The pressures within the CRI and EI ion source were determined to be critical variables for the proper function of the overall LC CRIMS system. High pressure within the reaction volume is desirable in order to increase the number of collisions between the particle and the reactant gas. This increase in collision number aids in the decomposition and oxidation of the particles to the desired products and is maintained using a single stage momentum separator placed before the CRIMS microwave cavity and a downstream restriction placed between the reaction cell and EI ion source. Difficulties with LC CRIMS exhibited in previous experiments, including incorrect 45/44 ratios and different peak profiles for m/z 44 and 45, are eliminated with the higher reaction cell pressure. The increased pressure also results in an increase in sensitivity due to complete conversion of analyte molecules to fully oxidized products.

Flow injection analysis of amino acids, monosaccharides, nucleotides, phenytoin and erythromycin showed routine signal-to-noise ratio (S/N) of 10:1 with 20-50 ng injected. Corresponding on-column S/N were obtained with injections of approximately 100-200 ng depending on the chromatographic separation efficiency. The limit of detection(LOD) (S/N of 3:1) appeared to be about 10 ng for most compounds under flow injection analysis (FIA). The sensitivity of multiply labeled compounds gave LODs of less than 10 ng as demonstrated by FIA of $^{13}C_2$-cytosine. Injections of mixtures of glucose and $^{13}C_1$-labeled glucose gave a straight line for a plot of [corrected m/z 45]/[m/z 44] vs. the fraction of $^{13}C_1$-glucose injected (Figure 1). A similar straight line result was obtained for ^{15}N-glutamine when the peak area for m/z 31 was plotted against the amount of ^{15}N-glutamine injected. A separation of selected amino acids (lysine, leucine, alanine, glutamine, asparagine and ^{15}N-arginine) and ^{13}C-glucose showed the isotope selective detection capabilities of LC CRIMS yielding peaks in the m/z 31 and 45 mass chromatograms corresponding to elution of the ^{15}N-glutamine and $^{13}C_1$-glucose respectively (Figure 2).

Conclusion:

Selective detection of ^{13}C and ^{15}N-labeled species at nanogram levels have been demonstrated. Linear response is obtained for injections of both ^{13}C and ^{15}N labeled standards which demonstrates the quantitative potential for the LC CRIMS technique. Challenges that remain include the lowering of background by minimizing air leaks and mechanical pump oil backstreaming, and by using cleaner HPLC solvents. A decrease in background by these methods should result in detection limits approaching 1 ng.

APPLICABILITY OF LC/TOFMS WITH A PULSED SAMPLE INTRODUCTION INTERFACE FOR THE DETECTION OF BIOCHEMICALS AND PAHS

Alan P.L. Wang and Liang Li*
Department of Chemistry, University of Alberta
Edmonton, Alberta T6G 2G2, Canada

Mass spectrometry combined with liquid chromatography can be a very powerful technique for trace analysis of thermally labile and nonvolatile molecules including many highly water-soluble organic pollutants and biochemicals in complex matrices. At present, most LC/MS systems utilize scanning MS (sectors or quadrupole) for LC detection. To our best knowledge, no suitable interface has yet been developed for combining conventional HPLC capable of handling high flow rates with time-of-flight mass spectrometry (TOFMS). However, TOFMS has the potential to become a very important tool for LC detection with several unique features including its versatility and higher detection sensitivity with no mass limit. Thus, we plan to develop an alternative LC/MS system based on TOFMS with a pulsed sample introduction (PSI) interface developed in our laboratory [1].

In the PSI interface [1], sample molecules carried by a liquid carrier are vaporized by passing through a heated capillary tube and then through a sample vaporizer of a high temperature pulsed nozzle. The resulting sample vapors are introduced into TOFMS in a pulsed form and ionized by laser-induced multiphoton ionization. Here we show that a conventional LC can be readily combined with TOFMS using the PSI interface. Figure 1 shows the schematic diagram of the LC/TOFMS experimental setup. The TOFMS system has been described previously [1]. The LC solvent delivery system consists of a Shimadzu LC-600 programmable liquid pump. A Rheodyne Model 7125 syringe loading sample injector with a 20 μL sample loop is used for sample injection. In between the column and the PSI interface, a Shimadzu SPD-M6A photodiode array detector is used for obtaining a UV chromatogram.

Some preliminary results from our initial studies of the PSI interface for LC/TOFMS are outlined as follows:

(a). Applicability of the interface. More than 100 compounds have been studied with this PSI interface. These include ionic dyes, PAHs, plant regulators, catecholamines, neuroleptic drugs, amino acids, and small peptides. A typical mass spectrum is shown in Figure 2. This laser ionization spectrum is obtained by injecting the sample directly into the interface with methanol as the carrier at a flow rate of 1 mL/min. In general, no thermally decomposed products are detected. In addition, extensive fragments can be generated for structural analysis by using high laser powers.

(b). Precision and Memory effects. We find that reproducible results can be readily obtained. The average RSD is in the range of 4-8%. No severe peak tailing and memory effects are found.

(c). Sensitivity and Quantitation. It is found that for the current system the detection limits are compound dependent. For instance, at present, the detection limits are 10 pg for aniline, ~ 5 ng for indole-3-acetic acid, and 100 pg for tryptamine. For quantitation, excellent linearity over two orders of magnitude of analytical range can be obtained.

(d). Flow rate and Type of liquid carrier. It was found that reproducible results can be readily obtained with a flow rate of 0.5 to 1.5 mL/min. Water, methanol, acetonitrile, and a mixture of these solvents can be used as the mobile phase.

(e). Interfacing LC with TOFMS. Figure 3 shows the chromatograms of indole-3-acetic acid, tryptamine, and tryptophol. A mixture of 3 μg of each component is injected into the column. The separation is performed isocratically with a mobile phase of water:methanol (40:60) at a flow rate of 1 mL/min. A reverse phase C_{18} column is used for separation. Under the experimental conditions used, three components are not well separated as indicated by the UV chromatogram shown in Figure 3(A). Figure 3(B) is the total ion chromatogram obtained by using the LC/TOFMS technique. A boxcar integrator is used for monitoring the total ion intensity. Figures 3(C), (D) and (E) are the selective ion chromatograms for indole-3-acetic acid, tryptamine, and tryptophol, respectively. These chromatograms are obtained by narrowing the gate of the boxcar integrator to selectively monitor the peak intensity of the individual molecular ion. As Figure 3 illustrates, the ion chromatogram is almost the same as the UV chromatogram in terms of peak shapes and retention times. No peak broadening and other chromatographic distortions are found.

In this presentation, we have shown that the LC/TOFMS system can be applied for the detection of small biochemicals and PAHs. The major goal of this research is to develop a LC/TOFMS system that would have high sensitivity with pg or low ng detection limits and have mass resolution above 2000. Moreover, it would provide qualitative information based on laser ionization and/or electron

impact mass spectra for reliable molecular identification. Thus, the future work on the development of LC/TOFMS is mainly focused on the improvement of mass resolution from currently 300 to above 2000 by modifying the current linear TOFMS system into a reflectron-type TOFMS. Furthermore, we will develop an electron beam for performing electron impact ionization in order to extend the LC/TOFMS technique to molecules that are not ionized by using the current laser ionization method.

Detection of Nonvolatiles via Liquid Injection Into Atmospheric-Pressure DC and RF Glow Discharge Source/Mass Spectrometry

D. M. Lubman, J. Zhao and J. Zhu, Department of Chemistry
The University of Michigan, Ann Arbor, MI 48109

In this work atmospheric pressure DC and RF discharges in helium have been used as ionization sources for organic samples introduced by liquid injection into atmospheric pressure ionization mass spectrometry (API/MS). The DC glow source operates typically in the range up to 1 mamp of current at less than a kilovolt, although the source can be operated up to a discharge current of 10 mamps. Even at the high current used in this work, the protonated molecule, MH^+, is observed with little or no fragmentation for many of the samples studied. It has been shown that the glow discharge initiates a series of ion-molecule reactions similar to that of a corona source; however, the glow produces helium ions and metastables as a primary set of reagents. These primary species then react with water clusters to form a relatively stable set of reagent ions. Ionized water clusters are formed that serve as the protonating agents for the trace organic analytes in the positive mode. The glow discharge penetrates into an extended region of space often several mm from the tungsten tip at currents three orders of magnitude higher than the corona. The glow source follows the I vs. V relationship characteristic of the analytically useful "abnormal" glow discharge. The detection limits achieved for API glow discharge detection are typically in the low femtomole region for organic molecules including small biological neurotransmitters, drugs, pesticides, PTH-amino acids and explosives.

The atmospheric pressure glow discharge ionization source is shown in figure 1. The system consists of a heated pneumatic nebulizer, a vaporization chamber, a glow discharge ionization chamber and a differentially pumped dual orifice interface. A liquid chromatography pump delivers the sample dissolved in a solvent through the heated pneumatic nebulizer assembly to the vaporization chamber where the sample is vaporized and the solvent removed. The sample then passes through a duct into a separate second chamber where it is ionized by the glow discharge source in 1 atm helium. The resulting ions pass through a pair of differentially pumped skimmers, which sample the on-axis component of the ion beam. The ions are then mass analyzed and detected by a SpectraEl atmospheric pressure ionization quadrupole mass spectrometer.

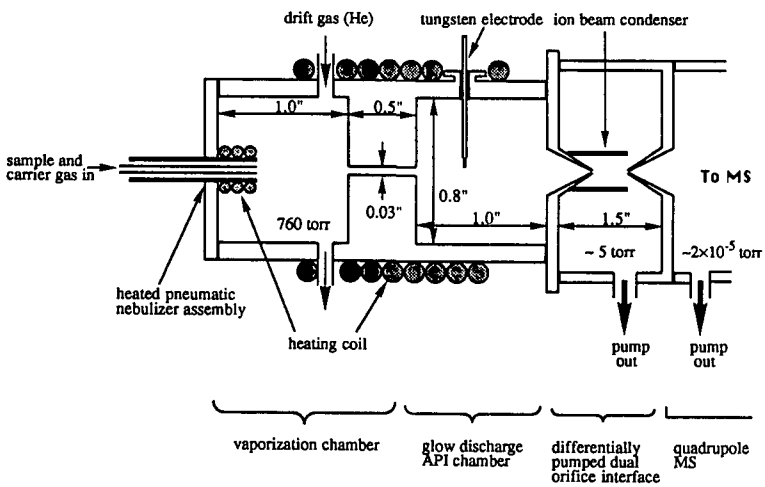

Figure 1. Atmospheric Pressure Glow Discharge Ionization Source

A typical API/glow discharge mass spectrum for tyramine injected in liquid methanol at 30 ul/min is shown in figure 2. A key observation is that despite the high discharge current of ~ 1 mA, the MH^+ peak is obtained without fragmentation. This is generally true for a host of neurotransmitters, drugs and pesticides. The sensitivity using the SIM mode for tyramine was 1.8 pg and linear quantitation was obtained over at least three orders of magnitude. In some cases the linear range extended out over 4 orders of magnitude, but above this range the quantitation curve very rapidly becomes nonlinear. In figure 3 is shown the API/glow discharge MS for a tripeptide. Although MH^+ is observed it is accompanied by some fragmentation under the condition of these experiments. In this case cleavage occurs along the peptide bonds to produce fragments which easily reveal the structure of the peptide. In our most recent work an RF discharge in helium has been used to obtain even greater sensitivity in detection.

RECENT DEVELOPMENTS IN PACKED COLUMN SFC-MS AND SFE-SFC-MS

D E Games, J V Beaman, P J Jackson, S Scalia and D Thomas

Mass Spectrometry Research Unit, University College of Swansea, Singleton Park, Swansea SA2 8PP, United Kingdom.

Packed column supercritical fluid chromatography (SFC) is complementary to both GC and HPLC. In the case of GC, it considerably extends the range of compounds amenable to analysis, whilst it offers the advantages of faster analysis, more rapid method development and higher chromatographic efficiency over HPLC. SFC is easier to interface to a mass spectrometer than HPLC because the mobile phase gas volumes generated are lower. However, attention has to be paid to providing a suitable restriction. We have effected SFC-MS using both modified moving belt[1] and thermospray[2] LC-MS interfaces and report here on interfacing using a particle beam LC-MS interface and studies of bile acid conjugates using a thermospray SFC-MS in the filament-on mode.

Supercritical fluid extraction (SFE) is currently creating considerable interest as an alternative to conventional extraction procedures, because of the speed of extraction; the selectivity that can be obtained, and the low toxicity of the fluids used for extraction. The technique can be used on-line with SFC or other forms of chromatography, or samples can be prepared off-line. We describe here our studies of β-blocker drugs in plasma and whole blood using SFE-SFC-MS with a thermospray interface and off-line SFE followed by SFC-MS of carbamate pesticides in potato using a moving belt interface.

Packed SFC-MS has been effected using a particle beam LC-MS interface with a linear restrictor and provision for the introduction of solvents and a helium make-up[3]. We have developed an interface consisting of a stainless steel capillary with an electrically heated copper tip. Restriction was provided by crimping the capillary to provide a suitable spray. Initial studies were conducted by direct injection of carbamate pesticides, tocopherols and a variety of drugs in supercritical carbon dioxide modified with methanol. Library searchable EI spectra were obtained. SFC-MS studies have been conducted with mixtures of tocopherols, mycotoxins, benzodiazepine drugs and extracts from timbo resin using either a bench top quadrupole instrument or a triple quadrupole instrument. Excellent retention of chromatographic performance was obtained and EI spectra gave excellent library matches. Figure 1 shows the computer reconstructed TIC trace obtained from a mixture of δ-, γ- and α-tocopherols. Full scan spectra were obtainable at the 20 ng injected level using the bench top instrument with 4.6 mm id columns. Use of 1 mm or 2 mm id columns gave better detection limits and CI spectra were obtainable using the triple quadrupole instrument.

A major criticism of SFC and SFC-MS has been their inability to deal with more difficult compounds. We have developed packed SFC methods for the analysis of both glycine and taurine bile acid conjugates[4]. SFC-MS in the negative ion filament-on mode yielded $[M-Na + H]^+$ ions and an acceptable TIC trace for a mixture of the sodium salts of glycocholic, glycochenodeoxycholic, glycodeoxycholic, glycolithocholic, taurocholic, taurochenodeoxycholic, taurodeoxycholic and taurolithocholic acids using a 5 μm cyanopropyl Zorbax 250 x 4.6 mm column with 20% methanol in carbon dioxide increased to 28% methanol over 1.5 min. after 4.5 min. The response for the taurine conjugates was much better than for the glycine conjugates which contrasts with the uniform response for both classes of conjugates obtained in previous thermospray LC-MS studies[5]. The technique was used to identify the bile acid conjugates in a bile sample from a patient with chronic hepatitis.

In our studies of the development of a multi residue method for the analysis of the carbamate pesticides, chloropropham, bendiocarb, propoxur, aldicarb, carbofuran, methiocarb, primcarb, carbaryl and oxamyl in food products, SFC and SFC-MS methods, using a moving belt with EI and CI have been developed for the separation and detection of these compounds. CI with methane gave the detection limits of between 1 and 10 ng by SIM for the carbamates. Off-line SFE was investigated using 2 g samples of potato spiked with mixtures of these carbamates. Recoveries determined by SFC varied between 73 and 89% for the various carbamates and their identities were confirmed by SFC-MS. Detection limits from spiked potatoes varied from 50 ng/g to 1 μg/g for the various carbamates. It should be noted that 0.8 mℓ of a dichloromethane solution was obtained from the extract and 10 $\mu\ell$ of this was used to make the measurement. Hence, with on-line SFE-SFC-MS much lower limits would be achieved or by using a much lower sample volume of rinse solvent.

SFE-SFC-MS has been used to identify β-blocker drugs in plasma and whole blood samples. Using filament-on thermospray SFC-MS in the positive ion mode, a mixture of timolol, alprenolol, metoprolol, propranolol, acebutalol, labetalol, prindolol, sotalol, atenolol and nadolol were analysed using a 25 cm x 4.6 mm id 3 μ spherisorb amino column; better detection limits and separation were obtained using a 2 mm id column. Spectra consisted of $[M + H]^+$ ions; however, use of the triple quadrupole instrument in the daughter ion mode with Krypton as collision gas enabled characteristic daughter ion spectra to be obtained.

Using SIM or selected reaction monitoring, detection limits for the drugs were in the low pg range. SFE-SFC-MS and SFE-SFC-MS-MS studies were conducted using an extraction cell interfaced to the SFC. 1 mℓ samples of plasma or blood were absorbed onto celite, placed in the cell and the optimal SFE conditions determined. Best extraction efficiencies were obtained from freeze dried samples and for timolol, extraction efficiencies in excess of 90% were obtained from plasma, whilst recovery from whole blood was 70-75%. Using SFE-SFC-MS with SIM, to date best detection limits are 40 ng $m\ell^{-1}$ of timolol in whole blood which is in the low therapeutic dose level. SFE-SFC-MS-MS enabled better specificity to be obtained and may provide lower detection limits.

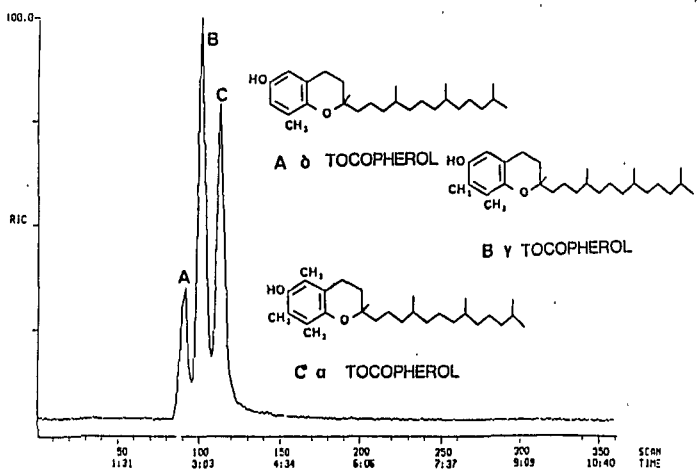

Fig. 1 TIC trace, particle beam SFC-MS of tocopherols, 5 μ Sherisorb ODS, CO_2 with 10% methanol, 4 $m\ell\ min^{-1}$ 200 psi, 58°C

CONCLUSIONS

Packed column SFC-MS enables a wide range of compounds to be readily analysed. Use of particle beam interfaces provides EI and CI mass spectra, although in our experience, moving belt interfaces provide better sensitivity. The use of SFE either off-line or on-line, enables better selectivity of extraction to be obtained and higher sample through-put. With the advent of improved commercial packed column SFC systems, we envisage much wider use of SFC-MS.

Continuous Flow FAB/MS: A concept to improve the sensitivity

J.Hau, W.Schrader and *M.Linscheid,
ISAS Institut für Spektrochemie, Bunsen-Kirchhoff-Str.11, W-4600 Dortmund 1; Germany

We have designed an ion source for continuous flow FAB (CFFAB) based on the previously described thermospray source comprising static quadrupol lenses. The source was made for a MAT 90 instrument and uses a conical extraction lens with an inner diameter less than 1 mm in a distance of c. 1.5 mm from the surface of the target (Fig.1). The conventional ion source assembly of the MAT 90 has been replaced by a quadrupole stack of appropriate length. The potential of the extraction cone is held only a few volts lower the accelaration voltage (4750 Volts) and the draw lens is normally adjusted to 2.5 kV. The quadrupoles had potentials of 1450 resp. 850 volts. It should be noted that the complete software control of the source parameters (e.g. the autotune option) can be used the with the home made source.

With this arrangement an increase in sensitivity by factors up to ten depending on the mass range has been observed; as additional benefit the source is stable over a long time of daily use (months) without the need of cleaning; only the conical extraction lens needs refurbishing occasionally. Since the cone is part of the retractable probe, this is no problem. For the evaluation of this ion source, we have studied several combinations of conventional and quadrupole ion optics with three differently shaped extraction lenses (conical and slit type) using the drug Isophosphamide (MW 261) and the peptide Gramicidin S (MW 1142) as reference compounds. Quantitative data have been obtained in scanning mode and with selected ion recording to allow a precise comparison. Furthermore, the same combinations were studied in static FAB with glycerol as matrix.

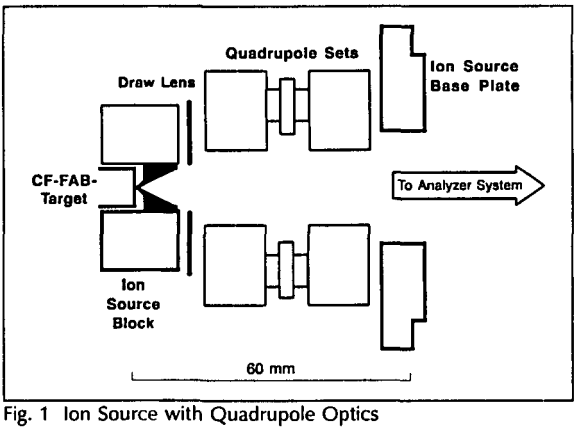

Fig. 1 Ion Source with Quadrupole Optics

We have been able to separate at least three homologoues admixed to the gramicidine S with molecular weights of 14 amu less and 14 amu more the Gramicidine S using microHPLC with a reversed phase column and CFFAB. One compound was detected at the 1 pmol level without approaching the detection limit. The cytostatic drug isophosphamide was determined with a detection limit of 1.5 ng/mL plasma using MID .

The results are summarized as follows:

A) The combination of a conical extraction lens with a quadrupole ion optic is the most sensitive combination.

B) The background ions between the glycerol clusters are strongly reduced in CFFAB (factor 5 to 10) and somwewhat in static FAB (factor 2).

C) The matrix clusters were not affected, the intensity remains essentially the same.

This means that the reduction of the chemical background (everything between the main clusters $(glycerol)^nH^+$) seems to be the main reason for the gain in sensitivity in our ion source. (see Fig. 2,3)
The explanation for the reduction may be threefold: It appears that the major portion of the sputtered matrix molecules is skimmed off. These ions usually give rise to numerous collisions and are therefore the main source for all kinds of background signals around the glycerol clusters. The strongly foreward sputtered analyte ions and the clusters can travel through the cone unaffected, giving an enhanced signal to background ratio. Secondly, the concentration of the analyte in the matrix at the spot from which ions can be extracted into the mass spectrometer is much higher, since the hole in the cone is of the same size than the capillary. The result from experiments with static FAB, where we observe an increase of the ratio by a factor two - smaller than in CFFAB, but statistically significant -, may indicate that the extraction directly from the surface of the target may be improved particularly for the clusters, since they encounter less collisions.

CONTINUOUS-FLOW FAST ATOM BOMBARDMENT LIQUID CHROMATOGRAPHY-MASS SPECTROMETRY OF OLIGONUCLEOTIDES

Richard B. van Breemen[1], Kenneth B. Tomer[2], and Leesa J. Deterding[1,2]
[1]Department of Chemistry, North Carolina State University, Raleigh, NC 27695-8204, and
[2]Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P.O. Box 12233, Research Triangle Park, NC 27709.

Because of the increasing importance of oligonucleotides in biotechnology and their potential use as antisense drugs (1), new sensitive and rapid methods such as liquid chromatography-mass spectrometry (LC-MS) are needed to rapidly determine the purity and confirm the molecular weights of synthetic oligonucleotides and oligonucleotide analogs and to analyze metabolites of new antisense oligonucleotide drugs. In our previous studies (2), we carried out the first continuous-flow fast atom bombardment (FAB) LC-MS analyses of oligonucleotides using a packed β-cyclodextrin HPLC column (4.6 mm x cm). The mobile phase contained triethanolamine as the FAB matrix at a flow rate of 200 µl/min, a solvent splitter so that only 5 µl/min entered the mass spectrometer, and 30 nmol of each oligonucleotide in mixtures were injected.

In the present study, nanoscale capillary HPLC columns were packed and operated at approximately 1 µl/min so that no solvent splitting was necessary and pmol quantities of oligonucleotides could be injected. In addition, coaxial flow of matrix to the continuous-flow FAB probe was used so that the matrix would not interfere with the chromatographic separations. Finally, a new affinity stationary phase for HPLC separation of oligonucleotides was synthesized, packed into capillary columns, and compared to C_{18} silica for the separation of oligonucleotide mixtures.

The final 25 cm of fused silica capillary tubing (75 µm x 150 cm) was packed using previously published procedures (3,4) with either 5 µm C_{18} reversed phase silica (YMC Inc.; Morris Plains, NJ) or thymidylsuccinamidopropyl silica, which was synthesized in our laboratory. For ion pair reversed phase separations, a 45 min gradient was used from 100:0 to 10:90 water/acetonitrile (v/v) containing 5 mM ammonium acetate. Oligonucleotides were eluted from the thymidyl affinity column using a 30 min gradient from 5 mM aqueous ammonium acetate to water/acetonitrile (50:50 v/v) containing 50 mM ammonium acetate.

In our previous study (2), the limits of detection for a series of oligonucleotides ranged from 3.5 to 43 pmol using a mobile phase consisting of water/methanol/triethanolamine (20:80:0.5; v/v/w). In order to determine the oligonucleotide quantity necessary for detection during scanning using continuous-flow FAB mass spectrometry with a mobile phase containing ammonium acetate, the limit of detection for 0.5 µl injections was determined without a chromatagraphic column. Profile scans were recorded at 5 sec intervals over the range m/z 500-1500 for the oligodeoxynucleotide d(GpCpGpC). The results, shown in Figure 1, indicate a limit of detection of approximately 70 pmol.

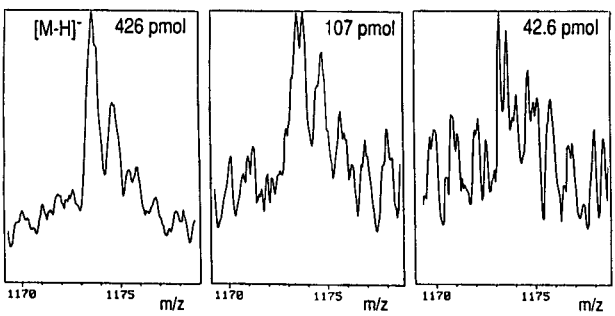

Figure 1. Limit of detection of the $[M-H]^-$ ion of d(GpCpGpC) using negative ion continuous-flow FAB mass spectrometry following flow injection of 0.5 µl aliquots. The mobile phase consisted of water/acetonitrile (80:20; v/v) containing 5 mM ammonium acetate.

The performance of each column was evaluated by separating mixtures of oligonucleotides at flow rates of approximately 1 µl/min using a UV detector or continuous-flow fast atom bombardment (CF-FAB) mass spectrometry with coaxial addition of a triethanolamine matrix solution (water/acetonitrile/triethanolamine; 50:50:0.75; v/v/w) at 2.5 µl/min. The oligonucleotides investigated ranged from two to six deoxynucleotides in length. Similar separation efficiencies were obtained using either the C_{18}-silica and thymidyl-silica columns. However, the selectivities were different. For example, oligonucleotides containing adenine, which would form hydrogen bonds with immobilized thymine, showed longer retention times on the thymidyl affinity column. An example of the reversed phase continuous-flow FAB LC-MS analysis of a mixture of dinucleotides is shown in Figures 2 and 3.

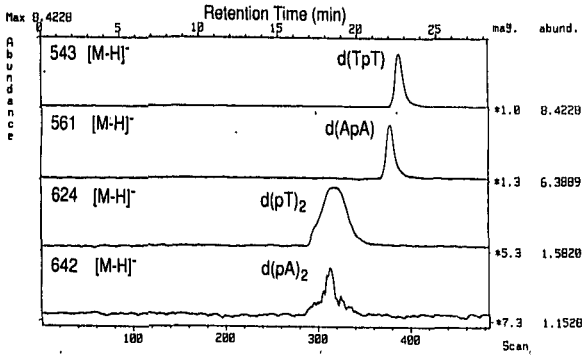

Figure 2. Reconstructed selected ion chromatograms showing the LC-MS separation of a mixture of dinucleotides followed on-line by detection of their deprotonated molecules using negative ion continuous-flow FAB. Approximately 300 pmol of each compound were injected onto a C_{18} reversed phase capillary column (75 µm x 25 cm). The mixture was prepared from two synthetic standards, $d(pT)_2$ and $d(pA)_2$, but was shown by LC-MS to also contain the dephosphorylated analogs $d(T)_2$ and $d(A)_2$.

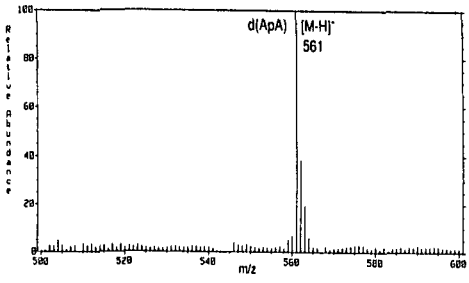

Figure 3. Negative ion FAB mass spectrum of the deoxypurine dimer, $d(A)_2$, obtained during the continuous-flow FAB LC-MS analysis shown in Figure 2.

Continuous-flow FAB LC-MS analysis of oligonucleotide mixtures has been demonstrated using nanoscale capillary HPLC. Because no splitting of the HPLC eluant is necessary, the entire sample reaches the UV or mass spectrometric detectors. Finally, a new affinity HPLC stationary phase has been synthesized and demonstrated to be complementary to reversed phase HPLC for the separation of oligonucleotides.

CHARTING OF RAT PITUITARY PEPTIDES BY CAPILLARY-COLUMN LIQUID CHROMATOGRAPHY- ELECTROSPRAY MASS SPECTROMETRY

G. J. Felstner, K. M. Swiderek, and T. D. Lee.

Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

MS peptide charting was previously introduced for the comprehensive analysis of peptide/protein compositions in tissue extracts [1, 2]. Thus far, the method has shown great promise for the analysis of neuropeptides in bovine and rat pituitary as well as the catfish pancreas [1, 3, 4]. Based on these results, it has been suggested that MS peptide charting could be of advantage for comparing neuropeptide profiles between different species and for studying the regulation of the neuronal, immune, and endocrine systems. The latter is potentially extremely useful, since it will allow a fast identification of those peptides/proteins that are regulated during a given biological event. Identification by MS peptide charting would be based primarily on detection of the corresponding molecular ion(s) and not require that the nature and/or structure of the peptide(s) of interest be known. More laborious structural and quantitative studies would be reserved for only those peptides that are definitively regulated. In contrast, the typical approach thus far has been to postulate the regulation of a specific peptide based on circumstantial evidence and then to prove it by radioimmunoassays; this approach has not always worked out. The potentially greatest advantage of MS peptide charting may therefore lie in its application to recalcitrant problems.

The first step towards our goal of using MS peptide charting to study neuroimmunoendocrine regulation has been the implementation of on-line LC-MS charting, since the latter allows us to add a quantitative aspect to our peptide charting by using mass chromatography. An initial evaluation using an ion-spray interface and a 1mm reversed phase column was very encouraging [3]. Here we report on our recent success in extending the sensitivity of our methodology as well as the mass range of observed pituitary proteins by using a capillary column (cc)-electrospray (ES) MS system (Finnigan TSQ700). We also provide a first example where MS peptide charting has identified a pair of peptides in rat anterior pituitary that appears to be differentially regulated between males and females. This is an important finding since it proves for the first time that it is possible to use MS peptide charting for regulation studies. Furthermore, to our knowledge this particular regulation is neither known nor has it been predicted, giving rise to the expectation that further development of the methodology will be rewarding.

The capillary gradient system used in this study comprises of two Harvard syringe pumps that preform a reverse gradient at low pressure in a separate gradient loop and an ISCO high pressure syringe pump that delivers either the sample or the gradient (directed by a switching valve) to a self-constructed capillary column (250um internal diameter, 10-20 cm long, packed with 5u C-18); all pumps and the switching valve are under control of a MacIntosh computer. The delivery of a preformed gradient from a loop downstream of the injector avoids the long delay times typically observed with standard LC systems at low flow rates.

ccLC-ES-MS spectra of the more abundant rat anterior pituitary peptides/proteins could be obtained on only 1% of a single pituitary extract; see, for example Fig. 1. A more typical analysis of 10% of a single pituitary

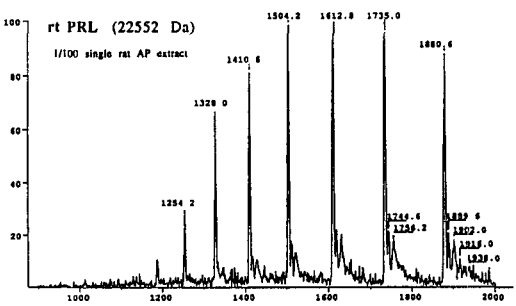

Fig. 1 LC-ES-MS spectrum of PRL (1/100th of a single rat AP)

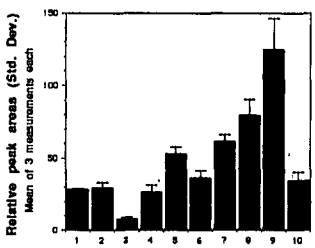
extract revealed at least 70 peptides/proteins. A large number of these could not be identified as known or predicted processing products of known precursors such as pOMC, pPRL, etc. This raises the question as to how one should go about their identification. One approach, which has been successfully applied in many molecular biological studies, is to make any full characterization of a peptide/protein dependent on the positive proof that its tissue abundance is under regulatory control. In this way we should be able to avoid wasting time and effort on the analysis of possible degradation products (e.g., of serum albumin). It also perfectly fits our ultimate goal of studying regulation.

The sensitivity achieved allowed us to perform repetitive charting experiments on the same extract and for the first time enabled us to study the reproducibility of our MS peptide profiles. Fig. 2 demonstrates the reproducibility thus far achieved on a single rat anterior pituitary extract. It shows the mean base peak areas for ten selected peptides (three consecutive measurements each). The standard error is ≤ 20% and gives rise to the expectation that it should be feasible to reach our goal of making LC-MS charting useful for regulatory effects of ≥30%. A general trend towards lower ion abundance with time was noticeable and is most likely due to sample precipitation and adsorbance on test tube walls. However, it is important to note that, in order for LC-MS charting to be useful for regulation studies, we do not have to nor do we intend to measure absolute quantities (which could only be done with internal standards). Rather, we are interested in the relative ratios of the ion abundance of adjacent LC peaks.

Fig. 2

Reproducibility of coLC-ES-MS charting
1/10 single mLE rat anterior pituitary extract



10 representative peptides:

1. MM 9249; 2. JP MM 1884; 3. MM 9991; 4. MM 5707; 5. MM 4964, 6. MM 11,470, 7. g-LPH MM 4386; 8. MM 8094; 9. MM 8564, 10. MM 21,901

Table 1. Ion abundance for AP peptides with mass 5787 and 5707. Comparison for male and female LE rats

m/z	816	828	952	966	828/816	966/952
m1k	0.82	1.53	1.61	3.31	1.87	2.06
m1l	0.88	1.46	1.84	3.48	1.66	1.89
m4a	1.80	3.71	2.28	4.98	2.06	2.18
m4b	1.54	3.89	2.22	5.66	2.53	2.24
m5a	2.19	3.97	2.40	4.71	1.81	1.96
m5b	0.69	1.31	0.62	1.22	1.90	1.97
f3b	3.16	1.02	4.54	1.48	0.32	0.22
f4a	3.91	2.07	4.75	2.54	0.53	0.53
f4b	6.31	3.53	8.90	3.72	0.56	0.42
f4c	2.12	0.89	2.47	1.44	0.42	0.58
f7a	1.37	0.86	1.82	1.06	0.63	0.58
f7b	1.35	0.81	1.74	1.09	0.60	0.63

The above mentioned example that regulatory studies by LC-MS charting are possible and useful is presented in Table 1. The Table shows the ion abundances of the +6 H+ and +7 H+ ions of a pair of unresolved anterior pituitary compounds with masses 5787 and 5707. Since they are degradable by trypsin, they are considered to be peptides. In adult male rats the ion abundance ratio is approximately 2:1, whereas in adult female rats it was found to be 1:2 or less. While neither the structure of these peptides nor their biological role(s) are yet known, we notice that the mass difference is consistent with a phosphorylation or sulfation. This is a first most encouraging example that MS charting will be useful for studying the regulation of the hypothalamic-pituitary-adrenal (HPA) axis; other tissues are likely to follow. Given the good sensitivity of our method, comprehensive analyses of the many existing rodent models of human diseases and even the study of transgenic mice now appear a distinct possibility. MS charting may also become an important tool for studying the effects and side-effects of new and old drugs.

INFLUENCE OF AEROSOL SIZE ON RESPONSE FACTORS AND LINEARITY IN PARTICLE BEAM LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY INTERFACING

W. Eric Harris, Katherine Edman, J. Chris Richardson and *Richard F. Browner
School of Chemistry and Biochemistry, Georgia Institute of Technology
Atlanta, Georgia 30332-0400

While particle beam LC/MS has shown itself to be a technique of great value for both identification and quantitation of complex mixtures,[1] including both environmental[2] and biomedical[3] samples, there remain a number of unanswered questions regarding certain quantitative aspects of the technique. In particular, several groups[2] have studied the question of linearity of calibration graphs at low concentrations of analyte, without successfully resolving this issue.

In this study, we have attempted to correlate analyte transport through a particle beam interface with analytical signals for a series of polynuclear aromatic species of widely different volatilities (naphthalene, pyrene and naphthacene). The shapes of the analytical curves have been correlated with the relative volatilities of the compounds. The calibration curves for naphthacene are quite linear in the range 1-50 ng injected ($r^2 = 0.995$), whereas those for pyrene and naphthalene are increasingly non-linear as the volatility increases.

The addition of a matrix, such as ammonium acetate, has been suggested for use as a carrier in order to increase linearity, but such studies have not led to any consistent improvement in linearity. In this study, the use of a moderately volatile matrix species, pyrene, has not led to any consistent improvement in the linearity for volatile species. However, the addition of a pyrene matrix greatly enhanced the response sensitivity for naphthalene, especially at low naphthalene concentrations. At higher naphthalene concentrations, the enhancement decreased, and the analytical response for naphthalene tended towards a common value with or without the addition of matrix (Fig. 1).

In order to understand the mechanism of transport better, analyte was collected using a low pressure impaction surface for collection of particles, together with a subsequent cryogenic trap for collection of vapors. In all instances, the ion count change correlated well with the change in collected mass of material. This emphasizes that the non-linearity of calibration graphs in particle beam LC/MS is essentially a transport phenomenon, which in turn is related directly to the size (and hence momentum) of the combined analyte/matrix particle. A highly *involatile* matrix will inhibit the vapor pressure of a volatile species in the interface and so may restore its transport efficiency close to the predicted (vaporization free) value.

