proton affinity with the number of oxygen atoms in the ether: as the number of oxygen atoms increases, the relative proton affinity increases. The trend is: 12-C-4 < 3-GLYME < 15-C-5 < 4-GLYME < 18-C-6 < 4-GLYCOL < 21-C-7 < 5-GLYCOL. For the trends in ammonium ion affinities, the crown ethers with larger cavity sizes (18-crown-6 and 21-crown-7) demonstrate unusually high affinities relative to the acyclic ethers, and in fact these two crown ethers show the greatest affinities of all the ethers. The trend is: 12-C-4 < 3-GLYME < 4-GLYCOL < 15-C-5 < 5-GLYCOL < 4-GLYME < 18-C-6 < 21-C-7. The ammonium ion is a bulky tetrahedral guest with four hydrogens for possible participation in intramolecular binding to oxygen sites. The pre-organized macrocycles with larger cavity sizes more easily accomodate the configuration necessary for optimum multiple hydrogen-bond interactions to the ammonium ion, whereas the acyclic ethers have greater entropic barriers to arranging to the appropriate geometry.

In order to study the effects of hydrogen-bonding interactions in gas-phase host-guest complexes, proton-bound complexes between a crown ether and amine were formed and then collisionally activated to induce dissociation. The formation of only protonated crown ether molecules and/or protonated amine molecules from these types of CAD experiments was presumed to indicate that the overall weakest bonding interactions in the selected ion-complex were the hydrogen-bonds involved in complexation, and the activation barrier to dissociation by decomplexation was lower than the activation barriers for subsequent covalent bond cleavages within the crown ether or amine. Alternatively, the formation of fragment ions corresponding to covalent bond cleavages within either the amine or crown ether portion of the ion-complex was assumed to indicate that the total hydrogen-bonding association energy of the complex was sufficiently large to result in a high activation barrier to dissociation, one which also allowed access to subsequent competitive skeletal cleavages of the amine or crown ether ions.

The strikingly distinctive types of dissociation behavior obtained for two different crown ether/amine ion-complexes are shown in Figure 1. As shown, the CAD spectra of hydrogen-bonded complexes formed between 18-crown-6 and pyridine or 18-crown-2/aminoethanol are compared. Since pyridine and 2-aminoethanol both have similar gas-phase basicities, 213.1

kcal/mole and 213.4 kcal/mole, respectively, they provide an interesting comparison of complex formation with 18-crown-6, whose gas-phase basicity is estimated as 216.0 kcal/mole. Activation of the 18-crown-6/2-aminoethanol ion-complex results in extensive fragmentation of the crown ether ring (Figure 1B) by losses of ethylene oxide units, even under single collision conditions. In contrast, collisional activation of the 18-crown-6/pyridine ion-complex results in formation of predominantly protonated pyridine and protonated 18-crown-6 (Figure 1A) with little fragmentation of the crown ether ring, even under multiple collision conditions.

Figure 1B shows the dissociation spectra of the 18-crown-6/2-aminoethanol complex, one in which multiple hydrogen-bonding interactions between the two organic substrates are an important factor. For example, the binding interactions may include: coordination of two of the crown ether oxygens to two of the amine hydrogens, proton-bridge formation between one of the crown ether oxygens and the nitrogen atom, and one final hydrogen bond between an ether oxygen and the hydroxyl hydrogen of the aminoalcohol. Ions due to cleavages and rearrangements of covalent bonds in the crown ether skeleton are predominant. This behavior suggests that the interaction energy of the complex is so high that the internal energy necessary to surpass the dissociation threshold is also sufficient to cause subsequent skeletal cleavages in conjunction with decomplexation reactions.

A potential energy diagram which may used to rationalize how these complexes dissociate is shown in Figure 2. As shown by the solid line, for strongly-bound complexes both the activation barrier to decomplexation and the reverse activation energy for formation of the intact protonated crown ether are large. Under these circumstances, the protonated crown ether resulting from decomplexation is internally hot and may undergo spontaneous dissociation by cleavages of the macrocyclic skeleton, especially when the barriers to subsequent dissociation are relatively low (as is the case for protonated crown ethers). As shown by the dashed line, weakly-bound complexes have low activation barriers to dissociation, and thus subsequent skeletal fragmentation is not promoted after decomplexation.

Finally, the thermochemistry of the dissociation reactions of protonated crown ethers was estimated to obtain an understanding of the energetics of fragmentation of protonated macrocycles. Each of the dissociation reactions examined are 14 - 35 kcal/mole endothermic, and these values set the lower bounds on the extra energy required by any protonated crown ether to promote dissociation. Additional energy may be required to surmount other activation or entropic barriers. However, as a first-order estimation of the energetics involved in dissociation of the crown ether/amine complexes, these numbers suggest that some of the complexes must be bound by at least 14 - 35 kcal/mole in order for the subsequent crown ether cleavages to occur.

Kinetics and Thermodynamics of Functional Group-Selective Ion-Molecule Reactions of Disubstituted Ethanes

Erika Eichmann and Jennifer Brodbelt
Department of Chemistry and Biochemistry
University of Texas, Austin, Texas, 78712.

The importance of functional group interactions and substituent effects in determining the outcomes of reactions both in solution and in the gas-phase has long been recognized. For example, the interactions between various functional groups within complex molecules have been shown to have important consequences on the physical properties and reactive and dissociative patterns of these molecules. In some cases, remote group participation can promote reactive channels inaccessible to related molecules lacking the interacting group. The converse is also true: the presence of an additional functional group can prevent certain reactions, either through steric or electronic interactions, which would otherwise be expected to predominate.

An understanding of the fundamental reactions between substituents is needed for the development of site-specific reactions for characterization of biologically relevant compounds, . We have undertaken this study of simple disubstituted ethanes in order to illustrate the assertion that the reactive and dissociative properties of structurally and electronically similar molecules can be dramatically different. The objectives included comparison of the ion-molecule reactions of dimethyl ether ions with ethylene glycol and its monomethyl and dimethyl ethers, comparison of the formation *rates and relative favorabilities of formation for all observed products, examination of the formation* mechanisms for each product obtained, and investigation of the thermodynamic properties which presumably govern the reactions observed.

Previous studies in our group have shown that upon reaction with dimethyl ether ions, substrates typically yield one or more of several product ions, depending on the nature, position, and orientation of their functional groups: $(M + 13)^+$, $(M + 15)^+$, $(M + 1)^+$, $(M + 45)^+$, $(M + 47)^+$. Although the $(M + 45)^+$ and $(M + 47)^+$ adduct ions, or collision complexes, are not always observable in the ion trap, previous studies have shown that the $(M + 1)^+$, $(M + 13)^+$, and $(M + 15)^+$ ions all originate directly from these ions. Whereas the diol and the monoether gave significant amounts of $(M + 13)^+$ product ions, and no evidence of formation of $(M + 15)^+$ ions, the diether exhibited exclusive formation of the $(M + 15)^+$ product ion.

A log plot of the reaction profile data for the ion-molecule reaction between 2-methoxyetahnol and the 45^+ ion is shown below, in Figure 1. Similar plots were constructed for each of the other compounds studied. In each case, the DME 45^+ ion was isolated, and allowed to react for 0-500 ms with each substrate. The results of all three reactions are similar, but rate of disppearance of the 45^+ ion is fastest for reaction with the diether and slowest for reaction with the diol.

The fact that only the two compounds which possess hydroxyl groups form the $(M + 13)^+$ product is in complete accord with the mechanism previously determined for this reaction in other systems, and indicates that the same sort of mechanism may be operative here. Presumably, either of the two nucleophilic oxygen atoms of any of the three substrates may attack the positively polarized methlene group of the methoxymethylene cation (m/z = 45) within the collision complex previously described, resulting in the covalently bound $(M + 45)^+$ adduct shown. Because of the higher nucleophilicity of the methoxyl group, the attack by the ether oxygen atom may be slightly favored over that of the hydroxyl oxygen atom. However, this small difference, with respect to the energy available for the reaction, is not likely to cause a dramatic change in reactivity. The change is most likely manifested in the subsequent step of the reaction, which is clearly functional-group dependent. If a nearby proton such as the one remaining on the attacking oxygen atom is available, it is transferred to the oxygen atom from the dimethyl ether portion of the adduct. An oxonium ion is formed, and the carbon-oxygen bond is immediately cleaved, and a molecule of methanol is lost. Obviously, if there is no available proton, the proton transfer reaction required for formation of the $(M + 13)^+$ ion cannot occur, and this $(M + 45)+$ dissociation pathway is not feasible.

In order to support the conclusions made in the present study and to assist in the the interpretation of future results, we have begun to use computer modelling to estimate the thermochemistry of the processes in question. This type of analysis is especially useful cases such as this, in which differences in potential reaction sites are to be considered. As seen in this study, dimethyl ether is a particularly selective reagent, and examination of the heats of reaction for the various processes which can occur gives insight into the reasons for this selectivity.

The estimated heats of formation for the $(M + 45)^+$ adducts of ethylene glycol, 2-methoxyethanol , and ethylene glycol dimethyl ether, and all of the possible $(M + 13)^+$ and $(M + 15)^+$

dissociation products are listed in Table 1. For the mixed compound, two entries are made. The first concerns the ions resulting from reaction at the hydroxyl site, and the second those resulting from reaction at the methoxyl site. Also listed are the approximate heats of reaction for the formation of the $(M + 13)^+$ and $(M + 15)^+$ ions by the mechanisms proposed. The values listed clearly demonstrate the reasons for the observed behavior.

The heats of formation for the covalent $(M + 45)^+$ adducts are quite low, as compared with those for the final products observed. Although the internal energy of the ion-molecule complex is somewhat dissipated by the formation of the covalent bond, this reaction does not completely thermalize the resulting ions. In addition, the conditions in the ITMS do not promote collisional deactivation of the newly formed ions. As a result, the covalently bound $(M + 45)^+$ product spontaneously dissociates. These thermodynamic values are thus consistent with the fact that no $(M + 45)^+$ ions are observed for these substrates, and support the idea that the $(M + 13)^+$ and $(M + 15)^+$ ions observed are the secondary products of the ion-molecule reactions between M and the 45^+ ion.

The heats of formation for the $(M + 15)^+$ product ions are lower than those for the $(M + 13)^+$ ions, but the formation of $(M + 13)^+$ is favored over that for $(M + 15)^+$, even when both products can form. The heats of reaction for the $(M + 13)^+$ formation reaction are substantially different from those for formation of $(M + 15)^+$. Whereas the $(M + 13)^+$ reaction is very slightly **exothermic**, the $(M + 15)^+$ reaction for the same compound is slightly **endothermic**. Thus, it is not surprising that for ethylene glycol, only the former is formed. On the other hand, the only possible product for the diether is $(M + 15)^+$, and for this substrate, the reaction is exothermic. Therefore, it follows that exclusive formation of $(M + 15)^+$ is observed.

For 2-methoxyethanol, both the methyl cation transfer and methylene substitution processes are possible. However, by comparing the heats of reaction for the two paths, we note that whereas the $(M + 15)^+$ formation reaction is disfavored for both reaction sites, $(M + 13)^+$ formation at the hydroxyl site is slightly exothermic. Again, this data supports the assertion that the $(M + 13)^+$ pathway is the favored dissociation route for the $(M + 45)^+$ adducts. In addition, this data provides support for the idea that a hydroxyl group is more likely to attack the DME 45^+ ion.

Gas phase ion-molecule reactions of f-transition element ions are fundamental in establishing reactivity and stability of new compounds to be synthesized by condensed phase chemistry.[1] In this work, we report the use of Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometry to characterize the products of gas phase reactions of various lanthanide ions (Ln^+) with 1,3,5-tri-*t*-butylbenzene ligand, (L). *This work constitutes the first comprehensive comparison of reactivity of Ln^+ with a common ligand across the entire lanthanide series.*

Lanthanide ions were generated by laser desorption of the metal or metal oxide. Organic ligands were introduced to the vacuum chamber as neutral molecules, either by direct placement on the sample holder (solid) or by leakage through a gas inlet system (liquid or high vapor pressure solid). Singly charged metal ions were selected and reacted with the neutral molecules of the ligand in gas phase during the reaction period. The sandwich complex, LnL_2^+ (sometimes as the sole product) was observed in each case, as well as other products in some cases (see Table 1).

Here we report experimental results for Y^+ and Sc^+ in addition to all of the lanthanide rare earth ions (except for Pm^+). Table 1. summarizes the main products of reactions of all of the rare earth ions with 1,3,5-tri-*t*-butylbenzene at neutral pressure of 10^{-7} to 10^{-6} torr (measured from the source side of the dual ion trap of an EXTREL FTMS-2000). The main sandwich products of these reactions are LnL_2^+, $[LnL_2 - H_2]^+$, and $[LnL_2 - CH_4]^+$ which are formed with or without the breakage of C–H or C–C bond(s) of the ligand. From the relative abundances of ion-molecule reaction products as a function of ion-neutral reaction period, we are able to show that the metal ion reacts first with one ligand (with or without bond breakage), followed by addition of a second intact ligand to form the sandwich complex (see Figure 1 and Table 1). We are able to account for the stability and reactivity of the various lanthanide complexes in terms of the energy required to promote a 4f electron to a 5d level in each case.[2] Evidently the d-electron is needed to coordinate with (e.g.) two hydrogen atoms to produce bond cleavage. Thus, for example, Eu^+ and Yb^+ have high promotion energies and are unreactive toward C–H bond cleavage by the lanthanide ion (see Figure 1 and Table 1). It is also interesting to note that we are able to produce LnL_2^+ complexes for some lanthanides for which attempts to prepare the corresponding LnL_2 compounds by condensed phase chemistry have not yet succeeded.[1] This work was supported by NSF(CHE-9021058) and the Ohio State University.

Nucleophilic Substitution Reactions in Difluorobenzene-Alcohol Mixed Cluster Ions

George M. Daly and M. Samy El-Shall*
Department of Chemistry
Virginia Commonwealth University
Richmond, Virginia 23284-2006

Introduction

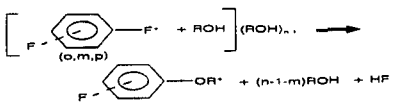
Nucleophilic substitution reactions are among the most basic and important reactions in chemistry. Many aspects of these reactions are still incompletely understood. These include the effects of different nucleophiles in the attacking and leaving groups and the question whether the reactions proceed through stepwise pathways involving metastable intermediates. The present study deals with intra-cluster nucleophilic substitution reactions in difluorobenzene-alcohol cluster ions. The reactions occur following the electron impact ionization of the neutral mixed clusters.

Experimental

Difluorobenzene-alcohol clusters generated by pulsed adiabatic expansion in a supersonic cluster beam apparatus, were ionized by EI and subsequently mass analyzed in a quadrupole mass spectrometer [1,2].

Results

Figure 1 displays the mass spectrum observed from the EI ionization of p-fluorobenzene-methanol mixed clusters. In addition to methanol, p-fluorobenzene and their mixed clusters, the spectrum shows two peaks corresponding to p-fluoroanisole ion and p-fluoroanisole-methanol dimer ion which result from the intra-cluster nucleophilic substition reaction between p-fluorobenzene radical cation and methanol molecules according to



Similar results were obtained for other alcohols such as ethanol, isopropanol and t-butanol. Isotopic and pressure studies indicate that in all cases, the 1:1 p-fluorobenzene-alcohol dimer does not participate in the reaction in agreement with Brutschy et al.[3,4] who used resonant two-photon ionization to study these intra-cluster reactions. This result is consistent with the failure to observe the analogous ion-molecule reaction in the gas phase despite the large exothermicity of about 100 kJ/mol [4]. However, the ionic intermediates can be stabilized at high pressure and therefore the anisole ions can be generated as observed by Meot-Ner using pulsed high pressure mass spectrometry [5]. Another interesting feature of these reactions is the observation of the fluoroanisole ion solvated with only one alcohol molecule. This is in contrast to the reaction with water where the analogous phenol ion can be solvated with many water molecules.

Our results indicate that the reactivity of different alcohols towards nucleophilic aromatic substitution in p-fluorobenzene varies according to: t-butanol > isopropanol > ethanol > methanol. This trend correlates with the ionization potential of the nucleophile. The results also indicate that the reactivity of different difluorobenzene isomers varies according to o > m $\geq$ p. This points out the role of dipole interaction in the stabilization of the intermediates.

Determination of Electron Capture Rate Constants Using a Pulsed e-beam High Pressure Mass Spectrometer

W. B. Knighton and E. P. Grimsrud, Department of Chemistry, Montana State University, Bozeman, MT

Introduction: Electron Capture Mass Spectrometry (ECMS) is one of the most sensitive techniques for the analysis of numerous molecules of environmental and biomedical importance. The inherent sensitivity provided by ECMS is due to the fact that the EC rates for many molecules are extremely rapid, up to 2 orders of magnitude faster than those of the fastest ion-molecule reactions. However, present understanding of the factors that control the EC rates of molecules is very poor. The few EC rate constants that have been measured for large molecules vary widely and in an apparently unpredictable manner. Clearly, additional measurements of EC rate constants are needed if new insights concerning the basis of EC rates are to be determined.

We report here a new method for the measurement of EC rate constants, k_{ec}, of any molecule, M, of interest. By this technique, the EC rate constants for 16 substituted nitrobenzenes (NB) have been measured. These compounds are known to capture electrons by the resonance EC process

$$M + e \underset{k_{-a}}{\overset{k_a}{\rightleftharpoons}} M^{-*} \underset{k_b}{\overset{CH_4}{\rightarrow}} M^- \quad (1) \qquad \text{for which} \qquad k_{ec} = k_a \frac{k_b[CH_4]}{k_b[CH_4] + k_{-a}} \quad (2)$$

Under the conditions of this study $k_b[CH_4] \gg k_{-a}$ so that $k_{ec} = k_a$ is determined here.

Experimental: All the measurements reported here were obtained using a pulsed e-beam high pressure mass spectrometer (PHPMS) which has been previously described (1). For these EC rate determinations, for example NB, a mixture containing known concentrations of NB and a reference compound, CH_3I, is leaked into the ion source. Following the e-beam pulse, the secondary electrons are rapidly thermalized within the CH_4 buffer gas, and then undergo competitive electron capture to either NB or CH_3I. A requirement of this method is that the negative ions produced by the EC reactions of NB and CH_3I must not react with the parent neutrals. This has been previously demostrated for CH_3I and the substituted NB's (2). Under these conditions the ratio of the intensities of the NB^- and I^- ions is then dependent only on the concentrations of NB and CH_3I and their individual EC rate constants as shown:

$$\frac{I_{NB^-}}{I_{I^-}} = \frac{k_{ec,NB}[NB]}{k_{ec,CH_3I}[CH_3I]} \quad (3)$$

I_{NB^-} and I_{I^-} are obtained from the areas under their respective ion peaks in the mass spectrum. The EC mass spectra of all the NB derivatives exhibited minor peaks, in addition to M^-, and have been accounted for in the data analysis. To verify the value of the EC rate constant for CH_3I at 125°C, SF_6 was used a reference compound. The EC rate constant for SF_6 is well known ($k_{ec}=4.5\times10^{-7}$ ml/s (3)) and provides an anchor point for our measurements. The value of $k_{ec}=1.4\times10^{-7}$ ml/s for CH_3I thereby determined compares favorably with $k_{ec}=1.6\times10^{-7}$ ml/s measured by Alge et al (4). All of the EC rate constants reported here are based on $k_{ec}=1.4\times10^{-7}$ for CH_3I at 125°C.

Results and Discussion: Determinations of the EC rate constants for 16 substituted NB derivatives are shown in Table 1. Also shown in Table 1 are the electron affinities (EA) previously reported (5) for each compound. Table 1 shows that the NB derivatives possess a wide range of EC rate constants.

Since the EA of each compound provides a measure of the exothermicity of its electron attachment reaction, a positive correlation of k_{ec} with EA might have been expected to exist within this closely related set of compounds. However, a plot of k_{ec} versus EA clearly showed that no such correlation exits. Only for the subset of molecules consisting of the para-substituted derivatives (excluding p-MeNB) is a potential correlation between k_{ec} and EA suggested by these data.

We also considered the possibility that $k_{ec}=k_a$ is dependent on the existence of electronically excited states for M^- having energies slightly below that of the ground state of M. The presence of these excited states would increase the density of bound states available to the incoming electron and thus an increase in k_a might be expected. Support for this suggestion is provided by the absorption spectra of the molecular anions for the dinitrobenzene isomers shown in Figure 1. The ground state energy of M is placed on the wavelength scale of Figure 1 by calculating the wavelength of light equivalent to the molecules EA. The presence of absorption bands at wavelengths greater than that of the EA indicates the presence of these low lying excited energy levels for M^-. The absorption spectra provided in Figure 1 indicate the presence of such states for o-NO_2NB^- and p-NO_2NB^-,

while they are absent for m-NO_2NB^-. This might explain why the EC rate constants for o-NO_2NB and p-NO_2NB are much larger than that of m-NO_2NB.

Conclusion: We have provided here a unique data set of EC rate constants for a series of closely-related organic compounds. The EC rate constants of NB derivatives show little correlation with their known EA's. Therefore, the relative EC rates are not determined by the overall exothermicities of the reactions. However, we have identified a possible correlation of k_{ec} with the existence of low lying excited electronic energy states of M^-.

A STUDY OF THE S_N2 REACTIONS OF Cl^- WITH METHYL BROMIDE, ETHYL BROMIDE, ISO-PROPYL BROMIDE AND N-BUTYL BROMIDE AT ATMOSPHERIC PRESSURE USING AN ION MOBILITY SPECTROMETRY / MASS SPECTROMETRY APPARATUS

Kevin Giles and Eric P. Grimsrud
Department of Chemistry, Montana State University
Bozeman, Montana 59717

The body of kinetic data available on ion-molecule reactions at pressures above a few Torr is surprisingly small. The idea of studying ion-molecule reactions at atmospheric pressure is appealing from a fundamental point of view where the effects of multiple collisions on the outcome of a reaction can be determined. This idea has been realized with the development of the kinetic ion mobility / mass spectrometry (KIMMS) apparatus with which kinetic data on ion-molecule reactions can be measured at atmospheric pressure. The first systems to be studied with this new technique have been the S_N2 reactions of Cl^- with the alkyl bromides MeBr, EtBr, i-PrBr and n-BuBr at 125°C in 640 Torr of nitrogen.

The KIMMS apparatus, illustrated in Figure 1, consists of three major sections: an ion mobility spectrometer (IMS); a mass spectrometer (MS); and a gas handling plant (GHP). Ions of interest are generated in the IMS using a ^{63}Ni radioactive foil and drift under the influence of an electric field towards a Faraday plate/MS detection system through counterflowing N_2 gas. Ions are admitted to the 'drift region' in pulses using an electrostatic shutter (Tyndall gate) and their arrival time spectrum monitored at the Faraday plate. At the centre of the Faraday plate is a 50 μm orifice through which ions enter the MS. Ion-molecule reactions are studied by seeding the N_2 drift gas with small quantities of a reagent neutral gas. This is achieved with the GHP in which the reagent molecule of interest is first diluted in 2500 Torr of N_2 and then flows into the main N_2 drift gas through a fused silica capillary. The occurrence of a reaction in the drift region modifies the ion arrival time spectrum at the Faraday plate. These modified arrival time spectra obtained as a function of reagent neutral concentration in the drift gas can be analyzed to give a reaction rate coefficient. The ion signals in the MS can also be used to provide an independent measurement of the rate coefficient as well as identifying the ion species present in the IMS.

In the present study, the Cl^- reagent ions were generated from CCl_4 vapour in the ion source. The present results, together with those obtained by Caldwell et al.[1] at 4 Torr using a pulsed e-beam high pressure mass spectrometer, are presented in Table 1. Good agreement is obtained between the reaction rate coefficients determined in the present study using the IMS and MS data. The present results for the EtBr, i-PrBr and n-BuBr reactions are, within error, the same as those obtained by Caldwell et al.[1] indicating pressure independence over the range from 4 to 640 Torr. However, the MeBr reaction is some three to four times faster at 640 Torr than at 4 Torr. These results can be understood in terms of the double well potential energy surface ascribed to these reactions as well as other observations made by Caldwell et al.[1] These reactions are thought to proceed via a Cl^-.RBr intermediate which passes through a concerted S_N2 transition state to a ClR.Br^- intermediate and then on to products. The degree of stabilization of the first reaction intermediate is expected to influence the overall reaction kinetics. Caldwell et al.[1] observed that the Cl^-.RBr intermediates were in equilibrium with the buffer gas at 4 Torr for EtBr, i-PrBr and n-BuBr and hence no change in the reaction kinetics would be expected at increased pressure. However, the Cl^-.MeBr intermediate was not observed to be in equilibrium at 4 Torr, consequently the observed pressure dependence for the reaction is a result of increased collisional stabilization of the reaction intermediate at 640 Torr.

The KIMMS has been shown to be a valuable technique for the study of ion-molecule reactions at atmospheric pressure and is expected to be applicable to a wide range of studies. The apparatus and the present results are discussed in more detail in a recent paper.[2]

Table 1 : Rate Coefficients ($cm^3\ s^{-1}$) for the Reaction of Cl^- with MeBr, EtBr, i-PrBr and n-BuBr at 125°C.

	Present Study, 640 Torr		Previous Study, 4 Torr[1]
	IMS	MS	
MeBr	3.4×10^{-11}	3.4×10^{-11}	8.8×10^{-12}
EtBr	1.1×10^{-11}	1.3×10^{-11}	9.7×10^{-12}
i-PrBr	8.0×10^{-13}	7.6×10^{-13}	6.2×10^{-13}
n-BuBr	2.2×10^{-11}	2.2×10^{-11}	2.0×10^{-11}

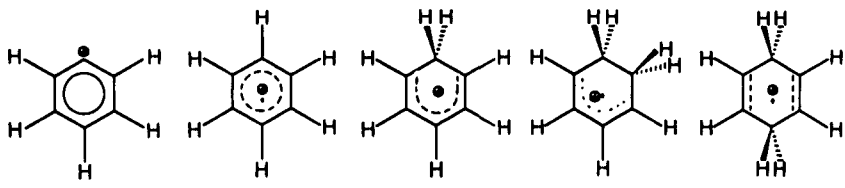
The present rate coefficients are reproducible to ±20%.
IMS rate coefficients are determined from reaction modified ion arrival time spectra. MS rate coefficients are determined using the loss of the reagent ion signal as recorded in the mass spectrometer.

Reactions of Benzenoid Ions with Atomic Hydrogen

*Simon Petrie, Gholamreza Javahery and Diethard K. Bohme,
Department of Chemistry and Centre for Research in Earth and Space Science, York University, North York, Ontario, Canada M3J 1P3.

Reactions of hydrocarbon ions with atomic hydrogen occur within sooting flames and within dense interstellar clouds. Few previous studies of such reactions, dealing only with ions having three or fewer carbon atoms, have been reported.[1] The formation of aromatic compounds within flames, and their proposed formation within circumstellar envelopes, indicate that the reactions of larger aromatic ions with H will also be important in these environments. As a first step in this direction, we report here the results for reactions of the ions $C_6H_5^+$, $C_6H_6^{+\cdot}$, and $C_6H_7^+$ with $H^\cdot$.

Reactions were studied in a selected-ion flow tube which has been described previously.[2] Atomic hydrogen was generated by the action of a microwave discharge upon H_2 (2-4% H_2 in He);[3] the efficiency of $H^\cdot$ generation was determined using the method of Tosi et al.[4] The hydrocarbon ions (I), (II) and (III) were produced as follows: $C_6H_5^+$ and $C_6H_6^+$, by electron impact upon chlorobenzene and benzene respectively; $C_6H_7^+$, by proton transfer from CO_2H^+ upon benzene. No evidence was observed to indicate the presence of higher-energy, non-cyclic isomers of $C_6H_6^+$ and $C_6H_7^+$, although both linear and cyclic forms of $C_6H_5^+$ (~ 1:1) were generated in accordance with previous studies.[5-7] The phenylium ion (I) was distinguished by its more rapid reactivity with H_2.[7]



I II III IV V

The results obtained are listed in Table 1.

Some of the observed non-reactions are surprising. Notably, none of the possible H-atom transfer reactions

$$C_6H_n^+ + H^\cdot \rightarrow C_6H_{n-1}^+ + H_2 \quad (1)$$

(all of which are exothermic for the ions in question) occurred measurably, while the most exothermic association reaction

$$c\text{-}C_6H_5^+ + H^\cdot \rightarrow c\text{-}C_6H_6^{+\cdot} \quad (2)$$

also failed to occur. These findings suggest that various structural factors are important in determining the reaction efficiency.

The failure of H-atom abstraction can be reconciled with the likely formation of collision complexes structurally similar to (II), (III), (IV) and (V). H_2 loss from (II) cannot occur as a 1,1 process, while (1,1) H_2 loss from (IV) and (V) produces ions which are anticipated to have substantially higher heats of formation than the lowest-energy isomer (II). H_2 loss from (III) appears feasible, leading to (I) without rearrangement; however, in the reaction of $C_6H_6^{+\cdot}$ with $H^\cdot$ only association (and not $H^\cdot$

transfer) is observed. We contend that the singlet association channel (which accounts for 1/4 of collisions between doublet $C_6H_6^{+\cdot}$ and doublet $H^\cdot$) is saturated, while the triplet association channel is very inefficient. To support this proposal, we note that the observed effective bimolecular association rate for $C_6H_6^{+\cdot} + H^\cdot$ is close to the expected $k_L/4$ and remains constant over the accessible pressure range 0.2 - 0.6 Torr. The inefficiency of association between c-$C_6H_5^+$ and $H^\cdot$ (a more exothermic process than association of $C_6H_6^{+\cdot} + H^\cdot$) is attributed to poor overlap between the C_6 π^6 system and the nascent C-H σ^1 bond, thus impeding formation of the ground-state $\pi^5\ \sigma^2$ configuration.[9]

We note also that our preliminary studies of reactions of the naphthalenoid hydrocarbon ions $C_{10}H_7^+$, $C_{10}H_8^{+\cdot}$, and $C_{10}H_9^+$ with $H^\cdot$ and with H_2 show analogous results: the association reactions $C_{10}H_7^+ + H_2$ and $C_{10}H_8^+ + H^\cdot$ occur, while other reactions are not observed.[10] This suggests that the structural factors mentioned here for $C_6H_n^+$ ions will likely apply to larger aromatic hydrocarbon ions also.

Table 1: Reactions of $C_6H_n^+ + H^\cdot$.

Reactant ion	Products	k_{obs}[a]	k_L[a]	$-\Delta H^\circ_{trf}$[b]	$-\Delta H^\circ_{assn}$[b]
c-$C_6H_5^+$	-	<0.01	1.9	9	88
l-$C_6H_5^+$	-	<0.005	1.9	3	42
$C_6H_6^{+\cdot}$	$C_6H_7^+$	0.25	1.9	16	81
$C_6H_7^+$	-	<0.01	1.9	23	41

Notes:
a. k_{obs} is the observed effective bimolecular rate coefficient; k_L is the calculated Langevin collision rate coefficient. Both are expressed in units of 10^{-9} cm^3 molecule^{-1} s^{-1}.
b. $-\Delta H^\circ_{trf}$ is the exothermicity of hydrogen-atom transfer reaction (1); $-\Delta H^\circ_{assn}$ is the exothermicity of association, calculated using values obtained from reference 8. Units are kcal mol^{-1}.

ISOMERIZATION OF ALKYLBENZENES BY ELECTROSTATIC ACTIVATION DURING GAS PHASE PROTONATION

H. H. Büker and H.-Fr. Grützmacher, Fakültät für Chemie
Universität Bielefeld, Universitätsstraße , D-4800 Bielefeld, Germany

Gas phase basicity (GB) and proton affinity (PA) are very important data of organic and element-organic molecules related to fundamental properties of these species. An accurate and trustworthy determination of these data is vital for gas phase ion chemistry. The most reliable technique for a determination of GB and PA is the measurement of proton transfer equilibria in the gas phase between the compound under study and a set of reference bases of known GB by FT-ICR, high pressure mass spectrometry, or a related method. A prerequisite for these measurements is a sufficient volatility of the compounds. This condition is not satisfied by most large organic molecules containing many functional groups. However, there are several methods known (for example CI, DCI, FAB) to prepare protonated molecules in the gas phase even from rather involatile organic compounds. This can be used for a determination of the GB by a *bracketing method.* Using this method it is assumed that the rate of an *exothermic deprotonation* is nearly collision controlled while an *endothermic deprotonation* is much slower. Thus, reacting a protonated molecule with a base of greater PA results in fast deprotonation, while deprotonation by a base of smaller PA is insignificant. *Many organic molecules rearrange by acid catalysis.* Proton induced isomerizations in the gas phase are also possible if the protonated molecules are generated with excess energy. *These isomerizations will interfere with a determination of GB and PA by the bracketing method.*

Some results of these proton induced isomerizations of alkylbenzenes are presented using FT-ICR and p-xylene as a test molecule. The stability of $C_8H_{11}^+$ decreases from m-$C_8H_{11}^+$ to o-$C_8H_{11}^+$ and p-$C_8H_{11}^+$ by 13 and 17 kJmol^{-1}, respectively. Hence, the protonation of p-xylene in the gas phase may give rise to substantial amounts of the protonated o- and m-isomers.

All measurements were performed using a Bruker-Spectrospin CMS47X FT-ICR spectrometer equipped with an external ion source and with pulsed valves for the introduction of reactants into the cylindrical ICR cell.

Condition A: p-Xylene was protonated in the external ion source by CI and transferred into the ICR cell containing a base of known GB at a constant partial pressure of *c.* 10^{-7} mbar. Condition B: The conjugated acid of a base of known GB was generated by CI in the external ion source and transferred into the ICR cell containing p-xylene at a constant pressure of $2.5 \cdot 10^{-8}$ mbar. After a reaction time of 5 s the $C_8H_{11}^+$ ions were isolated and a reference base of known GB was introduced into the cell by a series of pressure pulses at intervals of 1 s. The partial pressure of the base varies between $2 \cdot 10^{-7}$ and $5 \cdot 10^{-7}$ mbar.

In the case of a deprotonation of a mixture of isomeric $C_8H_{11}^+$ ions the intensity I(t) of all $C_8H_{11}^+$ ions is the sum of the intensity I(i) of the individual isomers and is given by

$$I(t) = \sum I_0(t).e^{-k_{exp}(t)t}$$

The results prove unequivocally the formation of a mixture of protonated o-, m-, and p-xylene by the protonation of p-xylene using $CI(CH_4)$ and $CI((CH_3)_2O)$. The composition of the mixtures as calculated from the trimodal intensity decay are given in Table 1 and 2.

To avoid any ambiguity about the species protonating the p-xylene a series of experiments was performed using conditions B. The acidic ions AH^+ (A = C_2H_5CN; CH_3OH, C_6H_6, C_3H_6, H_2O, C_2H_4) generated in the external ion source were used to protonate p-xylene in the ICR cell. Subsequently, the $C_8H_{11}^+$ ions formed in the cell were deprotonated by $HCOOC_2H_5$. This reference base quickly deprotonates *only* p-xylenium ions, and the $C_8H_{11}^+$ ions left correspond to a mixture of o- and m-xylenium ions. The results are shown in Table 3.

Table 1: Isomeric $C_8H_{11}^+$ ions generated from p-xylene by $CI(CH_4)$

reference base	GB[a]	p-xylene[b]	o-xylene[b]	m-xylene[b]
$HCOOC_2H_5$	775	17±5% eff > 50%	25±3% eff = 20±5%	58±2% eff = < 1%
$i\text{-}C_3H_7CN$	780	12±3% eff > 50%	25±2% eff = 39±4%	63±1% eff = < 1%

[a] $kJ \cdot mol^{-1}$ [b] eff = reaction efficiency

Table 2: Isomeric $C_8H_{11}^+$ ions generated from p-xylene by $CI((CH_3)_2O)$

reference base	GB[a]	p-xylene[b]	o-xylene[b]	m-xylene[b]
$HCOOC_2H_5$	775	83±4% eff > 50%	17±2% eff = 6.6±1%	

[a] $kJ \cdot mol^{-1}$ [b] eff = reaction efficiency

Table 3: Isomeric $C_8H_{11}^+$ ions generated by various Bronstedt acids

AH^+	GB(A)[a]	PA(A)[a]	ΔG_R[a]	ΔH_R[a]	$X_{isom.}$
C_2H_5CN	770	806	-2	+3	< 4%

C_6H_6	730	759	-42	-45	< 6%
C_3H_6	718	751	-54	-52	25%
H_2O	665	697	-107	-106	60%
C_2H_4	651	680	-121	-123	73%

[a] $kJ \cdot mol^{-1}$ [b] amount of isomerization of p-xylenium ions

Conclusion

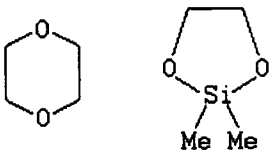
p-Xylene and very likely other polyalkylarenes isomerize easily on protonation in the gas phase to the more stable protonated isomers. This isomerization can be detected by analyzing the kinetics of the deprotonation by a series of bases of selected GB (a *"gas phase titration"*). As expected, the amount of isomerization depends on the excess energy imparted to the protonated molecule during the initial protonation by a conjugated acid AH^+ (compare Table 1 and 2)

No indication of slowly isomerizing p-xylenium ions is obtained. Obviously, the isomerization takes place in the collision complex during the protonation of p-xylene and is more or less quenched by the dissociation of the collision complex into the xylenium ion and the neutral base.
Besides on the exothermicity of the protonation the amount of isomerization of the p-xylenium ions depends on the nature of the conjugated acid AH^+. Polar reactant ions AH^+ enhance the isomerization (compare A = CH_3OH and C_6H_6 in Table 3). This indicates that electrostatic activation of the collision complex of the protonation reaction is also important.

A GC Artifact That Interferes with the Analysis of 1,4-Dioxacyclohexane in Monoethylene Glycol--Who Says Mother Nature Is Not Trying to Trick Us?

John Glass Green, The Dow Chemical Company, Research and Development,
Analytical and Engineering Sciences Laboratory,
Plaquemine, Louisiana 70765-0400

During the analysis of monoethylene glycol (MEG) for 1,4-dioxacyclohexane (1) by GC/MS using a DB-1701 column, an interfering material was observed. This material is especially insidious because it has fragments at m/z 88 and m/z 58, which are the major ions in 1,4-dioxacyclohexane. (Figure 1) The data presented here support the conclusion that the compound is an unusual 1,3-dioxa-2-silacyclopentane (2) derived from the reaction of MEG and the poly(dimethylsiloxanes) used in GC applications.



(1) (2)

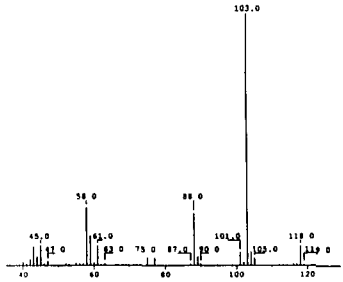


Figure 1

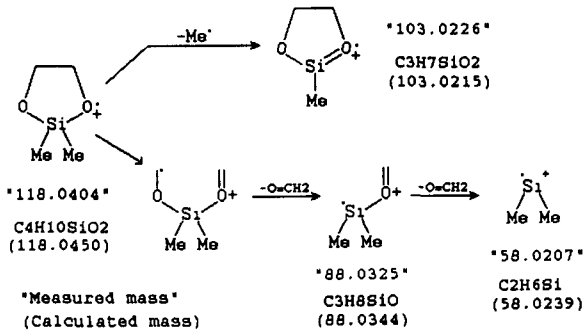
The presence of significant M+1 and M+2 peaks suggested that the compound possibly contained silicon. Exact mass values for the major ions are consistent with the presence of silicon also. The following scheme illustrates the proposed fragmentation mechanism and gives the exact masses obtained for the various ions.



In MEG spiked with 1,4-dioxacyclohexane, high resolution MS showed the presence of two different ions at both m/z 58 and m/z 88 from the single GC peak. The two m/z 58 ions were 58.0244 (C_2H_6Si,58.0239) and 58.0408 (C_3H_6O,58.0419). The two m/z 88 ions observed were 88.0317 (C_3H_8SiO,88.0344) and 88.0483 ($C_4H_8O_2$,88.0524). The two compounds appear as one chromatographic peak because of the slow scan cycle time in this analysis. The compounds elute about 5 seconds apart depending on GC conditions.

The same dioxasilacyclopentane is present in the analysis done on a DB-5 type column, as would be expected. With this column also, the 1,4-dioxacyclohexane is resolved only slightly from the dioxasilacyclopentane and both elute on the tail of the MEG peak.

Conclusions

Not only does this compound have the potential to complicate GC analyses but also it can interfere with GC/MS analysis because of the ions it has in common with 1,4-dioxacyclohexane in low resolution MS. In the worst case, this compound could result in a false positive result for 1,4-dioxacyclohexane. In absence of 1,4-dioxacyclohexane the artifact peak could be mistaken for the 1,4-dioxacyclohexane because of its similar spectrum and close elution time on either of the two columns used. Care should be taken to avoid mistaking the dioxasilacyclopentane for 1,4-dioxacyclohexane.

Future Work

Identification of this compound has led to the realization that a number of other compounds, glycols and alkanolamines, can produce similar artifacts. The analysis of these compounds is being examined to identify the artifacts produced with the expectation that some of the behavior of these difficult to analyze compounds can be explained.

Experimental

The GC/MS analysis, high resolution and exact mass measurements were made with a Finnigan/MAT MAT 95 high performance spectrometer operating at R=5000 and scanning at 4 sec/decade from 15 to 150 amu. Low resolution analyses were done at 1 sec/decade. The gas chromatography was done with a HP5890 Series II GC fitted with a 30M x 0.32 mm OD J&W DB-1701 or DB-5 capillary column. The injector was set at 250C, transfer line at 275C. Typically, 0.5 microliter of liquid or 1 ml of headspace was injected with a 60:1 split.

ON-LINE SFE/CLEAN-UP/SFC-MS OF PESTICIDES IN TISSUES

Veri Murugaveri, and Kent J. Voorhees, Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO 80401.

On-line supercritical extraction/clean-up in conjunction with benchtop GC/MS has been applied for the trace analysis of various toxic organic compounds in a variety of sample matrices. However, these on-line methods have not been applied to thermally labile compounds since the GC/MS techniques are not suitable for these compounds. The primary objective of this study was to develop an inexpensive benchtop electron impact mass spectrometer as a detector for an on-line SFE/clean-up/SFC flow system previously developed for the analysis of thermally labile carbamate pesticides in complex sample matrices[1].

The simplicity and versatility of benchtop GC/MS have made it a common analytical tool in most laboratories. Despite the proven advantages of supercritical fluid chromatography (SFC), the SFC/benchtop MS is still in its embryonic stage. This is primarily due to the level of sophistication involved in the interfacing techniques thus far reported in the literature. To date, there are only two reports cited[2,3] in the literature on SFC with benchtop MS, both resorting to CI to accommodate the high source pressures of SFC.

The ideal benchtop SFC/MS for routine analytical work should be as simple as its GC/MS counterpart, and also capable of operating in the EI mode to provide spectral information. This paper describes the development and evaluation of such a benchtop SFC/MS system employing EI for use in an on-line SFE/clean-up/SFC method previously developed in our laboratory.

A Leybold Inficon benchtop Auditor II quadrupole mass spectrometer (Perkin-Elmer Q-Mass 910) was modified for SFC work by altering the standard GC interface and adding increased pumping. The major changes were: introduction of an extra heater and thermocouple to allow for differential heating of the transfer line, and replacing the existing pumping manifold and the 50 L/s turbo pump with a new manifold of slightly larger diameter with a 4" flange and a new 160 L/s turbo pump. The existing ionizer, rod assembly, and electronics were used with no modifications except replacing the thoriated tungsten filament with rhenium. The tip of the interface was heated by the ion volume via a ceramic collar as depicted in Figure 1.

The SFC/EI-MS of thermally labile pesticides and various other analytes have been obtained with good chromatographic integrity and low nanogram full scan sensitivity. The chromatograms shown in Figure 2 show the separation and detection of a solution containing picogram levels of three carbamate pesticides including Diuron, Bendiocarb, and Carbaryl in a selected ion mode. The signal to noise ratio for these selected ion peaks was calculated to be 2700:1, 297:1 and 606:1 for Diuron, Bendiocarb, and Carbaryl respectively. The SFC/EI-MS total ion chromatogram and the corresponding mass spectrum of a pesticide is shown in Figure 3. The separation and detection of mixtures containing 15 ng each of ten polynuclear aromatic hydrocarbons in the full scan mode is shown in Figure 4. These preliminary evaluations have shown the ease and feasibility of converting a commercial benchtop GC/MS system into a SFC/EI-MS system. The significance of this benchtop SFC/EI-MS system is its simplicity and sensitivity, comparable to a benchtop GC/MS, which could make SFC/MS a routine analytical tool.

IMPORTANT EXPERIMENTAL PARAMETERS IN HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY THERMOSPRAY AND PARTICLE BEAM MASS SPECTROMETRY

Johnny D. Reynolds, Ciba-Geigy Corporation, P.O. Box 18300, Greensboro, NC 27419

INTRODUCTION

The use of high-performance liquid chromatography (HPLC) for the analysis of agricultural products has increased with the development of new higher molecular weight and thermally labile compounds. Conventional HPLC detection methods can not provide the crucial balance between compound specificity and sensitivity that is required. While mass spectrometric detection can provide this balance, compound specificity and sensitivity will depend upon the HPLC conditions and the type of HPLC mass spectrometry (MS) interface utilized.

OBJECTIVE

The experimental complexities associated with HPLC thermospray (TSP) and particle beam (PB) MS affect compound specificity and response. In order to exploit the full capabilities of these MS techniques, experiments using triazine compounds (Table 1) were conducted to establish the relative influence of controllable parameters on compound specificity and MS response.

EXPERIMENTAL

The experimental system (Figure 1) was operated in either a column mode or a loop-injection mode (switches S1 and S2 in position A or B, respectively). A Rheodyne 7125 injector (I) was used in the loop-injection mode. All MS data were collected under the following conditions unless otherwise noted: 1) Waters 600 MS System Pump (W1) was operated at 0.2 ml/min (PB) or 0.5 ml/min (TSP); 2) Waters Column Oven (W2) contained a Sperisorb ODS column with 3μm particles (100 mm x 2 mm (PB) or 3 mm (TSP)) from Keystone Scientific that was maintained at 35°C; 3) Waters 490 UV Detector (W3) was operated at 210 nm; 4) Waters 600 MS Post-Column Pump (W4) was operated at 0.1 ml/min (PB) or 0.4 ml/min (TSP) to deliver 0.10 M NH_4OAc in 80:20 $MeOH:H_2O$; and 5) Finnigan TSQ 700 mass spectrometer (TSQ) was operated at a source temperature of 200°C. TSP vaporizer temperature was 90°C. Finnigan PB interface temperature and He pressure were 50°C and 50 psi, respectively. All MS/MS experiments were conducted at a collision offset of 20 V and with an argon collision cell pressure of ≈2 mtorr.

HPLC REQUIREMENTS

MS parameter optimization was dependent upon the HPLC conditions needed to obtain the desired separation. The triazine compounds were easily separated using a mobile phase composition of 40:60 acetonitrile:water (Figure 2).

HPLC PB METHANE CHEMICAL IONIZATION MS

PB methane chemical ionization (CI) MS parameters optimized the same for all three triazine compounds. CI MS response was affected more by PB interface temperature than He pressure (Figure 3; data for atrazine is representative; no post-column buffer). Ion source temperature had the smallest effect on CI MS response (Figure 4; no post-column buffer), while post-column buffer concentration had the largest effect (Figure 5). Initially signal/noise ratios (S/N) increased with increasing buffer concentration (Figure 6), but decreased at higher post-column buffer concentrations because of higher chemical noise levels.

HPLC PB ELECTRON IONIZATION MS

PB electron ionization (EI) MS parameter optimization data for the triazine compounds were as noted in the PB CI MS data. One notable difference in the PB EI MS data was that S/N decreased more rapidly at higher buffer concentrations due to increasing chemical noise levels.

HPLC TSP MS

While TSP vaporizer temperature had a larger effect on MS response than ion source temperature, post-column buffer concentration had the greatest effect. TSP MS S/N maximized over approximately the same post-column buffer concentration range that was noted in the PB MS data (Figure 6).

SPECIFICITY COMPARISON

Specificity (structural information) results were analogous for PB EI MS mode and for PB CI and TSP MS/MS modes. However, limits of detection for these MS modes were different (Table 2).

CONCLUSIONS

1) The relative importance of controllable parameters on PB EI and CI MS response for these triazine compounds decreased in the following order: post-column buffer concentration > interface temperature > interface pressure > ion source temperature. 2) In PB and TSP MS, a limited post-column buffer concentration range exists in which S/N are enhanced. 3) For given HPLC conditions, TSP MS offers the best limits of detection for these triazine compounds. 4) Structural information for the triazine compounds is best obtained by TSP MS/MS since it offers the best limits of detection for the given HPLC conditions.

A New Probe for Use with Thermospray Ion Sources

Steven M. Musser, Kevin D. White and James A. Sphon
Division of Contaminents Chemistry, USFDA, Washington, DC 20204

Introduction

Thermospray is a practical ionization method for interfacing liquid chromatography with mass spectrometry. Since its introduction, a vast number of compounds that would otherwise have been very difficult to analyze using mass spectrometry have been successfully identified and quantitated. Our laboratory has found this technique to be very useful, particularly when applied to the analysis of drugs and their metabolites from biological matrices. Unfortunately, one of the drawbacks associated with thermospray is that nonvolatile salts and other nonvolatile materials tend to degrade its performance, ultimately clogging the probe and destroying it. Several solutions to this problem have been developed, including replaceable sapphire tips and fused silica liners, however both methods have limitations. Since a considerable expense is incurred if the entire probe must be replaced, we have designed a new probe which has very little cost associated with it and allows for the rapid replacement of the capillary tube itself.

Probe Modifications

A standard thermospray probe (Vestec Corp., Kirby, TX) that had been become clogged was used for the modifica-tions. The inner stainless steel (SS) capillary was drilled out and one end of the outer 1/4" o.d. SS tube was machined with 10/28 threads. A 1/4" length of SS tubing with a 1/16" hole in the center was pressed into the opposite end of the tube. Onto the threaded end of the tube was placed a PEEK HPLC adapter (Upchurch Scientific, Oak Harbor, WA). A Teflon coated iron-constantan thermocouple (Omega International, Stamford, CT) was placed at the tip of the probe and epoxied into place. A 15" length of 0.004" i.d. x 1/16" o.d. SS capillary tubing was passed through the PEEK adapter and secured at the tip with a set screw. A vacuum tight seal was made at the adapter with a PEEK nut and vespel ferrule. The total cost involved in these modifications was approximately $ 35.00.

Mass Spectrometry

A Vestec model 201 quadrupole mass spectrometer equipped with a thermospray only ion source was used for all experiments. The instrument was scanned from 120 to 400 amu in 1 second. The block temperature was held at 300 °C and the probe tip and control temperatures were optimized for each probe used. Generally the control temperature was in the range of 160-170 °C. An aqueous mobile phase of 50 mM ammonium formate was pumped at 1 ml/min. When the replaceable tip probe was used, a 75 um orifice was selected. Three injections of 2 ug each of a standard solution of adenosine (Sigma Chemical Co., St. Louis, MO) were made for each probe in both the discharge and regular thermospray modes.

Discussion

The principal difference in the design of the new thermospray probe (figure 1) is that the vacuum seal on the inner SS capillary is resealable, whereas it is permanent on the original one. Thus, when the capillary becomes clogged, it may be replaced for a nominal cost instead of purchasing a new probe. A comparison of results obtained with the new probe design and older designs shows that sensitivity is slightly better with the new design, although there is more fragmentation. Increased fragmentation may be due to the way the temperatures were optimized and can be decreased by adjusting the temperatures for minimum fragmentation instead of maximum signal. Another advantage of the new design is its experimental flexibility. When it is desirable to enhance or remove reactions that occur as a result of the vaporization process on stainless steel, various internal diameters of capillary tubing along with special coatings, such as glass lined stainless steel may be interchanged without the need for expensive machining of new probes.

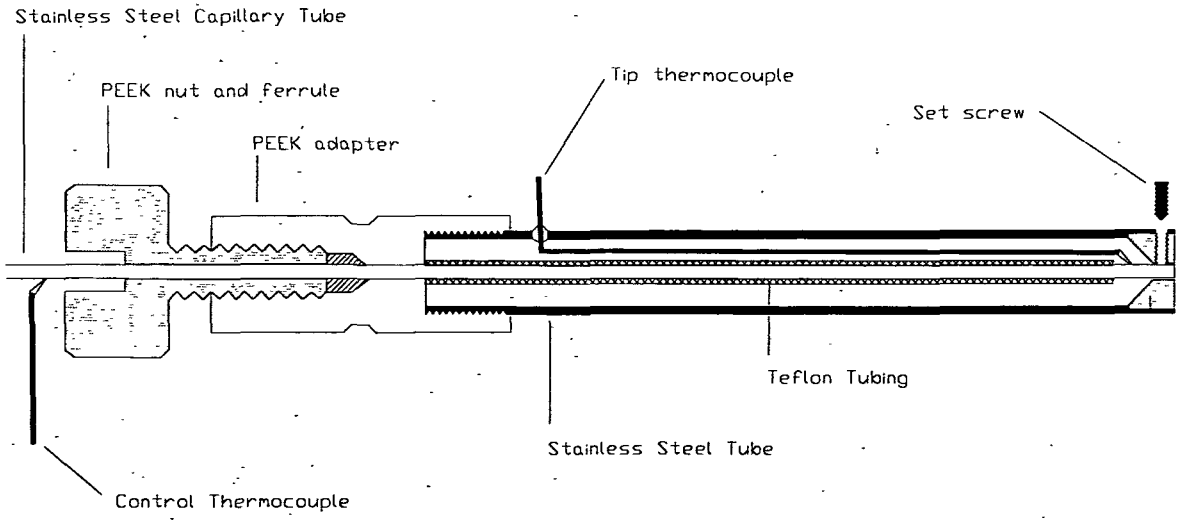

Figure 1. Schematic drawing of the new thermospray probe design.

FLOW INJECTION-PHOTOLYSIS-THERMOSPRAY-MASS SPECTROMETRY

John M. Ballard and Nelu Grinberg

Rahway, NJ 07065

INTRODUCTION

The products of photochemistry are usually characterized by spectroscopic investigations (NMR, MS, IR, UV etc.) of isolated compounds. Knitted, open-tubular reactors (KOTR's) constructed from PTFE permit continuous flow photochemistry to be coupled with ultra-violet, fluorescence or electrochemical detectors (1). The use of a thermospray vaporizer to interface a KOTR to a mass spectrometer has not been previously reported; however, the application to forensic drug analysis of continuous photolytic derivatization with thermospray mass spectrometric detection is currently under study (2).

We have investigated the potential of on-line photochemistry-mass spectrometry for,

1) the detection/identification of products of synthetic photochemistry,

2) the structural elucidation of unknown compounds by degradative photolysis,

and 3) the study of the kinetics of photolysis.

EXPERIMENTAL

An LC solvent delivery system (Model 600-MS; Waters, Milford, MA) was used to pump the mobile phase (acetonitrile) through a PTFE KOTR (Model KRC 15-50; 15m x 0.50mm ID x 1.6mm OD; overall dimensions approx. 170 x 40 x 1 cm) which was irradiated by the output from a low pressure, 254nm mercury vapor lamp (PHRED; both from Aura Instrumentation, Staten Island, NY). The KOTR was connected to a variable wavelength, UV/Vis detector (Spectroflow 757, Applied Biosystems, Ramsey, NJ) and the effluent from the UV detector was directed to a Finnigan MAT TSQ 70B mass spectrometer via a thermospray TSP2 interface. Ionization was effected by applying 900-1000 volts to the discharge electrode and positive ion data were acquired. Manual injections of compounds in solution (500-1000 ppm; 50-100uL) into the mobile phase were made via a Waters U6K injector.

RESULTS AND DISCUSSION

The well known photochemical reduction of benzophenone to benzopinacol, $(C_6H_5)_2C(OH)C(OH)(C_6H_5)_2$, was used as a model system to study synthetic photochemistry (3). Injection of a solution of benzophenone dissolved in isopropanol into the mobile phase set at a flow rate of 0.7mL/min (irradiation time ca. 6 min.) gave a thermospray spectrum which indicated the formation of benzopinacol by ions at m/z 367 $(M+H)^+$ and m/z 349 $(MH-H_2O)^+$; ions at m/z 243 and 225 were assigned to $(M+H)^+$ and $(MH-H_2O)^+$ for $(C_6H_5)_2C(OH)C(OH)(CH_3)_2$ (A), which was the major product. Ions at m/z 301 and 283 due to $(M+H)^+$ and $(MH-H_2O)^+$, respectively, were presumed to arise from further reaction of (A) with acetone which was derived by photochemical oxidation of isopropanol. Similarly, the photochemical reaction of benzophenone with toluene gave $(C_6H_5)_2C(OH)CH_2C_6H_5$ as the major product, indicated by ions at m/z 275 $(M+H)^+$ and m/z 257 $(MH-H_2O)^+$, together with benzopinacol.

The CAD daughter ion spectrum of the ion at m/z 360 of heptyl physostigmine (heptastigmine,[B]; injected as a solution of the tartrate salt) was compared with the photolysis-thermospray full-scan

spectrum of (B). Although the spectra were different, several ions were common to both and mass chromatograms showed that many of the ions generated by CAD were also generated at low levels by photolysis.
The photolysis-thermospray spectrum of a macrolide antibiotic, FK-520, showed many peaks not present in the UV lamp-OFF mode. These results suggest that photolysis and CAD may provide complementary data for structural elucidation.

The thermospray mass spectra of triplicate injections of (B) were recorded separately under UV lamp-ON and UV lamp-OFF conditions at flow rates of 0.8, 1.0, 1.2 and 1.4mL/min; these corresponded to irradiation times of approx. ~5.4, 4.3, 3.5 and 2.9 min., respectively. Area counts (C_{on} and C_{off}) for the $(M+H)^+$ ion at m/z 360 were measured under the two conditions. A plot of ln (C_{on}/C_{off}) vs. Irradiation time was linear (R^2 = 0.999), indicating that the photochemical cleavage of (B) followed first-order kinetics; the intercept on the X-axis may correspond to an induction period. Similar kinetics were observed for the $(M+H)^+$ ion at m/z 870 of a cyclic heptapeptide (MK-0852).