The effect of highly *volatile* matrices, such as ammonium acetate, was also studied for its effect on highly *involatile* species, using NaCl as a model. Scanning electron microscope (SEM) images of collected particles showed clearly that the transport efficiency of NaCl is greatly reduced by the presence of a matrix of ammonium acetate, and that the average size of the collected crystals is also reduced. We interpret this to mean that the volatile matrix expands explosively while passing through the momentum separator, probably as it passes through the Mach disk in the first stage of the separator. The rapid expansion which results causes the analyte dispersed throughout the dry particle to be ejected as a large number of small crystalline particles, which are then pumped away from the interface, so reducing the NaCl transport.

While further work remains to be carried out in order to reduce the non-linearity which is found for certain volatile compounds, it appears that the problem should be minimal for less volatile species and should be capable of elimination for more volatile species through the use of an appropriate involatile carrier material.

In our previous studies of the quantitative potential of liquid chromatography/ particle beam/ mass spectrometry (LC/PB/MS), a carrier process associated with the LC mobile phase matrix was discovered. Enhanced ion abundances were observed for a variety of polar compounds when coeluting substances or ammonium acetate were present in the mobile phase. Also, a tendency toward non-linear responses was observed for many compounds. Positive enhancements may cause positive bias in quantitative analyses of real world samples where unexpected substances may coelute with target analytes.

The purpose of this research was to study LC/PB/MS mass transport and calibration and determine its effects on quantitative measurements. Specifically, coeluting isotopically labeled internal standards were used to see if the ruggedness and accuracy of LC/PB/MS quantitative analyses would be improved. While external calibration (as determined in multi-laboratory studies) has produced acceptable accuracy and precision when good quality control procedures were used, daily recalibration was often necessary due to daily fluctuations in instrument response.

The most reliable calibration method for real world environmental samples appears to be the use of coeluting isotopically labeled internal standards. When these compounds coelute with their unlabeled analogs, the resulting calibration curves plotting the ratio of analyte integrated area to coeluting labeled internal standard integrated area versus the amount of analyte injected are linearized. Also, because ratios of response are used in isotope dilution, the calibration curves are stable over longer periods of time. Figure 1 compares external calibration versus isotope dilution calibration over thirteen days for 3,3'-dichlorobenzidine. Isotope dilution calibration compensates for fluctuations in response and reduces recalibration. These calibrations are linear because increases in the amount of native analyte injected increases the transport efficiency of both the coeluting labeled and native species to about the same extent and compensates for the mass transport effect.

Figure 2 also displays this effect. Chromatographic conditions were adjusted to force caffeine and ethylene thiourea (ETU) to coelute. Fifty nanograms of caffeine were quantified in the presence of varying amounts of ETU (0, 50, 250, 500, 1250, and 5000 ng) using external and isotope dilution calibration. Calibration curves for caffeine were created using both methods. For isotope dilution, caffeine-$^{15}N_2$ was added at constant concentration to all calibration solutions and a curve plotting the ratio of unlabeled caffeine integrated area to caffeine-$^{15}N_2$ integrated area versus the amount of unlabeled caffeine injected was created. As seen in Figure 2, the use of external calibration (no internal standard) caused positive bias for all mixtures due to the increased transport of caffeine by the ETU carrier. For example, although only 50 ng of caffeine was injected, quantitative analysis using external calibration in the presence of 5000 ng of ETU gave an incorrect calculated amount of 110 ng caffeine. However, when coeluting caffeine-$^{15}N_2$ was added to the same mixture (50 ng of caffeine and 5000 ng of ETU) and quantified using isotope dilution, a correct value of 51 ng was calculated. The ETU carrier increases the transport of the unlabeled caffeine and the coeluting caffeine-$^{15}N_2$ to the same extent and the ratio of response of these two is the same as when a carrier (ETU) is not present. Unexpected coeluting substances are probable in the real world samples. They should also affect the transport of native and labelled species to about the same extent and therefore, isotope dilution is recommended for accurate quantitative analysis. However, isotope dilution calibration may be limited by the availability and cost of the labeled species and the requirement for coelution.

PARTICLE BEAM-LC/MS AND THE USE OF STABLE ISOTOPE LABELED INTERNAL STANDARDS FOR QUANTITATIVE ANALYSIS

Daniel L. Norwood and Brian P. Downey; Glaxo Research Institute, Five Moore Drive, Research Triangle Park, NC 27709

INTRODUCTION

Particle Beam (PB) is a Liquid Chromatography/Mass Spectrometry (LC/MS) interface technique designed to separate HPLC eluent from target analytes, allowing direct introduction of the desolvated analytes into an EI or CI source. Recent studies suggest that fundamental problems may exist in quantitative applications of PB-LC/MS using stable isotopically labeled internal standards that co-elute with their target analytes.[1] These problems may arise from a PB carrier effect which is characterized by enhanced ion abundances for co-eluting compounds and may result in non-linear response. This report describes an investigation of the utility of PB-LC/MS for quantitative analysis using stable isotopically labeled internal standards. A quantitative assay using isotope dilution PB-LC/MS was developed and validated for sensitivity, linearity, and precision. Target compounds included caffeine, benzo(ghi)perylene, di-n-octylphthalate and bis(2-ethylhexyl)phthalate.

EXPERIMENTAL

All mass spectra were collected with a VG LINC Particle Beam Interface and a VG Trio-2 Quadrupole Mass Spectrometer in the electron ionization mode. Calibration curves for each of the target compounds were generated by injecting 50 µL for each of five samples containing 0.25, 1, 5, 10, and 25 µg/mL of target compound and a constant 5 µg/mL of isotope labeled internal standard.

RESULTS

The target compounds for evaluation of the particle beam interface for isotope dilution quantitation were chosen based upon polarity, isotopic label, and chromatographic co-elution. The effect of polarity on linearity was assessed with caffeine/$^{13}C_1$-caffeine and benzo(ghi)perylene/d_{12}-benzo(ghi)perylene. Bis(2-ethylhexyl)phthalate/$^{13}C_1$-bis(2-ethylhexyl)phthalate and di-n-octylphthalate/d_4-di-n-octylphthalate were used to determine if there was a kinetic isotope effect on linearity. Finally, the effect of chromatographic co-elution on linearity was assessed by analyzing caffeine/$^{13}C_1$-caffeine (co-eluting) and benzo(ghi)perylene/d_{12}-benzo(ghi)perylene (baseline resolved). The method was linear over a range of 12.5 - 1250 ng injected for all target compounds analyzed. In cases where an isotope overlap exists between a target compound and it's isotope labeled analog, relative responses were calculated according to models described in the literature.[2]

The detection limit was less than 9 ng injected for each target compound. The relative standard deviation of the relative responses was less than 2 % for 3 consecutive 250 ng injections of di-n-octylphthalate and bis(2-ethylhexyl)phthalate.

The existence of a particle beam carrier effect was demonstrated by showing that peaks present in the selected ion traces of drug product impurities co-eluted with the peaks present in selected ion traces for m/z 149, 167, and 279, which pertain to a phthalate impurity in the mobile phase.

Electron ionization spectra were obtainable by PB-LC/MS for a wide range of pharmaceutical products.

CONCLUSION

Isotope dilution is an effective quantitation technique for PB-LC/MS. The variable transport efficiency observed with the PB interface can be compensated for by using isotope dilution quantitation. Validation experiments performed on a quantitative assay for benzo(ghi)perylene, caffeine, di-n-octylphthalate, and bis(2-ethylhexyl)phthalate showed that analyte response is linear over at least two orders of magnitude using PB-LC/MS. The assay is sensitive and provides reproducible injection results. There is evidence to suggest that a PB carrier effect exists, with negative implications for identification of trace organic impurities in pharmaceuticals.

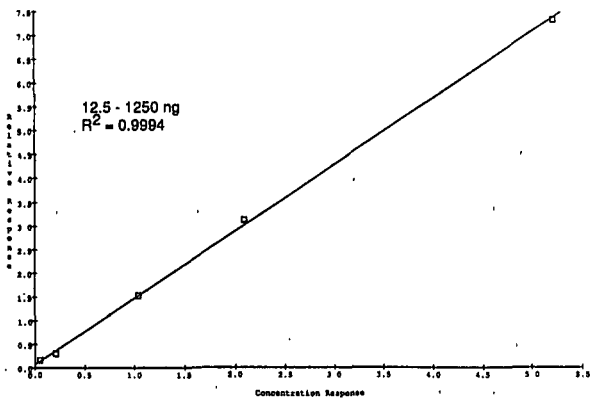
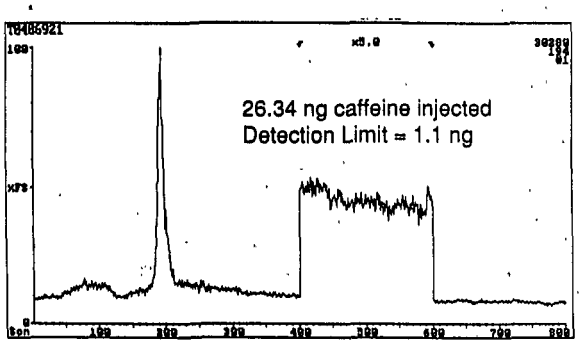
Caffeine Linearity



PARTICLE BEAM-LC/MS SENSITIVITY



Phase Transfer Catalyzed Derivatization of L-Tryptophan and L-Kynurenine and their Quantification by Particle Beam LC-NCI MS

R. L. Boni, J. T. Simpson, K. Saito, and S. P. Markey
Section on Analytical Biochemistry, NIMH, Bethesda, MD 20892.

Introduction

In extrahepatic tissues, the enzyme indoleamine-2,3-dioxygenase (IDO) limits the rate at which L-tryptophan (TRP) is metabolized via the kynurenine pathway. Stimulating the immune system of small animals with interferon-γ results in induction of IDO activity and increased concentrations of neuroactive metabolites L-kynurenine (KYN) and quinolinic acid (1). Increased synthesis of $^{13}C_6$-quinolinic acid by human macrophages incubated with $^{13}C_6$-TRP in the presence of interferon-γ has been demonstrated in vitro (2). We have developed a particle beam LC-NCI MS method suitable for tracing the metabolism of isotopomers of TRP to KYN in various cultured cells and incubated tissue slices which are being used to model kynurenine pathway activation in whole animals.

Experimental

[$^{18}O_2$]-TRP and [$^{18}O_3$]-KYN were synthesized by exchange in 1.4 M HCl/H_2[^{18}O] at 70°C for 48 hours (4). [$^2H_4$]-KYN was biosynthesized by incubating U373 glioblastoma cells in RPMI 1640 medium containing 2 mM 2',3',5',6',7'-[$^2H_5$]-TRP (MSD isotopes) for 48 hours. Deuterated kynurenine was purified by HPLC on a 100 x 4.6 mm id 3 µm ODS Hypersil column run isocratically with 2% acetonitrile:0.1 M ammonium acetate (adjusted to pH 4 with acetic acid) at a flow rate of 1.0 mL/min. Fractions containing deuterated kynurenine were collected, freeze-dried, reconstituted in water and used as internal standard.

A method of phase transfer catalysis (3) was modified for the pentafluorobenzylation of TRP, KYN, and the internal standards. To 25 µL aliquots of TRP and KYN standards (or 10-25 µL cell culture or tissue incubation medium) and 25 µL internal standard solution were added 250 µL of 0.1 M tetrabutylammonium hydrogen sulfate in 1 M ammonium hydroxide (pH 10-11) and 250 µL of 0.13 M pentafluorobenzyl bromide in methylene chloride. Each sample was vortexed for 2 minutes, ultrasonicated for 1 hour, and extracted with 1.0 mL of toluene. The upper organic layer was removed and evaporated under a stream of nitrogen. Residues were reconstituted with 100 µL toluene and transferred to autosampler vials.

These methods were used to quantify the production of ($^{13}C_6$)-KYN from ($^{13}C_6$)-TRP in cultured cells and tissue slices. Human monocytes, THP-1, were incubated with 50 µM ($^{13}C_6$)-TRP in RPMI medium with and without the addition of 100 IU of interferon-γ. Lung slices from gerbils (immune stimulated with pokeweed mitogen, 500 µg ip, or saline treated controls) were incubated with 50 µM ($^{13}C_6$)-TRP in Eagles' minimum essential medium for 48 hours. Samples of media were analyzed by LC/MS after phase transfer catalyzed derivatization.

Normal phase HPLC was carried out on a Hewlett-Packard 1050 series LC system equipped with a 5 µm Hypersil column, 100 mm x 2.1 mm id at a flow rate of 0.4 mL/min and mixed mobile phase (toluene:ethyl acetate). Solvent polarity was programmed: 100% toluene, 0-2 min, 92% toluene:8% ethyl acetate, 2.01-8 min, 100% toluene, 8.01-10 min with a 5 min post-time (total run cycle time of 15 min).

LC eluent was introduced into the mass spectrometer via a HP 59980B Particle Beam Interface. Helium nebulizer pressure was 50 psi and interface temperature maintained at 48°C. NCI-MS was performed on a HP 5989 mass spectrometer with methane as reagent gas at a source pressure of 1 torr. Source and quadrupole temperatures were 250°C and 100°C, respectively. Selected ion monitoring of the prominent $(M\text{-}PFB)^-$ ions at m/z 383, 385, 387, 389, 391, 393 (dwell time = 100 msec) was used for quantification.

Results and Discussion

The conditions used for phase transfer catalysis were optimized to yield PFB derivatives of both the carboxyl and amino functionalities of TRP and KYN. Adjustment of pH to between 10 and 11 was important to ensure that the basic amino functions were non-protonated allowing extractive alkylation to occur. Alkaline conditions pH>12 were avoided to reduce amino acid degradation.

Reverse phase LC did not provide the desired analyte separation in a rapid manner. Normal phase LC provided rapid and complete (>1 min) separation of KYN and TRP, allowing excess derivatizing reagent and reaction by-products to be diverted from the mass spectrometer. Additionally, the use of volatile organic solvents minimized maintenance on the particle beam interface.

NCI mass spectra of the PFB derivatives of TRP and KYN exhibited prominent $(M\text{-}PFB)^-$ ions at m/z 383 and 387, allowing quantification at the ng level. Mass Spectra of the PFB derivative of $[^{18}O_2]$-TRP contained a dominant ion at m/z 387, but spectra for the PFB derivative of $[^{18}O_3]$-KYN gave ions at both m/z 391 and 393 due to back-exchange during derivatization. Deuterated compounds, synthesized $[^2H_4]$-KYN and commercial D,L-tryptophan-ß-$[^2H_2]$ (MSD Isotopes), produced prominent ions at m/z 391 and 385, respectively. These isotopomers did not exhibit back-exchange during derivatization and were better suited as internal standards.

Standard curves for TRP and KYN with ^{18}O internal standards were linear (r>0.99) over the range 1 to 100 ng/sample (0.25 to 25 ng injected). Standard curves for TRP and KYN with deuterated internal standards were linear(r>0.99) over the range 1 to 250 ng/sample

The developed method was used to quantify the production of $(^{13}C_6)$-KYN from $(^{13}C_6)$-TRP by cultured cells and tissue slices. The concentrations of $(^{13}C_6)$-KYN were calculated from the standard curve of Peak Area Ratio KYN/$[^2H_4]$-KYN vs. ng/sample. Interferon-γ increased 48 h conversion to $(^{13}C_6)$-KYN from 0.8% to 55% of the substrate $(^{13}C_6)$-TRP. For gerbil lung slices, pretreatment with pokeweed mitogen increased 48 hour conversion to $(^{13}C_6)$-KYN from 0.5% to 3.8% of substrate $(^{13}C_6)$-TRP.

Determination of Exchangeable Protons by Hydrogen-Deuterium Exchange Employing a Particle Beam LC/MS Interface

*James L. Little, Lee Allen Cook, Building 150, Eastman Chemical Company, Eastman Kodak Company, Kingsport, Tennessee, 37662

Introduction. The determination of exchangeable protons (protons attached to heteroatoms such as nitrogen, oxygen, sulfur) by mass spectrometry is often useful in differentiating isomers. Exchangeable protons can be determined by derivatizations (e.g. silylation and acetylation) or by hydrogen-deuterium exchange. The latter technique is best in LC/MS (liquid chromatography/mass spectrometry) because no shift in retention time of the analyte is observed. Hydrogen-deuterium exchange can be employed via solid probes analyses without chromatography. However, the number of exchangeable protons in minor components is often obscured by interfering species at much higher concentrations in the mixture.

We have employed particle beam LC/MS in the CI and EI modes to differentiate C- versus O-alkylation products in a variety of polymer and resin intermediates. It is important to differentiate these types of products since they can be chain-terminators or chain-branchers in the end products. In addition, we routinely employ the technique for many other classes of compounds, since isomers often can be distinguished by their number of exchangeable protons. Hydrogen-deuterium exchange can be employed in thermospray and direct liquid introduction LC/MS analyses, but the CI gas is limited by the HPLC eluent employed and large quantities of labelled reagent are required. Particle beam LC/MS is much more versatile in that the exchange medium is not limited by the HPLC eluent and that very little labelled reagent is needed.

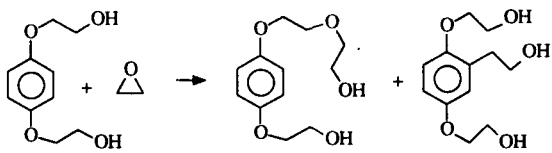
Mechanism/Choice of Gases. The reaction mechanism [1,2] of chemical hydrogen-deuterium exchange involves two steps. First the compound is ionized and then exchangeable protons on the charged species are exchanged for deuterium from the neutral reagent gas present in the source. This requires that the neutral reagent gas or gas mixture contains a large population of exchangeable protons. In other words, gases such as deuterated methane cannot be employed. We have employed primarily deuterated ammonia in the positive ion mode, but other gases or gas mixtures are employed:

$$ND_3 \Longrightarrow ND_4^+$$
$$CD_3OD \Longrightarrow CD_3OD_2^+$$
$$D_2O \Longrightarrow D_3O^+$$
$$ND_3/NH_2CH_3 \Longrightarrow ND_3CH_3^+$$
$$ND_3/N_2O \Longrightarrow OD^-$$

A mixture of deuterated ammonia and a small amount of methylamine can be employed because the latter regent gas has a higher proton affinity than ammonia.

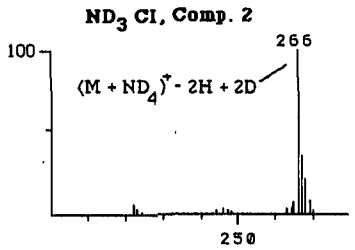
Normally only protons directly attached to heteroatoms such as nitrogen, oxygen, and sulfur are exchanged. However, protons attached to aromatic rings or adjacent to carbonyl groups such as ketones can be fully or partially exchanged under certain circumstances [1,2].

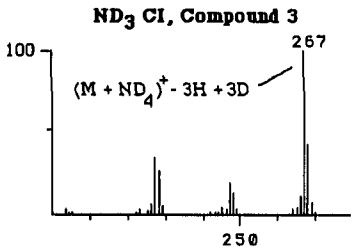
Typical Results. Bis(2-hydroxyethyl)hydroquinone, Compound 1, is produced by the reaction of hydroquinone with ethylene oxide. Over-reaction of product with ethylene oxide can yield many different impurities. The ethylene oxide can react on oxygen or the aromatic ring to yield isomers which are shown below:



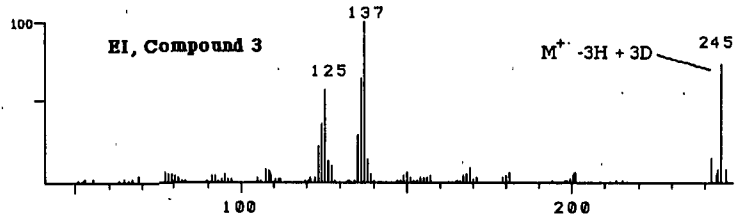
1 2 (MW 242) 3 (MW 242)

The determination of the number of exchangeable protons can easily distinguish these two impurities which are both present in the reaction mixture. The molecular ion regions of the deuterated ammonia chemical ionization spectra for Compounds 1 and 2 are shown below. A m/z range of 90-1000 amu's was scanned in the analyses.





Deuterium Exchange in EI Spectra. Preliminary work shows that deuterated ammonia can be employed in the electron impact (EI) mode to determine the number of exchangeable protons when a molecular ion is present. This is useful when an appropriate gas cannot be found for chemical ionization. The EI mass spectrum for Compound 3 is shown below:



LC/MS Interface. The Vestec particle beam interface is utilized with flows up to 1.5 ml/min of aqueous 0.1 molar ammonium acetate for the determination of exchangeable protons. The efficiency of hydrogen exchange was not found to vary when the sweep of helium through the interface membrane was varied from 0.25 to 6.0 liters/minute. However, values for other parameters such as the reagent ion intensities, signal to chemical noise, and absolute sensitivity changed significantly. A flow of 2.5 to 3.5 liters/minute through the membrane was found to be the best compromise for the compounds evaluated.

Chemical Ionization Gas Manifold. The use of a wide variety of chemical ionization gases or gas mixtures is greatly facilitated by the availability of a versatile gas manifold. Plans are available from the authors for the chemical ionization manifold employed in this work. The manifold quickly and easily selects from six different gases with independent flows for each gas, can be employed for mixing gases, allows easy replacement of gases, can me moved between mass spectrometers, and stores excess reagent gas lecture bottles.

PARTICLE BEAM LC-MS SPECTRA OF ANIONIC SURFACTANTS

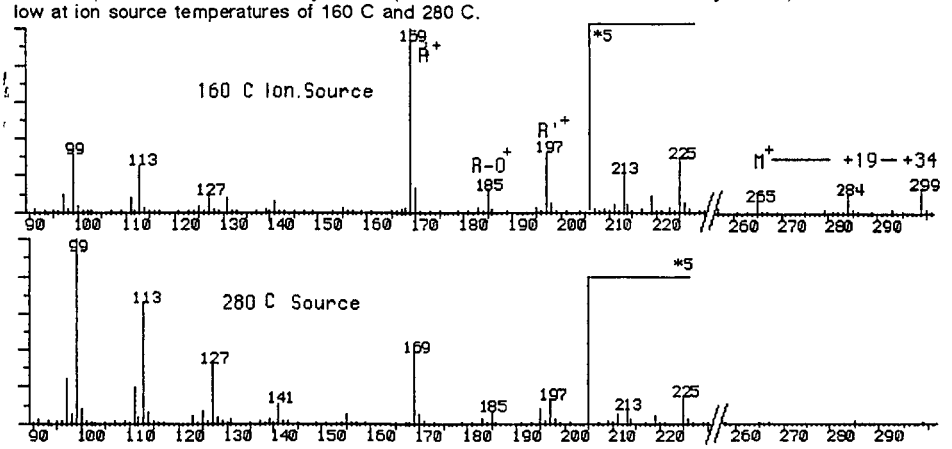
Bruce H. Solka, Helene Curtis, Inc., Chicago IL, 60639

The particle beam (PB) LC-MS interface is shown to be a useful sample introduction technique for mass spectral characterization of anionic surfactants. These commercially important detergents have annual US consumption of about 4-6 billion pounds. As non-volatile organic salts, their mass spec analysis has been limited to desorption techniques such as FAB or thermospray. Analysis of unknowns or of impurities in commercial grade detergents can benefit from the more informative fragmentation in EI or CI spectra available with the PB technique if the required volatilization does not cause loss of structural integrity of the anionic surfactant.

PB-CI-MS spectra of these anionics reveal competetive flash desorption of intact ionic species and pyrolytic formation of aliphatic alcohols. The effect of ion source temperature on the on the competition of these volatilization processes is opposite to that shown earlier for quaternary ammonium compounds (1): increasing temperature decreases the relative amount of intact ionic species.

Spectra were obtained by direct flow injection of one ug samples into a post-LC column flow of 0.6 ml/min 50/50 water/methanol with methane CI. An Extrel ELQ-400 MS with the Extral Thermabeam PB interface was used.

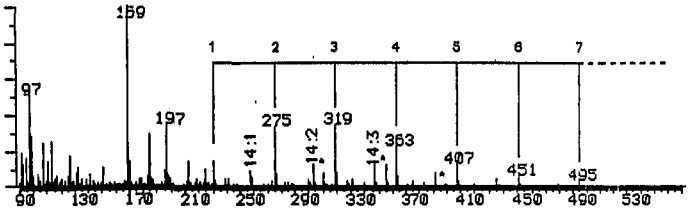
<u>Linear Alkyl Sulfates</u> 
The CI spectra of Sodium Dodecylsulfate (which contains about 20% tetradecylsulfate) is shown below at ion source temperatures of 160 C and 280 C.



The 12-carbon molecular species and two mobile phase adduct ions are seen at masses 265, 284 and 299 at low source temperature but are substantially reduced at the higher source temperature. The mass 185 and 169 ions from the the pyroltically generated dodecanol show the usual increase in alkyl chain fragmentation at higher temperatures as seen in CI spectra of alcohols introduced in traditional manner. The negative ion CI spectra (not shown) of this material has stable molecular anion, with alkyl fragments from loss of SO_3 and H_2SO_3, and SO_2, SO_3 and $HOSO_3$ ions.

<u>Ethoxylated Alkyl Sulfates</u> 
Commercial ethoxylated alkyl sulfates contain a broad distribution in number of ethoxyl units in the molecule. Because that number has a strong effect on surfactant properties, it is an important parameter in the analysis of these materials. The CI spectra of 2-mole ethoxylated dodecyl sulfate is

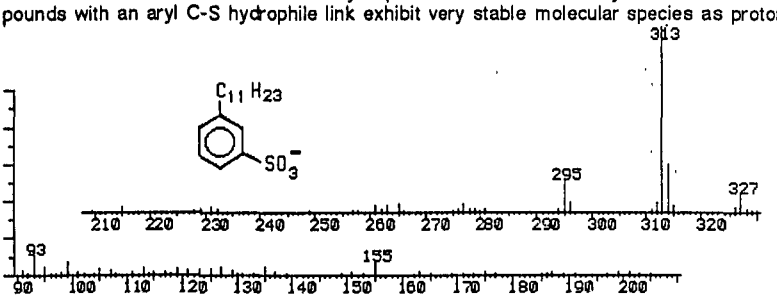
shown below. In addition to ions analogous to those mentioned for the unethoxylated sulfate,



a series (n=1 through 7) of protonated ethoxylated alcohols shows the ethoxylate distribution. As in the case of the alkyl sulfate, the intact molecular ions (*) are present but of low intensity. Of the total one ugm sample, the individual oligomers in this mix average about 150 ngm each.

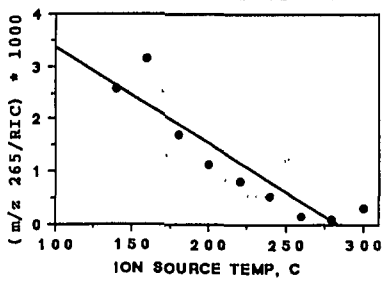
Undecylbenzene Sulfonate.

In contrast to the anionics where the hydrophile is bonded to the alkyl chain via a C-O-S bond, compounds with an aryl C-S hydrophile link exhibit very stable molecular species as protonated acid :



Finally, it was previously shown that increasing source temperature over the 160-300 C range increased the ratio of flash vaporization of intact quaternary ammonium ions over pyrolysis amines by about a factor of three. This trend is reversed for the alkyl sulfates where significant decrease in the proportion of intact molecular species is observed at higher temperatures:

EFFECT of TEMPERATURE on DESORPTION of INTACT DODECYL SULFATE



This behavior is apparently related to the relative activation energies between the two sets of competetive processes(2).

These results illustrate that the PB interface provides structurally useful mass spectra of non-volatile anionic surfactants. It is also shown that increasing impact target temperature may not necessarily improve the quality of the desired information.

Application of Thermal Kinetics to Carbon Ion Clusters

Chava Lifshitz, Pablo Sandler and Tikva Peres
Department of Physical Chemistry and
The Fritz Haber Research Center for Molecular Dynamics
Jerusalem 91904, Israel

There has been great interest recently in carbon cluster ions. An important but somewhat illusive property of these clusters, which is related to the occurrence of certain magic numbers in their spectra, is their binding energy. Direct determination of these binding energies for large cluster ions, such as C_{60}^+, from appearance energy measurements of their dissociation products, is impossible due to extremely large (~ 30 eV) kinetic shifts[1]. A model-free approach to the determination of binding energies from kinetic energy distributions has recently been developed by Klots[2]. An alternative approach involves application of a spherically symmetric potential consisting of a long-range ion/induced dipole interaction and a short-range hard sphere potential[3].

We have measured center-of-mass product kinetic energy release distributions (KERDs) for C_2 desolvations from C_5^+, C_{60}^+, C_{70}^+ and several other carbon ion clusters. These distributions were fit to either one of the following expressions:

$$p(\epsilon) \simeq \epsilon^{\xi} \exp(-\epsilon/k_B T^{\ddagger}) \tag{1}$$

$$p(\epsilon) \simeq \exp(-\epsilon/k_B T^{\ddagger}) \, [1-\exp(-BL_{max}^2/k_B T^{\ddagger})] \tag{2}$$

where ϵ is the kinetic energy, $0 < \xi \leq 1$, k_B is Boltzmann's constant, $B = \hbar^2/2(I_1+I_2)$ is the rotational constants, I_1 and I_2 are the moments of inertia of the product fragments, L_{max} is the maximum value of the orbiting angular momentum quantum number and $T^{\ddagger}$ is the temperature of the transition state.

The experimental KERDs when fit to (1) or (2) yield the temperature $T^{\ddagger}$ of the transition state. This in turn is related to a 'bath temperature' T_b and through T_b to the evaporation (i.e. binding) energy via Trouton's rule.

The center-of-mass product KERDs for $C_5^+$and C_{60}^+ are given in Fig. 1. An example of the fit of eqn. 2 to the experimental distribution for C_{60}^+ is shown in Fig. 2. Expressions (1) and (2) yield binding energies of 6.05 eV and 5.45 eV, respectively for C_{60}^+, with an average of 5.75 ± 0.3 eV.

We are in the process of improving the treatment of the data and finding out whether the binding energies follow the relative activation energies for evaporation required to explain decay constants of metastable carbon clusters[2,4] and form 'magic' shells.

Laser desorption laser ionization mass spectrometry of metalofullerenes.

M.S. de Vries, H.E. Hunziker, H.R. Wendt, R. Johnson, N. Vannoni, D. Bethune, M. Hoinkis, and J. salem. IBM, Almaden Research Center, 650 Harry Rd., San Jose, CA 95120-6099

Metallofullerenes, prepared by arc vaporization of especially prepared composite carbon metal rods, were analyzed by laser desorption, laser ionization mass spectrometry. First, it will be shown that the metallofullerene complexes are not formed in the laser desorption step itself, but rather are present in the bulk material on the surface, prior to analysis. It can also be shown that laser desorption can be used to vaporize intact unstable metallofullerenes that decompose upon slower heating. The second step in the analysis is photoionization, so its merits need to be discussed.

These experiments were carried out in a laser desorption jet cooling apparatus. Essentially, molecules on a surface are laser desorbed, entrained in an Ar supersonic expansion and detected downstream by (multi)photon ionization and time of flight mass spectrometry. Desorption was performed both with 532 nm light from a doubled Nd-YAG laser, and with 248 nm light from a KrF excimer laser. No difference was observed. Ionization was done with 193 nm excimer laser radiation. It is important to prove that the metalofullerenes that are observed where not formed by complex formation during the analysis. Figure 1 shows a mass spectrum obtained from a sample that contained a dried toluene extract of a mixture of (a) lanthanum containing soot and (b) soot that was produced without lanthanum form 13C graphite. Clearly both soot (a) and soot (b) produce C_{60} as well as C_{70}, however only soot (a) produces a metallofullerene, La C_{82}. If this species would have been produced by desorption or jet cooling, then we would have also observed the 13C enriched metallofullerene. This demonstrates that in fact the metallofullerene is present on the surface, prior to analysis.

Generally laser desorption can be used for analysis of organics that are unstable upon heating, because, with a laser pulse of the order of nanoseconds, compounds can be volatilized while avoiding thermochemical decomposition. In the case of fullerenes that advantage is not always crucial, since these species appear to be quite stable upon heating. However, for metallofullerenes that is no longer necessarily true. Figure 2, top panel, shows a laser desorption mass spectrum of arc soot from composite rods containing Gadolinium in addition to carbon. As can be seen, the dominant species in the spectrum is GdC_{60}, followed by GdC_{70}. In various experiments the soot was heated, in either stainless steel or quartz ovens, in vacuum, to various temperatures, ranging from 300 C to 700 C. It was found that most metalofullerenes sublime at temperatures comparable to their bare fullerene analogues. In other words the sublimation temperature increases with number of carbons and is not significantly affected by the metal addition. However, the lighter metallofullerenes, such as the C_{60} and C_{70} species are decidedly unstable. The bottom panel of Figure 2 shows a mass spectrum of the soot after heating, while the middle panel shows a mass spectrum of the sublimed material. It appears that the species that were dominant in the spectra of the untreated soot, decompose or otherwise react upon slow heating. They can however be volatilized by rapid laser heating. It is remarkable that the least stable metallofullerenes are those formed with the most stable bare fullerenes.

It is noted that toluene extraction, which is very selective for C_{60} and C_{70}, is in the case of metallofullerens generally selective for the C_{82} species instead. There is an apparent trend towards more multiple metal species with decreasing ionic radius. Scandium, with the smallest ionic radius is a special case, in that toluene solubility seems to be less selective. Sc_2C_n species are observed with n ranging from 80 to 90 (even numbers only) with peak heights in the same order of magnitude. Monoscandium and triscandium, giving small peaks in the mass spectrum, are observed with EPR

Finally it needs to be pointed out that care should be exercised in interpreting photoionization mass spectra, since relative ionization efficiencies are unknown. In the case of bare C_{60} the ionization potential is higher than the photon energy and 193 nm photons cause two photon ionization. We find that for all La fullerenes the ionization depends linearly on laser fluence, and is therefore probably a one photon process. This strongly suggests that the addition of the La lowers the ionization potential to below 6.3 eV.

Examination of Fullerene Growth and Doping by Laser Desorption FTMS*

Robert L. Hettich and Robert N. Compton
Analytical Chemistry Division, Health and Safety Research Division
Oak Ridge National Laboratory

FTMS can be used with either laser desorption/ionization or thermal desorption electron impact ionization FTMS for the characterization of the fullerene content of a variety of samples. We have undertaken a series of experiments which are designed to examine the parameters which influence fullerene growth. Fullerene samples, C_n where n =60-300, were generated by laser ablation of a graphite rod in a quartz vial maintained under a static pressure of a buffer gas (300 Torr). These samples were then examined by laser desorption FTMS to characterize the identities and abundances of fullerenes present. Varying the pressure and identity of the buffer gas resulted in dramatic changes in the abundances of fullerenes generated. In general, the noble gases He and Ne were much better than Ar and Xe for the production of fullerenes, implying that the cooling of the laser plume is critical. This result may imply that the smaller gases (i.e. He and Ne) are more suitable for cooling the active fullerene growth species, which may be C_2. Diatomic buffer gases such as O_2, N_2, and D_2 virtually quench formation of large fullerenes. These diatomic buffer gases most likely are atomized in the laser plume and react with the growing carbon chains to prematurely terminate carbon cluster growth.

A variety of synthetic methods have been used for the preparation of fullerenes which are doped with heteroatoms such as fluorine, hydrogen, and oxygen. FTMS was then used to characterize these modified fullerenes. Thermal desorption electron impact is a soft ionization technique for these compounds but is quite dependent on compound volatility. Laser desorption is less sensitive to compound volatility and should provide a more accurate measure of the actual sample composition; however, this technique can induce substantial fragmentation of the doped fullerenes. Thermal desorption followed by low energy electron capture of the fluorinated fullerenes favors non-dissociative ionization, producing $C_{60}F_x^-$ where x is even-numbered, whereas laser desorption/ionization results in substantial dissociative electron capture to yield $C_{60}F_x^-$ where x is odd-numbered. The greatest degree of fluorination observed in the mass spectra was $C_{60}F_{48}$ and $C_{70}F_{56}$, with $C_{60}F_{46}$ and $C_{70}F_{53}$ as the most abundant constituents, as shown in the thermal desorption mass spectrum, Figure 1. The use of a number of different ionization methods indicated that this was the highest level of fluorination in the actual samples and that the fragmentation in the mass spectrometer was not significantly altering the sample. Charge exchange reactions were used to bracket the electron affinities of these species as well as examine a lower limit for their ionization potentials. In particular, $C_{60}F_x$ will not charge exchange with C_{60}^- (EA = 2.65 eV), but will charge exchange with both NO_2^- (EA = 2.3 eV) and phenoxy anion, $C_6H_5O^-$, (EA = 2.36 eV). Figure 2 illustrates the reaction of $C_{60}F_x$ with the $(M-H)^-$ ion of phenol. This spectrum was obtained by introducing phenol at a static pressure of 2×10^{-6} Torr into the vacuum chamber and then ionizing this compound by low energy electron capture. This process forms primarily $(M-H)^-$ for phenol at m/z 93. Simultaneously, $C_{60}F_x$ is being thermally desorbed from the stainless steel probe tip at a temperature of 250 °C. After a suitable reaction delay to cool the ions, all ions except m/z 93 are ejected from the cell. An additional delay is added to allow the phenoxy anions to react with the neutral $C_{60}F_x$, which results in charge transfer, as shown in Figure 2. These charge bracketing experiments imply electron affinities EA = 2.5 $\pm$ 0.15 eV for $C_{60}F_x$ where x = 44, 46. These values imply that even though many fluorines have been added to the fullerene structures and have dramatically reduced the double-bond conjugation, the electron affinities of the fluorinated C_{60} species are quite close to the electron affinity of C_{60}. $C_{60}F_x$ will not charge exchange with C_{60}^+, implying that the ionization potential of $C_{60}F_x$ is greater than the ionization potential of C_{60}, which is 7.6 eV.

Catalytic hydrogenation reactions have been used to generate species such as $C_{60}H_{18}$, $C_{60}H_{36}$, and $C_{70}H_{36}$. More extensive reaction conditions and times did not result in further hydrogenation. Research is currently directed at examination of this difference in degree of fullerene reduction with hydrogen as opposed to fluorine as well as elucidation of the structures and properties of these modified fullerenes.

The structures of the remarkably stable carbon cluster C_{60}, first discovered in vapour from laser irradiation of graphite and subsequently produced in macroscopic quantities by resistive heating of graphite under an inert atmosphere [1], is now widely accepted as a truncated icosahedron ("soccer ball"), while the homologue C_{70} is assigned an ellipsoidal cage structure ("rugby ball"). Recently it was shown that C_{60} and C_{70} fullerenes isolated from samples of condensible compounds and soot collected from controlled combustion of benzene in pre-mixed laminar flames were spectroscopically indistinguishable from fullerenes prepared from graphite [2, 3]. Analysis of the flame generated soots by high performance liquid chromatography (HPLC) with ultraviolet spectroscopic detection also revealed the presence of several additional components with fullerene-like characteristics [2, 3].

The flame-generated soot extract and two commercially available soot extracts, produced by resistive heating of graphite in an inert atmosphere, have been characterised by HPLC coupled on-line with mass spectrometry (LC-MS) using atmospheric pressure chemical ionization (APCI). Positive ion spectra were obtained using a post-column addition of benzene to the source which ensured that the dominant mechanism for formation of positive ions from the sample was electron transfer to $C_6H_6^{+\cdot}$ ions formed in a corona discharge. Negative ion APCI spectra were obtained using LC-MS conditions identical to those used for positive-ion work but omitting the benzene [3]. Under these conditions, ionization of the fullerenes proceeds via electron and chloride attachment (the Cl^- arising from the dichloromethane in the HPLC mobile phase).

The additional components present in the flame soot have been identified as isomers of C_{60} (peak B in Figure 1a), C_{70} (peaks C and 9 in Figure 1c), and C_{76} (peak 10 in Figure 1e). These newly observed isomers have characteristic UV spectra and are thermally unstable, appearing to undergo conversion to the more stable fullerenes in boiling toluene [3]. The flame generated material also contains isomeric forms of the larger carbon clusters (Figures 1g and 1h) as well as $C_{60}O$ and $C_{70}O$ compounds (Figures 1b and 1d).

The isomers of C_{60}, C_{70} and C_{76} were not detected in either of the graphite-derived soots. However, one of the soots did contain a significant amount of $C_{60}O$ (only one isomer corresponding to peak A in Figure 1b) and $C_{70}O$ (two isomers corresponding to peaks 7 and 8 in Figure 1d). The second graphite-derived soot, which was probably produced in a more reducing environment than the first, contained previously undiscovered hydrogenated fullerenes, including $C_{60}H_2$, $C_{60}H_4$, $C_{70}H_2$ and $C_{60}CH_4$, while the oxides were not detected [4]. The flame-generated material contained all of these minor constituents, together with complexes of C_{60} with larger aliphatic molecules as well as large quantities of polycyclic aromatic hydrocarbons.

Formation of Fullerenes in MeV Ion Track Plasmas

G.Brinkmalm, *P.Demirev, D.Fenyö, P.Håkansson, B.U.R. Sundqvist,
Dept. Rad. Sciences, Uppsala University, Box 535, Uppsala, 75121 SWEDEN

The existence of a new allotropic form of carbon - closed shell pure carbon structures (**fullerenes**) - was predicted by Kroto *et al.* [1] on the basis of laser ablation mass spectrometry results. The spectacular discovery of Krätschmer *et al.* [2] of a method for synthesis of macroscopic amounts of C_{60} and C_{70} lead to the explosive growth of research on fullerene properties. Recently it was demonstrated that positive ions of even numbered carbon clusters (C_n^+, n= 40 to > 200) are ejected when MeV primary ions (with velocities exceeding the Bohr velocity) interact with a specific polymer: poly(vinylidene difluoride) -PVDF, $-(CH_2CF_2)_n-$, [3,4]. The distribution of cluster sizes suggests that stable, closed carbon-cage structures - fullerenes - are formed. Most of the energy of fast MeV ions is deposited in a solid target via ion-electron collisions in an ion track in times of the order of 10^{-15}s. The track is axially symmetric along the direction of the incoming ion. Plasma-like conditions are formed in an infratrack, a cylindrical region roughly 5 Å in radius where the energy density is greatest. If the relaxation times of the electronic subsystem in the solid are slow, as in the case of insulators, material is sputtered from the solid. This phenomenon is termed electronic sputtering and is exploited in e.g. a specific version of SIMS - plasma desorption mass spectrometry. The ejection of positive ions of even numbered pure carbon clusters as a result of the interaction of a single fast MeV ion with a polymer, containing only 30% of C atoms, is a new specific effect of the electronic sputtering phenomenon.

We have investigated specific aspects of the electronic sputtering of fullerenes from PVDF. These include the dependence of the fullerene ion yield on the electronic stopping power and charge state of the incident projectile and the initial radial velocity distributions of ejected ions. Measurements of the yield and initial velocity distributions of the ejected cluster ions are performed in a reflectron time-of-flight mass spectrometer. Swift atomic ions (9.9 MeV ^{16}O, 19.7 MeV ^{32}S, 48.6 MeV ^{79}Br and 78.2 MeV ^{127}) with the same impact velocity are generated in the Uppsala EN-tandem accelerator. The data are compared to data for ions, ejected by MeV projectiles from synthetic (prepared according to Krätschmer *et al.* [2]) fullerene (C_{60} and C_{70}) targets. A stronger dependence of the yield for the C_{60} ions desorbed from PVDF targets ($Y \sim (dE/dx)^{34}$) than for ions from targets with preformed C_{60} ($Y \sim (dE/dx)^{20}$) has been observed. We have performed study on the initial radial velocity distribution of carbon clusters of different sizes obtained in electronic sputtering from PVDF. A potential merit of this study is the possibility it affords for determining the origin of the secondary ions relative to the ion track, created by the primary MeV ion impact. The radial velocity distribution for cluster ions ejected from the polymer, differ markedly from those of synthetic fullerene targets. While C_{60} and C_{70} ions from synthetic fullerene targets have ejection angle distributions symmetric along the target surface normal, the mean take-off angle of carbon cluster ions ejected from PVDF is in the direction of the incoming primary ion. Such an effect is encountered for the first time in MeV ion sputtering. The dependence of the carbon cluster ion yield on the primary ion charge state is given in fig. 1. The charge state on the does not influence the cluster ion yield which is an indication that layers from the polymer that are deeper than the charge equilibration length in the solid are excited to form fullerenes. We have also found that the

carbon cluster yield as a function of thickness of the polymer film increases and saturates at around 300Å.

All experimental data suggest that fullerenes are formed as a result of a single primary ion impact and that they are ejected from an axially expanding infratrack plasma region. These findings bear implications for the mechanism of fullerene formation in general giving estimates of the required time frame and spatial domain.

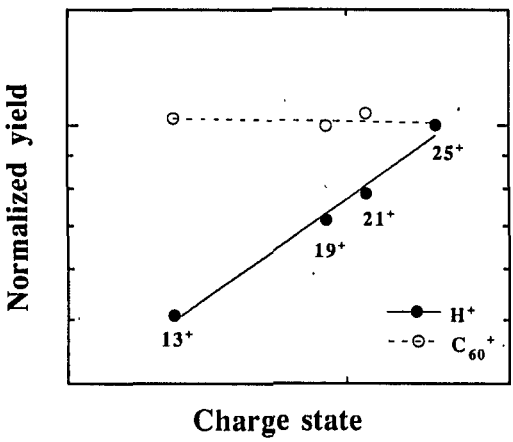

Fig.1. Charge state dependence of the yield of carbon cluster ions ejected from PVDF.

C_{60}; A RADICAL SPONGE AS DETERMINED BY ELECTROSPRAY, LASER DESORPTION, FAST ATOM BOMBARDMENT, AND CHEMICAL IONIZATION MASS SPECTROMETRY

C. N. McEwen, P. J. Krusic, J. Lazar, R. G. McKay, Z. Lam, and B. S. Larsen

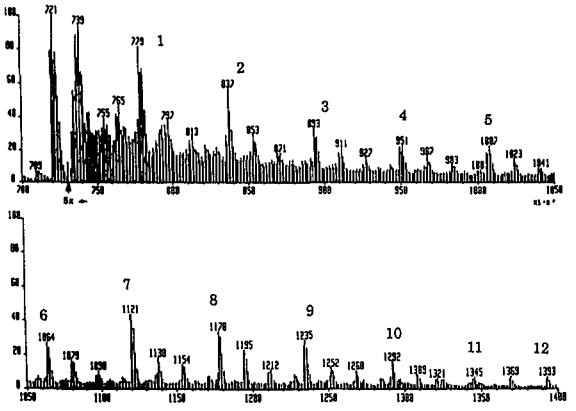
Corporate Center for Analytical Sciences
The Du Pont Company
P.O. Box 80228
Wilmington, DE 19880

The facile radical reactivity of C_{60} in solution,[1] discovered in our laboratories, prompted us to assess various mass spectrometric ionization techniques to determine the product mix of the solution phase radical/C_{60} reactions. In addition, we have shown that C_{60} undergoes facile reaction with radicals in the ion source when methane is introduced at pressures common to chemical ionization.[2] The in-source radical reaction is shown to occur between alkyl radicals (and hydrogen atoms) with C_{60} on the ion source walls.

Depending on the ionization method used, different results are observed for the C_{60} studies. Determining if a solution reaction of C_{60} has occurred and to what extent requires more than one ionization method to confirm the results. Caution should also be exercised when interpreting mass spectra of fullerenes run by any mass spectral technique in which condensation and vaporization can occur from a surface before ionization. For example, using methane under electron attachment conditions results in a 16 Da addition to the molecular ion, which was shown by accurate mass measurement to be addition of CH_4 (CH_3 + H).[2] Sixteen Dalton additions to C_{60} have been interpreted as oxidation products in other studies.[3]

In the original work by Krusic, et. al.[1], benzyl radical and methyl radical additions to C_{60} in solution were observed by positive ion FAB. The mass spectra showed that at least 15 benzyl groups and 34 methyl groups were attached to C_{60}. Electron attachment (EA) mass spectra supported the FAB results, although spectral differences were observed. Differences in the mass spectral results were most pronounced with the reaction products from the solution reaction of t-butyl radicals with C_{60}. The EA (nitrogen gas) spectrum showed only the m/z 720 isotope cluster of C_{60}, whereas the positive ion FAB mass spectrum (Figure 1) showed at least 10 and possibly 12 t-butyl groups attached to C_{60}. Negative ion FAB showed less extensive addition products, but ion intensities were low, and may account for the spectral differences. Negative ion laser desorption (LD)

C_{60}/t-Butyl Radical-Solution Reaction FAB (+) (NBA)



FTMS of the same reaction mixture showed up to eight t-butyl groups attached to C_{60} (Figure 2, normalized to m/z 737). The FAB and LD spectra both showed abundant ions corresponding to 16, 17, 32, and 33 Da additions to C_{60} and C_{60}/t-butyl products. These ions would appear to be related to oxidation, but alkyl radical and hydrogen atom additions cannot be ruled out.

Positive and negative ion electrospray (ES) ionization of this sample failed to show any ion current related to the expected products. C_{60} also failed to produce ions in electrospray, but addition of tetramethylphenylenediamine (TMPD) to a solution of C_{60} causes charged transfer in solution and results in a negative ion ES spectrum. A sample of C_{60}/t-butyl anion (as a lithium salt) in acetonitrile gave a very intense electrospray mass spectrum of the t-butyl/C_{60} adduct (Figure 3). These results suggest that C_{60} products can be observed in electrospray if they are charged in solution.

Department of Chemistry
Virginia Commonwealth University
Richmond, Virginia 23284-2006

Introduction

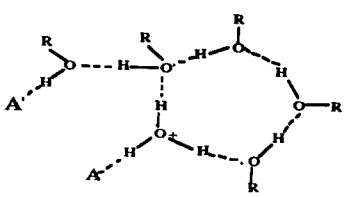
Hydrogen-bonded cluster ions have been the subject of intensive investigations with regard to thermochemistry, intra-cluster reactions and dissociation dynamics. Few experiments have been able to provide structural information, particularly for large clusters. Mixed clusters with protic components and blocking groups can be used as structural probes. The blocking of hydrogen-bonding positions around a core ion results in strong shell effects, disfavoring the addition of further blocked components after all the hydrogen bonding sites are occupied. In this paper, we report the observation of magic numbers in ternary clusters composed of water, methanol and acetonitrile. These results help to understand the energetic effects on the structures and distributions of ternary cluster ions.

Experimental

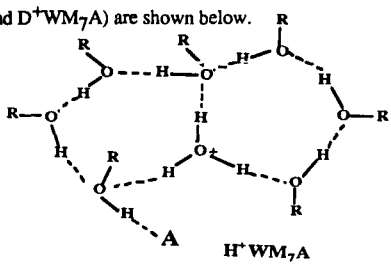
Mixed clusters, generated by pulsed adiabatic expansion in a supersonic cluster beam apparatus, were ionized by EI and subsequently mass analyzed in a quadrupole mass spectrometer [1,2].

Results

Figure 1 displays a typical 70 eV EI mass spectrum observed from the ionization of a cluster beam generated from the expansion of a 1:1:1 vapor mixture of CH_3CN, CD_3OD and D_2O in He carrier gas. The prominent peaks in the mass spectrum are due to blocked clusters such as $D^+M_nA_2$ and $D^+WM_nA_3$ with n=0-4 where M, A and W are methanol, acetonitrile and water, respectively. The maximum ion intensity within the $D^+WM_nA_m$ sequence for n=0-4 occurs for m=3 as shown in Figure 2. This indicates that these clusters can incorporate three CH_3CN molecules which terminate the extensions of three hydrogen-bonded chains. For n=5 and 6, the maximum ion intensity occurs for clusters containing only two acetonitrile molecules. This suggests the formation of a cyclic hydrogen-bonded structure. When the cluster of the $D^+WM_nA_m$ sequence contains seven methanol molecules, a magic number appears for m=1. The structures proposed for these clusters ($D^+WM_5A_2$ and D^+WM_7A) are shown below.



$H^+WM_5A_2$



H^+WM_7A

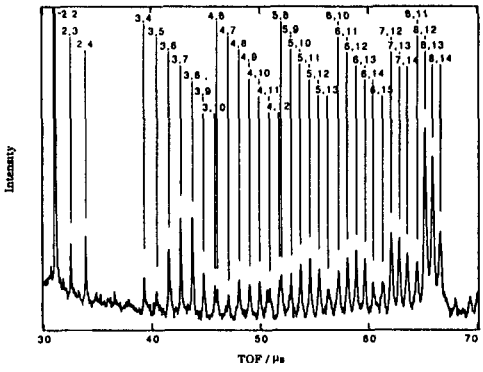
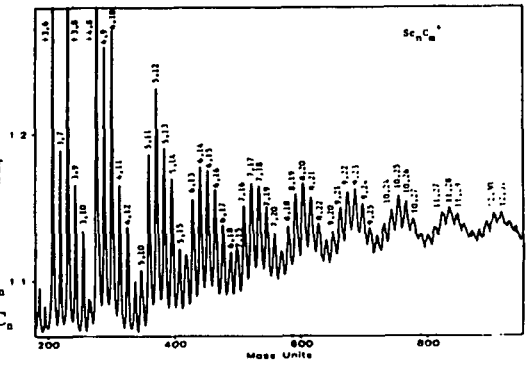
Laser Induced Plasma Dehydrogenation: The Formation of New Type Clusters

Z. Y. Chen and A.W. Castleman, Jr.
Department of Chemistry,
The Pennsylvania State University,
University Park, Pennsylvania 16802

Two reaction channels have been found when several organic and inorganic hydrogen-containing compounds are introduced into the carrier gas of a plasma reactor coupled with a laser vaporization metal cluster source: dehydrogenation to produce pure elemental clusters; and dehydrogenation to produce binary clusters such as transition metal cabrides, nitrides, silicides and oxides which are very important candidates as new electronic materials. With this technique, it is now possible to study chemical structures and photophysical properties of these transition metal binary compounds in gas phase.



Using a time-of-flight mass spectrometer system, experiments are conducted to investigate the the following cluster production reactions:



1. Production of Elemental Clusters: C_n, Si_n

$$C_2H_4\ (g) + Ti\ (rod) + h\nu \longrightarrow C_n$$

2. Production of Binary Clusters:

* Transition Metal Carbides: Ti_nC_m, Sc_nC_m, W_nC_m

$$C_2H_2\ (g) + Ti\ (rod) + h\nu \longrightarrow Ti_nC_m$$

$$C_2H_2\ (g) + Ti\ (rod) + h\nu \longrightarrow Ti_nC_m$$

* Transition Metal Nitride: $(TiN)_n$

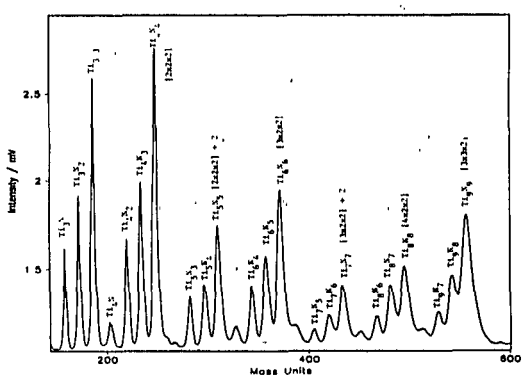
$$NH_3\ (g) + Ti\ (rod) + h\nu \longrightarrow (TiN)_n$$

* Transition Metal Silicides: V_nSi_m, Ti_nSi_m

$$SiH_4\ (g) + V\ (rod) + h\nu \longrightarrow V_nSi_m$$

* Transition Metal Oxides: Sc_2O_3, $(TiO)_n(TiO_2)_m$

$$H_2O\ (g) + Ti(rod) + h\nu \longrightarrow (TiO)_n(TiO_2)_m$$



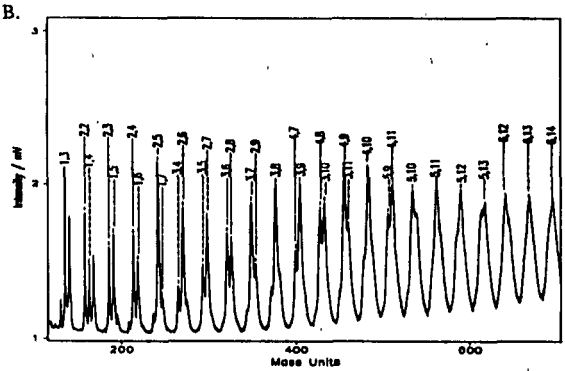


Figure 1. TOF mass spectra of (a) Ti_nC_m cluster series, marked as (m,n); (b) Sc_nC_m; (c) Ti_nN_m; (d) V_nSi_m. The spectra are obtained in a laser vaporization-metal plasma reactor into which reactants in He is flowed. Ionization of the neutral clusters is done by photoionization with a third harmonic of a YAG laser (355 nm).

1) Mass spectrometry

a) Experimental

The Time of Flight (TOF) measurement were realized with the SuperDepil Mass Spectrometer TOF23, equipped with an electrostatic mirror that allows the study of metastable ions [1]. On this mass spectrometer, the involatile species can be desorbed and ionized by three different techniques :

-Fission Fragments (MeV ions) from ^{252}Cf
-keV ions from a pulsed Cesium ion source
-U.V. light from a pulsed N_2 laser (337 nm)

In this work the single ion counting has been used for TOF measurement and the secondary ion (SI) yield of a given mass is defined by the number of detected SI divided by the number of primary ion bombarding the sample. With laser shots the yield is an apparent yield at a certain power density, because a large number of photons hit the sample.

The synthesis and chemical separation of C_{60} was made in Montpellier according to the procedure described in the reference [2]. Various types of samples were prepared : soot and extracted C_{60} powders compressed in pellets, fullerenes deposited on an aluminized mylar foil by evaporation under vacuum from soot. Thin layers of C_{60} were also made with a few drops of toluene solution deposited on Al-mylar foils.

The same target was bombarded by the three probes, negative and positive spectra were recorded.

b) Results

Similar spectra in positive and negative mode have been obtained with keV ions, ^{252}Cf and UV laser, whatever the type of target analyzed. In all case molecular ions C_{60}, C_{70} and higher fullerenes up to C_{400} are emitted and detected. An example of TOF spectrum is shown in the figure 1, it is the positive SI desorbed by laser from a pellet of soot and iron. Small differences exist. The fragments C_{54-58} and C_{62-68} ions are emitted with kev and MeV ions, but not with the laser at low power. There are however produced at higher laser power. The study of ion metastability shows that less than 1 % of positive molecular ions decays in flight. Negative molecular ions are less stable since the rate of decay varies between 50 and 80 %. Laser desorption gives a lower metastability than the impacts but the metastability of the negative fullerene ions increases with laser irradiance

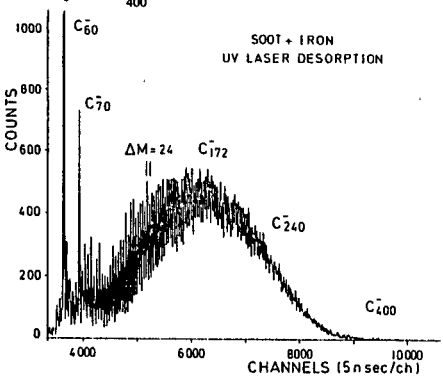

Figure 1

If we consider the ratio C_{70}/C_{60} for different enrichment, there is another difference between the three desorption probes. The ratio values obtained with the laser at the power threshold of emission correspond to the enrichment determined by others methods, like R.M.N. for example. The

ion impact (keV and MeV) produced more C_{70} ions with respect to C_{60}, the ratio is twice the maximun value obtain with UV laser desorption. The ratio C_{70}/C_{60} increases by 30 % with the laser power from the irradiance threshold to 4 times this value, then decreases when the power is enlarged. This behavior and the values of ratio C_{70}/C_{60} are similar with negative and positive secondary ions. The difference observed between ion impacts and laser shots indicates that the emission mechanisms are different and the fragmentation is related to the internal energy given by the impact of ions and the laser power.

Another difference between the three desorption probes is the SI yield. It is observed that MeV ions are more efficient than keV ions, by a factor 30 for atomic projectile and only 2.5 for cluster impact (Cs_2^+) at the same energy. In the same condition the number of desorbed molecules reached 10^5 and more per laser shot. These results are in agreement with others comparisons made with organic compound [3].

The preparation of the target plays a major role in the ionization of the desorbed species. The ratio between negative and positive ions is very sensitive to organic compounds added to the C_{60} powder. The ionization mechanisms are not understood and more investigation with various targets and organic adducts would be very useful and are in progress at the laboratory.

2) High energy (MeV) fullerene beam.

A Cs ion gun delivering a high intensity beam of Cs^+ at 20 keV was used to bombard a target of C_{60}. The target is a mixture of fullerene powder and iron compressed at 200 kg/cm^2. The sputtering of this target produces negative fullerene ions which are accelerated to 20 keV. A magnet allows to select C_{60}^- or C_{70}^-, then a preacceleration to 180 keV was used before entering the tandem accelerator. On this section, an ion bunching and deflection plates can be used to pulse the beam before the injection in the tandem.

In the accelerator, the C_{60}^- beam is first accelerated to the energy (V + 0.2) MeV, V beeing the high voltage applied on the terminal which varied from +7 to 14 MV. At the high voltage terminal there is a gas cell containing N_2 gas for stripping. With very low pressure in the gas cell we have obtained multiple ionization of C_{60}^{n+} with n = 1, 2, 3. These positive ions are then accelerated in the second section of the Tandem. The ions reache the energy of (n+1).V + 0.2 MeV, for example 20.2 MeV for V=10 MV and the charge 1+. After the Tandem, the C_{60} beam travels 10 m and goes almost straight trough a 90° magnet at the maximun field (1.5 T). The fragments are deflected by this magnet.

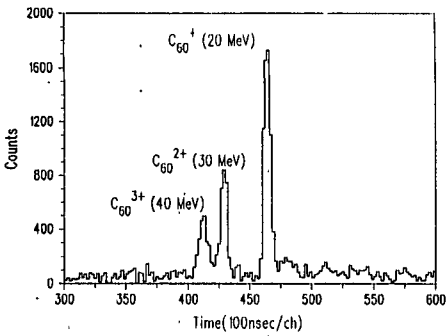

Figure 2

Behind the magnet, an ion and electron detection system was especially installed. Time of flight measurement were made between the deflection system and the detector. The TOF distance was about 50 m. Figure 2 shows a TOF spectrum with the presence of 3 peaks corresponding to $C_{60}^{1+,2+,3+}$, for an optimized pressure. An ionization and transmitted particle yield of 10^{-3} has been estimated.

The success of this experiment is due to the high stability of the C_{60} molecule and to the high yield of ionization in the gas cell. The multiple degree of ionization is very likely obtain in one collision. The MeV Fullerene Beam is now available for basic research and applications. Several experiments in the field of ion-gas and ion-solid interaction are under way.

Development of an Organic Cluster-Secondary Ion Mass Spectrometer

B. D. Cox, M. A. Park, and E. A. Schweikert
Center for Chemical Characterization and Analysis
Texas A&M University
College Station, Texas, USA

Introduction

Polyatomic ions, when used as projectiles in a secondary ion mass spectrometry (SIMS) experiment, have been shown to give enhanced secondary ion yields. This enhancement is typically defined as:

$$E = Y_n(A)/nY_0(A)$$

where $Y_n(A)$ is the yield of A type secondary ions due to cluster ion impact, n is the number of constituents in the cluster, and $Y_0(A)$ is the yield of A for the constituent atoms of the cluster. A keV energy cluster projectile would be expected to atomize near the surface. Each atom of the projectile would receive a proportional amount of energy and could then interact with the analyte surface independently. Assuming linear conditions the secondary ion yield should simply be a function of the number of atoms in the cluster. It has been shown, however, that clusters give rise to nonlinear effects. These nonlinear effects typically manifest themselves in the form of enhanced secondary ion yields (E>1). Enhanced secondary ion yields have been observed for homonuclear metal clusters (e.g., Au_2^+, Au_3^+), heteronuclear ionic clusters (e.g., $Cs_nI_{n-1}^+$), and small organic clusters (e.g., phenylalanine, coronene). The least understood of these is the interaction of the organic projectiles with the analyte surface. The difficulty in producing a continuous beam of organic projectiles has hindered the development of a model specific to organic projectile interactions. It is for this reason that we began to develop the organic cluster-SIMS spectrometer used for these experiments.

Experimental

The experimental set-up is shown schematically in figure 1. A 337 nm nitrogen laser (Laser Science, Inc.), with a ~3ns pulse width, is used to produce primary cluster ions. The laser was focused onto the sample using a 10 cm focal length fused silica lens (Oriel). Estimating a focused spot size of ~0.1 mm^2 the laser power was ~1 X 10^7 Watts/cm^2. Primary ions were accelerated into the first drift region via a potential drop of +15-30 keV between the source foil and a 90% transmission grid. Deflection plates were occasionally used to remove low mass ions from contributing to the secondary ion mass spectrum. For these experiments the target foil was biased negatively (-1 to -10 keV). Therefore, the primary ions were accelerated twice before actually striking the target. Reported primary ion kinetic energies were the sum of the potential drops in each acceleration region. Secondary ions, desorbed from the target, were accelerated into the secondary ion leg and separated according to the square root of their mass-to-charge ratio (m/q). Their arrival times were detected by a MCP detector in a chevron array.

An external trigger was used to pulse both the laser and the constant fraction discriminator (CFD). The latter pulse was converted to a NIM logic signal by the CFD and then used to start the time-to-digital converter (TDC). Electrons produced at the target foil were used to mark the stop of the primary ion TOF as well as the start for the secondary ion TOF. A software package developed in house by Park et. al. was used to collect and analyze the data.

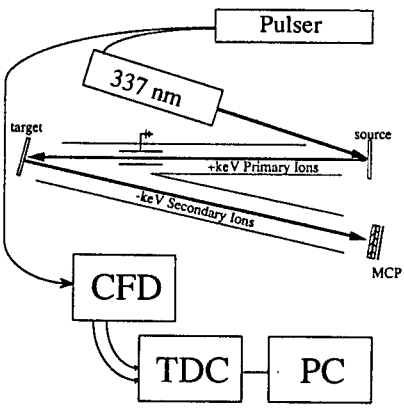

Figure 1: Cluster-SIMS set-up

Results and Discussion

Figure 2 shows the results of an analysis of the purified C_{60}. For this experiment the target shown in fig. 1 has been replaced by a MCP detector. We typically refer to this as a primary ion TOF spectrum. This spectrum was collected at near threshold irradiance, and shows abundant peaks at m/q = 720, 360, 120, and 72. Possible compositions for each of the peaks are displayed on the spectrum. As we increased the laser power we noticed an increase in the number of fragment ion peaks, as well as an increase in the intensity of the previously mentioned peaks; with the exception of m/q=360.

Using deflection plates to remove low mass contributions we were able to collect a primary ion mass spectrum of soot. This spectrum shows an intense peak for both stable fullerene molecules, C_{60}^+ and C_{70}^+. The ratio of their respective peak intensities was close to that reported by Hertel et. al. With the deflection plates turned off and the laser intensity *reduced* we were able once again to see an intense peak at m/q=360. Note from this spectrum the drastic reduction in the singly charged fullerene molecules.

In an attempt to verify the direct laser oxidation of C_{60}^+ to form C_{60}^{++}, we replaced the MCP detector with a CsI target foil. Once again we were able to detect the presence of the m/q=360 peak by monitoring the electrons detected at the end of TOF-2. The next step was to collect secondary ion spectra for both the singly charged and doubly charged C_{60}. This was accomplished by setting a coincidence window on the primary ion electron peak. The resulting coincidence spectrum was made up of only those secondary ions desorbed by the primary ion of interest. A typical coincidence spectrum is displayed in figure 5. This spectrum resulted from the impact of C_{60}^{++} onto the CsI target. The total potential drop across both acceleration regions (Experimental) was +17 keV. As it turned out this spectrum was remarkably similar to the +34 keV C_{60}^+ induced secondary ion mass spectrum. A more quantitative assessment showed the secondary ion yield of C_{60}^{++} at 17 keV and C_{60}^+ at 34 keV to be equivalent.

Fullerene Distributions determined by Laser Fourier Transform Mass Spectrometry: Laser Desorption vs. Laser Ablation

William R. Creasy and Jeffrey A. Zimmerman
IBM Corp., Dept T67, P. O. Box 8003, Endicott, NY 13760

Recent progress has been made in the solvent extractions of high mass fullerenes from graphite soot using a variety of solvents and extraction conditions [1-6]. In some cases, individual fullerenes were isolated by liquid chromatography [1,5], but in other cases the entire fullerene distributions was analyzed using SIMS [4], FAB [2], STM [6], or Laser Desorption Mass Spectrometry using a number of different laser wavelengths (LDMS or LMMS) [3,4,6]. However, it is known that laser ablation of some types of non-fullerene containing materials, such as some polymers [7,8] can produce positive-ion fullerene spectra. Therefore, it is useful to determine under what conditions the measured fullerene distribution is affected by polymerized solvent formed during the extraction or by residual high boiling-point solvents in the extract.

Laser mass spectrometry (LMMS) was done using the 266 nm radiation from the fourth harmonic output of a Nd:YAG laser and an Extrel FTMS-2000 Fourier Transform Mass Spectrometer. Solutions of the extract are dried on glass slides prior to laser desorption. Some of the solvent extractions have been described previously [4,6]. The solvents which were used for extractions include xylenes (b.p. 139°C), 1,3,5 trimethylbenzene (162°C), 1,2,4 trichlorobenzene (214°C), α,α,α trichlorotoluene (221°C), and methyl naphthalene (241°C) [4]. In addition, high temperature, high pressure extractions [6] were done using xylene, toluene, and carbon tetrachloride in close vessels or in an autoclave.

Comparisons between LMMS and SIMS mass spectra were done for some of the high boiling-point solvents [4]. Both types of positive ion spectra show that some high mass fullerenes are extracted from the soot. However, the fullerene distributions for the material extracted by 1,2,4-TCB were in poor agreement, since the LMMS spectra showed a much higher molecular weight distribution of fullerenes.

Previous studies have used negative ion LMMS spectra to detect extracted fullerenes [3,5]. Mechanistically, the high temperature negative ions which have enough energy to fragment should also detach the electron and thus not be observed. Similarly, fullerenes that grow in the gas phase during ablation are also expected to be hot and should also not attach an electron. Thus, negative ion distributions should be less susceptible to either growth or fragmentation processes. In general, fullerene negative ion distributions are not observed from polymer ablation even when positive ion fullerenes are detected, although there is at least one exceptional case in which such negative fullerene ions were observed from ablation of an aromatic polymer [8]. However, the observation of similar positive and negative ion fullerene distributions should be a reasonable criterion for concluding that high molecular weight fullerenes are present. Quantification of the distribution is difficult due to the unknown dependence of ionization or electron attachment cross sections with the molecular weight. Sensitivity is also an issue, since the positive ion mass spectra seem to be more sensitive to fullerenes than the negative spectra. Differences between the spectra suggest that other processes are occuring.

For analysis of many of the extractions, the fullerene distributions in the positive and negative ion mass spectra agree very well. For example, for the high-temperature xylene extraction, a fullerene distribution up to about 2000 amu is observed in both spectra, as shown in the figures. In the negative ion spectra, there is also a fractionation effect such that, for increasing numbers of laser pulses, the abundances of C_{60}, C_{70}, and C_{84} decrease and the higher mass fullerenes become dominant. This effect is difficult to explain unless desorption of the fullerenes is occuring. The fullerene distribution for extraction with 1,3,5 trimethylbenzene is similar, although the fullerenes are not as abundant in the spectra. The most abundant and highest mass fullerenes are observed for the methyl naphthalene extract, with a distribution up to 2500 amu. However, this solvent has the disadvantage that it is difficult to remove after the extraction due to its high boiling point.

Other extracted materials gave less clear-cut mass spectra. For α,α,α TCT, if the extract was analyzed soon after drying at room temperature, a fullerene distribution up to 3500 amu was observed in the positive ion

spectrum. However, in the negative ion spectrum, a large signal from Cl^- was observed but not fullerenes, indicating that solvent was still present. After the sample was dried for an extended period (several months), the positive ion fullerene distribution extended only to about 1600 amu, but it agreed with the negative ion distribution. This result suggested that solvent remained with the extract and contributed to the formation of higher mass fullerenes during ablation than were present on the surface.

The spectra for 1,2,4 TCB is more difficult to interpret. The positive ion fullerene distribution extended above 3000 amu, which was much higher than the comparable SIMS spectrum [4]. The negative ion spectrum did not contain fullerenes, but only some hydrocarbon ions in the mass range of 30-200 amu. The observed negative ions clearly were not related to fullerenes and were indicative of the presence of a polymer. Therefore, it is not clear whether the positive ion fullerenes are due to extracted fullerenes or to polymer ablation.

Laser ablation of raw soot showed that fullerenes were present in the positive ion mass spectrum, but not in the negative spectrum. This result suggests that the fullerene ions are formed in the ablation, although it does not necessarily mean that the soot does not also contain extractable fullerenes. It suggests that a possible method for making films of high mass fullerenes is by laser ablation of the soot, similar to the methods used for laser ablation processing of high temperature superconductors.

An extraction was also attempted using supercritical CCl_4 in an attempt to avoid polymerization of the solvent. No polymerization was observed, but LMMS analysis of the extract showed only a very weak fullerene signal. However, some of the extract was volatile, allowing an electron impact mass spectrum to be obtained. This mass spectrum showed the presence of perchlorinated aromatics such as C_6Cl_6 and $C_{10}Cl_8$. It appears that the fullerenes or the soot were attacked and degraded by the solvent to form the chlorinated products.

In summary, the mass spectra indicate that some high temperature extractions were successful in removing fullerenes from the soot. However, interpretation of the spectra must be done with caution, since factors such as the presence of solvent and polymers can affect the observed distributions. The negative ion spectra may give more reliable distributions, although they seem to be less sensitive. To determine quantitative distributions, it will be necessary to correct for dependence of ion formation and detection efficiency on the molecular weight.

DESORPTION IONIZATION/TANDEM MASS SPECTROMETRY OF FULLERENE ENDOHEDRAL COMPLEXES AND ADDUCTS

John H. Callahan, Mark M. Ross, Stephen W. McElvany
Herb Nelson, and JoAnn Milliken
Chemistry Division, Naval Research Laboratory
Washington, D.C. 20375

Since the introduction of a technique by which bulk fullerenes can be synthesized, numerous studies have been directed toward the elucidation of the properties of C_{60}, known as buckminsterfullerene. More recently, efforts have been directed toward the synthesis and characterization of derivatives of the fullerenes. These derivatives fall into two general classes: endohedral complexes are those derivatives in which elements are inserted inside the fullerene cage; other derivatives fall into the class in which the outside of the fullerene cage is chemically modified. Various groups have been directing efforts toward the synthesis of both types of derivatives, with considerable success. Our efforts have also been directed toward the synthesis of endohedral and exohedral derivatives of the fullerenes, and their characterization by thermal desorption tandem mass spectrometry.

We have been interested in two aspects of the formation of endohedral complexes. As first shown by Schwarz and coworkers[1], and later in this laboratory[2] and that of Gross coworkers[3], endohedral complexes of fullerenes can be formed by gas phase collisions with He (and other gases as well). The resulting complex, $He@C_{60}^{+}$, has been confirmed to be endohedral by a number of gas-phase techniques. Endohedral complexes can also be formed by standard fullerene synthetic techniques. Following the work of Smalley (Rice), Whetten (UCLA) and the IBM group, we have prepared La/fullerene endohedral complexes by arcing graphite rods loaded with a 20% mixture of La_2O_3 in an inert atmosphere. The products have been analyzed by thermal desorption/negative chemical ionization mass spectrometry (usually using methane as a buffer gas). The thermal desorption mass spectrum obtained from the raw soot is shown in figure 1b. The spectrum is characterized by a series of La-containing fullerenes. When the material is extracted, the mass spectrum in figure 1a is obtained. The major La-containing species are $La@C_{82}$ and $La_2@C_{80}$. When the residue from the extraction is analyzed, it is largely similar to figure 1b, with the exception that $La@C_{82}$ and $La_2@C_{80}$ are depleted. These results suggest that $La@C_{82}$ and $La_2@C_{80}$ are selectively extracted by pyridine, for reasons that remain unclear.