CONCLUSIONS

The products of photochemical synthesis can be detected/identified which can aid in determination of the mechanism.
Photolysis-Thermospray-mass spectrometry may be able to generate spectra which are comparable or complementary to those generated by MS/MS for structural elucidation.
The kinetics of photolysis can be readily determined; this will aid in optimizing conditions for fragmentation.

WATER AS A USEFUL CALIBRANT FOR THERMOSPRAY MASS SPECTROMETRY

Fong-Fu Hsu
Department of Medicine
Washington University School of Medicine, St. Louis, Mo 63110

Thermospray LC/MS calibration has been mainly carried out using polyethylene glycol (PEG).[1] The shortcomings of PEG as a calibrant have been instrument contamination[2] and thermospray vaporizer clogging.[3] Several approaches have been proposed to improve thermospray positive ion tuning and calibration,[2,4-6] however few methods have been reported for negative ion calibration. Stout and daCunha[4] used trifluoroacetic acid (TFA)-ammonium cluster ions. Although the method can be used for negative ion calibration, it suffers from several drawbacks: (1) the ion current is mainly (95%) concentrated in the TFA·$[CF_3COO]^-$ ion (m/z 227); (2) the unpredictable nature of the ion pattern of the spectrum due to variable amounts of ammonia being incorporated in the cluster ions; and (3) calibrants deposit in the vacuum tubing external to the heated mass spectrometer manifold. Later on, Stout and daCunha[5] also utilized heptafluorobutyric acid and perfluorodecanoic acid, and their ammonium salts as calibrants. However, the method encounters the difficulty of limited solubility of the perfluorinated alkyl acids in water and the persistence in the mass spectrometry of ions from the calibrants.

I have found that in negative ion detection with either filament-on or discharge ionization mode, water cluster ions up to a mass of 792 daltons (the mass range of our machine is 10-800 daltons, therefore the upper range may be higher) can be observed simply by introducing pure water into the mass spectrometer while the repeller voltage is set to maximize the ions at high mass end (e.g. it is approximately -120 volts for m/z 306). The water cluster ions disappear quickly upon switching to a new mobile phase.

The thermospray mass spectra of the water molecules were obtained using a Vestec 210 N (Houston, TX) LC/MS equipped with a Teknivent (St. Louis, MO) Vector 1 data system. Before obtaining mass spectra, pure water at a flow rate from 0.5 ml/min to 1.0 ml/min was applied to the mass spectrometer to wash the ion source. The wash continued until no background ion other than water clusters was observed. The mass spectra were then acquired. At 0.5 ml/min flow, the vaporizer temperature and vapor temperature were set at 181°C and 254°C respectively. There are two major series of ion species in both filament-on (Figure 1) and discharge ionization (Figure 2) spectra. In filament-on ionization mode, negatively charged water cluster ions $(H_2O)_n^-$ dominate the spectrum. The most intense ion is m/z 288 of probable composition $(H_2O)_{16}^-$. Below m/z 197, the deprotonated water cluster ions $[(H_2O)_n\text{-}H]^-$ (n=1 to 10) appear to be the major species. Ions at 18 dalton intervals are seen throughout each of these mass ranges.

In the discharge ionization mode, m/z 53, assigned the composition $[(H_2O)_3\text{-}H]^-$, becomes the most abundant ion. The deprotonated water cluster ions $[(H_2O)_n\text{-}H]^-$ (n=1 to 44), again at 18 dalton intervals, are the major ions and are accompanied by the negatively charged cluster ions $[(H_2O)_n]^-$. The occurence of ions at m/z 278, 296, 314, 332 etc., suggests that doubly-charged

ions are also formed. These may correspond to $[(H_2O)_n-2H]^{2-}$ clusters where n is an odd-numbered value, thus for example m/z 278 could be $[(H_2O)_{31}-2H]^{2-}$. Doubly-charged ion species where n is an even-numbered value will have the same m/z value as the principal singly-charged ions in the spectrum. No significant change in ion species or the ion abundances in the spectra (not shown) obtained between flow rate 0.5 ml/min and 1.0 ml/min has been observed. However, the repeller voltage is crucial to the cluster ions appearance. A similar observation has been reported by others.[2,4-6] It should be mentioned that once the calibration has been optimized for negative ions, the same calibration can also be used in the acquisition of positive ion mass spectra.

The utilization of water as a calibrant for thermospray mass spectrometry has the following advantages:(1) There is no contamination, in fact, water is regularly used in thermospray mass spectrometry for on-line and off-line source clean-up. (2) A comprehensive calibration of the mass spectrometer over the range from 10 to 800 daltons is obtainable. (3) The 18 dalton ion intervals are predictable.

Analysis of oligosaccharides using a thermospray or an electrospray interface with sodium acetate containing mobile phases.

W.M.A. Niessen, R.A.M. van der Hoeven, A.P. Tinke and J. van der Greef.
Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

A variety of liquid chromatographic methods is used in the analysis and characterization of oligomeric sugars as for instance obtained by chemical and enzymic degradation of plant cell wall polysaccharides. Identification of unknown oligomers is performed by time-consuming fractionation and purification techniques, followed by characterization by MS and NMR. On-line liquid chromatography mass spectrometry (LC-MS) might allow a more rapid characterization of oligosaccharides in terms of molecular weight and structure. As primarily aqueous mobile phases are used in liquid chromatography, thermospray is the interface of choice for this type of application. The development of a thermospray LC-MS method for oligosaccharide analysis (up to DP = 10) is reported here. Preliminary results with electrospray ionization are reported as well. All experiments were performed on a Finnigan MAT TSQ-70 mass spectrometer, equipped with a 20 kV conversion dynode detection system.

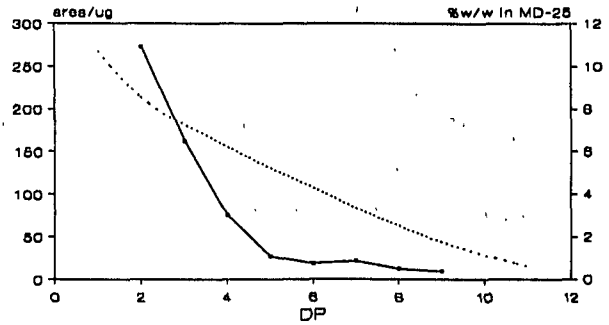
With conventional mobile phases applied in thermospray LC-MS, i.e., containing ammonium acetate, thermally-induced liquid-phase ammoniolysis of oligosaccharides takes place to monomeric sugars (the most abundant ion is m/z=180 due to $[C_6H_{10}O_5 + NH_4]^+$). Such a mobile phase is not suitable for the characterization of oligosaccharides.

In FAB, FD and other desorption methods, the addition of small amounts of alkali salts is used to enhance the signal for oligosaccharides. Sodium acetate containing mobile phases are generally considered incompatible with thermospray LC-MS. In our experiments, however, it appeared possible to work with sodium concentrations of 10^{-4}-10^{-3} mol/l without serious problems with source contamination or vaporizer clogging.

The thermospray mass spectra of neutral oligosaccharides under these conditions are characterized by strong sodiated molecules $[M+Na]^+$ and the absence of fragmentation. With larger oligosaccharides (DP>4), also doubly-charged disodiated molecules $[M+2Na]^{2+}$ are observed.
With acidic oligosaccharides, besides peaks due to a sodiated acid $[M+Na]^+$, peaks are observed for sodiated sodium salts $[M-H+2Na]^+$ as well.

An aqueous solvent system containing sodium acetate can be used in the reversed-phase separation of oligosaccharides. However, reversed-phase chromatography is not a very powerful separation method for complex oligosaccharide mixtures. Via an anion micromembrane suppressor, the on-line coupling of Dionex high-performance anion-exchange chromatography is also possible. Anion-exchange chromatography is widely used in the separation of sugar oligomers. On-line HPAEC-MS is described in another poster.

Response in LC-thermospray-MS, measured as peak area per injected amount, as a function of the degree of polymerisation (DP).



This solvent system is also compatible with electrospray ionization. As an example, the electrospray mass spectrum of an unknown oligosaccharide and its interpretation is given.

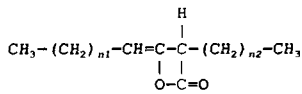
HPLC/MS Analysis of a Neutral Sizing Agent Using Thermospray and Particle Beam Interfaces

Jeffrey M. McGuire and Craig C. Lynch
Hercules Incorporated, Research Center
1313 N. Market St,. Wilmington, DE 19894-0001

In the process of "sizing" paper, cellulosic fibers are given hydrophobic properties that lead to enhanced resistance to aqueous penetrants. Traditionally, paper has been made at an acid pH with rosin and alum (aluminum sulfate) used to meet sizing requirements. Recently, there has been a shift to alkaline papermaking due to advantages associated with this process.

Alkylketene dimers (AKDs) (I) are neutral sizing agents that are now widely used.



I

A fatty acid fraction consisting mainly of palmitic and stearic acids normally acts as the starting material for the preparation of AKDs. This results in the substitution of long-chain alkyl groups on the ß-lactone ring, i.e., values of 13 or 15 for *n1* and *n2*.

During the development of a nonaqueous reversed-phase (NARP) high-performance liquid chromatography method for the determination of AKD content in various matrices, questions arose concerning the identity of several peaks observed in the HPLC chromatograms. For example, as shown in **Figure 1**, in addition to the major peaks corresponding to the C_{32}, C_{34}, and C_{36} AKDs, numerous smaller peaks were also observed. Thus, HPLC/MS was employed to aid in the identification of these peaks. Both thermospray (TSP) and particle beam interfaces were investigated.

A filament-on TSP mass spectrum of the C_{32} AKD (molecular weight 476) is shown in **Figure 2**. This spectrum is typical of the AKDs in that all of the spectra contain a protonated molecular ion (MH^+),and are dominated by an intense fragment ion at 28 daltons less than MH^+. This ion is believed to arise from the loss of carbon monoxide due to protonation of the AKD, followed by ring opening of the ß-lactone and subsequent loss of CO.

Figure 3 shows the EI (70-e.v.) mass spectrum of the C_{32} AKD. As indicated in the insert, a molecular ion was observed (m/z = 476) although the relative intensity was low (< 0.5%). The

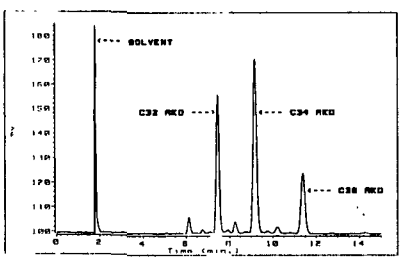


Figure 1. NARP-HPLC Chromatogram of AKD

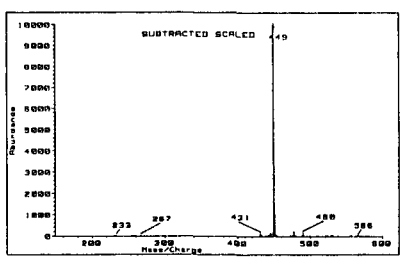

Figure 2. TSP mass spectrum of C_{32} AKD

m/z = 420 ion has been assigned to the $(M - 2CO)^{+\cdot}$ structure, a typical fragment ion previously noted in the mass spectra of several low molecular weight ketene dimers (1). A series of ions centered around m/z = 310 have been assigned to the $C_nH_{2n}^{+\cdot}$ and $C_nH_{2n-1}^{+}$ fragments from the alkyl side chains of the ketene dimer. The nature of the m/z = 98 base peak ion is currently in question, although it is believed to be $C_6H_{10}O^{+\cdot}$, resulting from opening of the ß-lactone ring and cleavage of the alkyl side chains. This type of EI mass spectrum is typical of the AKDs.

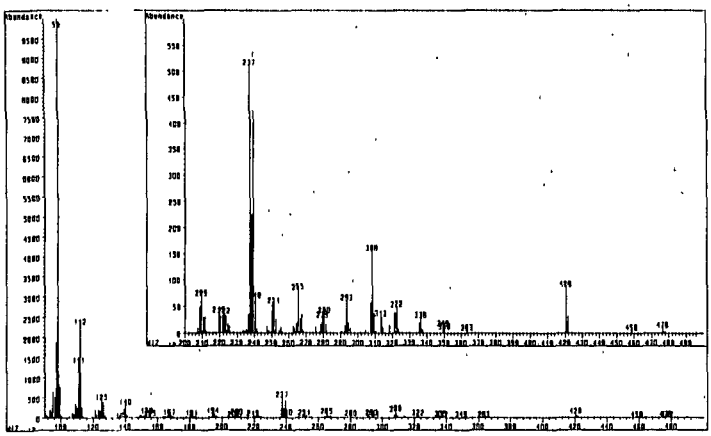

Figure 3. EI mass spectrum of C_{32} AKD

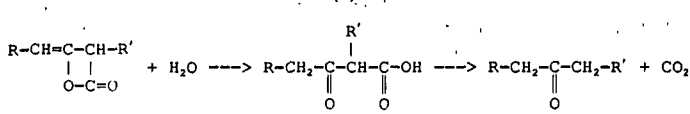
The methane CI mass spectra for the AKDs, also acquired using the particle beam interface, show both the MH^+ ion and the fragment ion at 28 daltons less than MH^+, similar to the spectra obtained using the thermospray interface. However, in the methane CI spectra the pseudo-molecular ion was equal in intensity to the $(MH-CO)^+$ fragment ion.

Finally, hydrolysis of AKDs leads to the formation of unstable ß-keto acids, which decompose into ketones and carbon dioxide as shown below (2):



Dipentadecyl ketone, heptadecyl pentadecyl ketone, and diheptadecyl ketone were identified in the TSP analysis by examination of extracted ion profiles (EIP). Under the thermospray conditions of this analysis, the ketones produced mass spectra dominated by the MH^+. Thus, an analysis of the EIPs for m/z = 423, 479 and 505 indicated that the ketones were coeluting with AKD homologs corresponding to odd carbon numbers, such as C_{31}, C_{33} and C_{35}.

SEPARATION AND CHARACTERIZATION OF AUTOXIDATION PRODUCTS OF ALKYLPYRROLES BY HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY WITH THERMOSPRAY MASS SPECTROMETRY

Mingshe Zhu, Anthony P. DeCaprio and David C. Spink, Department of Environmental Health and Toxicology, SUNY at Albany; and Wadsworth Laboratories, NY State Dept. of Health, Albany, NY 12201

Autoxidation of alkyl-substituted pyrroles is a phenomenon with important toxicological and chemical implications. 2,5-Hexanedione (2,5-HD), the neurotoxic γ-diketone metabolite of n-hexane, reacts with protein amines to yield 2,5-dimethylpyrrole adducts. This reaction is required for the development of hexane neurotoxicity[1]. Pyrrole formation is followed by autoxidation reactions, resulting in covalent protein crosslinking[2]. In addition, the storage stability of petroleum-based fuels is greatly affected by the autoxidation of 2,5-dimethylpyrrole contaminants and polymerized products[3]. However, little structural information about these autoxidation products is available because they are extremely insoluble and the intermediates in their formation appear to be very unstable[4]. This paper reports a method employing high-performance liquid chromatography (HPLC) with thermospray mass spectrometry (TSP-MS) for the analysis of autoxidation products of 2,5-dimethyl-N-alkylpyrroles. In addition, we describe a methylene bridge structure of alkylpyrrole oligomers which has not been previously reported.

Autoxidation of 1-(2-hydroxyethyl)-2,5-dimethylpyrrole (HEDMP) was carried out in 200 mM sodium phosphate buffer, pH 7.4 (5% v/v) at 37°C, under air or $^{18}O_2$. A solution of 1.19 M N^{α}-acetyl-glycine-L-lysine-methyl ester, acetate salt (GK-dipeptide) was incubated with 0.19 M 2,5-HD under the same conditions as with HEDMP to form 2,5-dimethyl-N-dipeptidepyrrole Analysis of autoxidation products of these alkylpyrroles was carried out with a TSP HPLC/MS system which consisted of a Waters HPLC, Vestec TSP interface and Hewlett-Packard quadrupole MS. Chromatography was on C_{18} with 0.1 M NH_4Ac and gradients of CH_3CN up to 50% (v/v).

The autoxidation of 2,5-dimethyl-N-alkylpyrrole in aqueous solution yielded a complex mixture of products, which were separated and characterized by TSP HPLC/MS. Fig. 1 is the total ion current (TIC) chromatogram recorded during HEDMP autoxidation sample analysis. TSP mass spectra of HEDMP autoxidation products corresponding to major peaks are summarized in Table 1. These products were categorized into two groups: 1) non-polar alkylpyrrole oligomers without incorporated oxygen, including a dimer (peak 6) and a trimer (peak 7), and 2) polar, oxygen-containing alkylpyrrole monomer species, such as peaks 1,2 and 3 Kinetic studies showed that oligomerization was the dominant autoxidation pathway, with production of unstable dimers and trimers and, ultimately, a high-molecular-weight sediment. The TS mass spectrum of the HEDMP dimer is shown in Fig. 2, together with the proposed structure which was confirmed by ^{1}H-NMR. The TS mass spectrum of the dimer formed by autoxidation of the pyrrolylated GK dipeptide is shown in Fig. 3. In both cases, cleavage of the two C-C bonds of the methylene bridge occurred readily during the thermospray process, resulting in fragment ions which are characteristic of this linkage.

* autoxidation under $^{16}O_2/^{18}O_2$

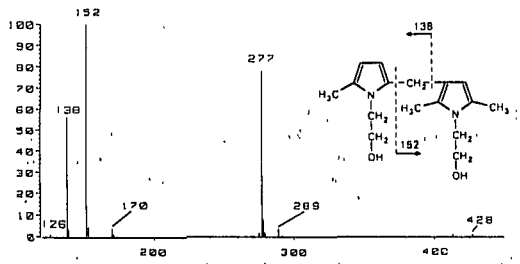

Fig. 2 TSP mass spectrum and structure of HEDMP dimer.

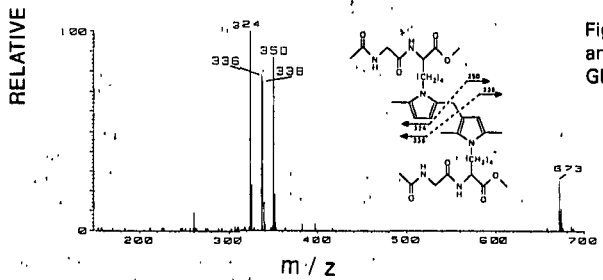

Fig. 3. TSP mass spectrum and structure of pyrrolylated GK-dipeptide dimer.

In conclusion, these data suggest that TSP HPLC/MS is an appropriate technique for separation and characterization of autoxidation products of 2,5-dimethyl-N-alkylpyrroles, and that pyrrole-pyrrole dimerization of 2,5-dimethyl-N-alkylpyrrole may play an important role in 2,5-HD-mediated protein crosslinking.

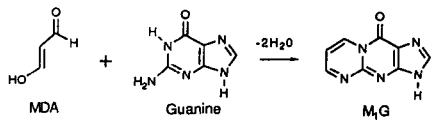
INTRODUCTION

Malondialdehyde (MDA) is a product of oxidative lipid metabolism, arising as a by-product during prostaglandin biosynthesis and an end product of lipid peroxidation [1]. It is mutagenic in bacterial and mammalian test systems and is carcinogenic in rodents [2]. An important rationale for considering it as a risk factor for cancer is the association of high dietary fat intake with mortality from breast and colon cancer. Such an association can be duplicated in experimental animal investigations and appears to be correlated to the unsaturated fat content of the diets. MDA reacts with deoxynucleosides *in vitro* to produce a variety of adducts that have been characterized previously [3]. The order of reactivity of DNA bases with MDA is guanine > adenine > cytosine > thymine. Thus, it would be predicted that the MDA-guanine adduct (M_1G) would be the major product of reaction between MDA and DNA.



MATERIALS & METHODS

Chemicals. M_1G was synthesized by reaction of MDA with guanine and purified by MPLC (>98% pure). [$^2H_2$]-MDA was synthesized in our laboratory for use in the synthesis of [$^2H_2$]-M_1G via the same route employed or the preparation of M_1G. All other chemicals were reagent grade and solvents were HPLC grade. The C_{18} SPE tubes (Supelclean LC-18, 6 mL tubes) were purchased from Supelco (Bellefonte, PA). Dihydro-M_1G (DHM_1G) was synthesized by reaction of M_1G with $NaBH_4$ at 37°C for 2 hrs. Calf thymus DNA was purchased from Sigma.

Solid-phase extraction. The C_{18} solid phase extraction (SPE) tubes (Supelclean LC-18, 6mL) were washed with 5 mL methanol followed by 5 mL water prior to use. Samples were loaded onto the prewashed SPE tubes which were then washed with water (5 mL) and eluted with methanol (5 mL).

HPLC/ECD. HPLC with electrochemical detection was employed for isolation of M_1G from DNA hydrolysates. Briefly, the method involves the reduction of M_1G by $NaBH_4$ to DHM_1G, which is electrochemically more active than the parent compound. HPLC was carried out using an Altex Ultrasphere ODS column (5u, 4.6 mm x 250 mm) and a Varian 9010 pump equipped with a Shimadzu L-ECD-6A detector. The electrode potential of the Shimadzu detector was +800 mV for all determinations. The electrochemical cell, column, and the guard column were housed in a Shimadzu CTO-6A oven maintained at 40°C. The mobile phase was 2% methanol in 50 mM potassium phosphate (pH 5.5) and was maintained at a flow rate of 1 mL/min.

Thermospray Mass Spectrometry. Mass spectral data were obtained on a Nermag R30-10 triple quadrupole mass spectrometer. The spectra were collected and processed using a SIDAR data system. Thermospray ionization mass spectra were obtained using a thermospray interface based on the Vestec design. Thermospray conditions were optimized for M_1G as follows: capillary temperature (250°C), source temperature (265°C) and the voltage of the repeller electrode (250 V). The photo-multiplier after the third quadrupole was set at 600 V. Thermospray LC/MS system consisted of a Hitachi L-6200 intelligent pump, a Valco C6W injector, and a Supelcosil LC-18 (4.5 mm x25 cm; 5μ) column and the mobile phase was methanol:0.05M ammonium acetate pH 6.5 (20:80; v/v) at a flow rate of 1.5 mL/min. The effluent from the HPLC column was introduced into the ion source of the mass spectrometer via the thermospray interface. Tandem mass spectrometric data were obtained by selection of the protonated molecular ion (MH^+) of M_1G through the first quadrupole, and allowing it to undergo collisionally induced dissociation (CID) with argon in the collision cell, which is a RF only quadrupole. The ions from the collision cell were mass analyzed by the third quadrupole and were detected on the final photomultiplier detector at 600 V. The collision gas pressure (2.0 E-6 torr) and collision energy (30 eV) were optimized to obtain maximum sensitivity for the fragment ions.

RESULTS

Thermospray and Tandem Mass Spectrometry. The thermospray mass spectrum of M_1G showed a dominant protonated molecular ion at *m/z* 188. CID of the MH^+ ion of M_1G (*m/z* 188) with argon resulted in the formation of daughter ions at *m/z* 79 and 106. The thermospray mass spectrum of $[^2H_2]$-M_1G showed a dominant protonated molecular ion at *m/z* 190. CID of the MH^+ ion for $[^2H_2]$-M_1G (*m/z* 190) resulted in the formation of daughter ions at *m/z* 81 and 108 confirming the assignment of the fragment ions obtained for non-deuterated M_1G. It was established in a series of dilution experiments that the detection limit for M_1G using the SIM mode was 50 pg M_1G injected on column (S/N 5:1). The thermospray mass spectrum of DHM_1G showed a dominant ion at *m/z* 190 corresponding to the protonated molecular ion. CID of the MH^+ ion of DHM_1G (*m/z* 190) resulted in the formation of daughter ions at *m/z* 56 and 135. The thermospray mass spectrum of $[^2H_2]$-DHM_1G showed a dominant ion at *m/z* 192, corresponding to the protonated molecular ion of the molecule. CID of the MH^+ ion of $[^2H_2]$-DHM_1G (*m/z* 192) resulted in the formation of the expected daughter ions at *m/z* 58 and 135, thereby confirming the assignment of the fragment ions.

Characterization of M_1G from hydrolysates of DNA treated with MDA. Calf-thymus DNA (5 mg) was dissolved in 5 ml water and pH of the solution was adjusted to pH 5. DNA solution was treated with 50 mM tetraethoxypropane (TEP) for 4 days at 37°C. DNA was precipitated by addition of 0.5 ml of 3M sodium acetate buffer (pH 4.4) and 15 ml cold methanol. The DNA was reduced by treatment with sodium borohydride at 37°C for 2 hours. The DNA was depurinated by treatment with 0.1N HCl, and DNA bases were isolated by C_{18} solid phase extraction. The SPE extract was subjected to HPLC with electrochemical detection as described in methods section. The chromatogram obtained for the DNA extract had a major peak at a retention time of 43.6 min. The retention time of synthetic reduced M_1G was 43.7 min. The peak at 43.6 min was collected, evaporated to dryness and resuspended in the initial mobile phase of HPLC system used for thermospray LC/MS. The sample was injected on the thermospray LC/MS system. The reconstructed ion chromatogram for m/z 190 showed a peak at 12.8 min. The thermospray mass spectrum of that peak showed an intense ion at m/z 190 (Fig. 1a). This indicated that the isolated compound was DHM_1G. Tandem mass spectrum of the ion at m/z 190 showed ions at m/z 56 and 135 (Fig. 1b), which was similar to that obtained for synthetic DHM_1G. This confirmed that the compound isolated from HPLC was in fact DHM_1G. Hence, M_1G was formed during the treatment of calf-thymus DNA with TEP.

DETERMINATION OF BRODIFACOUM RODENTICIDE IN A FOOD SAMPLE USING NEGATIVE ION THERMOSPRAY LC/MS

Mantai Z. Mesmer, Rick A. Flurer, and R. Duane Satzger
National Forensic Chemistry Center, U.S. Food and Drug Administration
1141 Central Parkway, Cincinnati, OH 45202

The NFCC is frequently called upon to analyze samples of material from incidents of consumer product tampering. In such tampering cases it is absolutely essential that adulterants be unambiguously identified when present, or that adulteration can be ruled out with certainty when a suspected tampering has in fact not occurred. Because a false negative or a false positive could have costly consequences, there is no room for error. Therefore, mass spectrometric confirmation of identity is generally required.

A sample consisting of oatmeal contaminated with small amounts of green powder was recently submitted to the NFCC for analysis. Based on previous attempts at analysis by gas chromatography and the green color of the contaminant, it was suspected that the green powder was a commercially available rodenticide. Because the active ingredient of such rodenticides is the superwarfarin brodifacoum, our efforts were concentrated on the detection of brodifacoum in this sample.

There are two mass spectrometric methods in the literature for the determination of brodifacoum[1,2]. The GC/MS method of Ray et al. involves oxidation with chromic acid followed by methylation with trimethylanilinium hydroxide. The species actually detected is methyl-4-bromobenzoate, and the detection limit for brodifacoum is approximately 0.06 μg/g. This method is not specific for brodifacoum, however. For example, bromadiolone will also give a positive response in this detection scheme. Steffenrud et al. briefly touch on the analysis of brodifacoum in a paper concerned with mobile phase modification to enhance sensitivity in filament-on negative ion thermospray LC/MS. They demonstrated the detection of 50 ng of brodifacoum by flow injection using triethylammonium formate buffer. We have now expanded upon this work to develop a thermospray LC/MS method for the detection of brodifacoum from commercial rodenticides in samples from consumer product tampering cases.

The liquid chromatographic solvent delivery system consisted of a Hewlett-Packard 1090 liquid chromatograph and a Hewlett-Packard 1050 pump for post-column addition of buffer to the mobile phase. Separations were carried out on a Supelco Supelcosil LC-18 5μm, 250 mm x 2.1 mm ID column. The mobile phase consisted of 20/80 water/acetonitrile at a flow rate of 0.2 ml/min; 50 mM triethylammonium formate buffer was added post-column at a flow rate of 0.8 ml/min. Mass spectra were acquired on a Hewlett-Packard 5989A mass spectrometer using the Hewlett-Packard thermospray probe and ion source. The chromatographic conditions were optimized first on a Hewlett-Packard 1050 HPLC system.

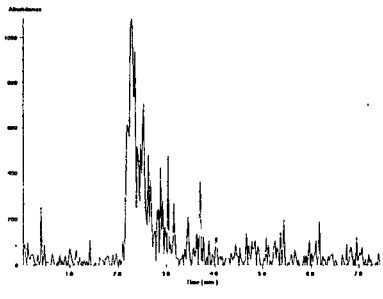

Figure 1. Total ion chromatogram of brodifacoum standard.

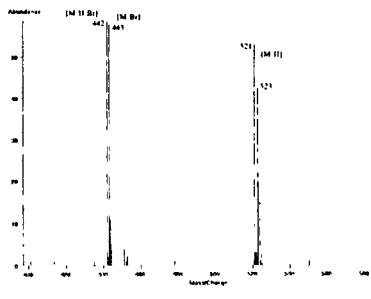

Figure 2. Mass spectrum of brodifacoum standard.

Adulterant was isolated from oatmeal by shaking through a sieve. Samples were prepared by extracting 202 mg of D-Con Mouse Prufe II bait or bait isolated from contaminated oatmeal with 2.0 ml of methylene chloride saturated with formic acid for 2.5 hours (30 minutes of sonication and 2 hours of shaking). The methylene chloride layer was then taken to dryness with a stream of nitrogen, and the residue was dissolved in 200 μL of mobile phase. The injection volume was 10 μL for all samples except the oatmeal extract, which was 20μL. A 24 ppm brodifacoum standard was also run. Extraction recoveries were at least 90% based on UV-VIS data.

The total ion chromatogram of brodifacoum standard is shown in Figure 1. The cis and trans isomers are observed as a single tailing peak approximately 1.7 min. wide at the baseline. The mass spectrum obtained by averaging across the entire peak is shown in Figure 2. The $[M-H]^-$ ion cluster due to the presence of bromine is at m/z 521 and m/z 523. The ion at m/z 442 corresponds to loss of bromine from the ions at m/z 521 and m/z 523. The ion at m/z 443 corresponds to loss of bromine from the brodifacoum molecule to form the $[M-Br]^-$ ion.

The total ion chromatogram of bait extract obtained from adulterated oatmeal is shown in Figure 3. The cis and trans isomers are baseline resolved, and elute at much longer retention times than the standard. The averaged mass spectrum for the cis isomer at retention time 10.5 min. is shown in Figure 4. The mass spectrum for the trans isomer is similar, and both are also similar to the mass spectrum for brodifacoum standard, except for the reduced abundances of the ions at m/z 442 and m/z 443. This reduced abundance may be a matrix effect on the ionization process of brodifacoum, and could be related to the matrix effect observed on the isomer retention times.

Negative ion thermospray LC/MS is an effective technique for the determination of brodifacoum in oatmeal. A full scan mass spectrum can be easily obtained for approximately 50 ng of brodifacoum injected on column. This method could be successfully applied to the determination of brodifacoum in many other matrices.

The Identification of Low Level Impurities and Decomposition Products in Albuterol Sulfate by On-Line Linked Scanning Thermospray LCMS

Roger Dinallo, Walter Davidson, Keith McKellop, Gordon Hansen, Juergen Nagel, Arvind Shah, and Hal Butler
Boehringer Ingelheim Pharmaceuticals Inc., R&D Center, Ridgefield, CT 06877

INTRODUCTION

The regulatory requirement for the identification and batch to batch control of low level impurities which may be present in active ingredients has become a critical issue in pharmaceutical development. Methods which have been generally employed for the elucidation of these impurities consist of collection of individual LC fractions followed by off-line spectroscopic analysis. This approach is clearly time consuming, and is generally only successful with compounds which have a simple impurity profile.

We have developed and previously reported, modifications to our Kratos MS25 which enable us to obtain accurate mass measurements and MS/MS linked scan data with on-line Thermospray LCMS[1].

We wish to report the identification by thermospray LCMS and LC MS/MS of impurities present in a batch of Albuterol sulfate which were present at approximately the 0.1% level.

STRATEGY

1. Obtain molecular weights corresponding to peaks of interest from low resolution LC/MS experiment
2. Obtain linked scans at constant B/E and B^2/E for Albuterol (parent compound) and related standards.
3. Assign fragmentation pathway for parent compound and verify with available standards.
4. Obtain linked scans for unknown by on-line LC MS/MS.
5. Assign unknown structures

EXPERIMENTAL

Kratos MS25RFAQ with Thermospray LCMS interface

HPLC conditions: Supelco 5um LC8-DB, 15 cm x 4.6 mm i.d., Mobile Phase: 90:10 0.1M Ammonium Acetate / Acetonitrile, Flow Rate: 1.0 ml/min, Wavelength: 280 nm. **LC/MS conditions:** Source Temp: 210, Vaporizer Temp:223, Block Temp:217. **MS resolution:** 600, Start mass 600, Scan Rate: 3 sec/dec, Scan Time: 2.3 sec. **Linked Scans at constant B/E, B^2/E:** start mass: 400, scan rate: 10 sec/dec. **Data Collection:** Raw Data Acquisition

DISCUSSION

Low Resolution LC/MS

The low resolution Thermospray LCMS data provided molecular weight information, but little structural detail. Nevertheless, the data suggests that the molecular weights observed for six of the contaminants may be closely related homologs and synthetic intermediates of Albuterol. The molecular weights are as follows: Albuterol - mw 239, peak #1 - mw 253, peak #2 - mw 281, peak #3 - mw 223, peak#4 - mw 237, peak #5 - mw 253, peak #6 - mw 327, peak #7 - mw 460. The molecular weights and retention times of peaks 6 and 7 are consistent with previously identified synthetic by-products (benzyl ketone and albuterol dimer, respectively, fig. 2)

Albuterol MS/MS

Linked scans at constant B/E and B2/E were obtained for Albuterol. The ions observed are consistent with the fragmentation pathway illustrated in figure 1.

MS/MS - Albuterol Homolog Standards

B/E and B^2/E spectra were obtained for Albuterol ketone and aldehyde standards. This data con-

firmed the fragmentation pathway proposed for albuterol in fig. 1 and indicates that related homologs can be differentiated by the following diagnostic fragments in the MS/MS spectra:

1. The loss of water directly from the molecular ion only occurs when hydroxyl "**A**" is present.
2. The loss of water which is observed after the t-butyl cleavage only occurs when hydroxyl "**B**" is present.
3. The α-cleavage fragment "**C**" indicates which portion of molecule has been modified

Elucidation of Impurities

The proposed structures shown in fig.2 were determined by the MS/MS spectra obtained from the on-line LCMS experiments. These spectra were interpreted using the fragmentation mechanisms observed for Albuterol and related standards outlined in fig. 1.

The structures proposed for peaks 2, 3, and 4 are consistent with either previously identified synthetic precursors or impurities. The structure proposed for peak 5 is supported by the loss of methanol from the molecular ion - analogous to the first loss of water from albuterol. The structure proposed for peak 1 is supported by a 14 amu shift in the cleavage product, with no modification to either hydroxyl group. Several possibilities exist for this structure, the one proposed is most consistent with likely contaminants. No MS/MS data was obtained for peaks 6 and 7. The observed molecular weights and LC retention times however, are consistent with previouly identified impurities.

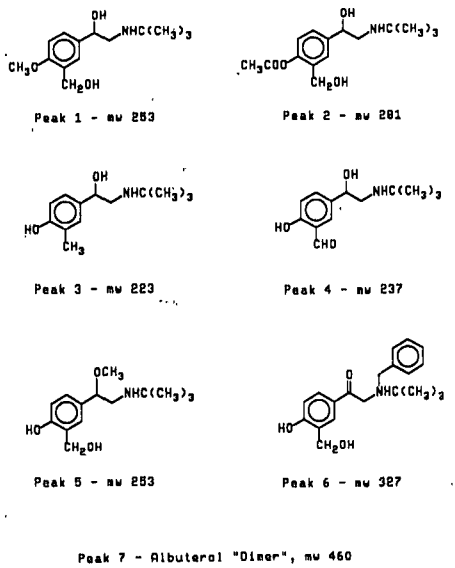

FIG. 2.

IDENTIFICATION AND CONFIRMATION OF A SOIL METABOLITE OF BIS(TRICHLOROMETHYL)SULFONE BY HPLC/THERMOSPRAY MS

Benjamin Y. Giang

ICI Americas, Inc., Western Research Center, 1200 South 47th Street, Richmond, CA 94804-0023

HPLC/UV/Radioactivity monitor (RAM) analysis of extracts of soil samples that were treated with bis(trichloromethyl)sulfone (N-1386 biocide) detected the presence of two unknown peaks. The earlier unknown eluted one minute prior to the N-1386 peak and the second eluted about seven minutes after the N-1386 peak. The HPLC used was a Perkin-Elmer Model Series 410 LC Pump equipped with Rheodyne Model 7125 injector and Perkin-Elmer Model 95 UV/Visible detector. The column used was a Perkin-Elmer 3 cm x 4.5 mm stainless steel column packed with 3 µm ODS. The mobile phase used was a mixture of acetonitrile/water (85/15 v/v) flowing at a rate of 0.8 mL/min. The RAM used was a Radiomatic Flo-one-beta Model IC radioactivity flow detector.

Positive-ion (PI) EI and $(CH_4)CI$ mass spectra of N-1386 exhibit no molecular ion. The EI spectrum resembles that of hexachloroethane suggesting the ejection of SO_2 from the molecule. Such behavior makes it impossible to use PI mass spectrometry for the positive identification of this compound. Negative-ion (NI) CI spectrum of N-1386 retains the SO_2 functional group. Therefore HPLC/thermospray (TSP)-MS operated in the NI mode was used for the identification of the unknowns.

HPLC/NI-TSP-MS detected the same two components which appeared in the HPLC/UV/RAM chromatograms of the soil extracts. The resultant mass spectra are listed below:

Peak #1

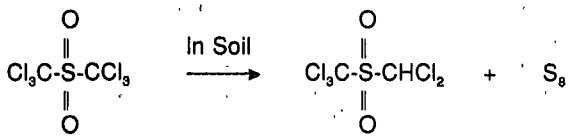
m/z	INTENSITIES	INTERPRETATION	IDENTIFICATION
147	100	$Cl_2CH\text{-}SO_2^-$	
149	70	(P+2) for 147	
151	10	(P+4) for 147	
181	8	$Cl_3C\text{-}SO_2^-$	
183	10	(P+2) for 181	
264	0	M^-	$Cl_2CH\text{-}SO_2\text{-}CCl_3$ Pentachloro-dimethylsulfone

Peak #2

m/z	INTENSITIES	INTERPRETATION	IDENTIFICATION
128	100	$S_4^{\cdot}$	
130	10	(P+2) for 128	
256	0	$M^{\cdot}$	S_8

When the same sample was analyzed by GC/PI-EIMS, the resultant mass spectrum of the second component showed that it was elemental sulfur.

After Peak #1 was tentatively identified to be pentachlorodimethylsulfone a standard of this compound was prepared by the hydrolysis of N-1386 in 2.5% aqueous NaOH solution. The chemical structure of this standard was confirmed by mass spectrometry, proton NMR, and carbon-13 NMR. This standard was used to confirmed the identity of Peak #1 by comparing their mass spectra, HPLC retention time, GC retention time, and other pertinent data. The results showed that the unknown was indeed pentachlorodimethylsulfone.

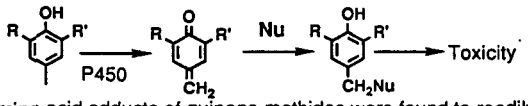


THERMOSPRAY LC/MS CHARACTERIZATION OF PROTEIN ADDUCTS WITH QUINONE METHIDES

*Shern B. Turnipseed, Judy L. Bolton, John A. Thompson, Division of Pharmaceutical Sciences, University of Colorado, Boulder, CO, 80309-0297

INTRODUCTION

Alkyl phenols can be metabolized by cytochrome P450 and peroxidases to quinone methides by two successive 1-electron oxidations[1]. Quinone methides are electrophilic species which can bind covalently to nucleic acids and proteins, causing cytotoxicity and genotoxicty.



The amino acid adducts of quinone methides were found to readily fragment under thermospray-mass spectrometry (TSP-MS) conditions to yield only two major ions corresponding to the benzyl and amino acid halves of the conjugate. The excellent qualitative information provided by these spectra suggested that thermospray LC/MS could be a useful technique to detect and identify adducts formed in biological systems.

METHODS

Preparation of Adducts: Quinone methides were prepared from the corresponding phenols via oxidation by lead dioxide or silver oxide. Modified amino acids were synthesized by allowing an acetonitrile solution of quinone methide to react with a solution of amino acid at pH 7.4 for 2 hr at 25 °C. Hemoglobin was covalently modified by treating a solution of the protein with an excess of quinone methide at 25 °C for 1 hr. The heme was removed from the adducted protein by precipitating the apoprotein with 1% HCl in acetone. The globin was denatured, and the solubilized protein was hydrolyzed by two 12-hr incubations with Pronase E (Protein:protease = 10:1)[2] at 37 °C. The hydrolysates were then filtered, extracted with ether and analyzed by TSP LC/MS.

TSP LC/MS Conditions: Thermospray data was obtained using a HP5988A MS with thermospray interface and HP1090 LC system. The thermospray source was operated in the filament-on mode at 350 °C. HPLC separation was performed using a 15-cm Beckman C18 column and the following solvent conditions: 30% methanol-70% 0.1M ammonium acetate buffer (pH 4) for 5 min, increased to 90% methanol over 40 min. The mass spectrometer was either scanned from m/z 140-400 or the major fragment ions were measured by SIM.

RESULTS AND DISCUSSION

TSP mass spectra of amino acids adducts are (in general) characterized by abundant fragment ions corresponding to the protonated amino acid (AAH^+) and benzyl (Bz^+) cations; weak MH^+ ions are also observed. Figure 1 shows the TSP mass spectra of two amino acid conjugates of 2-*tert*-butyl-4,6-dimethylphenol (BDMP). The TSP spectra of modified peptides indicate that these species also produce the diagnostic Bz^+ ion; other ions correspond to fragments from the peptide portion of the conjugate. Hemoglobin was treated with quinone methides, subjected to enzymatic hydrolysis, and the modified amino acid residues were identified by thermospray LC/MS. Ion chromatograms of the benzyl cation were used to selectively detect modified residues in the protein hydrolysate. Confirmation of each amino acid adduct was conducted by selected ion chromatograms for the protonated amino acid and molecular ion of the modified residue. Figure 2 shows selected ion chromatograms for BDMP-Lysine in the hydrolysate of BDMP modified hemoglobin. Other amino acid residues of hemoglobin which were modified by BDMP-QM are histidine, cystine and tyrosine. Reaction of hemoglobin with BHT-QM, the quinone methide derived from the more sterically hindered 2,6-di-*tert*-butyl-4-methylphenol, forms these adducts to a lesser extent than BDMP-QM, which is expected from their relative rates of reaction with the individual amino acids.

DIRECT MIXTURE ANALYSIS BY THERMOSPRAY MASS SPECTROMETRY: CHARACTERIZATION OF COMMERCIAL JUICE DRINKS BY FACTOR ANALYSIS OF THERMOSPRAY MASS SPECTRA.

John P. Toth
Institute of Food and Agricultural Science
University of Florida, Gainesville, FL 32611

Natural and processed foods are complex mixtures whose complete chemical characterization often requires extensive sample pretreatment and high resolution chromatography prior to spectral analysis. For many purposes, however, (for example determination of age, geographic origin or the presence of adulteration) it is sufficient to obtain spectra that are characteristic of an entire mixture without identifying individual chemical constitutents. Thermospray mass spectrometry appears to be a very useful technique for such fingerprinting purposes: it is compatible with water-soluble samples and provides relatively simple spectra dominated by pseudo-molecular ions. We are therefore investigating the potential of this approach using commercial juice drinks both as model analytes and as samples of immediate practical interest.

Five commercial juice samples were introduced to a Vestec model 201 thermospray mass spectrometer, without pretreatment or chromatographic separation, via a 100-uL sample injector. Each mixture was injected in triplicate, and mass spectra were averaged over the entire elution envelope. The averaged spectra, shown in Fig. 1, are complex, with ions at virtually every m/z value in the range 100 - 400. The spectra are also similar to one another, with the most prominent feature in each being the series m/z 198, 180, 162, ..., representing ammonium adducts of hexose monosaccharides and successive losses of H_2O. A much less abundant series at m/z 360, 342, ..., represents analogous disaccharide ions. These major features resemble the thermospray spectrum of sucrose shown in Fig. 1. The discriminating power of these spectra lies in subtle differences in intensity ratios rather than in the presence or absence of characteristic ions, necessitating the use of multivariate data analysis.

Multivariate data reduction techniques such as factor analysis are often used to discern subtle differences among complex spectra such as those encountered in pyrolysis mass spectrometry. Accordingly, the five juice spectra have been subjected to factor analysis using the ISMA multivariate analysis and graphic program developed by Windig, et al[1]. Each juice sample was run in triplicate, producing fifteen thermospray sepctra from which were calculated fifteen factors F1, F2, ..., F15. As is typical in factor analysis, the bulk of the information resides in the first few factors, with the remaining factors representing the noise in the data. For these data, only F1 - F3 appear to be significant.

Under the computational conditions used here, F1 represents the mean of the fifteen spectra and therefore reflects the common mono- and disaccharide components, which are not of interest in this study. As seen in Fig. 2, F2 discriminates among juice types, with negative values for grape-based juices and positive values for others;

F3 discriminates between pure juices (negative values) and juices diluted with water and corn syrup (positive values). In this way the subtle differences among the five juice spectra result in a clear delineation of four different categories in F2-F3 space. Clustering of thermospray data in a two-dimensional factor space can thus be used to characterize unknown samples using data acquired with no chromatography and little or no sample preparation.

QUANTITATIVE ANALYSIS OF AMIPRILOSE IN HUMAN PLASMA BY FLOW INJECTION ANALYSIS USING THERMOSPRAY MS AND SELECTED REACTION MONITORING

C. ROCHA, P. HAROLDSEN, AND I.J. MASSEY
SYNTEX RESEARCH, PALO ALTO, CA, 94304

Amiprilose hydrochloride is a C-3 substituted hexose sugar that is currently under investigation for treatment of rheumatoid arthritis. To support PK and bioequivalence studies a sensitive and specific method for the quantification of amiprilose in plasma is required. Existing methodology for the quantification of amiprilose in plasma relies upon fluorescence detection following a laborious derivitization or time-consuming and problematic electrochemical detection (1). Because the existing methodology did not meet our requirement for rapid sample analysis, a new method for the quantification of amiprilose was developed.

Amiprilose and an internal standard (D6-Amiprilose;labeled at the methyl groups of the isopropylidene ring) are extracted from basified plasma into ethyl acetate. The organic extract is evaporated to dryness and the residue is dissolved in 200 ul of 100mM ammonium acetate (pH 6.8). A 20 ul aliquot of the final extract is injected into a reverse phase C-2 column (15 mm x 3.2 mm, 7 micron) and eluted with a mobile phase consisting of 5/95 acetonitrile/100mM ammonium acetate at a flow rate of 1 ml/minute. The HPLC effluent is introduced into a Finnigan TSQ 70 mass spectrometer via a thermospray interface. Ionization is achieved by means of the thermospray process. Quantification of amprilose is accomplished by selected reaction monitoring (SRM). The C.I.D. transitions monitored (0.5 sec/scan) are m/z: 306 -> 104 for amiprilose (Figure 1) and m/z: 312 -> 104 for the internal standard. Figures 2 and 3 show the TSP/MS/MS chromatograms obtained from the analysis of extracts from plasma spiked with 0.5 - 40 mcg of amiprilose and 4 mcg of the internal standard.

Linear calibration curves are obtained in the range of 0.50 - 40 mcg of amiprilose per aliquot of plasma using 1 ml of plasma for analysis (Figure 4). The intra-assay (intra-day) variability of this method is $\leq$ 6.1% at all concentrations. The %recovery of amiprilose (found/added) ranges from 98 - 104%.

This method was utilized for the analysis of >1000 plasma samples collected during a bioequivalence study. The PK data from this study are presented in Figure 5. Control samples, prepared by spiking a known concentration of amiprilose into plasma collected from untreated humans, were analyzed along with the study samples to determine the inter-assay variability of the method. The data from the analysis of the control samples (Figure 6) demonstrate that the method is reproducible as measured by the coefficient of variability (%CV).

In conclusion, the TSP-MS/MS collision induced dissociation spectra of amiprilose (20ev collision energy, 0.9 mtorr argon) produces an intense product ion which provides the basis for the establishment of a simple and sensitive approach to quantitative analysis of amiprilose by MS/MS. Minimal sample preparation is required prior to analysis. Analysis is rapid (1 min/injection), accurate (injection to injection variability = 5%), and reproducible (intra- and inter-assay variability $\leq$ 10.6% at all concentrations). The method provides an increase in sample throughput of 30x over that of existing methods.

The Use of a Fluorinated Ion Pairing Agent in the Analysis of Catecholamines by Thermospray LC/MS

*Alexander B. Schilling, The Hewlett-Packard Company, Naperville, IL. 60566

Introduction:

Catecholamines are a group of neurotransmitters of interest to workers in biology and medicine. The liquid chromatographic analysis of catecholamines normally employs an ion pairing agent such as octane sulfonic acid to improve the retention and separation of these polar compounds on reverse phase columns. Thermospray (TS) LC/MS has been succesfully applied to the analysis of catecholamines. Using octane sulfonic acid (usually as the sodium salt) can result in clogging or fouling of the vaporizer in the thermospray probe. The use of volatile organic salts as electrolytes in place of nonvolatile inorganic salts has been a requirement in thermospray to avoid clogging the probe. In an analogy to this practice a search was conducted to find an organic ion pairing agent that would maintain good chromatography and avoid system degradation during normal thermospray operation.

Experimental Method:

A mixture of catecholamines including dopamine, epinephrine, norepinephrine and several metabolites were run on a HP 5989A LC/MS/DS with a thermospray source using a 1090L HPLC with a diode array detector (280 nm). Scan data were acquired in positive ion mode from 100-300 amu or in SIM with a source temperature of 250 C, a fragmentor voltage of 170 V and the filament on. A Supelco LC-18-DB column (4.6 x 250 mm, 5u particle) and an isocratic solvent system was used consisting of 77:23 (0.1 M NH4Ac pH 4.0 with 0.0003M pentadecafluorooctanoic acid:0.1 M NH4Ac in methanol with 0.05 % formic acid and 0.0003 M pentadecafluorooctanoic acid). A flow rate of 1.0 mL/min was maintained as well as a column temperature of 40 C. The thermospray vaporizer was set to 108 C. The injection volume was 3 uL.

Results and Discussion:

Pentadecafluorooctanoic acid was found to be a good replacement for the sulfonic acid normally employed in the chromatography of catecholamines. Usually these compounds are chromatographed using a solvent system containing a higher proportion of aqueous mobile phase (90:10). An isocratic system using a 77:23 ratio was used to improve the sensitivity for these compounds with the thermospray interface. Even with the higher organic component the retention times for the catecholamines using this novel ion pairing agent were still sufficient for adequate chromatographic resolution. Sensitivity for these compounds in SIM was found to be on the order of a picomole for each of the neurotransmitters although some of the metabolites and internal standards were somewhat less sensitive. No degradation of the probe or source conditions was observed during extensive use. Due to the potentially corrosive nature of this ion pairing agent, proper venting of exhaust gasses from the thermospray pumping system is essential.

DEVELOPMENT OF GRADIENT ELECTROCHROMATOGRAPHY / ESI / MASS SPECTROMETRY

František Pehal, Carol E. Parker and Kenneth B. Tomer
Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O.Box 12233, Research Triangle Park, N.C. 27709

Electro-chromatography is a chromatographic separation method using an electrically driven flow (1-3). In pseudo-electrochromatography (PEC) an electrical potential of 10 - 40 kV is applied across a packed column concurrent with mobile phase delivery as in conventional HPLC. Thus PEC combines both electrical and pressure driven flows (4-6). The high pressure mobile phase is delivered by conventional HPLC pumps at typical pressures of 500 to 2000 PSI. In PEC there are two new factors - electroosmotic flow and electrophoretic mobility - that do not exist in common liquid chromatography. We have investigated PEC using four different chemical mixtures - sulfonamides, brevetoxins, oligosaccharides (ABEE derivatives) and peptides. For the comparison each group of substances was run with the same analytical conditions twice - with high voltage on (PEC) and without high voltage (HPLC). A conventional (Gilson-302) HPLC gradient solvent delivery system was used for solvent delivery. The mobile phase flow from the pump was split prior to the microinjector using a fused silica restrictor going to waste. The proportion of mobile phase flow going to waste is controlled by a microregulator The nanoscale column used in these experiments consists of a 120 cm long by 75 μm i.d. fused silica column. The column is packed to a depth of 40 cm with Hypersil 8. A short, 0.2-0.5 mm, length of fused silica tubing, drawn out to a fine tip, is used as a frit. The restrictor (fused silica tube 17 μm i.d. x 25 cm) serves as a high voltage insulator between the microinjector and the analytical column. The connection between the restrictor and the column was made by means of a modified stainless steel zero dead volume fitting (Supelco) which also serves as the high voltage electrical contact. This part of the system was placed in a plexiglass box fitted with safety interlocks (identical as that used for our CZE/MS interface). This separations technique has been coupled with MS using electrospray ionization.(7)

MASS SPECTROMETER

The mass spectrometer used is a VG 12-250 quadropole mass spectrometer that has been fitted with a Vestec 611B Electrospray source and controller. A modified Vestec ESI probe, identical to that used for CZE/ESI/MS or nCLC/ESI/MS experiments, is used for interfacing the PEC column with the mass spectrometer. The column is inserted into the sheath flow column of the ESI probe. The end of the analytical column is at the ESI needle, which acts as ground for the PEC column (3 Kv).

For UV-detection a 50 μm i.d. fused silica capillary tube with a window, prepared by removing a small section of the polyimide coating from the fused silica capillary, was connected to the outlet end of a analytical column. The end of this transfer line was placed into a grounded buffer solution. All data in this paper was obtained by selected ion monitoring.

The examples shown here demonstrate the feasibility of the coupling of Pseudo-electrochromatography/ESI/MS system (PEC/ESI/MS). Good separations are observed. Separations can be different from those obtainable by NCLC or CZE alone and generally more rapid than by NCLC alone. Our PEC system is simple and can be used either as nCLC (without high voltage) or Electrochromatography system (without pressure, not demonstrated). The columns are quite easy to pack. PEC might be another way to solve problems in LC and CZE techniques. Future plans involve incorporation of Ph gradients in the system.

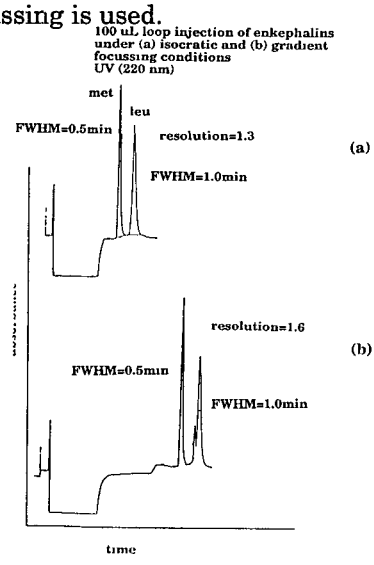
Parameters Affecting Resolution in Capillary Liquid Chromatography (LC) with Ultraviolet and Mass Spectrometric (MS) Detection

*W. Bart Emary, Mary Pat Knadler, Marion Merrell Dow Inc., Indianapolis, IN 46268-0470

Dilute samples in the concentration range from 10^{-9}M to 10^{-8}M often are analyzed for quantitative trace analysis or metabolite ID work. These concentrations are not practical in capillary LC because small injector volume and short on-column path lengths are normally used. Two approaches were used to increase the detectability of analyte. The first examined large loop sizes. Sensitivity is enhanced for both UV and MS detection. The second approach studied the use of a relatively long path length, UV detector cell of 1 μL volume, 5 mm path length.

Since conventional loop sizes range from 5 to 100 μL and are relatively large compared to the capillary LC peak volume, resolution will be poorer as peak widths increase. We have been investigating the use of large volume injections and have attempted to minimize dispersion as the loop was emptying onto the head of the column using low organic strength. The elutropic strength was then increased and separation occurs. We call this "gradient focussing" and compared it to isocratic elution. Figure 1 shows a 100 μL injection of enkephalins onto a 320 μm ID C_{18} column. The resolution under isocratic conditions is 1.3 and is 25% larger when gradient focussing is used.

Figure 1



To improve UV sensitivity at trace levels, we compared a microbore (1μL) cell with long path length (5 mm) to on-column detection. The CV[4] detector allows the same instrument (i.e. lamp, light detection device) to be used for the comparison. Only the cell is changed for experiments. In Figure 2, the top UV trace shows the on-column cell and the bottom the microbore cell. As expected, resolution is less for the 1 μL z-cell, 80% of on-column detection. The sensitivity is improved by ca. 59x for the microbore cell compared to on-column.

Micromixers have been evaluated for mixing efficiency at 20-50 μL/min flow rate. The performance of the mixers is shown in Figure 3. The system mixing volume is the time required for the response to equal 2/3 of its final value. The system response with the Lee mixer was found to be 7μL and was twice that for the Upchurch mixer.

ANALYSIS OF CORTISOL METABOLITES BY LC-CRIMS

Yohannes Teffera and Fred P. Abramson, George Washington University School of Medicine, Department of Pharmacology, Washington, DC 20037, Matt McLean and Marvin Vestal, Vestec Corp, Houston, TX 77054, Domenick Vicchio and Alfred L. Yergey, NICHHD, NIH, Betheseda, MD 20892.

INTRODUCTION: Corticosteroids are biologically active compounds that influence various aspects of human physiology. Endogenous cortisol is one of these group of compounds that has received great attention. Current LCMS methods used to investigate aspects of cortisol metabolism lack the selectivity necessary to perform experiments regarding diurnal variations in cortisol metabolism. This report describes the results of our work in developing a selective method that can be used for the analysis of cortisol metabolites in urine.