We have characterized the La/fullerene complexes by thermal desorption tandem mass spectrometry on both sector and triple quadrupole instruments. Relatively robust collision condition conditions are necessary to effect fragmentation of the $La@C_{82}$ complex. For example, it is possible to effect C_2 and C_4 loss only with multiple collisions with Xe at collision energies greater than 150 eV in the triple quadrupole instrument. No evidence for La loss is observed, consistent with the endohedral hypothesis. High-energy (keV) collisions with He also effect successive C_2 loss. Additionally, there is also evidence that gas-phase endohedral complex formation occurs. Figure 2 shows the MIKES spectrum obtained (on a reverse geometry BEqQ instrument) from 8 keV collisions of $La@C_{82}^{+}$ with He. The MIKES scan shows a significant "foot:", and a "satellite" peak on the low energy side of the main beam peak. When the MIKES scan is done with the quadrupole (Q) set to pass m/z 1127 ($He+La@C_{82}^{+}$), a sharp peak appears at the location corresponding to the satellite peak in the MIKES scan (inset, figure 2). This peak is shifted down in energy by the center-of-mass collision energy, as expected if an endohedral complex is formed in the gas phase. Thus, it is possible to form the gas-phase endohedral complex $HeLa@C_{82}$ from the synthetic complex.

LASER DESORPTION FTICR STUDIES OF ELECTROCHEMICALLY-MODIFIED C_{60} THIN FILMS

Z. Guan, S.-L. Yau, D. A. Laude Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX78712

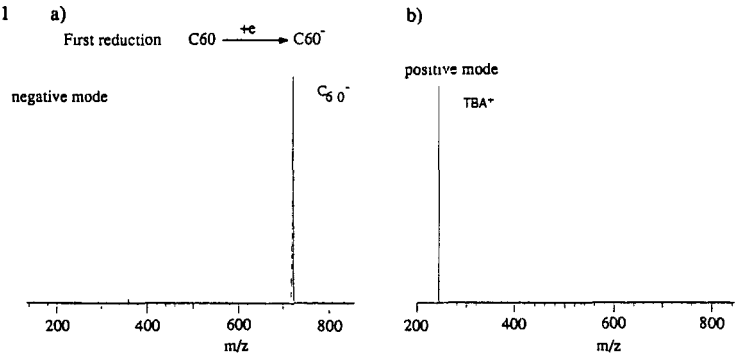
The cyclic voltammetric (CV) behavior of C_{60} thin films in MeCN differed significantly from that found for solutions of C_{60}, e.g., in benzene or CH_2Cl_2. The unusual hysteresis indicated that large structural or resistive changes occured upon reduction. It was proposed that structural rearrangements of the C_{60} film involved trapping of the electrolytic counter ion of tetra-n-butylammonium (TBA^+)[1]. However, this proposed mechanism was not confirmed. In this study, laser desorption mass spectrometry (LDMS) is used to characterize the change of the C_{60} film on the electrode surface after electrochemical redox processes.

The experiment is performed by using a gold-plated laser desorption probe as the working electrode in electrochemical reactions. Thin films are solvent casted and modified as desired by different potential steps and cycles in the electrochemical cell. The electrode is then rinsed with dry MeCN, and sealed in a vial with parafilm inside the drybox. The probe is removed from the drybox and transferred into the vacuum chamber via a glovebag purged with Ar to prevent contact with the air and possible reactions with water vapor and oxygen. Species on the electrode are desorbed and ionized under plasma ignition conditions and then trapped and detected by FTICR.

Electrochemistry was carried out in MeCN containing 0.1 M $(TBA)PF_6$ as the supporting electrolyte in single compartment cells with a Pt counter electrode and a Ag wire quasi-reference electrode (Ag QRE). Solutions were prepared in a drybox under a He atmosphere and added to the electrochemical cell. The LDFTICR experiments were performed on a spectrometer assembled with components that constitute the Extrel FTMS-2000 including a 3.0 Tesla superconducting magnet and differential pumped dual cubic ion cell. A Spectra Physics DCR-2 Nd:YAG laser operated at 1064 nm in the Q-switch mode with a 8-ns pulsed width was used for laser desorption. Laser light was transmited through a fiber optic which terminated about 0.5 mm from the sample surface. A 1-mm^2 area of the electrode was subjected to a laser irradition of up to $3x10^8$ W/cm^2.

When a probe coated with C_{60} film in MeCN was immersed in MeCN containing 0.1 M $(TBA)PF_6$ for 1 h and then rinsed thoroughly with dry MeCN and transferred to the mass spectrometer, the spectra show only the presence of C_{60}^- (negative mode) and C_{60}^+ (positive mode) (m/z=720). If the same experiment was carried out without rinsing with fresh MeCN, the positive ion spectrum also showed the presence of TBA^+ (m/z=242) while the negative ion spectrum showed PF_6^- (m/z=145) because of carryover of some electrolyte with the C_{60} film. The laser desorption mass spectra of the film upon complete reduction to C_{60}^- at -0.75 V vs Ag QRE for about 50 min followed by rinsing with MeCN is shown in Fig.1a. This positive ion

Fig. 1



spectrum shows TBA^+ as the only positive ion present, suggesting that C_{60}^- will not ionize during the laser pulse to form a cation. The negative ion spectrum (Fig.1b) obtained by applying the laser pulse to different spots on the probe is similar to that of neutral C_{60} and shows only the C_{60}^- structure, as proposed from the electrochemical studies.

In another study, a fresh C_{60} film was fully reduced, and then completely reoxidized. Depth profiling LD/FTICR results in both positive (Fig. 2a-d) and negative (Fig. 3a-d) ion mode were obtained. The first laser firing exhibited only C_{60} ions but subsequent firings suggested the presence of trapped ions in the C_{60} matix. For example, Fig. 2b,c show both C_{60}^+ and TBA^+ while Fig. 3b,c show small amounts of PF_6^- in addition to C_{60}^-. The presence of Au^+ and Au^- by the fourth laser firings indicates that the first three pulsed removed essentially all of the C_{60} film from the site of laser ablation.

LDFTICR experiments also were performed on C_{60} films which were reduced to the second reduction state. However, mass spectra exhibit abundant ions at m/z 720 in negative ion mode but the absence of C_{60}^{2-} ions at m/z 360. This is attributed to the instability of C_{60}^{2-}. One interesting feature of the second reduction spectra is the presence of an ion at m/z 736. Although this could be attributed to $C_{60}O$ (M.W. 735.9945), FTICR accurate mass measurement of the ion (M.W. 736.0336) suggests $C_{60}CH_4$ (M.W. 736.0318) as the more likely molecular formula.

Information about the extent of doping and dissolution of the films was obtained by quartz crystal microbalance studies, which measure the change of mass by monitoring shifts in the frequency of the film/Au/quartz crystal during a potential scan or step. Consistent with LDFTICR results, no frequency changes are seen on the anodic sweep during reoxidation step. This suggests that TBA^+ remains in the lattice after the reoxidation of the reduced forms to C_{60}, and indicates a new type of "ionic charge trapping" in C_{60} films. This trapping phenomenon perhaps accounts for the large splitting seen in the CV waves of C_{60} films.

CHEMICAL COMMUNICATION BETWEEN CELLS TRYING TO OVERCOME A VIRAL INFECTION: DECIPHERING THE CODED MESSAGES BY TANDEM MASS SPECTROMETRY

Donald F. Hunt, Hanspeter Michel, Jeffrey Shabanowitz, Andrea Cox, Terri Davis, Wanda Bodnar, and Tracey Dickinson

Department of Chemistry, University of Virginia, Charlottesville, Virginia 22901

Cytotoxic T lymphocytes (CTL) are an arm of the immune system concerned with recognition of host cells that express new antigens as a result of viral infection or transformation. CTL do not recognize new antigens directly, but only as short peptides bound to cell surface class I molecules of the major histocompatability complex (MHC). It is thought that newly synthesized viral proteins are degraded into peptides in the cytoplasm, transported to a subcellular compartment, the endoplasmic reticulum, where they bind to class I molecules, and are subsequently expressed on the cell surface. The identification of mutants defective in a presumptive peptide transporter involved in this process has indicated that peptides derived from normal cellular proteins are also processed in the same way in uninfected cells and are important for the correct folding and cell surface expression of most class I MHC molecules. The crystal structures of three class I molecules have revealed a deep cleft containing unexpected electron density that has recently been shown to represent one or more bound peptides.

In the present work we have employed the combination of microcapillary HPLC and electrospray ionization tandem mass spectrometry to sequence peptides presented by the class I molecule, HLA-A2.1 (1). To date, complete sequences for eight of the peptides and partial sequences on eleven others, have been obtained. Each of the completely sequenced peptides is a nonamer. This strong constraint on the length of peptides bound to the A2.1 molecule is consistent with the length restriction found in peptides bound to other class I molecules. In addition, all of the completely sequenced peptides contain Leu/Ile at position 2. In HLA-A2.1, the B pocket of the protein is composed of several hydrophobic residues and is capable of accomodating a Leu or Ile side chain. In addition, the electron density corresponding to bound peptide is comparable to that found in HLA-B27 and shows a strong projection into the B pocket. The similarity of these features leads us to suggest that the interaction of a conserved Leu or Ile residue at position 2 with the B pocket is a primary determinant of peptide binding to HLA-A2.1.

To identify possible precursor proteins for the processed antigen sequences, the PIR data base was searched in a manner that allowed X residues to be assigned as either Leu or Ile. Only 3 peptides gave 100% matches with proteins in the library. The sequence SLLPAIVEL occurs in the 65 kDa α- and β-regulatory subunits of human protein phosphatase 2A and also in the human transformation associated protein, p61. The latter protein is complexed in vivo with polyoma middle T-antigen and exhibits only 2 amino acid differences with the α-regulatory subunit of the phosphatase 2A. Both protein phosphatase 2A and p61 are found in the cell cytoplasm and p61 is estimated to represent 0.01-0.02% of the total cellular protein. The sequence, YLLPAIVHI, appears in a human protein known as p68. This molecule is associated with the nuclear membrane, and has been shown to exhibit both RNA dependent ATPase activity and RNA unwinding activity . Finally, the sequence, TLWVDPYEV is found in TIS21, a protein of unknown function that is a member of the primary response group of genes induced by growth factors. While a direct precursor-product relationship between these proteins and the isolated peptides can only be inferred, the presence of these proteins in human cells provides additional strong suggestive evidence for the processing and presentation of internal cell proteins by class I MHC molecules.

In order to demonstrate that the peptides identified actually bound to HLA-A2.1, the eight completely sequenced peptides were synthesized and tested in a competitive binding assay. In cases where no complete match was found, a mixture of Leu and Ile was incorporated at positions specified by X. The HLA-A2.1 expressing cell line JY was incubated with the $M1_{57-68}$ peptide of influenza A virus, in the absence or presence of a 8-10 fold molar excess of one of the competitor peptides, and then assayed for their ability to be lysed by M1 peptide specific, HLA-A2.1 restricted CTL clones. All eight peptides strongly inhibited recognition under these circumstances but had no effect on recognition by a human alloreactive cell line that is specific for HLA-A2.1. A similar

lack of inhibition was also seen with two murine xenoreactive cell lines specific for A2.1. These results establish that all of these synthetic peptides in fact bind to HLA-A2.1.

All of the above structural data were recorded on extracts of 10^8 cells containing 20 and 50 pmol of HLA-A2.1 from C1R-A2.1 and JY cells, respectively. If all HLA-A2.1 molecules contain bound peptide, the total peptide yield should also be 20 or 50 pmol. By this measure, the yields of the major peptide species, 100-500 fmol, suggest that these individual peptides represent between 0.08% and 1.2% of the total peptide bound. Depending on the cell and the peptide, this would correspond to as few as 100 complexes per cell or as many as 3,000. Although these numbers may be underestimates if there has been peptide loss during purification, they are in accord with those obtained for viral peptides and with the number of peptide/class II MHC complexes required to stimulate T cells. The number of different peptides presented by HLA-A2.1 molecules from a particular cell line can also be estimated from mass spectrometer data. The yield of the 60 peptides detected in either cell extract amounts to about 10% of the amount expected. If the remaining processed antigens go undetected because they are all present at similar levels near that of the background, 30 fmol, the total number of different peptides presented by HLA-A2.1 could be as high as 1,500.

In addition to the above work, we have also characterized the peptides presented by the HLA A2.1 molecule on the surface of mutant cells having a processing defect that prevents transport of proteolytic fragments out of the cytoplasm and into the endoplasmic reticulum (2). In this case only seven dominant peptides were found in association with the class I molecule. These peptides were usually larger than nine residues and were found in association with the HLA A2.1 molecule in normal cells as well. These peptides were derived from signal peptide domains of normal cellular proteins. This result suggests that proteolysis of signal peptide domains in the endoplasmic reticulum is a second mechanism for processing and presentation of peptides for association with class I molecules

Presentation of antigens to the immune system by class II molecules involves a different process than that described above. Exogeneous proteins enter the cell by phagocytosis, endocytosis, or internalization of the cell membrane and are processed in acidic endosomal compartments and become associated with MHC class II molecules. We have also studied class II antigens by microcapillary HPLC electrospray ionization tandem mass spectrometry and find that 650 to 2,000 different peptides are associated the murine class II molecule, I-A^d (3). Sequences for nine of these have been obtained. All of the peptides were derived from secretory or integral membrane proteins that are synthesized by the antigen presenting cell itself. Peptides were 16 to 18 residues long, had ragged NH_2- and COOH- termini, and contained a six residue binding motif that was variably placed within the peptide chain. Binding data on truncated peptides suggest that the peptide groove on class II molecules can be open at both ends.

Use of microcapillary HPLC in combination with electrospray ionization on a triple quadrupole mass spectrometer has provided direct estimates on the number and size of the peptides presented by class I MHC molecules and has generated complete sequence information on eight processed antigens present in sample mixtures at the subpicomole level. This same approach is expected to facilitate direct identification of peptides produced upon viral infection or cellular transformation that are potential targets for T cell recognition. The relatively small number of cells required for analysis by tandem mass spectrometry should also make possible the accumulation of data from tissue samples as well as cells in culture, perhaps leading to the identification of tissue specific autoantigens. The use of tandem mass spectrometry for antigen sequence analysis promises to greatly enhance our knowledge of peptide/MHC interactions.

Modern Immunology; The Challenge of Carbohydrate Structure: Characterization by ESI-MS and Collision Induced Dissociation.

Vernon N. Reinhold, Bruce B. Reinhold, S.H. Stephen Chan. Harvard University School of Public Health, Boston, MA 02115

The body defends itself against a host of infectious agents, viral, fugal, bacterial, and parasitic by a vast and complex system defined as the immune response. With an elaborate integration of processes that span the consequences of microbial invasion to the elimination and control of disease, this fundamental response represents a paragon of molecular biology with an astounding interplay of structural specificity at remarkable sensitivity. An understanding of the immune system at the molecular level is just starting to be unraveled. Presently, the analytical focus is on protein structure, in large part, a consequence of the modern analytical instrumentation available to determine protein and nucleic acid structure. Glycosylated molecules have long been integral components of cellular immunity, from the classical studies of blood typing to the cellular response to endotoxins. However, the role of protein and lipid glycosylation in most situations remains largely explored. Whether they serve as modulators of protein structure, receptors, signal transducing agents, or simply protective decoys against proteolytic destruction, the structure-function relationships will certainly intertwine. Supported by studies using a combination of site-directed mutageneicity, carbohydrase inhibitors, and enzymatic deglycosylation, it is now apparent that glycoproteins of different glycotype and glycoform, (altering linkage, and branching patterns), exhibit unique and functional activities. These results strongly suggest that glycosylation needs to be pursued with greater structural specificity and an equal measure of sensitivity.

In an effort to address this challenge, we have combined chemical pre-treatment to increase sensitivity and impart greater molecular specificity. Two structural entities are available for modification, the hemi-acetal reducing end and, as a consequence of differing linkage and branching, the pattern of cis-glycol groups. Sensitivity has been captured with pentafluorobenzyl derivatization coupled with supercritical fluid chromatography-negative ion chemical ionization MS. Molecular specificity has been greatly enhanced by periodate oxidation. For complex glycans supercritical carbon dioxide is of insufficient polarity to solubilize these analytes at the pressures currently available. These materials are directly analyzed by ESI-MS following periodate oxidized, reduction, and permethylation. The products exhibit comparable sensitivity with SFC-NCI-MS and appears to be more generally applicable. This direct approach is drawn for a biantennary glycan (top, next page). At the bottom of the adjacent page is presented the ESI-MS of a high mannose glycotype, using this derivatization strategy.

Networking of Diverse GC/MS Data Systems for Electronic File Transfer of Custom Formatted Raw Data File Sets

*C. D'Arienzo, P. J. Gale and A. I. Cohen,
Bristol-Myers Squibb Pharmaceutical Research Institute
New Brunswick, New Jersey 08903

Utilizing negative chemical ionization GC/MS methods developed and validated in our laboratory, we perform quantitative analysis on tens of thousands of clinical and preclinical study samples each year. The vast amount of data acquired on a number of HP based computer operating systems including Pascal, RTE-A and HP-UX (Unix) must be transferred in extraction/instrument run sets to a remote IBM mainframe computer for statistical, toxicological and pharmacokinetic evaluation.

Our GC/MS software automatically produces a separate integration file in binary format that contains peak areas for each sample in a run. Through custom programming, the peak areas from each discrete binary file are extracted and formatted into one large ASCII file which then contains all the data required for quantitation of the run set. These run sets are qualified according to SOP-defined-criteria by downloading the ASCII file to a Macintosh and manipulating the data in Microsoft Excel. Appropriate networking hardware such as coaxial cabling and networking boards were installed on each of the computers containing the GC/MS operating systems as well as on the lab's two Mac IIci's. Additionally, software for each system was installed to provide terminal emulation and TCP/IP (transmission control protocol/internet protocol), a *de facto* standard that provides both binary and ASCII file transfer as well as remote login. These additions formed a local area network (LAN) that connected the five mass spectrometers within the lab to permit facile transfer of the formatted ASCII raw data files among systems (Figure 1).

A bridge provided the hardware interface required to connect the GC/MS operating systems to the DEC VAX/VMS machines which are on the company's wide area network (WAN). A bridge, rather than direct cabling to connect each instrument's operating system to the WAN, was utilized to shield us from slowdowns that can result from heavy network "traffic". The two Mac IIci's were directly connected to the WAN. TCP/IP loaded onto the VAX/VMS systems provided the necessary file transfer services. Once on the WAN, we have access to the remote IBM mainframe via a data line and TCP/IP services (Figure 1).

In summary, a formatted ASCII file is generated on the GC/MS operating system, electronically transferred to the Macintosh through the LAN, qualified using Microsoft Excel, then transferred to the remote IBM mainframe through the WAN for final storage and processing. *There is no manual data entry at any point* (Figure 2).

Automatic detection of GC/MS chromatographic peaks along with the mass spectra of the corresponding components is a problem of obvious interest, which has been approached by the method of 'reconstructed spectra' (1).

When the mass spectra have to be recorded in the full mass range with a good sensitivity, the high performances of capillary columns result in low sampling of each chromatographic peak. Classical methods of data analysis (based on peak shape) and noise elimination (smoothing) are thus not possible; only threshold methods remain allowed.

The reconstruction method presented here, based on self-adjusting threshold determinations, allows detection of chromatographic peaks sampled by one or two spectra only among important noise.

The program includes the following steps : (i) for each mass, construction of a schematized mass chromatogram reduced to its significant maxima; (ii) summing of all the schematized mass chromatograms and constructions of schematized total ion chromatogram; (iii) construction of "cleaned" mass spectra corresponding to each chromatographic peak detected; (iv) elimination of the remaining unsignificant peaks by iterative correction of the schematized chromatograms : use of new thresholds based on the height of uncertain peaks which do not correspond to a detected chromatographic peak.

As an example, step (i) proceeds as follows :

1 - Detection of all local maxima and corresponding peak heights.

2 - Noise evaluation : when ion intensity is not zero, more than half of the n peaks are due to noise. The average height of the n/2 smallest peaks gives an (under)estimate of noise.

3 - Selection of the significant peaks :

- the peak must correspond to a non-zero intensity for at least two consecutive points
- the peak height must be larger than a threshold depending on noise, background intensity, total ion intensity. If the peak height is much larger than the threshold, the peak is labeled as certain and cannot be eliminated during correction procedure of step (iv).

The program was tested on Chrompack GC column test mixture, using two sets of conditions :

1 - Very large variation of total ion current : Usual dilution of the sample in CH_2Cl_2, EI ionization. The whole data set was analyzed including solvent zone.

2 - Very low signal/noise ratio : High dilution in CH_2Cl_2, CI ionization using CH_4. Data were acquired in the mass range 50-400, resulting in important CI background at low masses.

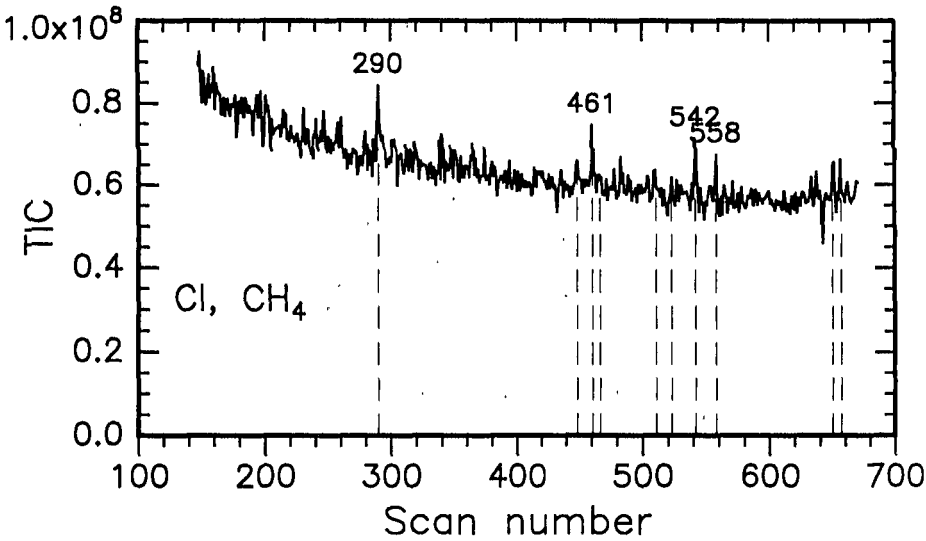
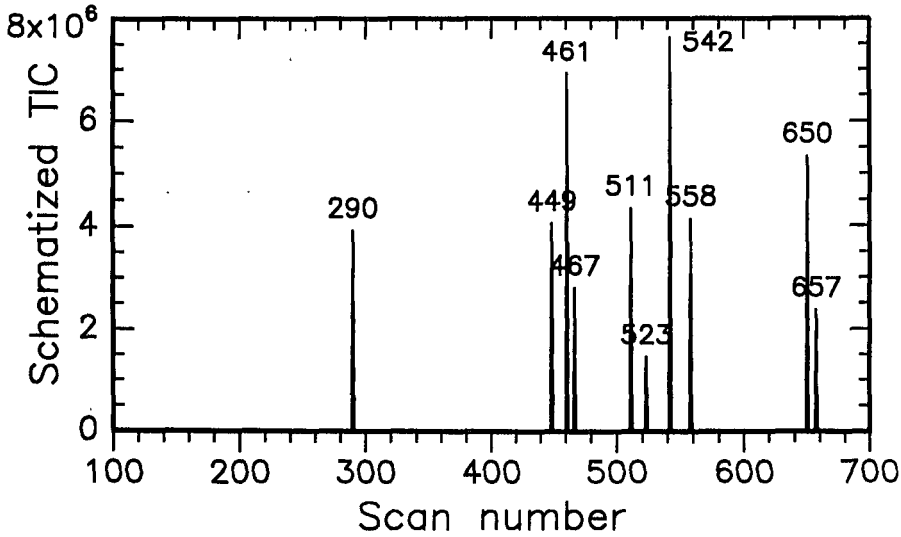
The raw and schematized total ion chromatograms under conditions 2 are given below. Each detected peak corresponded to the spectrum of a real compound.





Robust Fitting Techniques Applied to FT/MS Calibration

Sanford Shew, EXTREL FTMS, Inc., 6416 Schroeder Road, Madison, WI 53719

In Fourier Transform Mass Spectrometry (FT/MS®), calibration serves to establish a relationship between observed frequency ν and mass-to-charge ratio m/z. Typically, the relationship is given by Equation 1:

$$m/z = \frac{A}{\nu} + \frac{B}{\nu^2} \tag{1}$$

where A and B are the parameters to be fit [1]. Often, fewer than ten data points are used in the fitting procedure.

If the data set includes a slightly erroneous point, linear least squares (LLS) fitting, the most commonly used parameter estimation technique, will skew an otherwise excellent fit and result in less than desired mass accuracy. Robust fitting techniques are designed to recognize the presence of these outlying points and allow the fit not to be unduly influenced. In this study, five parameter estimation techniques, linear least squares, Kalman filtering [2], minimization of absolute deviations [3], adaptive Kalman filtering [4], and iteratively reweighted least squares (IRLS) [5], are examined for their ability to reject an outlier in a test data set. Also, Monte Carlo simulation is used to estimate the errors on the fitted parameters.

The test data set was produced from a perfluorotributylamine spectrum; one frequency in the peak list was manually changed by about 0.004% to simulate an outlier. Figure 1 reports fitted parameters for A and B from Equation 1, including error estimates, for LLS fitting. Figure 2 shows a plot of the residuals as a function of $1/\nu$.

parameter	estimate	error estimate
A	4.670789×10^7	4.9×10^3
B	-3.207221×10^9	5.4×10^8

RMS of residuals: 14.637 ppm

Figure 1. Results from linear least squares fit with test calibration set.

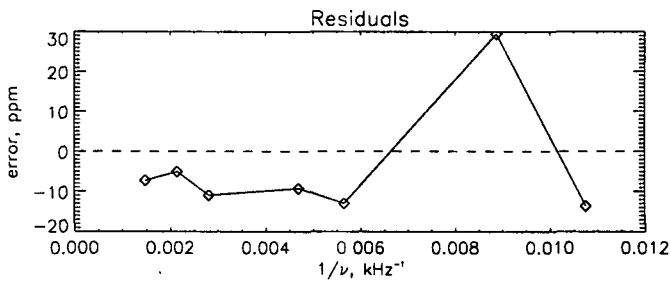


Figure 2. Residuals plot for linear least squares fit with test calibration set.

Figures 3 and 4 show analogous information for the results from IRLS fitting.

parameter	estimate	error estimate
A	4.670819×10^7	2.3×10^3
B	-3.171957×10^9	4.0×10^8

RMS of residuals: 16.142 ppm

Figure 3. Results from iteratively reweighted least squares fit with test calibration set.

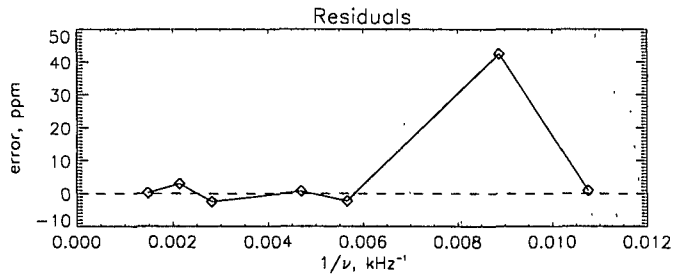

Figure 4. Residuals plot for iteratively reweighted least squares fit with test calibration set.

Comparison of Figures 2 and 4 indicates that while inclusion of the outlier point in LLS fitting leads to relatively large residuals for all calibration points, the influence of the outlier is minimized by IRLS fitting. Although the RMS of the residuals for IRLS fitting is larger than that for LLS fitting, the fit produced by IRLS fitting is better, as judged by the magnitudes of the individual residuals of the points excluding the outlier. With this and similar test data sets, Kalman filtering behaved much like LLS fitting, while adaptive Kalman filtering and minimization of absolute deviations exhibited robustness similar to IRLS.

The errors estimated by Monte Carlo simulation for each parameter were similar among the various fitting techniques. *A* apparently is estimated with much higher precision than is *B*.

A Graphic Interface for a Factor Analysis System with Mass Spectrometry Applications

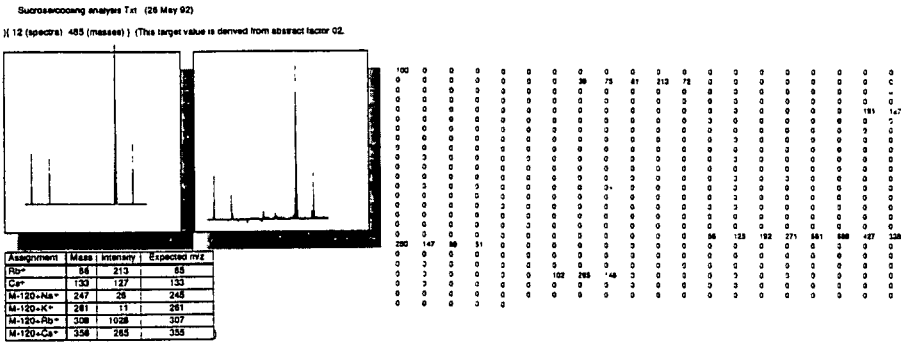
Aubrey McIntosh and Jennifer Brodbelt, Department of Chemistry
University of Texas at Austin, Austin, Texas 78712

Factor analysis is a powerful tool for use in mass spectrometry. It provides mechanisms to identify the number of varying components in a data set, reconstruct the spectra of the 'pure' component, and quantify those component levels. We have chosen to investigate the utility of factor analysis in investigating ion-molecule reactions, as a method to enhance the utility of initial experiments with newly developed ionization sources, and as a method to aid the systematic study of ion-trip operation.

The paradigm of chromatographic factor analysis is useful when working with any series of systematically varied underlying variables. Traditional factor analysis applications to chromatography become intuitively applicable to more basic investigations. Some traditional applications include sophisticated background correction and peak resolution in GC/MS, specifically to fully resolve, quantify, and spectrally characterize peaks. Factor analysis methods are useful as an adjunct to difficult chromatographic separations. Through the chromatographic paradigm extension, research, method development efforts, and routine analysis in laser desorption or other fundamental techniques are potential beneficiaries for efficient and easy factor analysis tools.

Novel mass spectrometry applications include analysis of factors relevant to ion-molecule reactions in the quadruple ion trap. Investigations of pressure, reaction time, collision energy, enantiomeric discrimination and other effects can result in sets of peaks (chromatograms) containing similar spectra, as well as low intensity peaks. For example, spectra of sucrose laser desorbed with alkali halide salts show changing detail in the spectra as the reaction time is varied. Factor analysis of this data reveals ion-current vs reaction time profiles of selected ions, and allows digital removal of the noise from the spectra.

The reported graphic interface tailored to mass spectrometry enhances the utility of factor analysis. The results of factor analysis are expressed quite naturally as a component ion current, and a component spectra. Decisions are often made by the chemist based on interpretations of these graphics. We have developed a tool that presents the factor analysis information graphically, and allows the chemist to manipulate the graphs with a mouse. The graphs may be copied directly into documents or user as input to additional principle component analysis or other computer processing. The direct visualization of the target factors, as well as the ability to edit them and iterate through the target factor evaluation phase results in rapid development of target factors.



COMPUTER-AIDED SEQUENCE DETERMINATION OF PEPTIDES: A COMPARATIVE STUDY OF STRUCTURAL INFORMATION OBTAINED FROM LSIMS AND ELECTROSPRAY MASS SPECTRA*

M. J. Bertrand, D. Faubert, P. Thibault and D. Zidarov
Regional Center for Mass Spectrometry, Department of Chemistry
University of Montreal, Montreal, Canada, H3C 3J7

Since the introduction of desorption-ionization techniques, mass spectrometry is rapidly becoming an important tool in protein chemistry. Its unique capabilities not only permit the determination of molecular weights well above 200 kDa, but also primary structure information of small peptides can be deduced from tandem mass spectrometry (MS/MS). Based on the fragmentation patterns of peptides, sequence assigment can be deduced from the observed ions in the MS/MS spectra using typically less than 1 nanomole of sample. Without prior knowledge of amino acid composition or partial sequence strings, however, the assigment can be subjective and progressively difficult beyond 8 residues or so. In order to facilitate the sequencing process several computer programs have been developed for the computer-assisted interpretation of the mass spectra. Our recent interest in the characterization of proteins by enzymatic cleavage with LC/MS/MS analysis of the residual peptides has lead us to extend our peptide sequencing package "PEPTIDE" to include the use of nominal masses by the addition of the algorithm "Quick-Pep" which is designed to process MS or MS/MS data acquired on quadrupole or sector instruments and generated by commonly used ionization techniques. Another goal of the program was the optimization of the speed of execution so that it would allow almost "on-line" sequencing during LC-MS/MS analysis. Since Quick-Pep is able to analyze data obtained from several mass spectral approaches, the primary objective of this study was to examine the comparative limits of identification of peptides that can be achieved by the program for different mass spectral techniques. The techniques that were chosen for the comparaison are LSIMS/MS, LSIMS-MS/MS and ES-MS/MS. A secondary objective of the study was to identify the important factors that affect the limit of identification in each of the technique.

The initial experiments involved the use of conventional mass spectra generated by LSISM-MS. Several peptides, ranging in molecular weight from 555 to 1602, were studied and the spectra were systematically analyzed by Quick-Pep. Since conventional spectra are heavily contaminated by matrix interferences it was essential to remove the background from the spectra before identification could be achieved. In most cases it was impossible to correctly identify the compounds without filtering the spectra. Removal of background using a constant threshold was inefficient because higher thresholds resulted in the elimination of sequence peaks while lower thresholds resulted in the presence of to many background peaks However, when an efficient background treatment routine was used the identification, which took tens of seconds, was almost always correct for most peptides below mass 1600 and the limits of identification were the lowest Identification limits for typical peptides analyzed by LSIMS-MS are given below.

Bradykinin	(MW 1059)	1888 picomoles
Eledoisin	(MW 706)	2832 picomoles
Octapeptide	(MW 921)	3257 picomoles

In the conventional LSIMS-MS spectra the limits of identification are generally in the nanomole range and the spectra have to be treated for background in order for identification to be achieved. Factors that affect the limit of identification in LSIMS-MS are mainly the elevated background and the reduced fragmentation observed at higher masses. For peptides above m/z 1600, the sequence ions are either absent or lost in the background.

The second set of experiments involved LSIMS-MS/MS spectra acquired in the MCA mode. The spectra of the $(M+H)^+$ ions were obtained on an hybrid spectrometer using the RF only collision cell pressurrized with argon. The use of these experimental conditions was necessary in order to be able to compare the results obtained with those of a triple quadrupole on which electrospray MS/MS experiments have been conducted. The masses of the peptides were maintained relatively low in order to avoid discrimination by the quadrupole. The results obtained in LSIMS-MS/MS indicate that the peptides can be correctly identified after treatment of the raw spectra for background and identification limits for typical peptides are provided below

Eledoisin	(MW 706)	71 picomoles
Octapeptide	(MW 921)	108 picomoles

Typical results obtained by Quick-Pep for LSIMS/MS/MS analysis reveal that the algorithm is, most of the time, able to correctly identify the peptides analyzed after filtering of the raw MS/MS

data and that limits of identification are in the range of 50-100 picomoles. Factors affecting the limit of identification in LSIMS-MS/MS are mainly ion transmission and the fragmentation properties of the peptides which depend on mass and structure.

Identification limits were also measured using CA spectra of $(M+2H)^{+2}$ ions generated by electrospray ionization. Figure 1 shows the ES/MS/MS spectra of bradykinin obtained with 15 and 1.5 picomoles The 15 pmole spectrum was correctly identified by Quick-Pep Interestingly, the $(M+2H)^{+2}$ spectrum of some peptides lack some sequence ions because of the presence of a very basic residue in the structures. Quick-Pep has built-in provisions to deal with these special situation cases, as shown in Figure 2b, and the program will complete the most probable subsequences found by providing the amino acid complement. In ES-MS/MS the identification limits vary for typical peptides in the picomole range as indicated below

Bradykinin	(MW 1059)	1.5 picomoles
Renin inhibitor	(MW 1317)	100 picomoles
angiotensin I	(MW 1295)	150 picomoles

The results obtained in ES-MS/MS indicate that the limits of identification are usually in the picomole range and that the spectra are generally dominated by a, b and y-type ragments The factors that affect the limit of identification are ion transmission and the fragmentation properties of the peptides Sequence ions can be missing because of the presence of basic residues and identification can be difficult because of the presence of doubly charged fragments in the spectrum as shown for substance-P in Figure 2a.

Structural Elucidation of Branched Oligosaccharides: MS/MS of Divalent Metal-Ion Coordinated Oligomers

*Zhongrui Zhou and Julie Leary, University of California, Berkeley, CA 94720

Our previous research has demonstrated that MS/MS of lithium coordinated oligosaccharides can be used to determine the linkage position in linear glucose polymers. The work described herein is the next step in this identification process which involves coordinating more suitable metal ions to branched oligomers. Precursor and product ion MS/MS experiments were conducted on the $^{26}Mg^{++}$, $^{44}Ca^{++}$, and Co^{++} coordinated branched isomers, 3-fucosyllactose and B-trisaccharide, but only $^{26}Mg^{++}$ data is discussed in this presentation.

Figure 1 is the MS/MS spectrum of $^{26}MgCl^{+}$ coordinated to 3-fucosyllactose and B-trisaccharide. Both show losses of HCl and fucose which gives rise to the ion at m/z 367. From this ion, which now represents the linear 1,3 or 1,4 dissacharide, the typical C_2, C_3, and C_4 losses are observed [1,2]. The fragmentation patterns are similar to that of lithium coordinated disaccharides with 1,4 and 1,3 linkage, respectively. Additionally, ring cleavage on the non-reducing fucose ring (m/z 439) is observed only for B-trisaccharide and we believe this to be specific for the 1,2 cleavage at the branch point. The mechanism of this cleavage is currently under investigation.

To help explain the fragmentation behavior of these branched trisaccharides, we have conducted PM3 semiempirical calculations to determine the most stable conformation of these branched isomers. The most stable structure for the 3-fucosyllactose isomer is shown below. In this case $^{26}Mg^{++}$ is coordinated to the nonreducing galactose ring through one ionic bond, and two weak bonds. This allows for ring opening of the reducing ring with subsequent retro-aldol reactions and loss of the specific C_2, C_3, and C_4 neutrals.

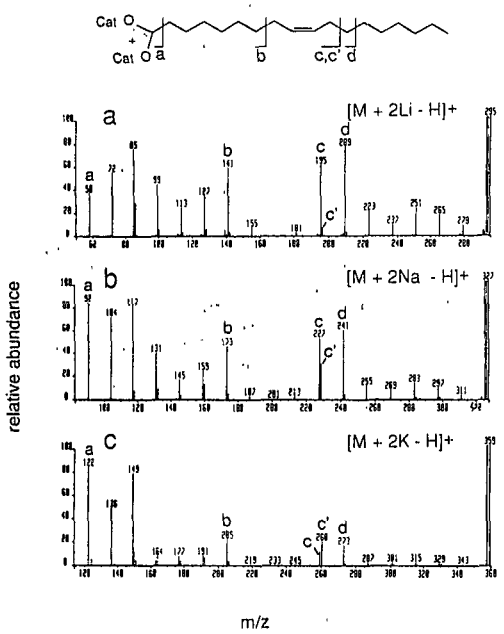
IMPLICATIONS OF THE CHARGE SITE IN FORMATION OF "CHARGE - REMOTE" RADICAL CATIONS

Miquel Antoine and Jeanette Adams: Department of Chemistry, Emory University, Atlanta, GA 30322

Fragmentations produced by fast atom bombardment (FAB) followed by collision-induced decomposition (CID) of unsaturated fatty acids, esters, and alcohols cationized with alkali metals were studied. The CID mass spectra, obtained by first field-free region linked scans at a constant ratio of B/E, illustrate a series of closed-shell charge-remote product ions and an open-shell radical cation that results from allylic cleavage distal to the charge site (Figure 1).

Figure 1



Comparing Figure 1a to 1b and 1c shows that the relative abundance of the allylic radical cation c' increases, whereas the abundance of the adjacent closed-shell product ion c decreases, with increasing size of alkali metal ion. The data are summarized in Table 1. To further investigate the chemistry, effects of collision gas pressure on formation of the c' and c ions were studied: These data are in Table 2.

Table 1.Relative abundances of product ions from Figure 1.

product ion	% of main beam		
	Li^+	Na^+	K^+
$(C_{11}H_{17}O_2Cat_2)^+$	0.36	0.35	0.13
$(C_{11}H_{18}O_2Cat_2)^{\cdot +}$	0 04	0.20	0.22

Several conclusions can be drawn from the data. One fact is that the c closed-shell ions do not arise via a two-step radical mechanism from the adjacent c' radical cations, as proposed previously (1). If this were the case, the abundance of the c' allylic radical ion should decrease, and the abundance of the adjacent c closed-shell ion should increase, with increasing collision gas pressure.

Table 2. Relative abundances of product ions from CID of $[M + 2K - H]^+$ ions

product ion	% of main beam			
	% beam reduction			
	0	10	30	60
$(C_{11}H_{17}O_2K_2)^+$	0.012	0.017	0.022	0.042
$(C_{11}H_{18}O_2K_2)^{\cdot +}$	ND	ND	0.012	0.051

Another conclusion is that the charge site *must* be affecting as least some of the "charge-remote" fragmentations otherwise the two "charge-remote" fragment ion abundances would not be altered with changing size of metal ion. Furthermore, the results in *both* Tables 1 *and* 2 can not be explained by simple kinetic arguments. The data can be understood, however, from competing decompositions of structurally distinct precursor ions. This idea is shown schematically in Figure 2. The linear structure shown in Figure 2A would undergo classic charge-remote fragmentations via mechanisms previously proposed (2-4), but the cyclic structure shown in Figure 2B in which the charge is stabilized by interactions with the double bond would undergo a *charge-induced*, lower energy, cleavage to give the allylic radical cation c'. Thus, increasing the relative population of the cyclic structure would cause the charge-induced radical cation c' to increase significantly. The probability of forming the cyclic structure would increase with increasing size of metal ion because the charge site would be increasingly destabilized in the linear structure but stabilized in the multi-bonded cyclic structure (5). Additional research is currently being conducted to further address these ideas.

FURTHER INVESTIGATION OF THE FUNDAMENTAL PROCESSES INVOLVED IN FAB/LSIMS TECHNIQUES

G. J. C. Paul, R. Théberge and Michel J. Bertrand
Regional Center for Mass Spectrometry,
Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7

At present, a widely-accepted explanation of the mechanism of analyte ionization in FAB/LSIMS remains elusive despite the efforts of many researchers in this field. At the heart of the issue is whether analyte ionization predominantly occurs in the condensed phase as a consequence of fast atom/ion bombardment or in the gas phase above the liquid matrix through ion-molecule reactions. The study in this laboratory of ether-containing compounds forming anomalous $(M-H)^+$ in FAB/LSIMS has proved fruitful in shedding further light on the ionization processes involved in these techniques. In LSIMS work involving derivatized sugars, predominant $(M-H)^+$ formation in the molecular ion region was observed (Figure 1) where five different liquid matrices were employed. In contrast, for $CI(NH_3)$ experiments performed at 150°C, $(M+H)^+$ is the major molecular ion with the $(M-H)^+$ intensity negligible. These results are summarized in Table 1. Similar trends were also apparent for a series of 4-alkyl-2-phenyl-1,3-dioxolanes, where $(M-H)^+$ formation was favored in FAB using magic bullet as the liquid matrix while $(M+H)^+$ was the major molecular ion in $CI(NH_3, i\text{-}C_4H_{10}, CH_4)$.[1,2] In terms of the gas phase ionization model for FAB, the protonated matrix molecule is assumed to be the major reactive ionic species in the selvedge region. However, the dominant formation of $(M-H)^+$ in FAB/LSIMS compared to $(M+H)^+$ in CI cannot be rationalized in terms of the gas phase hydride ion affinities of the respective reactant ionic species.

An alternate explanation of the FAB results is that protonation and hydride abstraction occur in the condensed phase as competitive ion-molecule reactions. In the condensed phase, the activation energy barriers to the formation of $(M+H)^+$ and $(M-H)^+$ are related to the solvation energies of the appropriate transition states for each reaction. If a charge seperation transition state exists in the hydride abstraction reaction, this transition state would be better solvated than the corresponding proton transfer transition state, leading to a lower activation energy barrier for $(M-H)^+$ formation with respect to $(M+H)^+$.[2] In terms of the respective reaction rate expressions, shown below, the solvation effect leads to $k_2 >> k_1$ and, consequently, predominant $(M-H)^+$ formation in FAB. This condensed phase ionization model, therefore, explains the domination of $(M-H)^+$ in FAB for ether-type compounds, which, as previously discussed, could not be rationalized by the gas collision model.

$$\frac{d[(M+H)^+]}{dt} = k_1[M][R_xH^+] \qquad (1)$$

$$\frac{d[(M-H)^+]}{dt} = k_2[M][R_yH^+] \qquad (2)$$

This model, however, does not fully explain the FAB(MB) data for the deuterated 4-alkyl-2-phenyl-1,3-dioxolanes, shown in Table 2. The anticipated reaction rate expression for D^- abstraction is shown below where the reactant species are assumed to be the same as those for H^- abstraction.

$$\frac{d[(M-D)^+]}{dt} = k_3[M][R_yH^+] \qquad (3)$$

For 4-butyl and 4-hexyl-2-phenyl-1,3-dioxolane-2-d, the $(M+H)^+$ intensity is similar to that of $(M-D)^+$ during the first minute of FAB, which is in contrast to the domination of $(M-H)^+$ for the 2-H acetals (Table 2). This occurrence can be explained in terms of a smaller rate constant, k_3, for $(M-D)^+$ formation in the condensed phase (3) with respect to k_2 for $(M-H)^+$ formation (2) which is a consequence of the kinetic isotope effect. Thus, $(M-D)^+$ and $(M+H)^+$ formation are competitive processes ($k_3 \approx k_1$) accounting for the significant intensity of both species in the initial stages of FAB. An additional element of the FAB data for these deuterated compounds is the dramatic time dependence of the relative $(M-D)^+$ and $(M+H)^+$ intensities, illustrated in Figure 2. A much smaller variation in $(M-H)^+$ and $(M+H)^+$ intensities is seen for the non-deuterated acetals (Table 2). This effect may reflect the greater build-up with time of those reactant electrophilic species responsible for D^- abstraction (R_yH^+) compared to those for protonation (R_xH^+). In terms of the reaction rates (1) and (3), it is thought that $[R_yH^+]$ increases with time faster than $[R_xH^+]$ and subsequently the relative intensity of $(M-D)^+$ increases with respect to $(M+H)^+$. Although still present, this effect is much less important for

the non-deuterated acetals as $k_2 >> k_1$. This time dependence of the molecular ion species in FAB strongly suggests that reactive precursors are generated in the condensed phase by fast atom beam-induced ionization. It is difficult to interpret the time-dependent FAB results in terms of gas phase ionization. For 4-decyl-2-phenyl-1,3-dioxolane-2-d, a significant time effect on the molecular ion intensities is not observed in FAB(MB) with $(M-D)^+$ major for the duration of the experiment (Table 2). This could be due to the increased surface activity of this acetal compared to 4-butyl and 4-hexyl-2-phenyl-1,3-dioxolane-2-d, where the increased rate of formation of R_yH^+ with respect to R_xH^+ on fast atom bombardment is more quickly reflected by the $(M-D)^+:(M+H)^+$ ratio. The presence of lower intensity matrix peaks in FAB(MB) for 4-decyl-2-phenyl-1,3-dioxolane-2-d with respect to the other deuterated acetals supports this interpretation. The proposed surface concentration effect for 4-decyl-2-phenyl-1,3-dioxolane-2-d may also help explain the difference in time profiles for 4-butyl and 4-hexyl-2-phenyl-1,3-dioxolane-2-d in FAB(MB) and FAB with no supporting matrix (Table 2). The domination of $(M-D)^+$ for the pure 2-d acetals for the duration of FAB may be a direct consequence of the increased surface concentration of the acetals in these experiments relative to that in a magic bullet matrix. Only small concentration effects are observed on the relative molecular ion intensities for the non-deuterated acetals (Table 2) as $k_2 >> k_1$.

Iron-Mediated [4 + 2] Cycloaddition of 1,3-Dienes with Alkynes

R. Bakhtiar, J.J. Drader and D.B. Jacobson
Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

The Diels-Alder reaction is a versatile and convenient route to stereospecific synthesis of six membered rings.[1] The low reactivity of unactivated alkynes and alkenes as dienophilic reagents, however, is a major limitation of this [4 + 2] cycloaddition process.[2] Transition metal complexes have been found to facilitate dienyne cycloadditions, presumably *via* eta[3] complex formation and reductive elimination.[3,4] We have found that [4 + 2] cycloaddition of 1,3-dienes with ethyne and propyne to yield six membered rings is a facile process for atomic iron cations in the gas phase by using Fourier transform mass spectrometry (FTMS).[5]

Fe^+ was generated by laser desorption/ionization form a high purity iron foil with Fe(1,3-butadiene)$^+$ formed by dehydrogenation of 1-butene, process 1, and Fe(cis-1,3-pentadiene)$^+$ formed by reaction 2. 1-Butene and cis-1,3-pentadiene were

$$Fe^+ + \text{1-butene} \longrightarrow FeC_4H_6^+ + H_2 \qquad (1)$$

$$FeC_2H_2^+ + \text{cis-1,3-pentadiene} \longrightarrow FeC_5H_8^+ + C_2H_2 \qquad (2)$$

introduced into the vacuum chamber *via* a pulsed solenoid inlet valve. A static argon pressure of 1 X 10^{-5} Torr was maintained throughout the experiments and serves both the facilitate ion thermalization prior to reaction and as the target for collision-activated dissociation (CAD).

Fe(1,3-butadiene)$^+$ reacts rapidly (efficiency ca. 1.0) with ethyne and propyne to yield primarily dehydrogenation, reactions 3 and 4, with a small amount (< 10%) of

$$FeC_4H_6^+ + C_2H_2 \longrightarrow \underset{\underset{1}{\sim}}{FeC_6H_6^+} + H_2 \qquad (3)$$

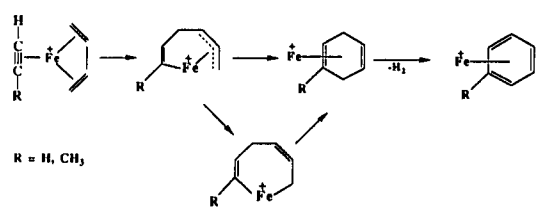
$$FeC_4H_6^+ + HCCCH_3 \longrightarrow \underset{\underset{2}{\sim}}{FeC_7H_8^+} + H_2 \qquad (4)$$

bare Fe^+ observed. CAD of each of the products of reactions 3 and 4 yield exclusive formation of Fe^+ indicating C-C bond formation between diene and dienophile. CAD breakdown curves (fragment ion abundances VS. kinetic energy) for 1 and authentic Fe(benzene)$^+$ are identical (same products and energy dependency). In a similar fashion, CAD breakdown curves for 2 and authentic Fe(toluene)$^+$ are identical. In contrast, CAD of isomeric $FeC_7H_8^+$ ions, Fe(cycloheptatriene)$^+$ and Fe(norbornadiene)$^+$, yield significant ligand cleavage products.

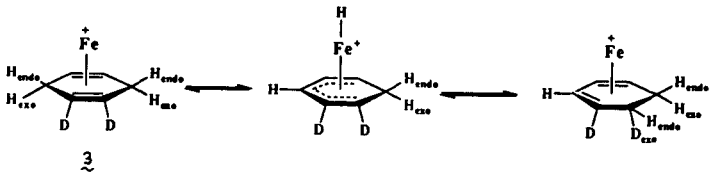
Additional structural information on 1 and 2 was obtained by ion/molecule reactions. Both 1 and Fe(benzene)$^+$ undergo identical reactions with C_2H_2 and benzene-d_6 with rapid adduct formation observed. CAD of each of the $Fe(C_6H_6)(C_6D_6)^+$ adducts yields a C_6H_6:C_6D_6 loss ratio of 1:1. Both 2 and Fe(toluene)$^+$ react identically with propyne to yield exclusive, rapid adduct formation. These structural studies (CAD combined with ion/molecule reactions) strongly support formation of Fe(benzene)$^+$ in reaction 3 and Fe(toluene)$^+$ in reaction 4.

A proposed mechanism for formation of Fe(benzene)$^+$ and Fe(toluene)$^+$ in reactions 3 and 4 is presented in Scheme I. The high efficiency of reactions 3 and 4 suggest

Scheme I



no significant barriers for these processes. Formation of Fe(1,4-cyclohexadiene)$^+$ and Fe(1-methyl-1,4-cyclohexadiene)$^+$ from ethyne and propyne, respectively, is highly (ca. 50 kcal/mol) exothermic. Subsequent dehydrogenation yields the corresponding Fe(benzene)$^+$ and Fe(toluene)$^+$ complexes. Scheme I predicts that ethyne-d_2 would react with Fe(1,3-butadiene)$^+$ to yield exclusive elimination of H_2. Here, [4 + 2] cycloaddition initially forms species 3 with Fe^+ bridging the ring and only the endo-ring hydrogens available for abstraction by iron. Reversible hydrogen abstractions result in migration of the double bonds around the ring (process 5), however; only



(5)

the two original endo-ring hydrogen atoms are available for elimination. Ethene-d_2 reacts with Fe(1,3-butadiene)$^+$ to yield 97% H_2 loss and 3% HD loss (only trace of D_2 loss is seen). The selective H_2 loss with ethyne-d_2 is consistent with the mechanism proposed in Scheme I. Absence of methane elimination with propyne is also consistent with Scheme I where initial cycloaddition yields Fe(1-methyl-1,4-cyclohexadiene)$^+$ which can only undergo dehydrogenation (reversible hydrogen abstraction yields an exo-methyl species, e.g., process 5).

Ethyne reacts with Fe(cis-1,3-pentadiene)$^+$ to yield both dehydrogenation and methane loss, reactions 6 and 7. [4 + 2] cycloaddition, Scheme I, would yield two

$$FeC_5H_8^+ + C_2H_2 \xrightarrow{0.17} FeC_7H_8^+ + H_2 \quad (6)$$

$$FeC_5H_8^+ + C_2H_2 \xrightarrow{0.83} FeC_6H_6^+ + CH_4 \quad (7)$$

possible 1,4-cyclohexadiene-iron complexes, one with an endo-methyl group and one with an exo-methyl group. The endo-methyl species would yield methane loss whereas the exo-methyl species would yield dehydrogenation. The high propensity for methane elimination, process 7 suggests that [4 + 2] cycloaddition prefers to proceed in such a manner to have the methyl group oriented in the endo-ring position. We are currently studying this aspect in more detail.

GAS PHASE SUBSTITUTION OF HALOBENZENES BY AMINE RADICAL CATIONS A STUDY BY FT-ICR

D. Thölmann and H.-Fr. Grützmacher, Fakultät für Chemie;
Universität Bielefeld, Universitätsstraße, D-4800 Bielefeld, Germany

The radical cations of mono- and dihalogenated benzenes react with NH_3 in the gas phase by substitution of a halogen substituent[1]. This ion/molecule reaction is rather slow because of a substantial activation barrier of the rate determining addition of the nucleophile to the unsaturated radical cation. In agreement with a theoretical interpretation of this addition step by the *configuration mixing model* of Shaik and Pross[2] the rate of the reaction decreases with an increasing difference of the ionization energy (IE) of NH_3 and the halogenated arene and increases with the dipole moment of the (neutral) halobenzene.
The reaction model predicts that the addition step of a substitution reaction between a neutral halobenzene and the radical cation of a nucleophile should be fast, probably resulting in a collision controlled total substitution reaction. This type of reaction has been studied by FT-ICR spectrometry using methylamine (IE 8.97 eV[3]) and dimethylamine (IE 8.23 eV[3]) as a nucleophile and chlorobenzene (**1**), bromobenzene (**2**), iodobenzene (**3**), 1,2-dichlorobenzene (**4**), 1,3-dichlorobenzene (**5**), 1,4-dichlorobenzene (**6**), 1-chloro-2-iodobenzene (**7**), 1-chloro-3-iodobenzene (**8**), and 1-chloro-4-iodobenzene (**9**) as substrates. The experimental procedure for the determination of the ion/molecule rates is the same one as described before[1]. The results are presented in Table 1 - 3.

Table 1: reactions of halobenzene radical cations with neutral methylamine

radical ion	k_{total} [a)]	eff_{total}	k_{subst} [a)]	eff_{subst}	k_I/k_{Cl}
$1^{+\cdot}$	11.0	67%	8.7	53%	
$2^{+\cdot}$	11.0	69%	9.2	58%	
$3^{+\cdot}$	7.6	49%	5.7	37%	
$4^{+\cdot}$	11.0	69%	8.6	54%	
$5^{+\cdot}$	8.6	54%	5.5	34%	
$6^{+\cdot}$	7.1	44%	5.4	34%	
$7^{+\cdot}$			7.3	47%	1.4±0.2
$8^{+\cdot}$			6.3	41%	1.4±0.2
$9^{+\cdot}$			4.4	28%	1.8±0.3

a) $\cdot 10^{-10}$ [$cm^3 molecule^{-1} s^{-1}$]

The substitution reactions of the radical cations of halobenzenes **1** - **9** with methylamine exhibit large efficiencies (Table 1) but still show a rate decrease for the iodobenzene radical cations **3**, **7** - **9** and the 1,4-dichlorobenzene radical cation **6**. Similarly, substitution is observed for the reaction of the methylamine radical cation with the neutral halobenzenes with the exception of iodobenzenes. The efficiency of the substitution is always < 50% (Table 2), and no positional effect is observed in the case of the dichlorobenzenes.
Substitution of a halogen is also observed for the reaction of dimethylamine radical cations with all neutral halobenzenes studied but the reaction efficiencies are rather small (Table 3). The reaction rate increases from chlorobenzene **1** to iodobenzene **3** and is especially slow for the 1,3-disubstituted substrates **5** and **8**.
Exothermic addition and exothermic total substitution is calculated for all reaction systems studied. The substitution effect and positional effect on the reaction of a neutral halobenzene with an amine radical cation is different from those observed for the reaction of halobenzene radical cations with a nucleophile,

indicating that the addition step is not rate determining in the former case. The slow exothermic reaction of dimethylamine radical cations with the halobenzene must be due to an additional reaction step being rate determining in this case. A slow rearrangement of the ammonium substituent in the addition product into the ipso-substituted isomer prior to the elimination of the halogen substituent is suggested as the rate determining step

DETERMINATION OF METAL TO NITROGEN BONDING IN NUCLEOBASE COMPLEX CATIONS

Qingmei Zha and Michael J. Dube
Department of Chemistry, Brown University
Providence, RI 02912

Transition metal complexes are now considered to be the possible chemotherapeutic agents since the first study reported in the late sixties that the flat platinum (II) complex cisplatin was proven to be active to against cancer. Recently, studies also showed the interactions between some planar orthometallated palladium (II) complexes and DNA. The mechanistic studies have shown that the transition metals in these complexes are needed for binding of the complexes to DNA. To study the binding between the transition metal and DNA, a group of palladium (II) organometallic complexes were prepared. In these complexes, a nucleobase (adenine, guanine, purine or hypoxanthine) bridges two palladium (II) complexes, where the ligands are 2-(meta-R-phenyl)-1,10-phenanthroline. Two palladium atoms link two nitrogen atoms on the nucleobase, respectively. There are three possible combinations of metal to nitrogen bonding: (1) both are covalent bonds, (2) both are coordinated covalent bonds and (3) one is a covalent bond and the other is a coordinated covalent bond.

In these nucleobase complex cations, the palladium atom would be positively charged if the metal to nitrogen bonding is a coordinated covalent bond while it would remain neutral if the metal to nitrogen bonding is a covalent bond. The different bonds would also lead to different proton numbers on the nucleobase. Thus, the total proton number in these complex cations can reveal the information of metal to nitrogen bonding. Fast atom bombardment (FAB) mass spectrometry has proven to be a versatile ionization method for the analysis of inorganic, organometallic and coordination compounds [1]. The masses of complex cations observed in the FAB mass spectra can be used to determine the total proton numbers and whether there are different metal to nitrogen bonds.

The isotope distributions of palladium were carefully calculated before mass spectral analysis. Two of the six palladium isotopes, mass 106 and mass 108, have natural abundances of 27.3% and 26.7%, respectively. The isotope distribution of two palladium atoms (Fig. 1) indicates that the most abundant peak is at mass 210, which is four mass units less than the combination of the two most abundant isotopes of palladium (106 + 108). For a given composition of a palladium (II) nucleobase complex cation, $C_{43}H_{30}N_9O_2Pd_2$, the most abundant peak is at mass 916, which is two mass units less than the combination of the isotopes of 106 and 108. However, there are two other major peaks whose abundances are only 5% less than the most abundant peak. The masses of these two peaks are two mass units more and two mass units less than the most abundant peak, respectively (Fig. 2).

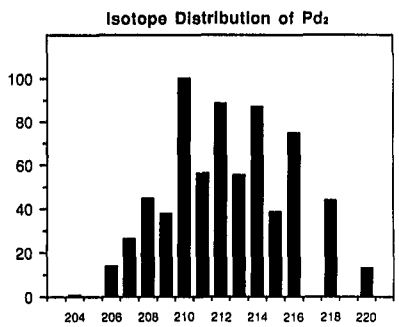

Fig. 1

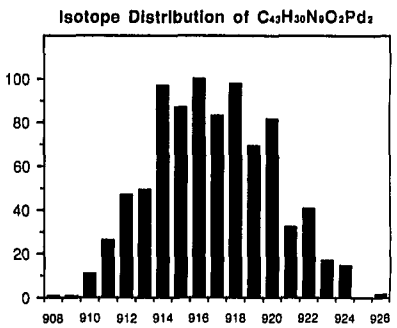

Fig. 2

FAB mass spectral analysis was performed on a Kratos MS-80 double focusing mass spectrometer operating at an accelerating voltage of 4 kv. A fast atom saddle-field gun

(Iontech FAB-11NF) is mounted on a standard Kratos FAB source. The xenon atom beam was generated with a kinetic energy of ca. 8 kv. It is noticed that these complexes do not generate FAB mass spectra under normal operation conditions using conventional matrices such as glycerol, thioglycerol and 3-nitrobenzyl alcohol (NBA). It has been reported [2] that a key point for obtaining FAB mass spectra of Pd(II) organometallic complexes is the pretreatment of samples. The pretreatment of samples was as follows: first, add approximately 20 μg of sample into 10 μl of methanol, stir it to suspend the sample and remove the suspended sample onto a FAB probe tip; then place 1 μl of NBA matrix on the tip before methanol was totally evaporated, stir it again and wait approximately 5 minutes to perform mass spectral analysis.

Our previous study on mass spectral analysis of palladium (II) organometallic complexes [2] has shown that the predominant ions observed were the molecular ions M^+ in the FAB mass spectra using NBA matrix. The protonation was observed as a minor process. It is expected that the palladium (II) nucleobase complex is ready to generate the cation ions by eliminating the anionic moieties which stabilize the cationic complexes.

FAB mass spectra of nucleobase complexes are shown in Fig. 3. The cation cluster was observed as the major ions at high mass region. The average mass spectrum of 5 to 10 scans is very close to the theoretically calculated mass distribution. It would indicate that in these nucleobase palladium (II) complex cations, the two palladium to nitrogen bonds are different: one is a covalent bond and the other is a coordinated covalent bond. Thus, one palladium atom is positively charged and the other remains neutral.

PROFILING OF EXTRACELLULAR PRODUCTS FROM *ERWINIA AMYLOVORA* BY ON-LINE LIQUID CHROMATOGRAPHY-ELECTROSPRAY MASS SPECTROMETRY.

G. J. Felstner

Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

Fire blight is an economically important, necrotic disease of apples and pears, caused by the bacterium *Erwinia amylovora*. It is presently controlled by streptomycin, but plasmid-mediated resistance against this antibiotic is spreading. Development of new control agents or the transfer of fire blight resistance to current pear and apple varieties by amending their genetic repertoire will first require a thorough understanding of the underlying virulence mechanisms. For quite some time now, I have been involved in identifying potential virulence factors of *E. amylovora*. In 1988, I suggested that the disease may be explained by the excretion of dihydrophenylalanine [1]. The potency of dihydrophenylalanine as a virulence factor of *E. amylovora* has been independently confirmed, but it was also found that not all virulent strains produce it [2]. Since then, I use metabolic profiling by LC-ES-MS to screen for additional virulence factors and reported last year on the tentative identification of three siderophores. This number has grown to at least six. Other then first thought, they now appear to belong to a class of hydroxamate siderophores known as deferrioxamines (DFO) that generally are composed of acetyl-, succinyl (SA) and ω-amino-α-N-hydroxy-aminoalkanes (DAA, for example, N-hydroxy-diaminobutane (DAB) or N-hydroxy-diaminopentane (DAP)). They readily form 1:1 complexes with Fe^{3+}. The chelation of two trivalent cations per DFO under ES-MS conditions, which I observed previously [3], remains to be explained.

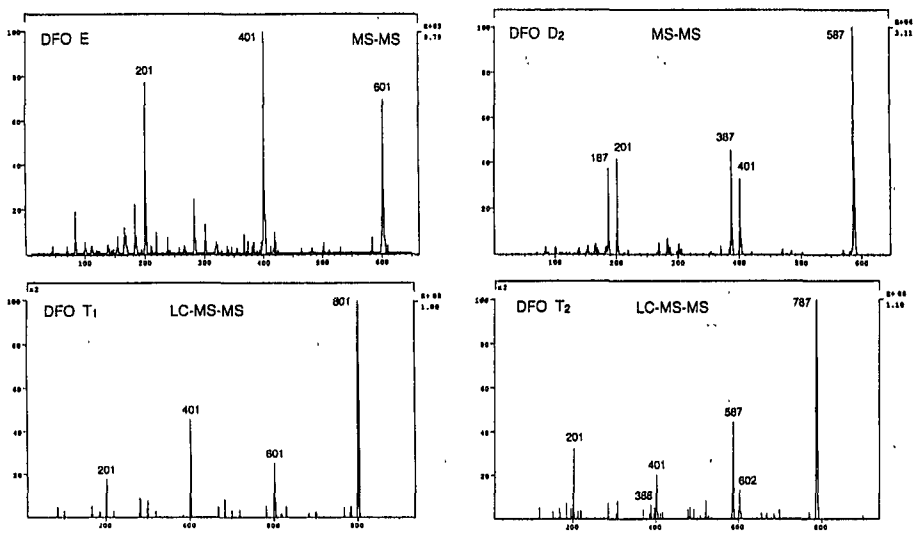

Fig. 1

From LC-ES-MS-MS studies (Fig. 1), a general major fragmentation mechanism seems to emerge (at least for the cyclic DFOs), namely the consecutive loss of monomeric SA-DAA units. The two major siderophores have thus been tentatively identified as the trihydroxamates DFO E (mass 600; 3 SA, 3 DAP) and DFO D_2 (mass 586; 3 SA, 2 DAP, 1 DAB), respectively, which are widely distributed in the

microbial world. A third one has a molecular mass of 572 consistent with a composition of 3SA, 1 DAP, and 2 DAB. Such DFO was previously only observed during a directed fermentation when the precursor 1,4-diaminobutane was fed to *Streptomyces olivaceus* Tü 2718 [4]. However, most interesting is the apparent discovery of three novel *tetra*hydroxamates, designated T_{1-3}. The tentative structural assignment of two of them, T_1 (mass 800; 4 SA, 4 DAP) and T_2 (mass 786; 4 SA, 3 DAP, 1 DAB), was straightforward, since their collision induced dissociation seems to follow the same pathways that are observed for the trihydroxamates (Fig. 1). T_3 contains two SA-DAP units plus other as of yet unidentified structural elements. Despite their increased ring size (compared to the trihydroxamates), the tetrahydroxamates are still able to form 1:1 complexes with Fe^{3+}. Based on multiply charged molecular ion patterns, preliminary evidence has also been found for larger molecules; for example Fig. 2 seems to indicate a molecular mass of 3748.

The siderophores are probably necessary for induction of fire blight in that they enable *E. amylovora* to compete with its host for iron. Vice versa, the biosynthetic pathways of DFO production may provide a mechanism for fire blight control. However, the main siderophores of *E. amylovora* (DFOs E and D_2) are also produced by the saprophyte *Erwinia herbicola* and this rules out that they alone are *sufficient* for fire blight pathogenesis. The 3-dimensional structures of the novel tetrahydroxamate iron complexes are unknown but it is conceivable that they, like the trihydroxamate iron complexes, form flat polar structures that are believed to be important for iron uptake across cell walls [5]. Screening of wildtype and avirulent mutant strains should reveal whether the tetrahydroxamates are important for the virulence of *E. amylovora*. The nature of the larger molecules is not yet known, but there is a good chance that they are peptides because peptides are particularly amenable to detection by ES-MS. If so, then it is conceivable that they may play a role in the induction of a mild hypersensitive defense reaction in a host plant. This would trigger host cell leakage and in turn promote further growth of *E. amylovora*. Previously, it was thought that direct bacterial-plant cell-cell contact, possibly via a cell surface protein of *E. amylovora*, was necessary for initiating such a process. If the putative polypeptides can be confirmed than this subject may require a reevaluation.

Characterization of the Heterogeneous N-terminal Fatty Acylation of Two Bovine Retinal Proteins; Reexamination of Myristoylation of cAMP-Dependent Protein Kinase

Johnson, R.S., Neubert, T.A., Dizhoor, A.M., Ericsson, L.H., Kumar, S., Olshevskaya, E., Hurley, J.B. and Walsh, K.A.
Dept. of Biochemistry and Howard Hughes Medical Institute, University of Washington, Seattle, WA 98195

Rod transducin, a heterotrimeric GTP-binding protein comprised of α, β, and γ subunits, couples photolyzed rhodopsin to the activation of cGMP phosphodiesterase in the vertebrate visual signal transduction cascade. Tryptic fragments of the α subunit were analyzed by HPLC coupled directly to a nebulization-assisted electrospray ion source of a triple quadrupole tandem mass spectrometer. Heterogeneous acylation by lauroyl (C12:0), myristoyl (C14:0), (cis-5)-tetradecaenoyl (C14:1), and (cis,cis-5,8) tetradecadienoyl (C14:2) of the N-terminal glycine was observed. Low energy tandem mass spectra of the doubly charged N-terminal tryptic peptides shown in Fig. 1 demonstrate that all four peptides have identical amino acid sequences and that the observed mass differences are due to variations in the N-terminal acyl groups. To determine the positional isomers of the unsaturated fatty acids, the peptides were subjected to ozonolysis and the mass shifts resulting from cleavage of the carbon-carbon double bonds were determined. These results indicated that both the C14:1 double bond and the double bond of C14:2 proximal to the carbonyl were in the Δ–5 position. In agreement with this observation, the GC retention times of the corresponding fatty acid methyl esters matched that of standards.

An additional bovine retinal protein, recoverin, was also found to be similarly acylated. In this case, the first indication that this protein was modified by unusual fatty acylation was made by mixing unmodified recombinant recoverin and native recoverin and acquiring an ESI mass spectrum of the mixture. The mass difference was 208 u, where addition of myristic acid would be 210 u. A limited tryptic digest of recoverin was fractionated by HPLC off-line, and N-terminal peptides containing the same acyl groups as observed in transducin were identified by ESI-MS and tandem mass spectrometry.

These findings on the two retinal proteins necessitated a reexamination of at least one other previously reported myristoylated protein in order to determine if this heterogeneous acylation was a general phenomenon missed in earlier work. Towards this end, a Lys-C digest of cAMP-dependent protein kinase isolated from bovine heart was examined by LC/MS, and it was found that this protein contained only a myristoylated N-terminus as previously reported (2). However, heterogeneity in the amino acid sequence of the N-terminal tryptic peptide - Myristoyl-Gly-(Asn/Asp)-Ala-Ala-(Thr/Ala)-Lys - was observed.

The significance of these findings is not yet apparent, although its tempting to speculate that heterogeneous acylation of the retinal proteins helps modulate protein-protein interaction, and could serve as a basis for explaining visual transduction under varying light intensities. Its significant that a protein isolated from heart (cAMP-dependent protein kinase) was found only to be myristoylated, which suggests that N-terminal acylation is a tissue-specific phenomenon.

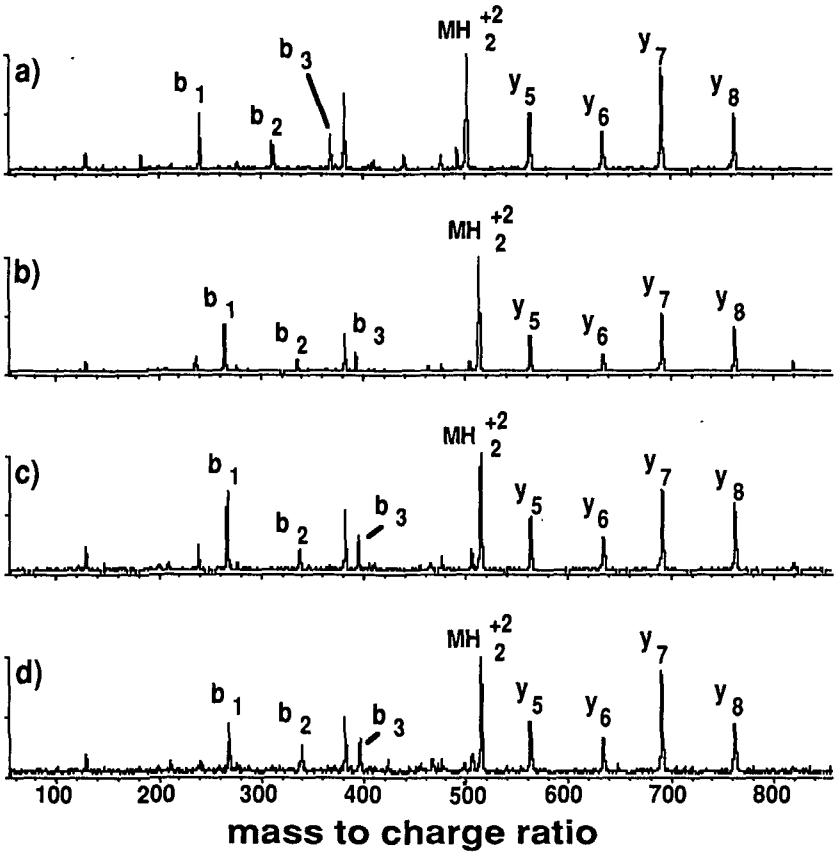

Figure 1: Low energy tandem mass spectra of the doubly-charged precursor ions of four N-terminal tryptic peptides isolated from the alpha subunit of transducin. All of the peptides have identical amino acid sequences (Gly-Ala-Gly-Ala-Ser-Ala-Glu-Glu-Lys), but differ in the N-terminal acyl group - (a) C12:0, (b) C14:2, (c) C14:1, and (d) C14:0.

5-Lipoxygenase (5-LO) is an enzyme that catalyses the oxidation of arachidonic acid to 5-hydroperoxyeicosatetraenoic acid (5-HPETE), and its further dehydration to form leukotriene A4. As it catalyses the first step in the biosynthesis of the leukotrienes, 5-LO has been the subject of intensive investigations as a potential target for anti-inflammatory chemotherapy.

The mammalian lipoxygenases 12-LO, 15-LO and 5-LO all contain a single firmly bound non-heme iron, and they have been shown to undergo a turnover dependant inactivation. Recent studies[3] have shown that 5-LO is rapidly inactivated by trace amount of hydrogen peroxide. In early studies[1] on rabbit reticulocyte 15-LO, oxidation of 1 mol methionine/mol enzyme to methionine sulfoxide, presumably in the active site, was found to occur during inactivation of 15-LO due to product hydroperoxide. However, this result was not confirmed by a more recent study[2].

It has long been assumed that inactivation of 5-LO during turnover results in oxidation of 1 mol methionine to methionine sulfoxide. Our objective in this study was to determine whether or not methionine sulfoxide was formed during the inactivation of 5-LO. The methodology involves using ^{18}O labeled H_2O_2 to inactivate 5-LO, followed by base hydrolysis of the enzyme, and precolumn derivatization by phenylisothiocynate (PITC) to form PTC-amino acid[4], and measuring PTC-Met$S^{18}O$ formation by thermospray LC/MS.

Most PTC-amino acids showed base peak of $(MH-H_2O)^+$ using thermospray LC/MS. This base peak was chosen for SIM of PTC-MetSO and PTC-Met. Trace amounts of methionine sulfoxide were found in all 5-LO hydrolysates (native, H_2O_2 and $H_2O_2{}^{18}$ inactivated). $H_2O_2{}^{18}$ inactivated 5-LO sample did not show any methionine sulfoxide formation due to $H_2O_2{}^{18}$. The peak corresponds to PTC-MetSO^{18} (m/z:285.1) was 10% of that for PTC-MetSO (m/z:283.1), which was in the range of nature isotope abundance contributions from ^{34}S and ^{13}C. In summary, the inactivation of 5-LO by H_2O_2 was not accompanied by the oxidation of methionine to methionine sulfoxide. It is most likely that another oxidizable amino acid residue is involved in the inactivation.