EXPERIMENTAL: A 10 mL aliquot of 24 hr urine from patients infused with d_3-cortisol at a rate of 16-32 μg/hr[1] was hydrolyzed using β-glucuronidase, and fractionated using a C-18 SEPPAK cartridge. The methanol fraction was subjected to a reversed phase HPLC analysis using a C-18, 150 X 4.6 mm column (Alltech Associates). The solvent system used water with 0.05% trifluoroacetic acid (TFA) (A) and 10% acetonitrile in methanol with 0.05% TFA (B). A Vestec Universal Interface[2] (Vestec Corporation, Houston,TX) was used to couple the LC to a Dupont 21-492 mass spectrometer. For chemical reaction interface mass spectrometry (CRIMS) hydrogen was the reactant gas. The mass at 3.0219 corresponding to the reaction product HD was used for single ion monitoring. A resolution of 2000 separated the HD signal from the adjacent H_3 signal.

RESULTS AND DISCUSSION: Cortisol is metabolized into several metabolites which are excreted mainly as sulfate and glucuronide conjugates. To measure the diurnal variation in cortisol metabolism, it is essential to separate them all. It is also desirable to avoid the hydrolytic step if the detection method is adequately responsive to the conjugates. The mass spectrometric detection of the conjugates has been difficult mainly due to difficulty in ionization. However, since in CRIMS the compounds are converted to small molecules prior to introduction into the mass spectrometer, the detection of intact conjugates is not expected to present difficulty. We used a reversed phase HPLC method that increased retention times of the conjugates and also separated all the major cortisol metabolites. When analyzed by regular LCMS with the Universal Interface, less than a microgram of standards gave adequate mass spectrometric responses indicating that LCMS can be used to detect cortisol metabolites in urine.

The TIC of a sample isolated from hydrolyzed urine from a patient receiving deuterated cortisol showed the presence of a number of compounds unrelated to cortisol. However, the retention times and mass spectra of a few of the peaks in the LCMS chromatogram corresponded to those of cortisol metabolites. The mass spectra of the two largest peaks corresponding to the retention times of THF and THE are shown in Figure 1. The spectra show intense signals for molecular ions of THE at m/z 364 and THF at m/z 366. In addition, the fragmentation patterns were consistent with the structures of the metabolites and were similar to the results obtained from regular EIMS. It should be noted that the molecular ion abundance in these experiments was by far superior to that obtained by regular EIMS which is characterized by facile dehydration of these molecular species. The use of the Universal Interface in these experiments appears to reduce this dehydration process. In spite of these excellent results for a few of the metabolites, other peaks corresponding to cortisol metabolites were either not found or were found co-eluting with impurities. Furthermore, attempts to selectively plot the deuterated cortisol metabolites at M+3 also failed.

The results obtained with the regular LCMS experiments indicate that a more selective method is needed for the analysis of cortisol metabolites. One such method is CRIMS which is routinely used in our laboratory in conjunction with GCMS[3]. Our next step, therefore, was to utilize CRIMS to increase selectivity. In hydrogen-scavenged CRIMS experiments the label is detected as HD. Such detection is extremely selective due to the low natural abundance of deuterium. Several preliminary experiments were performed to optimize LC-CRIMS. Figure 2 shows the LC-CRIMS HD chromatogram of a mixture of d_2-tyrosine and d_3-cortisol. A very good signal-to-noise ratio is obtained with a detection limit of 2 to 2.5 ng. The ultimate test was if CRIMS could be use to detect cortisol

metabolites in urine. When a sample isolated from an aliquot of 24 hr urine from a patient receiving deuterated cortisol was analyzed by LC-CRIMS, the deuterium selective chromatogram showed three peaks which were identified based on their retention times as cortisol, THF and THE.

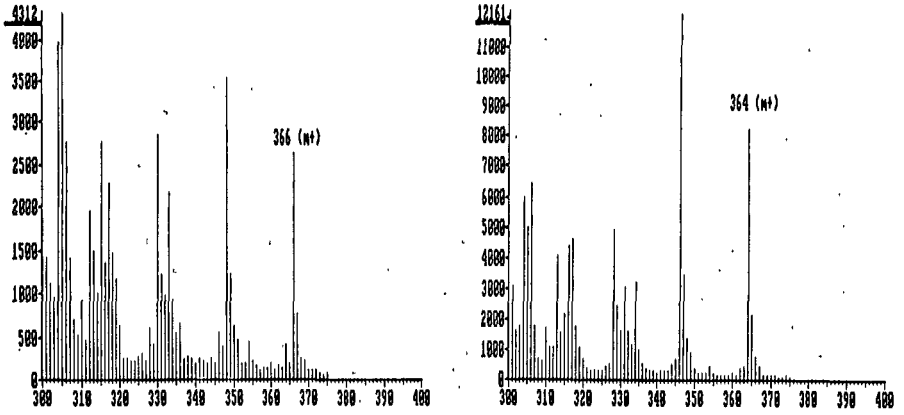

Figure 1. Mass spectra of THF (Left) and THE (Right) from LCMS analysis of urine.

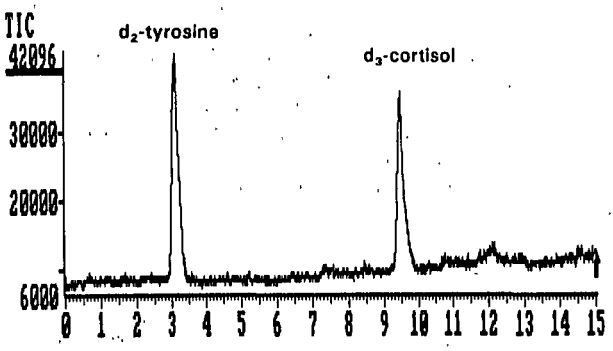

Figure 2. LC-CRIMS HD chromatogram of d_2-tyrosine (90 ng) and d_3-cortisol (60 ng).

CONCLUSION: We have developed a deuterium-selective method for HPLC detection using CRIMS as an interface. Preliminary experiments show that this selective method can be used to study metabolism in biological systems. Further optimization of a wide range of experimental details will be made to provide enhanced sensitivity that will be needed to quantify less abundant products of cortisol metabolism.

EFFECT OF RESTRICTOR HEATER AND ION SOURCE TEMPERATURES ON CHEMICAL IONIZATION MASS SPECTRA OF MATERIALS FOLLOWING SUPERCRITICAL FLUID CHROMATOGRAPHY

Henry T. Kalinoski * and Leonard O. Hargiss
Unilever Research U.S. 45 River Road Edgewater, NJ 07020

One advantage claimed for capillary supercritical fluid chromatography (SFC) is the potential to analyze materials of insufficient volatility for analysis using gas chromatography (GC). This would be useful in the analysis of mixtures of higher molecular weight compounds (generally above 1,000 Daltons) or compounds possessing numerous functional groups, such as carboxylic acids or hydroxyl groups. To permit full utility of the technique, the facility to analyze these types of materials should extend to SFC interfaced with mass spectrometry (SFC/MS). One approach that has been successful is to derivatize materials, as is done to allow GC and GC/MS analyses. Derivatization is not always practical or completely desirable in the analysis of unknown mixtures.

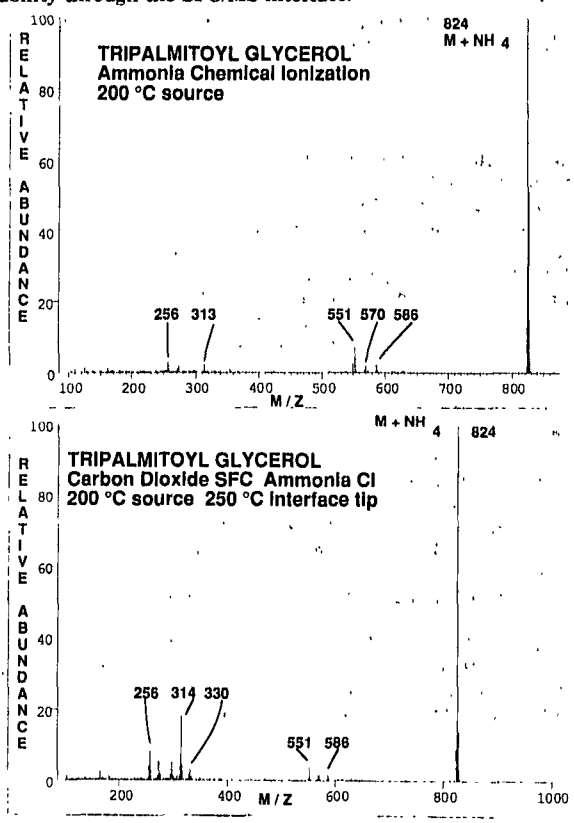
Ideally, conditions developed for SFC with detectors such as flame ionization (FID) should be directly transferrable to SFC/MS. The interface of SFC to such gas-phase detectors relies on the use of a flow (pressure) restriction device, such as a pinhole orifice, frit, taper or length of narrow-bore tubing, to maintain fluid conditions to the point of detection. Rapid expansion of the high pressure mobile phase results in substantial cooling of the fluid and materials directly contacting the fluid. This can result in loss of analyte to condensation and restrictor plugging. This cooling is generally overcome by maintaining the restrictor in a heated region inside the detector (in an FID) or using an auxiliary heater in an SFC/MS interface.

Unfortunately, the conditions developed for SFC/FID do not always transfer directly to SFC/MS, possibly due to the larger pressure difference (therefore, greater cooling on expansion) in SFC/MS or to the inefficient heat transfer obtained in SFC/MS interface heaters. Conditions yielding high resolution separations and low detection limits in SFC/FID often yield little to no mass spectral information or result in restrictor plugging in SFC/MS. This is particularly true for SFC/MS analyses of the higher molecular weight, low volatility and more polar analytes.

In an effort to understand the variables influencing the SFC/MS interface and their effects on the resulting chemical ionization (CI) mass spectra, a series of compounds were analyzed using both direct chemical ionization (DCI) and SFC/CI/MS under a variety of interface heater and ion source temperatures. One thought was to operate both the interface and ion source at the highest possible temperatures to compensate for inefficient heat transfer and avoid sample condensation on the ion source. DCI was used to ensure that useful mass spectra, i.e., high relative abundance molecular species and limited fragment ion production, could be produced over the range of ion source temperatures to be used for SFC/MS. The DCI experiments were conducted with the SFC operating at the conditions to be used for SFC/MS, so that the amount of carbon dioxide in the ion source would be equivalent in both cases. For the compounds studied, ammonia positive ion chemical ionization gave the greatest abundance of parent species, $(M + NH_4)^+$. Only one type of flow restrictor, the frit type, was used and its position was not changed through the course of these experiments. No information on the role of restrictor type or position within the heated region was obtained.

Both ion source and interface heater temperatures affect the mass spectra produced following capillary SFC. The effects of ion source temperature are minimal, with lower ion source temperatures generally producing greater relative abundance of molecular species, but increasing the residence time of analyte species in the ion source. This results in "tailing" of chromatographic peaks and an apparent decrease in chromatographic resolution. Optimum ion source temperatures for DCI were not necessarily optimum for SFC/MS analyses. Chemical ionization mass spectra produced following SFC are generally different than those produced using DCI, even when ion source conditions for the two techniques are nominally equivalent. CO_2 is not responsible, as a high ion source concentration of CO_2 did not increase fragmentation in DCI. Differences found, lower abundance of parent species, greater fragmentation and different fragment ions, must be due to the influence of the interface heater. Higher interface heater temperatures resulted in an increase in fragment ion production, in some cases to the point of not producing a molecular species. Simply raising ion source and interface tip temperatures does not ensure production of usable SFC/MS spectra.

Further work suggested by the present study includes an evaluation of other restrictor types and of restrictor position in the heated region, modifications to increase heat transfer in the interface tip and the role of mobile phase modifiers in maintaining analyte solubility through the SFC/MS interface.



Chemical Ionization With a Particle Beam LC/MS Interface on an Ion Trap Mass Spectrometer

Donald M. Eades, Brent L. Kleintop, Richard A. Yost,
Department of Chemistry, University of Florida, Gainesville, FL 32611

INTRODUCTION

Our lab has coupled a Finnigan prototype 3-stage PB interface directly to an ion trap mass spectrometer (ITMS), in a manner similar to that previously reported by Bier et al. [1]. The ability of the ITMS to acquire EI and CI data in alternating scans makes CI with the PB/ITMS system an attractive complement to the EI information normally obtained with a PB interface. Since methane reagent ions were totally consumed by the large amount of solvent reaching the trap, we have investigated using solvent ions for CI. Our objective was to develop an appropriate CI method to use for alternating scans with an EI method to obtain both molecular weight and structural information of pesticides. Solvent-CI was investigated using methanol and acetonitrile and was accomplished by using either Mass Selective Solvent-CI (MSS-CI) or Non-Mass-Selective Solvent-CI (NonMSS-CI). MSS-CI accumulates reagent ions (protonated solvent) during a reagent reaction period. The reagent ions are then mass selected and allowed to react with analyte neutrals during the CI reaction period. NonMSS-CI accumulates reagent ions during the CI reaction period and no mass selection is performed. NonMSS-CI also utilyzes a small DC voltage (+5V) during ionization in order to eject EI created ions of greater m/z than the reagent ions. Diuron (mw = 232 amu) was chosen as a test compound for its distinctive dichlorinated molecular pattern. This pattern gives evidence to the relative contribution of EI and CI to the mass spectrum.

RESULTS

CI Reagent Ion Accumulation

Figure 1 shows the effect on the intensity of the CI reagent ion (protonated methanol) when the ionization time is varied in the presence of both a small and large amount of diuron; note that no reaction period was used. The presence of ten-fold more analyte during ionization significantly reduces the amount of reagent ion available for CI. MSS-CI exhibits reduced reagent ion abundance compared to NonMSS-CI due to both the inefficiency of the mass selection step and the consumption by the analyte during the time required for mass isolation.

The CI reaction time yielding the maximum $(M+H)^+$ intensity for the analyte is dependent on analyte concentration. Long CI reaction times are optimum for small amounts of analyte whereas short CI times are optimum for large amounts. This is demonstrated in Figure 2 where CI reaction times of Mass Selected CH_3CN - CI were varied for two amounts of diuron. Optimum CI reaction times were 50 and 5 ms for 18 and 216 ng of diuron, respectively.

RF Level Dependence

Optimum RF levels (low mass cutoffs) for ionization, reagent reaction, and CI reaction were investigated. Optimum RF levels for ionization and reagent reaction occur between 10-15 amu. This places the reagent ion at a stable q-value near 0.3; at $q<0.1$ & $q>0.8$, ions are not stored efficiently. For the CI reaction, it is important to select an RF level that efficiently stores both the CI reagent ion and the CI product ion. Figure 3 shows intensity of the CI product ion, $(M+H)^+$ of diuron, versus CI RF level for MSS-CI using CH_3OH. The CI product ion, m/z 233, is not efficiently stored at 10 amu; at 32 amu the CI reagent ion, m/z 33, is not efficiently stored. The drop in signal at 24 amu ($q=0.65$ for m/z 33), however, was not expected. To investigate this, MSS-CI using CH_3CN was used to store m/z 42 (protonated acetonitrile) for 50 ms. Results from varying the CI RF level are shown in Figure 4. It was observed that the two minima ($q=0.65$ & $q=0.8$) correspond to ion motions with frequencies equal to 1/4 and 1/3 the drive frequency. At these q-values, the reagent ions absorb energy from the drive frequency and are ejected.

Analytical Concerns

Scan functions using optimum reaction times and RF levels for CH_3CN were used to generate the spectra of diuron shown in Figure 5. NonMSS-CI gives more EI-like character than MSS-CI as is evident by the abundant 72^+ ion, which is the base peak in the EI spectrum, and the increased abundance of the ions at m/z 232 and 234, which correspond to M^+ and $(M+2)^+$. MSS-CI shows less fragmentation and approaches the ideal CI molecular ion pattern for diuron which is expected to be 100% for m/z 233; 10.7% for m/z 234; 65.3% for 235; 7.0% for 236; 10.6 % for 237.

Mass Selective CH_3CN - CI was used to generate a diuron standard curve. Flow injection and LC analyses are compared in Figure 6. Compared to flow injection, LC analysis shows a reduced slope at the low end and a substantial increase in slope at the high end. The same standards exhibit linearity when employing EI scan functions. This suggests that this is inherent to the CI process. Both plots show non-linearity below 50 ng, presumably due to inefficient PB transport, and non-linearity above 900 ng due to insufficient amounts of CI reagent ions.

The Use of a Solvent Saturated Nebulizer Gas to Improve Sensitivity in Particle Beam LC/MS

*Terry Whitt, The Hewlett Packard Company, Dallas, Tx. 75081
Patrick Jeanville, DuPont Agrichemicals, LaPorte, Tx. 77027
Alexander B. Schilling, The Hewlett-Packard Company, Naperville, IL. 60566

Introduction:

The particle beam (PB) LC/MS interface operates by pneumatically generating a monodisperse aerosol from a LC effluent stream and then employing a momentum separator to remove gaseous solvent from a desolvated particle beam. The PB interface operates at highest efficiency when the mobile phase composition is predominantly organic. At a high aqueous composition (>50%) the sample signal strength may drop by 70% or more. Some workers employ the post column addition of an organic solvent to improve the response when using a mobile phase with a high aqueous composition. However this approach may sometimes lead to unacceptable band broadening.

The present study examines the effect of attempting to presaturate the nebulizer gas with an organic solvent on instrument response.

Experimental Conditions:

Mass spectrometry was performed on a HP 5989A GC/LC/MS/DS equipped with a particle beam interface and a 1090L HPLC. All samples were run under EI conditions in either scan (50-400 amu) or SIM. Source temperature was 225 C, and the GC interface temperature was held at 280 C. A presaturator (bubbler) was constructed that allowed helium nebulizer gas to bubble through an organic solvent prior to entering the nebulizer. The solvent system used was isocratic (90:10) water:acetonitrile at a flow rate of 0.4 mL/min. Samples were made up as 20 ng/ul solutions in mobile phase. Nebulizer and interface conditions were optimized for sample sensitivity. A series of samples including lactose, glucose, and a sulfonyl urea herbicide (HARMONY) were chromatographed on an reversed phase column.

Results:

Initially a small increase in sensitivity was found for using the bubbler connected to the particle beam at room temperature (26° C). However additional experiments were conducted at higher and lower temperatures to examine any temperature dependence for the sensitivity enhancement. At 4° C the bubbler was found to significantly enhance sensitivity by as much as ten times over the effect at room temperature. Conversely, at an elevated temperature (70°C) a significant decrease in signal was observed. This effect was independent of the compound used. These observations suggest that the bubbler temperature and therefore the gas temperature may play a role in improving the sample transport efficiency of the particle beam, perhaps by changing the particle size distribution produced by the nebulizer.

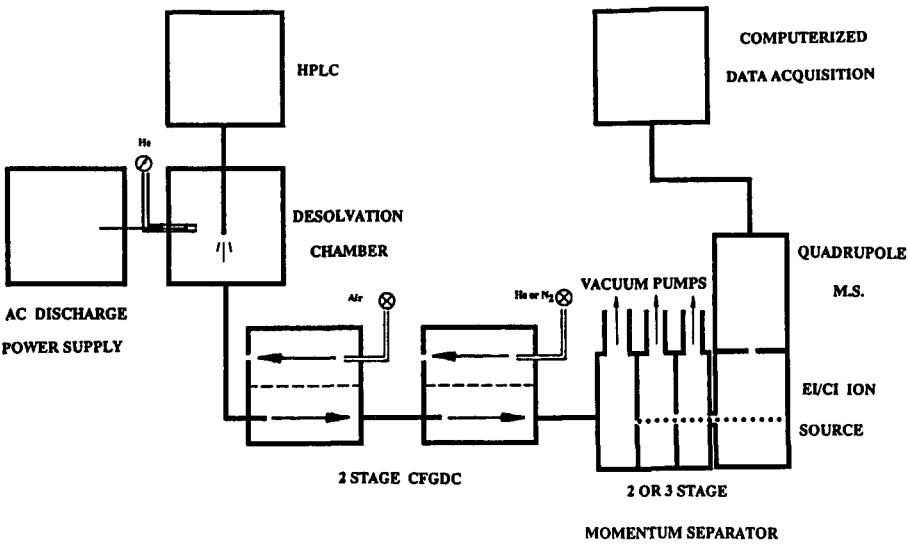
INCREASED SENSITIVITY FOR LC/PARTICLE BEAM/MS

Jon G. Wilkes, Iphigenia Leonidou, Marvin L. Vestal.
Vestec Corporation, 9299 Kirby Drive, Houston, TX 77054

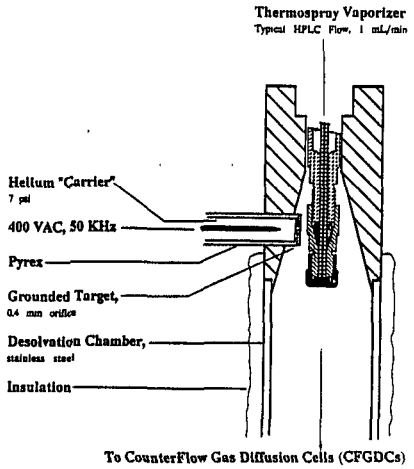
The sensitivity of LC/Particle Beam/MS (LC/PB/MS) has generally been disappointing. Optimum sensitivity requires the use of a 75:25 organic solvent:water mobile phase with a volatile salt or organic acid buffer. These requirements amount to significant limitations for the technique. Omission of the buffer reduces signal by a factor of about 20. Use of 100% water or organic mobile phase reduces it by another order of magnitude. These sample losses have been attributed to condensation effects after liquid nebulization or to size discrimination against small particles in the momentum separator which creates the particle beam. That these losses may also be significantly caused by static electrification in the nebulization process was a major hypothesis of this work.

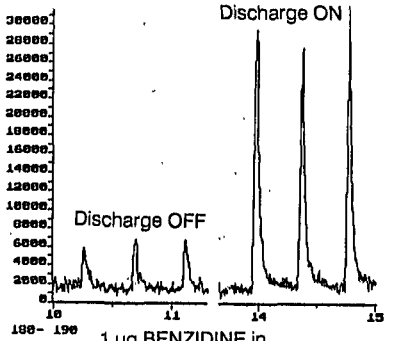
An experimental LC/PB/MS system was developed which contained features designed to (1) neutralize charged aerosol, (2) eliminate or reduce condensation, and (3) reduce the use of helium in the aerosol transport and solvent removal portions of the system. Specifically, it contained an alternating current corona discharge device, two counterflow gas diffusion cells (CFGDCs) and a three stage momentum separator. A block diagram of this system is shown below.



The figure at the top of the next page shows, on the left, a cross section of the AC neutralization apparatus, and on the right, replicate injections of benzidine test analyte with the discharge turned off (A) and with it on (B).

The AC discharge device emulated the aerosol neutralizing action of an ammonium acetate buffer exactly. In the buffer's presence, it made no difference. In its absence, it dramatically increased efficiency of sample transmission. These results demonstrate that the sample loss mechanisms involve static electric phenomena and that such losses can be eliminated without addition of chemicals to the LC mobile phase.





Use of the modified two stage CFGDC resulted in sensitivities for benzidine vaporized from 1.0 mL/min flows of 80% aqueous mobile phases which were about half that observed for benzidine nebulized from 75% organic solvents. This represents a five-fold increase in sensitivity compared to experiments done with the unmodified system. The two stage feature also permitted use of clean air in the first stage sweep to remove most of the vaporized LC solvents and another gas of choice in the second stage for optimal transmission into the mass spectrometer ion source.

With the three stage momentum separator and the choice of helium as the second stage CFGDC sweep gas, benzidine response was almost equal to that observed with the two stage separator. However, the anticipated increase in sensitivity for the test analyte was not observed, at least for the case of the particular geometry of the EI/CI ion source used in this work.

Quantitative results from the several different experimental arrangements are summarized and compared in the Table below. Note: a rule of thumb in evaluating the quality of fit for a calibration curve is that the Coefficient of Multiple Determinations, R^2, should have a value equal to or greater than 0.99.

Common Factors: Liquid flow 1.0 mL/min; 70 eV EI ionization; Vaporizer and Interface gas flows optimized.

High Temperature Vaporization in Particle Beam Liquid Chromatography/Mass Spectrometry Interfacing

J. Chris Richardson and Richard F. Browner, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

INTRODUCTION

Particle beam is one of the few LC/MS interfaces that is solely a "transport" interface. The analyte is merely desolvated and transported to the mass spectrometer as solid crystals. Therefore, a wide variety of vaporization / ionization techniques may be used. The method of choice has been vaporization by collision with a resistively heated source block followed by electron impact or chemical ionization. However, many compounds are too involatile or thermally labile to be vaporized and ionized effectively by these techniques. Some[1,2] have demonstrated decreased thermal degradation with the use of an extremely hot target, consisting of electrically heated nichrome ribbon. Also, softer ionization methods such as FAB and SIMS have been used with varied success in this laboratory. Two related methods soft enough to ionize very large biomolecules are laser desorption and matrix-assisted laser desorption. The purpose of this paper is to test the feasibility of obtaining particle beam / laser desorption spectra, both matrix-assisted and *non*-matrix-assisted.

EXPERIMENTAL

Experiments were performed on an HP 5988 quadrupole mass spectrometer. The normal ion source was completely removed to accommodate the laser. The experiments shown here were carried out with virtually no ion optics, and no focussing of the incoming particle beam. The laser in use is a continuous wave, 3W Argon ion laser, operated in the multi-line mode at 457.9-514.5nm, focused to a power density of ~10^3 W/cm^2. The laser is focussed onto a blackened ceramic probe which is placed in the path of the particle beam.

RESULTS

Figures 1 and 2 show the LD spectra for flow injected cholesterol and naloxone at 10ug/uL. Notice the lack of water loss by cholesterol. Figure 3 is the matrix-assisted LD spectrum of Aerosurf, a large quaternary ammonium salt. The matrix used was methyl red at a ratio of about 100:1 added prior to injection. Figures 4-6 are spectra obtained by direct insertion and further demonstrate the potential of this technique. All three of these compounds are difficult or impossible to analyze by normal PB methods.

CONCLUSIONS

The preliminary results put forth by this paper show that laser desorption mass spectrometry has the potential to significantly widen the scope of compounds that can be analyzed by particle beam LC/MS. Spectra exhibiting intact adduct or protonated molecular ions for compounds normally difficult to analyzed by particle beam have been obtained.

SURFACE IONIZATION OF QUATERNARY AMMOMIUM SALTS IN PARTICLE-BEAM MASS SPECTROMETRY

R.A.M. van der Hoeven, A.P. Tinke, W.M.A. Niessen and J. van der Greef.

Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden, The Netherlands.

Surface Ionization (SI) possesses the highest possible ionization effiency of over 99%. When an atom or a molecule is adsorbed on a surface, it can be desorbed as a positive ion with a yield proportional to:

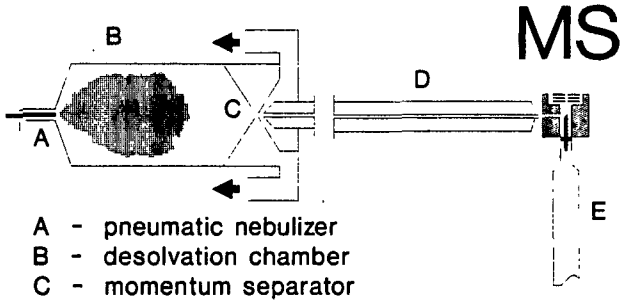
$$\exp(\phi - IP)/kT \qquad \text{(Saha-Langmuir)}$$

ϕ = the surface workfunction
IP = the molecular ionization potential
k = the Boltzmann constant
T = the temperature

Schade and co-workers [1,2] described the use of SI for the determination of TAA salts. Mass Spectra were obtained at surface temperatures higher than 500 °C. For dimethylamine and trimethylamine, compounds with a relatively low ionization potential, a 60- and 600-fold gain in sensitivity can be observed compared to EI. However, compounds with higher ionization potentials give poorer signals in SI.

A way to overcome the energetic barrier and to increase the ionization efficiency, even for molecule surface systems that conventially are not amenable to SI, is to increase the molecular kinetic energy by the use of a hyperthermal molecular beam in combination with GC-MS [3].

The Particle-Beam (PB) interface is also described to form a beam of molecules and molecule aggregates. Therefore, the potential of SI in combination with PB mass spectrometry was investigated. A series of tetraalkylammonium (TAA) salts were used as test compounds.



A - pneumatic nebulizer
B - desolvation chamber
C - momentum separator
D - transfer tube
E - FAB probe and FAB target

For the SI experiments a modified FAB target was positioned in the ion volume in such a way, that the molecular beam hitted the surface in an angle of 45°. Either copper or platinum-coated targets were used. A comparison was made between SI and EI for the different salts with respect to the formed ions and the detection limits.

Although not all experimental parameters are fully explored, best results are obtained with low liquid flow rates, high helium flow rates and using 0.01 M sodiumacetate in methanol at a probe tip temperature of 400 °C. Detection limits in EI are not below 100 ng, whereas in SI 1 ng can be obtained.

The appearance of SI at 250 °C in this experimental setup suggests, that the molecular beam has a certain amount of kinetic energy, in comparison with the experiments by Schade and co-workers, where the starting point was about 500 °C.

Although in SI no structural information can be obtained, the use of MS-MS can induce fragmentation. The fragments which are formed, are the same as in EI.

There were no differences observed by using a Cu- or a Pt-tip for the SI experiments. The maximum probe temperature is 400 °C. Sofar it is not possible to ionize other compounds than TAA salts. using other surfaces or applying higher surface temperatures may be sufficient to overcome the energetic barrier

The Determination of Components in Turmeric by Liquid Chromatography-Mass Spectrometry

R.D. Hiserodt, R.T. Rosen, T.G. Hartman, J. Lech, E.K. Fukuda, T.H. Roshdy, Y.P. Wang, C.H. Vestal, and C-T.Ho

Center For Advanced Food Technology and Food Science Department, Rutgers University, New Brunswick, NJ 08903

Turmeric has been used as a coloring agent in food. Its major component is bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-one, known commonly as curcumin. It is a conjugated phenolic antioxidant with antimutagenic properties.

An exhaustive extraction with methanol yielded an reddish residue which was analyzed by LC and LC-MS. The separation of the components in the residue was accomplished using a polymer based C-18 column. The sample was analyzed by thermospray and Particle Beam LC-MS. Particle Beam LC-MS was utilized in both the electron ionization and chemical ionization (isobutane) modes. The colored components curcumin (MW=368), demethoxycurcumin (MW=338), and bisdemethoxy curcumin (MW=338) were detected as well as a photo-decomposition product (MW=366). Also detected were a series of low molecular weight components including coumaric acid (MW=164).

A combination Vestec Particle Beam EI-CI source was used with the Vestec Universal Interface. This interface is used for sample enrichment prior to momentum separation and is very effective for the removal of solvent so that chemical ionization results solely from the reagent gas of choice.

Performance data was obtained on the source. A scan from mass 10-100 using a 50% ACN/H_2O mobile phase showed the absence of an ion at m/z=18 which indicated the efficient removal of water by the membrane separator. The m/z=57/43 ratio for isobutane indicates the pressure in the source is about 0.3 Torr.

A large (M+H)+ ion at m/z=107 was obtained for xylene (the ratio of mass 107/106 was about 2/1). This compound is not easily protonated as it has a low proton affinity. The ion at m/z = 91 which is normally the base peak in the EI mass spectrum, is only 10% abundance in the Particle Beam-CI mass spectrum. This shows that the Vestec EI/CI source will produce CI spectra of high qaulity.

Particle Beam-CI is a viable alternative to thermospray LC-MS for polar organic compounds. There are two advantages. The first is lower operating pressure and increased sensitivity as the analyzer pressure is about 10^{-6} Torr compared to 10^{-5} Torr for thermospray. The second advantage is increased sensitivity due to fewer background ions.

The disadvantage of particle beam CI versus thermospray is is the loss of volatile organic compounds through the membrane separator when using the particle beam interface.

LC/MS ANALYSIS OF ESTRONE AND ESTRADIOL IN BIOLOGICAL SPECIMENS

H.Y. Tong* and K. Ng, CIBA-GEIGY Corp., Analytical Research,
444 Saw Mill River Road, Ardsley, NY 10502

Due to the physiological significance of estradiol and estrone, their detection in biological specimens is of considerable interest. These assays are currently carried out by chromatographic separations, followed by NMR or MS analyses[1,2]. The MS analyses often require derivatization. This presentation demonstrates direct analyses of estradiol and estrone by LC/MS. Further more, it compares the results from LC/MS analyses with different interfaces.

The analyses were performed on an HP1090 LC/HP5988A MS equipped with thermospray (TSP) and particle beam (PB) interfaces. The target analytes in biological fluid samples were separated on a Zorbax ODS (8 cm x 4.6 mm) column. Different combinations of aqueous ammonium acetate, methanol and acetonitrile were used to achieve an acceptable LC separation and also for sensitivity studies. The LC flow rates were 0.5 ml/min and 1 ml/min for the PB and TSP analyses, respectively. A on-line UV/vis detector was operated at a 200 nm wavelength.

LC/TSP/MS was used because it is believed to provide better sensitivity for these classes of compounds. Figure 1 illustrates the TSP spectra of estrone and estradiol standards under a flow injection of 25% methanol in 0.12 M ammonium acetate. The $[M + NH_4]$ and $[M + H]$ ions dominate the spectra of both analytes. The $[MH - H_2O]$ ion is another feature fragment of estradiol. The reason for this is that estradiol eliminates H_2O more readily than estrone. Different mobile phases at various pH were used to investigate the behavior of analytes in the TSP process. The results are briefly summarized as follows. First, the relative intensities of $[MH]$, $[MNH_4]$, and $[MH-H_2O]$ ions of estradiol, compared with estrone, is more sensitive to the pH of mobile phase. Identification of these two analytes in a complex biological sample can be complicated as a result of the competition of interfering compounds in sample matrices for proton and ammonium ions. Secondly, the response of estradiol is much lower than that of estrone. A 60 ng estrone standard was detected

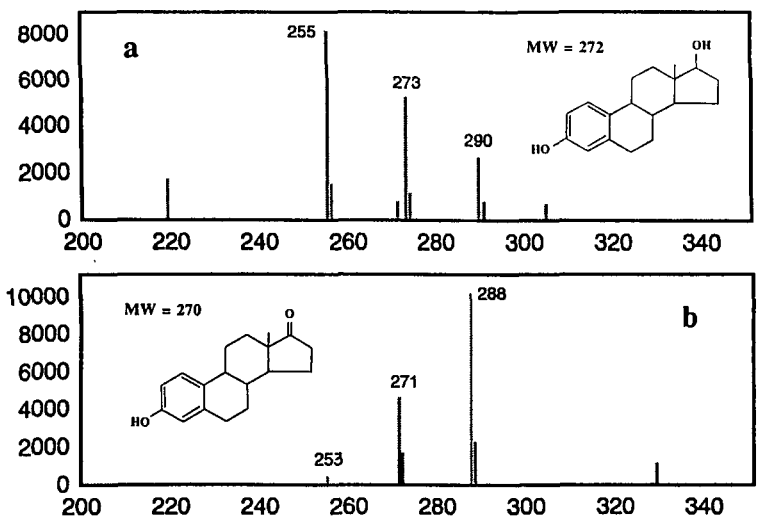

Figure 1. Thermospray mass spectra of (a) estradiol and (b) estrone.

under the optimized experimental conditions. Third, as a mobile phase, a 25% of methanol in 0.12 M ammonium acetate gives better sensitivities for both analytes, but any addition of acetonitrile into the mobile phase reduces the analyte responses substantially. However, acetonitrile is needed to elute estradiol and estrone from the ODS column.

The major ions observed for estradiol and estrone in the LC/PB/MS under a positive chemical ionization (methane) are the $[M + H]^+$ and $[MH\text{-}H_2O]^+$. The loss of water is likely due to the high source temperature used and is also more easy for estradiol. The LC/PB/MS spectra of analytes are more reproducible than their TSP spectra, partially due to the absence of ammonium acetate in the LC/PB/MS analyses. The particle beam interface is more tolerant of various mobile phases hence, acetonitrile results in a good sensitivity for both estrone and estradiol. This is critical for a on-line LC separation of these two analytes from potential interferences in the sample matrices. Figure 2 illustrates a portion of the TIC as well as the mass spectral data of a biological sample analyzed for estradiol and estrone. Under the LC/PB/MS conditions developed, those two target analytes can be clearly distinguished on the basis of their mass spectra as well as their LC retention times.

In summary, for the analyses of estrone and estradiol at picomole levels, the LC/PB/MS is preferred over the LC/TSP/MS while an ODS column is used for LC separation because of the compatibility, overall sensitivity and reproducibility.

Introduction

Particle beam interfaces for coupling liquid chromatography and quadrupole mass spectrometers have been successfully introduced some years ago. In the meantime they are also adapted to high resolution sector type mass spectrometers.

This paper describes the performance of a particle beam interface for coupling liquid chromatography to a Finnigan MAT 95 Q high resolution tandem mass spectrometer (LC/MS/MS). With this instrumentation, high resolution LC/EI/MS and LC/MS/MS spectra of several non derivatized sesquiterpene lactones in plant extracts of *Arnica montana* are recorded. The method allows easy determination of the empirical formula and the acquisition of structural information of the major components in the extracts without previous purification.

PBI interface

The sensitivity of the particle beam interface maximized for solvents with low heat capacities (methanol > acetonitrile > water). Furthermore, optimal sensitivity was obtained at low solvent flow rates (about 0.3-0.6 $mL \cdot min^{-1}$). For the present application, the flow rate was set to 0.8 mL/min. This higher flow rate became necessary to maintain the performance of the liquid chromatographic separation. The loss in sensitivity relative to 0.4 mL/min could be mitigated by increasing the rate of the helium flow to 1.0 mL/min. Since sensitivity was no problem in this context, these conditions were a reasonable compromise. The desolvation temperature was optimized for the solvent system methanol/water (45-50 °C). The source temperature was set to obtain suitable vaporization with minimal thermal degradation (250° C).

Results

The PBI/EI/MS spectra and the GC/EI/MS spectra of Helenalin are identical. The PBI interface obviously doesn't cause any thermal degradation. Under these optimal conditions, CI/MS (Fig. 1) and EI/MS/MS spectra of Helenalin can easily be recorded.

Santonin which is a sesquiterpene lactone commonly used as internal standard was used to test the high resolution performance under PBI conditions. The precise masses were measusered with magnetic scanning at 10,000 resolution with PFK as internal standard.

Summary

The PBI interface described allows the adaption of liquid chromatography to a high resolution tandem mass spectrometer for highly versatile applications.

Under full scan conditions, detection limits of low resolution magnetic scans and daughter ion scans were in the 100 ng range for most sesquiterpene lactones. Complete high resolution mass spectra with good accuracy (better than 3 mmu) could be obtained in most cases on 5 µg samples.

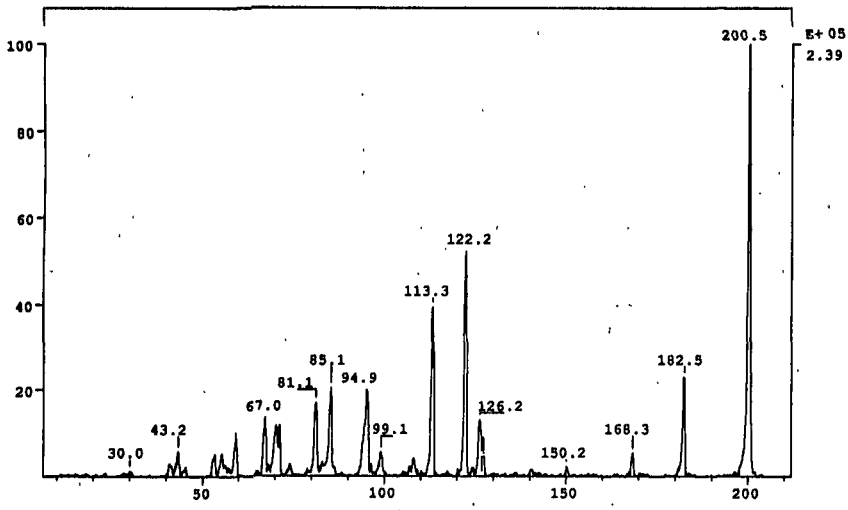

Fig. 1: Daughter ion spectrum of *m/z* 200 ($[M+H]^+$ of Tussilagin).

Experimental

Sample preparation:

1 kg of pulverized flowerheads of Arnica montana were extracted in methanol for 24 hours. After evaporation of the extract to dryness (282 g), 200 g dry residue were treated over night with 500 mL 0.25 M H_2SO_4 solution and zinc powder. This solution was filtered and shaken 3 times with 500 mL CH_2Cl_2 and diethylether. The aqueous residue was alkalized to pH 9 and again extracted with CH_2Cl_2. The resulting CH_2Cl_2-solution was dried over Na_2SO_4 and evaporated to dryness. The following descending thin layer chromatography ($CHCl_3$-Methanol-water: 5:6:4) separated the compounds of interest from other impurities. Resulting dry extract: 28,8 mg alkaloids.

Fast Atom Bombardment mass spectrometry:

Accurate Mass and MS/MS Analysis of a Pesticide Mixture by Particle Beam LC/MS

S. Slahck, J. Baird, Mobay Corporation, Kansas City, MO 64120-0013 and R. Kingston, P. Scullion, M.R. Green, C.J. Porter and *P.A. Bott, Fisons Plc., VG Analytical, Manchester, M23 9LE, England.

Particle Beam LC/MS is emerging as one of the simpler and more versatile techniques for the analysis of a wide range of compounds of medium to low volatility and polarity. Samples may be ionised either by electron impact or chemical ionisation at low nanogram quantitation levels. Library searchable spectra are readily obtained by low resolution electron impact ionisation.

Coupling a Particle Beam interface to a magnetic sector mass spectrometer enables the possibility for accurate mass measurements at high resolution to determine elemental compositions to be made. Also, when coupled to a hybrid mass spectrometer, structural analysis by MS-MS should be realisable.

The objective of the present work was to analyse a pesticide mixture by on-line Particle Beam LC-MS to determine the suitability of Particle Beam for accurate mass measurements and MS-MS.

Reverse phase LC chromatography was performed on a Du Pont Zorbax ODS (5µm) 25x0.46 cm ID column, with a mobile phase flow rate of 1.5µl/min. The mobile phase was acetonitrile/water. Gradient elution was as follows - Time 0 min 60/40 ratio; 1 min 60/40 ratio; 10 min 90/10 ratio; 20 min 100/0 ratio.

Mass spectrometry was performed on a VG AutoSpec-Q hybrid mass spectrometer. The pesticide mixture (250ng/1µl) was analysed by low resolution EI (1000RP) for library searching. Elemental compositions were determined at high resolution (7500 RP) in both EI and CI modes. Daughter ion spectra of the molecular ion of selected components of the mixture were obtained at unit mass resolution by scanning the quadrupole with the magnet set to transmit each consecutive molecular ion.

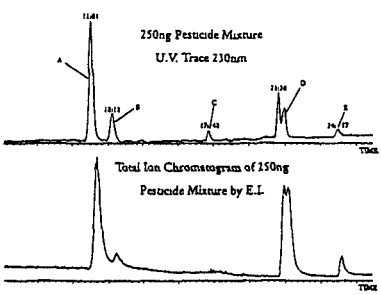

Figure 1.

Elemental Compositions

(Molecular ion from Peak E)										

Table 1.

Figure 1 shows the U.V. detector trace at 230mm and the total ion chromatogram from the mass spectrometer. This good correlation demonstrates that the particle beam interface does not adversely affect the LC separation process.

Table 1 gives the elemental compositions of each component, showing that good accurate measurements are readily made. Good quality, high resolution CI spectra may be obtained as shown in Figure 2 for component E. The MS/MS daughter ion spectrum of peak E, in Figure 3 demonstrates the suitability of the technique for structural analysis by MS/MS.

Particle Beam is a sensitive technique that enables on-line analysis to be made. The interface does not significantly impair the chromatographic separation of the L.C. column. The sensitivity is such that in the nanogram quantitation range, accurate mass measurements may be made and good quality MS/MS data obtained.

"Particle Beam LC/MS Analyses of Compounds of Environmental Interest using a Quadrupole Ion Trap Mass Spectrometer"

Brent L. Kleintop, Donald M. Eades, and Richard A. Yost
Chemistry Dept., Univ. of Florida, Gainesville, FL 32611

Coupling a particle beam (PB) interface with a quadrupole ion trap mass spectrometer (ITMS) would appear to be an appealing choice for many environmental applications employing LC/MS. Unlike most other LC/MS interfaces, PB interfaces are capable of producing structural information from EI spectra which may allow identification of unknown compounds. Also, the acknowledged full-scan sensitivity of the ITMS offers the detection limits necessary for environmental analyses. Ion traps, however, have seen little use in LC/MS systems primarily because of the large amount of solvent introduced by most LC/MS interfaces. Introducing large amounts of solvent can cause undesired ion/molecule reactions and space charging, which may cause loss of spectral quality and sensitivity. Fortunately, the extreme versatility of the "software-intensive" ITMS allows the construction of custom scan functions which can minimize the adverse effects of residual solvent ions by ejecting them prior to mass analysis. This allows acquisition of quality EI mass spectra which compare favorably to library spectra and spectra obtained by solids probe/ITMS analysis.

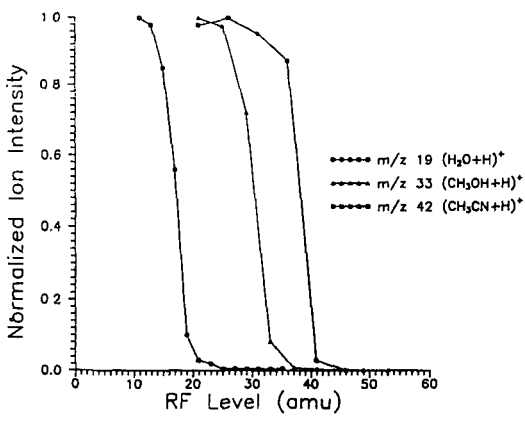
Experimental

All experiments were performed on a Finnigan MAT Ion Trap Mass Spectrometer coupled to a prototype Finnigan MAT particle beam interface. The system utilized the filament endcap of the ion trap as the PB target. Typical target temperature of 250°C were obtained by two 10 W heater cartridges which were controlled by an external feedback control circuit. Separations were performed using a Hewlett-Packard 1090 HPLC.

Results

As expected, the large amount of residual solvent introduced into the trap caused space charging which resulted in poor spectral quality. The effects were minimized by ejecting solvent ions prior to mass analysis. This was accomplished by raising the RF level to impose a low mass cutoff in the trap. Figure 1 illustrates how the ion intensity of the $(M+H)^+$ ions of common LC solvents is affected by elevating the RF voltage for 15 ms following ionization. As a particular solvent ion species approaches its respective low mass cutoff, it is efficiently ejected from the ion trap. This reduces space charge and allows acquisition of EI spectra which compare favorably to both library spectra and spectra obtained from solids probe/ITMS analyses.

Figure 1



Unlike commercially available interfaces, the interface used in these studies employs three stages of momentum separation. The additional third stage of pumping reduces the number of solvent molecules which reach the trap and are subsequently ionized. ITMS chamber pressures

are typically 50X higher when using only two stages of pumping. The removal of more solvent also appears to improve the overall performance of the PB/ITMS system. EI mass spectra of caffeine obtained using three stages of pumping compare favorably to library spectra, while spectra obtained using two stages typically exhibit more "CI character" in that the $(M+H)^+$ is typically the dominant molecular ion peak.

An EI mass spectrum of diuron obtained from an LC/PB/ITMS analysis of a pesticide mixture is compared to a library spectrum and a spectrum obtained from a solids probe/ITMS analysis in figure 2. The spectra compare favorably in both fragmentation pattern and relative fragment ion intensities. The instrument calibration curve of diuron in figure 3 shows a good linear model exists (r^2 = 0.9984) from injection of 20-500 ng. Non-linearities at the ends of the calibration curve are presumably due to particle beam transport problems at the low end and the onset of space charging caused by too many analyte ions at the high end. The instrument detection limits shown in figure 4 are all within the range of interest for environmental pollutants in water and wastewater.

Acknowledgements

The authors would like to acknowledge the U.S. EPA/EMSL (Cincinnati, OH) for providing the funding for this work. We also acknowledge the Finnigan Corp. for graciously providing the particle beam interface. We also wish to thank Dr. Tom Behymer for fruitful discussions of particle beam and LC operation.

AUTOMATED SAMPLE ANALYSIS ON THE HP MS ENGINE USING PARTICLE BEAM INTERFACE

P.R. Das, R. Malchow, B. Evans and B. Pramanik
Schering-Plough Research Institute
60, Orange Street, Bloomfield, NJ, 07003

Mass Spectrometry is an essential part of the drug discovery programs at Schering. In a pharmaceutical laboratory like ours, an increasing demand is being placed on analysing a large number of samples quickly for molecular weight and structural information. This is mainly to support synthetic chemists in their drug discovery efforts who depend heavily on the timely availability of mass spectral results. Many of these samples are amenable to EI/CI analyses and the common practice so far has been manual probe insertion techniques. As an alternative to these time consuming and labor intensive methods, we chose a system for automating the output for regular low resolution EI/CI spectra. However, unlike previous and, in many cases, current practice using automated direct exposure probes and GC autoinjectors or expensive robotic systems, we use an LC autoinjector and particle beam interface to introduce samples into the mass spectrometer. In our experience, the polarity range of samples that respond favorably to particle beam ionization exceeds those responding favorably to GC conditions.

Typically, the samples are dissolved in methanol and introduced by flow injection technique with 100% methanol (flow rate 0.4 ml./min) as the solvent. Since no separation is required, only a guard column is placed on-line between the pump and the interface to remove particulate matter. Typically 4 μl sample solution is injected and the analyte is ionized by conventional EI or CI in the source. Currently about 12 analyses per hour can be performed with two injections per sample. The post acquisition processing step (including printout of spectra) has also been automated. Automation can be set up to perform EI and CI (positive and negative) analyses in succession.

Representative positive and negative ion CI spectra, obtained under automated analysis, are shown in Figures 1 and 2. It was found that a majority of compounds that are amenable to ionization by direct insertion probe respond favorably to particle beam. EI spectra obtained are also very similar to those obtained by sector instruments and are library searchable.

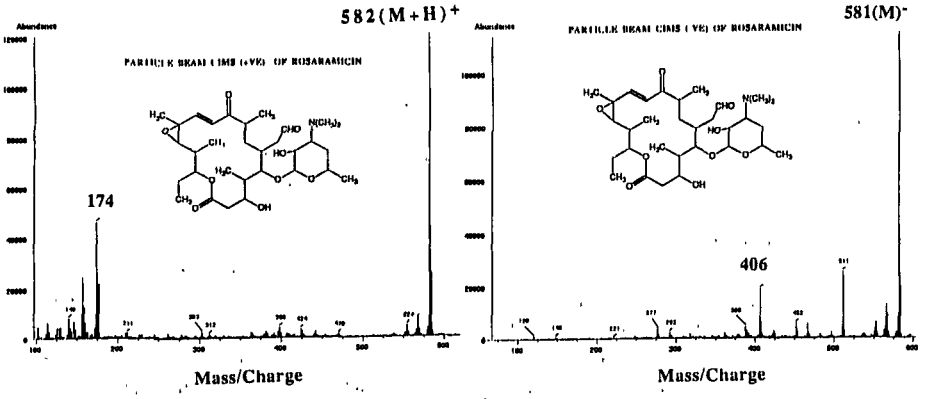

Figure 1

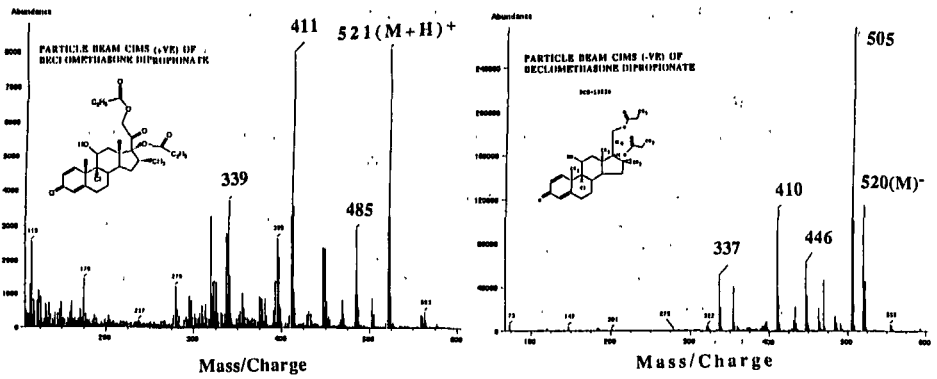

Figure 2

The ability to analyse a large number of samples using automation thereby freeing an operator's time for other tasks has made this system ideally suited for our laboratory. Efficiency and productivity has been dramatically increased by eliminating manual sample introduction and data processing. An added feature is the simplicity and reproducibility of instrument operation.

Quantitative Isotope Dilution Analysis Using Particle Beam LC/MS

Daniel R. Doerge[1] and Min Zhou[2].
[1]National Center for Toxicological Research, Jefferson, AR 72079
[2]Hawaii Sugar Planters' Association, Aiea, HI 96701

INTRODUCTION

The use of particle beam (PB) LC/MS as a tool for quantitative analysis of organic compounds has been limited by the fluctuations in MS response observed in both intraday and interday analyses. The ideal way to avoid this problem is the use of isotopically labeled internal standards (IS). However, a putative deficiency of PB-LC/MS comes from reports that signal enhancement occurs upon coelution of native and labeled analytes (carrier effect) (1). The proposed mechanism for this coelution enhancement was chemical complex formation leading to larger particle sizes and hence, increased transmission efficiency through the PB interface. The purpose of this study was to determine the origin of the carrier effect in order to develop quantitative methods employing PB-LC/MS.

EXPERIMENTAL

Isotopically labeled compounds were obtained from commercial sources. Mass spectrometry was performed using a Trio 2A equipped with a LINC PB interface (VG BioTech, Altrincham, U.K.). Positive ion spectra were obtained using EI (70 eV) and full scan conditions (70-650 in 1 sec). Analyte amounts were determined from peak areas of specified ions. LC was performed using a Perkin Elmer series 10 isocratic pump equipped with either a Waters Novapak C18 or Hamilton PRP column or in flow injection analysis mode (FIA) with a flow rate of 0.5 mL/min. GC was performed using a Hewlett Packard 5890 equipped with a DB5 column (25 m, 0.25 μ) with He flow at 1 mL/min.

RESULTS AND DISCUSSION

Coelution of native caffeine (25-1000 ng) with $^{13}C_1$ (25 ng) led to significant coelution enhancement of the IS signal. While the magnitude of the coelution effect (IS signal with coelution/IS signal without coelution) was dependent on several experimental parameters (e.g., desolvation temperature, mobile phase composition, nebulizer), when the data were plotted in the form of an isotope dilution experiment (native/IS response ratio vs. native/IS concentration ratio), identical plots resulted. This suggested that an experimental parameter equally affected both native and IS signals.

To test this hypothesis, the same experiment was repeated using GC since no coelution effects have been reported. While no coelution enhancement was observed in the GC experiment, the isotope dilution plots for GC and PB interfaces were identical. This suggested that there were no limitations of the use of PB-LC/MS for quantitative isotope dilution methods as previously performed by GC.

To determine the effect of spectral overlap in the coelution effect, the experiment was repeated using $^{13}C_3$-caffeine. The addition of 3 isotopic substitutions serves to eliminate spectral overlap between native and IS signals. In this case, no coelution enhancement of IS signals was observed. In addition, isotope dilution plots for triply labeled caffeine were linear (cc=0.99). Since the chemical differences between singly and triply labeled caffeine are slight, it is unlikely that any possible complex formation in the coelution phenomenon would be affected. These results suggest that spectral overlap beween native and IS signals through normal isotope patterns and fragmentation are required for the observation of the coelution effect.

The role of detector nonlinearity on the coelution effect was examined by increasing the GC column split ratio to decrease the absolute response from the MS so that the gain setting was similar to that used in the PB experiment. Under these conditions, large coelution effects were seen with GC/MS. **These observations confirm that spectral overlap and detector nonlinearity cause the coelution effect in PB-LC/MS** (1).

Isotope dilution PB-LC/MS was applied to the analysis of caffeine in coffee and atrazine in groundwater. The accuracy and precision obtained demonstrate that PB-LC/MS is a viable tool for use in quantitation of thermally labile or involatile compounds.

The Optimization of HP-Particle Beam LC/MS Interface by Statistical Experimental Design

Sunkwei Huang, Noe Garza and Steve B. Glancy
Hoechst Celanese Corp., 1901 Clarkwood Rd., Corpus Christi, TX 80469

Sensitivity and ionization softness are used to gauge the settings for a particle beam LC/MS interface. The sensitivity is a measure of the relative efficiency with which the particle beam delivers the solute into the ionization chamber. The ionization softness is a measure of the relative ease of delivery subsequent ionization. Many variables may influence the solute delivery. Normally, the optimization procedure involves adjusting each factor independently and repeatedly until a perceived optimum is reached. As with all optimization schemes this approach is subject to faults optimum. Moreover, one may never reach the true optimum using the "one variable at a time" approach if the variables interact [1]. There are several methods for optimizing a process including simplex algorithms and experimental design. A designed experiment is used to understand the process and map the relationships among the variables within an operating space through math models.

In prelude to running the experiments, all of the known variables were considered and evaluated for appropriateness for inclusion in the model. However, for the sake of simplicity, some of the variables pertaining to the interface design characteristics were treated as constants. These include the pumping capacity, the position of the fused silica tube in the desolvation chamber, the skimmer size and the ion source temperature. Consequently, only five variables such as the acetonitrile mobile phase composition, LC flow rate, nebulizer flow pressure, desolvation chamber temperature, and the ammonium acetate concentration in the mobile phase were evaluated for their effects on Hewlett-Packard particle beam system. P-methoxy-1-phenyl acetic acid (M.W. 166) was used as a model compound for this study, and ion source temperature was set at 250°C throughout this work. The experiments were based on a responsive surface modeling design to allow the examination of the main effects, interactions, and some of the quadratic terms. There were 32 points included in the model. The data were analyzed using the computer program RS/Discover running on a VAX 6410.