THE LEUCINE ZIPPER PEPTIDES: ION SPRAY MASS SPECTROMETRIC DETECTION OF NONCOVALENT DIMERS

Jack Henion and Yu-Tsyr Li, Drug Testing and Toxicology, NYS College of Veterinary Medicine, Cornell University, 925 Warren Dr., Ithaca, NY 14850, and Bruce Ganem, Department of Chemistry, Cornell University, Ithaca, NY 14853.

INTRODUCTION

Ion spray mass spectrometry (MS) has been reported for the detection of noncovalent enzyme-substrate and receptor-ligand complexes by our laboratory. To extend the application of ion spray MS to the detection of other noncovalent interactions in biological macromolecules, the leucine zipper peptides were studied.

The leucine zipper peptides have 33 amino acids containing a repeating leucine every seven residues. These peptides associate in the micromolar concentration range to form a stable noncovalent dimer in aqueous solution through hydrophobic interactions by interdigitating the leucine repeat from each side of the chain. This leucine repeat peptide was found in several DNA binding proteins and the dimerization of the peptide is required for the DNA binding to the protein. Two leucine zipper peptides, GCN4 (wild type, MW = 4037 dalton) and N16V (mutant type, MW = 4022 dalton) in which asparagine 16 is replaced by valine 16, were studied using continuous introduction ion spray MS and MS/MS under physiological pH conditions (pH 5.0) in aqueous acetate buffer. The observed dimers were detected by their multiply protonated *odd* charged states. The technique of tandem MS can show the stronger associated dimer of N16V which agrees with the known analysis by circular dichroism (CD) spectra.

EXPERIMENTAL

The sample, GCN4 or N16V (1 mM of each), was introduced respectively in 100% aqueous buffer (10 mM ammonium acetate, pH 5.0) by continuous infusion of the sample (2 μL/min) at ambient temperature through an ion spray interface using 2 secscans with 10 scans summed. The mass spectrometer, a Sciex TAGA 6000E upgraded to an API III, was operated in the single-MS and MS/MS modes. Collision-induced dissociation (CID) experiments were accomplished with argon at collision energies of 60 eV (laboratory frame) and at a declustering potential of 60 V.

RESULTS AND DISCUSSION

Both dimers of GCN4 and N16V peptides were detectable via their multiply protonated *odd* charge states of ions from ion spray MS (Figure 1). The ion current signals of dimers from odd charge states from both GCN4 and N16V were very weak; however, compared with GCN4, a five-fold increase in the total ion intensity of N16V was observed. This suggests an increase in hydrophobic interactions because asparagine16 is replaced by valine16 in N16V, thus giving both a leucine repeat and a valine repeat occuring every seven amino acid residues. This might influence the ion evaporation mechanism of ionization such that the N16V ions are more stable in the gas phase than the condensed phase of the droplets. Thus ions that are more hydrophobic may enter the gas phase more readily.

The mass spectrum of the stronger N16V dimer did not show a more abundant dimer than that of GCN4 from a single-MS experiment (Figure 1). Tandem MS was used to further investigate both dimers. From the MS/MS study of GCN4 and N16V dimers of the *odd* charge states (e.g., choosing +7 dimer as a precursor ion), the dimer precursor of N16V showed less dissociation to +3 and +4 monomers as product ions than GCN4 under identical experimental conditions (Figure 2) in agreement with analogous studies obtained from the known circular dichrosim (CD) spectra.

The dimers of leucine zipper peptides are detectable via their multiply protonated *odd* charge states by ion spray MS and MS/MS. However, the gas phase behavior of these interesting peptides needs further study to more fully characterize their noncovalent dimer interactions and their behavior in the gas phase.

ACKNOWLEDGEMENTS

This research was supported by a grant from the Cornell Biotechnology Program, which is sponsored by the New York State Science and Technology Foundation, a consortium of industries, the U.S. Army Research Office, and the National Science Foundation. We thank professor Peter kim for generously providing leucine zipper peptides (GCN4 and N16V).

Structural Characterization of Guanylin: An Endogenous Activator of Intestinal Guanylate Cyclase

K.L. Duffin, K. Fok, C.E. Smith, J. Kato and M.G. Currie, Monsanto Corporate Research, Monsanto Company, St. Louis, MO 63198.

INTRODUCTION

Guanylate cyclase is comprised of a group of proteins that share a common enzymatic function of producing cyclic GMP, but differ quite remarkably in their selectivity toward activation by ligands. The three major types of guanylate cyclase are the soluble, particulate, and intestinal (cytoskeletal-associated particulate or STa-sensitive) forms and each is regulated by different ligands(1,2). Activation of the soluble guanylate cyclase occurs in response to nitric oxide (EDRF), whereas activation of the particulate enzyme occurs in response to the natriuretic peptides (atrial natriuretic peptide, brain natriuretic peptide, and C-type natriuretic peptide) (1,2). An endogenous activator of the intestinal guanylate cyclase has not previously been identified. However, the heat stable enterotoxin (STa) from E. coli is known to selectively activate this form of the enzyme (3,4). The intestinal form is predominantly found in the intestinal epithelial cells with the largest number of receptors oriented toward the lumen (1,2). STs are acidic peptides that contain 18-19 amino acids in length with six cysteines and three disulfide bridges that are required for full expression of bioactivity (5). The increase of intestinal epithelial cyclic GMP elicited by STs is thought to cause a decrease in water and sodium absorption and an increase in chloride secretion. These changes in intestinal fluid and electrolyte transport then act to cause secretory diarrhea. In developing countries, the diarrhea resulting from STs causes many deaths, particularly in the infant population. STs are also considered a major cause of traveler's diarrhea in developed countries. They have also been reported to be a leading cause of morbidity and death in domestic animals (6).

In the present study, we designed a bioassay in order to search for a potential endogenous ligand that activates the intestinal guanylate cyclase. This bioassay is based on the demonstration that T84 cells in culture respond to ST in a selective and sensitive manner with graded increases of intracellular cyclic GMP. This bioassay revealed that the intestine as well as the kidney possessed an active material. Purification of this material from the rat intestine was accomplished and the structure was determined to be a 15 amino acid peptide with 4 cysteines that must be disulfide-linked for bioactivity. The peptide, termed guanylin, also possesses a high degree of homology with STs.

Materials and Methods

Cell Culture. A cultured human colon carcinoma cell line (T84) was obtained from the American Type Culture Collection (Rockville, Maryland) at passage 52. Cells were grown to confluency in 24-well culture plates with a 1:1 mixture of Ham's F12 medium and Dulbecco's modified Eagle's medium, supplemented with 10% fetal calf serum, 100 IU/ml penicillin, and 100 ug/ml streptomycin. Cells were used at passages 54-60.

Cyclic GMP determination. Monolayers of T84 cells in 24-well plates were washed twice with 1 ml/well DMEM, then incubated at 37 C for 10 min with 0.5 ml DMEM containing 1mM isobutylmethylxanthine (IBMX), a cyclic nucleotide phosphodiesterase inhibitor. The media was then aspirated and the reaction terminated by the addition of ice cold 0.5 ml of 0.1 N HCl. Aliquots were then evaporated to dryness under nitrogen and then resuspended in 5 mM sodium acetate buffer, pH 6.4. The samples were subsequently measured for cyclic GMP by RIA.

Purification of Guanylin. Rat jejunums that were flushed of luminal contents with 50 ml of saline and immediately placed on dry ice were obtained from Bioproducts for Science (Indianapolis, IN). The jejunums were thawed, minced, and boiled for 10 min in 1M acetic acid. The extract was centrifuged at 20,000 g for 20 min at 4 C. The resulting supernatant was filtered and applied to a octadecasilyl (C18) Sep Pak (Waters, Milford, MA). The column was washed with 10% acetonitrile, 0.1% trifluoroacetic acid (TFA), H_2O and eluted with 60% acetonitrile, 0.1% TFA, H_2O. The eluted peptide fraction was lyophilized and resuspended in 50 ml of distilled water containing 0.8% ampholytes, pH range 3-10 and applied to a preparative isoelectric focusing cell (Rotofor, Bio-Rad, Richmond CA). The sample was focused for 150 min at 12 Watts constant power. The fractions were harvested, pH determined, and bioassayed. The active fractions, which focused around pH 3.8, were then refocused under similar conditions and the resulting active fractions were lyophilized. The sample was then resuspended in 1 ml of 10% acetonitrile, 0.1% TFA, H_2O and applied to a C18 semi-preparative HPLC column (Vydac, Hesperia, CA), and eluted at a flow rate of 3 ml/min. The following gradient was used to fractionate the sample: 10% acetonitrile, 0.1% TFA to 30%

acetonitrile, 0.1%TFA in 180 min. The active fraction was then determined by bioassay and lyophilized. This sample was resuspended in 1 ml of 10% acetonitrile, 0.1%TFA, H_2O and applied to a phenyl analytical HPLC column (Vydac, Hesperia, CA). The conditions for elution were similar to that described above for the semi-preparative column except the flow was 1 ml/min. The active fraction was lyophilized and then resuspended in 1 ml of 10% acetonitrile, 0.1%TFA, H_2O. The sample was then applied to a C18 analytical HPLC column (VYDAC, Hesperia, CA) and eluted according to the above description for the phenyl column. The active fraction was identified by bioassay and lyophilized. The sample was reconstituted in 1 ml of 10% acetonitrile, 0.1% TFA,H_2O and reapplied to the analytical C18 column and eluted by a gradient of 10% acetonitrile, 10mM ammonium acetate, H_20 (pH 6.2) to 30% acetonitrile, 10mM ammonium acetate, H_2O (pH 6.2) in 180 min. The active fraction was lyophilized and reconstituted in 0.05 ml of 0.1% TFA, H_2O. The sample was then applied to a C8 microbore column and eluted by an increasing gradient of 0.33%/min of acetonitrile, 0.1%TFA, H_2O. Two separate batches of purified peptide were then subjected to sequence analysis.

N-terminal protein sequence analysis. Automated Edman degradation chemistry was used to determine the NH_2-terminal protein sequence. An Applied Biosystems, Inc. model 470A gas phase sequencer (Foster City, CA) was employed for the degradations using the standard sequencer cycle, 03RPTH.

Electrospray Mass Spectrometry. Individual samples of native and synthetic guanylin were purified by microbore C8 reversed-phase HPLC (Brownlee Aquapore RP-300 7 micron column, P.J.Cobert, St. Louis, MO) and eluting fractions of the peptides were collected and concentrated to approximately 8 pmol/uL for mass-analysis. Sample solutions were introduced to the mass spectrometer via injection into a stream of acetonitrile : H_2O : TFA (1000:1000:1, v:v:v), which continuously flowed to the mass spectrometer at a flow of 10 uL/min. Three microliters of each of the concentrated guanylin samples was injected to obtain the results that are presented. A Sciex API III triple-quadrupole mass spectrometer (Thornhill, Ontario, Canada) equipped with an atmospheric pressure ion source was used to sample positive ions produced from an ionspray interface. Product ion MS/MS spectra of synthetic guanylin were acquired by fragmenting the $(M+H)^+$ at m/z 1515.6.

DISCUSSION

An endogenous activator of intestinal guanylate cyclase has been discovered after purification from rat intestinal tissue. Gas-phase sequence analysis of the ligand provided the amino acid composition to 14 places. Electrospray mass spectrometry yielded a molecular weight of 1515 u, which included the first 14 amino acids and a C-terminal cysteine that was not detected by sequence analysis. The final sequence of the peptide, which was named guanylin, is

PNTCEICAYAACTGC

Comparison of the molecular weights of guanylin before and after reduction with dithiothreitol confirmed the presence of two disulfide bonds. A peptide containing the same amino acid sequence was synthesized, air-oxidized to form the disulfide breidges, and purified by reversed-phase HPLC. Two minor components and a major component that had the same molecular weight of 1515 u were separated on the reversed-phase column. Tandem mass spectrometry was used to dissociate each of the three HPLC-purified compounds to determine their disulfide pairings. The first component, which has the same elution time an d activity of native guanylin, yielded an MS/MS spectrum that indicated peptide disulfide pairings of 4-12 and 7-15. The second component, which was the most abundant but was inactive, yielded an MS/MS spectrum indicating 4-15 and 7-12 disulfide pairings. The third component, also inactive yielded an MS/MS spectrum indicating 4-7 and 12-15 disulfide pairings. The mass spectrometric and other structural data therefore have led to the primary structure of the endogenous ligand of intestinal guanylate cyclase..

+(present address: PE SCIEX, Thornhill, Ontario, Canada)

SUMMARY

Mass spectrometric techniques have been developed to evaluate the sequence-specific interaction of transition metal ions with peptides and protein surface metal-binding domains. A 53-residue portion of the dimerization domain from the 67-kDa human estrogen receptor protein (ERDD) was synthesized and evaluated by matrix-assisted UV laser desorption/ionization (MALDI) time-of-flight (TOF) and electrospray ionization (ESI) mass spectrometry (MS) in the absence and presence of Cu(II) ions. Several stable ERDD-metal ion complexes were observed in the presence of Cu(II) ions. The most stable ERDD-Cu complex, however, was formed with 2 Cu(II) ions bound per ERDD.

INTRODUCTION

Techniques enabling the direct observation of sequence-specific peptide-metal ion interactions are essential if we are to understand fully how transition metal ions regulate biomolecular recognition events. We have demonstrated that peptide-metal ion complexes involving one or more N-ligands (His residues) or S-ligands (Cys residues) are stable to the volatilization and ionization processes associated with MALDI and ESI mass spectrometry; information regarding peptide-metal ion interaction stoichiometry, affinity, selectivity, and interaction mechanism(s) can be obtained (1-8).

We have now used MALDI-TOF and ESI to investigate the mechanism(s) by which Cu(II) ions interfere with cooperative hormone binding to the estrogen receptor protein dimer. To determine whether Cu(II) ions interact directly at the receptor dimer interface, a 53-residue portion of the human estrogen receptor dimerization domain was synthesized and evaluated by MALDI-TOF and ESI in the absence and presence of added Cu(II) ions.

EXPERIMENTAL

A 53-residue portion of the estrogen receptor dimerization domain (D473-L525) was prepared by solid phase chemical synthesis, purified, and characterized as described previously (4). There are 7 His residues and no Cys residues within the ERDD. MALDI was performed on a Vestec Model 2000 linear TOF mass spectrometer as described previously (1,5) using 2,5-dihydroxybenzoic acid as the matrix. Aqueous solutions of the ERDD were analyzed by ESI on a Vestec Model 201 single quadrupole mass spectrometer as described previously (5,6).

RESULTS

The synthetic 53-residue ERDD was determined to have a predominantly helical secondary structure by vacuum UV circular dichroism; the indicated structure was not altered in the presence of added Cu(II) ions. The determined molecular mass of the metal-free ERDD (6168.5 $\pm$ 0.5 Da), observed by both MALDI-TOF and ESI, was essentially the same as the calculated mass (6168.36 Da). Formation of stable ERDD-Cu complexes was confirmed by both MALDI-TOF and ESI. Up to 3 bound Cu were observed by MALDI-TOF. By ESI, relatively minor quantities of the ERDD were observed with as many as 4 to 5 bound Cu(II) ions, however, the ERDD with 2 bound Cu(II) ions represented the most abundant molecular ion observed in each charge state (5^+ to 9^+) (see Figure). The 7^+ charge state was the most abundant with and without bound Cu. The Cu-binding stoichiometry at saturation (2:1 Cu:ERDD) was also verified by spectrophotometric UV titration.

CONCLUSIONS

ERDD metal binding capacities indicated by MALDI-TOF and ESI, although not identical, were in general agreement with results obtained by traditional spectroscopic methods. The helical dimerization domain of the estrogen receptor protein readily binds 2 Cu(II) ions with apparently high affinity. In contrast to results obtained for the "zinc-finger" metal-binding structures within the DNA-binding domain of this protein (7), there was little or no evidence (ESI charge envelope or circular dichroism) for an alteration in ERDD conformation with bound Cu. Additional work is required to identify the specific residues involved.

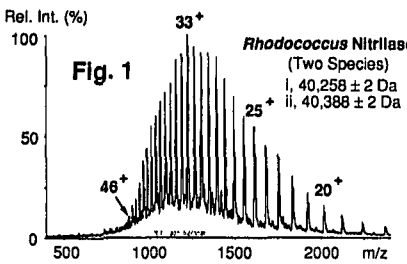
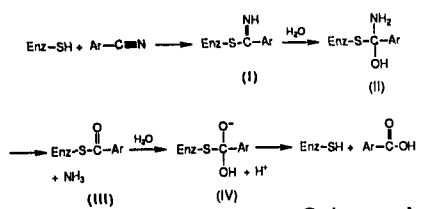
6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

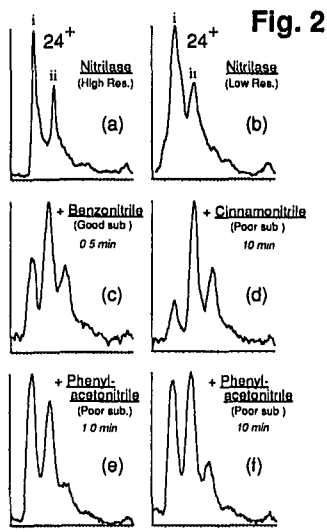
Enzymes greatly accelerate chemical reactions, often by many orders of magnitude. Highly specific enzyme reactions are involved in many biological regulation processes that ensure survival and well-being of the living species. Mechanisms and inhibitions of enzyme reactions constitute important aspects of enzymology and pharmaceutical research. Electrospray ionization mass spectrometry (ESI-MS), which offers high mass accuracy and is capable of studying biochemical systems in the near-physiological solution state, is opening up new windows to look into enzyme reactions.

Nitrilase hydrolyzes nitriles to their corresponding carboxylic acids. *Rhodococcus* nitrilase, made of two co-existing species (MW 40,258 and 40,388 Da, see Figs. 1 and 2a) of similar functions, catalyzes the hydrolysis of aromatic nitriles (Scheme I). ESI-MS detected the elusive intermediates of the catalysis reaction, i.e., the covalent complexes between the enzyme and various aromatic nitrile substrates (Figs. 2c-f). The enzyme was denatured by adding glacial acetic acid during the reaction with various substrates, thus trapping the intermediate enzyme-substrate complexes (either species I or III in Scheme I). The mass increases of the enzyme were consistent with the masses of the nitrile substrates. Since the measurements were done under denaturing conditions, the detected intermediates were most likely to be covalent in nature. No adducts were found if nitrilase was denatured before adding the substrates, indicating that the complex formation required an active enzyme. This also showed the observed adducts were indeed covalent, as the formation of non-specific noncovalent adducts would not depend on when the enzyme was denatured. Substantial amounts of the intermediates were trapped after 10-min incubation, even for the poor substrates whose nitrile-to-acid conversion took more than 24 hours (Figs. 2d and 2f). This showed that the rate-limiting step of the reaction was the breakdown of the intermediate complex, not the initial binding between the enzyme and the substrate.





Scheme I



ESI-MS was also used to provide insight into the mechanism of the inhibition of cysteine protease papain (MW 23,422 Da, full spectrum not shown) by a hydroxylamine derivative, $PhCH_2OCO$-Phe-Gly-NH-O-CO-(2,4,6-Me_3)Ph. It revealed that in addition to forming a novel covalent enzyme-inhibitor complex of sulfenamide (-CONH-S-) type with papain, the inhibitor also produced another major papain adduct 32 Da higher than the native enzyme. This adduct peak could be eliminated by including reducing agent DTT in the enzyme solution and removing the solution oxygen via nitrogen agitation prior to the addition of the inhibitor (see Fig. 3a, where the 19+ charge-state region is shown). This evidence suggested that the adduct was due to oxidation of the enzyme. Without DTT, even at 10:1 inhibitor/enzyme ratio the oxidation adduct was still the largest peak in the electrospray mass spectrum. This showed that the major contribution to the observed overall inhibition activity had come from the inhibitor-induced enzyme oxidation, as confirmed by other biochemical tests. Removing the solution oxygen however adding no DTT, another inhibitor-induced papain adduct 16 Da higher than the native enzyme was detected (Fig. 3b). Apparently this new adduct was the transient oxidation intermediate which was sensitive to both reduction and further oxidation. These experiments show that inhibition of papain by the peptidyl hydroxamate follows a complex mechanism of dual pathways (Scheme II), i.e., the inhibitor-induced oxidative inactivation and the usual active-site blocking by the inhibitor, and the former is far more competitive than the latter. The ESI-MS results also prove that the oxidation is stepwise via a transient intermediate.

In summary, ESI-MS provides exciting new means for characterizing enzymatic reactions. The high measurement precision and mass resolving power of ESI-MS are very valuable for probing the mechanistic details. The ability to study biochemical systems in the near-physiological solution state makes ESI-MS particularly suitable for catching the transient reaction intermediates.

Particle-Beam FAB-MS of Trypsin Generated a-Lactalbumin Peptidess

*Thomas C. Marecic and Samuel Mitrovich, Jr.
Extrel Corporation, Pittsburgh, PA 15238

INTRODUCTION

There is a definite need for a quick and relatively simple method to obtain molecular weight information from proteolytically produced mixtures of peptides. Such mixtures are easily separated by gradient HPLC and detected by UV absorbance. Unfortunately, a UV trace gives little structural information. What we have done is chromatographically separate, by gradient LC, a mixture of trypsin generated peptides and characterize them directly on-column by Particle-Beam FAB-MS. This was accomplished using standard WATERS HPLC pumps, standard bore columns and normal (0.8mL/min) flow rates. Solvent composition was water/acetonitrile with the aqueous load being 95%. Glycerol matrix was added post column. Molecular weights were obtained for all peptides within the range scanned (400-1800 amu). The weights obtained were confirmed by comparing to available sequence data. Particle-Beam FAB-MS can be used to confirm pnmary protein structure as well as a mapping technique This technique avoids the need for µ-bore columns and µL flow rates that are used in continuous flow FAB.

EXPERIMENTAL

Sample Preparation:

Alpha-lactalbumin at 5 mg/mL was disolved in ammonium formate buffer at pH 7.8 and trypsin was added to make the final concentration 10:1 (w/w). The digestion was stopped after 24 hours by the addition of formic acid. For this analysis 40 µL (14.4 nmoles) of digest was loaded on column.

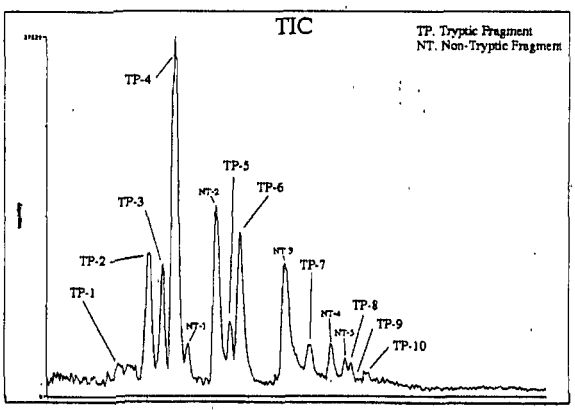
Liquid Chromatography:

WATERS 600MS pump with a 490 MS detector
WATERS C-18, 3.9 X 300 mm reverse phase column.
Water/ACN-95/5 to 40/60 , 30 min, linear grad., 0.4 mL/min.
Glycerol (1.0%) in MeOH added post column at 0.4 mL/min.

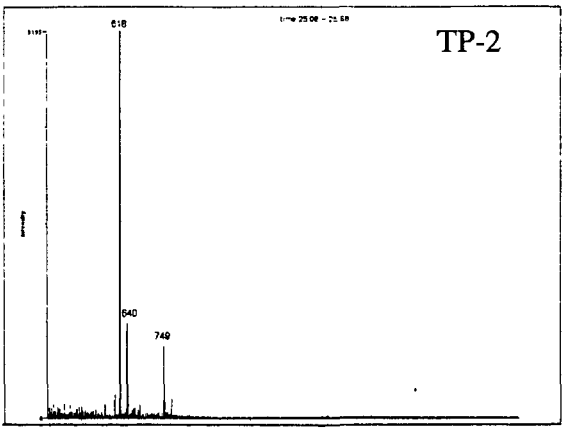
Mass Spectroscopy:

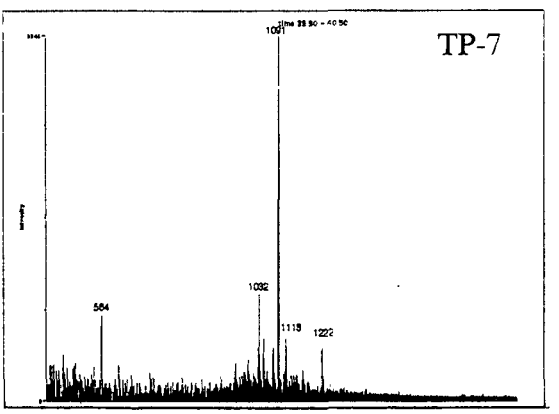
EXTREL ELQ-400 mass spectrometer.
ThermaBeam LC-MS interface.
Antex cesium ion gun power supply.

RESULTS



PEAK	$(M+H)^+$	SEQUENCE
TP-1	616	KILDK
TP-2	618	EQLTK
TP-3	708	ALBSEK
TP-4	488	ILDK
TP-5	607	IWBK
TP-6	711	BEYFR
TP-7	1091	LNQWLBEK
TP-8	1200	YGINYWLAHK
TP-9	1686	FLNNNLTNNIMBYK
TP-10	1204	LNQWLBEKL





CONCLUSION

- A standard trypsin digestion of alpha-lactalbumin was analyzed using ThermaBeam/FAB
- This analysis was accomplished using standard WATERS hardware (pumps and UV detector) and columns as well as standard gradient conditions and flow rates
- The solvents contained an ion-pairing reagent.
- Glycerol (FAB matrix) was added post column so as not to engender a change in LC conditions.
- Over the range scanned (400 to 1800 amu) there were 10 possible tryptic peptides. Masses were obtained for all. These masses matched predicted values
- Non-tryptic cleavages occurred- notably from a chymotryptic cleavage of one specific peptide. Chymotrypsin is a common contaminant of trypsin preparations- even those treated with TPCK.
- Monitoring a proteolytic digestion at the level of specificity shown here would be extremely difficult if not impossible using just traditional techniques
- This technique allows the use of traditional protein chemistry techniques with little or no modification. It is transparent.
- LC development can be done off line using a UV detector and easily switched on line to the mass spectrometer.
- A UV detector and mass spectrometer can be used in tandem to maximize the information obtained on any similar preparation.

MATRIX-ASSISTED LASER DESORPTION MASS SPECTROMETRIC ANALYSES OF RAT LIVER CYTOCHROME P450 2B1

*Sydell Lewis[+], Kunquan Yao[++], and Maria Almira Correia[++]
[+]Finnigan MAT, San Jose, CA 95134
[++]Dept. of Pharmacology & the Liver Center, UCSF, San Francisco, CA 94143

INTRODUCTION

Microsomal membrane bound Cytochrome P450's are hemoproteins that play pivotal roles in the oxidative/reductive metabolism of various physiologically relevant endobiotics and xenobiotics. These proteins have highly hydrophobic active sites designed to accommodate both the prosthetic heme and lipophilic substances.

It is now understood that certain substrates in the course of their metabolism destroy the participating P450 in a process classified as a mechanism-based or "suicide" inactivation. Thus some substrates are activated to products that alkylate the heme or the apoprotein, whereas others result in heme fragmentation to products that alkylate or acylate the apoprotein irreversibly. While the N-alkylated heme is amenable to isolation and structural characterization, the heme-alkylated/acylated apo-P450's have defied structural characterization. With the advent of two mass spectrometric ionization techniques: matrix assisted laser desorption (LDMS) and electrospray ionization (ESI), this problem can now be effectively circumvented. Indeed we have recently used ESI to structurally characterize a heme-alkylated active site apo-P450 2B1 peptide. (Yao, Falick, and Correia submitted FASEB J. 6 A1566 (1992).

In the present work we have begun to evaluate how well LDMS on a time-of-flight mass spectrometer can be applied to the characterization of both the native P450 2B1 protein and 2B1 peptide digests.

EXPERIMENTAL

Male Sprague Dawley rats were pretreated with sodium phenobarbital (80 mg/kg/day i.p.) for 5 days. P450 2B1 was purified from rat liver microsomes according to the procedure described by Waxman et.al. (J. Biol. Chem. 257:10446 1982). Inactivation of P450 was mediated with Cumene Hydroperoxide (CuOOH). Lysyl Endopeptidase-C Digestion was performed on both the native and CuOOH inactivated 2B1 protein. The mixture was incubated in the presence of 8M urea at 60° C for 30 min. Lysyl endopeptidase-C (Lys-C) was added to P450 2B1 at a molar ratio of 1/200. Samples were analyzed by matrix assisted laser desorption ionization (LDMS) on a Finnigan MAT LASERMAT™ time-of-flight mass spectrometer. Sinapinic acid was used as the matrix. One to ten picomoles of sample were analyzed. The native 2B1 digest and CuOOH inactivated digest were analyzed prior to separation by HPLC.

RESULTS AND DISCUSSION

Figure 1 is the LDMS spectrum of the native 2B1 P450 protein. This spectrum was obtained by averaging 5 laser shots in real time. The measured average mass was 56335 daltons. Due to its highly hydrophobic nature, the P450 2B1 protein is difficult to analyze. In addition, the protein was analyzed in the presence of 100 mM phosphate buffer and therefore required a relatively high laser power to obtain reasonable signal to noise.

Figure 2 is the LDMS spectrum from the native Lys-C digest mixture. This sample was analyzed in 0.1M Tris buffer, and 8M urea at pH 9. Ten peptides were identified.

Spectra obtained from analysis of the alkylated/acylated Lys-C peptide digest were more difficult to interpret. The residual inactivating constituents present in the sample caused suppression and peak broadening. However, a mass was observed which corresponded to the heme-alkylated active site apo-P450 2B1 peptide identified earlier. In order to improve upon the results obtained with these samples studies were performed on standards using other matrices

and internal standards . The spectra shown in figures 3 and 4 were obtained from the LDMS analysis of the same sample of fetuin Lys-C peptide digest in sinapinic acid and α-cyano, 4-hydroxycinammic acid (CHCA) (recently reported by Chait) . CHCA has also proved to work very well with bovine serum albumin (BSA) of MW 66420. As soon as new samples are available we intend to try analysis with CHCA and also use BSA as an internal standard.

CONCLUSIONS

1. The loss of electronic absorption spectrum of P450 and the HPLC chromatogram of the P450 digest monitored at 400 nm indicate that the porphyrin ring of the prosthetic heme of P450 2B1 was destroyed after incubation of the hemoprotein with CuOOH.
2. LDMS analysis can be successfully performed on the native P450 2B1 protein which is highly hydrophobic and difficult to analyze by other methods.
3. The native Lys-C digest of P450 2B1 is also amenable to LDMS analysis. However, the inactivated digest was difficult to analyze because of the presence of buffers and other interfering constituents. It was therefore not possible to ascertain if modification of the P450 2B1 peptides occurred.
4. New matrices and the use of internal standards could improve LDMS analysis of P450 2B1 protein digests and other P450's. These techniques will be tried as soon as new samples can be generated.
5. The quality of LDMS spectrum with regard to resolution, baseline and mass accuracy is very dependent upon the matrix used.

Analysis by FAB-MS of the PKA and PKC Phosphorylation Sites in the Linker Region of Mouse P-glycoprotein.

P. Browne, E.K.-H. Han, E. Nieves*, S.B. Horwitz and G.A. Orr
Albert Einstein College of Medicine; Bronx, N.Y. 10461

Tumor cells that are grown in culture and selected for resistance to a hydrophobic chemotherapeutic agent of natural product origin may develop a cross-resistance to a variety of structurally and functionally unrelated compounds. Such cells have developed the multidrug resistance (MDR) phenotype that is characterized by the overproduction of a plasma membrane glycoprotein termed P-glycoprotein (P-gp; see 1,2). P-gp (140 - 170 KDa, approximately 1280 residues) consists of a small family of highly related glycoproteins. P-gp is encoded by two classes of *mdr* genes, 1 and 2. In human, there is one member of each class, whereas in mouse there are two members (*mdr* 1a and *mdr* 1b) in class 1 and one member in class 2. Human MDR1, mouse *mdr*1a and mouse *mdr*1b encode proteins capable of mediating MDR. The function of the class 2 genes is not known. Sequence analysis of the mdr genes indicates that they are composed of two homologous halves, each containing a nucleotide binding consensus sequence. Hydropathy plot analysis suggests that each half of P-gp has 6 transmembrane spanning domains with both the N- and C- termini having a cytoplasmic orientation. The two homologous domains are separated by an intracellular linker region. Studies indicate that P-gp is an energy-dependent drug efflux pump with a broad specificity for hydrophobic compounds. Little information exists on the regulation of P-gp or the mechanism by which it pumps drugs out of the cell.

P-gp is phosphorylated *in vivo* and attempts have been made to explain the role of phosphorylation/ dephosphorylation in regulating the activity of the pump. Several serine/threonine kinases including protein kinase A (PKA), protein kinase C (PKC) and protein kinase P have been implicated in the phosphorylation of P-gp. P-gp contains PKA consensus sites in the linker region. However, the role of phosphorylation in P-gp function and regulation remains unresolved, and the phosphorylation sites within P-gp are poorly defined.

Our objective was to use FAB mass spectrometry to map the sites of PKA and PKC phosphorylation in synthetic peptides corresponding to segments of the linker region of mouse P-glycoproteins encoded by *mdr*1a and *mdr*1b.

The *mdr*1a (RSTRKSICGPHDQDRKLST) and *mdr*1b (SIYRSVHRKQDQERRLSM) peptides were synthesized by the Einstein Laboratory for Macromolecular Analysis. The *mdr*1a and *mdr*1b linker region peptides were phosphorylated by either PKA or PKC. Spectra of samples were obtained on a Finnigan MAT-90 at a resolution of ~1400 in the positive ion mode and scanned from 300 or 400 to 3000 at 10 sec/ decade. FAB was used for sample desorption and ionization. Samples of peptides, 1-2 uL, were added to 1 uL of matrix, 1% TFA in monothioglycerol, on a static probe. The spectra of the non-phosphorylated and phosphorylated *mdr*1b peptide is shown in Figure 1. There was no evidence for the incorporation of additional phosphate groups (indicated by an increase of 80 amu) into either peptide. Upon treating the phosphorylated peptides with alkaline phosphatase, FAB-MS revealed the loss of the $(M+H)^+$ ion for the phosphorylated peptide and the reappearance of the $(M+H)^+$ for the parent peptide. The phosphorylated peptides were digested with V8 protease and/or trypsin to determine the actual site of modification. The results for the *mdr*1a peptide are presented in Table 1.

An ion at m/z 742.5 was obtained for the V8 protease digestion of the PKA phosphorylated *mdr*1b peptide, corresponding to V8 fragment RRLSM plus 1 phosphate. The ion for the N-terminal V8 fragment for this peptide was not detected. But, from the tryptic digestion we were able to show that the other two serines were not phosphorylated by PKA.

From the PKC phosphorylation of *mdr*1b, ions at m/z of 662.2 (RRLSM) and 1726.1 (SIYRSVHRKQDQE + 1 phosphate) were obtained, after V8 digestion, indicating that PKC was not utilizing the PKA site. Upon further treatment with trypsin, ions at m/z of 538.3 (SIYR) and 578.3 (SVHR + 1 phosphate) were obtained.

A similar analysis was performed on the PKA or PKC phosphorylated *mdr*1a peptide and the results are presented in Table 1. With *mdr*1a, both PKA and PKC phosphorylated the same serine residue (RKSI). Under these conditions there was no evidence that PKA phosphorylated the sequence RKLSM which corresponds to the PKA site in *mdr*1b.

The PKA and PKC phosphorylation sites found *in vitro* do not necessarily imply that these sites are utilized *in vivo*. Also, there are other serine/threonine residues present in the linker region of P-gp which can serve as potential sites for phosphorylation *in vivo*. Here we show that FAB MS can be used to map precisely the phosphorylation sites of P-gp and to determine the differences of the phosphorylation site(s), if any, between *mdr*1a and *mdr*1b. The ability to determine the phosphorylation sites in *in vivo*-derived P-gp peptides allows one to use site-directed mutagenesis to evaluate which site(s) is/are important for the regulation

TABLE 1
Ions observed from tryptic fragments of PKA and PKC phosphorylated mdr1a.

	MH^+	PKA	PKC	Sequence
T1	175.1	-	-	R
T2	363.2	ND	ND	STR
T3	147.1	-	-	K

APPLICATION OF MASS SPECTROMETRY FOR IDENTIFYING MODIFICATIONS OF HUMAN SERUM ALBUMIN EXPOSED TO HYDROGEN PEROXIDE

Jeffrey W. Finch[1], Kevin L. Schey[1], Daniel R. Knapp[1], and Rosalie K. Crouch[2]
Departments of Cell and Molecular Pharmacology[1] and Ophthalmology[2]
Medical University of S.C., 171 Ashley Ave., Charleston, SC 29425

Introduction: Human serum albumin (HSA, mw 66,439) contains 17 disulfide bridges and a single free sulfhydryl group, Cys^{34} (1). Albumin has been proposed to serve as a sacrificial antioxidant in biological systems subject to attack by oxygen radicals from hydrogen peroxide (2). In the rat and human cornea, albumin has been shown to be oxidized by H_2O_2, and a role for albumin as an antioxidant has been proposed for this system (3). This finding is of clinical importance concerning the widespread use of contact lens disinfecting solutions containing 3% hydrogen peroxide.

In assessing antioxidant activity of albumin, Radi et al. indirectly studied oxidation of the free thiol group on bovine serum albumin (BSA) incubated with hydrogen peroxide (4). Short incubation periods resulted in a 44% loss of thiol groups which were arsenite-recoverable (suggesting RSOH formation), while longer incubation periods resulted in nonrecoverable loss of thiols (suggesting formation of biologically irreversible RSO_2H and RSO_3H). The purpose of our study was to confirm by mass spectrometry that Cys^{34} of HSA is oxidized by hydrogen peroxide, to identify other sites of oxidation, and to assess the extent of oxidation for these sites.

Experimental: Fatty-acid free HSA (30 nmol) was incubated with 1.5 % H_2O_2 for 4 hr, and H_2O_2 was removed by ultrafiltration. Native HSA or oxidized HSA was reduced, carboxymethylated, and cleaved with trypsin (substrate/enzyme 100:1). Reversed-phase HPLC analysis of the tryptic digests of native and oxidized HSA was carried out using a Vydac C_{18} column (250 x 4.6 mm), monitoring absorbance at 214 nm. The column was held for 5 min at 100% solvent A (H_20 + 0.10% TFA) and ramped with a linear gradient to 70% solvent B (CH_3CN + 0.84% TFA) at 90 min, with a 0.5 ml/min flow rate. Liquid SIMS analysis using a glycerol/NBA matrix was carried out with a JEOL JMS-HX110/HX110 four sector tandem mass spectrometer. A Cs^+ source operating at 25 kV was used with MS1 operating at a full accelerating voltage of 10 kV, and a resolution of 3,000. Electrospray MS spectra were recorded on a Nermag R30-10 triple quadrupole instrument, equipped with a custom electrospray interface. A needle potential of 4.3 kV was employed with the capillary held at 250 V and heated to 100 °C. HPLC fractions containing oxidized peptides were analyzed by manual Edman degradation/MS using a modified procedure of Tarr (5).

Results: After analyzing the individual HPLC fractions from the tryptic digest of native HSA by ESI and LSIMS, approximately 72% (based on amino acid count) of the protein sequence was mapped. Mass analysis of tryptic peptides in HPLC fractions eluting near the end of chromatograms (Figure 1) from normal HSA and oxidized HSA digests, revealed that Cys^{34} had been oxidized to cysteic acid and that methionine residues were oxidized to methionine sulfoxide. However, extent of oxidation for each residue varied depending on location in the protein sequence. A summary of the reversed-phase HPLC and MS data obtained for each peptide containing an oxidation site is shown in Table 1. Extent of oxidation for residues in HSA was assigned a value on a scale of 1 to 5 (1-lowest, 5-highest extent of oxidation), based on the relative $(M + H)^+$ ion intensities from LSIMS data of tryptic peptides from HSA treated with peroxide. For Cys^{34}, the ion signal of the oxidized peptide was half the intensity of the peptide containing the unmodified residue (rating: "1"), indicating only partial oxidation of this residue. In contrast, the MS data indicated that extensive oxidation of Met residues occurred (with ion intensities of peptides containing oxidized Met a factor of 5 or greater than the corresponding peptides containing unmodified Met) for HSA exposed to peroxide, with essentially complete oxidation of Met^{548} (rating: "5"). The identity of peptide sequences containing oxidized residues was confirmed by manual Edman/MS analysis.

Conclusions: For HSA exposed to 1.5% H_2O_2 for 4 hr, five sites of oxidation have been identified: Cys^{34}, Met^{123}, Met^{298}, Met^{446}, and Met^{548}. It is likely that the other two methionine residues, Met^{87} and Met^{329} are also oxidized; however, no ion signals were detected for peptide sequences containing these residues in the tryptic digest of oxidized HSA. We estimate that only one-third or less of the free Cys^{34} groups are oxidized, which supports the theory that this residue is located within a hydrophobic cleft of the protein (6). Oxidation of the Met residues is extensive and varies with location in the protein, suggesting a relationship between oxidation of these residues and protein three-dimensional structure. Extensive oxidation of Met residues suggests that these groups could play a role in determining antioxidant properties of HSA and other proteins.

The combination of HPLC and MS analysis is effective in locating oxidation sites in proteins such as HSA which have been exposed to H_2O_2 and oxygen radicals. This approach should prove useful in examining alterations of HSA in the cornea under conditions of high oxidant stress, such as the case of prolonged exposure to peroxide from contact lens disinfecting solutions. In addition, the application of mass spectrometry to study alterations of proteins in cells and tissues exposed to high oxidant stress could be useful for assessing damage to the biological system and for identifying proteins which can act as sacrificial antioxidants.

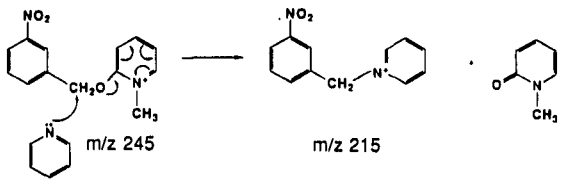
2-Fluoro-1-Methylpyridinium Tosylate and N-Chloroformyl Betainyl Chloride as Derivatization Reagents for FAB

Samuel A. Testino, Jr., Kenneth L. Busch, and John N. Haseltine
School of Chemistry and Biochemistry
Georgia Institute of Technology
Atlanta, Georgia 30332-0400

Fast atom bombardment mass spectrometry (FAB-MS) has been shown to provide high quality mass spectra for compounds that are present in the matrix as ionic species. Therefore, biological molecules are often reacted with a derivatization reagent to produce a charged species prior to FAB-MS analysis. We have been investigating the utility of two compounds, 2-fluoro-1-methylpyridinium tosylate (FMP) and N-chloroformyl betainyl chloride (CFBC), as derivatization reagents for FAB-MS. FMP and CFBC react with hydroxyl, sulfhydryl, and amino groups, in the presence of a base catalyst, to produce charged quaternary ammonium derivatives.

FMP Reaction with m-NBA. In the process of performing derivatization experiments with FMP, it was observed that a lavender solution resulted upon the addition of the derivatization mixture to a m-NBA matrix. Consequently, the reaction of FMP with m-NBA in the presence of pyridine as a base catalyst was investigated to identify any artifact peaks in the FAB mass spectrum associated with this reaction. The positive ion FAB mass spectrum of the lavender solution showed initial evidence of the N-methylpyridinium derivative of m-NBA at m/z 245. Interestingly, this solution changed color, and its FAB mass spectrum changed, over a period of a few hours at room temperature. The lavender solution faded to orange, and finally yellow, as the pyridine acted as a nucleophile to produce the final product ion at m/z 215.



FMP Derivatization of an Alkanethiol. Alkanethiols have been used to immobilize DNA onto a gold surface for subsequent analysis by scanning tunneling microscopy [1,2]. The reliability and reproducibility of the DNA image obtained is dependent on the purity of the thiol used for immobilization - even only slightly impure thiols can give rough surfaces in the imaging area. Recent images acquired by Bottomley using octadecylthiol as the DNA linker showed "pinpoint" defects suggesting that the thiol used was impure. Electron ionization and FAB of the thiol provided evidence for a disulfide impurity, but no clear evidence for the presence of thiols of varying chain lengths. After FMP-derivatization, however, a more conclusive identification of the impurities present in the octadecylthiol was made by a parent ion scan of m/z 126, a characteristic fragment ion of FMP-derivatized thiols (Figure 1). Thiols possessing 2 carbons up to 19 carbons could be identified. These thiols have the general formula $C_nH_{2n-1}SH$ and, therefore, must contain one double bond.

CFBC Derivatization of Cholesterol. Many compounds do not give a strong signal for the molecular ion in FAB-MS. In some cases, this can make it difficult to assign the correct molecular weight to the compound. Such is the case with cholesterol. The major peak due to cholesterol in its FAB mass spectrum in a m-NBA matrix is due to a loss of water from the parent molecule (m/z 369). The most abundant peak in the molecular ion region is $(M\ \ )^+$ (m/z 386), and not $(M+H)^+$, as is common in FAB. In contrast, the positive ion FAB mass spectrum of the CFBC-cholesterol derivative is much simpler (Figure 2). The peak at m/z 487 is due to the CFBC-cholesterol derivative. A parent ion scan of m/z 118, a fragment ion characteristic of CFBC-derivatized alcohols, aided in confirming this assignment.

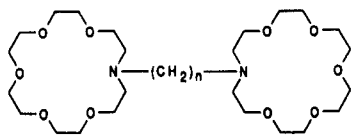
FAB/MS Analysis of Novel Synthetic Bola-amphiphiles and their Interactions with Cations

Bert C. Lynn, Jr.,* Jesus Mallen, and George W. Gokel
Department of Chemistry, University of Miami, Coral Gables, FL 33124 U.S.A.

Bola-amphiphiles are compounds that contain two polar head groups at opposite ends of one or more connecting chains. The chains are nonpolar and the compounds are thus amphipathic. Such structures can be represented as O———O in which the circles stand for polar head groups. The schematic suggests the origin of the name: a bola is a South American weapon in which two leather balls are connected by a string. A traditional amphiphile could be represented as O———; such compounds can form bilayers by interdigitation of the hydrophobic tails. Because there are polar head groups at both ends of a bola-amphiphile or bolyte, the compounds are capable of forming monolayer, rather than monolayer, membranes. A variety of head groups have been utilized but the first example of crown-ether-containing bolytes has been recently reported from our laboratory. These novel structures form a previously unknown type of vesicles (niosomes, bola-amphisomes)[1] but their interactions with cations have not been assessed. The FAB/MS technique presented an excellent opportunity to examine the interplay of several covalently connected macrorings with single and multiple cations.



Where n = 10, 16, or 22

Synthetic access was gained to the simple bolytes such as [aza-18-crown-6]–$(CH_2)_{10}$–[aza-18-crown-6] by formation of the amides (azacrown + diacid chloride) followed by reduction ($LiAlH_4$/THF).[1] Preparation of the *tris*(bolytes) or "double-bolas" involved more elaborate methods that will be reported in due course. The FAB mass spectra were acquired on a VG Trio 2 mass spectrometer. Samples were desorbed from *m*-nitrobenzyl alcohol matrix using a 6.5 kV xenon atom beam. For the complexation studies, an appropriate concentration of cation in methanol, the selected bolyte, and the matrix were mixed on the FAB probe. The CAD spectra were acquired on a VG Trio 3 mass spectrometer using source conditions identical to those described above. The collision gas (Ar) pressure was varied from 0.5 to 2.0 mbar and the collision energy was varied from 5 to 50 eV (lab frame).

We have previously shown that the FAB/MS technique is applicable to complex macrocyclic compounds[2] and, indeed, that cation binding constants may be estimated from the data. The FAB spectra of the bolytes were dominated by $[M+H]^+$ and $[M+2H]^{++}$ ions. Addition of cations (C) produced $[M+C]^+$, $[M+H+C]^{++}$, and $[M+2C]^{++}$ ions subject to the cation concentration (see Fig. 1). Unexpectedly, addition of an excess of cation produced ions consistent with $[M+C+C{\bullet}A]^+$ where C•A represents the source of the cation. The $[M+C+C{\bullet}A]^+$ ions were observed with the following salts: KNO_3, KSCN, KCl, and $KClO_4$. CAD analysis indicated that the only product of $[M+C+C{\bullet}A]^+$ was $[M+C]^+$ (elimination of the salt). No doubly-

charged ion was observed perhaps reflecting the binding energy of salt versus cation complexation by the macrocycle. The FAB spectrum of the tris(bolyte) not only contained the unusual $[M+C+C{\cdot}A]^+$ ions, but also contained $[M+C+2(C{\cdot}A)]^+$ ions. FAB analysis of the channel-forming compound, which schematically has the structure ———O———O———O———, showed that a complex with a single K^+ predominated even though multiple binding sites are present. This suggests that the molecule may, in the gas phase, fold into a "channel-like" conformation as presumed for the membrane-bound system.[3]

Structural Analysis, Biosynthesis, and Activities of a Novel Class of Antimicrobial Peptides from the Skin of *Bombina orientalis* (or Asian Toad)

B.W. Gibson*, D. Tang, N. Phillips, D. Medzihradszky, M. Tullius, R. Mandrell
University of California, San Francisco, CA 94143-0446
and
M. Kelly and E.R. Spindel
Oregon Regional Primate Center, Beaverton, OR 97006.

We have recently isolated and sequenced several peptides from the skin secretions of the Asian Toad (*Bombina orientalis*) using a combination of HPLC/MS, LSIMS, electrospray MS and MS/MS techniques. Five of these peptides were found to be amphipathic, cationic peptides of 25-27 amino acids in length. All of these peptides have sequence similarity to the magainin class of antimicrobial peptides [1,2] and bombinin [3], a peptide first isolated over 20 years ago but thought to possess undesired hemolytic activities. The sequence of the most abundant member (bombinin-like peptide-1, or BLP-1) is as follows:

Gly-Ile-Gly-Ala-Ser-Ile-Leu-Ser-Ala-Gly-Lys-Ser-Ala-Leu-Lys-Gly-Leu-Ala-Lys-Gly-Leu-Ala-Glu-His-Phe-Ala-Asn-NH_2

Sequence analysis of these peptides were carried out using a Kratos Concept 11HH four-sector mass spectrometer. Unfortunately, the data contained in the MS/MS spectra were not sufficient to completely sequence these large peptides. However, after endoproteinase Lys-C digestion of these peptides and HPLC separation, the resulting four peptides produced by cleavage of three internal lysines gave excellent CID spectra that allowed for the unambiguous assignment of the all amino acids, including the six Leu/Ile residues. Subsequent cloning of the precursors encoding these peptide confirmed the accuracy of our sequence determinations [4].

The BLPs have been assayed for antibiotic and hemolytic activity and found to be more potent than magainin (a related antimicrobial peptide from *Xenopus laevis*) in their ability to kill bacteria. However, no significant hemolytic activity was found for these peptides which suggests a selectivity for prokaryotic over eukaryotic membranes. The molecular basis for antibacterial activity is presumed to be due to their predicted amphipathic α-helical structures which is supported by circular dichroism measurements that found significant helical content (63-69% α-helix) in trifluoroethanol. A cDNA library was also constructed from the skin of *B. orientalis* and screened with an oligonucleotide probe complementary to the C-terminus of BLP-1. Several clones were isolated and sequenced, and each precursor was found to encode two BLP peptides.

In addition to the BLPs, a second family of hydrophobic peptides were predicted to exist based on known processing signals contained in these precursor polypeptides at their C-termini. Their presence was confirmed after an ethanol extraction of the amphibian secretions was carried out, greatly enriching the concentrations of these highly hydrophobic peptides. MS/MS analysis of the intact peptides gave excellent CID spectra in all cases, but gas phase Edman sequencing failed after 4-5 cycles, presumably due to hydrophobic wash out. FMOC synthesis of one of the major peptides in this group,

Ile-Leu-Gly-Pro-Ile-Leu-Gly-Leu-Val-Ser-Asn-Ala-Leu-Gly-Gly-Leu-Leu-NH_2

allowed us to carry out extensive physical characterization studies. Our preliminary results indicate that these peptides form α-helices in trifluoroethanol, but appear to form type II β-turn structures in non-helix inducing solvents. Further studies are in progress to assay the biological activities of this novel hydrophobic class of amphibian peptides, which may suggest therapeutic applications.

This work was supported by NIH grants RR01614 and CA39237, and support from the NSF instrumentation program for purchase of the tandem mass spectrometer.

FURTHER DEVELOPMENTS OF CAPILLARY GAS CHROMATOGRAPHY - CHEMICAL REACTION INTERFACE / MASS SPECTROMETRY USING A BENCHTOP GC/MS

Donald H. Chace, Diane S. Roe, and David S. Millington, Department of Pediatrics, Division of Genetics and Metabolism, Duke University Medical Center, Durham, N.C. 27710

Chemical reaction interface mass spectrometry (CRIMS) is a technique for selective detection of substances enriched with stable isotopes[1-2], radioactive isotopes [3] and certain elements [4]. This technique utilizes a microwave-powered cavity that completely decomposes a substance to its elements in the presence of an excess of a reactant gas resulting in the formation of stable polyatomic species containing 2-5 atoms. The composition of these species reflects the elemental content of the original substance. The stable isotopes, ^{13}C, ^{15}N, and $^{2}H(D)$, are often used as tracers in biochemistry and pharmacology to study endogenous and exogenous metabolism of specific substrates. These isotopes can be utilized in a qualitative manner (to find new metabolites) or to obtain quantitative information (metabolite kinetics, estimation of pool sizes). Conventional GC/MS techniques measure the ratio of labeled molecular species $(M + X)^+$ to unlabeled molecular species M^+ where X is the number of isotopes (^{13}C, ^{15}N, ^{2}H) added to the molecule. These methods are structure dependent and lack generality since the molecular species must be known and abundantly produced. It is often difficult to determine the relative contribution of isotopes when more than one type is present in the same molecule. These limitations do not apply to CRIMS. The technique is versatile in that conventional GC/MS can be performed by simply turning off the microwave power. In a previous study [2], isotope dilution techniques using CRIMS were developed on a magnetic sector instrument. In the present study, similar experiments were performed to evaluate a benchtop GC/MS.

(2-^{13}C,^{15}N)-glycine (MSD isotopes, 99 atom %) was added to unlabeled glycine to produce mole ratios ranging from 0.009 - 0.974. Leucine was added as an external control. Samples were prepared by methylation using 3 N methanolic HCl followed by N-acylation using heptafluorobutyric anhydride. One μL of each derivatized mixture was analyzed by GC-CRIMS in duplicate. The quantity of unlabeled glycine injected was either 6.5 or 0.65 nmol. In the same injection, the quantity of leucine was either 3.8 or 0.38 nmol. The operation of GC-CRIMS is described in detail elsewhere [1]. The microwave power is transmitted by a microwave cavity (Vestec Corporation, Kirby TX) similar to a design previously reported [1]. This cavity is powered by a Model MPG-4 100W, 2450 MHz microwave supply (Opthos, Rockville, MD). A Hewlett Packard Model 5890 gas chromatograph equipped with a split/splitless injector was used with a 30 m DB-1, 0.25 mm i.d., 1.0 μm film thickness, capillary column (J&W Scientific, Folsom CA). Sulfur dioxide (Matheson Gas Products) was used as the reactant gas. The capillary gas chromatograph and CRI was connected to a Trio-1000 benchtop quadrupole mass spectrometer (FISONS-VG). The parameters for data acquisition were the same for all experiments. Selected ion monitoring was performed at *m/z 44, 45, 30, and 31* with a total cycle time of about 0.8 sec (0.2 sec/mass, interchannel delay 0.01 sec).

Detection of ^{13}C and ^{15}N enrichment was achieved using SO_2 as the reactant gas and monitoring $^{12}CO_2$ at *m/z* 44, $^{13}CO_2$ at *m/z* 45, ^{14}NO at *m/z* 30, and ^{15}NO at *m/z* 31. Mole ratios of labeled to unlabeled glycine were calculated for each standard mixture. The calculated isotopic abundance ratio of $^{13}CO_2/^{12}CO_2$ was obtained from the theoretical ratio of atoms of ^{13}C and ^{12}C present in the mixture of labeled and unlabeled derivatized glycine. Experimental APEs were calculated from the areas of peaks in the ion current chromatograms. The isotopic abundance ratio of $^{13}CO_2$ to $^{12}CO_2$ was measured experimentally by peak areas for glycine mixtures at two concentrations. These data were combined and a linear regression analysis performed. These results are shown in *Figure 1.* The correlation coefficient of the entire data set was 0.999 with a slope of the regression of 1.028 and an intercept of 0.001. These data show excellent accuracy (a slope of 1 and intercept of 0 represents 100% accuracy for this analysis). As shown in Table 1, the limit of detection for enriched glycine at 6.5 nmol of unlabeled glycine was equivalent to 0.26 atom % excess (APE) or a mole ratio of 0.024. For 0.65 nmol of glycine, the APE was 2.84 or a mole ratio of 0.24. The mean coefficient of variation of duplicate analyses was 4%. The coefficient of variation for the isotopic abundance ratio of $^{13}CO_2/^{12}CO_2$ for the analysis of 18 replicate injections of 3.8 nmol of unenriched leucine was 5% (0.0122 ± 0.0006) and of 10 replicate injections of 0.38 nmol of unenriched leucine was 7% (0.0116 ± 0.0008). For this example, 5 standard deviations above the mean accounts for greater than 99% of all measurements for leucine at

natural abundance. Therefore, the predicted minimum detectable enrichment of ^{13}C is 0.15 APE. This prediction correlates well with the experimental limit of detection of 0.26 APE.

CRIMS has been shown to accurately quantify the ^{13}C atom percent excess of labeled glycine with a high degree of precision using a "benchtop" GC/MS. The ability to detect an excess of ^{13}C present in a molecule is in part based on the ability to make precise measurements. Replicate analysis of unenriched leucine predicted a minimum detectable enrichment of 0.15 APE for ^{13}C. The experimental natural abundance of $^{13}CO_2$ from leucine analysis was equal to the calculated natural abundance within experimental error. These data (accuracy and precision) are an improvement of those previously reported using a magnetic sector instrument.

Investigation of the Thermal Decomposition of 13-C,15-N Isotopic Labeled Algae with Pyrolysis Mass Spectrometry

Robbins R.C., Harper A.M., U.S. Army, Chemical Research and Development Center, Edgewood, MD 21010-5423

INTRODUCTION

Isotopic labeling of chemicals has been traditionally used in mass spectrometry to profile reaction mechanisms. However, most studies have been limited to compounds of relatively low molecular weight. For very large and complex mixtures, chemical exchange of labeled nuclei might occur which would limit the value of data.

OBJECTIVE

In this experiment, the degree of chemical exchange during pyrolysis of labeled algae is examined. Curie point pyrolysis and molecular beam pyrolysis were investigated to determine the extent of isotopic scrambling.

PROCEDURE

A test matrix was setup using unlabeled algae, 13-C labeled algae, 15-N labeled algae, 13-C,15-N labeled algae and poly vinyl chloride. Curie point pyrolysis was carried out using 661 degree centigrade wires. Samples were suspended in methanol and 3 micrograms samples were applied to the wires. The heated atmospheric pressure helium pyrolysis (Molecular Beam Mass Spectrometry) were carried out with the same test matrixes as above. Samples of 3 milligrams were loaded into quartz boats and heated to 660 degrees centigrade in a stream of helium. Both series of experiments were carried out on Extrel triple quadrupole mass spectrometers. The labeled algae of greater than 95% isotopic purity, was purchased from Merck Co.

DISCUSSION OF RESULTS

Molecular beam MS of unlabeled algae showed clusters of ions around m/Z 55, 69, 84, 98, 111, 124, 138, 151, 166 and predominate peaks at m/Z 185, 186, 213, 227, 256. Peak shifts from 3 to greater that 10 amu for the correlated clusters are observed in the pyrolysis spectrum of 13-C-labeled algae.

However, the molecular beam pyrolysis mass spectrum of the algae-pvc mixture was compared with a computer generated linear combination of pvc and algae pyrolysis spectra, and the difference spectra of the two might be interpreted to indicate the presence isotopic scrambling around m/Z 125, 137, 151, 178 and 213.

CONCLUSION

Preliminary data analysis indicates that no isotopic occurs during Curie point and molecular beam pyrolysis of binary mixtures of labeled and unlabeled algae. Isotopic scrambling was not observed in Curie point pyrolysis of the algae-pvc mixture. This data suggests that conditions during molecular beam pyrolysis might vary from Curie point pyrolysis and allow for nuclear exchange. However the influence of pvc is uncertain and will be investigated in future studies.

ACKNOWLEDGEMENT

GC/MS Investigation of the Glutamic Acid to Proline Pathway in *Lemna minor* using ^{13}C and ^{15}N Isotopic labeling

Connie C. Bonham, Karl V. Wood and David Rhodes
Dept. of Biochemistry (C.C.B.), Dept. of Chemistry (K.V.W.) and Dept. of Horticulture, Purdue University, West Lafayette, IN 47907

INTRODUCTION

The pathway of proline biosynthesis from glutamate in bacteria involves the catalytic action of three enzymes; γ-glutamyl kinase, γ-glutamylphosphate reductase, and Δ^1-pyrroline-5-carboxylate (P5C) reductase (Adams and Frank, 1980). Although P5C-reductase has been characterized from higher plant tissues (LaRosa *et al*, 1991), and ^{15}N tracer studies strongly suggest that glutamic acid is the nitrogen donor for proline in higher plant cells (Rhodes *et al*, 1986), it is only recently that the gene encoding a putative bifunctional γ-glutamyl kinase and γ-glutamylphosphate reductase has been cloned from higher plant sources (Garcia-Rios *et al*, 1991). We here present ^{13}C and ^{15}N tracer evidence confirming a precursor-product relationship between glutamate and proline in a higher plant.

EXPERIMENTAL

A steady-state pulse-chase experiment with $^{13}CO_2$ and $^{15}NH_4^+$ as isotopic tracers was used to probe the glutamic acid to proline pathway in *Lemna minor*. Plants were grown in a carbon-nitrogen stat device (Sims *et al*, 1990). Time-courses of isotopic labeling of $^{13}CO_2$ of the gas phase of the vessel, and $^{15}NH_4^+$ of the growth medium are shown in Fig. 1. Samples of plant tissue were removed from the vessel at various time intervals during this labeling experiment, and amino acids were isolated, purified by ion exchange chromatography and derivatized to N-heptafluorobutryl isobutyl (N-HFBI) derivatives as described by Rhodes *et al* (1986). Gas chromatography-mass spectrometry of major fragment ions containing the nitrogen moiety and various carbon moieties of the derivatives of the amino acids was then used to determine isotopic labeling. All mass spectra were obtained on a Finnigan 4000 mass spectrometer equipped with a Hewlett-Packard 5890 Series II gas chromatograph. The samples were injected on to a DB1, 30 m x 0.25 mm column, programmed from 100°C for 4 min to 240°C at 10°C/min. Electron impact spectra of the major fragments were obtained by scanning from 220 to 320 amu. Fig. 2 shows the observed time-course of labeling of the M - α-carboxyl (4C + 1N) fragment ion of glutamate which would be expected to serve as carbon and nitrogen donor of the M - α-carboxyl (4C + 1N) fragment ion of proline, assuming operation of the glutamate ---> proline pathway. Fig. 3 shows the observed labeling kinetics of proline, and the best-fit computer simulated labeling patterns using the model which assumes that glutamic acid is the precursor of proline (via neglible pools of intermediates). The model was executed by iteratively varying the turnover rate (R) of the metabolic pool of proline, and the fraction of the total proline pool localized in a metabolically inactive storage pool (S). Goodness-of-fit was determined by computing total sums of squares (TSS) of differences between observed and simulated values, at each combination of R and S tested. Fig. 4 illustrates that TSS is minimized (see arrow) when the metabolic pool of proline is envisaged to be turning over at a rate of 90%/h (R = 90), and when the storage pool of proline is envisaged to be 30% of the total proline pool (S = 0.3).

CONCLUSIONS

We conclude that free proline must exist as two discrete pools in *Lemna minor*, one which behaves as a product of glutamate, and a second which is metabolically inactive. The latter pool may be localized in the vacuole. This method may be of general utility in exploring precursor-product relationships in plant amino acid metabolism, and quantitatively determining the fluxes via (and degree of compartmentation of) amino acid pools *in vivo*.

KINETIC ANALYSIS OF UREA COMPARTMENTS IN END-STAGE RENAL DISEASE PATIENTS USING STABLE ISOTOPE-LABELED UREA

Fred Abramson, Philip Pearson, Susie Lew, and Juan Bosch
George Washington University School of Medicine and Health Sciences
Departments of Pharmacology and Medicine, Washington DC 20037

INTRODUCTION

Modern dialysis procedures are capable of rapid removal of urea so that the time required to cleanse a patient's blood can be reduced from six hours to two or less. This represents urea clearances of 500 mL/min or more. Under these conditions, the limited diffusion of urea from less accessible compartments in the body reduces the overall efficiency of a dialysis procedure. The purpose of this study was to determine the volumes of the readily accessible and less accessible urea compartments as well as the rate constants for diffusion between them.

EXPERIMENTAL METHODS

Patients and protocol: Seven patients with end-stage renal disease and five normal control subjects were used. Each was given 100 mg of $^{15}N_2$-^{13}C-labeled urea (MSD Isotopes) in 5 mL saline as a 2 minute infusion. Blood samples were collected in EDTA Vacutainers at times from 2 minutes to 480 minutes postdose. Most patients were studied in the afternoon following their routine hemodialysis. This minimized the isotopic cross-talk between endogenous and labeled infused urea.

Urea analysis - the problem: There is no fully satisfactory method for derivatizing urea for GC/MS analysis of isotopomers. The bis-TMS derivative gives sharp peaks while the chromatography of nonsilylated derivatives is poor. However, the presence of two Si atoms in the molecule creates a complex isotope pattern. With the high, constant levels of unlabeled, endogenous urea contributing a significant amount to the +2 and +3 masses, the limit of detection for the labeled tracer urea was compromised. The following isotopic pattern for the $[M-15]^+$ fragment used for analysis is from a polynomial expansion program courtesy of Dr. John Strong, FDA:

m/z	%
189	100
190	17.6
191	8.2
192	0.94

Urea analysis - the method: Our method was adapted from Matthews and Downey, Am J Physiol **246**: E519, 1984. One hundred μL of plasma was precipitated with 1 mL of ice-cold ethanol. After centrifugation, the supernatant was transferee to a tube containing 1.5 mL of 1M acetic acid. This was transferee to a BioRad PolyPrep AG 50W-X8 ion exchange column that had previously been washed with 4 mL of 1M acetic acid and was washed with another 4 mL of 1M acetic acid after the sample had been loaded. The urea was contained in the 4th mL of the 3M ammonium hydroxide elution solution. This was dried under nitrogen at 80° and derivatized with 50 μL each of MSTFA and acetonitrile at 100° for 30 minutes.

The gas chromatography was carried out at 145° on a 0.25 mm OD fused silica capillary column coated with 0.25 μ DB-5 giving a retention time of 2.5 minutes. Two μl were injected with a 20:1 split. The instrumentation consisted of: a Varian 3300 GC; an Extrel C50/400 quadrupole mass spectrometer; and a Teknivent Vector 1 data system. Masses 190, 191, and 192 were monitored in EI mode and represent [M-15] bisTMS-urea isotopomers containing: one natural atom of ^{13}C from endogenous urea; two atoms of ^{15}N from an internal standard; and two atoms of ^{15}N and one atom of ^{13}C as were incorporated into the injected tracer. The m/z 189 signal representing the normal

isotopic version of bisTMS-urea was always off-scale, so that the [M+1] at m/z 190 was used to monitor the endogenous urea. Its concentration was computed by adding 10 ng of $^{15}N_2$-labeled urea to 0.1 mL of preinfusion plasma; the controls were spiked with 2 ng. The data were analyzed by a 2-compartment kinetic model (PCNONLIN).

RESULTS

Analytical: This method was successful in providing a means to assay tracer levels of urea in the presence of high endogenous levels of urea as found in patients without renal function. We could analyze the triply-labeled urea tracer out to 480 minutes in almost every patient. The 12 samples needed for each study could be processed and analyzed in one day. The isotope-dilution method of measuring plasma urea were consistent with the clinical laboratory values of BUN, after correcting for the molar weights of nitrogen vs. urea.

Kinetic: All subjects yielded plasma concentrations that were well fit by a 2-compartment kinetic model. There was considerable variability in the compartmental characteristics of the patients and the controls. We were initially surprised by the equivalent t½s for the patients and controls, but realized that the clearance of the $^{15}N_2$-^{13}C-labeled urea we were observing was not primarily due to a renal mechanism, but to a metabolic nitrogen exchange reaction presumably mediated by intestinal microflora.

DISCUSSION

The success of this method depended primarily on the judicious balance of the various isotopic species. The high level of [M+2] from endogenous urea recommended that triply-labeled urea be the tracer. Although it is nearly 3 times more expensive than doubly-labeled urea, the great difference in [M+3] vs. [M+2] permitted smaller tracer doses, thus providing greater economy. The doubly-labeled urea that was used as a calibrant was also carefully dispensed so that its abundance was comparable to m/z 190.

CONCLUSIONS

We have modified the method of Matthews and Downey to provide a yet more efficient way to measure urea kinetics. The significant differences are:

1. Using MSTFA rather than BSTFA to reduce the solvent tail which improves sensitivity and reduces total analysis time.

2. Using triply-labeled urea to remove a significant amount of interference from endogenous urea to permit detection of as little as 0.2 mole % excess urea.

The compartmental sizes of urea among subjects demonstrate considerable variability that will have consequence in the design of optimal dialysis protocols.

IMPROVED MEASUREMENT OF STABLE ISOTOPE RATIOS IN CRIMS

Jozef J. Kusmierz and Fred P. Abramson, George Washington University
Department of Pharmacology, 2300 Eye Street NW Washington D.C. 20037

INTRODUCTION

In this study we have evaluated the Teknivent Vector 2 data interface and software for its ability to improve precision and sensitivity of stable isotope ratio measurements for ^{15}N and ^{13}C compared to the Vector 1 system. The two major improvements are:

1. The Vector 2 system has 100x greater dynamic range than the Vector 1 so that the mass spectrometer could be operated at high sensitivity in order to maintain a linear signal when examining large samples.
2. The Vector 2 system allows variable integration times for different ions.

In addition, these experiments were performed on a more sensitive quadrupole mass spectrometer (Extrel C50/400).

EXPERIMENTAL

Isotope dilution: In our experiments (2-^{13}C, 1,3-$^{15}N_2$)-caffeine (99 atom %, Cambridge Isotopes) was added to unlabeled caffeine to produce isotope dilutions ranging from 0.00005 to 0.05 for nitrogen and from .00005 to 0.0125 for carbon. All solutions were prepared in 2 ml of acetonitrile and 1 μL containing 300 ng of unlabeled caffeine was injected using splitless mode.

GC-CRIMS analysis. The microwave powered chemical reaction interface decomposes organic compounds in the presence of helium. The decomposition products react with small added amounts of a second gas to produce stable molecules which reflect the elemental composition of the original compound. The stable molecules are analyzed by a mass spectrometer. A Varian 3300 gas chromatograph equipped with a split/splitless injector (Varian Model 1075) was used with a 30 m 0.25 mm i.d., 0.25 μ thick DB-5, capillary column (J&W). Ultra-pure carrier grade helium (Air Products) and specially prepared SO_2 (Matheson) as a reactant gas were used. The column head pressure was 20 psi and injector temperature was 250 °C. Two minutes after injection of a 1ul sample in splitless mode (valve closed for 1.5 min) at 50 °C, the column temperature was quickly raised to 215 °C and kept constant. The microwave cavity was powered by a 100 W 2450 MHz power supply. The microwave power and mass spectrometer were turned on at 6 min after injection when solvent was no longer present.

Isotope ratio measurements. All experiments were performed on a Extrel C50/400 quadrupole mass spectrometer equipped with either a Teknivent Vector 1 or Vector 2 data acquisition interface and software. For both studies we kept the same total acquisition cycle time in order to maintain at least 30 samples across the GC peak. For Vector 1 experiments the total cycle time was 0.359s for ^{13}C and ^{15}N and each mass (44 and 45, or 30 and 31) was integrated for 5 ms and averaged 35 times. For Vector 2 experiments the total cycle time was 0.38s. For ^{15}N, m/z 31, was integrated 15.5 times longer than m/z 30. The integration time for ^{13}C, m/z 45, was 9.1 time longer than integration time of the ion m/z 44. These times are in accordance with the inverse of the square root of the natural isotope ratios which statistically produces the most precise isotope ratios. However, we calculated isotope ratios by using areas under the M+1 trace to the area under base peak for $^{12}CO_2$ or ^{14}NO.

RESULTS

Our objective in this study was to evaluate the Teknivent Vector 2 system and its ability to improve precision and sensitivity of stable isotope ratio measurements for ^{13}C and ^{15}N. We chose caffeine as our model compound. We used CRIMS to generate CO_2 and NO and monitored $^{12}CO_2$ and $^{13}CO_2$ at 44 and 45 and ^{14}NO and ^{15}NO at 30 and 31. The natural abundances of $^{13}CO_2$ and ^{15}NO were determined using unlabelled caffeine and were found to be 0.011907 ± 0.000150 (CV

= 1.26%) and 0.0042502 ± 0.000069 (CV = 1.62%) for Vector 1 and 0.011888 ± 0.000074 (CV = 0.62%) and 0.0042206 ± 0.000025 (CV = 0.59%) for Vector 2 respectively.

The determined ^{13}C and ^{15}N atom % excesses with the Vector 1 system are plotted versus isotopic dilution in Figure 1. The measured results show good linearity. However the lowest APE's for ^{13}C (0.005 and 0.025) fall below + 2SD of the natural value.

Figure 2 shows ^{13}C and ^{15}N atom % excesses generated with the Vector 2 system plotted versus isotopic dilution. The results show very good linearity. The last two points for ^{13}C fall again below +2SD of the natural abundance of ^{13}C. However the measured excess ratios for ^{13}C and ^{15}N are linear for all dilutions.

From these data we determined that the minimum detectable APE's of ^{13}C and ^{15}N measured with Vector 2 system were 0.015 and 0.005 respectively.

In general, data from the Vector 2 system shows at least two times better precision and sensitivity compared to Vector 1. This improvement is attributed to variable integrating time setting offered by Vector 2. Indeed the measured signal to noise ratios for m/z 45 and m/z 31 were 2.5 times better for Vector 2 than for Vector 1 while the signal to noise ratios for m/z 44 and m/z 30 for Vector 2 were 0.75 times of that for Vector 1.

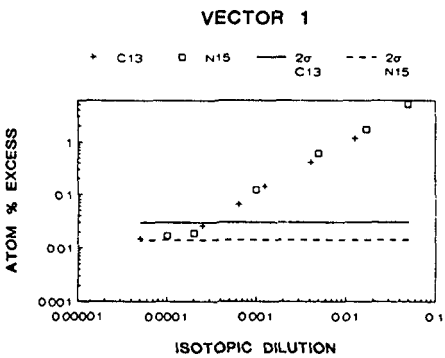

Figure 1 The atom % excesses of ^{13}C and ^{15}N for Vector 1.

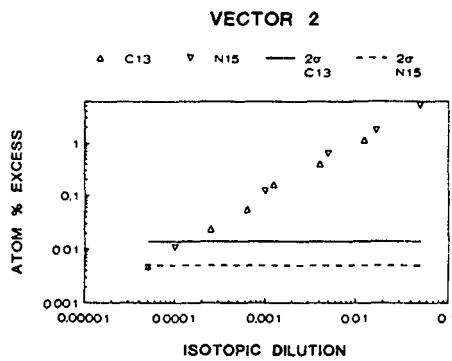

Figure 2 The atom % excesses of ^{13}C and ^{15}N for Vector 2.

CONCLUSIONS

The Teknivent Vector 2 system improves overall precision and sensitivity of stable isotope ratio measurements by at least a factor of two compared to the Vector 1 system.

With CRIMS coupled to a quadrupole mass spectrometer and the Vector 2 data system, we have improved stable isotope ratio measurements of 13C and 15N by a factor of 10 compared to our previously reported results (Chace and Abramson, BEMS 19: 117, 1990).

Tellurium Determination by GC-MS in Biological Samples

Suresh K. Aggarwal[1,2], Michael Kinter[2] and David A. Herold[1]
[1]VA Medical Center / University of California, San Diego, CA 92161
and [2]Department of Pathology, University of Virginia, Charlottesville, VA 22908

INTRODUCTION

Tellurium is a rare trace element with previous interest mainly limited to the semiconductor fabrication industry. Interest in the metabolism of this element has become of increased interest due to a new drug. The anti-tumor drug, AS-101 [ammonium tri-chloro(dioxoethylene-O-O'-)tellurate], is the first tellurium (Te) containing compound which has been identified to possess immunomodulating properties and minimal toxicity. In view of the extremely low doses proposed for use in laboratory animals and humans, we have developed a GC-MS method for Te using 4-fluorophenyl magnesium bromide (4-FPMB) as a derivatizing agent.