The results fit the quadratic model very well, as indicated by the R-sq. and R-sq-adj. values in Table 1. The model includes an important quadratic term in solvent and other interaction terms (Table 1). Consequently, the optimal conditions for sensitivity occur at flow rate of 0.2 ml/min, 45% ACN, 55 psi nebulizer pressure, 35°C desolvation temperature in the presence of 0.02 N of ammonium acetate, as shown in Figure 1. The optimal condition for the softness (the ratio of the molecular ion to its major fragment ion) follows nearly the same trend. The resulting optimal response surfaces for both the sensitivity and softness are shown in Figures 2 and 3 respectively.

The present results have significant implications when comparing with Extrel's thermobeam interface [2]. First, both the peak area and softness of the HP-particle beam are optimized at the low flow rate and about 50% of the organic modifier, whereas the peak area and the softness of the Extrel's thermobeam are optimized at the low and high percentage of organic modifier respectively. Second, the addition of ammonium salt is an significant factor for HP's particle beam but not for Extrel's thermobeam inerface. Finally, from the quality of model fitting, the HP's particle beam appears to give better reliable and quantitative results, but the additional option for adjusting the nebulizer temperature in Extrel's thermobeam makes it capable of operating at higher LC water content.

Collision Cell Modifications on a Four Sector Tandem Mass Spectrometer.

*W. Yu, S.A. Martin and H.A. Scoble,
Genetics Institute, One Burtt Road, Andover, MA 01810

Tandem mass spectrometry has been widely utilized for determining the primary structure of peptides and other biomolecules adding another dimension to the information obtained from the mass measurement of molecules. The ultimate goal of this technique is to achieve efficient bond cleavage in the molecule via energy transfer and obtain reproducible and predictable fragmentation patterns from which the sequence may be deduced. Different types of instrumentation and energetic processes have been applied to peptide characterization each with a varying degree of success. A number of studies have used high energy collision-induced dissociation combined with a modern four sector mass spectrometer. This approach has a number of advantages including; high resolution and mass accuracy, high information content and reproducibility of the fragmentation patterns. These features combined with the unique fragmentation pathways obtained via high energy CID make this an appropriate technique for solving structural problems especially in situations where the protein is posttranslationally modified. The goal of this investigation is to enhance the efficiency and sensitivity of high energy tandem mass spectrometry on our high performance tandem instrument.

Several factors, including ion transmission (precursor and product) and fragmentation efficiency may contribute to the overall efficiency of high energy CID in a four sector tandem mass spectrometer. We previously reported (ASMS91) that precursor ions may have higher apparent CID efficiency when they undergo collision at lower kinetic energy (lab frame) in a four sector mass spectrometer. Under the appropriate conditions, high energy CID fragmentation patterns of peptides were retained at lower kinetic energies by using a heavier collision gas. However, the overall sensitivity or "spectrum quality" did not increase significantly, partially due to low ion transmission efficiency of the original MS/MS interface at higher floating cell potentials. In this work, we present modifications to the MS/MS interface of a JEOL HX110/HX110 tandem mass spectrometer (Figure 1), which aims at higher ion transmission efficiency over a broad range of conditions and better collection efficiency for product ions.

Several discrete modifications were made in the MS/MS interface region (Figure 1) and their effects on the overall ion transmission were measured individually and as a complete unit (Figure 2). Based on the work of Allison et al. (*J. Am. Soc. Mass Spectrom.* 1991, 2, 322-355) an einzel lens was added prior to the retardation lens of the collision cell to reduce the precursor ion beam diameter. The collision cell block was reduced in size to increase the number of ions which entered and exited the gas chamber and remove any stray electrical fields. Finally, a second active element was incorporated after the collision cell block to enhance the collection efficiency of the product ions. The effects of these modifications on overall ion transmission are plotted in Figure 2 as a function of the potential difference between the accelerating voltage and the collision cell potential (Vacc-FC). In the original MS/MS interface the overall transmission efficiency at (Vacc-Fc) values less than 1000 volts was on the order of 20%. The new cell block (EZ and AF2 off) achieves a factor of 2-4 improvement in this transmission efficiency. This is further enhanced by activating the einzel lens (EZ) and the second focusing element (AF2). An MS/MS spectrum of angiotensin I obtained with the modified MS/MS interface at a cell potential of 9.2 kV using xenon as the collision gas exhibited classical high energy CID fragmentation patterns, i.e. a, d and w ions. Furthermore, the precursor ion transmission was 92% and the overall CID efficiency was estimated to be 7.5%.

The improvements outlined above have resulted in dramatically higher overall ion transmissions at high floating cell potentials and sufficient sensitivity to acquire good quality CID spectra in the lower energy regime. The enhancement in ion transmission results in higher CID efficiency and enhanced sensitivity in our tandem mass spectrometer.

Precursor ion scanning utilising a four sector tandem mass spectrometer:- application to mixture analysis

J H Scrivens, K Rollins, R C K Jennings ICI Materials PO Box No 90, Wilton, England
R S Bordoli, R H Bateman Fisons VG Analytical, Manchester, England

1. Introduction

Although multi-sector instruments are very largely used to collect product ion spectra of FAB or LSIMS derived ions, they are capable of many of the more interesting scans previously developed for multi-quadrupole or hybrid instruments.. The most commonly used scan in MS-MS experiments, other than the product ion scan is probably the precursor ion scan. This has been shown to be useful in mixture analysis, structural work, and compound class identification. Unit mass resolution of both product and precursor ions may be obtained with low collision energies being employed. Precursor ion scans can of course be carried out on conventional two sector instruments, but only with a limited (2-300) resolution.

The implementation of precursor ion scans on multi-sector instruments is difficult. Two methods have been attempted; the first, and most difficult, involves scanning both magnets simultaneously in opposite directions. The second approach involves using an electrically floated collision cell and making use of the energy transmission window to transmit a product mass with a range of energies determined by the masses of its precursors. This is the approach used here.

2. Experimental

The experiments were carried out using a VG ZAB-T instrument of BEBE geometry. The ESA in MS2 is of novel inhomogeneous design, which by adjusting the range of voltages applied can change the focal point, focal plane angle, and focal plane flatness of MS2. The full energy transmission of MS2 in this instrument is 1.34:1. In these experiments an accelerating voltage of 8000 volts has been used with the collision cell floated to 6000 volts. This gives a maximum energy ratio of product ions of 1.33:1. Under these conditions therefore all precursors to a selected product should be observed.

3. Results

Figure 1 shows the precursor ion spectrum of m/z 393 from caesium iodide. This shows precursors to m/z 3510. By using signal averaging methods ions to 4549 have been seen. The mass measurement accuracy of these ions has been found to be 0.2 daltons RMS.

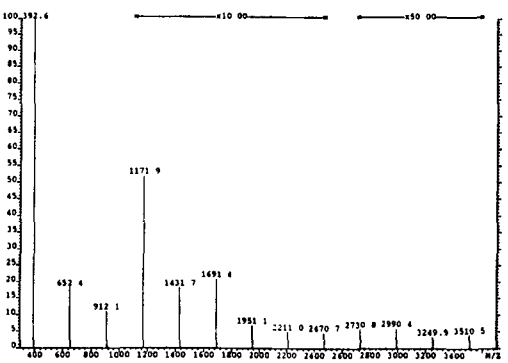

Figure 1

A precursor ion scan of m/z 31 ex hepty| triazine showed precursors upto and including the molecular ion at m/z 1185. This corresponds to a mass ratio of >38:1.

Figure 2 shows the precursor ion scan of m/z 152 ex dibenzsuberone. This molecule fragments to give competitive losses of m/z 28 corresponding to the elements of CO and C_2H_4 respectively. This ion at m/z 180 can then fragment further to the ion at m/z 152. In the precursor scan the doublet at m/x 180 is resolved needing a resolution of >5000.

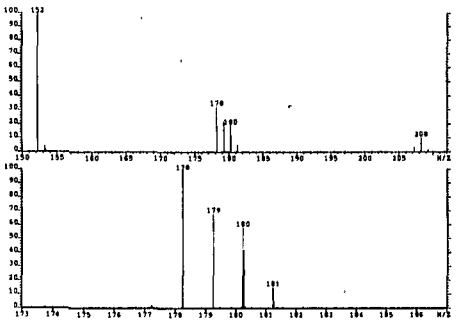

Figure 2

Figure 3 shows the precursor ion scan of m/z 120 and m/z 136 ex leucine enkephalin of molecular weight 555 daltons. (Tyr-Gly-Gly-Phe-Leu), together with the LSIMS spectrum. The product ion at m/z 120 can be formed from the ion at m/z 279, whilst the ion at m/z 136 is formed from m/z 278. This is clearly shown in the precursor ion spectra.

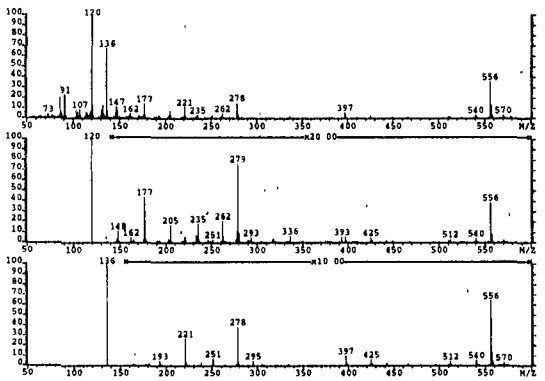

Figure 3

4. Conclusions

- Precursor ion scanning has been successfully implemented on a four sector instrument
- Good product (unit mass) and precursor (>5000) resolution has been demonstrated with access to kilovolt collision energies being possible.
- A mass ratio of >38:1 has been shown with an upper mass of 4549 having been observed in the precursor ion scan of m/z 393 ex caesium iodide.
- The utility of the approach in a variety of applications has been demonstrated.

The characterisation of cationic surfactants by LSIMS and FD methods with four sector mass spectrometry

J H Scrivens, K Rollins, M J Taylor, R C K Jennings
ICI Materials, PO Box No 90, Wilton, England TS68JE

1.Introduction

FAB, LSIMS and FD techniques have been used by a number of groups in the characterisation of surfactant formulations. These techniques give information regarding molecular species but often little structural information. MS-MS methods have been used to provide the complimentary structural information. High energy CID giving rise to remote site fragmentation has been of great use in probing the detailed structure of the alkyl chains present in these molecules. The coupling of FD with MS-MS gives particular sensitivity problems. The work of Boerboom et al in the FOM institute in Holland on homemade equipment showed the potential of this approach. In this work we have used both LSIMS and FD ionisation, coupled with MS-MS in the study of a number of quaternary ammonium salts. The product ion spectra obtained from the two techniques are compared.

2.Experimental

A number of commercial quaternary salts were studied. These included Empigen BAC, Arquad 2C/75, and Arquad S/50. LSIMS spectra were obtained using a Cs gun operating at 30kev. Field desorption spectra were obtained using emitters supplied by Linden ChroMasSpec (Bremen FRG) with the sample applied to the emitter using the standard syringe technique. All spectra were run on a VG ZAB-T four sector instrument of BEBE geometry. The instrument is equipped with an array detector which, together with the use of an inhomogeneous ESA in MS2, enables a mass range from 1.4:1 (at 500 resolution FWHH), to 1.02:1 (at 5000 resolution) to be obtained. This makes FD-MS-MS on mixtures a practical reality. A collision energy of 4kev was employed with argon as collision gas and 75% attenuation. The array was operated at a mass ratio of 1.2:1 with a resolution of 1000.

3. Results

Figure 1 shows the LSIMS spectrum of Empigen -BAC. The main components of interest are the di-methyl mono-alkyl benzyl quaternary salts with the alkyl chain corresponding to C12, C14, and C16. Figure 2 shows the FD spectrum of the same compound. As has been observed generally for these compounds, less fragmentation is present in the FD spectra enabling small components to be identified with a little more confidence. The product ion spectra of m/z 304 obtained from both LSIMS and FD are shown in Figure 3. The C_nH_{2n+2} losses associated with remote site fragmentation are observed in both spectra. The product ion spectra are qualitatively very similar. This was found to be generally observable for the whole class of cationic surfactants studied, even though the FD generated ions show less fragmentation in the conventional spectra.

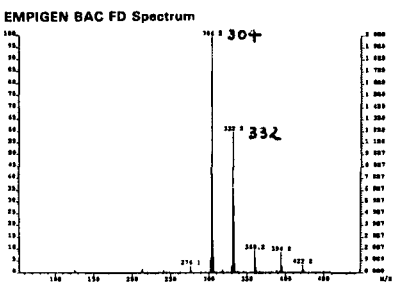

Figure 1

EMPIGEN BAC LSIMS Spectrum

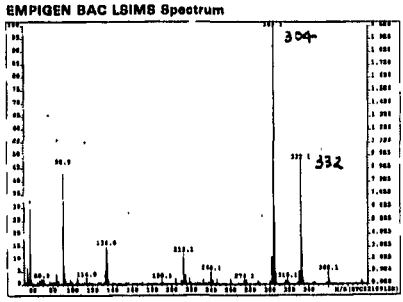

Figure 2

Comparison of EMPIGEN BAC m/z 304 Product Ion Spectra

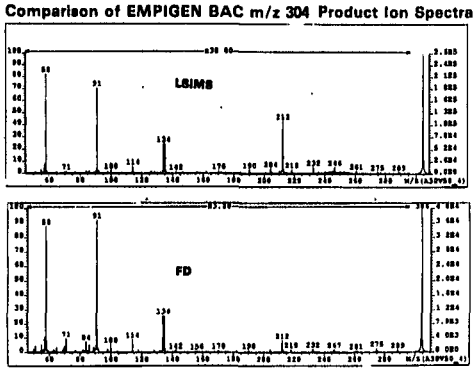

Figure 3

4. CONCLUSIONS

- Field desorption and LSIMS have complimentary features for the study of quaternary ammonium salts.
- FD gives more general information regarding the molecular species present.
- MS-MS data is essential for detailed structural identification.
- The remote site fragmentation exhibited by this class of compound makes structural work easier.
- Product ion spectra of ions formed via FD or LSIMS show only qualitative differences.

The use of a four sector instrument equipped with wide mass range array detection enables FD-MS-MS to become a routine technique.

MS^3 Using Tandem Mass Spectrometry

Lee Tetler[1], Syd Evans[2], John Moncur[2], Colin Moore[2] and Barry Wright[2]

[1]Centre for Mass Spectrometry, UMIST, Manchester, UK

[2] Kratos Analytical, Barton Dock Road, Manchester, UK

The requirement for more detailed structural information of compounds is placing increasing demands on the analytical chemist. MS-MS experiments have greatly assisted in the elucidation of structures, however there is often significant information that is not provided by such a technique. In this respect the MS-MS-MS (MS^3) mode allows a unique and comprehensive study of both primary and secondary ion structure, derived from collision-activated fragmentation or selective reactivity in ion/molecule reactions brought about with a reactive collision gas.

MS^3 mass scans have been performed on tandem 4-sector (EBEB) and hybrid (EBqQ) mass spectrometers. In both cases, daughter ions were produced in the first field-free region after the ion source using high energy (8keV) CID. Particular daughter ions were then selected by the first two sectors (EB) using metastable scanning relationships. These daughter ions were subsequently collided in either a Flexicell or RF-only quadrupole collision cell to produce grand-daughter (MS^3) ions. Both MS2 types (EB and qQ) were linked to the metastable reference voltage of MS1 to give accurate energy tracking of the grand-daughter ions to low mass values.

A CONCEPT I HQ was used to acquire the grand-daughter fragment ion scans using LSIMS for primary ion production.

Figure 1 shows a grand-daughter spectrum from a 12 nmole sample of a naturally-occurring substance, taxol, for the reaction 854 → 569 → grand-daughters. The MS-MS spectrum of the same parent ion produced a complex pattern and the MS^3 data enabled less ambiguous ion identification to be made.

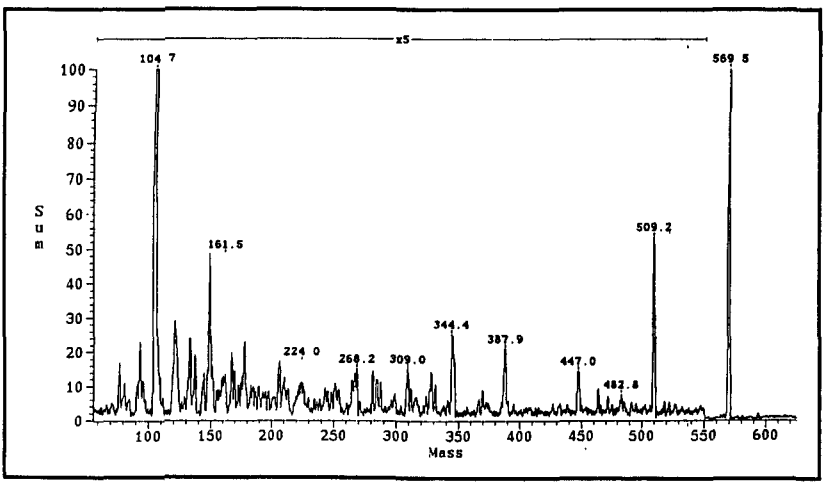

Figure 1: MS^3 spectrum of 854 → 569 → grand-daughters from taxol using EBqQ

A CONCEPT II HH with an array detector on MS2 was used to obtain the 4-sector MS^3 data. Daughter ions were formed in MS1 using metastable scanning relationships. Grand-daughter ions were created when daughter ions underwent CAD in the Flexicell situated between MS1 and MS2. Collision energies of 4keV to 8keV could be used with He as the collision gas. A normal B/E scan was used on MS2 to assign grand-daughter masses except that in this case E was referenced to the ESA energy in MS1, so that a single calibration could be used for any combination parent/daughter ion mass and collision energy. An array detector with a 4% mass window was used to acquire grand-daughter spectra using mass-stepping software control.

A grand-daughter spectrum from Leucine-Enkephalin (556 → 425 → grand-daughters) is shown in Figure 2. This peptide has a structure YGGFL. In this case the daughter ion b4 is fragmented in the Flexicell to give a series of grand-daughter ions dominated by a and b series ions. Ions at m/z 333 and 241 are probably due to glycerol cluster losses (m/z 92) from the isobaric ion at m/z 425, originating from the glycerol FAB matrix.

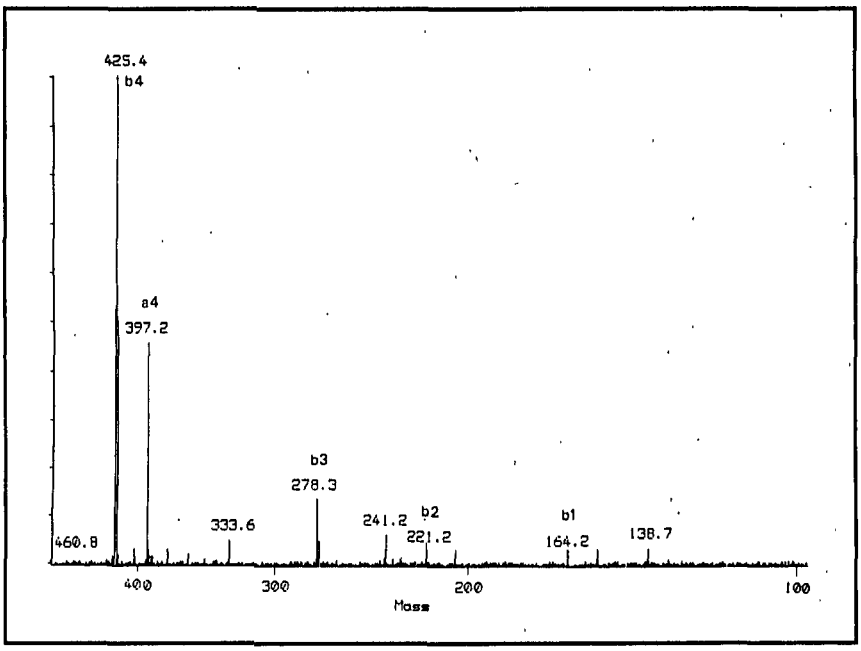

Figure 2: MS^3 spectrum of 556 → 425 → grand-daughters from leu-Enkephalin using EBEB

USE OF A MULTISECTOR HYBRID SPECTROMETER TO ELUCIDATE THE ORIGIN OF AN ARTEFACT PEAK OBSERVED IN LINKED SCANNING AT CONSTANT B/E

Yves Mouget, and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7

The scanning of two or more fields simultaneously in a mass spectrometer, known as linked scanning, has become a valuable tool in the study of ion structures. Difficulties with the resulting spectrum may arise when a fragmentation pathway does not correspond to the pathway under investigation. The resulting peak is referred to as an artefact peak. While artefact peaks can be misleading, the study of their origin can be revealing with regards to the fragmentation patterns. An example of an artefact is found in the constant B/E linked scan of the fragment ion of m/z 299, in N,N- bissalicylidene 1,2-phenylenediamine (MW 316). When performed on an instrument of EB geometry[1], a peak appears at m/z 290 8 as seen in Figure 1 By calculating the apparent mass of the metastable ion, $m^*=m_2^2/m_1$, the authors proposed the transition 316 ---> 299, occurring in the first field free region (FF1), as a possible origin for the artefact peak However, when the same linked scan is performed on an instrument of EBE geometry, the peak is absent from the spectrum Several reasons suggest a different origin than the one formulated above The first considers the fact that the ESA is at 0.9725 of its full potential when the artefact is transmitted, while it should be at 0.9462 for the fragment 299 from 316 to be transmitted Thus this fragment could never reach the magnetic sector during the scan A second clue comes from the broader peak shape. If the other peaks were formed in FF1, then this peak should be just as well resolved, therefore, suggesting its formation in FF2. This would also explain why the artefact is not observed in *the linked scan on an EBE geometry, where the additional energy loss by the ion is filtered out It thus seems* likely that the fragmentations leading to the artefact involve more than a single fragmentation in FF1. The purpose of this study was to use an Experiment Design software in order to elucidate the origin of the artefact peak. The experiments were performed on a VG Autospec-Q mass spectrometer of EBEqQ geometry which was controlled by the specially developed version of OPUS. This software which has already been partly describe[2] permits an independent control of each analyzer and the possibility of custom designing any scan.

The fragmentation pathway leading to the artefact peak would, therefore, be compatible with two consecutive fragmentations occurring in FF1 and FF2 The conditions of the initial B/E scan of ion 299 served as the starting point for this study, and thus any suggested fragmentation pathway is bound by the mathematical relationships: $m_2x/m_1y=0.9725$, and $m_3^2x/m_1z^2=282.8$. Using the analyzers available on the Autospec-Q, a scan of E2 behind the magnet was programmed, while setting the first two analyzers (E1,B) to the values imposed above. The resulting scan can be seen in Figure 2, indicating a single peak at an equivalent average energy of 7570 V Since the energy is 0 946 times the accelerating voltage, and thus different from E1, it is again evident that a second fragmentation takes place between the two ESAs Using the equation obtained from this observation, $m_3x/m_1z=0.946$, the system can be solved in order to obtain the corresponding ratios

$$m_1/x=316, \quad m_2/y=307.4, \quad m_3/z=299$$

These solutions become a set of conditions that must be obeyed when solving the fragmentation pathway and can be partly confirmed by an appropriate quadrupole scan. Such a scan indicates a single peak at m/z 299, in accordance with the proposed fragmentation sequence It must be stressed that most ions produced as a result of changes in charge states would not be observed because of the value imposed on the deceleration voltage This sequence is, however, difficult to accept for singly charged ions since it requires a mass loss of 8 6 amu in FF1, followed by a second loss of 8.4 in FF2. The results obtained, therefore, imply the existence of precursor ions of masses to charge ratios of 316 and 307.4. A magnet scan, however, does not show any significant peak at masses corresponding to 307.4, implying that this peak is extremely weak or non-existent. It is thus necessary to investigate fragmentations apparently involving the ion of m/z 307.4 by using unusual scans. One such example involves scanning the magnet while E2 was set to the original value of E1. This scan for metastable precursors having only 0 9725 of the original kinetic energy confirmed the fragmentation sequence leading to the formation of an ion of m/z 299, ($307\ 5^+ \text{-->} 299^+$). While the fragment mass can be confirmed by a quadrupole scan, the origin of 307 4 cannot be determined from this scan In contrast to the results above in which the ion of m/e 307 4 can only be deduced from mathematical calculations, a B/E scan programmed to transmit ions of m/e 307 5 shows several fragment ions (Figure 3). The most interesting peaks appear at masses 299 and 300, since both of them involve the loss of unusual masses, 8 5 and 7.5. In order to reproduced the original experiment on an instrument of EBE geometry, the Experiment Design Function was used to perform a B/E1 scan, while maintaining E2 at 0.946 (Figure 4) The resulting spectrum shows a narrow and a large peak which is 3 mass units wide The potential of the first ESA is calculated at 0 975 for the peak present at $m^*=284.5$. This value implies a fragmentation between the two ESAs, and the peak width suggests it occurred before the magnet Alternatively, the wide peak could be either the result of a fragmentation with a very large energy release, or several fragmentations whose energy ratios and metastable masses are very close together. Since the latter is unlikely, and considering the width of the peak in Figure 2, the first possibility merits investigation. When the energy released during a fragmentation is calculated from the MIKES spectrum in Figure 2, the energy release value found, assuming x=2, is 1.6 eV, which is compatible with the fragmentation of a doubly charged ions from two conceivable sequences

$$632^{++} \text{---------->} 615^{++} \text{---------->} 598^{++} \quad \text{or} \quad 632^{++} \text{---------->} 615^{++} \text{---------->} 299^{+} + 299^{+}$$

Such fragmentations involve a mass loss of 17, which is a more reasonable loss, especially considering the presence of OH groups in the molecule. Both sequences account for the energy ratios, the metastable masses as well as the m/z of 299 detected by the quadrupole. While ions at half masses corresponding to doubly charged monomers are present in the spectrum of the magnet scan, only very weak ions are sometimes seen at masses corresponding to the singly charged ions of the proposed species. This does not negate the existence of doubly charged ions, whose peaks would coincide with the singly charged monomers in the spectrum. When the above experiments are repeated using a softer ionization technique in order to decrease the probability of forming doubly charged ions, the artefact peak is greatly reduced and barely observable

By using the discrimination of additional analyzers on an instrument of EBEqQ geometry, it was possible to confirm a more complicated fragmentation procedure than the one originally proposed, and to determine a series of mathematical conditions that must be met if the ions are to pass through the analyzers. These state that a mass to charge ratio of 316 for the parent ion, 307.5 for the first fragment ion, and 299 for the second fragment ion are the solutions to the problem. Since a mass loss of 8.5 for singly charged ions is highly improbable, a consideration must be given to doubly charged dimers. Although these ions do not appear significantly as singly charged masses, evidence of their existence and involvement can be suspected through different scans, ionization techniques and measured values for the kinetic energy released in the transition.

Applications of MS/MS/MS Experiments to Structural Characterization of Coenzyme A and Modified Adenine Compounds

Nancy J. Jensen and Terry Sumpter
Research Center, Philip Morris USA, Richmond VA 23261

The MS/MS/MS (MS^3) experiment is a very useful technique for obtaining enhanced structural information from large molecules which undergo limited fragmentation in the MS/MS (MS^2) experiment and in elucidating decomposition mechanisms. Although this technique has been used for some time with ion trap and ion cyclotron resonance (ICR) mass spectrometry, the application to four sector instruments is fairly recent (1).

In this work we have developed methods and appropriate minor instrumental modifications to perform the MS^3 experiment on the JEOL SX 102/SX 102 double-reverse geometry four-sector instrument and subsequently applied the analyses to the characterization of modified adenine compounds. These commercially obtained materials consisted of Coenzyme A (Co A), palmitoyl Coenzyme A (pal-Co A), flavin adenine dinucleotide (FAD), β-nicotinamide adenine dinucleotide (NAD), β-nicotinamide adenine dinucleotide phosphate (NADP), and 3-aminopyridine adenine dinucleotide (3-AAD). These compounds were selected as a group for study as they are complex molecules with considerable structural similarity which give very limited fragmentation in the MS^2 experiment. Although the initial goal of this study was enhanced structural information, by studying second generation decompositions the results showed that what appeared to be similar fragments in the MS/MS experiment actually had some very distinct differences in terms of mechanisms. All of the compound studied yield limited fragmentation in the MS/MS analysis. A typical example is the analysis of Co A (Figure 1A) which yields four principle ions that can be related, with consideration for protonation and hydrogen transfer with cleavage. Although the MS/MS spectrum is a simple spectrum, the MS^3 analysis shows that it is actually a composite of two spectra as the result of fragmentation from two different sites of protonation (Figures 1B and 1C). Specifically, the ion of m/z 261 is formed from protonation on the pantothentic portion of the molecule and the other ions are formed from protonation of the adenine portion of the molecule. Additional structural information is obtained in the MS^3 analysis of the first-generation ion of m/z 261which yields a series of ions not observed in the MS/MS spectrum that may be related to the pantothenic acid structure (Figure 1C).

The fragmentation of pal-Co A is quite analogous to that for Co A and again MS^3 analysis provides evidence for two sites of protonation on the parent ion. The MS^3 fragmentation of m/z 1006 -> 499 -> ? of the chain portion of the molecule is particularly informative as the fragments below m/z 261 are essentially the same as the MS^3 fragmentation from the first-generation ion of m/z 261 for Co A , while the fragmentation in the range of m/z 499 to 261 is charge remote fragmentation of the palmityl chain (Figure 2).

Evidence for multiple protonation sites on the parent ion are also found for FAD and 3-AAD in the MS^3. However, in contrast NAD and NADP exhibit a series of sequential cleavages implying a single site of protonation on the nicotinamide portion of the molecule (Figure 3). This difference

is not obvious in the MS/MS analysis. Further mechanistic information is obtained for NAD and NADP in the MS^3 analysis including the fact that water loss occurs upon CID of only those first generation ions bearing both ribose rings and that first generation ions bearing both ribose rings yield an ion of m/z of 232. This ion is most likely formed as the result of rearrangement.

In conclusion, as expected additional structural information was obtained from the MS/MS experiment especially in the case of Co A and pal-Co A. In addition, insight into fragmentation mechanism is obtained including evidence for multiple sites of protonation in some cases, mechanism of water loss and evidence for rearrangements in first-generation ions.

Multi-analyzer techniques applied to the identification of high energy CAD product ions in hybrid MS.

Ralph S. Orkiszewski, Odile Burlet and Simon J. Gaskell

Baylor College of Medicine, Houston, TX 77030.

Tandem mass spectrometry using collisional activation (CA) of precursor $[M+H]^+$ ions has been widely successful in generating structural data for peptides, including information on sequence and post-translational modification. Major differences in fragmentation patterns may be observed following low energy CA (usually performed in quadrupole devices or their equivalent) and high energy CA (as generally performed on four sector instruments) but both regimes have successfully generated structural information. A significant limitation of the low energy method arises from the inability to distinguish leucine (Leu) and isoleucine (Ile) residues, a distinction which is usually made clear in the high energy experiment by the appearance of "d" or "w" ions associated with beta/gamma cleavage of the amino acid side-chain. Tandem mass spectrometers of hybrid (BEqQ; B = magnetic sector; E = electric sector; q = rf-only quadrupole; Q = quadrupole mass filter) design permit both high energy CA (in the first or second field-free regions) and low energy CA (in q). Thus, an appropriate strategy for peptide characterization involves an initial analysis incorporating low energy CA of $[M+H]^+$ ions; when the presence of leucine or isoleucine residues is indicated, high energy CA is performed. If good resolution of both precursor and product ions is required, the preferred form for the latter experiment on a BEqQ hybrid instrument is an extension of a mass-analyzed ion kinetic energy spectrometry (MIKES) experiment, with unit resolution of product ions achieved using the quadrupole mass filter (Q). This may be accomplished using linked E/Q scanning but at considerable sacrifice in transmission. Since the principal objective of the high energy CA experiment, in this instance, is the observation of *specific* d or w ions, the requisite information may be obtained by experimentally simpler procedures: (i) selection of the candidate fragment ion using Q and narrow range scanning of E; or (ii) selection of the relevant ion, using E, and scanning of Q to define m/z with unit resolution. These approaches have been evaluated here.

All analyses were performed using a VG ZAB SEQ hybrid tandem instrument of BEqQ geometry. Ions were produced by fast atom bombardment (Xe^0; 8keV), using a liquid matrix of 2,2'-dithiodiethanol/thioglycerol (1/1), saturated with oxalic acid. Spectra were acquired using the VG 11/250 data system.

Figure 1 shows the detection of product ions derived from the protonated peptide, SIGSLAK (designated using the single letter amino acid codes), using several modes of analysis. Low energy CAD (in q) provides an informative product ion spectrum (Fig. 1a) but fails to distinguish between leucine and isoleucine residues at the 2 and 5 positions. Fig. 1b shows the conventional MIKES spectrum of product ions derived from high energy CAD. Extensive sequence information is apparent, including signals provisionally attributed (as indicated) to d_5 and w_6 ions; assignments are, however, uncertain in view of the limited mass resolution achieved by E scanning. Figures 1c and 1d show expanded plots of relevant regions of the MIKES spectrum, together with spectra derived by E scanning (across a similar range) and filtering of product ions through Q set to transmit m/z 388 (for detection of the putative d_5 ion) or m/z 543 (w_6). The responses obtained confirm the formation of these product ions, thereby indicating the assignments of Ile^2 and Leu^6. Figs. 1e and 1f show the results of application of the second procedure for unequivocal assignment of the m/z ratios of the selected components of the MIKES spectrum. E was set to the appropriate value for transmission of the MIKES peak and Q was scanned across a narrow range. The MIKES peak apparently corresponding to the w_6 ion yielded a single component (of m/z 543) in the m/z spectrum (Fig. 1f). In contrast, the MIKES peak attributed to d_5 was shown to be heterogeneous with respect to m/z; the d_5 fragment (m/z 388) corresponded to a minor component of the multiplet (Fig. 1e).

Given the requisite instrumentation, the optimal procedure for detection of the products of high energy decompositions of peptides is B2/E2 scanning with a four-sector mass spectrometer. When precursor ion resolution is not critical, any instrument incorporating a double focussing sector component may be used to detect high energy decompositions occurring in the first field-free region. The BEqQ instrument, as illustrated here, provides the further option of satisfactory resolution of both precursor and product ions by exploiting the resolution of the quadrupole mass filter to define the mass/charge ratios corresponding to signals in the MIKES spectrum.

Sequential MS (MS^3 and MS^4) Studies of Water Loss from Peptide $[M+H]^+$ Ions: Further Evidence of Intra-Ionic Interactions. Kevin D. Ballard and Simon J. Gaskell, Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030

Water loss is a frequently observed fragmentation of peptide $[M+H]^+$ ions. There are three possible sources for the oxygen lost during dehydration in peptides: a) carboxylic acid groups, including the C-terminus and acidic side chains; b) hydroxyl-containing side chains; and c) the peptide backbone. Previous studies with C-terminally $^{18}O_2$-labelled peptides indicated considerable variability among peptides in the site of dehydration. Other recent studies have indicated the importance of the conformations adopted by peptides in the gas phase. In light of these considerations, the present studies were undertaken to investigate further the dehydration of peptide $[M+H]^+$ ions.

Tandem MS analyses were performed with a VG ZAB-SEQ hybrid instrument of BEqQ configuration under FAB conditions. Conventional product ion spectra were obtained by manual selection of the precursor ion with the BE portion of the instrument, with scanning of Q to detect the first generation product ions formed in q. For second generation product ion spectra, appropriate settings of B and E were established to select first generation product ions formed in the field-free region between the ion source and B. Ions so selected were subjected to CAD in q, with subsequent *m/z* analysis of the second generation product ions with Q. The instrumental setup for third generation product ion spectra was similar, except that E was set to transmit second generation product ions formed between B and E. Q was again scanned to analyze the third generation product ions formed in q.

The conventional product ion spectrum of $[^{18}O_2]$TRKR demonstrated that this peptide dehydrates primarily through the loss of $H_2{}^{18}O$, indicating that the C-terminal carboxylic acid group is the primary site of dehydration in this peptide. A similar spectrum of delta sleep inducing peptide (WAGGDASGE) as the tris-methyl ester derivative showed a strong water loss, which could involve either peptide backbone oxygen or the serine hydroxyl group. The second generation product ion spectrum representing the $[M+H]^+ \rightarrow [M+H-H_2O]^+ \rightarrow$ products reaction sequence for this peptide pinpointed the serine residue as the site of dehydration but did not distinguish between the involvement of the carbonyl contributed by the serine and the serine hydroxyl. The conventional product ion spectrum of the same peptide as the tris-methylated, bis-trifluoroacetylated derivative showed that protecting the serine hydroxyl dramatically reduced the relative abundance of the $[M+H-H_2O]^+$ species, and abolished the loss of water from the B and Y" ions.

The $[^{18}O_2]$labelled pentapeptide RPPGF dehydrates primarily through the loss of $H_2{}^{16}O$, indicating the involvement of one or more of the oxygens of the peptide backbone. The second generation product ion spectrum representing the $[M+H]^+ \rightarrow [M+H-H_2{}^{16}O]^+ \rightarrow$ products sequence strongly suggested that the oxygen of the peptide bond nearest the N-terminus is the primary site of dehydration with this peptide. This finding was confirmed by the third generation product ion spectrum representing the $[M+H]^+ \rightarrow [M+H-H_2{}^{16}O]^+ \rightarrow [(B_4'+{}^{18}OH)-H_2{}^{16}O] \rightarrow$ products reaction sequence (Figure 1). The conventional product ion spectrum of $[^{18}O_2]$leucine-enkephalin exhibited the loss of both $H_2{}^{16}O$ and $H_2{}^{18}O$, indicating the involvement of both the C-terminus and either peptide backbone oxygen or the tyrosine hydroxyl (although the latter possibility is unlikely due to aromaticity). The second generation product ion spectrum representing the $[M+H]^+ \rightarrow [M+H-H_2{}^{16}O]^+ \rightarrow$ products sequence indicated that the backbone oxygen contributed by either the first or the second glycine residue is involved in the loss of $H_2{}^{16}O$. Figure 2 shows the corresponding second generation product ion spectrum representing the $[M+H]^+ \rightarrow [M+H-H_2{}^{18}O]^+ \rightarrow$ products sequence. This spectrum demonstrated the occurrence of considerable intra-ionic isotope exchange with this peptide when $H_2{}^{18}O$ is lost from the C-terminus.

We conclude that the mechanism of dehydration varies considerably among peptides. The dehydration can involve the loss of carboxylic acid oxygen, side-chain hydroxyl oxygen, or peptide backbone oxygen, and more than one of these mechanisms can occur in a single peptide. It is clear that complex intra-ionic interactions occur during the dehydration of peptide $[M+H]^+$ ions, and it is likely that the observed differences among peptides in the mechanism of dehydration reflect the particular three-dimensional conformations adopted by each peptide $[M+H]^+$ ion in the gas phase.

The Tailing Signal on the Low Energy Side of the Main Beam In MIKES Spectra Is Attributable to Source Phenomena. Kevin D. Ballard and Simon J. Gaskell, Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030

A pronounced tailing signal (decreasing in intensity from high to low kinetic energy) is frequently observed during MIKES analyses of fast atom bombardment (FAB) desorbed ionic species. This "tail" is observed under both unimolecular decomposition (Figure 1) and high energy CAD conditions. The tail begins at the low energy side of the main (precursor) beam, and generally decreases in intensity toward lower kinetic energy values, often extending across 30% (or more) of the range below the kinetic energy of the precursor. The upper portions of this tail can be as intense as some of the identifiable product ion peaks in the MIKES spectrum, and less intense product ion peaks may be obscured by the tail. These studies were undertaken to elucidate the nature of the tailing signal observed in MIKES spectra, utilizing the sequential momentum, kinetic energy, and *m/z* analyzing capabilities of a BEqQ hybrid instrument.

RESULTS. *m/z* deconvoluted MIKES analyses demonstrated that the tailing *precursor ion* signal observed under helium CAD conditions is too short to account for the protracted MIKES tail, and a tailing *precursor* signal is not observed at all under unimolecular decomposition conditions. Measurements of the *m/z* values of the ionic species comprising the MIKES tail demonstrated that ions higher in *m/z* than the chosen precursor are present throughout the tail, with *m/z* increasing as kinetic energy decreases. Table I shows the measured *m/z* values of ions at various points along the tail of the MIKES spectrum of bradykinin(1-5) (*m/z* 573), along with the calculated velocity and momentum for ions of the measured *m/z* and the selected kinetic energy (with unit charge assumed). In each instance, the higher *m/z* ions which appeared in the MIKES tail had the same momentum as the chosen precursor, indicating that they were formed in either the ion source or FFR1, i.e. at some point preceding the magnetic field. In two instances, ions lower in *m/z* than the chosen precursor were detected, in addition to ions of higher *m/z*. These were genuine product ions formed in FFR2 since they had the same velocity as the chosen precursor. The existence of intact, source-formed $[M+H]^+$ ions with reduced kinetic energy was demonstrated through several types of tandem mass spectrometric experiments. These $[M+H]^+$ ions with reduced kinetic energy do not appear to have undergone collisional deceleration since they do not possess increased internal energy (as judged by observation of their fragmentation patterns). Figure 2 presents *m/z* deconvoluted ion kinetic energy "spectra" of leucine-enkephalin $[M+H]^+$ ions (*m/z* 556, filled triangles) and *m/z* 393 ions from cesium iodide (filled circles). The individual data points represent

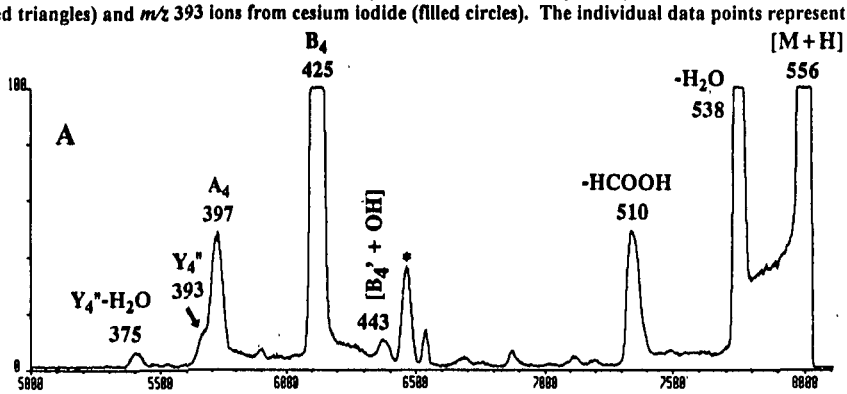

Figure 1. MIKES spectrum of leucine-enkephalin obtained at high gain under unimolecular decomposition conditions.

the maximum intensity values from *m/z* deconvoluted, energy selected momentum analyses of these analytes with the source operated at 8 keV. The inset shows similar data for the same analytes, obtained under identical instrumental conditions, with the detected signal intensity (I) expressed as a fraction of the main beam intensity (I_M). These data demonstrate the tailing character of the kinetic energy distribution of ions emerging from the source. The population of ions exiting from the source under FAB conditions thus incorporates the characteristics necessary to account for the MIKES tail, namely the presence of ions of *m/z* higher than the chosen precursor (due to matrix and other background ions), which possess reduced kinetic energy such that their momentum is identical to that of the selected precursor. These ions may arise via desolvation and declustering processes in the acceleration region of the ion source, or via FAB or chemical ionization processes in regions removed from the FAB target.

Determination of Gas Phase Cation Affinities of Modified and Basic Amino Acids using a Hybrid Mass Spectrometer

Odile Burlet and Simon J. Gaskell

Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030,
and the Department of Chemistry, University of Houston, Houston, TX 77204-5641

The relative gas phase proton and metal cation affinities of amino acids can be assessed using a kinetic method established by Cooks and co-workers [1]. This approach is based on the rate of competitive reactions observed during the spontaneous decomposition of a cationized heterodimer composed of two amino acids, A_1 and A_2:

$$[A_1\ A_2 + \text{Cation}]^+ \longrightarrow [A_1 + \text{Cation}]^+$$
$$\longrightarrow [A_2 + \text{Cation}]^+$$

The relative proton [2] and sodium [3] affinities of the 20 L-amino acids have been reported using a double focusing instrument of BE geometry in the MIKES mode (selection of the precursor ion with B, decomposition between B and E, and analysis of the product ions by scanning E). Here we describe analyses using a hybrid mass spectrometer of BEqQ geometry allowing for the selection of the precursor ion with B and E, decomposition in the rf-only quadrupole, and analysis of the product ions by scanning Q. It was demonstrated that the Q scanning approach was superior to the MIKES approach for the detection of product ions with respect to resolution, sensitivity, reproducibility and elimination of extraneous signals. The expected rankings for gas phase proton and sodium affinities were observed (Arg > His > Lys).

The effect of common peptide derivatization procedures on the gas phase proton affinity of individual amino acids was assessed (Table). Conversion of arginine to dimethylpyrimidylornithine (DMPO) achieved the expected reduction in proton affinity whereas conversion of cysteine to pyridylethylcysteine enhanced the proton affinity. Application of these derivatization procedures to peptides is then expected to influence the sites of charge-directed fragmentation and to modify the charge distribution between complementary fragments The gas phase proton affinity of *N*-acetylglycine was shown to exceed that of glycine itself, suggesting that, in protonated peptides, the amide bonds may be competitive as sites of protonation with the N-terminal amino group.

Different rankings were observed for the relative proton and metal cation (Na^+ and Li^+) affinities of the most basic amino acids and analogues: Arg > DMPO > His > Lys for proton affinities and Arg > His > DMPO > Lys for metal cation affinities. Histidine in particular showed significantly higher relative metal cation than proton affinities as illustrated by the Figure. Moreover, histidine was observed to bind two lithium ions during the spontaneous decomposition of the lithiated heterodimer $[His.Lys+Li]^+$. Analysis incorporating ^6Li demonstrated that this product ion arose from the decomposition of the dilithiated tetramer $[His.Lys+Li]_2^{2+}$, which was not distinguished from the monolithiated heterodimer $[His.Lys+Li]^+$ precursor ion. Differences in relative proton and metal cation affinities for histidine, histidine methyl ester and histidinamide suggested a metal cation interaction involving the amino acid side-chain and the carboxyl or analogous moiety.

MATRIX ASSISTED LASER DESORPTION AT VISIBLE WAVELENGTHS USING A TWO-COMPONENT MATRIX†

D. S. Cornett, M. A. Duncan, I. J. Amster
Department of Chemistry, University of Georgia, Athens Georgia, 30602

In the search for new matrix compounds, recent studies suggest that effective matrix materials must possess several characteristics:[1-4] i) The matrix must absorb the laser light used for desorption. Generally ultraviolet or infrared wavelengths are used because they match electronic or vibrational transitions of the matrix molecule, coupling the energy of the laser into the matrix. ii) Explosive evaporation of the matrix must occur when irradiated by the laser in order to transfer analyte molecules into the gas phase. iii) Protection of the analyte from thermal decomposition following irradiation must be provided by the matrix compound. iv) Finally, matrix molecules must facilitate proton or cation attachment to the analyte. Typically, a matrix consists of a solid or liquid phase of a single compound which is chosen to provide all of the above features. However, evidence suggests that part or all of these properties can be provided by components of a matrix mixture. Using mixtures, it may be possible to choose components which individually optimize the matrix environment.

We have recently discovered a two-component matrix mixture from which we have been able to desorb ions as large as the tetramer of bovine albumin (m/z 265,000 kDa) using 532 nm laser radiation. The matrix mixture utilized in these studies is composed of 3-nitrobenzyl alcohol (3-NBA) and rhodamine 6G (R6G). Typically, 1.5 μl of 10^{-1} M R6G in methanol and 10 μl of 10^{-4} M protein in methanol were mixed with 1 μl of 3-NBA on a 5 mm diameter stainless steel probe tip. After allowing the methanol to dry, the sample was placed in a home-built time-of-flight mass spectrometer for analysis. Ions formed by 532 nm desorption (10^7 W/cm^2, 0.1 mm^2 circular spot) were accelerated to 15-25 keV and allowed to drift a distance of 1.5 m before being detected by an electron multiplier tube. Figure 1 compares mass spectra of bovine insulin obtained by 308 nm desorption from 3-NBA and 532 nm desorption from the 3-NBA/R6G mixture. Readily apparent is that spectral quality does not diminish significantly with desorption at the longer wavelength. Both samples show good signal stability for more than 1000 laser shots per spot as well as enhanced cluster formation. One important difference is the absence of multiply charged clusters when using 532 nm desorption. Figure 2 is a mass spectrum of bovine albumin clusters using 532 nm desorption from the matrix mixture. Again, the spectrum is quite comparable to albumin spectra we have obtained from UV desorption from 3-NBA.

We believe the ionization mechanism to be a strong absorption of 532 nm radiation by R6G ($\varepsilon_{532} \approx 6\times10^4$ l mol^{-1} cm^{-1}) followed by energy transfer to the bulk solution, causing explosive evaporation and protonation of the protein by 3-NBA. Consistent with this, attempts to use either component, R6G or 3-NBA, alone as a matrix for 532 nm desorption have proven unsuccessful. These experiments show that the properties required of a matrix need not be provided by a single compound. The results suggest that the important features of a matrix can be individually optimized, and that further improvements of the matrix assisted laser desorption technique should be possible using this approach.

Design and Construction of a Tandem Time-of-Flight Mass Spectrometer which Utilizes Laser-Induced Photodissociation

*M. A. PUZYCKI, R. D. MCLANE, P. R. VLASAK, AND C. G. ENKE, Department of Chemistry, Michigan State University, East Lansing, MI 48824

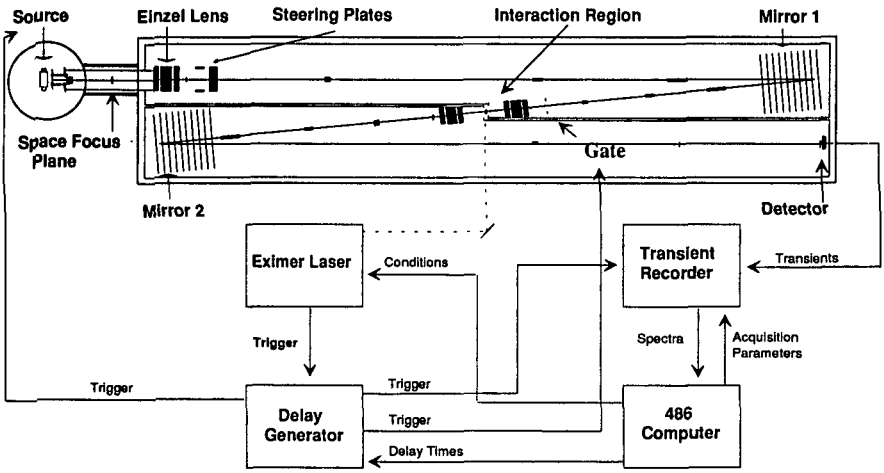

Figure 1

The tandem time-of-flight instrument under construction in our laboratory (Figure 1) was designed to obtain complete MS/MS spectra from compounds eluting from a capillary gas chromatographic column, while maintaining at least unit mass resolution for both parent ion selection and daughter ion analysis. To meet this goal the instrument needs to acquire at least 10 daughter spectra per second. Such speeds require maximum utilization of sample molecules and ions, efficient fragmentation of parent ions, and array detection of the daughter ions produced.

The electron impact source designed for this instrument utilizes two opposing filaments from which electrons are continuously emitted and focused into an ionization region. A potential well is established by a combination of the electron space charge and the potentials applied to the source electrodes. Storage times on the ms time scale have been achieved, providing for an efficient use of sample molecules and a high density of ions in each parent ion packet. An extraction pulse is applied to the rear electrode accelerating the ions out of the ionization region. A second acceleration field allows for focusing the spatial distribution of the ions at a plane just outside of the source.[1]

1. B. A. Mamyrin, V. I. Karataev, K. V. Shmikk, and V. A Zagulin, *Sov. Phys. JETP*, 1973, 37, 45.

Parent ion packets are separated due to their mass dependent velocities. A grid-free ion mirror (Mirror 1) [2] focuses the space-focus-plane image at the interaction region (R=1500). The timing of a 15 ns excimer laser pulse focused at the interaction region will select the desired parent ion. Parent ion packets of all m/z values are 0.8 mm long at the interaction point, while the laser pulse will be focused to a width of about 0.5 mm. An ion of m/z 250 moves 0.3 mm during the 15 ns laser pulse, resulting in complete illumination of the ion packet. Unit resolution for parent ion selection is expected to m/z 1500. All ions reaching the interaction region before the chosen isomass parent ion packet must be gated out to avoid interference.

Laser photodissociation introduces a controllable, mass independent amount of energy into an ion. In addition, since PID is a collision-free process, the velocity distribution of the daughter ions is minimized. Given that PID cross-sections for organic ions are quoted at 10^{-17} to 10^{-19} cm^2 [3], and that photon densities are $6x10^{20}$ cm^{-2} for ArF at 248 nm, calculations indicate that PID efficiencies could approach 100% for some ions.

After fragmentation, the daughter ions have the same velocity as their parent ions, but only a fraction of the parent ion energy. These daughter ions also have a fraction of the kinetic energy distribution of the parent ion packets combined with the kinetic energy distribution acquired in the PID process. Mirror 2 cannot provide both daughter ion mass separation and energy focusing. Acceleration of the ions just following the interaction region, gives the daughter ions mass dependent velocities and reduces the relative range of daughter ion kinetic energies. With a parent ion energy of 500 eV and a secondary acceleration of 1000 eV, the range of energies for a selected parent and its daughters will be 1000 to 1500 eV. For Mirror 2 to achieve perfect energy focusing, the ions should have approximately the same kinetic energy. Thus, the lower the first stage acceleration, and the higher the secondary acceleration, the better the focusing provided by Mirror 2. Simulation using a simple linear mirror indicates that resolving power of the second mass analyzer should yield unit mass resolution for all daughters of parents with m/z as high as 1000.

Daughter spectra will be produced by summation of successive time-array-detected transients using either a LeCroy Transient Recorder or an MSU Integrating Transient Recorder.

Successful implementation of this instrument requires that many functions are accurately and precisely controlled. These include the timing of the source extraction pulse (±1 ns), the opening and closing of the gate (±1 ns), the firing of the laser (±3 ns), and the triggering of the transient recorder (±1 ns). To meet these requirements a LeCroy 4222 delay generator (±2 ns) and a laser pulse synchronizer (reduces jitter and drift to ±2 ns) are utilized and controlled remotely via GPIB interfaces using LabWindow software on a 486 computer.

This system will generate 500 transients per second (limited by the laser). If approximately 50 transients are summed for each daughter spectrum, 10 daughter spectra per second will be produced. With this rate of acquisition a substantial amount of MS/MS information can be obtained for a chromatographically eluted component.

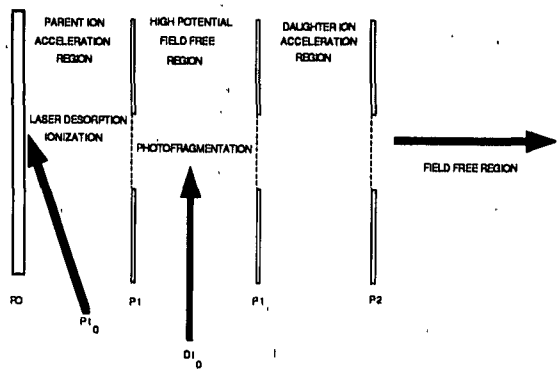
A Novel Method of Performing MS/MS Experiments on a Laser Ionization Time of Flight Mass Spectrometer

Richard C. King and Kevin G. Owens
Department of Chemistry, Drexel University,
Philadelphia, Pennsylvannia, 19104.

Tandem mass spectrometry has proven to be a valuable tool for determination of the primary structure of biomolecules. MS/MS methods have also been used to study important ion formation mechanisms. MS/MS experiments are routinely done on tandem sector and quadrupole instruments as well as ion cyclotron resonance mass spectrometers.[1-3] To date very few attempts have been made to do MS/MS experiments by time of flight mass spectrometry.[4-8]

In this presentation we describe a novel method of performing MS/MS experiments on a laser time of flight mass spectrometer. The focus of the presentation is the theoretical description of MS/MS by laser time of flight mass spectrometry. We will present a detailed explaination of the theory behind the method including consideration of the space and velocity focussing conditions for parent and daughter ions and the instrumental configuration necessary to meet these conditions.

LASER DESORPTION IONIZATION/LASER FRAGMENTATION
TIME OF FLIGHT MASS SPECTROMETRY/MASS SPECTROMETRY
ION SOURCE SCHEMATIC DIAGRAM



The difference between the typical time of flight ion source and the one diagramed here is the addition of the high potential field free region. Fragmentation in a region of electric potential gradient would produce daughter ions with different initial potential energies. Fragmentation in a field free region eliminates this condition.

The separation of the two regions of acceleration by a field free region also allows the selection of the energy given to parents and daughters to be independent of one another. It is this ability that allows the parent ion velocity to be set easily to different values at the time of fragmentation. The ability to easily change the parent ion velocity at the point of fragmentation (or the daughter ion initial velocity) will allow experiments to be performed to establish parent - daughter relationships when more than one parent ion is fragmented.
The discussion to this point has been based on the fact the ions will separate in time and space as they travel to the point at which they are fragmented in the high potential field free region of the ion source. In the case where more than one parent ion is in the volume of the fragmentation laser, the daughter ions formed must be related back to the parent which formed them. The conditions described above provide no means of determining the parent - daughter relationship.

The ion source configuration shown here will provide a means of determining the parent daughter relationship. The velocity of the parent ions at the point of fragmentation is determined by the acceleration in the parent ion acceleration region. This region accelerates the parent ions to equal kinetic energies. The parent ions of different mass will have different velocities. The velocity of the parent upon fragmentation becomes the daughter ion initial velocity. By changing the parent ion acceleration, we change the daughter ion initial velocity and consequently, the daughter ion flight time. Since only the parent ion acceleration is changed, the difference in daughter flight time has to be due only to the change in initial velocity (ie parent velocity). And since the velocity of the parent is a function of its mass, the time differences observed in the daughter time of flight can be related back to the parent from which it was formed Once the parent daughter relationship is established, the daughter masses can be assigned.

An Improved Instrument Design for the Measurement of Surface-Induced Dissociation Efficiency

*T.E. Kane and V.H. Wysocki, Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284;
J. Perel, Phrasor Scientific, Inc., Duarte, CA 91010.

A tandem mass spectrometer built to investigate collisions of polyatomic ions with a surface has been modified to allow determination of the efficiency of surface-induced dissociation. The instrument consists of two Extrel 4000 AMU quadrupoles positioned at 90° with a surface placed to intersect the ion optical path. A special probe and surface assembly has been designed that allows (i) any one of four surfaces to be positioned within the ion path and (ii) rotation of the surface. The surface is usually positioned 45-50° relative to the ion beam from Q_1. Surfaces ranging from smooth metal to self-assembled monolayers of alkane thiols reacted onto vapor-deposited gold have been examined by our group. The three self-assembled monolayers investigated here were prepared by the spontaneous assembly of octadecanethiol, perdeuteroicosanethiol and 2-(perfluorooctyl)-ethanethiol on gold. In many cases, particularly for $CF_3(CF_2)_7(CH_2)_2S$-Au surfaces, the ion neutralization is greatly decreased (70% compared to 99% for stainless steel).

Efficiency can be described as the degree of signal loss after the activation process. Ideally, a measurement of the ion signal both before and after the surface will yield a percent value of lost signal. Unfortunately, the act of measuring can affect the signal's integrity. In this experiment, we calculate surface efficiencies by mechanically altering select lenses into Faraday plates, (figure 1) thereby intercepting the ion current immediately before and after the surface. Advantages to this method are (i) that modifications to the instrument are kept at a minimum and (ii) it is possible to first take a SID spectrum and then measure ion current throughout the instrument without major retuning (figure 2).

The efficiency is described in this experiment as I_3/I_1. It may be possible to map out ion current loss throughout the instrument, including loss caused by focusing problems.

Measuring m/z 2 on a TSQ700: Instrument Modifications and Stability Studies.

Hugh Gregg
Lawrence Livermore National Laboratory
PO Box 808, Livermore CA 94550

We have been using tandem mass spectrometry in the Oil Shale Project at LLNL for almost 10 years. This work has centered around the analysis of pyrolysis gases, enabling us to better understand the chemistry and kinetics of oil shale retorting. Our home-built triple quadrupole mass spectrometer was becoming less able to keep up with our increasing research demands, so we purchased a new instrument and dedicated our original TQMS to the 4 tonne/day pilot scale retort.

One of the pyrolysis products of oil shale is hydrogen. In order to completely characterize the pyrolysis gases, we need to measure and quantify hydrogen. The Finnigan TSQ700 that we purchased has a lower mass range of 10u, so we commissioned Urs Steiner and Alan Schoen (Finnigan engineers) to design and install modifications to enable us to scan m/z 2.

Two problems prevent a stock TSQ700 from observing m/z 2: First, the RF detector in the feedback loop from the collision cell is a passive device, and the potential drop across a diode prevents the RF generator from operating at the low voltages required for m/z 2. Second, the control over RF power in the quadrupoles is too coarse. The RF only units will pass m/z 2 only over a narrow power setting, and good control is needed to optimize parameters at this extreme setting.

The solution to the first problem was to add an active RF detector to the collision cell. This was accomplished by physically cutting the Q3 detector circuit off another card and mounting it "piggy-back" over the passive Q2 detector. To increase the control of the RF circuits, the RF detector capacitors were increased (i.e. the spacers separating the capacitor plates were machined to half length). This increased the gain of the detector circuit, and compensating reductions in gain to the driver circuits were performed (see Figure 1). The net result is twice as many DAC steps are available for tuning, but also a mass range reduced by a factor of two. Some instrument control procedures had to be modified to reflect this reduced range.

Tuning the instrument for very low masses is difficult. Since many of the parameters have an extremely narrow range of acceptable values, it is easy to "lose the beam". In addition, an artifact peak is often present below m/z 1.5. This "peak" is an electronic artifact, and can act similar to a real peak.

The result of these modifications is an instrument that can scan from m/z 2 to 1000 in the low mass range, and up to 2000 in the high mass range (a sample of tris-(perfluoro-nonyl)-s-triazine on a solids probe gave us unit mass resolution at m/z 1485). Figure 2 show two scans from a four hour run of 1% hydrogen (1.9×10^6 counts) in helium (105×10^6 counts) mixture; peak shape, resolution and calibration all remained constant. Figure 3 shows the instrumental drift over four hours; the ratio of intensities changes by only about 5%. Finally, Figure 4 shows how sensitive the instrument is to careful tuning; the individual DAC steps are clearly seen in the insert.

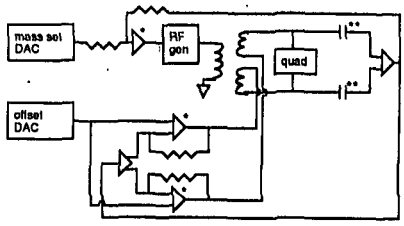

Figure 1: Simplified schematic of the changes made: The RF detector capacitors** were made smaller and the gain of several op-amps* were changed to compensate.

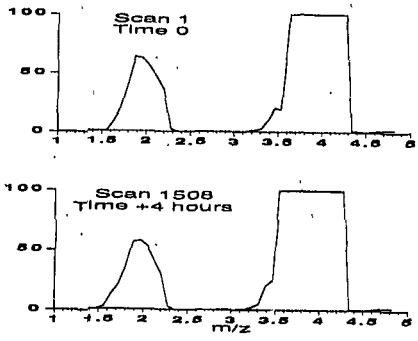
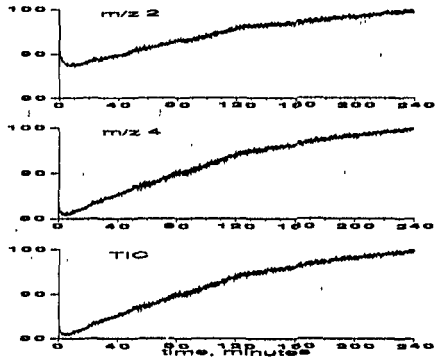


Four hour run of 1% H2 in He
Figure 2



Instrumental drift over 4 hours
Figure 3

Figure 4: The power setting of the RF-only quadrupoles is critical - the signal is only about 25 DAC steps wide.

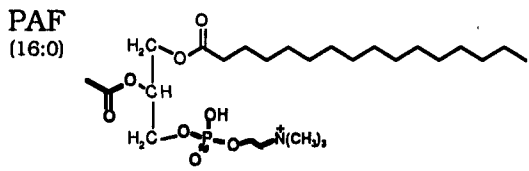
Differentiation, Identification, and Quantitation of Platelet Activating Factor in Complex Phospholipid Mixtures Using Fast Atom Bombardment Triple Quadrupole Mass Spectrometry

Mark J. Cole[1] and Christie G. Enke[2]

[1]*Drug Metabolism Department, Central Research Division, Pfizer Inc, Groton, CT 06340*
[2]*Department of Chemistry and Center for Microbial Ecology, Michigan State University, East Lansing, MI 48824*

A rapid mass spectrometric method for the differentiation, identification, and quantitation of platelet activating factor (PAF) molecular species (Structure 1) in complex phospholipid mixtures has been developed. The method is based on the difference in the dissociation products, obtained during collisionally-activated dissociation (CAD), between PAF and non-PAF phospholipid ions. The phospholipids are desorbed and ionized using fast atom bombardment and dissociated under low-energy CAD conditions in a triple quadrupole mass spectrometer. In the positive ion mode, the protonated molecule of PAF, as with all species of phosphatidylcholines, readily dissociates to lose its phosphocholine head group as a daughter ion (Figure 1a). A parent scan for this ion identifies the masses of the phosphatidylcholine species present in the phospholipid mixture. In the negative ion mode, the methyl-abstracted molecule of PAF produces a dissociation product ion at m/z 59, which represents the O-acetyl group in the *sn*-2 position (Figure 1b). A parent scan for this ion identifies which of the phosphatidylcholine species are PAF species. The dual use of both of these scan modes thus provides differentiation and identification of the PAF molecular species present in a crude phospholipid mixture (Figure 2).



Structure 1. Structure of PAF. The significant structural features are shown in boldface.

Quantitation is performed using a lyso-phosphatidylcholine (1-Caproyl-sn-glycero-3-phosphocholine) as an internal standard and is linear over the 1 ng to 200 ng range measured (Figure 3). The presence of non-PAF phospholipids in the samples did not interfere with the identification or quantitation of PAF, even when these phospholipids were present at concentrations more than an order of magnitude greater than those of PAF. Preliminary results using ionspray ionization suggest a detection limit for PAF of at least 50 pg, which is 200 times lower than that obtained using FAB.

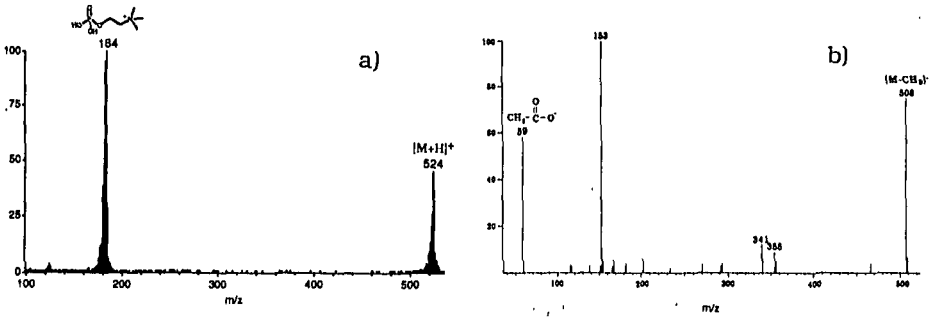


Figure 1. *a)* Positive ion CAD spectrum of protonated PAF showing the ion representing the phosphocholine head group at *m/z* 184. *b)* Negative ion CAD spectrum of methyl-abstracted PAF showing the ion representing the O-acetyl group at *m/z* 59.

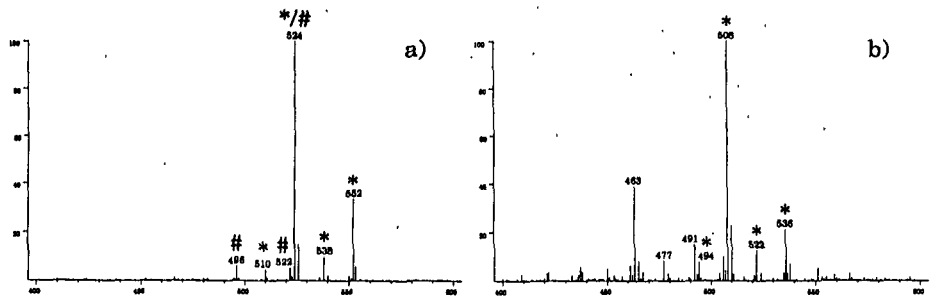

Figure 2. An example of the dual use of positive parent ion scans for the phosphocholine head group, and negative parent ion scans for the O-acetyl group, in differentiating PAF species from lyso-phosphatidylcholine species in a mixture. *a)* Positive parent ion scan for *m/z* 184, which represents the phosphocholine head group. All lyso-phosphatidylcholine species are detected in this spectrum. *b)* Negative parent ion scan for *m/z* 59, which represents the O-acetyl group. The PAF species are differentiated from the non-PAF species in this spectrum. (* = Peaks representing PAF species, # = peaks representing lyso-phosphatidylcholine species)

COLLISION-INDUCED DISSOCIATION OF BREVETOXIN PbTx-3

Harry B. Hines

Toxinology Division, USAMRIID, Ft. Detrick, Frederick, MD
21702-5011

Brevetoxins are a family of neurotoxic, cyclic polyether compounds produced by the dinoflagellate Ptychodischus brevis. One of the toxins, PbTx-3, has received considerable attention because it is moderately toxic to mammals and can be easily radiolabelled by reducing PbTx-2, the aldehyde form of PbTx-3. Mammalian metabolism of PbTx-3 is largely unknown, although efforts have been initiated to elucidate the pathways. In these studies, information obtained by MS/MS will be important. A MS/MS study of PbTx-3 was conducted to investigate the feasibility of molecular characterization.

A Finnigan MAT TSQ 700 instrument was used in the ammonia desorption chemical ionization mode. Argon was used as the collision gas.

At 10 eV (lab frame) and 1 mtorr, only loss of water and ammonia were noted. Increasing the gas pressure to 2 mtorr, but leaving the collision energy constant, enhanced fragmentation to include losses from the terminal side chain of the molecule. These losses accurately indicated the structure of the side chain. Cleavages also occurred in the J and K rings, which provided additional structural information for the side-chain terminus. Large intermediate fragments were also obtained, which helped define the backbone structure. Results obtained for PbTx-2 were different. This brevetoxin fragmented little, even with higher collision gas pressure.

These results demonstrate that MS/MS will be useful for structural studies of PbTx-3 metabolites, especially for the molecular terminus containing the side chain. High relative intensities for some daughter ions indicated that they may be useful for detection and confirmation as well. Loss of the lactone moiety presents the greatest difficulty because this is where ammonia adduction occurs. It will not be possible to detect metabolites where this functionality is lost or modified to the point that it is incapable of adduction or ionization.

Approaches to Enhancing Associative Ion-Molecule Reactions in a Triple Quadrupole Mass Spectrometer

Anthony P. Annacchino, Jr., Jodie V. Johnson and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville, FL 32611

Introduction

The interpretation of how biological macromolecules such as DNA react with potentially hazardous chemicals is of great importance. Our laboratory has demonstrated the ability to detect gas-phase reaction products between carcinogenic electrophiles and model nucleophiles in the collision cell of a triple quadrupole mass spectrometer. Ion-molecule reactions in the collision cell have been used to evaluate the reactivities of a series of mutagenic allyl halides towards several nucleophiles. **Figure 1** shows an example of the associative ion-molecule reaction of cytosine ions and allyl bromide to produce adduct ions typical of those normally observed.

It has been shown that most DNA/RNA bases and nucleosides are reactive with electrophiles of this type. However, some nucleophiles such as adenine react to a very small extent with the allyl halides. Accordingly, studies have been performed that involve trapping ions in the center octapole of a TSQ 70 triple quadrupole mass spectrometer to enhance formation of product ions. By trapping ions for subsequent reactions in Q2, longer reaction times are permitted. This leads to higher sensitivities for some associative reactions.

Description of System

Essentially, ions are trapped in Q2 by varying the potentials applied to the lenses immediately before (L23) and after (L31) the center octapole in a specific and repetitive manner. An illustration of the time profiles of the voltages applied to the entrance and exit lenses is depicted in **Figure 2**. The lens voltages are changed according to TSQ 70 Instrument Control Language (ICL) procedures that were specifically designed to facilitate ion trapping in Q2.

Although there was no difficulty in trapping ions using these procedures, detection of the ion pulse as it exits Q2 required that an external circuit be connected to the L31 200V Lens Driver PCBA. The circuit was designed to control the time that L31 opens by triggering it off the scan pulse. As **Figure 3** illustrates, the circuit allows for detection of the entire ion pulse.

Results and Discussion

Presence of helium buffer gas

The presence of helium in Q2 greatly enhances ion trapping ability, as illustrated in **Figure 4**. This increased ion trapping efficiency is due to several effects that the helium gas has on the incoming ions. The helium buffer gas slows down ions as they enter Q2, thus allowing them to be trapped more effectively. The helium also permits ions to exit Q2 in a much narrower and more intense pulse than without helium, thus allowing the use of a lower multiplier setting for detection, and greater sensitivity.

Q2 Ion Trapping Efficiency Studies

Upon observation of **Figure 5**, it is clear that ions can be trapped in Q2 of the TSQ 70 for long periods of time in the presence of helium buffer gas. Although ion peak heights decrease rapidly at first, ion intensities stabilize quickly with increased trapping time. This suggests that this method of trapping ions for subsequent reactions may increase product ion formation for even the most kinetically hindered associative ion-molecule reactions, allowing for reaction times on the order of several minutes.

Q2 Trapping for Enhancement of Associative Ion-molecule Reactions

It is known that the associative ion-molecule reaction between adenine $M^{+\cdot}$ (m/z 135) ions and allyl chloride normally proceeds to a small extent. Therefore, one would expect that an increase in reaction time would increase product ion formation up to the point of kinetic equilibrium. As seen in **Figure 6**, increasing trapping time does enhance product ion (m/z 176) formation up to a plateau which is presumably where kinetic equilibrium is established. Thus, trapping ions in Q2 for subsequent reactions can increase the generation of product ions.

Macrolides are a class of antibiotics produced by the Streptomyces soil bacteria. Macrolide antibiotics are known for their activity against gram-positive bacteria and *Mycoplasma* pneumonial. While erythromycin is, perhaps, the most commonly prescribed macrolide in the United States, other members of this class have been developed, and are commonly used in other countries. Macrolides are usually detected by the method of bioassay and thin-layer chromatography. In this report, we describe the spectra of these compounds obtained by ESI/MS and ESI/MS/MS and ESI skimmer-induced decomposition.

As part of a study on the structure determination of these compounds by mass spectrometry, we have investigated the MS/MS spectra of a series of these macrolides at high collision energy (8kV, FAB ionization, tandem MS) and at low collision energy (15-20 eV, ESI ionization, Finnigan TSQ-700 triple quadrupole MS equipped with a Finnigan ES interface and source. In addition, we have obtained the skimmer-induced fragmentation spectra of these compounds using a Vestec electrospray source interfaced to a VG 12-250 quadrupole mass spectrometer.

A wealth of structural information can be obtained from the MS/MS spectra of macrolide antibiotics. In ESI/MS analysis of these compounds at low skimmer voltages, very little fragmentation is usually observed, the dominant species usually being the protonated molecular ion. The fragmentations which occur in ESI/MS/MS usually occur between the rings, and thus can often help to localize a substituent onto a given ring. These fragmentations can be enhanced on an ESI/MS instrument by increasing the skimmer voltage. For most of the compounds in this study, a skimmer voltages of +18-25 V gave spectra which most closely resembled the ESI/MS/MS data obtained from the triple quadrupole (Figure 1).

Even more structural detail can be obtained from FAB/MS/MS. In FAB/MS/MS additional cleavages within the sugar ring lead to small but significant peaks which can help localize a substituent to one of two carbons. For example, the mass of the sugar moiety lost in formation of the $[M+H-(S-H)]+$ ions from EMA is 14 mass units higher than in OL due to the presence of the methyl group on this sugar ring. Similarly, comparison of the masses corresponding to the losses S_2 and S_3 for these two compounds locates the methyl group to either C-3" or C-4" (Figure 2).

No information about the location of substituents on the aglycone, however, is provided by the MS/MS data, but the fact that there is a substituent, and its localization to the aglycone can be obtained from the MS/MS data. For example, if ions corresponding to the sugar and the amino sugar are unchanged, or if the losses of the sugar and the amino sugar are unchanged, but the molecular weight has increased, the substituent must be located on the aglycone. For example, Spiramycin I and Spiramycin III differ in mass by a propionyl group, but the FAB/MS/MS data shows that the sugar and amino sugar losses are unchanged, so the proprionyl group must be on the aglycone. Similarly, comparison of the losses giving rise to S_2 and S_3 indicates that the methyl group in EMA is either on C-5" or C-6".

In conclusion, ESI/MS/MS, ESI skimmer-induced dissociation, and FAB/MS/MS all provide useful structural information on macrolide antibiotics. All three techniques can localize a substituent to either one of the sugar rings, or the aglycone. Information from FAB/MS/MS, however, can also give information on substituent position within the ring, to one of two carbons.

Figure 1

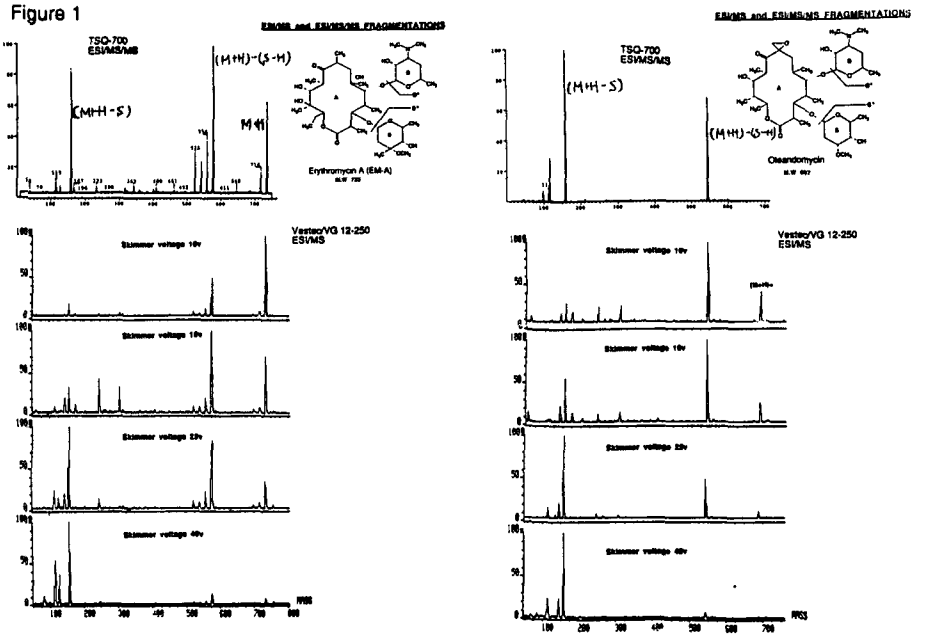

Figure 2

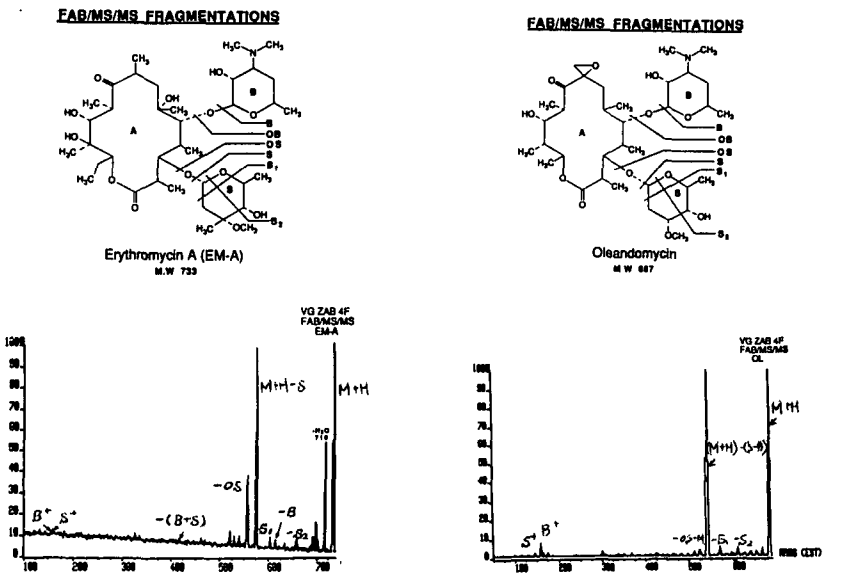

Collisional Activation Spectra of Penicillins and Cephems: ESI/MS/MS and ESI Skimmer-Induced Decomposition

*Y. Shida and K. O'Hara, Tokyo College of Pharmacy, Tokyo, Japan, and
C.E. Parker and K.B. Tomer, Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709

Since the discovery of penicillin in 1928, penicillins and the structurally-similar cephems have become important antibiotics for both human and animal use, effective therapeutic agents against both gram-positive and gram-negative bacteria.

As part of a study on the structure determination of these compounds by mass spectrometry, the MS/MS spectra of a series of 17 penicillins and cephems were examined at low collision energies (15-20 eV, electrospray ionization (ESI), Finnigan TSQ-700 triple quadrupole MS). The resulting spectra were compared with skimmer-induced decomposition spectra obtained using a Vestec electrospray source interfaced to a VG 12-250 quadrupole mass spectrometer.

When ESI was first introduced, it was often described as a gentle ionization technique yielding predominantly protonated molecular ions. While we have found this to be true for larger molecules, some of the smaller molecules we have studied give fragment ions which often contain useful structural information and which allow isomer differentiation. Under ESI/MS conditions, penicillins and cephems exhibit fairly extensive fragmentation, even with a small voltage difference between the skimmer and the nozzle, although abundant molecular ions (or sodiated molecular ions) are still observed.

Two common fragmentation pathways for cephems are loss of the R_4 group (when R_4 is not H), and cleavage across the lactam ring (Figure 1). With higher skimmer voltages, both of these processes occur but increased fragmentation of the sidechain (c,e,f) is also observed. When doubly-charged ions are formed, they are at lower relative abundance in the higher-energy collision spectra. In penicillins, which have no R_4 group, the dominant processes again involve cleavage of the lactam ring. Both the ESI/MS and ESI/MS/MS fragmentation patterns are useful, and give complementary structural information. During the course of these studies, we became interested in the differences observed between the ESI mass spectra obtained on the two different instruments, as well as the differences observed between the ESI/MS/MS spectra and ESI skimmer-induced mass spectra.

In general, the VG12-250 ESI/MS mass spectra show more fragmentation and the VG12-250 skimmer-induced dissociation spectra show more low-mass ions (and more ion abundance in the low-mass region) than do the corresponding TSQ700 ESI/MS and ESI/MS/MS mass spectra. These observations are not unrelated. In the skimmer-induced dissociation process, there is no selection of a particular parent ion. All of the ions in the source can potentially undergo CID, yielding a more complex set of product ions and a mass distribution shifted towards lower masses. This can be seen in the spectra of cefotiam (Figure 2a), where several types of ions are present in the source, and the ESI/MS/MS and skimmer-induced CID spectra are quite different. When there is only one type of ion formed in the source, as is the case for ampicillin (Figure 2b), the ESI/MS/MS and ESI skimmer-induced dissociation spectra are very similar.

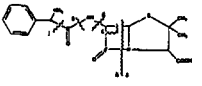
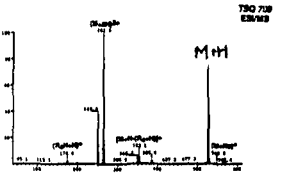
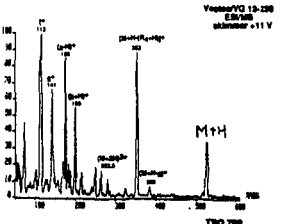
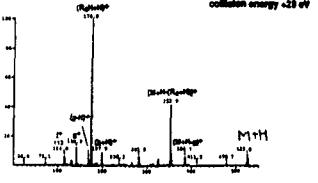
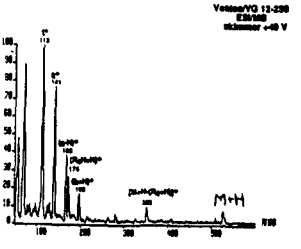
AMPICILLIN











Collisional Activation and LC of Aminoglycosides using FAB and ESI / MS.

John R. Perkins, Leesa J. Deterding, Carol E. Parker and Kenneth B. Tomer,
Laboratory of Molecular Biophysics, NIEHS, Research Triangle Park, NC 27709.

Introduction

The aminoglycosides are a series of natural and semisynthetic drugs which are active against a broad spectrum of microbes. As with other veterinary antibiotics where the half life of the drugs is sufficiently long then the risk of the presence of residues occurs in tissues prepared for human consumption. The low levels at which these drugs may be present necessitates sensitive analytical methodology. The polar nature of these drugs precludes the use of GC methods and their lack of absorptivity hinders the use of UV detection so LC/MS becomes the method of choice.

Our initial experiments involved the investigation of ESI/MS for the analysis of these compounds where the spectra yielded the $(M+2H)^{2+}$ ion as the base peak except for streptomycin which yielded the $(M+2H+H_2O)^{2+}$ ion. Additional fragmentation was obtained with increasing skimmer voltage. We have previously noted that the sensitivity of electrospray is compound dependent and the aminoglycosides seemed to be relatively insensitive. We have also noted that the sensitivity of low molecular weight compounds can suffer greatly due to the presence of cluster ions. Thus the formation of the $(M+2H)^{2+}$ ion becomes something of a disadvantage particularly for neomycin [$(M+2H)^{2+}$=308] and paromomycin [$(M+2H)^{2+}$=308.5] which are obscured by a background cluster of m/z=307.

The problems encountered with ESI/MS analysis of the aminoglycosides combined with our continuing interest in the FAB/MS/MS of biomolecules has led us to investigate the use of collisional activated decomposition of the aminoglycosides with coaxial continuous flow FAB. Coaxial continuous flow FAB utilizes a pair of coaxial fused silica capillaries to independently deliver the flow of analyte and the FAB matrix. This system allows the independent optimization of the analytical mobile phase and the FAB matrix. Coaxial continuous flow FAB is ideal for the acquisition of MS/MS spectra since a high flux of analyte is delivered. This system has been used to acquire CAD MS/MS spectra of the aminoglycosides. We have also performed preliminary experiments investigating LC/coaxial CF-FAB/MS.

Results and Discussion

The aminoglycosides were initially studied using coaxial continuous flow FAB/MS where the $(M+H)^+$ ion was obtained as the spectral base peak together with some fragment ions. We then employed coaxial CF-FAB/MS/MS analysis of the aminoglycosides to obtain additional information from the aminoglycosides For coaxial CF-FAB/MS/MS the aminoglycosides were desorbed as positive ions and then collisionally activated.

CAD spectra of the $(M+H)^+$ ions yielded structurally informative ions. The major ions in the CAD spectra resulted from fragmentations of the glycosidic bonds, labelled A to D on the collisionally activated spectrum of sisomicin (Figure 1). Beyond these simple fragmentations the spectra are widely variable. Neomycin and paromomycin differ by the substitution of CH_2OH for CH_2NH_2 in the neamine portion of the neomycin molecule. The only other diagnostic fragment seen for neomycin results from S_1 cleavage of the neobiosamine B ring whereas paromomycin yields fragments resulting from S_1 and S_2 cleavage of all the sugar rings together with numerous other ions with a relative ion abundance of >10%. Amikacin, a semisynthetic aminoglycoside, contains a long chain substitution on the deoxystreptamine ring. It was found that several fragments resulted from cleavage of a glycosidic bond followed by cleavage down the $NHCOCHOHCH_2CH_2NH_2$ chain. CAD spectra of homologs (streptomycin and dihydrostreptomycin) readily localized the point of substitution in the molecule. During acquisition of FAB/MS spectra the ion resulting from $(M+H+H_2O)^+$ formed the base peak in the spectrum of streptomycin (m/z=600). FAB/MS/MS of this ion also localized the point of addition of water to the molecule.

Ultimately we are interested in the on line LC-MS determination of the aminoglycosides. We present a separation of the gentamicin complex using a gradient from 0 to 10% acetonitrile over 30 minutes (Figure 2). This corresponds to an injection of 9.2 ng of the gentamicin complex which corresponds to an average injection of 20 pmole of each. Analysis of the same mixture by full scan nCLC/ESI/MS where 47 ng was injected on column yielded peaks which were close to detection limits. We are currently investigating the use of higher perfluorinated carboxylic acids to aid

retention of the aminoglycosides.

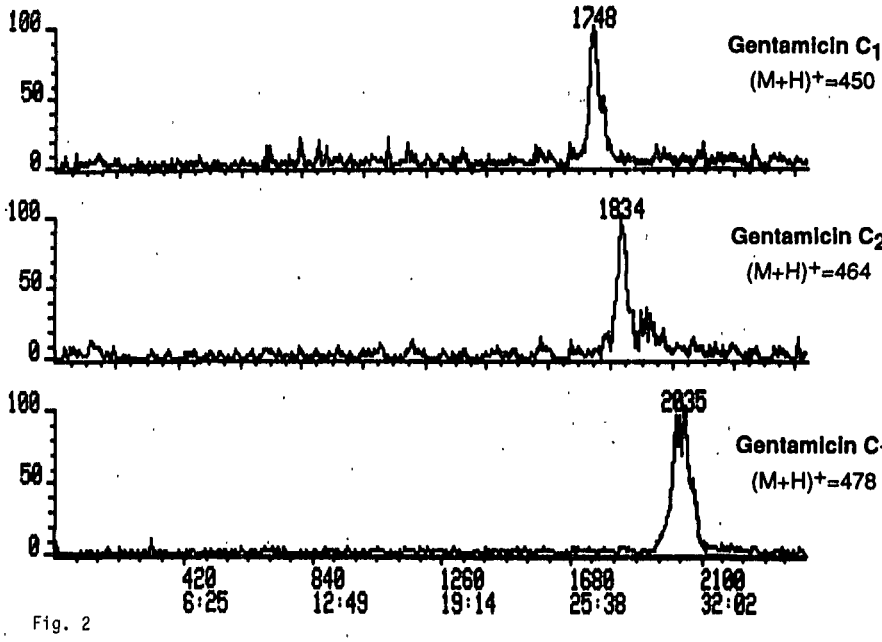

Fig. 2

INVESTIGATION OF THE FRAGMENTATION OF SINGLY- AND DOUBLY-CHARGED IONS OF NEUROMUSCULAR BLOCKING AGENTS USING ELECTROSPRAY/TANDEM MASS SPECTROMETRY

Diane Rindgen and Paul Vouros, Department of Chemistry and
the Barnett Institute, Northeastern University, Boston, MA 02115

Pancuronium and vecuronium bromide (Figure 1) are quaternary ammonium steroids that interrupt the neurotransmitter action of acetylcholine by binding at the cholinergic receptor sites located on skeletal muscle cells. These neuromuscular blocking agents are used clinically to induce muscle relaxation during surgery and to facilitate mechanical ventilation in the intensive care unit. Currently, analytical methodology is available capable of detecting these compounds at the nanogram level in biological samples (1-4). There is the need, however, for further assay development with increased sensitivity and selectivity in order to address issues such as the transport of these compounds across the blood-brain barrier, their presence in cerebrospinal fluid and the potential interactions of the two muscle relaxants. Toward this end, electrospray ionization/mass spectrometry (ESI/MS) and ESI/MS/MS were investigated for detection of these compounds.

CID experiments were performed on a Finnigan MAT TSQ700 triple quadrupole mass spectrometer equipped with an Analytica of Branford, Inc. electrospray ionization source. Sample introduction was by constant infusion at a flow rate of 2.0 uL/min. The sheath liquid consisted of a 50/50 isopropyl alcohol/water solution with 1% acetic acid. Argon was used as the collision gas and the collision energy was 25 - 50 eV. SIR experiments were performed on a VG Quattro triple quadrupole mass spectrometer equipped with a VG electrospray ionization source. A solution of 50/50 acetonitrile/water with 1% acetic acid was continuously infused at a flow rate of 2.5 uL/min. Samples were introduced via a Rheodyne injector with a 0.5 uL internal sampling loop.

The normal scan ESI spectra of pancuronium and vecuronium show characteristic doubly-charged ions identified as $[M - 2Br^-]^{+2}$ (*m/z* 287) for pancuronium and $[M - Br^- + H^+]^{+2}$ (*m/z* 279) for vecuronium. The presence of these two unique doubly-charged ions allows for differentiation of the two compounds. To date, this has not been possible in a single analysis. CID of the doubly-charged ions produces both singly- and doubly-charged product ions resulting primarily from neutral eliminations associated with the acetyl and piperidyl groups. Proposed product ion structures are given in Tables 1 and 2. Similar losses have been observed in high energy metastable decompositions of singly-charged ions of these compounds following thermal dealkylation and chemical ionization (5). The predominant doubly-charged product ion in the CID spectrum of $[M - Br^- + H^+]^{+2}$ of vecuronium corresponds to the loss of acetic acid (*m/z* 250). This product ion appears in the CID spectrum of $^2H_3$-3-acetyl vecuronium suggesting a preferential loss from the 3-position. Four singly-charged product ions at *m/z* 431, 417, 357 and 332 are formed which presumably contain an epoxide functionality. The CID spectrum of the singly-charged, $[M - Br^-]^{+1}$, ion of vecuronium shows losses involving acetic acid occurring at both the 3- and 17-position as evidenced by the appearance of labeled product ions in the CID spectrum of singly-charged (*m/z* 561) $^2H_3$-3-acetyl vecuronium. The CID spectrum of the $[M - 2Br^-]^{+2}$ ion of pancuronium indicates that the combined loss of acetic acid and N-methyl piperidine (*m/z* 207) generates the most intense doubly-charged fragment ion. The *m/z* 287 doubly-charged ion of pancuronium also displays a tendency to undergo unimolecular decomposition in the rf-only collision region of the mass spectrometer. CID of singly-charged, $[M - Br^-]^{+1}$ (*m/z* 653), pancuronium produces an intense fragment ion originating from loss of the second bromide counter-ion and $C_6H_{14}N^+$.

Single ion recording of the $[M - 2Br^-]^{+2}$ ion of pancuronium illustrates the potential for low picogram level detection using ESI/MS. Triplicate injections of 12 pg of material show good reproducibility and a signal-to-noise ration of 4.5 to 1.

In summary, ESI/MS couples the advantage of low level detection with the ability to differentiate between pancuronium and vecuronium bromide thereby expanding the utility of mass spectrometry in studies on the pharmacokinetic and pharmacodynamic properties of the muscle relaxants. We plan to continue this work by evaluating the analytical utility of the above-mentioned transitions to further improve upon the selectivity of this technique.

APPLICATION OF FAB/MS/MS TO THE ANALYSIS OF ACYLCARNITINES FOR DRUG DISCOVERY

Somchai Suwanrumpha, William S. Fillers, Philip A. Bell, Sandor Barcza, and Emil W. Fu
Sandoz Research Institute, Sandoz Pharmaceuticals Corporation, East Hanover, NJ 07936

Fatty acids in the form of fatty acyl-CoAs are oxidized to form acetyl-CoA and acyl-CoAs with 2 fewer carbons, in a sequence of events that includes the action of different acyl-CoA dehydrogenases. Acyl-CoA dehydrogenases are characterized by their optimum activities towards substrates of different chain length, such as long-chain fatty acids (e.g. Oleic acid), medium-chain fatty acids (e.g. Octanoic acid), and short-chain fatty acids (e.g. Butyric acid). The major site of this β-oxidation is in the mitochondria. Fatty acyl-CoAs must be converted to acylcarnitines in order to cross the mitochondrial inner membrane. Many potential drugs are designed to inhibit the activity of these acyl-CoA dehydrogenases. Inhibition of a particular acyl-CoA dehydrogenase will lead to the accumulation of fatty acyl-CoAs of a particular chain length as well as their corresponding acylcarnitines. We have developed a FAB/MS/MS procedure to determine acylcarnitines in hepatocyte samples that were incubated with these potential drugs.

Acylcarnitines were analyzed as their methyl ester derivatives. The FAB/MS/MS experiments were developed by modifying the method described by Millington et al (1). The daughter ion MS/MS experiments for any acylcarnitine methyl ester cations yield a common fragment ion at m/z 99. This ion (m/z 99) which represents the $^{+}CH_2$-CH=CH-CO_2CH_3 moiety was used to determine its precursors in parent ion MS/MS experiments. Deuterated acetyl- (C_2), octanoyl- (C_8), and palmityl- (C_{16}) -N-[C^2H_3] carnitine methyl esters were used as internal standards.

The parent ion MS/MS spectrum of a control without drug hepatocytes incubated sample shows a prominent ion at m/z 218 which corresponds to acetylcarnitine (C_2) cation (Fig. 1). Ions that correspond to other longer chain acylcarnitine cations are not observed. This sample represents a complete β-oxidation process of long chain fatty acid (oleate, $C_{18:1}$), that was introduced into the cells, to acetyl-CoA (C_2). The ions at m/z 221, 305 and 417 are the M^+ of [$^2H_3$]acylcarnitine internal standards. The ion at m/z 239 arises from a compound that is not acylcarnitine but it also yields a daughter ion at m/z 99.

Figure 2 is the parent ion MS/MS spectrum from hepatocytes incubated with an agent designed to inhibit the activity of long-chain acyl-CoA dehydrogenase (optimum activity against long-chain fatty acyl-CoAs). The spectrum shows the accumulation of $C_{18:1}$ (m/z 440), C_{16} (m/z 414) and $C_{16:1}$ (m/z 412) acylcarnitines. Figure 3 is the parent ion MS/MS spectrum from hepatocytes incubated with an agent designed to inhibit the activity of medium-chain acyl-CoA dehydrogenases. The spectrum shows ions at m/z 384 and 358 which correspond to $C_{14:1}$ and C_{12} acylcarnitines. For the MS/MS spectrum of the sample that was incubated with the agent designed to inhibit the activity of short-chain acyl-CoA dehydrogenases, ions corresponding to short-chain acylcarnitines (C_4 and C_2) were observed.

The good reproducibility of the ion intensities can be achieved by adding isotopically labeled [$^2H_3$]-acylcarnitine internal standards. The coefficient of variation for the relative intensity of each detectable acylcarnitine was better than 3% (n=5) when normalized to the relative intensity of [$^2H_3$]-acylcarnitine.

Conclusion

A modified FAB/MS/MS procedure was developed to determine acylcarnitines in isolated hepatocyte incubation extracts. The procedure was used to analyze the effect of a number of pharmacological agents affecting fatty acid oxidation. Good reproducibility for this procedure can be achieved with suitable isotopically internal standards. The major advantages of this procedure are the simplicities of sample preparation and the speed of sample analysis. The sample preparation is minimal and the analysis time for the MS/MS experiment is less than 5 minutes per sample.

Acknowledgment

We thank Dr. Edwin B. Villhauer for the synthesis of isotopically labeled acylcarnitine internal standards, Dr. Laszlo Revesz for the synthesis of the investigational drugs, and Ms. Carol Dragland for the sample preparation.

METAL ION EFFECTS ON FRAGMENTATIONS OF ANIONIC COMPLEXES OF PEPTIDES THAT CONTAIN PROTIC SIDE CHAINS

Hong Zhao and Jeanette Adams, Department of Chemistry, Emory University, Atlanta, GA 30322.

Collision-induced decomposition (CID) of gas-phase $(M + Cat^{2+} - 3H)^-$ complexes (1) between peptides that contain either Asp, Glu, Tyr, His or Trp and the alkaline earth metal ions Mg^{2+}, Ca^{2+}, and Ba^{2+} were studied. In addition, some experments with the transition metal ions Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+} were performed.

Fragmentations of complexes that contain Mg^{2+}, Ba^{2+}, and Ca^{2+} are the same, but product ion abundances change. The relative abundances of $(c_{n-m} + Cat^{2+} - 2H)^-$ ions increase with increasing size of metal ion. In general, the highest mass C-terminal $(y_{n-l} + Cat^{2+} - 2H)^-$ ions also increase in abundance, while lower mass $(y_{n-m} + Cat^{2+} - 2H)^-$ ions decrease with increasing size of metal ion. CID spectra of YGGFLK display the changes, and the relative product ion abundances are reported in Table I.

Table I. % Abundances of $(c_{n-m} + Cat^{2+} - 2H)^-$ and $(y_{n-m} + Cat^{2+} - 2H)^-$ Product Ions in CID Spectra of YGGFLK and Alkaline Earth Metal Ions

metal ion	c_2	c_3	c_4	c_5	y_4	y_5
Mg	0.028	0.19	0.46	ND	0.47	0.091
Ca	0.085	0.54	0.67	0.12	0.26	0.18
Ba	0.20	0.86	0.86	0.12	0.39	0.20

Changes in relative abundances of $(c_{n-m} + Cat^{2+} - 2H)^-$ product ions with changing size of alkaline earth metal ion are different in cases in which the peptides contain binding sites that are specific for Ca^{2+} (see Table II). For example, it is proposed that Pro can help to arrange the binding site in the sequence -Asp-Val-Pro- so that it is specific for Ca^{2+} (2). The data in Table II show that ADVPAA complexes indeed decompose to give more abundant $(c_4 + Ca - 2H)^-$ ions (cleavage between the Pro and Ala residues) than $(c_4 + Mg - 2H)^-$ and $(c_4 + Ba - 2H)^-$ ions. AADVPA complexes, however, decompose to give less abundant $(c_3 + Ca - 2H)^-$ ions (cleavage between the Asp and Val residues) than $(c_3 + Mg - 2H)^-$ and $(c_3 + Ba - 2H)^-$ ions. This is because in the latter peptide, Pro is not involved in the binding site that gives rise to the $(c_3 + Ca - 2H)^-$ ions.

Table II. % Abundances of $(c_{n-m} + Cat^{2+} - 2H)^-$ Product Ions in CID Spectra of ADVPAA and AADVPA

peptide	metal ion	c_3	c_4
ADVPAA	Mg		0.63
	Ca		0.91
	Ba		0.76
AADVPA	Mg	0.091	
	Ca	0.083	
	Ba	0.12	

To compare alkaline earth metal ions to transition metal ions, gas-phase positive $(M + Cat^{2+} - H)^+$ and anionic $(M + Cat^{2+} - 3H)^-$ complexes between the transition metal ions Mn^{2+}, Fe^{2+}, Co^{2+}, and Ni^{2+} and peptides that contain protic amino acids were also studied. Positive $(M + Cat^{2+} - H)^+$ complexes that contain transition metal ions decompose, in general, to give the same types of product ions as those that contain alkaline earth metal ions (3). *Anionic* complexes that containing the transition metal ions, however, fragment to give significant different spectra and fragment ions. One example that demonstrates this is shown in Figure 1 for complexes between YGGFL and Ca^{2+} vs. the transition metal ions.

Structure Elucidation of a New Thiostrepton Type Antibiotic, Sch 40832

Birendra N. Pramanik, Mohindar S. Puar and Kwokei J. Ng, Schering-Plough Research Institute, 60 Orange Street Bloomfield, N.J. 07003

In the course of screening for novel pharmaceutically active microbial products from fermentation of soil microorganisms, the structure of a thiostrepton-type antibiotic, Sch 18640 was reported[1]. This report describes the structure elucidation of another novel sulfur containing peptide antibiotic, Sch 40832.

Sch 40832 (I) is the minor component of the antibiotic complex (also referred to as 13-384 complex) produced by Micromonospora Carbonacea var. Africana ATCC 39149. Taxonomy, fermentation, and isolation studies were reported[2] previously . Solvent extraction of the fermentation broth followed by chromatography afforded two everninomicins (Sch 27899 and 27900), chloramphenicol, Sch 40832, a diketopiperazine and other minor components. The structural elucidation of everninomicins Sch 27899 and 27900 have recently been reported[3] including in vitro antibacterial activity[4] of Sch 27899. Extensive spectral studies were carried to establish the structure of Sch 40832.

The molecular weight of Sch 40832 was established as 1940 based on FAB-MS, Cs^+-LSIMS, PD-MS and Ion-Spray-MS data. The positive ion Cs^+ liquid secondary ion mass spectrum of (I) (Figure 1) in thioglycerol-DMSO with 0.1% TFA displayed intense ions at m/z: 1941, 1942 and 1943; m/z 1941 represented the protonated molecular ion for the compound. Peak-matching Cs^+-LSIMS experiment using CsI as a reference provided an accurate mass of 1941. 6219 which corresponded to an elemental composition of $C_{84}H_{105}N_{18}O_{26}S_5$ (1941.6205 calculated) for compound (I). The isotope pattern of the molecular ion region of Sch 40832 (Figure 1) matched very well with the computer generated isotope profile of $C_{84}H_{105}N_{18}O_{26}S_5$ (see Figure 2).

MS/MS experiments of m/z: 1941 $(M+H)^+$ using ion-spray method generated a limited number of daughter ions at m/z: 1811, 1680, 1663, 1608, 1465 and 1209. The intense ions at m/z 1811 and 1680 corresponded to the successive loss of sugar units from the parent ion. This data is consistent with the results obtained from the normal FAB MS data (Figure 1).

In the proton NMR spectrum, all directly coupled protons in the molecule were assigned on the basis of the anlysis of 2D (^1H-^1H) D2 cosy and cosy LR. The homonuclear Hartman-Hahn (HOHAHA) experiment was utilized to delineate an entire proton spin system, e.g., the two units of the disaccharide moiety.

Carbon-13 NMR data, edited on the basis of an APT experiment, were analyzed by comparison with the data of thiostrepton and Sch 18640. The assignments of protonated carbons were confirmed by a 2D (^1H-^{13}H) heteronuclear correlation experiment. The assignments are presented in Table 1.

The presence of a methyl triplet at δ 0.99, coupled to a methylene residue at δ 1.55, 1.68, was assigned to thiostrepton (Thstn 10) 5-CH_3. The lack of further correlation confirmed that the ethyl moiety is connected to the quarternary carbon at position 4. The glycosidic bond was established at C-3 of Thr (1) on the basis of chemical shifts, which also led to the assignment of the 1,3 linkage between the sugars, tentatively assigned as B.D. Chromose A and B. The spectral data is consistent with the structure (1) in Figure 3.

Structural Studies of Isepamicin and its Analogs with Fast Atom Bombardment/Tandem Mass Spectrometry

*K.J. Ng, B.N. Pramanik, and P.R. Das
Schering Plough Research Institute, Bloomfield, New Jersey 07003

Isepamicin (Sch 21420) and its various analogs are a new class of aminoglycosides (1-N-(S)-3-amino-2-hydroxy-propionyl, HAPA, derivatives) derived from Gentamicin B. It has a broad spectrum of antibiotic activity against both Gram positive and Gram negative bacteria. It possesses biological properties which surpass those of gentamicin and amikacin [1-2]. Aminoglycosides are non-volatile and thermally labile. Earlier reports of mass spectrometric analyses of these types of compounds utilized techniques such as field desorption[3], chemical ionization [4], and emitter chemical ionization [5]. In this report we studied the high energy and low energy collision activated dissociation (CAD) spectra of isepamicin and its analogs to discern ion fragments that characteristically indicate the location of substituents in various analogs.

Low energy (12-40 eV) CAD spectra were obtained with a triple quadrupole mass spectrometer using a saddle field FAB gun with xenon atoms at 6 KV, ion source temperature of 50 °C, and a collision cell pressure of 2.2-2.4 millitorr. Argon was used as the collision gas. The samples were dissolved in glycerol/thioglycerol and aqueous triflouroacetic acid matrix. High energy (8 KeV) mass-analysed ion kinetic energy spectroscopy (MIKES) spectra were obtained with a double focussing mass spectrometer using Cs+ Ion Liquid Secondary Ion MS ionization with helium as the collision gas.

For low energy CAD, characteristic cleavages occurred at glycosidic linkages between the cyclitol units. Intense ions were observed from the garosamine, deoxystreptamine and 6-amino-6-deoxy-glucopyranose units of the molecules as well as ions derived from the loss of the outer cyclitol units from the protonated parent molecules. The high energy CAD MIKE spectra showed higher intensity of ions resulting from the loss of smaller fragments from the molecules. Representative high energy and low energy CAD spectra are shown in Figures 1 and 2. Results indicate that the combination of low and high energy CAD spectra obtained with FAB/SIMS ionizations are useful for the characterization of this class of compounds. CAD spectra of gentamicin B will also be discussed.

Analysis of Sulfonated Dyes and Optical Brighteners by Continuous-Flow FAB and Tandem Mass Spectrometry.

Anthony J. Borgerding and Ronald A. Hites
School of Public and Environmental Affairs and Department of Chemistry
Indiana University, Bloomington, IN 47405

Introduction. Interest in azo dyes has increased recently due to studies showing them and their metabolites to be potential carcinogens. These compounds are widely used in the textile industry, and millions of pounds are discharged with textile mill effluents each year. Many recent studies have described the analysis of these compounds by such techniques as LC-MS, CZE-MS and LC-MSMS, using a variety of ionization sources. We describe here the use of various collisionally-induced dissociation pathways to simultaneously analyze groups of dyes using parent-ion and neutral-loss scans. This simultaneous analysis allows samples to be analyzed by directly injecting them into the flow entering a continuous-flow fast-atom bombardment probe, bypassing chromatographic separation. Some of the dissociative pathways upon which these methods are based are common to many different dyes, while other pathways are unique; this creates a group of methods with varying levels of specificity.

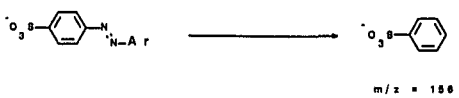
We also present here preliminary tandem mass spectrometric studies on optical brighteners. Several compound types are classified as optical brighteners, including coumarin derivatives and distyrylbiphenyls, but the most common brighteners used in the detergent industry are bistriazylaminostilbenedisulfonic acids. Until now, analysis of these compounds was limited to thin layer and high performance liquid chromatography. Our analysis of stilbene optical brighteners by CFFAB-MSMS have shown interesting fragmentation patterns that could be useful in developing specific analytical methods for these compounds.

Instrumentation. All analyses were done on a VG 30-250 triple quadrupole mass spectrometer equipped with a modified FAB source and continuous-flow FAB probe. The Ion Tech FAB gun was run using xenon atoms with 8 kV translational energy. For tandem mass spectrometry experiments, the collision gas was SF_6 held at a pressure of 1.0 mtorr as measured by a Baratron capacitance manometer. The CFFAB carrier solvent of water, methanol, and glycerol (50:45:5) was pumped into the mass spectrometer at a rate of 5 μL/min by an Isco μLC-500 syringe pump; 0.5 μL injections were made through a Valco CI4W valve.

MSMS Methods for Azo Dyes. Analysis by product-ion scans of the $(M-Na)^-$ ions for several different sulfonated azo dyes revealed typical fragmentation patterns and several product ions common to many dyes. The SO_3^- ion was found in the product-ion spectra of all sulfonated dyes. However, since this ion forms from the collisionally induced dissociation of nearly all sulfonated compounds, it is not specific for dyes. Instead, we used two other product ions and a neutral loss that are specific for sulfonated azo dyes.

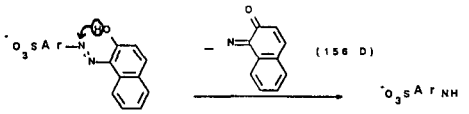
The most general of the methods is based on an azo cleavage of dyes containing an unsubstituted benzenesulfonate group to form a product ion at m/z 156 as shown in Scheme 1. Scanning the parents of this product ion detects all of the compounds containing the unsubstituted benzenesulfonate moiety.

Scheme 1



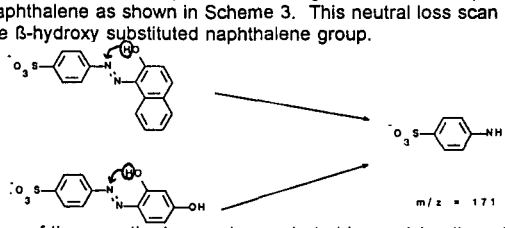
It was noticed that some, but not all, of the dyes containing this moiety also formed a product ion containing a monovalent nitrogen at m/z 171. The formation of this ion includes the transfer of a proton from a hydroxy group located at the ß-position relative to the azo linkage as shown in Scheme 2. Deuterium labelling studies have proved that the hydroxy group is indeed the source of the transferred proton. Scanning the parent ions of the ion at m/z 171 gives a signal only for compounds containing an unsubstituted benzenesulfonate group and a hydroxy group at the ß-position.

Scheme 2



Another specific method dependent on a hydrogen transfer from a ß-hydroxy group is scanning the neutral loss of mass 156. This corresponds to the fragmentation of compounds containing a ß-hydroxy substituted naphthalene as shown in Scheme 3. This neutral loss scan is therefore specific for dyes containing the ß-hydroxy substituted naphthalene group.

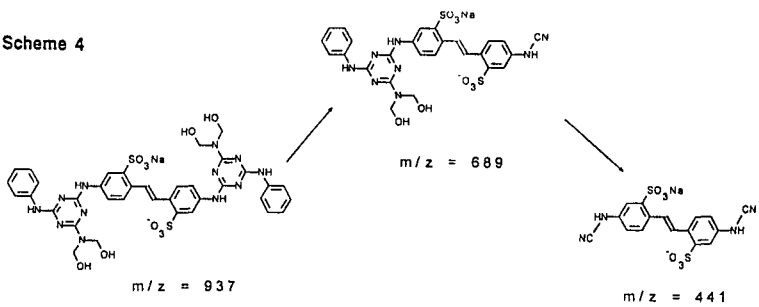
Scheme 3



The effectiveness of these methods was demonstrated by applying them to a mixture of eight azo dyes. As expected, the methods based on hydrogen transfer were the more selective than the parent-ion scan of m/z 156, which is based on a simple azo cleavage. Because no chromatographic separation was required, the analysis of all the compounds in the mixture took less than 5 minutes. It was noticed that 4 of the dyes, Acid Red 151, Acid Orange 6, Mordant Yellow 7, and Mordant Yellow 10, did not respond as well in the mixture as when they were analyzed separately. The other dyes in the mixture, Acid Orange 7, Acid Orange 8, Acid Red 88, and Metalin Yellow, were not affected. These latter four dyes are more surface active since they contain polar character on only one side of the molecule, while the dyes that were suppressed have polar character on both sides of the molecule, which lowers their surface activity and their ionization efficiency.

MSMS Analysis of Optical Brighteners. Product-ion scans were done on the $(M-Na)^-$ ions of bistriazinylaminostilbenedisulfonic acids that were found in commercial detergents. Under collisionally-induced dissociation, the triazine groups are broken open sequentially to form cyanamides as shown in Scheme 4. The ion at m/z 441 is common to all brighteners of this type, which should allow all of these compounds to be analyzed simultaneously by scanning the parents of this ion.

Scheme 4



CHARGE REMOTE FRAGMENTATION IN THE DISULFIDE-CONTAINING PEPTIDE, [PEN]-ENKEPHALIN, UNDER FAST ATOM BOMBARDMENT-COLLISIONALLY ACTIVATED DISSOCIATION CONDITIONS.

Yoon-Seok Chang[2], Douglas A. Gage[2], J. Throck Watson[1,2], Departments of Chemisty[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824

The challenge of complete sequence elucidation of peptides containing one or more disulfide bonds by FAB-collisionally activated dissociation-tandem mass spectrometry (FAB-CAD-MS/MS) is frequently more difficult than that presented by linear peptides because the disulfide bond interferes with the formation of sequence-related fragment ions. It is apparent that more detailed studies of the fragmentation behavior of disulfide-containing peptides is necessary to establish guidelines for better interpretation of the FAB-CAD-MS/MS spectra of unknowns. The conformationally restricted, cyclic, disulfide-containing enkephalin analog [2-D-penicillamine, 5-D-penicillamine]-enkephalin ([Pen]-enkephalin) has been chosen for the studies of mechanistic features of fragmentation under FAB-CAD-B/E (linked-scan) conditions.

Under CAD conditions, the unreduced protonated molecule of [Pen]-enkephalin (m/z 646) yields a relatively large number of fragment ions (Figure 1). The intense peak at m/z 352 represents b_3 ion formation together with reductive cleavage of the disulfide bond (-S-S-). Most of the peaks in the CAD spectrum, however, represent fragmentations of the peptide backbone with "unsymmetric" cleavage of the disulfide bond with charge retention on the N-terminus; the fragment ions generally do not contain a sulfur atom or a disulfide group.

In the cluster of peaks around m/z 234, peaks at m/z 233 and 234 are assumed to represent ions derived from the protonation of an amide-nitrogen, followed by cleavage of that peptide bond together with b-carbon cleavage of the side chain bond of a residue (here, $-(CH_3)_2C-S-$). The peak at m/z 235, however, is assumed to represent an ion formed by protonation of the N-terminal amine, followed by concomitant bond cleavages between carbon-carbon and carbon-sulfur atoms through the symmetry-allowed, concerted 1,4-elimination mechanism (Scheme 1).

This proposal of a charge-remote fragmentation mechanism was collaborated by "fixing" a positive charge at the N-terminus of the molecule, as had been done in fragmentation studies of linear peptides (1,2). The CAD spectrum (Figure 2) of the N-terminal ethyl-triphenylphosphonium (ethyl-TPP) derivative, on the other hand, shows few fragment ions and is dominated by the peak at m/z 523. This dominant ion also results from "unsymmetric" cleavage and corresponds to the analogous protonated species (m/z 235) in the spectrum of the underivatized peptide (Figure 1). Because location of a fixed positive charge at the one end of peptide induces charge remote fragmentation predominantly, this fragment ion should come from the charge-remote, 1,4-elimination mechanism as discussed for the underivatized molecule and illustrated in Scheme 1.

INVESTIGATION OF C-TERMINAL AMINO ACID EFFECT ON FRAGMENTATION OF N-PROTECTED TRIPEPTIDES BY HYBRID MS/MS

[1]Brenda L. Schwartz, [2]G. Dean Marbury, [1]Bruce W. Erickson, [1]Maurice M. Bursey

[2]Triangle Laboratories of RTP, Inc., Research Triangle Park, NC 27709

INTRODUCTION

The investigation of rearrangement ions in MS/MS spectra resulting from side chain interactions can provide insight into the conformations of gaseous peptide ions since they require the interaction of parts of an ion that are not contiguous. To address the relationship between the types and intensities of MS/MS products formed and proton transfer among side chain groups, a set of N-protected tripeptides, N-Cbz-Gly-Leu-Xxx-OMe and N-Cbz-Gly-Pro-Xxx-OMe, where Xxx = Arg, Lys, Orn, Glu, and Gln, was studied using FAB MS/MS on a hybrid tandem mass spectrometer. The importance of basicity and chain length of the C-terminal group in altering observed decompositions, specifically the loss of benzyl alcohol (108 Da) from the $[M + H]^+$ was explored through unimolecular and CAD processes as a function of collision energy.

RESULTS AND DISCUSSION

Consistent with previous results from our laboratory[1] on similar N-protected tripeptides with C-terminal arginine amides, the $[M + H - 108]^+$ fragment predominates in the MS/MS spectra of the proline peptides versus the leucine analogues (Figure 1). For example, the intensity of this ion in the CAD spectra for Cbz-Gly-Pro-Arg-OMe at E_{lab} = 10 eV is 26% compared to an abundance of 3% for the leucine peptide (Table 1). The suggested lowest energy mechanism for the benzyl alcohol loss involves contact[2] between the Cbz group and the end of the side chain of the C-terminal residue. The presence of proline opens another pathway for ion formation because of its higher proton affinity. Additionally, the basicity and chain length of the C-terminal residue also affect the formation of the $[M + H - 108]^+$ ion, with the loss being promoted by a more basic and longer chain length amino acid at the site (Figure 2). For example, under CAD at E_{lab} = 5 eV, the ion intensites are 20%, 10%, 5%, 3% and <1% for the Arg, Lys, Orn, Gln, and Glu proline peptides, respectively. The only noticeable trends with increasing collision energy were evident in CAD spectra with intensities of the $[M + H - 108]^+$ ions decreasing to $\leq$1% at 50 eV for all peptides.

EXPERIMENTAL

Cbz-Gly-Leu(Pro)-Xxx-OMe with Xxx = Arg, Lys, Orn, Glu, Gln were synthesized by coupling Cbz-Gly-Leu-OH or Cbz-Gly-Pro-OH (Bachem Bioscience, Inc.) with the appropriate C-terminal amino acid derivative using standard solution phase methods.

FAB mass spectra were obtained on a VG 70-250SEQ instrument (EBqQ) interfaced to a VAX Station 3000 data system, with 8 kV in MS-I. A cesium ion gun was operated at 30 kV (5uA emission), with glycerol matrix and 5-ul sample volumes. Product ion spectra were acquired in the MCA mode scanning from m/z 50 to 500 with the accumulation of 10 scans. Four collision energies were chosen ranging from 5 to 50 eV with CAD conditions at Ar pressures of 5×10^{-5} mbar.

Calibration Point for Measurement of MS/MS Spectra in Quadrupole Collision Cells

Krishnan R. Mohan and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, GA 30332-0400
Alan E. Schoen and Nigel Gore, Finnigan MAT, 355 River Oaks Parkway, San Jose, CA 95135

The reproducibility of MS/MS spectra depends on a number of instrumental factors, including collision gas pressure, collision energy, and rf tuning. Instrument-independent MS/MS spectra are a pre-requisite in order to compare these spectra, or to develop a database similar to the one available for EI mass spectra. Several protocols have been suggested for measurement of instrument-independent MS/MS spectra, but many of these can involve instrument parameters far removed from modes used in day-to-day operation. We suggest here a simple method for establishing standard instrument conditions for measurement of daughter ion MS/MS spectra from parent ions produced by both EI and FAB, two of the most prominent ionization methods. The independence of MS/MS spectra obtained under standard conditions was established by measurement of spectra on two separate instruments in different laboratories, and over a course of several years with a number of instrument operators.

A VG70SEQ hybrid mass spectrometer of EBQQ geometry and a Finnigan MAT TSQ700 triple quadrupole mass spectrometer were tuned to a set of MS/MS conditions using the PFK reference point described below, and then product ion MS/MS spectra were recorded for a number of different compounds under these standard conditions. The source pressure was 5 x 10^{-6} torr for both EI and FAB methods. Standard electron ionization conditions were used. Air was used as the collision gas for MS/MS experiments. Indicated pressures on the ionization gauge range from 10^{-5} to 10^{-6}mbar. However, the actual collision gas pressure within the cell is higher, and is quite likely within the millitorr range.

The ion at m/z 231 ($C_5F_9^+$) from Perfluorokerosene (PFK) is selected as the parent ion, and subjected to collision-induced dissociation. The relative intensities of daughter ions at m/z 69, 131 and 181 are monitored as a function of collision energy (eV) while keeping the target gas pressure constant somewhere within the range of 10^{-4} to 10^{-6} torr (measured), or a beam attenuation of approximately 30 to 70%. The collision energy at which the intensities of m/z 69 and m/z 181 are equal is defined as the calibration point at that collision gas pressure. The intensity of the product ion at m/z 131 is approximately the same at this calibration point (Fig. 1).

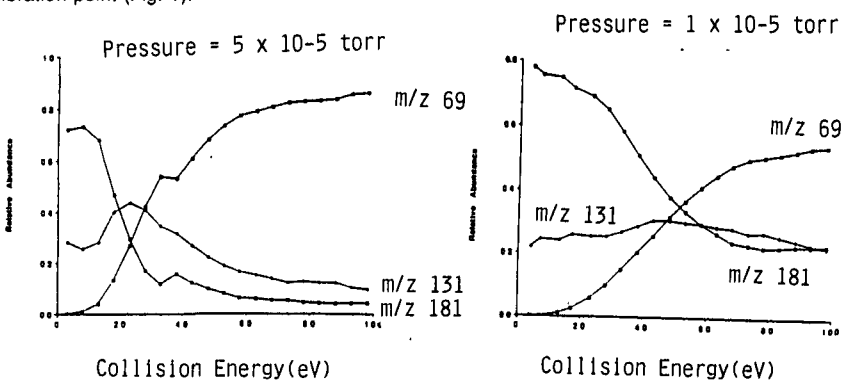

Fig. 1 **Variation of calibration point with collision gas pressure**

However, there is no overt requirement for the three intensities to be rigorously identical at the "isobestic" point. The lab collision energy at which the product ion intensities become equal increases, as expected, with a decrease in collision gas pressure. On a day-to-day basis, with the same indicated collision gas pressure, the reproducibility of the actual collision energy value was 1-2 eV. However, inter-laboratory reproducibility is far more significant in assessing the validity of the calibration point. MS/MS spectra from molecular ions of several different classes of compounds taken using the two different instruments at the calibration point were compared (Fig. 2). A quantitative comparison of these spectra was done by averaging the relative intensity ratios for the most abundant peaks (usually six to eight peaks were selected). Spectral similarity ranged from 90-95% for most test compounds. A small change in either direction from the calibration point collision energy does significantly increase or decrease the relative abundances of fragment ions; this high dependence is exactly what is desirable in a calibration measurement.

With the demonstrated success of the EI MS/MS calibration point, a study was carried out to find a suitable calibration procedure for FAB MS/MS. Among many compounds examined, only glycerol was found to provide a reproducible and easily identifiable pattern with appropriately spaced fragment ions. After calibrating the mass axis of the mass analyzer with cesium iodide, the ion at m/z 369 from glycerol is selected as the parent ion and is collisionally activated under conditions very similar to those used for EI as described above. The product ions at m/z 93, 185 and 277 are monitored as a function of collision energy at a constant target gas pressure. The collision energy at which m/z 93 and m/z 277 becomes equal is defined as the calibration point. The reproducibility of the calibration point was good and similar to EI mentioned earlier. Inter-laboratory studies with FAB MS/MS have not yet been completed.

In this work, a simple procedure for obtaining instrument-independent MS/MS spectra using EI and FAB is described using commonly used calibration compounds (PFK for EI and glycerol for FAB) as well as easily attainable instrument conditions. EI MS/MS spectra taken at the calibration point using two different instruments show good reproduciblity for many of the test compounds. Similar results are anticipated for FAB MS/MS as well. The comparability makes the data meaningful as well as a basis for a common database, similar to the one available for EI mass spectra.

Germany

Introduction

Alcohols such as Methanol or Ethanol are common solvents for the extraction of drugs from plants with Soxhlet extractors. The present paper describes the detection and identification of artefact compounds generated during the extraction process of flower heads of *Arnica Montana*. Fast Atom Bombardment Mass Spectrometry (FAB/MS) and Tandem Mass Spectrometry (MS/MS) are used for this analysis. The combination of both techniques allows the unequivocal identification of mixture components without prior separation.

Results

The FAB mass spectrum of the investigated alkaloid extract shows besides the glycerol cluster ions at *m/z* 93 and 185, major ions at *m/z* 70, 130, 144 (base ion), 200 and 241. The elemental composition of these ions were determined by peak match technique.

The MS/MS spectrum of the major constituent 2-Pyrrolidine acetic acid methyl ester with the $[M+H]^+$ ion at *m/z* 144 shows daughter ions at *m/z* 43, 59, 70 (base ion) and 85 which can be correlated with the structure of 2-Pyrrolidine acetic acid methyl ester. The *m/z* 130 ion is missing in the daughter ion spectrum while it appears in the standard FAB spectrum. This leads to the conclusion that the *m/z* 130 ion derives from the free 2-Pyrrolidine acetic acid ($[M+H]^+$). And indeed, the MS/MS spectrum of *m/z* 130 mainly shows the loss of 60 ($C_2H_4O_2$) to *m/z* 70.

Traces of 2-Pyrrolidine acetic acid anhydride (*m/z* 241) are formed at the same time. The protonated dimer of the 2-Pyrrolidine acetic acid methyl ester $[M_2H]^+$ at *m/z* 287 is created as an artefact of the FAB/MS experiment. Daughter ion spectra of both precursors show ions being characteristic of the corresponding structures.

The comparison of these results with data of an extraction with Acetone/Water confirms the hypothesis that the methyl ester of 2-Pyrrolidine acetic acid is generated during the extraction with methanol as solvent.

The parent ion spectrum of *m/z* 70 shows that all ions above 70 are correlated to it with the exception of *m/z* 200. The daughter ion spectrum of *m/z* 200 and the daughter ion spectra of the derived daughter ions *m/z* 182, 168 and 122 show structural elements of Tussilagin ($[M+H]^+$ at *m/z* 200, Fig. 1). This structure was additionally confirmed by TLC and NMR data.

Summary

FAB/MS/MS has shown to be a powerful method for a fast and reliable confirmation of proposals for structures in mixtures of unknown alkaloids. The applications shown here demonstrate, how easy classes of compounds can be determined by high resolution and tandem mass spectrometry. The use of a hybrid tandem mass spectrometer allows the evaluation of empirical formulas and fragmentation pathways without prior chemical derivatization.

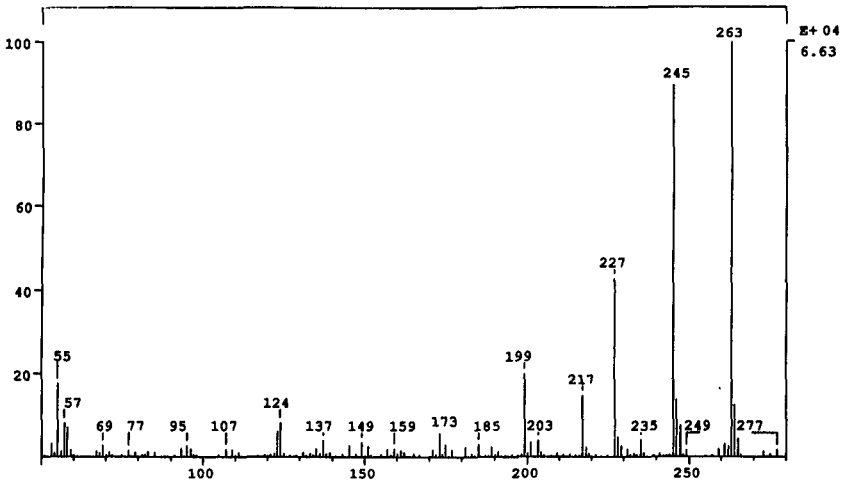

Fig. 1: CI/MS spectrum of Helenalin. Reactant gas: methane, inlet system: PBI, loop injection.

Liquid Chromatography

Column:	Millipore Nova PAK RP-18, 5 µ, 125 × 4 mm
Mobile phase:	Methanol (A)/ water (B)
Gradient:	0-2 min 45% A 2-4 min 45% A → 50% A 4-24 min 50% A
Injection volume:	20 µL corresponding to 20 µg raw extract or 200 ng of single standards.
UV detection:	225 nm
Temperature of the desolvation Chamber:	45° to 50°
Helium flow rate into the PBI interface:	1 mL/min

Preparation of the raw extract

Pulverized flowerheads (1g) of *Arnica montana* were extracted two times in 50 mL of 50% methanol at 60° C for 30 min. The two extracts were filtered, combined, and 1.5 mL of 0.1% Santonin in methanol were added. After a reduction to 50% (evaporation of the methanol), the aqueous residue was shaken three times with 100 mL ethyl acetate. These solutions were combined and dried over Na_2SO_4 and evaporated to dryness.

An MS/MS Method for Distinguishing the Regioisomeric Phenolic Metabolites of GR38032; Daniel L. Norwood, John S. Walsh, Satinder K. Sethi, Dixie L. Fisher; Glaxo Inc. Research Institute, Five Moore Drive, P.O. Box 13960, Research Triangle Park, NC 27709.

INTRODUCTION

GR38032 (1,2,3,9-tetrahydro-9-methyl-3-[(2-methyl-1H-imidazol-1-yl)methyl]-4H-carbazol-4-one) is a new $5HT_3$ antagonist indicated for the treatment of nausea and vomiting in certain patients undergoing cancer chemotherapy. It is metabolized in both rats and man to at least three phenolic metabolites differing only in the position of the hydroxy group. The electron ionization mass spectra of these regioisomers are very similar with no fragmentation processes of value in assigning the position of hydroxylation.

An MS/MS method has been developed for metabolite characterization, capable of distinguishing the primary hydroxy metabolite at sub-picomole levels in biological samples. The method is based on the difference in fragmentation of the molecular ion formed in EI when subjected to collision induced dissociation in either a triple quadrupole or hybrid mass spectrometer. The collision induced fragmentation processes of the EI-produced ions were compared with those from the protonated molecular ions formed by chemical ionization, liquid SIMS, and thermospray.

EXPERIMENTAL

The four hydroxy isomers of GR38032 were studied using electron ionization, chemical ionization (methane and isobutane reagent gases), thermospray (0.1% trifluoroacetic acid/CH_3CN 70/30 mobile phase), and liquid SIMS (glycerol matrix). Product ion CID spectra were obtained at 50-70% beam suppression (argon) and typically 35 eV collision energy.

Patient urine samples were incubated with glucuronidase, acidified, and extracted using BondElut CN solid phase extraction cartridges. Eluent was evaporated to dryness and reconstituted in CH_3CN prior to analysis.

RESULTS AND DISCUSSION

The EI mass spectrum of the four hydroxy derivatives are very similar, the only distinguishing feature being a small peak at m/z 123 in the 8-hydroxy species. Product CID scans of the molecular ion (m/z 309) also contains m/z 123, which was shown through accurate mass measurement and CID experiments to contain the imidazole portion of the molecule. The fact that this ion is seen only in the 8-hydroxy isomer indicates that the position of the hydroxyl group in the benzenoid ring is controlling fragmentation at the other end of the molecule.

Soft ionization techniques thermospray, chemical ionization and liquid SIMS were evaluated for usefulness in isomer differentiation. Chemical ionization mass spectra showed significant m/z 123 from all four isomers. Product ion CID spectra of the $[M+H]^+$ ions did not include significant m/z 123, from any of the three soft ionization techniques. Neither the mass spectra or product ion CID spectra were isomer-specific.

The basis of an EI method for monitoring the presence of the 8-hydroxy isomer was established. A limit of detection of 14 pmol was demonstrated by monitoring the transition m/z 309 to 123. Application to real samples was shown with patient urine samples using MCA data acquisition of m/z 309 product ions.

CONCLUSIONS

Low energy CID of EI-generated ions can be used to differentiate the 8-hydroxy GR38032 isomer from isomers at the 5, 6, and 7 positions. Experiments under soft ionization conditions were found not to be useful for isomer differentiation. The basis has been established for a method for detection of the primary hydroxy metabolite of GR38032 in biological fluids, with limits of detection in the low pmol range. Effectiveness for use with real samples has been demonstrated in a patient study.

CHARACTERIZATION OF *Z*-BLOCKED ISOMERIC DIPEPETIDES BY FAST ATOM BOMBARDMENT TANDEM MASS SPECTROMETRY AND KINETIC ENERGY RELEASED MEASUREMENTS

Ezio Mammoliti, Giovanni Sindona* and Nicola Uccella
Dipartimento di Chimica, Università della Calabria I-87030 Arcavacata di Rende (CS), Italy

The loss of chiral purity in the formation of the peptide bond is usually assessed by preparing di- and tripeptide models and checking their diastereomeric composition by means of a wide variety of analytical procedures.[1,2,3] The diastereomers of phenylalanyl-phenylalanine (Phe-Phe) and alanyl-phenylalanine (Ala-Phe) bearing the benzyloxycarbonyl (*Z*) and methyl protecting groups at the N- and C- terminal positions, respectively, have been chosen as model dipeptides for FAB-MS/MS investigations.[4]

The FAB spectra of the positive (+) ions obtained from m-nitrobenzyl alcohol (NBO) solutions of Z-(S)-Phe-(S)-Phe-OMe (**1a**), Z-(R)-Phe-(S)-Phe-OMe (**1b**) and of the alanine (Ala) derivatives Z-(S)-Ala-(S)-Phe-OMe (**1c**), Z-(R)-Ala(S)-Phe-OMe (**1d**) display abudant peaks due to CO_2 elimination from the correspondent $(M+H)^+$ species. Carbon dioxide elimination represents one of the competitive reaction undergone by the protonated molecular ion of carbobenzoxy aminoacids.[5] A structural rearrangement should be involved in the CO_2 elimination process from the ionized dipeptides **1a-d** which could be better evidenced from the unimolecular dissociations of the slow reacting species. The MIKE spectra of the $(M+H)^+$ precursors at *m/z* 461 obtained from compounds **1a** and **1b** (figure) display two main product ions at *m/z* 429 and 417 due to formal losses of methanol and carbon dioxide, respectively.

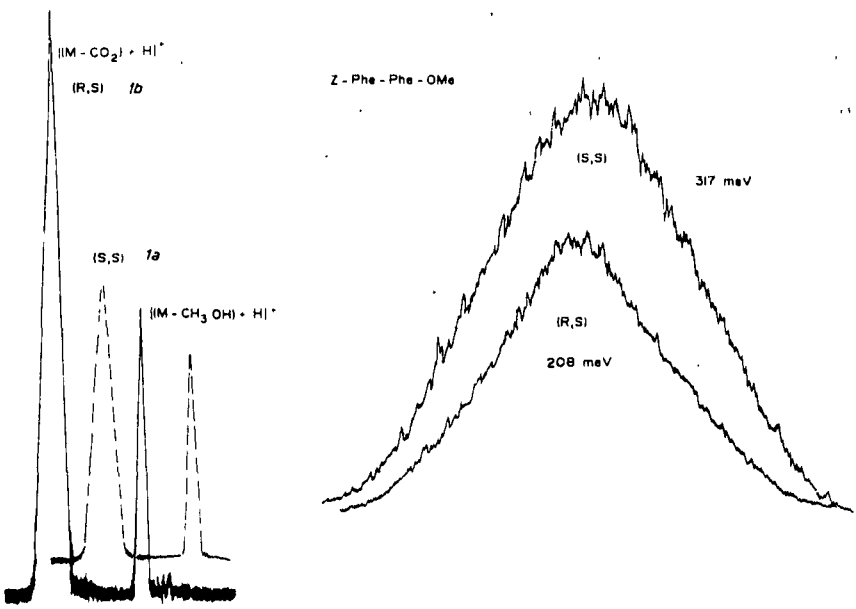

Figure. MIKE spectra of (S,S) and (R,S) *Z*-Phe-Phe-OMe dipeptides

The peak shapes associated to the formation of this species suggest that these two competing processes are characterized by the releasing of a different amount of kinetic energy (KER) which is partitioned also as a function of the stereochemistry of the reactants. The elimination of methanol from the ester function is a straightforward process , whereas the decarboxylation reaction , which is associated to a larger KER, has been investigated in more details in order to provide a rationale for the different behaviour of the two isomeric dipeptides. The evaluation of the reaction paths leading to *m/z* 417 has been accomplished by determining the spontaneous and collisional activated dissociations of this product ion, with reference to the gas-phase chemistry of the $(M+H)^+$ species produced by FAB from NBO solutions of either the N-benzylated (Bn) dipeptide Bn-(S)-Phe-(S)-Phe-OMe or N-benzyl-(S) phenylalanine methyl ester The MS/MS data allow to conclude that $(M+H)^+$ions produced by FAB from dipeptides **1a** and **1b** expell CO_2 units through two competing pathways which lead to two isobaric species, the most abundant being the protonated form of phenylalanyl-N-(benzyl)-phenylalanine, which requires a benzyl migration to the amidic nitrogen. The $(M+H)^+$ species at m/z 385 of the dipeptides Z-(S)-Ala-(S)-PheOMe (**1c**) and Z-(R)-Ala-(S)-PheOMe (**1d**), take, in the unimolecular dissociations, reaction paths similar to those verified for the species **1a** and **1b**. The MIKE and MIKE-CAD spectra of the $[(M-CO_2)+H]^+$ ions at m/z 341 show that **1c** and **1d** undergo decarboxylation mainly through a benzyl migration from the uretane to the amidic nitrogen. The elimination of CO_2 from all the examined species is, therefore, assisted by the migration of the labile benzyl group from the carbobenzoxy moiety. When this rearrangement involve the amidic nitrogen an highly ordered transtition state is required which brings this atom close to the benzyl carbon of the urethane group. The obtainment of the appropriate transition state configuration is affected by steric hindrances due to the dipeptide side chains. The KER value of 317, 208, 256 and 208 meV measured for the elimination of CO_2 from**1a**, **1b** **1c** and **1d**, respectively, points out that a release of sterical constrains is achieved when the N-terminal aminoacid bears a less bulky side chain group, i.e. methyl with respect to benzyl. It also shows that in the decarboxylation of Z-blocked dipeptides, a migration of the uretane benzyl group to the amidic nitrogen is preferred when the conformational equilibria needed to achieve the appropriate transition state geometry are not hindered by steric repulsions. When butyloxycarbonyl protected (Boc) dipeptides were examined, the known[6] tendence of this urethane group to undergo a preferred elimination of isobutene did not allow the differentiation of the (S,S) and (R,S) diastereomers.

The different relative heights of the main product ions displayed by the MIKE spectra of isomeric *Z*-Phe-Phe-OMe dipeptides can be used, therefore, in the assessment of the stereochemical control in the formation of the peptide bond by chemical synthesis.

Structural Characterisation of Glycosylceramides by Tandem Mass Spectrometry

Jonathan M. Curtis[1], Jan Holgersson[2], Peter J. Derrick[1], and Bo. E. Samuelsson[2]
[1]Institute for Mass Spectrometry and Dept. of Chemistry, University of Warwick, Coventry,UK.
[2]Department of Medical Biochemistry, University of Gothenburg, Sweden.

There is a need in glycobiology to have sensitive and structurally specific methods capable of distinguishing between isomers of glycosphingolipids(GSL's) and carbohydrates in general. Carbohydrate structures, for example, can act as receptors for leukocyte adhesion molecules and for microbial ligands including bacteria, bacterial toxins and viruses. Blood group ABO and related antigens are of carbohydrate nature. In order to understand the interactions of these species and their counterparts at the molecular level it is essential to develop methods to fully characterise their structures.

Recently, we have studied permethylated-reduced derivatives of GSL's by "in-beam" EI-MS and EI-MSMS using a 4-sector instrument (Kratos Concept IIHH). Although molecular ions of GSL's are only very weak in the EI spectra, intense immonium ions are observed which are due to loss of the alkyl group from the long chain base(LCB) with retention of the alkyl group from the acyl moiety (fatty acid, FA). As a result of heterogeneity in both the carbohydrate and fatty acid moieties, the resulting mass spectra are very complex so that it is essential to use MS/MS techniques to increase the level of structural information and to determine isomeric structures. To date this approach has been successfully applied to hexaglycosylceramides using a point detector[1], and extended to a heptaglycosylceramide structure using array detection[2]. The results presented here form part of a systematic study of the fragmentation modes of these fatty acid containing immonium ions, from porcine GSL's. It is envisaged that this will prove invaluable in the future identification of unknowns.

Great diversity in ceramide species is achieved by variations in the alkyl chain lengths and the degree of hydroxylation of the fatty acid and the long chain base. A structure containing a hexose plus non-hydroxy FA is isobaric with one containing a deoxyhexose plus hydroxy-FA. However, the MS/MS spectrum readily identifies the presence of a hydroxylated FA since two major fragment ions arising by cleavage α and β to the immonium ion double bond (eg. m/z 380 and 396 for a hydroxy 22:0 FA) differ by 30 units between hydroxy and non-hydroxy FA variants. Other ions are also characteristic eg. there are two series' of ions arising from charge remote fragmentations along the alkyl chain, which also differ by 30 mass units between the two forms.

The variation in FA chain length can be used to advantage in the interpretation of the spectra. The MS/MS spectra of two species differing only by their FA chain length, show identical fragmentation from the carbohydrate end, but fragmentation from the FA end results in a mass shift corresponding to the difference in alkyl chain length. Thus, fatty-acid containing fragment ions are easily recognised.

There is little change in the modes of fragmentation observed as the carbohydrate chain length is increased from one to three. The FA fragmentation remains unchanged, and a series of cleavages along the carbohydrate chain with retention of charge on the nitrogen atom are observed. These are dominated by cleavages of the hexose ring incorporating the ring oxygen and C1 .

N-Acetyl Hexosamine residues (HexNAc) are common constituents of glycoconjugates and so the effect of their presence on the MS/MS spectra is of importance. As has been noted previously[3], cleavage at the HexNAc glycosidic bond results in an oxonium ion in high abundance. In addition, cleavages along the carbohydrate chain are dominated by processes resulting in charge being localised on the HexNAc residue. This is in contrast to the case where only hexose residues are present , where fragmentation is directed towards charge retention at the ceramide N.

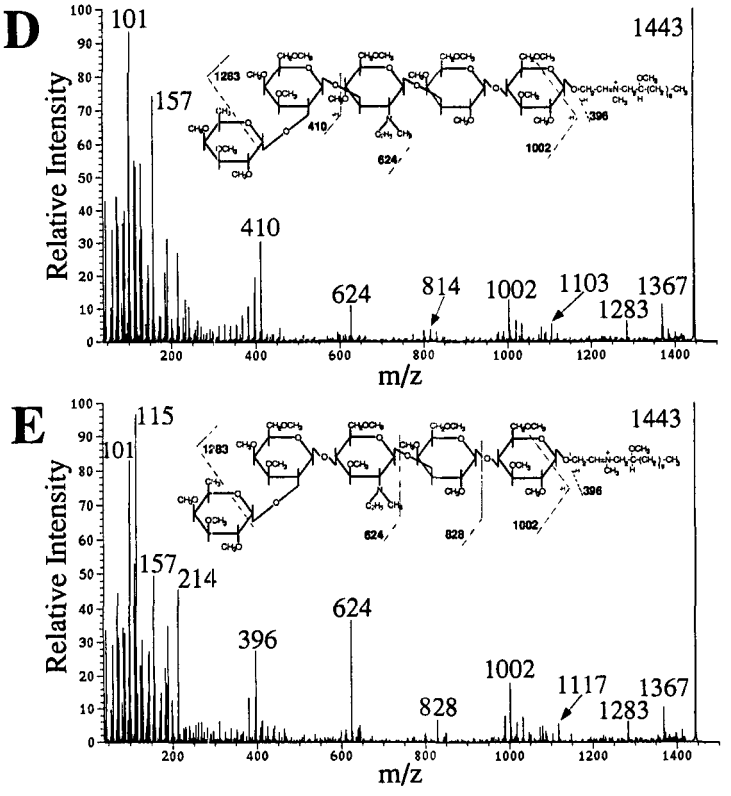
Fragmentation specific to linkage position maybe observed, as with the following isomeric structures

D Fucα(1→2)Galβ(**1→3**)**GlcNAc**β(**1→3**)-Galβ(1→4)Glcβ(1→1)-Ceramide

E Fucα(1→2)Galβ(**1→4**)**GlcNAc**β(**1→3**)-Galβ(1→4)Glcβ(1→1)-Ceramide

Compounds **D** and **E** differ only in the linkage position between the sub-terminal galactose and N-Acetylglucosamine residues {(1→3) or (1→4)}. However, the spectra are quite distinct, **D** giving a major fragment at m/z 410 which is absent in the spectrum of **E**. There are also large differences in the relative intensities of the low mass fragments, eg. m/z 115 is the base peak in E but only 50% of the intensity of m/z 101 in **D**. Other differences at higher mass are also observed eg. m/z 814 is absent for **E** . The mechanisms of these fragmentations have yet to be established.

FOUR SECTOR TANDEM MASS SPECTRA OF THE IMMONIUM IONS OF THE PERMETHYLATED-REDUCED PENTAGLYCOSLYCERAMIDES D AND E USING AR COLLISION GAS AND A COLLISION ENERGY OF 4KEV



Conclusions

Tandem mass spectrometry can provide structural information relating to carbohydrate sequence, location of hexosamine residues, linkage positions, and fatty acid composition from the immonium ions of glycosylceramides. Detailed studies of these fragmentations provide essential guidelines for elucidation of unknown structures. Currently, the limiting factor is one of sensitivity (especially for compounds having five sugar residues or higher) rather than structural specificity.

MECHANISTIC INVESTIGATIONS INTO THE FORMATION OF *N*-ACETYLCYSTEINE CONJUGATES OF 1,2-DIBROMO-3-CHLOROPROPANE: APPLICATION OF FAST ATOM BOMBARDMENT TANDEM MASS SPECTROMETRY AND GAS CHROMATOGRAPHY-MASS SPECTROMETRY

Gregory L. Weber, Rick C. Steenwyk, and Paul G. Pearson.

Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001.

The haloalkane nematocide, 1,2-dibromo-3-chloropropane (DBCP) was used extensively as a soil fumigant prior to the observation of oligospermia and infertility in male pesticide formulators exposed to DBCP. In experimental systems DBCP is a carcinogen, nephrotoxin, testicular-toxin and is mutagenic to *Salmonella typhimurium* TA 100. DBCP is known to interact with glutathione (GSH) to produce GSH conjugates that are excreted in urine, following additional biotransformation, as *N*-acetylcysteine conjugates. The initial metabolic event in the formation of these metabolites may be direct conjugation of DBCP with GSH or *via* conjugation of a cytochrome P-450 generated reactive intermediate. Here we report the identification of four *N*-acetylcysteine conjugates of DBCP by mass spectrometry and employ a *per*-deutero- analog of DBCP (D_5-DBCP) as a mechanistic probe to address the metabolic events in the formation of these conjugates.

Experimental: *N*-Acetylcysteine conjugates excreted in the urine of male Sprague-Dawley rats administered DBCP (80 mg/kg) or D_5-DBCP were converted to their methyl ester derivatives, separated by HPLC and examined by fast atom bombardment tandem mass spectrometry (FAB/MS-MS). FAB/MS-MS spectra were recorded on a Finnigan TSQ-70 triple quadrupole mass spectrometer. Samples were desorbed from a glycerol matrix using a saddle field Xenon fast atom gun operating at 8 keV. Collision-induced dissociation (CID) product ion and precursor ion spectra were recorded following CID in the 'rf-only' quadrupole (Q_2) employing argon as a collision gas (0.85 - 1mTorr). Molecular ions (MH^+) of metabolites were identified using precursor ion scans of m/z 176. Product ion spectra of the MH^+ species were obtained for the structural elucidation of the DBCP derived *N*-acetylcysteine conjugates. Those fractions having mass spectral characteristics indicative of mercapturic acids were converted to their *tert*-butyldimethylsilyl derivatives and analyzed by GC-MS. Separations were performed on a 20m x 0.18mm DB-17 column. The GC was interfaced to a Nermag R1010 single-stage quadrupole mass spectrometer operating in the full-scan electron ionization mode (70eV).

Results and Discussion: Four urinary *N*-acetylcysteine conjugates derived from DBCP were identified as: *N*-acetyl-*S*-(3-chloro-2-hydroxypropyl)cysteine (**I**), *N*-acetyl-*S*-(2,3-dihydroxypropyl)cysteine (**IIa**), an apparent regioisomer of **IIa** (**IIb**), and *N*-acetyl-*S*-(3-hydroxypropyl)cysteine (**III**). Under CID conditions characteristic fragment ions were observed for all the DBCP mercapturates arising from fragmentation on either side of the cysteinyl-sulfur to afford characteristic ions at m/z 176 and m/z 144 (Figure 1a). As a consequence precursor ion scans of m/z 176 were employed to: (1) Screen crude HPLC fractions for the presence of mercapturates and (2) Determine deuterium retention in *N*-acetylcysteine conjugates derived from D_5-DBCP (Figure 1b & 1c). Further characterization of *N*-acetylcysteine conjugates was accomplished by GC-MS allowing separation of regioisomeric metabolites **IIa** and **IIb**. Under GC-EIMS conditions the methyl ester *t*-butyldimethylsilyl ether derivatives of the DBCP mercapturates also displayed characteristic fragment ions. All the mercapturates showed a prominent M^+-57 fragment (loss of a *t*-butyl radical), as well as a fragment resulting from cleavage on the cysteine side of the sulfur atom (m/z 144). This approach was complementary to FAB/MS-MS and facilitated the assignment of the regiochemistry of metabolite **III**. Metabolites **I**, **IIa** (Figure 1) and **IIb** displayed quantitative retention of deuterium, an observation consistent with the formation of an episulfonium ion intermediate. Metabolite **III**, however, showed the retention of only three atoms of deuterium, implicating the involvement of cytochrome P-450 in its biogenesis (Figure 2).

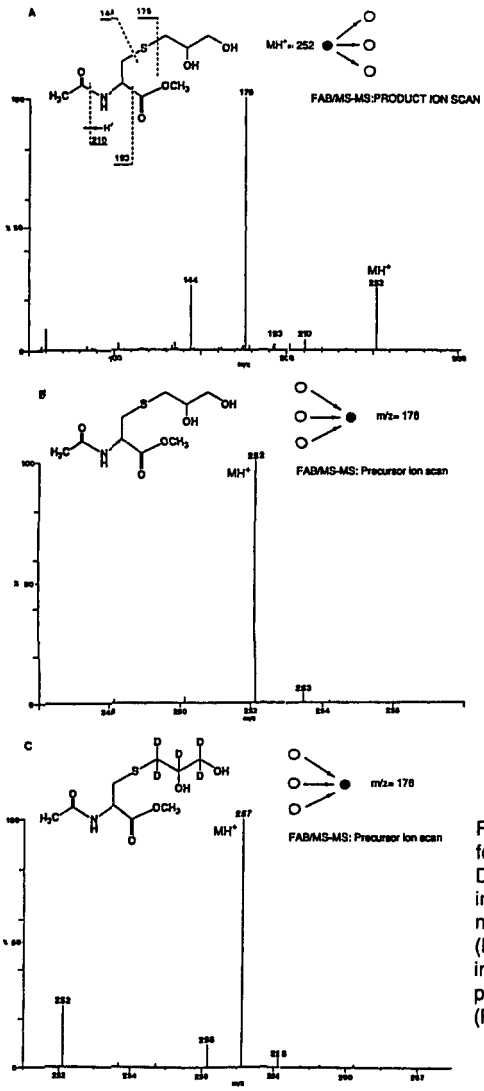

Figure 1. FAB/MS-MS spectra of **IIa** (methyl ester). (A) Product ion spectrum obtained by CID on MH^+= 252. (B) Precursor ion spectrum of m/z 176 from a rat dosed with D_0-DBCP. (C) Precursor ion spectrum of m/z 176 from a rat dosed with D_5-DBCP, illustrating quantitative retention of five atoms of deuterium from D_5-DBCP.

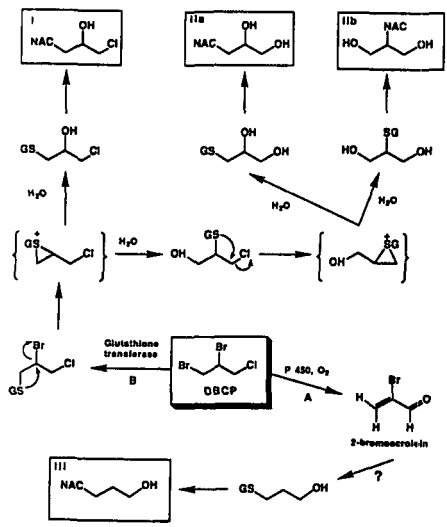

Figure 2. Proposed metabolic scheme for the formation of four *N*-acetylcysteine conjugates of DBCP. **I**, **IIa** and **IIb** may be formed *via* the intermediacy of reactive episulfonium ions, with net retention of deuterium from D_5-DBCP (Pathway B). **III** is formed by a mechanism involving retention of three atoms of deuterium possibly *via* the intermediacy of 2-bromoacrolein (Pathway A).

MASS SPECTROMETRY OF 2-THIENYL SUBSTITUTED BETADIKETONATE COMPLEXES OF SOME TRANSITION METALS.

With β-ketoenolate ligands the transition metals chromium, cobalt and rhodium form trivalent kinetically inert, neutral β-diketonate complexes, which are soluble in organic solvents. Their geometrical isomers (formed with unsymmetrical ligands) are separable by HPLC.

The positive ion EI mass spectra of some β-diketonate complexes of the type $Met^{III}(RCOCHCOC_4H_3S)_3$ have been examined with a VG7070E-HF double sector mass spectrometer (EB geometry). When Met = Cr the complexes are thermally stable and, in their mass spectra, abundant molecular ions are observed when R = CH_3, *t*-C_4H_9, CF_3, C_4H_3S or C_6H_5. This is also true when Met = Rh and R = CH_3 or *t*-C_4H_9 (the only Rh complexes studied). For complexes of Co^{III}, CoL_3^+ molecular ions were not detected. For these complexes the observed species of highest *m/z* was CoL_2^+.

Decompositions of ions collisionally activated prior to the electric sector were identified by product ion linked scan mass spectra (E/B constant) for selected precursor ions. Accurate mass measurements were made to determine the elemental compositions of ions when this was in doubt.

Chromium complexes. A representative mass spectrum, which shows most of the characteristic features, is shown in Fig. 1(a). The major fragmentation pathway of CrL_3^+ involves two successive losses of L· to give CrL_2^+ and CrL^+. CrL_2^+ also decomposes by migration of an aryl group, C_4H_3S or $C_6H_5^+$, to Cr to form $LCrAr^+$ with elimination of the remainder of the ligand.

Cobalt complexes. The failure of cobalt(III) complexes to yield a molecular ion, Fig. 1(b), is quite characteristic, whether caused by thermal instability of CoL_3, or by the ease of fragmentation of CoL_3^+ to CoL_2^+. The CoL_2^+ species decomposes by loss of L· or *t*-Bu· radicals. Migration of C_4H_3S to the metal is much less pronounced than for Cr. Thus, $LCoC_4H_3S^+$ is not observed, but $CoC_4H_3S^+$, *m/z* 142, is formed in low abundance.

Rhodium complexes. A representative mass spectrum is shown in Fig. 1(c). Major fragmentation pathways involve successive losses of L· and HL from RhL_3^+ when R = CH_3 (as shown) and of L· and (L-H) when R = *t*-C_4H_9 (not shown). Both complexes show losses of CO and C_4H_4S from RhL_2^+ but, in contrast to Cr(III) and Co(III) complexes, migration of the thienyl group to the metal is not observed.

Support of this work by the Natural Sciences and Engineering Research Council of Canada and by the Faculty of Graduate Studies of the University of Manitoba is gratefully acknowledged.

MASS SPECTRAL FRAGMENTATION PROCESSES IN DINITROAROMATIC COMPOUNDS. AN MS/MS CID STUDY

Jehuda Yinon

Department of Environmental Sciences and Energy Research
Weizmann Institute of Science
Rehovot 76100, Israel

The mutagenic and carcinogenic potential of nitroaromatics (an important class of industrial chemicals) and their degradation products, has created an increased interest in the health hazards that this class of compounds presents to the environment.

In order to contribute to the characterization of these compounds a collision induced dissociation (CID) study of dinitroaromatic compounds was carried out using a tandem BB mass spectrometer. Fragmentation pathways were determined in the electron impact mode. Samples were introduced through a modified solids probe [1] using the in-beam EI mode, at electron energy of 70 eV.

Loss of $NO_2^{\cdot}$ from the molecular ion is observed in most of the investigated dinitroaromatic compounds. In 2,3-dinitrotoluene, 2- and 4-amino dinitrotoluene loss of $NO_2^{\cdot}$ occurs only after loss of $OH^{\cdot}$. In other compounds loss of $NO_2^{\cdot}$ is not observed at all because of competitive processes,such as loss of $NO^{\cdot}$, CO_2, CH_2O, C_2H_4 or H_2O.

Loss of $NO^{\cdot}$ is observed in most of the investigated compounds. Exceptions are the dinitrobenzoic acids, where in the 2,4- and 2,5-isomers, loss of CO_2 is a competitive process, and in the 3,4- and 3,5-isomers, loss of $NO_2^{\cdot}$ is a competitive process. No loss of $NO^{\cdot}$ is observed in 3,5-dinitrosalicylic acid, 2,4-dinitroanisole and 4-amino-2,6-dinitrotoluene. In 2,4-dinitrophenol, 4,6-dinitro-o-cresol (Fig 1), 1-chloro-2,4-dinitrobenzene and 2,6-dinitro-4-chlorophenol (Fig 2), loss of $NO^{\cdot}$ produces a "dished peak", indicating a large release of kinetic energy associated with the decomposition [2,3]. Fig 3 shows the CID mass spectrum of the molecular ion of 2,5-dinitrophenol where no "dished peak" is observed.

Loss of $OH^{\cdot}$, due to an "ortho effect" occurs in compounds where a nitro group is ortho to a group containing a labile hydrogen, but is not observed when competitive processes, such as loss of $NO^{\cdot}$, $NO_2^{\cdot}$ or H_2O occur.

Decarboxylation process is observed in 2,4- and 2,5-dinitrobenzoic acid and loss of COH_2 in 2,4-dinitroanisole which can be explained by "nitro to nitrite" isomerization [4]. In 3,4- and 3,5-dinitrobenzoic acid the main fragmentation process is loss of $NO_2^{\cdot}$ followed by loss of $COH^{\cdot}$ and an additional $NO_2^{\cdot}$ group. Fig 4 shows the CID mass spectrum of the $(M-NO_2)^+$ ion of 3,5-dinitrobenzoic acid.

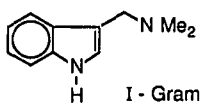
Bidimensional Mass Spectrometry in the Identification of Biogenic Amines

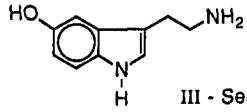
Ana M. Cardoso and A. J. Ferrer-Correia
Department of Chemistry, University of Aveiro
3800 Aveiro, Portugal

The collection of data in the B,E plane constitutes the essence of bidimensional mass spectrometry (metastable mapping), which provides a general picture of all the mestastable decompositions occurring during the flight path of the ions, specially in the first and second field free regions, during the acceleration and, occasionally, inside the magnetic and electric sectors.

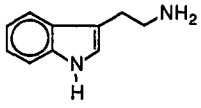
The electron impact bidimensional mass spectra of the biogenic amines shown below is reported.



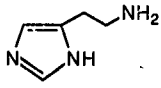
I - Gramine



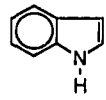
III - Serotonine



II - Tryptamine



IV - Histamine



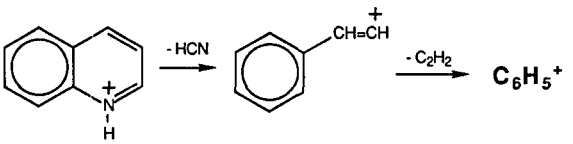
V - Indole

The bidimensional mass spectra were obtained on a reverse geometry mass spectrometer (VARIAN MAT 112S) connected on line to a microcomputer, by repeatedly scanning the magnetic field for several successive values of the electric sector voltage, with 70 eV electron energy and ion source temperature between 200 and 250 °C. The substances were introduced in the mass spectrometer as the free amines or the hydrochloride salts via a heated direct insertion probe.

The analysis of the bidimensional mass spectra of the biogenic amines listed allowed us to draw the following conclusions:

The molecular ions of histamine, tryptamine and serotonine fragment by loss of CH_2=NH via a McLafferty rearrangement involving the imidazole in the indole nucleus. In the case of gramine, besides elimination of CH_2=NCH_3 by an analogous process, loss of a methyl radical from the molecular ion and from the doubly charged molecular ion, in the first and second FFR, is also observed in the spectra. Heterolytic cleavage of the C_α - C_β bond of indoleamines produces, in the case of gramine and tryptamine, ion $C_9H_8N^+$, which

fragments by loss of HCN. In the case of serotonine, the unimolecular decompositions of ion $HOC_9H_7N^+$ are initiated in the hydroxyl group with loss of CO and H2O. The consecutive loss of CO (1st FFR) and HCN (2nd FFR) from the same ion $[146^+ \rightarrow 118^+ \rightarrow 91^+]$ results in a characteristic peak in the bidimensional mass spectra of coordinates $m^* = (118)^2/146$ and $E = (91/146)E_0$. Unimolecular decompositions initiated in the amino group are rare, which means that the information contained in these bidimensional spectra constitute a "fingerprint" of biogenic amines containing an indole nucleus. As an example the following metastable decompositions are observed in the spectra of the three indoleamines:



$$C_9H_7N^{2+} \rightarrow C_8H_6^{2+}$$

In the case of histamine loss of HCN from the molecular ion is also observed, as well as loss of NH_3 from ion $[M-1]^+$. Fragmentations characteristic of the imidazole nucleus constitute the vast majority of peaks in the spectrum of this substance.

All the information reported up to this point is based on the analysis of spectra where the electric sector voltage is varied from E_0 downwards. For indole an experiment where the electric sector voltage was increased from E_0 to $1.6E_0$ was carried out. Two "dish top" metastable peaks corresponding to the following charge separation reactions of the doubly charged molecular ion of indole were observed.

$$M^{2+} \rightarrow H_2CN^+ + C_7H_5^+$$

$$M^{2+} \rightarrow C_3H_3^+ + C_5H_4N^+$$

In conclusion the analysis of bidimensional mass spectra allows us to identify most of the metastable decompositions of singly and doubly charged ions of each substance and to establish the fragmentations specific of each biogenic amine or common to an ensemble of amines.

We are indebted to the Institute of Mass Spectrometry of the University of Amsterdam (The Netherlands), where accurate mass measurements, and some supporting CAD and metastable spectra were obtained.

The Dimethylaminomethyl Radical. A Neutralization-Reionization and Theoretical Study

Scott A. Shaffer* and František Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

The dimethylaminomethyl radical has been reported by Lossing to be one of the lowest ionization energy (IE) organic molecules with IE comparable to those of alkali metals.[1] However, the radical has not been prepared directly in the gas phase and its unimolecular chemistry has been unknown. We generate $(CH_3)_2N\text{-}CH_2^{\cdot}$ by Xe neutralization of 8 keV $(CH_3)_2N{=}CH_2^+$ prepared by dissociative ionization of 1,4-bis-dimethylaminobutane, using the tandem quadrupole acceleration-deceleration mass spectrometer (QADQ) described previously.[2] The neutralization-reionization ($^+NR^+$) spectrum (Xe/O_2 at 70% transmittance each) of $(CH_3)_2N\text{-}CH_2^{\cdot}$ shows a weak but discernible survivor peak at *m/z* 58, confirming the radical stability for >4 μs. The main fragmentation is loss of methyl followed by or combined with hydrogen losses giving rise to C_2H_4N molecules and radicals. Deuterium labeling in $(CH_3)_2N\text{-}CD_2^{\cdot}$ revealed a dominant loss of $CH_3^{\cdot}$ + D· consistent with the formation of $CH_3N{=}CH$ ions and radicals. The $^+NR^+$ spectrum of $(CH_3)_2N\text{-}CH_2^{\cdot}$ differs from the collisionally-activated dissociation (CAD) spectrum of the ion in the relative intensities of fragments at *m/z* 57, 30, 27, 26 and 14. The differences are further accentuated with $(CH_3)_2N\text{-}CD_2$ whose CAD shows mostly CH_4 elimination to form a $C_2H_4N^+$ ion, presumably $CH_2{=}N^+{=}CH_2$.

The $^+NR^+$ mass spectrum of $(CH_3)_2N\text{-}CH_2^{\cdot}$ is substantially different from the CIDI spectrum of the same radical formed from 8 keV 1,2-bis-dimethylaminoethane ion upon CAD/He at 30% transmittance. The latter spectrum shows the survivor ion at *m/z* 58 as the dominant peak, while the fragments at *m/z* 38-44 and *m/z* 25-30 are less abundant (Figure 1). By contrast, $^+NR^+$ spectra of $(CH_3)_2N{=}CH_2$ obtained with reionization reagents of increasing electron affinity (EA) (O_2, EA = 0.5 eV; N_2O_4, EA = 2.3 eV; ICl, EA = 2.4 eV; $TiCl_4$, EA = 2.9 eV) all showed low intensity survivor ions and only small variations in fragment relative abundances.

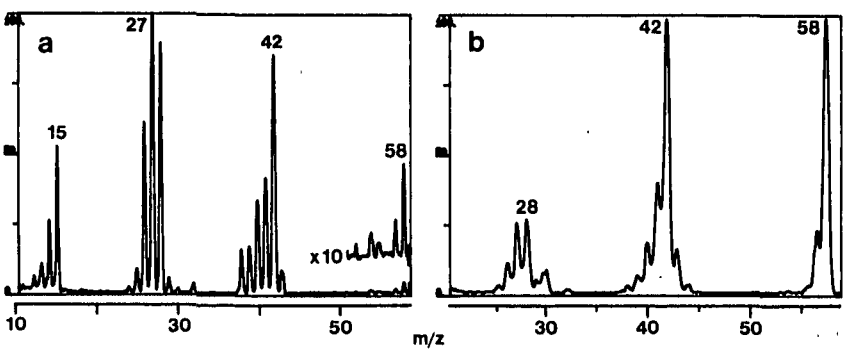


Figure 1. *(a) $^+NR^+$ (Xe/O_2, 70% transmittance) and (b) CIDI (He/O_2, 30/70% transmittance) spectra of $(CH_3)_2N{=}CH_2^+$.*

Ab initio calculations (MP4/6-31G*//6-31G* + 6-31G* zero-point vibrational energies) find $(CH_3)_2N\text{-}CH_2^{\cdot}$ as a stable structure. Its dissociation by loss of methyl requires 77 kJ mol^{-1} at 298 K compared with 109 kJ mol^{-1} from standard heats of formation. Vertical neutralization of $(CH_3)_2N{=}CH_2^+$ results in 71 kJ mol^{-1} vibrational energy deposition in the incipient radical due to unfavorable Franck-Condon factors. Likewise, vertical ionization of the vibrationally relaxed radical leads to 97 kJ mol^{-1} vibrational excitation in the ion (Figure 2). This is consistent with experiments that show little dependence of ion fragmentations on the nature of the reionization gas. The energy deposition upon neutralization and reionization is governed chiefly by the intrinsic properties of the ion and neutral species.

The calculated vertical IE (5.76 eV) agrees with the experimental value (5.8 eV). The radical adiabatic IE (4.75 eV) and the ion recombination energy (RE = 4.02 eV) are comparable with the IE of potassium (4.34 eV), confirming the alkali-metal like electronic properties of $(CH_3)_2N\text{-}CH_2^{\cdot}$.

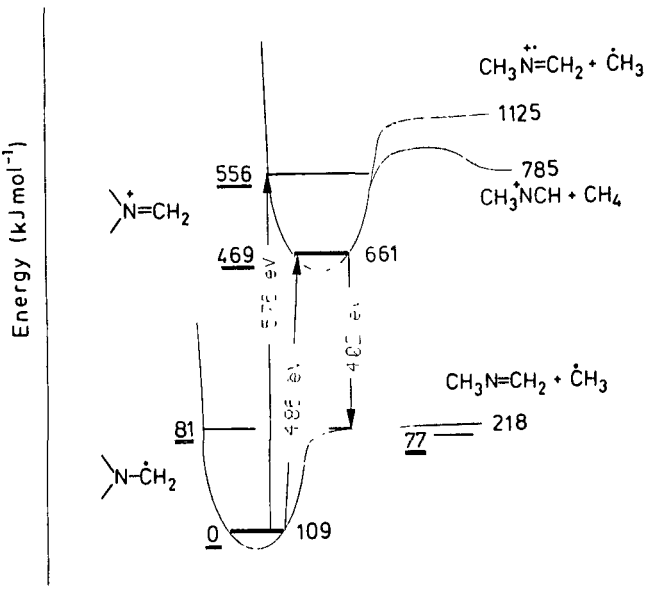

Figure 2. Energy diagram of $(CH_3)_2N\text{-}CH_2$ neutralization, ionization and dissociation (energy in kJ mol^{-1}).

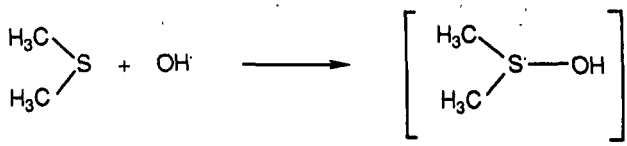
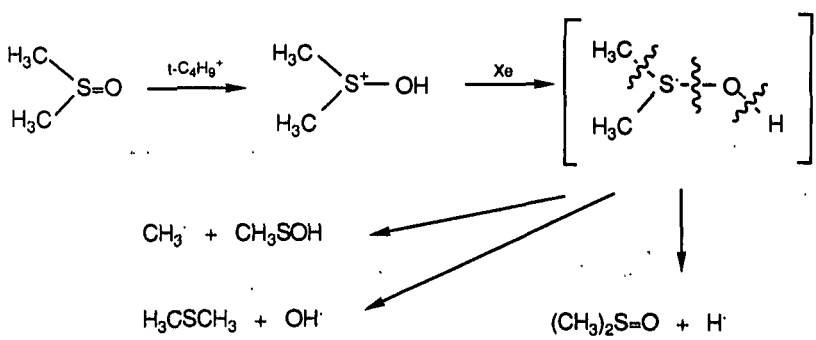
The Elusive Dimethylhydroxysulfinyl Radical. A Neutralization-Reionization and Theoretical Study

Ming Gu* and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

Photochemical oxidation of atmospheric dimethyl sulfide (DMS) with the hydroxyl radical is presumed to proceed via two competing channels, i.e. the hydrogen atom abstraction, and attack at the DMS sulfur atom. The primary adduct of the latter reaction, dimethylhydroxysulfinyl radical, $(CH_3)_2S\text{-}OH^{\cdot}$, has been postulated to be a reactive intermediate of an estimated half-life of 2×10^{-7} s.[1]



We generate the hypervalent $(CH_3)_2S\text{-}OH^{\cdot}$ and $(CD_3)_2S\text{-}OH^{\cdot}$ radicals by collisional neutralization with Xe (70% transmittance) of 8 keV $(CH_3)_2SOH^+$ and $(CD_3)_2SOH^+$, respectively, and analyze the products after reionization with O_2 (70% transmittance). The measurements were done on a tandem quadrupole acceleration-deceleration mass spectrometer described previously.[2] The precursor ions were prepared by mildly exothermic (ΔH = 14 kJ mol^{-1}) i-butane chemical ionization of $(CH_3)_2SO$ and $(CD_3)_2SO$. The neutralization-reionization ($^+NR^+$) spectra of $(CH_3)_2S\text{-}OH$ and $(CD_3)_2S\text{-}OH$ show no surviving molecular ions of lifetimes > 4.7 μs. The major dissociation paths are simple bond cleavages forming DMS at *m/z* 62 and CH_3SOH at *m/z* 64. In addition, loss of $H^{\cdot}$ from the hydroxyl group gives rise to $(CD_3)_2SO$ that is observed as a minor peak in the $^+NR^+$ spectrum of $(CD_3)_2S\text{-}OH^{\cdot}$. The analogous hydrogen loss from $(CH_3)_2S\text{-}OH^{\cdot}$ leads to $(CH_3)_2SO$ that dissociates rapidly to CH_3SO and $CH_3^{\cdot}$. The primary products undergo further extensive dissociations. CH_3SOH dissociates to $CH_3^{\cdot}$ and $SOH^{\cdot}$, the latter further dissociating to SO. DMS forms CHS and S as the most abundant secondary products. Similar dissociations are observed in neutral collisional activation ($^+NCR^+$) spectra of stable molecules $(CH_3)_2S$, CH_3SOH and $(CH_3)_2SO$ that were utilized for primary product identification.



The inherent instability of $(CH_3)_2S$-OH is corroborated by ab initio calculations (MP4/6-31G*//6-31G*) that found no bound doublet state for the hypervalent radical. The radical formed by vertical neutralization of $(CH_3)_2SOH^+$ is predicted to collapse to products without a potential energy barrier and with a large initial energy gradient (228 kJ mol^{-1} Å^{-1}). $(CH_3)_2S$ and OH· are the most stable products of $\Delta H_{f,298}$ = -193 kJ mol^{-1}, followed by CH_3SOH and CH_3·, and $(CH_3)_2SO$ and H (Figure). Freezing the C-O bond length in $(CH_3)_2S$-OH· leads to spontaneous collapse to CH_3SOH and CH_3· by C-C bond cleavage of $\Delta H_{f,298}$ = -164 kJ mol^{-1}. The O-H bond dissociation leading to $(CH_3)_2SO$ and H is the least exothermic process of $\Delta H_{f,298}$ = -95 kJ mol^{-1}. Based on theory and experiment $(CH_3)_2S$-OH· is suggested to be a transition state rather than an intermediate. The primary attack at sulfur by the hydroxyl radical thus can be reversible, but cannot lead to reaction branching and formation of different products. The parallel dissociations of $(CH_3)_2S$·-OH to products of widely different heats of formation is explained by the formation of distinct electronic states in the neutralization process. These repulsive electronic states rapidly dissociate before converting their electronic energy into the vibrational energy of the ground state.

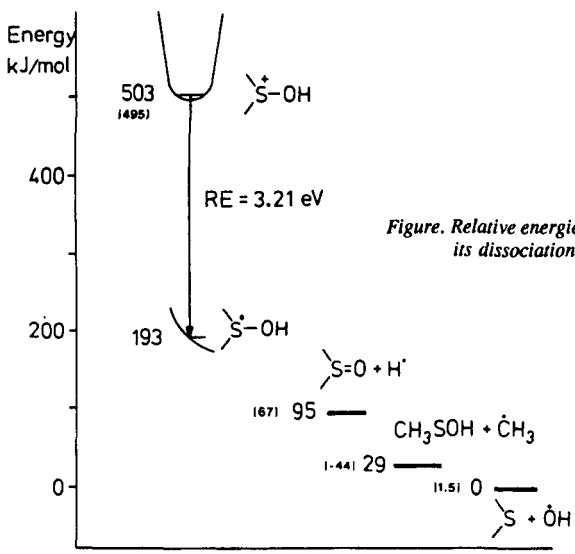


Figure. Relative energies of $(CH_3)_2S$-OH and its dissociation products.

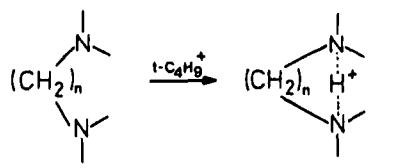
Hypervalent Organic Ammonium Radicals by Neutralization-Reionization Mass Spectrometry

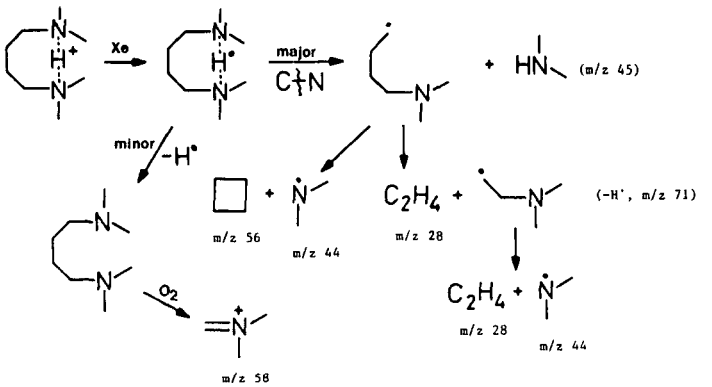
Scott A. Shaffer* and Frantisek Turecek
Department of Chemistry, BG-10, University of Washington,
Seattle, WA 98195

Small hypervalent radicals, e.g., $H_3O^{\cdot}$, $NH_4^{\cdot}$, $CH_5^{\cdot}$, $CH_3OH_2^{\cdot}$, $(CH_3)_2OH^{\cdot}$, $C_2H_5OH_2^{\cdot}$, $CH_3NH_3^{\cdot}$, etc., have been studied intensively by experiment and theory and found to have short lifetimes, while their dissociations exhibited unusual deuterium isotope effects. A peculiar feature of small hypervalent ammonium radicals is their tendency to undergo competing N-H and C-N bond dissociations despite great differences in the corresponding reaction exothermicities *(1,2)*. In this work we examine possible stabilization factors in larger hypervalent radicals generated by Xe neutralization of protonated aliphatic diamines and aromatic amines. The neutralization-reionization ($^{+}NR^{+}$) measurements reported here were done on the tandem quadrupole acceleration deceleration (QADQ) mass spectrometer allowing observation and collisional activation of transient neutral species within 5-7 μs *(3)*. $(M+H)^{+}$ ions of a series of bis-1,n-(dimethylamino)alkanes (n=1-6) were generated by isobutane CI.



Ion source and collisionally activated dissociations of these $(M + H)^{+}$ ions show dominant C-N bond heterolysis and loss of dimethylamine, whereas dissociations of odd-electron M^{+} give predominantly $Me_2N^{+}{=}CH_2$. By contrast, hypervalent radicals formed from $(M + H)^{+}$ upon neutralization with Xe (70% transmittance) show at least two competing primary dissociations. The major route is due to C-N bond homolysis to form $HNMe_2$ which is detected at *m/z* 45 after reionization with O_2 (70% transmittance). The complementary $Me_2N\text{-}(CH_2)^{\cdot}$ radicals undergo carbon-carbon and carbon-nitrogen bond cleavages to eliminate chain fragments (C_2H_4 to C_6H_{12}) that are detected as stable ions after reionization. The complementary dimethylaminoalkyl radicals are mostly unstable and do not survive reionization. A minor dissociation route is due to loss of $H^{\cdot}$ from the hypervalent radical followed by fragmentation of the reionized amine to form mostly $Me_2N^{+}{=}CH_2$. The low relative abundance of the latter, which could also be formed by the hydrocarbon chain fragmentation, and its major dissociation product (C_3H_6N) indicates a low branching ratio for the initial loss of H. A third possible path is indicated by the C_2H_6N fragment that could also be formed as $CH_2{=}N^{+}HMe$ by α-cleavage of the stable $(MH - CH_3)$ molecule upon reionization. However, the isomeric $CH_2{=}N^{+}HMe$ and Me_2N^{+} ions have not been distinguished.

Although the diamine hypervalent radicals are not detected as ions after 5-7 μs, their fast dissociations by C-N bond cleavage compete with rearrangements. For example, upon both neutralization-reionization and collisional activation the protonated propane, butane and hexane diamines undergo elimination of H_2 followed by losses



of $CH_3^{\cdot}$, C_2H_6N, and C_7H_7N. The occurrence of a competing rearrangement in the radicals suggests their lifetimes $\tau > 10^{-9}$ s, while a rearrangement after reionization would indicate $\tau > 5$ μs. We are currently investigating dissociations of deuterium-labeled derivatives to elucidate the H_2 elimination mechanism.

Neutralization with Xe of protonated benzyldimethylamine forms a hypervalent radical that dissociates by N-H and benzylic C-N bond cleavages. The C_7H_7 and $HNMe_2$ neutrals resulting from the former dissociation are detected directly by reionization with O_2. Benzyldimethylamine, the product of H loss, does not give a survivor ion, but is indicated through its characteristic $Me_2N^+=CH_2$ ion fragment. Benzylmethylamine, a product of N-CH_3 bond cleavage in the hypervalent radical is not formed in appreciable amount, as judged by the absence of its characteristic C_6H_6 and C_2H_8N fragments. Reionization by electron capture by the aromatic ring to form a transient zwitterion will be discussed.

THE UNIMOLECULAR REACTIONS OF HYPERVALENT AND HYPOVALENT SPECIES

Šárka Beranová, Michael J. Polce, Scott V. Boyle, and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron OH 44325-3601.

The unusual binding properties of hypervalent and hypovalent molecules, i.e. species having different number of valence electrons than prescribed by the octet rule, their possible involvement in chemical reactions and predicted occurrence in interstellar space have led to extensive theoretical and experimental research. These molecules which are difficult to study by conventional methods can be produced and characterized in the gas phase by neutralization-reionization mass spectrometry (NRMS). The present study explores routes to hyper- and hypovalent neutrals and establishes the stability and unimolecular reactions of the hypervalent tetramethyl ammonium radical.

Ammonium radicals, $NR_4\cdot$ (R: H, D or alkyl) contain a nitrogen atom surrounded by nine valence electrons and represent, therefore, hypervalent species. Previous studies have shown that $NH_4\cdot$, the isotopomers $NH_3D\cdot$, $NH_2D_2\cdot$, $NHD_3\cdot$, as well as the heavier homolog $CH_3NH_3\cdot$ have lifetimes too short for experimental detection; however, increased stability, originating from lower zero point vibrational energies of N-D versus N-H bonds, has been found for the perdeuterated radicals $ND_4\cdot$ and $CH_3ND_3\cdot$. Therefore, complete substitution with even heavier elements should induce similar stabilization. This is indeed confirmed with the tetramethyl ammonium radical.

The hypervalent tetramethyl ammonium radical $(CH_3)_4N\cdot$ was generated in the gas phase via charge-exchange neutralization of the corresponding cation (Eq.1):

$$(CH_3)_4N^+Br^- \xrightarrow{FAB} (CH_3)_4N^+ \xrightarrow{+\,e^-} (CH_3)_4N\cdot \qquad (1)$$

Neutralization of $(CH_3)_4N^+$ by collision with trimethylamine (TMA) yields the incipient tetramethyl ammonium radical; subsequent reionization with O_2 gives rise to the $^+NR^+$ spectrum of Figure 1. The presence of a sizable $(CH_3)_4N^+$ parent cation at *m/z* 74 in this spectrum proves that $(CH_3)_4N\cdot$ has survived intact, at least partly, for the time available between neutralization and reionization (~0.42μs). Consequently, a barrier prevents the spontaneous dissociation into $(CH_3)_3N$ and $\cdot CH_3$, and $(CH_3)_4N\cdot$ must have a ground state lying below the dissociation threshold for $\cdot CH_3$ loss. The spectrum of Fig.1 contains also abundant fragment ions originating from dissociation of the recovered $(CH_3)_4N^+$ parent cation after reionization and from reionization of any *neutral* fragments from dissociating $(CH_3)_4N\cdot$ radicals.

The stability of the tetramethyl ammonium radical could be attributed to the lower zero point vibrational energy expected for N-C vs. N-H bonds.

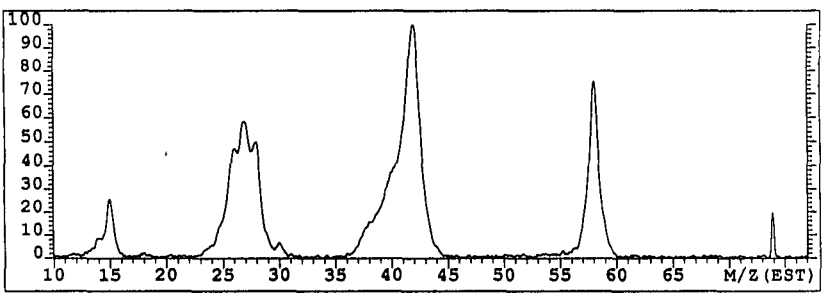

Figure 1. $^+NR^+$ TMA(80%)/O_2(60%) spectrum of $(CH_3)_4N^+$

The $^{+}NR^{+}$ He/O_2 and Xe/O_2 spectra of the tetramethyl ammonium ion contain no recovered parent cation (Fig. 2a, b). Helium as the neutralization target induces CAD instead of neutralization. Based on the CAD spectrum of $(CH_3)_4N^+$ (not shown) CAD causes mainly $CH_3\cdot$ and CH_4 eliminations, both of which are known to yield CH_3^+ after reionization. The smallest CAD fragment ion is CH_3^+, making $(CH_3)_3N$ the largest neutral loss. Reionization of $(CH_3)_3N$ gives characteristic ions at *m/z* 59, 58, 42, and 30-27 (Figure 2a). Note, that the peak at *m/z* 58 is narrow, consistent with a direct H· elimination from $(CH_3)_3N^{+}\cdot$. In contrast, the peak at *m/z* 58 in Figure 1 and in the CAD spectrum of $(CH_3)_4N^+$ is wider, consistent with CH_4 elimination from the neutralized-reionized or the original $(CH_3)_4N^+$, respectively. Using xenon for neutralization (Figure 2b) leads to a spectrum similar to that of Figure 1, but with no recovered parent cation. Apparently, neutralization with xenon produces an excited $(CH_3)_4N\cdot$ radical that either undergoes metastable decomposition or dissociates fully upon reionization. The broader *m/z* 58 in Figure 2b identifies the second route as the major decay pathway.

Experiments are also under way to determine the stabilities of hypovalent boronium radicals $BX_4\cdot$ (X: H, D, F) which have a deficiency, not a surplus, of valence electrons.

Fragmentation of Peptides Cationized with Metal Ions

D. S. Wagner and J. Allision, Michigan State University,
East Lansing MI 48824.

Collisionally activated dissociation (CAD) of cationized peptides, formed by fast atom bombardment (FAB), yields a number of sequence-specific ions that provide information on the primary structure. Several fragmentation mechanisms have been suggested for the formation of the commonly detected ions: **[a_n-H]Cat$^+$**, **[b_n+OH]Cat$^+$**, and **[y_n+H]Cat$^+$** (1-3), where Cat$^+$ is an alkali metal cation. Except for the formation of the unexpected **[b_n+OH]Cat$^+$** ion, which involves a rearrangement of the C-terminal carboxyl group to expel the C-terminal amino acid (3), few stable isotope-labeling studies have been performed to elucidate the structures and substantiate proposed mechanisms.

Labeling studies have been performed to provide insights into the structures of the fragment ions formed from [M+Cat]$^+$ ions (Cat$^+$=Li$^+$, Na$^+$, or K$^+$) and fragmentation mechanisms. These labeled peptides were designed to determine the origin of the H atom which shifts in the fragmentation processes. There are three possible sites from which these H shifts could originate: (i) from the α-carbon, which can be detected by using [H-V$^{\alpha d}$GV$^{\alpha d}$APG-OH] and [H-VGVA$^{\alpha d}$PG-OH], (ii) from the β-carbon or sidechain, which can be detected by using [H-V$^{\beta d}$GV$^{\beta d}$APG-OH] and [H-VGVA$^{\beta 3d}$PG-OH], (iii) From the amide N, which can be detected by using [D-V^{d}G^{d}V^{d}A^{d}PG^d-OD].

The CAD spectra obtained from peptides cationized with Li$^+$, Na$^+$, and K$^+$ lead to the same conclusions. By comparing the mass of molecular fragments formed by simple homolytic cleavage of skeletal bonds, it is clear that the observed ions corresponded to the following: **[a_n-H]Cat$^+$**, **[x_n-H]Cat$^+$**, **[b_n-H]Cat$^+$**, **[y_n+H]Cat$^+$**, **[y_n-H]Cat$^+$**, **[c_n+H]Cat$^+$** and **[z_n]Cat$^+$** ion series. The labeled peptides indicated the source of the shifting H's in the fragmentation processes, thus the ions structures were determined (Figure 1).

The data from the deuterated peptides suggest the source of the shifting H atom to form **[y_n+H]Cat$^+$** and **[c_n+H]Cat$^+$** is from an exchangeable site (amide N). The **z_n** ions represent C-terminal ions plus the cation without a H shift, apparently formed by homolytic cleavage of the N-C(R) skeletal bond, most likely forming a distonic ion. The cationized **d_n**, **w_n**, and **v_n** ions are present in greater abundance than in the CAD-B/E spectra of the protonated peptide but were determined to have similar structures.

The relative intensities of the CAD products are difficult to explain. One possibility is the [M]Cat$^+$ ions represent a distribution of "isomers", with Cat$^+$ residing at different locations on the peptide. If the fragmentation chemistry is remote-site, unaffected by the location of the Cat$^+$, when a skeletal bond cleaves, an equal number of N-terminal and C-terminal fragment ions would be detected. This is not observed. The peaks for the **a**-type ions are more intense than the **x**-type ions, suggesting that Cat$^+$ usually resides near the N-terminus. However, **y**-type ions are more abundant than **b**-type ions, which would suggest that Cat$^+$ favors C-terminal sites.

Another explanation is that the Cat$^+$ resides at an amide linkage, stimulating the fragmentation chemistry. Therefore, once the chemistry occurs, the terminal groups of the two fragments interact with and compete for Cat$^+$. It has been shown that Cat$^+$-molecule interaction energies parallel proton affinities (4).

The structures of the fragment ions from cationized peptides are the same as those formed by charge-localized derivatives(5), thus cationized peptides could fragment by analogous mechanisms. For example the **[a_n-H]Cat$^+$** and **[x_n-H]Cat$^+$** ions can form through a unified fragmentation mechanism, (Scheme 1), involving the expulsion of an H_2 molecule, where the **a** and **x** ions evolve from a common intermediate. The proton affinities suggest that Cat$^+$ will bond more strongly to the N-terminal fragment, thus the **a**-type ions are more intense. Likewise the **[b_n-H]Cat$^+$** and **[y_n-H]Cat$^+$** fragment ions can be shown to form by a common mechanism (Scheme

2), where the detected fragment contains the alkali cation. The proton affinities suggest that Cat^+ should bind to the C-terminal fragment, explaining the intense $[y_n+H]Cat^+$ peaks and weak peaks for b-type ions.

We conclude that *structures of the fragment ions are similar to those formed from charge-localized derivatives.* The cation appears to initiate the fragmentation, where the site of cationzation=site of fragmentation and the.relative intensities of the fragments suggest competition for Cat^+ following bond cleavage.

COMPARISON OF ELECTRON IONIZATION FRAGMENTATION OF METHOXY CINNAMATES TO THEIR PHOTOCHEMICAL REACTIONS

J. A. Biddle[1], L. R. Phillips[2], A. Del Grosso[2], and N.M. Roscher[1]
[1] Department of Chemistry, The American University, Washington, DC 20016, and [2] Center for Biologics Evaluation and Research, Food and Drug Administration, Bethesda, MD 20892

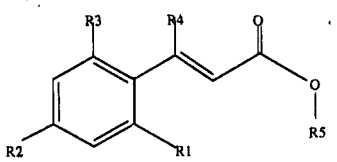
Summary:

Methoxy cinnamates were found to undergo an electron ionization-induced alpha-cleavage and McLafferty rearrangement. Despite similarities of these fragmentations to the Norrish Types I and II reactions, respectively, these compounds do not photolytically cleave but instead, only E-Z photoisomerization was observed.

Introduction:

Cinnamic acid esters are commerically available as sunscreen agents. Although, like other sunscreens, very little is known about their photochemical properties. In this research, we investigated the properties of these compounds. This study involved a number of synthesized cinnamic acid esters and their photchemical products which were then examined for mass spectral fragmentation patterns. The mass spectra of these compounds helped established that photoisomerization of the E-cinnamate (or Z) to the Z isomer (or E) was the major photochemical reaction for the cinnamates.

Cinnamic acid (3-phenyl-2-propenoic acid) [R1 to R5 = -H] is a naturally occurring compound with its derivatives finding uses in formulation of fragrances, sunscreens and more recently, in matrix-assisted laser desorption mass spectrometry:



R1 = -H or -OMe
R2 = -H or -OMe
R3 = -H or -OMe
R4 = -H or -Me
R5 = -H or -Et or - ethylhexyl

Various methoxy cinnamates were synthesized and their photochemical behavior investigated. Since most compounds were novel, spectroscopic characterization was necessary to ensure correctness of their chemical structures. The electron ionization mass spectra of these compounds were obtained, examined and intercompared.

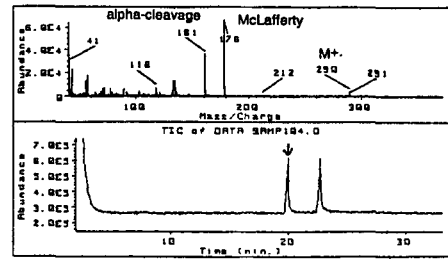
Methods:

Synthesis---Compounds were prepared by either the Reformatsky Reaction or by a modified Wittig Reaction, known as the Horner-Emmons (1).

Instrumental analysis---Electron ionization (70eV) mass spectra were recorded on a Hewlett-Packard 5995C gas chromatograph-mass spectrometer. All the samples were dissolved in chloroform prior to analysis.

Results:

The electron ionization mass spectra of these compounds were generally characterized by the presence of a mlecular radical cation, alpha-cleavage of the ester, McLafferty Rearrangement(s), loss of methoxy radical, and the presence of smaller mass fragments. Little, if any, differences were apparent between the E and Z isomers. The presence of a methoxy group(s) in the ortho-position favored loss of the methoxy radical from the molecular radical cations in preference to the alpha-cleavage and the McLafferty Rearrangement.



When the compounds were irradiated, only the E-Z isomerization was observed. These results were verified by GC/MS and Nuclear Overhauser Enchancement Spectroscopy (NOESY) NMR Experiments. From these analyses, the only photochemical reaction observed with methoxy cinnamates, was photo- isomerization. There was no chromatographic or spectroscopic evidences of other photochemical products, such as those expected from the Norrish Type I and II Reactions.

Conclusions and Futrue Directions:

Despite the similarities between electron ionization-induced alpha-cleavage and the Norrish Type I Reaction, and between the McLafferty Rearrangement and the Norrish Type II Reaction, the methoxy cinnamates did not photochemically cleave but instead, only E-Z photoisomerization, as shown by H-NMR, was observed.

The methoxy cinnamates are an interesting and an important class of compounds. A study on the photochemical products of methoxy cinnamates under other photochemical conditions would allow better understanding of the photoactivity of these compounds and their apparent resistence towards fragmentations.

A MS STUDY OF P-PHENYLENDIAMINE IN SLOW OXIDATION REACTIONS.

Jia-shen Wang
Clairol Inc., Stamford, CT 06922

P-phenylenediamine (PPD) is a primary intermediate, commonly used in oxida-tive hair coloring systems. Research effort has mainly been devoted to study the mechanism of the color-formation reactions and the nature of the colored products in various oxidative systems (1,2). In an analytical preparation, it has been known for years that this compound graduatedly formed dark color solutions in most solvents. Other than main com-ponents (3) no attempt has been given to investigate the detail of this processes. Our current objective is to determine the product profiles with the aim of developing better analytical methods.

EXPERIMENTAL:

MS:	*Finnigan* 4500 GC/MS
NMR:	QE-300, GE
TLC:	Silica Gel IB2-F plates (J.T. Baker)
	Solvent: CH_3OH-IPA-CH_2Cl_2 (3:2:95)

RESULTS AND DISCUSSION:

Sample preparation: PPD (5%) methanol solutions were allowed to form dark brown solutions by standing at room temperature. The color components were separated by TLC and identified by MS and NMR. Components eluted before PPP were the interesting species of this study. Five color components were obtained.

Structure elucidation: The five products of PPD are listed (by eluting order) below.

I. p-Nitroaniline.
II. N-(p-nitrophenyl) PPD
III. 4,4'-Diaminoazobenzene.
IV. p-Nitrosoaniline.
V. N-(p-Nitrosophenyl) PPD.

Compounds I and III are the most abundant species. The presence of these two in PPD basic solution have been reported in literature (3).

The mass spectra of compounds I, II, IV and V are shown in Figures 1 and 2. In mass spectra, the molecular ions of all these compounds are present with relatively high intensities. The reference spectra of compound I and III are readily available in the data system which allowed us to immediately identify these compounds. Through comparison the spectra of I and IV, the basic structure of compound IV has been elucidated. The prominent peaks suggest an NO_2 and an NO group in compounds I and IV, respectively. The structures of the other portions of these two compounds are the same. The same spectral features are also observed in the spectra of compounds II and V and allow us to elucidate the basic structures of these two. Further structure assignments were made based on the NMR data. Because of sample sizes, the NMR spectra obtained were not in high quality. The coupling patterns (ortho-couplings) of the aromatic hydrogens, however were recognizable. With this information and the basic structures obtained by MS, the absolute structures of these compounds were obtained.

CONCLUSION:

We have assigned three structures of color products formed in PPD solutions. The results have also demonstrated the combinated analytical capabilities of MS and NMR for making absolute structure assignments.

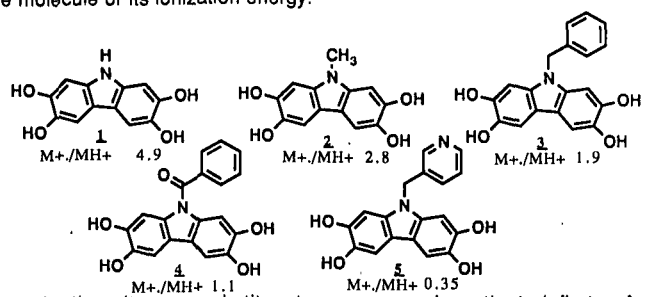
Formation of Radical Cations in Liquid Secondary Ion Mass Spectrometry in a Series of Carbazoles

Jeffrey P. Kiplinger and Richard S. Ware; Pfizer Central Research, Eastern Point Rd., Groton, CT 06340

Introduction. Neutral molecules analyzed using FAB or Cs^+ LSIMS almost invariably yield protonated molecules or cationized molecules in their spectra. A few exceptions have been reported in the literature, notably highly aromatic or canjugated molecules which have very low ionization energies but no polar functions to accept a proton. In these cases, it is a balance between the molecule's gas phase basicity and its ionization energy that determines the relative amounts of radical cation vs. protonated molecule present in the spectrum. We report here a similar finding in a series of carbazoles, which exhibit strong $M^{+\cdot}$ ions as well as the expected protonated molecules in their spectra. Since a series of these compounds was available in which both the nitrogen and the ring substituents varied, we were able to investigate some of the structural effects in this system which determine the ratio of $M^{+\cdot}/MH^+$.

Experimental. The compounds used in this study were synthesized by Dr. R. L. Dow, Pfizer Central Research, and used without further purification. All showed either the $M^{+\cdot}$ or MH^+ ion as the base peak in their spectrum. All mass spectrometric results were obtained using a Kratos Concept-1S spectrometer. The Kratos LSIMS source was equipped with an Antek Cs^+ ion gun, operated at a primary ion energy of 16 keV. The matrix chosen for LSIMS experiments must have an effect on the $M^{+\cdot}/MH^+$ ratio, due to differences in the relative basicities and oxidation potentials of common matrices. We therefore chose to make the matrix an experimental constant, and used magic bullet (1:4 dithiothrietol : dithioerythritol) for all experiments. The $M^{+\cdot}/MH^+$ ratio is easily measured from an averaged spectrum of ten scans. Background noise is subtracted, as are carbon isotope peaks from neighboring peaks. The relative peak heights are then measured directly.

Results and Discussion. Proton affinities for pyrrole and pyrrolidine are known; pyrrole is 74 kJ/mol less basic than its saturated form. This effect is easily explained using elementary organic chemistry: protonated pyrrole is isoelectronic with the antiaromatic cyclopentadienyl cation, so protonation is not favored. Obviously the same effect operated with the carbazoles. The M^+/MH^+ ratio will therefore be affected by structural changes which influence either the gas phase basicity of the molecule or its ionization energy.



Changes in the nitrogen substituent group were investigated first. As the series of compounds **1-5** shows, the $M^{+\cdot}/MH^+$ ratio can vary widely. In this small series, two effects are probably operating. The substituent group on nitrogen increases the molecular polarizability, which increases the basicity of the molecule. This is seen as the alkyl substituent is made larger, as in **1-3**. The difference between **3** and **5** calls attention to the other effect -- if a proton acceptor is available on the substituent group, the MH^+ ion is more favored. This is certainly the reason for the greater basicity of **4**, whose electron-withdrawing benzoyl substituent should not favor protonation at nitrogen. Note that these substituents should generally lower the ionization energy of the compounds, and this favors production of the radical cation. The effect of the substituent on the basicity of the molecule must therefore be dominant.

Changes in the aromatic ring substituents affect the $M^{+\cdot}/MH^+$ ratio as well, although these have proven more difficult to evaluate. We observe that changing the ring substituents from -OH to -OMe decreases the ratio (increases protonation) in cases where protonation takes place at nitrogen.

M+./MH+ 1.4

Semi-empirical AM1 calculations were carried out in an effort to explain this effect. Calculation of ΔH_f^o of the neutral and protonated molecules, combined with $\Delta H_f^o$of the proton yield the calculated proton affinity (PA). The PA's shown below are taken as accurate relative to one another, and their absolute accuracy is not considered important for our purposes. Their relative gas phase basicities (ΔG^o) should also be accurate, since the entropy changes should be similar for all the compounds. The calculations predict an increase in basicity on replacement of -OH by OME, whether the substituent is ortho or para to the carbazole nitrogen atom. While the calculated increase is small, the effect of several groups might be expected to accumulate. The calculations thus mirror the observed results.

The AM1 calculations indicate that little enhancement in the molecule's basicity or change in its ionization energy is to be expected from moving the substituent from a para to an ortho postion. The experimental results show that protonation is favored to a greater degree by this change. This effect apparently operates only when protonation is at nitrogen. Since AM1 calculations are known to handle through-space interactions poorly, we propose that this enhancement is due to a neighboring-group hydrogen bonding interaction, which stabilizes the protonated molecule and thus favors MH^+ production.

We conclude that several different structural effects are observable in this series. First, increasing the size of the N-substituent group increases basicity by increasing polarizability, but protonation is also highly favored if a proton acceptor is available on the substituent. We also observe a through-bond effect of the ring substituents on changing these from -OH to -OMe, and a through-space effect when a substituent capable of accepting a hydrogen bond is close to the protonated nitrogen.

LSIMS and ESMS of Disulfide Bonded Peptides

Francis Bitsch and Alain Van Dorsselaer.
Laboratoire de Spectrometrie de Masse Bio-Organique, URA 31,
Universite Louis Pasteur, Strasbourg, France.

In combination with Edman degradation, LSIMS was shown to be a powerful tool to characterize peptides consisting of several disulfide linked chains [1]. Specific fragmentation of disulfide bridges linking two or more peptide chains have already been described in LSIMS [2]. They were explained as reductions induced in the matrix under the high energy particle beam.

Since mechanisms involved in the cleavage of the disulfide bond under LSIMS are not yet completely elucidated, we have undertaken a comparative study in LSIMS and ESMS of homo- and heterodimer ranging from 900 to 6000 Da. Our studies have shown that :

1- The fragmentation of the disulfide bond is a major process in LSIMS but does not occur in ESMS, even by collision activation (CA) in the electrospray interface. Figure 1 shows the ESMS of a 4.7kDa peptide recorded at a nozzle/skimmer bias value of 70 volts. Mainly backbone fragmentations especially the Asp-Pro bond fragmentation were observed.

2- The type of the matrix used influences the fragment yield. The lowest yields were observed in 3-nitrobenzylalcohol.

3- In LSIMS, cleavage of bonds adjacent to the disulfide bridge yields peaks +32 Da and -32 Da from the disulfide bond fragment. The presence of distorted isotopical patterns of those fragments could be explained by the formation of radicals. Genesis of radicals under the high energy particle bombardment could be explained by fragmentation processes remote from the charge site since the protonation is supposed to occur on basic amino acids. Figure 2 shows the LSIMS (m/z 600 to 800) of a small disulfide bonded peptide.

4- LSIMS daughter ion mass spectra (MIKES and B/E linked scans) yielded mainly disulfide bond fragments especialy for higher molecular weight peptides (>2 kDa). CID-MS/MS of multiple charged ions from disulfide bonded peptides produced by electrospray ionization yields mainly classical backbone fragments but, as in the "source" generated spectra, no disulfide bond fragments were produced.

A study performed on disulfide bonded peptides finally showed that laser desorption (LD) only produces pseudo-molecular ions. Plasma desorption (PD) of disulfide bonded peptides yields a high amount of disulfide bond fragments [3]. The large peak width of the disulfide bond fragment peaks in PDMS are explained by the presence of fragments -32 Da and +32 Da as reported for LSIMS.

This work has demonstrated that electrospray ionization and laser desorption don't induce the disulfide bond cleavage of most of interchain disulfide bonded peptides. The resulting spectra therefore lack important and useful structural information. LSIMS and PDMS of disulfide bonded peptides typically yield peaks corresponded to the S-S bond fragmentation as well as of the adjacent C-S bonds. Remote fragmentation processes under high energy particle bombardment (LSIMS and PDMS) probably involve formation of intermediate radicals.

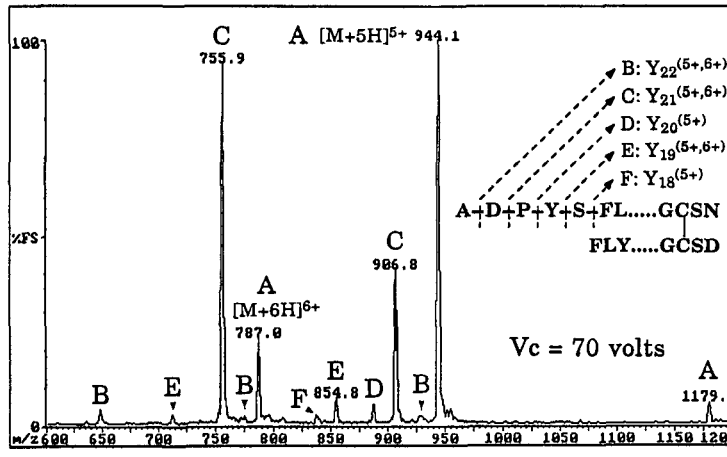

Figure 1: ESMS of a 4.7 kDa heterodimer recorded at nozzle/skimmer bias Vc=70 volts. A: multiply-charged ion peaks of heterodimer, M = 4716 Da.

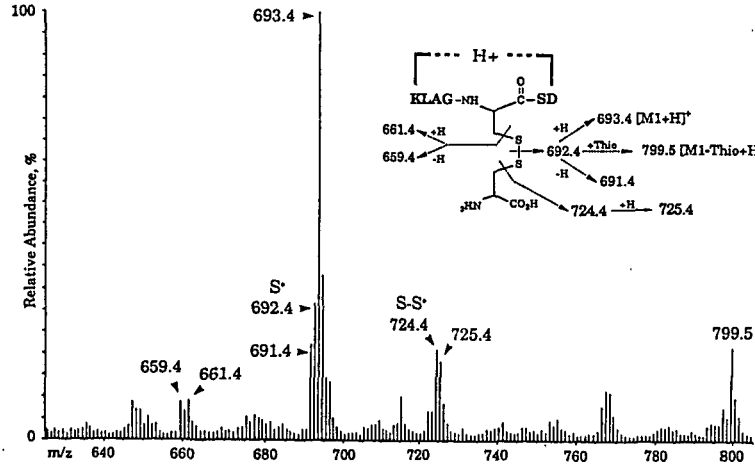

Figure 2: LSIMS of a 812 Da disulfide bonded peptide (disulfide bond fragment region; m/z 600 to 800). Matrix: 1-thioglycerol.

METHYLENE BLUE: A COMPREHENSIVE STUDY OF THE VARIATION OF THE PEAK INTENSITIES IN THE MOLECULAR ION REGION WITH EXPERIMENTAL CONDITIONS IN LSIMS/FAB

M. Allard, J. Visentini and M. J. Bertrand
Regional Center for Mass Spectrometry,
Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7

The study of reduction processes occurring in the matrix during FAB/LSIMS analysis has received considerable interest over the past few years. These reduction processes manifest themselves as isotopic peak intensities which deviate positively from theoretically expected values. Methylene blue, a phenothiazine dye, has received particular attention in this area since it exhibits extensive one and two-electron reduction processes. The extent of reduction has been observed to vary with experimental parameters including nature of matrix, analyte concentration, primary beam density, bombarding beam energy, and bombardment time. However, it is very difficult to make interlaboratory comparisons since all the important experimental parameters are often not reported. Common methods for expressing the extent of reduction, frequently referred to as the "enhancement ratio", assume that the excess peak intensity measured is due solely to the reduced species. However, this latter approach ignores the contribution of other reduction/oxidation (redox) processes as well as that of background signal. A computer program, Simulated Background and Reduction/Oxidation Calculations (SIMBROC), developed in our laboratory was used to determine the "true" extent of reduction so that it could be compared to the "apparent" reduction given by enhancement ratios. A systematic study of the effect of experimental parameters on the extents of these "true" redox processes was thus undertaken All data were acquired on a VG Autospec-Q mass spectrometer equipped with a caesium ion gun. Narrow voltage scanning spectra accumulated by multi-channel acquisition over a period of 5 minutes were used to make isotopic peak ratio measurements. The mathematical model upon which SIMBROC is based specifies that each redox process affecting the molecular ion cluster peaks must be accompanied by a hydrogen transfer. The Ox_n and Red_n values given by the program indicate the extents of oxidation and reduction respectively where n denotes the number of electrons/hydrogens transferred in the process Since the oxidation processes for this compound were found to be negligible under all experimental conditions, the rest of this work focusses on the reduction processes alone. The $Back_1$ and $Back_2$ values represent the alternating background levels calculated by the program. Since the background values provided by the program correspond well with those observed experimentally, SIMBROC was accepted as a viable tool for data treatment. In the initial stages of this work, it was discovered that the time of irradiation was sometimes producing large increases in isotopic peak intensities. An example of this effect was obtained in a 0.005M solution of methylene blue in a 0.2M thioglycerol/glycerol matrix as suggested by Kazakoff[1]. Although the (A+1)/A isotopic peak ratios corrected for theoretical isotopic contributions ("apparent" Red_1) showed an increase with time of irradiation, the results using SIMBROC showed that the "true" one-electron reduction process (Red_1) is essentially unaffected by beam exposure time. The increase in apparent Red_1 is due, therefore, not necessarily to an increase in the reduced species but to a decrease in the molecular ion, Red_0. It is not surprising that as time proceeds a build-up of secondary products is observed. Examination of the results given for two-electron reduction indicated that the time effect on the true process, Red_2, is only half as important as would be expected from apparent Red_2 values. It should be noted, however, that the "true" two-electron process varied with time while the one-electron process appeared to be unaffected.

The nature of the matrix plays an important role in affecting peak intensities in the molecular ion region as presented in Table I which gives the results for methylene blue in three different matrices. The "apparent" and "true" reduction extents (one and two-electron) can be compared for the different matrices and at three different beam fluxes. At all beam fluxes given in this table the apparent Red_1 is approximately two to three times the true value. In the cases of two-electron reduction the apparent Red_2 values are approximately four times greater than the true value. As indicated by the highlighted values in the table, however, when hydroxybenzenesulfonic acid (HBSA) is used as matrix, the "apparent" reduction values can be up to about ten times the true value. Contrary to the independence of the Red_1 true values in different matrices or at varying beam densities, the Red_2 true values show an increase with primary beam flux.The true Red_2 values were also found to vary with the nature of the matrix in the following decreasing order: thioglycerol>glycerol>HBSA From all the results obtained for both "true" one and two-electron reduction processes , it appears that only two-electron reduction is affected by matrix composition and primary beam density. Analyte concentrations also have an effect on the isotopic peak ratios. The (A+1)/A and (A+2)/A values, and their corresponding "apparent" reduction extents, are

usually much higher at the lower concentrations as illustrated in Figure 1 for solutions of methylene blue in glycerol at a beam density of 0.032 μA/mm^2. As seen in this figure, the effect is more pronounced for the (A+2)/A ratios than for (A+1)/A. Examination of the "true" reduction extents indicates that one-electron reduction is essentially not affected by concentration while the two-electron process shows a concentration effect. The effect of beam density on "true" reduction extents at different concentrations was also studied in order to determine whether the flux effect mentioned earlier was concentration dependent. The results for solutions prepared in glycerol indicate that an increase in the beam flux from 0.018 μA/mm^2 to 0.053 μA/mm^2 does not change the extents of one-electron reduction regardless of the analyte concentration yet causes greater extents of two-electron reduction as the analyte concentration increases. Earlier work conducted in our laboratory demonstrated that the primary beam energy does not affect the extent of "apparent" reduction. The SIMBROC results confirmed this effect for "true" reduction. This comprehensive study of the parameters affecting the extent of reduction observed in methylene blue has shown that the "apparent" reduction determined simply from (A+1)/A and (A+2)/A isotopic peak ratios is often misleading. Based on results obtained in this work, it appears that "true" one-electron reduction processes are independent of matrix composition, sample concentration and primary beam density while the "true" two-electron processes can be affected by these parameters

---

AN APPROACH TO THE EVALUATION OF THE TRUE EFFECT OF EXPERIMENTAL PARAMETERS ON THE OXIDATION/REDUCTION OBSERVED IN FAB/LSIMS

J. Visentini, M. Allard, D. Zidarov and M. J. Bertrand
Regional Center for Mass Spectrometry,
Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7

Matrix-analyte interactions causing reduction processes to occur in the matrix during FAB/LSIMS analysis often result in A+n ($A=(M+H)^+$) peak intensities which are substantially higher than those expected based on natural isotopic abundances. The extent of reduction observed is dependent on several parameters including analyte structure, sample concentration, matrix composition, time of irradiation, primary beam energy and density. The methods presently used for expressing the extent of reduction attribute the excess signal measured in the A+n peaks entirely to reduction products. This approach which measures "apparent" reduction, however,may be misleading since it overlooks the contribution of beam-induced background signal which can also vary with different FAB/LSIMS conditions. When studying the extent of "true" reduction, therefore, it becomes important to deconvolute the peak intensities in the molecular ion region. A computer program, Simulated Background and Reduction/Oxidation Calculations (SIMBROC), which is based on the simple mathematical model described by equations (1) to (8) below, was written to achieve this task. Data used in this study were acquired using narrow voltage scanning with multi-channel acquisition on a VG Autospec-Q. The program SIMBROC was written in Fortran 77.

(1) $I_{-3} = Back_2$
(2) $I_{-2} = Ox_2 + Back_1$
(3) $I_{-1} = A_1{*}Ox_2 + Ox_1 + Back_2$
(4) $I_0 = A_2{*}Ox_2 + A_1{*}Ox_1 + Red_0 + Back_1$
(5) $I_1 = A_3{*}Ox_2 + A_2{*}Ox_1 + A_1{*}Red_0 + Red_1 + Back_2$
(6) $I_2 = A_4{*}Ox_2 + A_3{*}Ox_1 + A_2{*}Red_0 + A_1{*}Red_1 + Red_2 + Back_1$
(7) $I_3 = A_4{*}Ox_1 + A_3{*}Red_0 + A_2{*}Red_1 + A_1{*}Red_2 + Back_2$
(8) $I_4 = A_4{*}Red_0 + A_3{*}Red_1 + A_2{*}Red_2 + Back_1$

The symbols **Ox** and **Red** are defined as those oxidation/reduction processes, respectively, which are accompanied by hydrogen transfers with the subscripts denoting the number of hydrogens/electrons transferred in the process. The variables $\mathbf{Back_1}$ and $\mathbf{Back_2}$ represent the level of background present in the molecular ion region. This background signal can be observed as three different pattern types in FAB/LSIMS spectra; namely, constant,a "picket-fence" distribution, and a modulated background signal. The use of only one background variable would impose a constant background over the molecular ion region. Although this is sometimes true, it is also important to consider the cases where background is distributed in the two other pattern types. By using two different background variables, therefore, the model allows some flexibility in the evaluation of the background contribution The I_k values on the left side of the equations represent the measured peak intensities with the subscript k denoting the position of the peak in the cluster relative to the parent ion at k=0 . The A_1, A_2, A_3, and A_4 values represent the first, second, third and fourth isotopic contributions, respectively. This model uses the system of equations (2) to (7) to generate estimate values for the processes and equations (1) and (8) to optimize the solution.

The input required for this program includes the empirical formula of the analyte used to calculate the theoretical isotopic peak ratios and the experimental peak intensities (I_{-3} to I_4) used in the simulation procedure. Since the Rosenbrock method used in this approach, is sensitive to the starting position and to the step function in the determination of a global minimum, an exact solution is calculated for equations (2) to (7) where $Back_1$ and $Back_2$ values are set equal. Once the Rosenbrock technique is placed at a reasonable starting point in space, the $Back_1$ and $Back_2$ variables become independent and the solution set giving the best fit with experimental data is found. Since the system of equations (2) to (7) is underdetermined, it has numerous solution sets. Furthermore, there may be several local minima in the region of the global minimum and the Rosenbrock method does not have the resolution necessary to ensure that the best solution is in fact the global minimum of the system. The solution is therefore further optimized by scanning separately the $Back_1$ and $Back_2$ variables at all positive values from 20 units below to 20 units above the Rosenbrock solution and with an interval of 0.01 units. The corresponding exact solution sets are stored in an array and the best solution in the array is selected by fitting experimental values simultaneously to equations (1) and (8). This procedure assures that the solution set is both the global minimum and physically significant.

The validity of the program SIMBROC was evaluated using test examples in which the peak intensities were calculated for situations in which the background and redox process variables were fixed at known values. The results presented in Table I indicate that the model can handle the constant and "picket-fence" background with at most 1% relative error in the extents of the processes while with the modulated background the relative error is less than 10%. The program was then successfully applied to systems showing predominant redox processes and to pentaphenylalanine where combined processes are involved. The results for the latter at different beam densities are shown in Table II and indicate in this particular instance that the trends as measured by the "apparent" reduction, Red_{app}, are not corroborated by the Red_2 values determined by SIMBROC. On the contrary, the results generated by the program indicate that the "apparent" trend in the (A+2)/A is most probably the result of background variation and not of two-electron reduction with beam flux. This rationale is further supported by the fact that the background values obtained by SIMBROC are in agreement with the experimentally measured background. It appears therefore that individual parameters have to be measured before any conclusion can be drawn on the trends observed in these systems.

TABLE I

Illustration of the ability of **SIMBROC** to handle the three basic types of background observed in FAB/LSIMS mass spectra

	CONSTANT		"PICKET-FENCE"		MODULATED	
	ACTUAL	SIMBROC	ACTUAL	SIMBROC	ACTUAL	SIMBROC

GENERATION OF QUASIMOLECULAR IONS IN FAB MASS SPECTROMETRY OF DERIVATIZED GLYCOSIDES AND NUCLEOSIDES

Qingmei Zha and Apostolos Dermatakis
Department of Chemistry, Brown University
Providence, RI 02912

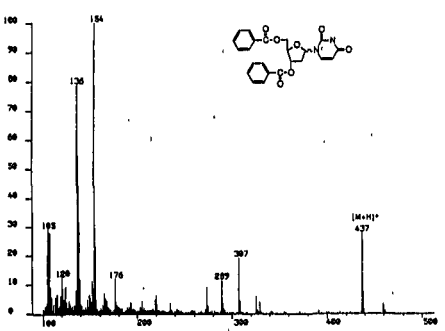
It was well established that FAB mass spectrometry produces the protonated molecular ions $[M+H]^+$. These energetically stable species provide ideal information for the determination of molecular masses. Recently, it was reported [1, 2] that in FAB mass spectrometry of some organic compounds, the quasimolecular ions observed in the molecular ion region are M^+ or $[M-H]^+$, rather than the protonated molecular ion $[M+H]^+$. Several reaction pathways were proposed in order to understand the generation of unusual quasimolecular ions. Although the conclusive mechanism has not been reached so far, it is suggested that some functional groups in those compounds may play a key role in the generation of unusual FAB mass spectra.

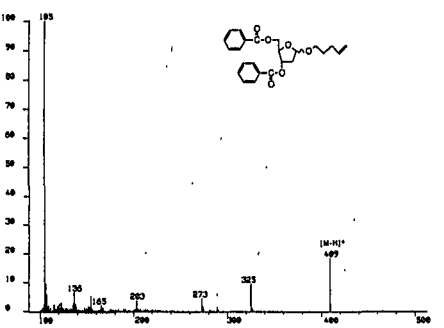
It was reported [3] that derivatized sugars produce unusual FAB mass spectra. The predominant quasimolecular ions observed in their spectra were not the protonated molecular ions $[M+H]^+$. To further study the generation of FAB mass spectra of sugar derivatives, a group of derivatized glycosides (pentenyl-2-deoxy-ribonosides) and nucleosides (2-deoxy-uridines) was synthesized and analyzed using FAB mass spectrometry. FAB mass spectral analysis of these derivatized glycosides and nucleosides was performed on a Kratos MS-80 double focusing mass spectrometer operating at an accelerating voltage of 4 kv. A fast atom saddle-field gun (Iontech FAB-11NF) is mounted on a standard Kratos FAB source. The xenon atom beam was generated with a kinetic energy of ca. 8 kv. 3-nitrobenzyl alcohol (NBA) was used as a liquid matrix.

The FAB mass spectra of derivatized glycosides and nucleosides indicate that the quasimolecular ions observed in the molecular region are different. For some compounds, the protonated molecular ions $[M+H]^+$ are observed as the major ions, but in most cases, the quasimolecular ions observed are M^+ or $[M-H]^+$. We placed a glycoside and a nucleoside, which were prepared by the same derivatization process, into a pair. The FAB mass spectra of a pair of compounds were then compared each other.

$[M+H]^+$ *vs.* $[M-H]^+$

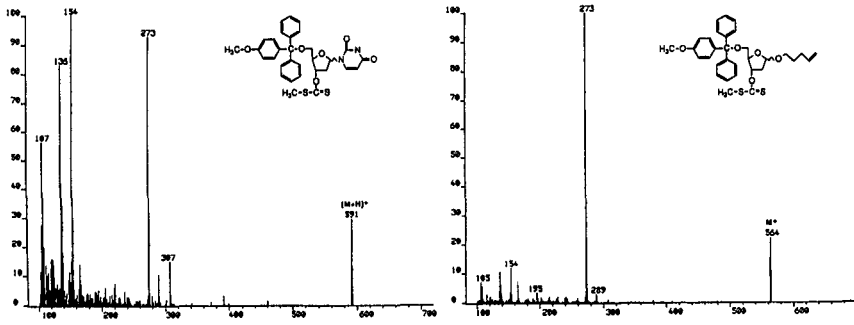
FAB mass spectrum of 2-deoxy-3,5-di-O-benzoyl-uridine gives a predominant protonated molecular ion $[M+H]^+$ at m/z 437. However, FAB mass spectrum of its glycoside analogue, pentenyl-2-deoxy-3,5-di-O-benzoyl-ribonoside gives a quasimolecular ion at m/z 409, which is two mass units less than expected protonated molecular ions. This would indicate that the observed quasimolecular ions correspond to $[M-H]^+$ rather than $[M+H]^+$.





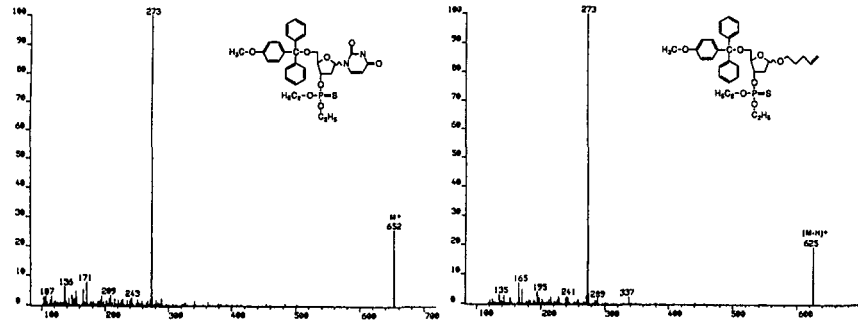
$[M+H]^+$ *vs.* M^+

The molecular weights of a nucleoside and a glycoside are 590 and 564, respectively. The nucleoside produces a normal FAB mass spectrum, namely, the protonated molecular ions $[M+H]^+$ were observed at m/z 591. However, the glycoside generates an even mass quasimolecular ion. This even mass ion corresponds to the molecular ion M^+.



M^+ *vs.* $[M-H]^+$

Both FAB mass spectra of a pair of compounds are unusual. The predominant ions observed at the molecular ion region are not the protonated molecular ions. The nucleoside gives the molecular ions M^+ while the glycoside generates the predominant $[M-H]^+$ions.



Although the reason that the different quasimolecular ions were observed is not very clear, it seems that the quasimolecular ions of the glycosides are always one mass unit less than those of its nulceoside analogues. It is suggested that the formations of $[M+H]^+$ and M^+ ions may undergo a similar reaction mechanism. The lack of a suitable protonation site caused by a steric effect may be the main reason that protonated molecular ions are not generated. It is also suggested that the formation of $[M-H]^+$ ions is probably caused by a rearrangement on the side chains of derivatized glycosides.

THE STUDIES OF SURFACE AND BULK COMPOSITION DURING FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Yu-Chie Chen and Jentaie Shiea
Dept. of Chemistry, Nat'l Sun Yat-Sen Univ., Kaohsiung
Taiwan, 80424

It has been shown that ions observed in FAB originate from depths near very surface of the matrix[1]. This observation is particularly important since it has long been recognized that the composition of the first few monolayers of liquid solutions will, in general, differ from the bulk composition.

In this regard, we have studied the surface and bulk composition of the solution by varying the matrix temperature and the surface activity of the analytes. Figure 1 shows the relative change in ion signal from n-dodecyltrimethylammonium-chloride (DTMA) and n-hexdecyltrimethyl-ammonium-chloride (HTMA) as a function of time at (a) room temperature and (b) -45°C. In the case of room temperature, the signal intensity of DTMA is higher than that of HTMA at short time and lower at longer time. This behavior is known already[2] and is suggested due to two competing processes: matrix evaporation (at short time) and stripping of surface layers by sputtering (at longer time). It is interesting to see that the relative change of ion signal for both amines with time are similar when the viscosity of the solution was increased by decreasing the temperature (Fig. 1b). The observation clearly shows when the mass transport processes are block in high viscosity condition (low temperature), surface activity effects no longer exist and the intensities of the signal of the analytes in FAB depend only on their bulk concentration. Similar results was obtained when the sample solution (equal concentration of decyltrimethylammonium bromide (DeTMA; m/z 200) and tetradecyltrimethyl-ammonium bromide (TTMA; m/z 256) in methanol) was applied on the surface of the freeze diglycerol matrix. In this case, analyte molecules were unable to diffuse into the matrix and the FAB spectrum reflected the surface concentration of the analytes which gave an equal signal intensity for both surfactants (Fig. 2a). This is different from when the analytes were dissolved in the matrix beforehand (Fig. 2b). The same effect can be seen when silica was added into sample solution which contains equal concentration of DeTMA and TTMA glycerol solution (Fig. 3). The silica was acted as adsorbent which drew both analytes into the solution and the dominance of more surface active component in FAB spectra no longer be seen.

We have also investigated the matrix evaporation effect to the ion signal intensity. In this experiment, DeTMA was dissolved in glycerol, sample solution was inserted and retrieved repeatedly for several times and the analyte signal was plotted against reinserted time. It can be seen that the analyte signal was higher than that in the rest of scans for each insertion (Fig. 4). This is due to increasing of surface concentration of the nonvolatile analytes as the matrix evaporates.

Gas Phase Ion Molecule Reactions of Anions of Esters With Neutral Alcohols

George W. Haas and Michael L. Gross

Midwest Center for Mass Spectrometry

University of Nebraska-Lincoln, Lincoln, NE 68588-0304

Esters have historical importance in biological functions as well as in industrial synthesis. To bridge the gap between the condensed phase and the gas phase, more understanding about the reactivity of esters in the gas phase is needed.

The purpose of this study is to investigate transesterification involving the enolate ions of esters and neutral alcohols. Normally base-catalyzed transesterification is viewed as the attack of an alkoxide ion at the carbonyl carbon, followed by the loss of a different alkoxide. The attack of an alkoxide is thought to proceed through a tetrahedral intermediate, with the hydrogen-transfer being rate determining in the gas phase[1].

For this study two different types of mass spectrometers were employed. The first type of mass spectrometer was the FT mass spectrometer. This instrument has the advantage of selecting and isolating an ion of choice in the cell of the instrument and then allowing a reaction to take place over time with neutrals. The other type of mass spectrometer used was a sector instrument equipped with a chemical ionization source. This instrument has the advantage that, due to its higher operating pressures, intermediates in reactions can be stabilized in order to study them.

Unequivocal evidence for the reactivity of enolate ions of esters with neutrals alcohols was obtained with an FT mass spectrometer by triple resonance (see Figure 1). The enolate ions of esters were produced (i.e., methyl acetate and ethyl acetate) by abstracting a hydrogen from the alpha carbon next to the carbonyl with CH_3O^- (from methyl nitrite). More information was provided by the FT mass spectrometer by studying the kinetics of the reactions. The data indicate that the starting enolate esters react via pseudo-first order reaction kinetics. The reaction rate increases for larger alcohols (i.e., methanol through 1-butanol), but no intermediate was observed in the FT mass spectrometer.

Additional information was acquired by FTMS by monitoring the reaction of the enolate ion of ethyl acetate and d_4-methanol (see Figures 2 and 3). The product and reactant enolate ion esters undergo replacement of the alpha carbons hydrogens with deuteriums as the reaction time increases.

An actual adduct was observed for the reaction of the enolate ion of ethyl acetate and d_4-methanol by the use of the sector instrument. Tandem sector results indicate the adduct structure, in part, is loosely-bound. An inverse isotope effect for the abstraction of an alpha hydrogen and loss of a neutral was also observed.

It is concluded that ester enolate anions react with neutral alcohols to undergo transesterification. Further studies on the adduct of the intermediate will provide additional information on the loosely-bound character, covalently-bound character, and or whether an ion-neutral complex is involved.

The Barrier to Methane Elimination from Ionized Butan-2-one: Theory and Experiment

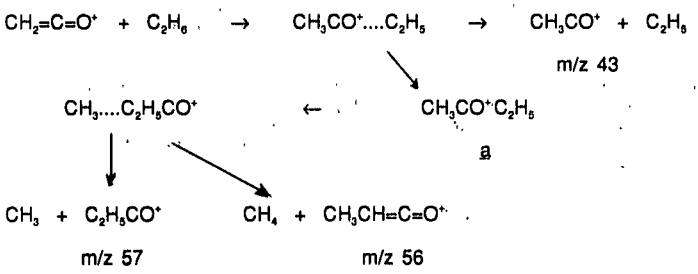
Charles E. Hudson and Mohammed Ahmed, Marine Biomedical Institute, Galveston, TX 77555 and Department of Marine Sciences, Texas A&M University at Galveston, Galveston, TX 77553 USA
Santiago Olivella, Department de Quimica Organica, Universitat de Barcelona, 08028 - Barcelona, Spain
C.S. Giam, Department of Marine Sciences, Texas A&M University at Galveston, Galveston, TX 77553 USA
David J. McAdoo, Marine Biomedical Institute, University of Texas Medical Branch, Galveston, TX 77555 USA

It has long been a puzzle why the metastable ion spectra of ionized acetone and pentan-3-one are dominated by losses of alkane (CH_4 and C_2H_6 respectively) while the metastable loss of CH_4 from ionized butan-2-one is only 5% of the CH_3 loss, despite the fact that CH_4 loss should be preferred thermodynamically.[1]

We have investigated the behavior of butan-2-one near the threshold of CH_3 and CH_4 losses by charge exchange, by ion molecule reactions, and by Ab Initio MO calculation.

When butan-2-one (IE=9.51 eV) is ionized by charge exchange with CS_2 (IE=10.07 eV) the butan-2-one ion (a) is observed, but its fragmentation products are not. When the ionizing reagent is $NH_3^{+\cdot}$ (IE=10.16 eV) the fragments are produced in the following intensity relative to a: CH_3CO^+ 11%, CH_3CHCO^+ 3.5%, $C_2H_5CO^+$ 35%. (Part of the difference may be due to kinetic energy effects.)

When ionized ketene (from butylrolactone) is reacted with ethane, product ions at masses 43, 56 and 57 are observed in the ratio of 100:3:15. Use of C_2D_6 as the reactant gas gave peaks at 43, 44 and 62 in the ratio 14:100:29. The mass 60 peak is present at a level of 3% or less if at all. Our mechanism is as follows:



Ab Initio UHF calculations (or RHF for even electron systems) predict that the TS for CH_4 loss from a should compete very poorly with methyl loss. However when correlation effects are included by optimization at the MP2 level, a much smaller barrier is predicted. This smaller barrier must be nearer to reality because loss of CH_4 is actually observed in the metastable ion spectrum of a. Table I gives results of representative calculations, including zero point energies calculated at the 6-31 G (d,p) level.

Table I

Relative energies of species from butane-2-one (kJ/M)

Species	$CH_3COC_2H_5^+$	$CH_3+C_2H_5CO^+$	TS for CH_4 loss	$CH_4+CH_3CHCO^+$	Complex

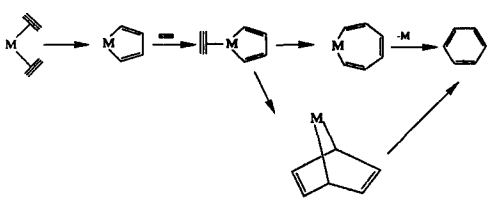
Fe^+ Catalyzed [2 + 2 + 2] Cyclotrimerization of Alkynes and Nitriles

R. Bakhtiar, J.J. Drader and D.B. Jacobson
Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

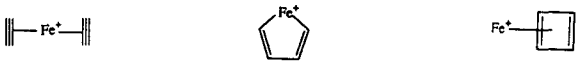
The cyclotrimerization of alkynes to yield benzene derivatives can be achieved by a variety of catalyst systems, both homogeneous and heterogeneous.[1] It is generally believed that aklyne cyclotrimerization proceeds through the intermediacy of a metallacyclopentadiene, Scheme I. Recently, Schwarz and co-workers demonstrated

Scheme I



that Fe^+ effects cyclotrimerization of acetylene by using neutralization-reionization mass spectrometry (NRMS).[2] They formally generated $Fe(C_2H_2)_3^+$ by displacement of three CO's from $Fe(CO)3^+$ by acetylene. Collision-activated dissociation (CAD) of $Fe(C_2H_2)_3)^+$ followed by NRMS revealed a dominant *m/z* 78 ion which was assigned as benzene.

We have used Fourier transform mass spectrometry (FTMS)[3] to expand on the elegant results of Schwarz and co-workers concerning acetylene cyclotrimerization mediated by Fe^+. We are particularly interested in the generation and structural characterization of three distinct $FeC_4H_4^+$ ions, 1-3, and probing their involvement in the cyclotrimerization of acetylene.



1 2 3

Two distinct $FeC_4H_4^+$ isomers are generated by reactions 1 and 2. Structural

$$Fe(CO)_2^+ + 2C_2H_2 \text{ ----------> } \underset{4}{FeC_4H_4^+} + 2CO \quad (1)$$

$$Fe(c\text{-}C_5H_6)^+ + O_2 \text{ ----------> } \underset{5}{FeC_4H_4^+} + (CH_2O_2) \quad (2)$$

studies (CAD combined with ion/molecule reactions) indicate that 4 consists of a bis(acetylene) structure, 1, whereas 5 contains an intact C_4H_4 unit, either structures 2 or 3. Both ions 4 and 5 yield react with acetylene to yield exclusive formation of Fe^+, reaction 3. Based on simple thermochemical arguments (i.e.,

$$\underset{\sim}{4},\ \underset{\sim}{5} + C_2H_2 \dashrightarrow Fe^+ + C_6H_6 \qquad (3)$$

conversion of three acetylenes to benzene is 144 kcal/mol exothermic) and the NRMS results of Schwarz and co-workers,[2] the neutral product in reaction 3 is probably benzene.

Reaction of C_2D_2 with both $\underset{\sim}{4}$ and $\underset{\sim}{5}$ is summarized in reactions 4 and 5 and yields both Fe^+ formation and displacement of C_2H_2. $\underset{\sim}{4}$ yields 60% C_2H_2 displacement whereas

$$\underset{\sim}{4} + C_2D_2 \dashrightarrow \begin{cases} \xrightarrow{60\%} Fe(C_2H_2)(C_2D_2)^+ + C_2H_2 & (4a) \\ \xrightarrow{40\%} Fe^+ + C_6H_4D_2 & (4b) \end{cases}$$

$$\underset{\sim}{5} + C_2D_2 \dashrightarrow \begin{cases} \xrightarrow{7\%} Fe(C_2H_2)C_2D_2)^+ + C_2H_2 & (5a) \\ \xrightarrow{93\%} Fe^+ + C_6H_4D_2 & (5b) \end{cases}$$

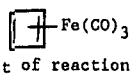
$\underset{\sim}{5}$ yields only 7% C_2H_2 displacement. Propyne reacts with $\underset{\sim}{4}$ giving primarily displacement of C_2H_2, however, $\underset{\sim}{5}$ yields primarily Fe^+ formation, reactions 6 and 7.

$$4 + C_3H_4 \dashrightarrow \begin{cases} \xrightarrow{88\%} Fe(C_2H_2)(C_3H_4)^+ + C_2H_2 & (6a) \\ \xrightarrow{12\%} Fe^+ + (C_7H_8) & (6b) \end{cases}$$

$$5 + C_3H_4 \dashrightarrow \begin{cases} \xrightarrow{14\%} Fe(C_2H_2)(C_3H_4)^+ + C_2H_2 & (7a) \\ \xrightarrow{86\%} Fe^+ + (C_7H_8) & (7b) \end{cases}$$

In accord with reactions $\underset{\sim}{4}$ and $\underset{\sim}{5}$, we believe that the product of reactions 6b and 7b is toluene. The dramatic difference in the fraction of acetylene displacement versus Fe^+ formation suggests that the structure of $\underset{\sim}{5}$ is the preferred intermediate for cycloaddition.

We are in the process of further characterizing the structure of $\underset{\sim}{5}$. We will synthesize cyclobutadieneirontricarbonyl which should yield the corresponding Fe(cyclobutadiene)$^+$ complex upon EI, process 8. We will characterize the the



$$Fe(CO)_3 \dashrightarrow FeC_4H_4^+ + 3CO \qquad (8)$$

structure of the product of reaction 8 and study its role in the cyclotrimerization of acetylene to yield benzene.

Generation and Characteristics of Transition Metal-Silylene and -Silene Complexes

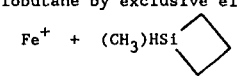
R. Bakhtiar, C.M. Holznagel and D.B. Jacobson
Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

Transition metal-silyl and -silylenes (silylene = $Si(R_2)$) have been implicated as intermediates in numerous reactions[1] including hydrosilylation, silicon-silicon coupling and silane polymerization, and chemical vapor deposition of silanes forming transition-metal silicides.[2] Transition metal-silylene complexes are implicated as key intermediates in silicon-silicon coupling reactions, however, there are few examples of these complexes in solution. The corresponding isomeric transition metal-silene (silene = $(R)_2Si{=}CH_2$) complexes are even more elusive in solution.

We have applied Fourier transform mass spectrometry (FTMS)[3] to generate isomeric Fe(silylene)$^+$ and Fe(silene)$^+$ complexes and subsequently characterize their properties (i.e., structure, reactivity, etc.). Fe(silylene)$^+$ and Fe(silene)$^+$ isomers are generated by reaction of Fe^+ with specific organosilanes. For example, Fe^+ reacts with dimethylsilane by exclusive dehydrogenation, process 1.[4] Reaction of

$$Fe^+ + H_2Si(CH_3)_2 \longrightarrow \underset{\underset{1}{\sim}}{FeSiC_2H_6^+} + H_2 \qquad (1)$$

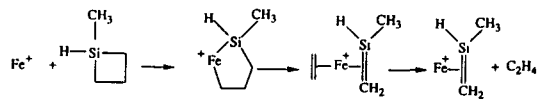
Fe^+ with $D_2Si(CH_3)_2$ yields exclusive loss of D_2 suggesting formation of a dimethylsilylene complex ($Fe{-}Si(CH_3)_2^+$, 1) in reaction 1. Fe^+ reacts with 1-methylsilacyclobutane by exclusive elimination of ethene, process 2. This reaction



$$Fe^+ + (CH_3)HSi\square \longrightarrow \underset{\underset{2}{\sim}}{FeSiC_2H_6^+} + C_2H_4 \qquad (2)$$

presumably involves initial insertion of Fe^+ into the strain weakened Si-C bond followed by ethene extrusion, Scheme I. This mechanism suggests formation of a silene complex($Fe(CH_2{=}Si(CH_3H)^+$, 2) in reaction 2.

Scheme I



The structure of the $FeSiC_2H_6^+$ ions produced in reactions 1 and 2 were probed by both collision-activated dissociation (CAD) and by specific ion/molecule reactions. The CAD spectra of the $FeSiC_2H_6^+$ ions, 1 and 2, are complex with a number of fragmentations observed (these include the following losses: H_2, CH_4, C_2H_4, C_2H_6, SiC_2H_6). Both 1 and 2 yield the same fragmentations, energy dependency, and overall fragmentation efficiency. This suggests that either 1 and 2 have the same structure or that rearrangement to a common intermediate precedes dissociation.

Specific ion/molecule reactions can be quite selective probes of ion structure. Neutral reagents can be selected that exploit the characteristic (unique) reactivity of different isomers. The $FeSiC_2H_6^+$ ions, 1 and 2, both yield adduct formation with ethene, reactions 3 and 4. The product of reaction 3 yields a second ethene addition

$$\underset{\underset{1}{\sim}}{FeSiC_2H_6^+} + C_2H_4 \dashrightarrow Fe(SiC_2H_6)(C_2H_4)^+ \quad (3)$$

$$\underset{\underset{2}{\sim}}{FeSiC_2H_6^+} + C_2H_4 \dashrightarrow Fe(SiC_2H_6)(C_2H_4)^+ \quad (4)$$

whereas the product of reaction 4 is inert with ethene. This difference in reactivity suggests distinct $FeSiC_2H_6^+$ structures for $\underset{\sim}{1}$ and $\underset{\sim}{2}$. Additional insight concerning structure is obtained by reaction with isotopically labeled ethene. $\underset{\sim}{1}$ reacts with C_2D_4 to produce mainly an adduct with some H/D exchange observed, reaction 5. The product of reaction 5a yields exclusive addition of a second C_2D_4 with no isotopic scrambling observed, process 6.

$$\underset{\sim}{1} + C_2D_4 \dashrightarrow \begin{cases} \xrightarrow{0.64} \underset{\sim}{1}(C_2D_4) & (5a) \\ \xrightarrow{0.12} FeSiC_2H_5D^+ & (5b) \\ \xrightarrow{0.12} FeSiC_2H_4D_2^+ & (5c) \\ \xrightarrow{0.12} FeSiC_2H_3D_3^+ & (5d) \end{cases}$$

$$1(C_2D_4) + C_2D_4 \dashrightarrow 1(C_2D_4)_2 \quad (6)$$

$\underset{\sim}{2}$ reacts with C_2D_4 and $^{13}C_2H_4$ to yield initial exclusive adduct formation, processes 7 and 8. Following adduct formation, a double H/D exchange (no single H/D exchange is observed) occurs with C_2D_4, process 7 and a single $C/^{13}C$ exchange is seen with $^{13}C_2H_4$, process 8. The secondary reactions suggest two distinct carbon atoms

$$\underset{\sim}{2} + C_2D_4 \dashrightarrow \underset{\sim}{2}(C_2D_4) \xrightarrow{C_2D_4} \text{H/D di-exchange} \quad (7)$$

$$\underset{\sim}{2} + {}^{13}C_2H_4 \dashrightarrow \underset{\sim}{2}({}^{13}C_2H_4) \xrightarrow{{}^{13}C_2H_4} 1C/{}^{13}C \text{ exchange} \quad (8)$$

atoms for $\underset{\sim}{2}$ *which is consistent with a silene type structure.* The isotopic exchange results suggest methylene exchange between silene and labeled ethene.

CAD of the $2(C_2D_4)$ and $2(^{13}C_2H_4)$ adducts yields exclusive loss of labeled ethene (no isotopic scrambling observed). These CAD results and the above reactions, processes 7 and 8, indicate that isotopic exchange for $\underset{\sim}{2}$ requires the presence of two ethene units. This result is puzzling and not well understood. Clearly, reactions with ethene (isotopically labeled) distinguish two distinct $FeSiC_2H_6^+$ isomers. Reactions 7 and 8 strongly indicate formation of $Fe(silene)^+$ in reaction 2. *Structural diagnosis of* $FeSiC_2H_6^+$ *formed in reaction 1 is less certain but it is* probably an $Fe(silylene)^+$ structure.

Mechanism of Unimolecular Dissociation of $(CH_3)SiH_2^+$ and $(CH_3)Si(Cl)H^+$

R. Bakhtiar, C.M. Holznagel, L. Pederson, M.S. Gordon and D.B. Jacobson
Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

The mechanism of the thermal decomposition of silanes is of considerable interest due to its relevance to the chemical vapor deposition (CVD) of silicon on surfaces.[1] We have applied both theory and experiment (Fourier transform mass spectrometry)[2] to study the unimolecular dissociation of $CH_3SiH_2^+$. The unimolecular dissociation of $(CH_3)Si(Cl)H^+$ was studied experimentally and the results compared to those for decomposition of $(CH_3)SiH_2^+$. The lowest energy pathway for decomposition of $(CH_3)SiH_2^+$ and $(CH_3)Si(Cl)H^+$ was probed experimentally by using a sustained "off-resonance" irradiation (SORI) pulse for collision-activated dissociation (CAD).[3] This method of CAD slowly activates an ion by multiple, low energy collisions thereby facilitating dissociation by the lowest energy pathway and is analogous to infrared multiphoton dissociation (IRMPD). Geometry optimizations were carried out at restricted Hartree-Fock (HRF) level of theory using 6-31G* basis set. Minima and transition states were determined by diagonalization of energy second derivative matrix (hessian). Single point MP4 energy calculations and MCSCF optimizations are currently in progress.

Conventional "on-resonance" irradiation for CAD of $(CH_3)SiH_2^+$ yields dehydrogenation (dominant) and methane elimination as the two primary CAD processes, reaction 1. SORI-CAD revealed exclusive dehydrogenation indicating that process 1a

$$(CH_3)SiH_2^+ \xrightarrow{CAD} SiCH_3^+ + H_2 \quad (1a)$$

$$(CH_3)SiH_2^+ \xrightarrow{CAD} SiH^+ + CH_4 \quad (1b)$$

is the lowest energy pathway for decomposition. Decomposition of $(CH_3)SiD_2^+$, produced by EI of $(CH_3)SiD_3$, was studied in order to gain additional insight into the mechanism of dehydrogenation. Again, dehydrogenation is the exclusive process observed upon SORI-CAD with nearly equal amounts of H_2 and HD elimination observed (no D_2 loss is seen).

The CAD results established that dehydrogenation is the lowest energy channel for decomposition for $(CH_3)SiH_2^+$, however, the mechanism is unclear due to the mixed isotopomer dehydrogenation for $(CH_3)SiD_2^+$. Dehydrogenation may proceed by three distinct mechanisms: 1,1-elimination from silicon, 1,2-elimination, and 1,1-elimination from carbon, process 2. The labeling results suggest that both processes

$$(CH_3)SiH_2^+ \longrightarrow CH_3Si^+ \; H_2 \quad (2a)$$

$$(CH_3)SiH_2^+ \longrightarrow CH_2SiH^+ + H_2 \quad (2b)$$

$$(CH_3)SiH_2^+ \longrightarrow CHSiH_2^+ + H_2 \quad (2c)$$

2b and 2c are occurring. Scrambling of the deuterium label by reversible process 3

$$CH_3SiH_2^+ \rightleftharpoons CH_2SiH_3^+ \quad (3)$$

prior to dehydrogenation would complicate interpretation of the labeling results. Hopkinson and Lien, using theory, found that process 3 is ca. 40 kcal/mol endothermic and occurs with little or no barrier in excess of the overall endothermicity.[4] Consequently, theory is required in order to understand the mechanism of

decomposition of $(CH_3)SiH_2^+$.

The three dehydrogenation processes, reaction 2, as well as methane elimination, process 1b, were studied by *ab initio* theory at the RHF/ 6-31G* level. Processes 2a and 2b have barriers of 86 and 87 kcal/mol,respectively, and are endothermic by 33 and 84 kcal/mol, respectively. The barrier for process 2c is unknown, however, it is endothermic by 102 kcal/mol. Methane loss, process 1b, has a barrier of 92 kcal/mol and is 46 kcal/mol endothermic. Processes 2a and 2b have the lowest barriers with their difference insignificant at the current level of theory. Dehydrogenation by 1,1-elimination from carbon, process 2c, is clearly the least favorable channel. The higher barrier for methane elimination, process 1b, is consistent with the SORI-CAD results.

The substantial barrier for dehydrogenation of $(CH_3)SiH_2^+$ (ca. 86 kcal/mol) indicates that rearrangement by 1,2-hydrogen atom migration, process 3, is readily accessible.[4] Because the $CH_2SiH_3^+$ isomer is energetically accessible and is formed with little or no barrier its role in the decomposition of $CH_3SiH_2^+$ was examined. The only energetically reasonable process is 1,1-elimination from silicon, process 4,

$$CH_2SiH_3^+ \text{ ----------> } CHSiH_2^+ + H_2 \qquad (4)$$

which has a calculated barrier of 49 kcal/mol. This barrier height, combined with the isomerization energy (ca. 40 kcal/mol) yields a total energy requirement for dehydrogenation by process 4 of 89 kcal/mol. Consequently, theory reveals three dehydrogenation channels with similar energy barriers, processes 2a, 2b and 4. The substantial barrier height for decomposition of $(CH_3)SiH_2^+$ indicates that considerable isotopic scrambling by process 3 will occur prior to dissociation of $(CH_3)SiD_2^+$ by CAD, as observed.

SORI-CAD of $(CH_3)Si(Cl)H^+$ yields exclusive HCl elimination, process 5, revealing

$$(CH_3)Si(Cl)H^+ \xrightarrow{\text{SORI-CAD}} SiCH_3^+ + HCl \qquad (5)$$

that it is the lowest energy process for dissociation. Ethene-d_4 reacts with $(CH_3)SiH_2^+$ to yield exclusively <u>one</u> H/D exchange, process 6. SORI-CAD of the product

$$(CH_3)Si(Cl)H^+ + C_2D_4 \text{ ----------> } (CH_3)Si(Cl)D^+ + C_2D_3H \qquad (6)$$

of reaction 6 yields exclusive elimination of HCl, process 7. This indicates that

$$(CH_3)Si(Cl)D^+ \xrightarrow{\text{SORI-CAD}} CH_2SiD^+ + HCl \qquad (7)$$

the lowest energy process for dissociation of $(CH_3)Si(Cl)H^+$ is 1,2-elimination of HCl. Absence of DCl loss, process 7, indicates that $(CH_3)Si(Cl)H^+$ does not undergo 1,2-hydrogen migration prior to fragmentation (e.g., process 3).

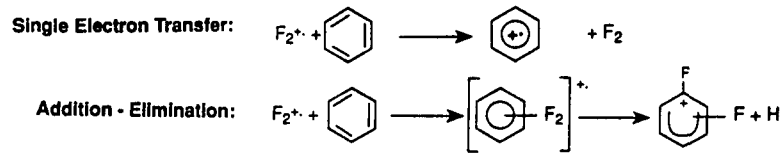
Reactions of $F_2^{+\cdot}$ with Aromatic Compounds in an Ion Trap Mass Spectrometer

*C.A. Haney[A], S.T. Purrington[A], H-Y. Lin[B], R.D. Voyskner[B]

A) Dept. of Chemistry, N.C. State University, Raleigh, NC 27695
B) Research Triangle Institute, Research Triangle Park, NC 27709

In this study we report the results of an investigation into the reaction of fluorine radical cation ($F_2^{+\cdot}$) with aromatic compounds in the gas phase. The results provide information regarding the mechanisms involved, the effect of aromatic substituents, the position of addition and the structure of the intermediate. An ion trap mass spectrometer (ITMS) was used for this study. Fluorine gas (5% in nitrogen) was introduced via a pulsed valve [1]. Fluorine radical cation (m/z 38) generated by 70 eV ionization, was mass selected using the apex isolation method [2] and the course of the reaction with aromatic molecules was monitored as a function of time (Figure 1). Two reaction mechanisms were observed, charge transfer reactions and electrophilic addition/elimination reactions (scheme 1).

Scheme 1



The products of the addition/elimination reaction are difluoriated species for all aromatic compounds studied. The competition between the two reaction pathways is effected by helium buffer gas pressure and aromatic substituents (Figure 2). With decreasing helium buffer gas pressures the charge transfer reaction increases. Increasing helium buffer gas pressure results in increased addition/elimination reactions.

The addition/elimination reaction was further investigated using deuterated aromatic reactants and by performing MS/MS experiments on the difluorinated product ions. All aromatic compounds studied show some addition/elimination products. The substituents on the aromatic compounds may exert a directing effect on the position of addiction of fluorine radical cation. A dominant ion corresponding to a retro Diels-Alder fragmentation suggests a [1,4] addition of the fluorine atoms.

The intermediate involved in the addition/elimination reaction was not observed in the product spectra. In addition, the effect of the helium buffer gas on the competitive reactions and the lack of substrate selectivity with the apparent site selectivity suggests the presence of an π- complex. The involvement of a π- complex intermediate in condensed phase fluorination reactions with aromatic compounds has been proposed [3,4]. In contrast to the condensed phase, the gas phase addition/elimination products are difluorinated species. In condensed phase molecular fluorination reactions, the products are monofluorinated species. It is interesting, however, that for the synthesis of 5-fluoruracil, the mechanism proposed is addition of F_2 followed by elimination of HF [5]. Perhaps, addition/elimination plays a more significant role in condensed phase fluoriations than previously thought.

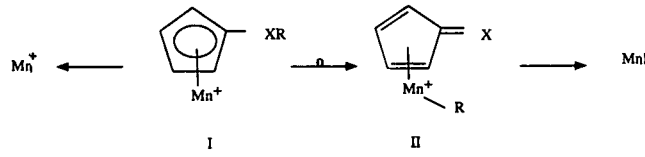
Structure and Reactivity of Cyclopentadienyl Manganese Ions, $RXC_5H_4Mn^+$, in the Gas Phase

*D.V.Zagorevskii, Yu.S.Nekrasov, C.W.Kazakoff and J.L.Holmes
Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5
Institute of Organo-Element Compounds, Russian Academy of Sciences, Moscow, Russia, CIS 117334.

Reactivity of $RXC_5H_4Mn^+$ ions, formed upon the ionization of $RXC_5H_4Mn(CO)_3$, in gas phase unimolecular decomposition and ion-molecule reactions has been studied.

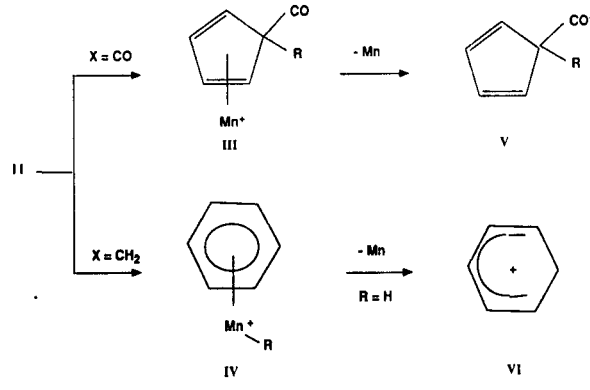
Among the metastable ions only unsubstituted and cyano derivatives retain their original nido-cluster structure, I, which is characterized by simple metal-ligand bond dissociation with Mn^+ ion formation.

For other XR substituents intensive isomerization occurs. The key intermediate, II, is produced by R migration to the metal atom. Decomposition of this II isomer leads to MnR^+ ions.



The degree of I --> II isomerization increases with increasing of electronegativity (reaches the maximum for OH and other heteroatomic groups) and mobility (from X=CO to $X=CH_2$) of migrating radical R.

Ions II can undergo further isomerization to III of IV type structures by the reverse migration of R from metal atom into cyclopentadienyl ring (for X=CO) or/and ring expansion (for $X=CH_2$). The latter is evidenced by the ring and methylene hydrogen atoms scrambling before water molecule loss from deuterated $MnC_5H_4CH_2OH^+$ ions. Ions III and IV are responsible for organic ions formation, V and VI respectively, according to Stevenson-Audier rule.

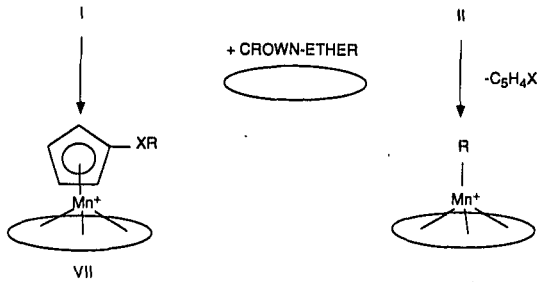


Collisional activation and neutralization-reionization (NR) experiments showed that some stable $RXC_5H_4Mn^+$ ions keep their original nido-cluster structure, one of whose characteristic is the presence of the recovery signal in the NR mass spectrum.

The structure of $RXC_5H_4Mn^+$ ions determines their behaviour in ion-molecule reactions (IMR) and can be explained by the degree of I --> II isomerization. Ions I, having a coordinatively and electronically more unsaturated Mn atom, are characterized by the higher overall effectiveness in IMR.

I-type ions react with their neutral precursor molecule forming binuclear products, $(RXC_5H_4Mn)_2(CO)_n^+$ (n=0, 3), whereas II-type ions undergo C_5H_4X group substitution leading to $(RXC_5H_4)(R)Mn_2^+$ ions.

Ions I and II react differently with crown-ethers in the gas phase [1] and in FAB conditions. Crown-ethers substitute C_5H_4X ligand in II-type ions, but they cannot replace the cyclopentadienyl ligand in ions I, forming adducts of VII-type.



The fate of the ligand molecule L in metastable adduct $RXC_5H_4MnL^+$ ions, where L = alcohol, ester, carboxylic acid, alkyl halide, depends upon the coordinative unsaturation at Mn. Thus for adducts to II ions the ligand L is lost intact in a metastable fragmentation, whereas for I-type ions, L may decompose. The latter reactions provide information about the relative metal-ligand bond strengths in $C_5H_5Mn(L')(L'')^+$ ions. The following orders have been obtained: ROH > RCH=C=O > C_2H_4, allyl; HCl ≥ oxirane > C_2H_4; HBr, HI ≈ C_2H_4; CH_2O > MeCl.

Molecule L, coordinated to the metal atom, decomposes not only "unimolecularly", but can also interact with the functional group in the substituent XR.

FAST-ATOM BOMBARDMENT MASS SPECTROMETRY OF PEROXO COMPLEXES OF MOLYBDENUM(VI)

*J.L. Gundersen, J. Greaves, C. Djordjevic[1].
Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, Virginia, 23062. [1]College of William and Mary, Department of Chemistry, Williamsburg, Virginia, 23185.

INTRODUCTION

Several novel molybdenum(VI) peroxo heteroligands have recently been synthesized and characterized.[1,2,3] Transition metal peroxo compounds, especially peroxo heteroligands are of interest for several reasons. They are reactive intermediates in catalytic oxidations, may be important in biological processes involving oxidation and are currently being tested for anti-tumor activity.

Fast-atom bombardment mass spectra (FAB-MS) of Mo(VI) peroxo heteroligands have not been reported, although the FAB-mass spectra of several other organomolybdenum complexes have been determined.[4-9] Of the spectra that have been reported, little fragmentation of the parent molecule is noted. Molybdenum lends itself well to mass spectroscopy. It has seven major isotopes that generate a distinctive pattern, making the identification of Mo-containing ions obvious.

EXPERIMENTAL

An Extrel ELQ 400-2 quadrupole mass spectrometer with a manufacturer supplied FAB system was used to obtain the spectra of the following molybdenum(VI) peroxo heteroligand complexes: $(C_3H_5N_2)_2[O\{MoO(O_2)_2H_2O\}_2]$ (1), $MoO(O_2)_2(C_2H_5NO_2)(H_2O)$ (2) and $K_2[MoO(O_2)_2(C_2O_2)]$ (3). Spectra were obtained in the negative and positive ionization modes. Scan ranges in the negative and positive modes were 100-700amu and 200-700amu, respectively. Positive and negative mass spectra were collected for compounds 1 and 2. Only positive ion spectra were collected for compound 3. The bombarding gas was xenon at 8kv and 100μA.

Compounds for analysis were synthesized by the authors according to previously reported procedures. A 1:1 mixture of glycerol (gly) and DMSO proved to be the best matrix for compounds 1 and 2. Diethanolamine (DEA) was the most effective matrix for compound 3. Other matrices tested are included in the results section.

RESULTS

Figure 1 shows the positive FAB mass spectrum of compound 1 with fragment ions identified. Loss of the ligand and water along with cleavage of the dimer was noted. Figure 2 illustrates the fragmentation pathways of the molecule. Compounds 2 and 3, both monomers, exhibited similar fragmentation patterns.

Several solvents were tested as possible matrices. Of these, gly/DMSO gave the most complete dissolution of compounds 1 and 2 while DEA proved to be the best matrix for compound 3. Compounds 1 and 2 did not dissolve in the DEA. In glycerol, compounds 1 and 2 dissolved to a lesser degree than with the gly/DMSO mixture. Compound 3 was very slightly soluble. Sulfur containing matrices, thioglycerol and "Magic Bullet" (dithiothreitol/dithioerythritol), caused decomposition of the compounds. A mixture of glycerol and glacial acetic acid (1/1) did not improve solvation of the compounds and resulted in increased adduct formation and complication of the spectra. None of the compounds dissolved in a mixture of 18-crown-6-ether and tetraglyme (the latter was used to solubilize the ether) or in MNBA(*m*-nitrobenzyl alcohol).

DISCUSSION

FAB-MS can be used as a quick and effective method for confirming the identity of Mo(VI) peroxo heteroligands. Molybdenum's isotopic pattern allows for simple identification of Mo-containing fragment ions. Unlike most other reports on FAB-MS of Mo complexes, significant fragmentation was observed in both the negative and positive ionization modes. Primary fragmentation patterns in both modes involve loss of the organic ligand. The positive mode also exhibits matrix adduct formation as well as some retention of the ligand. The composition of some Mo-containing fragment ions remains undetermined and may be the result of rearrangements. Fragmentation patterns for Compound 1 indicate cleavage of the dimer at the Mo-O bond.

Mass Spectra of Liquid Crystals

VII. Novel 1-phenyl-4-alkylcyclohexanol derivatives and various fluorinated compounds

Piet A. Leclercq
Laboratory of Instrumental Analysis, Eindhoven University of Technology
P.O. Box 513, 5600 MB Eindhoven, The Netherlands

INTRODUCTION

Liquid crystal displays (LCDs) are nowadays widely used. Most of the liquid crystals employed in display devices are of the nematic type. These compounds are applied in carefully balanced mixtures to achieve the required device specifications. The mixtures may contain many different classes of liquid crystals. New classes of compounds are continuously being developed.

Liquid crystal components used in twisted nematic LCDs are polar or non-polar molecules, with mostly two, three or four six-membered ring structures. The mass spectra of various classes of liquid crystals have been reported recently (1). In this paper the EI mass spectra of some new classes of compounds are presented. These classes include 1-(4-cyanophenyl)- and 1-(4-fluorophenyl)-4-alkyl-cyclohexanol derivatives, and various fluoro-phenyl and trifluoromethoxy-phenyl derivatives.

RESULTS AND DISCUSSION

The 70-eV electron impact (EI) mass spectra of 1-(4-cyanophenyl)- and 1-(4-fluorophenyl)-4-alkyl-cyclohexanol derivatives are exemplified in Figs. 1a and 1b, respectively. Molecular ions are present in all instances. The heaviest fragment ions measured originate from the loss of water from the molecular ions. The molecular ions lose alkyl radicals, and particularly $C_5H_{11}^{\bullet}$. Denoting the cyano or fluoro substituents as X, the spectra of these compounds display the base peaks at *m/z* (132 + X), corresponding to the ions $[XC_6H_4C_3H_4O]^{+\bullet}$. Odd-electron ions $[XC_6H_4C_2H_3O]^{+\bullet}$ are found at *m/z* (119 + X) in the spectra of both the fluoro-phenyl and the cyanophenyl cyclohexanols. Peaks at *m/z* (104 + X), (90 + X) and (76 + X) arise from the ions $[XC_6H_4CO]^{+}$, $[XC_6H_4CH_2]^{+}$, and $[XC_6H_4]^{+}$ respectively. In the spectra of the cyanophenyl compounds, the base peaks are accompanied by tall peaks 1 u higher in mass. The cyanophenyl - cyclohexanols also yield characteristic odd-electron ions $[RC_4H_7]^{+\bullet}$ at *m/z* (55 + R), where R represents the alkyl group.

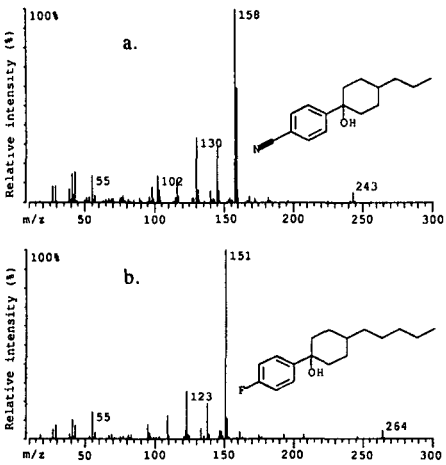

Figure 1. 70-eV EI mass spectra of
a. 1-(4-cyanophenyl)-4-propyl-cyclohexanol
b. 1-(4-fluorophenyl)-4-pentyl-cyclohexanol

The mass spectra of four 1-(4'-alkyl [1,1'-bi-cyclohexyl]-4-yl)- 4- (trifluoromethoxy)-benzenes are condensed in Table 1. These compounds give abundant fragment ions $[H_2C{=}CHC_6H_3OCF_3]^{+\bullet}$ at *m/z* 188, and ions at ± 13 u. The ions

$[RC_6H_{10}C_6H_7]^{+\bullet}$ at *m/z* (161 + R), and the ions $[RC_6H_{10}]^+$ at *m/z* (82 + R) are characteristic for the alkyl groups R.

The mass spectra of bicyclohexyl-ethyl-benzene derivatives are exemplified in Figs. 2a and 2b. These spectra contain the molecular ions, but are dominated by tall peaks at *m/z* 128 and 127 in the case of difluoro compounds, and at *m/z* 176 and 175 in the case of trifluoromethoxy compounds, corresponding to the substituted toluenes and the tropylium- or benzyl-like ions, respectively.

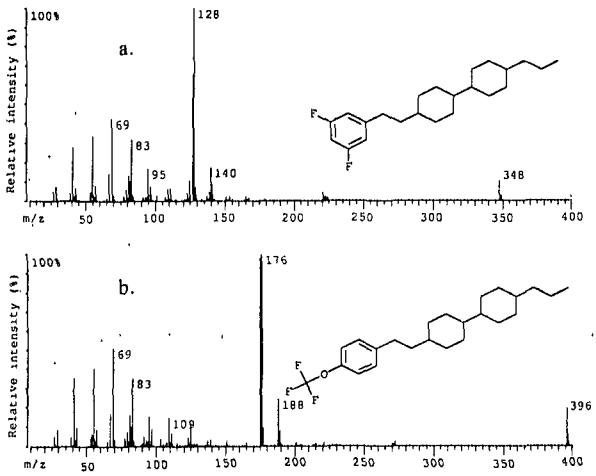

Figure 2. 70-eV EI mass spectra of
a. 1,3-difluoro-5-[2-(4'-(propyl[1,1'-bicyclohexyl]-4-yl)ethyl]-benzene
b. 1-[2-(4'-propyl[1,1'-bicyclohexyl]-4-yl)ethyl]-4-(trifluoromethoxy)-benzene

SELECTIVE DETECTION OF BROMINATED HYDROCARBONS BY A SILICON TETRAFLUORIDE-DOPED PHOTODETACHMENT-MODULATED ELECTRON CAPTURE DETECTOR

J.A. Bognar, W.B. Knighton, and E.P. Grimsrud
Department of Chemistry, Montana State University, Bozeman, MT 59717

The electron capture detector (ECD) for gas chromatography (GC) is well known for its utility in the trace environmental analysis of many halogenated compounds. In some applications, such as atmospheric analysis, improved specificity with regard to the halogens involved could be desirable.

A photodetachment-modulated ECD (PDM-ECD) is described here for the selective detection of brominated (and iodinated) compounds in the presence of chlorinated compounds, utilizing association reactions between SiF_4 and halide ions. A pulsed e-beam high pressure mass spectrometer (PHPMS) is also used to investigate the ion chemistry associated with the PDM-ECD responses.

A schematic of the PDM-ECD is shown in Figure 1. The ECD was maintained at a temperature of 150°C. Samples were introduced via a 1.0 mL sample loop, which was at the head of a 10 ft. x 1/8 in. column packed with 10% SF-96 on Chromosorb W. The column effluent (nitrogen) was mixed with a separate nitrogen stream which contained the SiF_4. The full intensity of a 100-watt Hg arc lamp was used without any filters or monochromators; the light beam was chopped at 83 Hz. A normal ECD response, δI_n, is sent to pen 1 of a two-pen chart recorder. It is due to Reaction 1:

$$RX + e^- \longrightarrow R + X^- \qquad (1)$$

The X^- ion undergoes photodetachment in the PDM-ECD, according to Reaction 2:

$$X^- + h\nu \longrightarrow X + e^- \qquad (2)$$

The resulting photodetachment-modulated signal, δI_m, is sent to pen 2.

Typical PDM-ECD responses to a multicomponent sample are shown in Figure 2. Figure 2A shows the δI_n responses, which remain relatively constant under the conditions used here. Figures 2B-2D show the δI_m responses for increasing SiF_4 concentrations in the detector gas. The changes in the chloride and bromide δI_m signals were initially attributed to only Reaction 3, where the halide ion is complexed by SiF_4, thus preventing photodetachment:

$$X^- + SiF_4 \rightleftharpoons X^-SiF_4 \qquad (3)$$

In Figure 2D, the δI_m response to CF_2Br_2 has not been fully eliminated. This is most likely due to the production of Br_2^- (about 20%), in addition to Br^-, when CF_2Br_2 undergoes electron capture. The Br_2^- ions are apparently not complexed by SiF_4, so Br_2^- photodetachment is not inhibited.

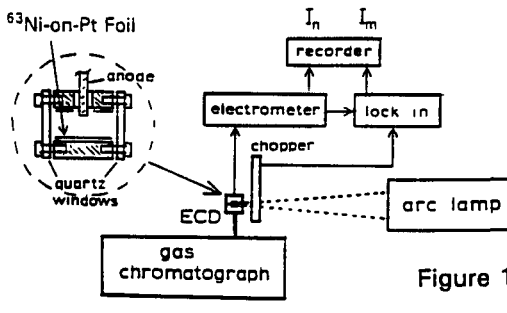

Figure 1. Schematic of the PDM-ECD used here.

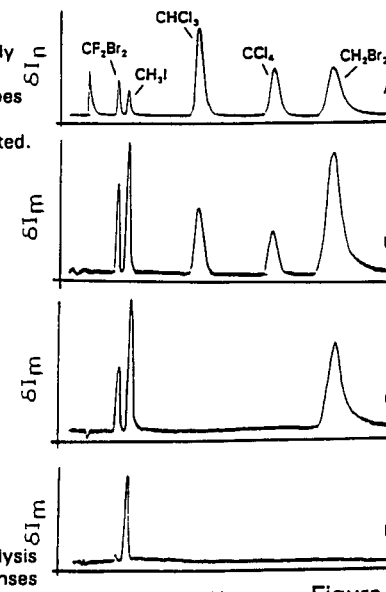

Figure 2. A: Normal PDM-ECD responses from the GC analysis of a multicomponent sample. B: Modulated (δI_m) responses with no SiF_4 added to the detector gas. C: δI_m responses with 350 ppb SiF_4 present. D: δI_m responses with 30 ppm SiF_4.

When making the PHPMS equilibrium constant measurements, the halide ions (X^-) are first produced by dissociative electron capture, and then react with SiF_4. It is assumed that the ion intensity ratios reflect the ion concentrations in the source. The equilibrium constant for Reaction 3 is calculated from Equation 4:

$$K_3 = [X^-SiF_4] / [X^-]\, P_{SiF4} \qquad (4)$$

K_3 was found to be 2.0 (±0.1) x 10^7 atm^{-1} for $X^- = Cl^-$, and 2.1 (±0.1) x 10^3 atm^{-1} for $X^- = Br^-$ at 150°C. No I^-SiF_4 ion could be detected, so K_3 for I^- is estimated to be less than 1 x 10^2 atm^{-1} at 150°C.

The results in Figures 2A-2D are in qualitative agreement with these K_3 values. However, under the conditions used for those experiments, Equation 4 predicts that about 12% of the Cl^- ions and 99.9% of the Br^- ions would remain uncomplexed by SiF_4. Thus, Reaction 3 alone does not adequately account for the results in Figures 2A-2D.

Evidence for processes other than Reaction 3 was found in the PHPMS experiments. In the full mass spectrum (Figure 3A), there are several unexpected ions in addition to the expected Cl^- and Cl^-SiF_4 ions. In Figure 3B, the mass spectrum was taken under the same conditions as Figure 3A, but with 1.0 mTorr water vapor added to the source. This significantly increased the intensities of the unexpected ions, especially $F^-Si_2F_6O$. Reactions 5-8 provide a pathway for its formation:

$$2\,SiF_4 + H_2O \rightarrow Si_2F_6O + 2\,HF \qquad (5) \qquad\qquad Cl^- + HF \rightarrow Cl^-HF \qquad (6)$$

$$Cl^-HF + SiF_4 \rightarrow F^-SiF_4 + HCl \qquad (7) \qquad\qquad F^-SiF_4 + Si_2F_6O \rightarrow F^-Si_2F_6O + SiF_4 \qquad (8)$$

The other significant ion is Cl^-SiF_3OH. Reactions 9 and 10 explain its formation:

$$SiF_4 + H_2O \rightarrow SiF_3OH + HF \qquad (9) \qquad\qquad Cl^- + SiF_3OH \rightarrow Cl^-SiF_3OH \qquad (10)$$

Figures 4A and 4B correspond to 3A and 3B except that Br^-, instead of Cl^-, is the reactant halide ion. Comparison of these figures shows that many of the processes operative for the Cl^- system also apply to the Br^- system. A mass spectrum for the I^- system with added water only gave one of the unexpected ions, I^-SiF_3OH (<5% relative intensity), and I^-.

A means of obtaining specific PDM-ECD responses to simple brominated and iodinated compounds in the presence of chlorinated compounds has been demonstrated here. In mass spectrometric experiments, it has been shown that a major portion of the effects of SIF4 on the PDM-ECD responses is caused by impurities in the detector gas. These impurities are less selective in their associations with halide ions, so the specificity of the PDM-ECD is less than what might be possible.

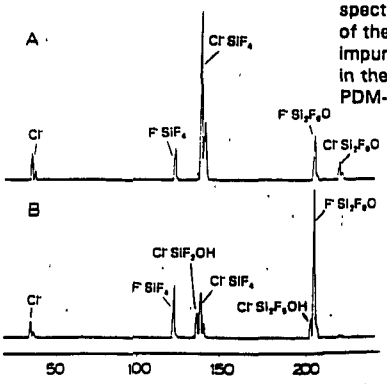

Figure 3

Figure 3. Mass spectra from the PHPMS involving Cl^-. In spectrum A, the source contains 0.2 mTorr CF_2Cl_2 and 0.30 mTorr SiF_4 in 4.0 torr methane. In spectrum B, 1.0 mTorr water vapor has also been added.

Adduct Ion Formation Pathways in Matrix Assisted Laser Desorption Mass Spectrometry

R.S. Brown and N.L. Gilfrich
Department of Chemistry, Colorado State University, Fort Collins, CO 80523

Adduct ion formation in matrix assisted laser desorption (MALD) mass spectrometry is a major impediment to the analytical utility of the technique for large mass-to-charge (m/z) ion species. This is due primarily to the limited mass resolving power (300-500) of the time-of-flight (TOF) mass analyzers currently being used with this technique. This mass resolution is not sufficient to resolve the matrix adduct ions from the protonated molecular ion species. This factor limits the accuracy of mass determinations for higher molecular weight analytes. In order to learn more about the nature of the matrix adduct ions formed in MALD and the fundamental mechanisms of the MALD process, investigations involving different matrix compounds were performed utilizing 337.1 nm. Several of these compounds are new MALD matrices, including α-cyano-4-hydroxy-3-methoxy cinnamic acid, 4-hydroxy-α-phenylcinnamic acid and 7-hydroxycoumarin. The results of these experiments are summarized in Table 1.

The matrix adduct ions formed for cinnamic acid derivatives include addition of the intact matrix molecule to the protonated molecular ion of the analyte protein and addition of photo decomposition products of the matrix (decarboxylation and dehydration). An exception to this pattern is 3,4,5-trimethoxycinnamic acid, for which no matrix dehydration adduct ion is observed. This would lead to the conclusion that dehydration of the matrix molecule occurs at the hydroxy ring substituent. Benzoic acid derivatives have also been examined and produce similar results, except for the two matrices of this type studied, no matrix decarboxylation product is observed as an adduct. Decarboxylation of the matrix molecule must therefore be due to the presence of the propenoic group present in the cinnamic acid type matrices but absent in the benzoic acid matrices. Anthranilic acid (2-aminobenzoic acid) produces a loss of ammonia adduct ion analogous to the matrix dehydration adduct observed with hydroxy substituted matrices and is due to the amine group on the ring in that molecule. Several alpha substituted cinnamic acid derivatives have been utilized as MALD matrices. Both α-cyano-4-hydroxycinnamic acid and 4-hydroxy-α-phenylcinnamic acid produce overall lower intensity matrix adduct ions relative to the protonated molecular ion peak. They also produce a higher intensity matrix decarboxylation adduct ion relative to the intact matrix adduct ion. The presence of an electron withdrawing substituent at the alpha site in the molecule must destabilize the acid group relative to the other cinnamic acid derivatives which have only a proton at that position. Both of these matrices also produce MALD mass spectra with greater multiple charging than is observed with other matrices. Again, this may be due to the alpha substituent favoring a greater amount of protonation. Multiple charging makes these matrices particularly desirable when working with larger molecular weight analytes because of the better detection efficiency possible for smaller m/z ions. Results for α-cyano-4-hydroxy-3-methoxycinnamic acid are similar to those results obtained with α-cyano-4-hydroxycinnamic acid. 3-Aminopyrazine-2-carboxylic acid was employed as a matrix but produced a large number of unresolved adduct ions which did not correlate to its chemical structure. With the addition of acetic acid (10 μl/ml) the number and intensity of these adducts was reduced. The remaining adduct ion appears to be due to the addition of acetic acid to the protonated molecular ion. 7-Hydroxycoumarin yielded similar results in that the mass spectrum collected from a sample with the conventional sample preparation procedures contained many unresolved adduct ion species peaks. The addition of acetic acid to this sample reduced the adduct ion species to a single adduct corresponding to the intact matrix molecule adhering to the protonated molecular ion. 7-Hydroxycoumarin also increases the multiple charging observed in the MALD mass spectrum. This matrix was chosen due to its absorbance at 337 nm and its enhanced acidity in the excited state as reported by Ireland and Wyatt (1). Multiple charging therefore may be due to enhanced protonation, in this case, related to the increase in acidity of the molecule in the excited state relative to the ground state, which has been suggested as an inherent part of the MALD mechanism (2).

The relative intensities of the low mass ions formed directly from the matrix for each of these compounds are listed in Table 2. For most matrices, ions are observed which correlate to protonation of the intact matrix, dehydration and decarboxylation of the matrix. Also common is Na^+ attachment to the intact matrix. Anthranilic acid (2-aminobenzoic acid), however produced no ions which were characteristic of its structure. The only ions present were those observed at low intensities in all of the spectra presumably due to impurities in the sample or solvents. This result suggests a mechanism for formation of matrix adduct ion species involving neutral desorbed matrix species rather than ionic matrix species. This neutral pathway is more likely also due to the greater percentage of neutral species produced in the laser desorption process relative to the number of ions (3).

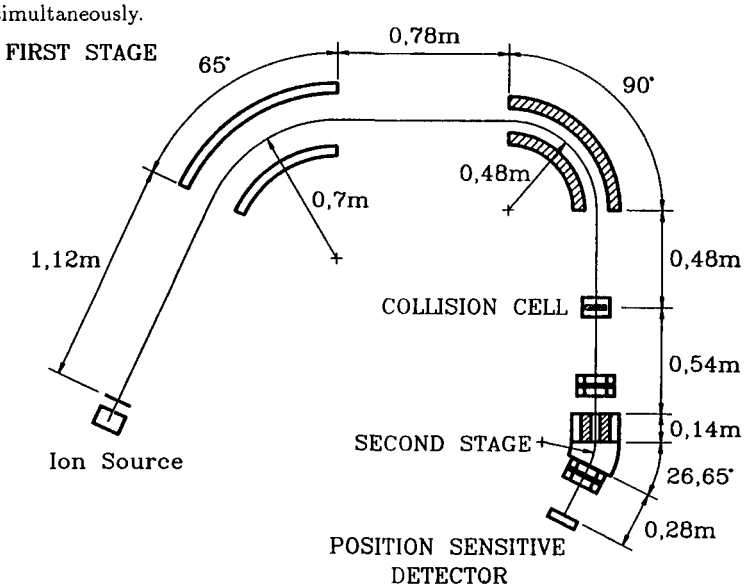
A New Tandem Mass Spectrometer with a Surface Induced Collision Cell

G.Li, A.Duhr and H.Wollnik
Universität Gießen, II. Physikalisches Institut, 6300 Gießen

Based on a double focusing mass spectrometer as a first stage, a new second stage double focusing Wien filter mass spectrometer was designed and built to study molecular dissociations. Since in collision activated dissociations the molecular fragments leave the collision cell with approximately the same velocity as the precursor molecule, a Wien filter was used as basic component of the second stage mass spectrometer [1].

The Wien filter was combined with a magnetic sector in a single magnet joke [1] such that angle and energy focusing (double focusing) is achieved simultaneously. To preserve a fixed overall length of the system also for different masses, two pairs of electrostatic quadrupoles are used before and after the magnet. This arrangement allows in addition to the double focusing condition a variable dispersion (zooming effect). To achieve maximum resolving power, abberation errors are compensated to second order by an inhomogeneous electrostatic condensor. All properties were calculated and optimized by the computer code GIOS [2].

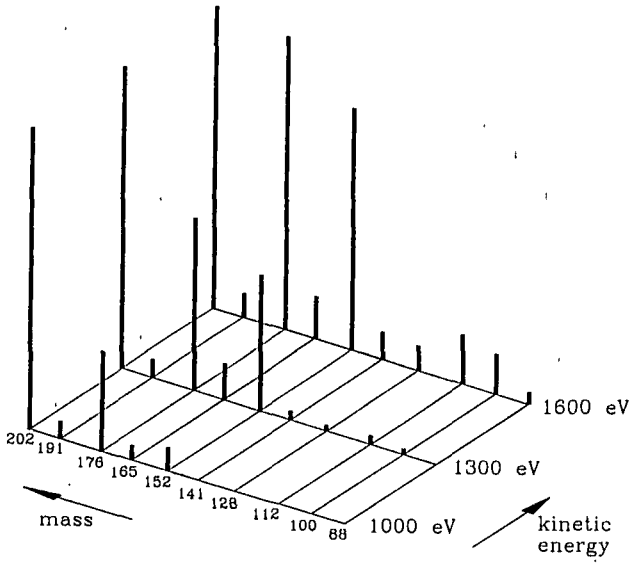
To make use of the zooming capabilities of the system, a position sensitive detector has been built that achieves a spatial resolution of 50 μm and an overall length of 40 mm. Using this detector, a mass intervall of up to $\pm$ 10 % around a given center mass can be recorded simultaneously.



A SID collision cell that uses the inner surfaces of a microchannel plate was constructed [3]. It achieves high energy uptake for the molecules combined with good forward bundeling.

Since the collision cell consists of a microchannel plate combined with two immersion lenses only, it can replace the exit slit at the end of the first stage as well as the entrance slit of the second stage.

In fig. 1 the complete system is shown consisting of the magnetic and electrostatic sector of the first stage, the collision cell, the electrostatic quadrupoles and sector fields of the second mass analyzer and finally the position sensitive detector.



In fig. 2 the energy dependance of the fragmentation pattern of pyrene ($C_{16}H_{10}$, m = 202 amu) is shown. Note the increasing amounts of smaller fragments with rising collision energy. The incident angle on the channel walls was about 2°. The achieved mass resolving power in the second stage does not exceed $m/\Delta m \approx 150$ although the Wien filter has an experimentally proven resolving power of $\approx m/\Delta m$ 2500 in a stand-alone operation. This discrepancy most probably is due to imperfect optics of the collision cell.

AN IMPROVED ELEMENT AND ISOTOPE SELECTIVE DETECTOR FOR HPLC

M.A. McLean, F.P. Abramson[1] and M.L. Vestal
Vestec Corp., 9299 Kirby Dr., Houston TX 77054
[1]George Washington Univ., Dept. of Pharmacology
Washington, DC 20037

Introduction:

In an effort to design an element and isotope selective detector for HPLC, we have combined particle beam LC/MS with a Chemical Reaction Interface for Mass Spectrometry(CRIMS). The CRIMS technique[1], originally developed as an element and isotope selective detector for GC, is based on the combustion of the chromatographic effluent in the presence of a reagent gas using a chemical reaction interface(CRI). The reagent gas is used to influence, and control, the combustion process in order to produce characteristic reaction products which uniquely reflect the elements and isotopes in the original molecule. For the selective detection of C and N, the reagent gas functions as a source of oxygen to yield the desired reaction products of CO_2 for carbon and NO for nitrogen. After combustion, the products flow directly into a mass spectrometer where they are identified using EI mass spectrometry. By changing the reagent gas it is possible to detect a variety of elements with very good sensitivity. As a GC detector, the technique has been successfully used in drug metabolism studies for the specific detection of C-, N-, D-, Cl- and S-containing metabolites.[2,3]

Experimental:

The key for transferring GC CRIMS technology to HPLC is to selectively transmit the analyte to the CRIMS system while removing the bulk of the LC solvent. This is accomplished by using a unique particle beam LC/MS system (Vestec Corp., Houston, TX) which efficiently dries the particle beam using a membrane-based gas diffusion cell. The particle beam, highly enriched in nonvolatile analyte, is delivered to the reaction interface in a He carrier flow having much the same characteristics as the effluent from a GC column. The particles enter the CRI where they decompose and react with the added reagent gas(SO_2) to form oxidized products. Mass channels 44, 45, 30 and 31 are monitored for the specific detection of carbon(as $^{12}CO_2$ and $^{13}CO_2$) and nitrogen(as ^{14}NO and ^{15}NO).

Results