EXPERIMENTAL

Standards: Tellurium metal (~56 atom % ^{120}Te, Oak Ridge National Laboratory, Oak Ridge, TN) was dissolved in nitric acid to be used as the internal standard for isotope dilution. Dilute solutions of the internal standard were prepared from this stock solution. These solutions were calibrated by reverse isotope dilution using natural Te as the primary standard.

Sample Preparation: For this study, $Te(FC_6H_4)_2$ was prepared by reacting Tellurium bis(trifluoroethyl)dithiocarbamate in Et_2O with the Grignard reagent, 4-FPMB. The excess 4-FPMB was destroyed with 100 µL of H_2O and 100 µL of 1 M HNO_3. Phenyl magnesium bromide was used in a similar manner to prepare $Te(C_6H_5)_2$.

Analysis: A Finnigan MAT 8230 mass spectrometer with a 10m x 0.32mm DB-1 bonded-phase fused silica capillary column with on-column injector was used for measurements. The EI mass spectrum showed two groups of Te isotope containing peaks: the molecular ion m/z 320 $[Te(FC_6H_4)_2^{+\cdot}]$ and the fragment ion at m/z 219 $[Te(FC_6H_4)^+]$. The molecular ion peak was of greater intensity and was used for the experiments. Precision and accuracy in the measurement of Te isotope ratios at the 10 ng injected level was determined by performing replicate measurements on several days. Selected ion monitoring with voltage peak switching was used for data acquisition and isotope ratios were determined by integrating the chromatographic peak areas.

RESULTS AND DISCUSSION

The fluorophenyl derivative (Figure 1) gave a more intense parent ion that the phenyl derivative (Figure 2) and was used for the further studies. Overall precision of 0.6 to 3.1% was obtained for the different Te isotope ratios. Memory effect was evaluated by sequentially analyzing two synthetic mixtures with ^{120}Te / ^{130}Te ratios differing by a factor of 50. As shown in Figure 3, no appreciable memory effect was observed for the measurement of m/z 310 / 320 ratios during sequential analyses of the two mixtures.

CONCLUSION

The absence of appreciable memory effect and the relatively intense molecular ion demonstrated the suitability of Te $(FC_6H_4)_2$ for Te determination at the parts-per-billion level.

Selenium Determination by GC-MS in Biological Samples

Suresh K. Aggarwal[1,2], Michael Kinter[2] and David A. Herold[1]

[2]Department of Pathology, University of Virginia, Charlottesville, VA 22908

INTRODUCTION

Selenium (Se) has been recognized as an important trace element for animal and human health because of its potential carcinopreventive and anticarcinogenic effects. One role of Se is as an antioxidant. The enzyme glutathione peroxidase, which lowers tissue peroxide levels by destroying hydrogen peroxide requires Se; however, high Se levels in the diet are toxic. The span between beneficial and toxic concentrations is small, so precise and accurate analytical techniques are required to distinguish between deficiency and toxicity. We have evaluated the suitablity of three different reagents to form stable piazselenols for Se determination by isotope dilution GC-MS. Precision and accuracy of isotope ratio measurements at the 10 ng level was determined. Memory effect was evaluated by the sequential analysis of solutions of natural Se and enriched ^{76}Se. The method was then validated by quantifying Se in urine reference material.

EXPERIMENTAL

Instrument: A Finnigan MAT 8230 mass spectrometer with a 10m x 0.32mm DB-1 bonded-phase fused silica capillary column with was used to determine chromatography, memory, precision and accuracy of isotope ratio measurements.

Reagents: The enriched ^{76}Se (>96 atom% ^{76}Se, Oak Ridge National Laboratory, Oak Ridge, TN) was derivatized and calibrated by reverse-isotope dilution GC-MS using the natural Se certified atomic absorption standard (Fisher Scientific, Fairlawn, NJ). Three different derivatizing reagents, 4-nitro-o-phenylenediamine (NPD), 3,5-dibromo-o-phenylenediamine (DBPD) and 4-trifluoromethyl-o-phenylenediamine (TFMPD) were investigated. NPD was obtained from Aldrich Chemical Co. (Milwaukee, WI). DBPD and TFMPD were prepared by reduction of 2,4-dibromo-6-nitroaniline (Aldrich) and 4-amino-3-nitrobenzotrifluoride (Aldrich), respectively, with $SnCl_2$ in absolute ethanol.

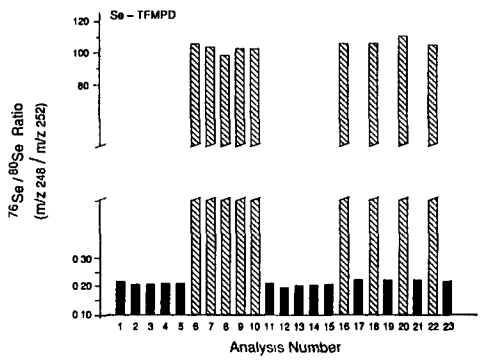
Sample Preparation: One mL of urine was mixed with internal standard in a Teflon beaker and digested with HNO_3 and H_3PO_4 overnight. Then the solution was heated at 70° C to reduce the volume and 50% H_2O_2 was added until no brown fumes were released. Formic acid was added to destroy residual HNO_3. The Se(VI) was then reduced to Se(IV) with HCl, lipids extracted with CH_2Cl_2 and the pH adjusted to 1 followed by addition of 100 µL of derivatizing reagent. After 30 minutes, the piazselenol was extracted with CH_2Cl_2, dried at RT and reconstituted in 20 µL of CH_2Cl_2 for analysis.

RESULTS AND DISCUSSION

The gas chromatography of Se-NPD, Se-DBPD and Se-TFMPD on a DB-1 fused silica capillary column showed the volatility order to be Se-TFMPD > Se-DBPD > Se-NPD, with the fluorinated piazselenol being the most volatile and therefore eluting at the lowest temperature. The sharp chromatographic peaks as well as the presence of a molecular ion in each of the mass spectra indicated the thermal stability of all three piazselenols at nanogram levels under these experimental conditions. The most abundant isotopic group, the molecular ion M^+, was used throughout these experiments to achieve the highest possible sensitivity. Overall precision values of 1 to 7% were obtained for Se isotope ratio measurements at 10 ng level. There were no significant differences in the overall precision values obtained using the three piazselenols. As expected, the precision values are better when the isotope ratios to be measured are close to unity and this can be achieved by optimum addition of the internal standard solution during the isotope dilution step. The memory effect is in the order Se-NPD > Se-DBPD > Se-TFMPD with Se-TFMPD showing no observable memory effect (Figure).
The calibrated ^{76}Se internal standard was then used to quantitate Se in the NIST freeze-dried urine reference material SRM 2670. The concentration values (Table) were calculated by using different isotope ratios in the three piazselenols. They are in good agreement with the NIST certified value. No significant difference is observed in terms of precision and accuracy for the concentration determination using any of the three derivatizing reagents.

CONCLUSION

Stable isotope dilution gas chromatography-mass spectrometry using any of the three derivatizing reagents (NPD, DBPD and TFMPD) can be used for the determination of Se in the urine samples. Out of the three reagents investigated, TFMPD is the best from the point of view of gas chromatographic behavior and memory effect in GC-MS system. All three reagents performed equally well in terms of precision and accuracy.



Origin of Specific Ions Used in the Quantitation of Polyamine Aryl Imines of Use to Monitor Cardiac Allograft Rejection

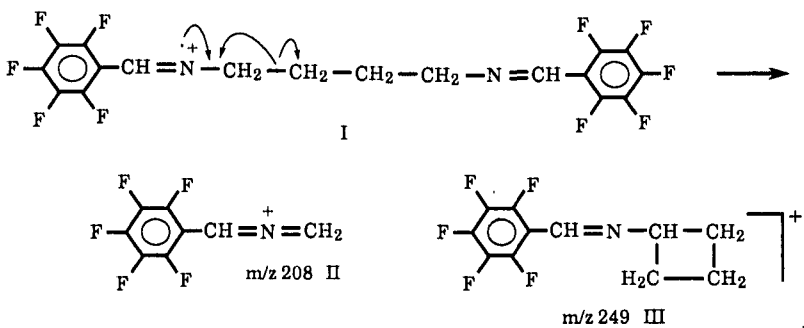
and
Department of Chemistry (R.A.D.)
University of Cincinnati, Cincinnati, OH 45221

All body fluids and tissue cells contain polyamines such as putrescine and cadaverine (1). Some studies have shown that changes in the levels of these polyamines are due to T-lymphocyte proliferation and heart transplant rejection (2). This fact has been successfully employed in the development of a noninvasive clinical method for the diagnosis of cardiac allograft rejection. GC, GC/MS and HPLC methods for the quantitation of these polyamines were developed. Since polyamines are not amenable for direct GC or GC/MS analysis, they need to be converted into their volatile derivatives before they could then be quantitated with such instrumentation.

Materials and methods: 1,3-propanediamine, 1,4-diaminobutane, 4-dimethylaminobenzaldehyde, and pentafluorobenzaldehyde were obtained from Sigma Chemical Company (St. Louis, MO). 1,4-diamino, 1',1',4,4'-tetra deuterobutane is a generous gift from M. Drue Denton. Pentafluorobenzylidene derivatives were prepared by the method described by Avery et al. (3). Other aryl imine derivatives were prepared as described by Day et al. (5).

A Kratos MS-80 high performance mass spectrometer interfaced with Carlo Erba gas chromatograph was used for all the analysis. DS-55 data system was used for data manipulation and exact mass measurements. The GC/MS system was operated in the electron impact mode and in the chemical ionization mode when necessary. The instrument was fitted with a 30 meter x 0.32 mm I.D. SPB-5 (Supelco, Bellefonte, PA) fused-silica capillary column. The effluent from the column is introduced into the mass spectrometer through a glass jet separator which is heated at a controlled temperature. Samples were introduced into the mass spectrometer both by GC and direct inlet probe for analysis.

The ion selected for the quantitation is m/z 208 (II) which results from the α-cleavage of the PFB derivative (I). On studying the mass spectrum of these derivtives, we observed the presence of an intense ion which is characteristic of each of these polyamines.



The fragmentation pathway identifying the origin of this ion is the focus of this study. We have earlier reported the elimination of aryl nitrile after H-migration to the C-terminal fragment in the electron impact mass spectra of aryl peptide methyl esters (4). We also reported the presence of an ion resulting from the elimination of HCN from the even electron fragment ion obtained after α-cleavage. In all the mass spectra of various aryl imine derivatives studied, we have observed the above phenomenon. In addition, we also observed an intense ion by the elimination of neutral aryl imine from the molecular ion $[M-(Ar-CH=NH)]^{+\cdot}$ for example, III. We have studied different aryl imine derivatives of propane diamine, butane diamine, pentane diamine and lysine methyl ester. In the case

of propane diamine imine (Schiff's base) derivative an ion derived from the aryl nitrile elimination with hydrogen transfer similar to the aryl imine peptide ester derivatives was observed.

The mass spectra of the butyl diamine and the pentyl diamine aryl imine derivatives exhibited an intense ion due to the elimination of aryl imine from the molecular ion. Many aryl imine derivatives, some with stable isotopes, were analyzed by mass spectrometry for this study, the list of which is provided below.

A STUDY OF VOLATILE FRUIT FLAVOUR BIOSYNTHESIS USING NON-INVASIVE DEUTERATED PRECURSOR LABELLING TECHNIQUES.

John M Allen, Daryl Rowan and G John Shaw.
Department of Scientific and Industrial Research, Private Bag, Palmerston North, New Zealand.

INTRODUCTION. Although volatile flavour (aroma) research is an active and rapidly changing field, detailed information on the biochemical mechanisms and control of volatile flavour production remains limited. At the molecular level, it is apparent that the biochemical pathways leading to a wide spectrum of volatile flavour compounds are mediated by complex multi-enzyme systems. In fruit, there is increasing evidence to suggest that many of these enzymes maintain a broad substrate specificity which enables the synthesis of a large number of volatile compounds from a limited number of flavour precursors.

In preliminary experiments we have investigated the incorporation of deuterium labelled precursors into the volatile flavour fraction of ripening apple fruit using a non-invasive, gas phase, technique in combination with GC-MS analysis.

EXPERIMENTAL. *Sampling Procedure*: 1 kg of fresh Red delicious apples were placed in a 10 litre round bottom flask, and held at 20°C. Labelled butanoic acids were synthesised and placed in a "U-shaped" tube (100μL) in the entry gas line into the apparatus. Purified air flowed through the apparatus at a constant flow rate of 60 mL min^{-1}. Under these conditions each n-butanoic acid was entrained over the apples for 12 hours. Headspace traps containing Tenax GC (60/80 mesh) were placed at the outlet for 4 hour sampling periods once or twice a day. Condensed headspace volatile flavour compounds were desorbed with 600 μL of diethyl ether using a centrifugation technique.

Gas Chromatography-Mass Spectrometry: Analyses were performed using a VG70-250S mass spectrometer directly linked to a HP5890 GC. The volatile flavour compounds were separated on a BP1 (25m x 0.32μm i.d.) bonded phase column which was temperature programmed as follows: 40°C for 5 min, ramped at 3°C/min to 280°. Inj temp 220°C, Interface temp 250°C. Helium, 2 psi. MS conditions were as follows: 70 eV, scan time/delay 0.5 sec/0.2 sec, mass range 500-29 amu, source temp 250°C, trap current 100 μA.

RESULTS AND DISCUSSION. In this study, exposing intact apples to volatile 2,2-dideuterobutanoic and 4,4,4-trideuterobutanoic acids in separate experiments selectively enhanced the *in vivo* biosynthesis of aliphatic esters containing C-4 moieties (Figure 1, 4,4,4-trideuterobutanoic acid labelling experiment only) either by direct esterification with endogenous aliphatic alcohols and/or indirectly by enzymatic reduction and then esterification (Table 1) primarily within the skin tissue. The effect of the treatment on the headspace profile was short-lived with concentrations of deuterated aroma compounds reaching a maximum 3 days after exposure. The aroma profile returned to normal levels after 5 days.

Using high performance capillary GC separation with a slow temperature programme ramp in conjunction with low- and high resolution MS, all deuterated products in the apple headspaces were identified and the position of deuterium labels confirmed by MS.

The utility of the method is clearly demonstrated in the case of the 4,4,4-trideuterobutanoic acid labelling experiment, in which all four possible products for the symmetrical ester, butyl butanoate, were distinguished (Table 2). In this case, the dominant mass spectral fragmentation processes provided a variety of diagnostic ions arising from a series of α, α', β, β+H, β'-H and β'+2H cleavages resulting in unequivocal information on the position of the deuterium labels.

These and other results (not shown) suggest that the enzyme, ester synthetase, in apple skin involved in esterification of deuterated acids has a preferred specificity for C4-C6 acids and alcohols. The biosynthetic transformations leading firstly to the reduction and then esterification of the deuterated precursor acid confirms the presence of active alcohol dehydrogenase in intact apple possessing NADH- and NADPH-linked activities and suggests that the reductive pathway, RCOOH → RCHO → RCH_2OH, is operational in the skin of this fruit. Work is continuing to define the nature of the acid to aldehyde conversion using deuterated acids in pre-climacteric fruit.

ACKNOWLEDGEMENTS. We gratefully acknowledge support for this work by the Foundation for Research, Science and Technology and the New Zealand Apple and Pear Marketing Board.

Investigation of MeIQx (2-amino-3,8 dimethylimidazo[4,5f]quinoxaline) Metabolites in Human Urine

W. G. Stillwell[1,2], R. J. Turesky[3], P. L. Skipper[1,2], and S.R. Tannenbaum[1,2]

Div. of Toxicology[1] and Dept. of Chemistry[2], Massachusetts Institute of Technology, Cambridge, MA 02139 and Nestle Research Centre[3], Lausanne 26, Switzerland

MeIQx is a carcinogenic heterocyclic amine which is formed in trace amounts in cooked meat. Metabolic biotransformation of MeIQx yields various polar conjugates (fig.1). Studies in animals showed that metabolites of MeIQx are extensively excreted in the bile and urine after a single ip dose (1). Unchanged MeIQx has also been measured in human urine after ingestion of cooked beef (2). However, little is known of the metabolism and excretion of this compound in humans. Our objective in the present work is to develop methods to identify and quantify the urinary products of MeIQx excreted in the human. Analysis of the excretion products will afford a better understanding of the ability of the body to metabolize these aromatic amines.

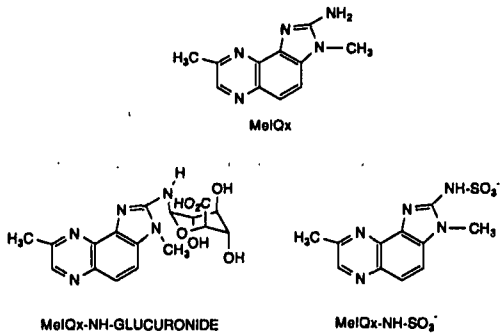

fig. 1. Structures of MeIQx and polar metabolites

Experimental

The amount of MeIQx excreted in human urine following ingestion of a cooked meat meal was determined using a negative ion chemical ionization GC/MS method (2). In the present study seven subjects each consumed 1 lb of pan-fried fish or beef. Urine collections were made 0-12 and 12-24 hr post meal. Aliquots of urine were analyzed both for unchanged MeIQx and after acid hydrolysis (1N HCl at 70° for 6 hr). Acid hydrolysis under these conditions cleaves the N^2-sulfamate and N^2-glucuronide conjugates to the parent amine. The samples (both non-hydrolyzed and hydrolyzed) were extracted, purified by immunoaffinity chromatography, and derivatized to form the di(bis(3,5-trifluoromethyl)benzyl) derivative of the amine. Analyses were performed using a Hewlett Packard 5987 GC/MS system. HP-1 capillary columns (12.5 meter) were used in the assay. The derivatized MeIQx and the deuterated internal standard were detected and quantified by selective ion monitoring of the ions at *m/z* 438 and *m/z* 441, respectively.

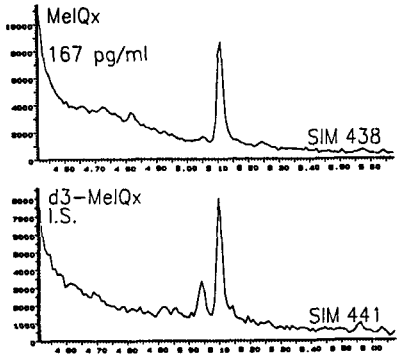
Analytical methods were also developed to purify and isolate the polar urinary metabolites of MeIQx. Following administration of MeIQx to rats the polar conjugates excreted in urine are readily identified and analyzed by HPLC and associated techniques (1). In order to isolate and analyze the trace amounts of the conjugates found in human urine a more extensive method is required. The conjugates were isolated by methanol:acetone precipitation of urine, C-18 column and ion-exchange chromatography, followed by aminopropyl column separation and HPLC. Acid hydrolysis of the isolated fractions containing the metabolites followed by GC/MS analysis of the amine was used to confirm the presence of the conjugates in human urine.

Results and Discussion

The amounts of MeIQx excreted in urine (both before and after acid hydrolysis) from seven subjects are shown in Table 1. Values ranging between 2 and 22 ng were detected in the individual urine collections. After acid hydrolysis the amounts increased approximately 4 to 10 fold in the urine of six of the subjects, while the urine of one subject showed essentially no increase. The following figure shows a selected ion monitoring trace of an acid hydrolyzed urine; 167 pg/ml of MeIQx was detected in this sample (subject D).

Table I. MeIQx in Urine 0-12 hr post-meal

	MeIQx in Urine			
Subject	non-hydrolyzed		acid hydrolyzed	
	pg/ml	ng/12hr	pg/ml	ng/12hr
A	3	2	12	9
B	5	6	30	44
C	14	10	156	106
D	25	22	167	111
E	11	10 5	121	115
F	6.5	6 5	7	7
G	1	2	9	20



The recovery of metabolites in urine carried through the purification procedure and aminopropyl column (ion-exchange) chromatographic separation was judged to be complete. After fractionation of an aliquot of urine using this method the isolated sulfamate and glucuronide conjugates of MeIQx were hydrolyzed to the parent amine. The quantity of the amine derived after acid hydrolysis of the sulfamate and glucuronide conjugates in the isolated fractions of urine is summarized below.

Analysis of Human Urine
Subject C

Step	50ml aliquot (7.15ng)	Recovery
1	CH_3OH Acetone ppt	100%
2	C-18 Resin	100%
3	AP - Ion exchange mode	100%

2 15ng remained after Step 3. This was fractionated on AP (normal mode) Three fractions were recovered:

Fraction	Metabolite	Amount (ng)
1	N-sulfamate	1.1
2	N-sulfamate	0.6
3	N-glucuronide	0.4
	(Total)	2 1

Conclusions

The results of this study indicate that amine sulfamation and glucuronidation are important conjugation reactions of detoxication of MeIQx in the human. NICI GC/MS provided a sensitive analytical method for the quantification of MeIQx metabolites in urine after separation into the fractions containing the sulfamate and glucuronide conjugates Acid hydrolysis to the parent amine was used to confirm the presence of the metabolites. Further work is being carried out to confirm the identity of the conjugates by direct mass spectrometry.

Derivatization Schemes: Determination of Aldehydes in Biological Samples by GC/MS.

Bernd A. Bruenner[1], A. Daniel Jones[2], and J. Bruce German[1]

[1]Department of Food Science and Technology
[2]Facility for Advanced Instrumentation
University of California, Davis, CA 95616

Peroxidation of polyunsaturated fatty acids in both food and biological systems can result in the formation of toxic and reactive aldehydes, such as hexanal and 4-hydroxy-2-nonenal (HNE). Sensitive and selective methods of analysis are necessary for their quantitation at low levels in biological matrices. Formation of the O-pentafluorobenzyl (PFB) oxime TMS ether derivative has been used for trace quantitation of HNE by negative ion selected ion monitoring (SIM)[1]. The method is limited, however, in that only one of many possible aldehydes which can form during lipid peroxidation is being measured. Additionally, the O-PFB oxime derivative failed to yield similar useful fragmentation for hexanal and nonanal (Fig. 1), prompting investigation into other derivatives which may yield intense and specific ions useful for quantitation of HNE and other aldehydes in a single analysis using SIM.

Derivatizing with hydroxylamine and silylating with N-methyl-N-(tert-butyldimethylsilyl)trifluoroacetamide (MTBSTFA) to form the tert-butyldimethylsilyloxime derivatives has been used to quantitate a number of aldehydes by GC using flame ionization detection[2], and HNE by GC/MS using SIM[3]. Such derivatives fragment under electron impact ionization primarily by loss of the t-butyl group, producing strong M-57 ions specific for the parent aldehyde and suitable for analysis by SIM (Fig. 2). These methods were modified in the current investigation by using d_2-HNE as an internal standard and attempting to simultaneously quantitate hexanal, nonanal, and HNE by SIM.

Samples were prepared by adding appropriate amounts (1-250 ng) of the various aldehydes and internal standard solution containing 50 ng of d_2-HNE to 250 μl of 0.1 M PIPES buffer pH 6.5 containing 0.05 M hydroxylamine, 200 μl of 2 mM EDTA pH 6.5, and 5 μl of 10 μg/μl BHT in a conical centrifuge tube. After incubating 15 minutes at room temperature, the aqueous phase was extracted three times with 1 ml aliquots of dichloromethane. The extracts were concentrated in Reacti-vials to about 20 μl under a stream of nitrogen, and 30 μl each of DMF and MTBSTFA were added and the samples incubated for one hour at 70°C.

Silylated samples were analyzed directly by splitless injection of 1 μl on a 15 m DB-5, 0.25 mm i.d. capillary column with 0.25 μm film thickness, with the GC programmed from 80°C to 285°C at 10°C/minute. Injector and transfer line temperatures were 270°C. Analysis was performed on a VG Trio-2 quadrupole instrument in the SIM mode. The M-57 ions of the tert-butyldimethylsilyloxime derivatives of hexanal (m/z 172), nonanal (m/z 214), HNE (m/z 342) and the internal standard, d_2-HNE (m/z 344) were monitored. Calibration curves were constructed by plotting the peak areas for the various aldehydes to that of the internal standard.

Limits of detection were approximately 100 pg (quantity injected, or about 15 ng/ml fluid) for HNE, and about 50 pg for nonanal and hexanal, since the M-57 ions of these two aldehydes contribute a larger percentage to the total ion current.

The relative standard deviations of the peak area ratios of a sample containing 100 ng each aldehyde for five repetitive injections were 29% for hexanal, 30% for nonanal, and 2% for HNE.

Calibration curves were linear over the range 1-250 ng of aldehyde per ml reaction medium; R^2 = 0.81, 0.98, and 0.98 for hexanal, nonanal, and HNE, respectively.

Other derivatives of the aldehydes were also prepared and their suitability for analysis by SIM evaluated on the basis of their fragmentation. Derivatization reagents included ethanolamine, 2-methylaminoethanol, and 0-t-butylhydroxylamine. These derivatives, however, failed to yield intense analyte-specific ions. Base peaks were non-specific fragments characteristic of the derivatizing reagent, and hence these derivatives were not considered useful for selective analysis of the aldehydes.

In conclusion, the method of SIM of the M-57 ions of the tert-butyldimethylsilyloxime derivatives is promising for the simultaneous quantitation of hexanal, nonanal, and HNE using d_2-HNE as an internal standard. Improvements in the percent relative standard deviations for hexanal and nonanal are desired. A modified version of this method will be used to quantify aldehydes in plasma samples exposed *in vitro* to ozone, cigarette smoke, and nitrogen dioxide.

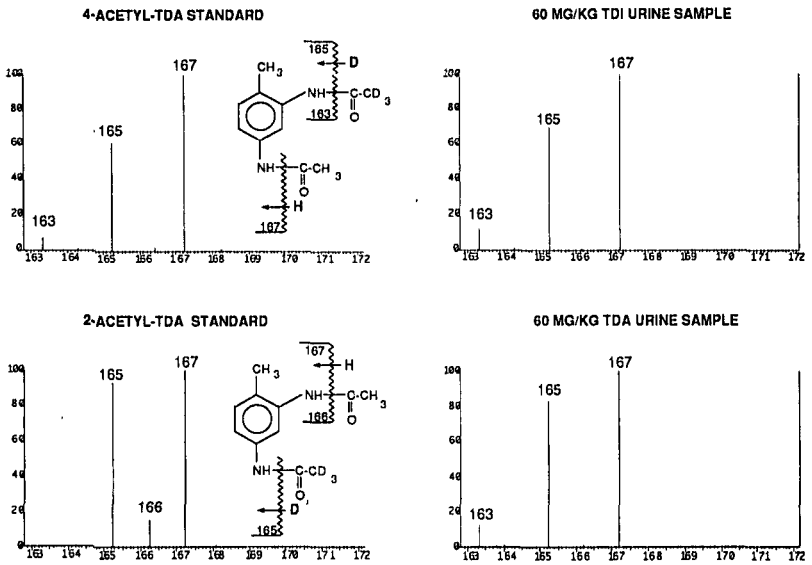
GC/MS/MS Identification and Quantitation of Metabolic 4-Acetyltoluene-2,4-diamine from the F344 rat.

Michael J. Bartels, Charles Timchalk and Fred A. Smith, Health and Environmental Sciences, The Dow Chemical Company, Midland, Michigan.

2,4-Toluenediamine (TDA) and 2,4-Toluenediisocyanate (TDI) are metabolized in the Fischer 344 rat, via the oral route, to monoacetyl-2,4-toluenediamine (Ac-TDA) and diacetyl-2,4-toluenediamine (Ac_2-TDA). A GC/MS/MS method was developed to characterize the structure of the Ac-TDA metabolite seen as a urinary metabolite in the rat. The same method was also used for the quantitative analysis of both the Ac-TDA and Ac_2-TDA metabolites.

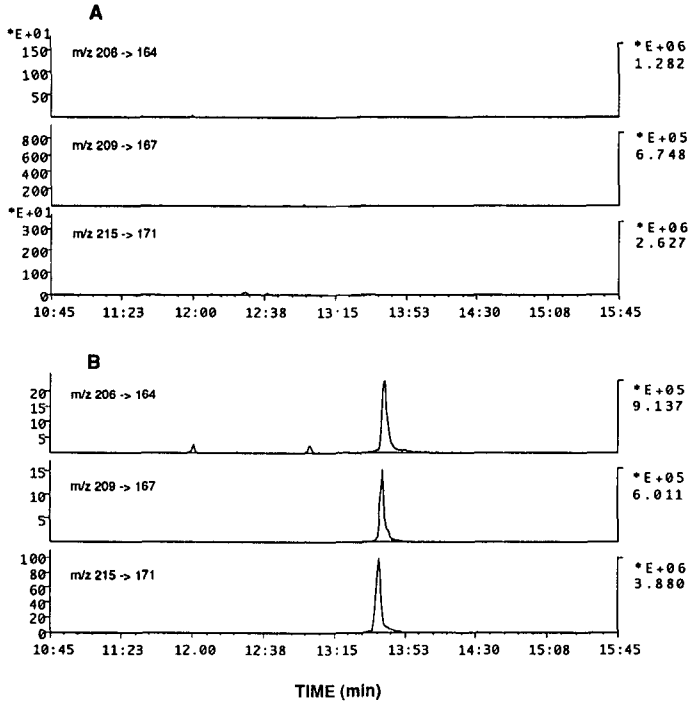
Urine samples from rats administered 2,4-TDA and 2,4-TDI (60 mg/kg, po) were fortified with an internal standard (D_6-Ac_2-TDA) and extracted with ethyl acetate. The extracts were derivatized with D_6-acetic anhydride to convert any metabolic Ac-TDA to a D_3-Ac_2-TDA derivative. EI-GC/MS/MS analysis of 2-acetyl- and 4-acetyl-TDA yielded different daughter ion spectra from the common parent ion (m/z 209). Analysis of metabolic Ac-TDA showed it *to be the 4-acetyl isomer. Subsequent GC/MS analysis of the metabolic AC-TDA, as the* heptafluorobutyryl derivative, confirmed the structure as 4-acetyl-TDA.

MS/MS SPECTRA (DAUGHTERS OF m/z 209) OF THE D_3-ACETYL DERIVATIVES OF 4-ACETYL-TDA AND 2-ACETYL-TDA



The GC/MS/MS method used for structural identification of metabolic Ac-TDA was also employed for quantitation of this metabolite and metabolic Ac_2-TDA. The two metabolites and the D_9-internal standard were found to have unique M-acetyl daughter ion spectra. Selected-ion monitoring of these daughter ions was performed to quantitate these two metabolites in rat urine.

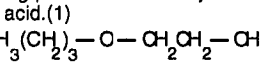
REPRESENTATIVE EI-GC/MS/MS CHROMATOGRAMS FOR ACETYL-TDA (m/z 209) AND DIACETYL-TDA (m/z 206) AS D_6-AC_2O DERIVATIVES (D_9-DIACETYL-TDA INT. STD., m/z 215) A) CONTROL URINE EXTRACT; B) EXTRACT OF URINE FROM RAT ADMINISTERED 60 MG/KG 2,4-TDI, po



QUANTITATIVE DETERMINATION OF ETHYLENE GLYCOL MONOBUTYL ETHER (2-BUTOXYETHANOL) AND 2-BUTOXYACETIC ACID IN BLOOD BY GAS CHROMATOGRAPHY WITH ELECTRON-CAPTURE NEGATIVE-ION MASS SPECTROMETRY

Barbara J. Markley, Health and Environmental Sciences - Analytical Chemistry Laboratory, Dow Chemical, Midland, MI 48674

INTRODUCTION: Butoxyethanol is a key ingredient in water- or solvent-based coatings and industrial and consumer cleaning products. The major metabolite of butoxyethanol in laboratory animals is butoxyacetic acid.(1)



Butoxyethanol
M.W. 118

Butoxyacetic Acid
M.W.132

Butoxyacetic acid is primarily responsible for the hemolytic effects seen in laboratory animals and which are the most sensitive indicators of toxicity for this compound.(1) A toxicology study will be performed in order to acquire data that will allow the construction of a reliable physiologically-based pharmacokinetic model for butoxyethanol. This model will include the kinetics of formation and disposition of butoxyacetic acid so that appropriate risk assessment procedures can be carried out (1). An analytical method for the determination of butoxyethanol and butoxyacetic acid will be described. The method utilizes internal standards and involves extractive alkylation followed by acylation. The samples are then analyzed by gas chromatography with electron-capture negative-ion mass spectrometry (selective ion monitoring) using methane as the ionization gas.

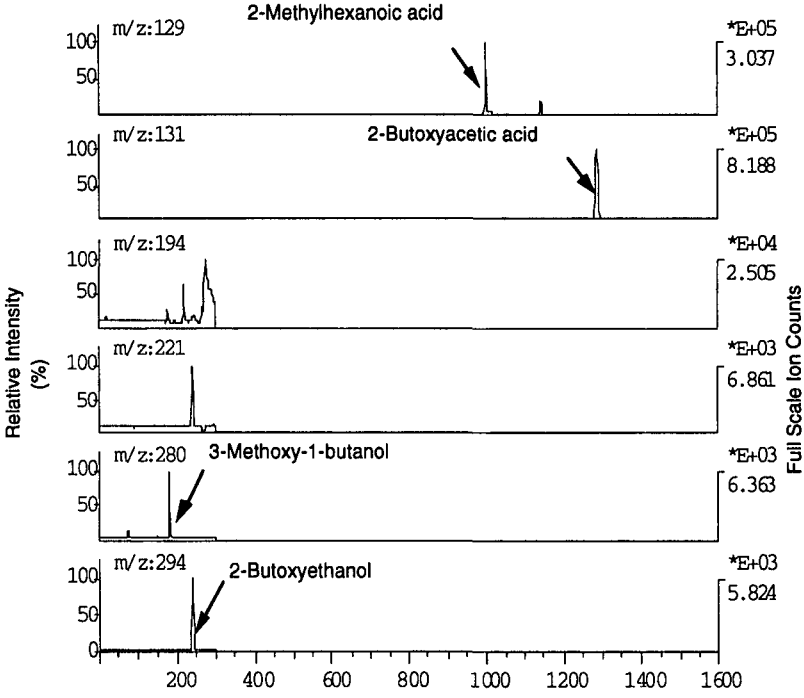
INSTRUMENTATION AND CHROMATOGRAPHIC CONDITIONS: The GC was a Hewlett Packard - model number 5890A with a Hewlett Packard Autosampler - model number 7673A and was operated in the splitless mode. The mass spectrometer was a Finnigan TSQ-70. The source was at 150 °C and the transfer line (interface) was at 280 °C. The reagent gas used was methane at a source pressure of 0.9 torr. The electron energy was 70 eV and the emission current was 200 µA. The mass spectrometer was operated in the electron-capture negative-ion selective ion monitoring mode. The ions that were scanned are 129, 131, 194, 221, 280, 294 at 0.1 sec/ion. The GC was started at 40 °C and ramped to 230 °C at 20 °C/minute, held at 230 °C for 3 minutes, ramped from 230 °C to 250 °C at 20 °C/minute, and held at 250 °C for 2 minutes. A J & W 30 meter x 0.32 mm DB-Wax, 0.5 µm film thickness column was used. Helium was used as the carrier gas with a column flow of approximately 1-2 mL/min.

SAMPLE PREPARATION: Rat blood was fortified with 2-butoxyethanol, 2-butoxyacetic acid, 2-methylhexanoic acid, and 3-methoxy-1-butanol (internal standards). The blood spikes were extractively alkylated with pentafluorobenzyl bromide (100 µL) into methylene chloride (1 mL) at 46 °C for 30 minutes. The methylene chloride layer was then removed, placed into a clean vial, and heptafluorobutyric anhydride was added (55 µL + 3 µL pyridine). The spike was then heated at 70-80 °C for 30 minutes. The spikes were then blown to dryness with nitrogen and then reconstituted in 100 µL of hexane.

RESULTS AND DISCUSSION: Linearity This method gave a linear response for the concentration range of 2 to 100 ng/mL for butoxyethanol and butoxyacetic acid with an average

recovery (relative) of 101% ± 32% for butoxyethanol and 136% ± 29% for butoxyacetic acid. Figure 1 is a typical chromatogram of a blood spike.

Figure 1: Representative chromatogram of blood spiked with butoxyethanol, butoxyacetic acid, and internal standards



CONCLUSION: A method has been developed to analyze for butoxyethanol and butoxyacetic acid simultaneously from blood using internal standards. The method that was developed utilized extractive alkylation followed by acylation, gas chromatography, and electron-capture negative-ion mass spectrometry (selective ion monitoring) using methane as the ionization gas. The limit of quantitation for this method has been set at 2 ng/mL. Further work is currently being done to improve the limit of quantitation by utilizing other derivatives.

DETERMINATION OF MERCAPTURIC ACID METABOLITES OF 1,3-DICHLOROPROPENE IN HUMAN URINE BY GC/MS/MS

Kathy A. Brzak and Patrick E. Kastl, The Dow Chemical Company,
Analytical Chemistry Laboratory, 1803 Building, Midland MI 48674

INTRODUCTION The mixture of cis- and trans -1,3-dichloropropene (1,3-D) constitutes the major portion of TELONE* II soil fumigant* (trademark of DowElanco). The metabolism of 1,3-D has been well studied in rats and mice as well as humans exposed to these compounds during field applications. The major portion of the absorbed dose in all three species is present as a urinary metabolite of 1,3-D, identified as the mercapturic acid conjugate (or N-acetyl cysteine conjugate; 1,3-D NAC)[1-3].

The inhalation of vapors represents the primary potential route of exposure when using this product. Biological monitoring studies have been conducted which attempt to correlate degree of exposure, absorbed dose and urinary 1,3-D NAC concentrations [4,5]. Previously reported urinary analysis methods for 1,3-D NAC suffer from being nonspecific (GC-FPD or GC-NPD) and from the presence of interfering endogenous urinary compounds which greatly reduce the attainable sensitivity [5-7]. This GC/MS/MS method was developed to eliminate these interferences from endogenous materials which will result in a more specific, sensitive analysis needed for current field studies. Also incorporated into this method is the use of a deuterium labeled analog of 1,3-D NAC as an internal standard to reduce the variability of results.

The mass spectrometer is operated in the chemical ionization mode where daughters m/z 75 and 77 result from collision induced dissociation of quasi-molecular MH^+ ion (methyl ester), m/z 252, and the chlorine-37 isotope, m/z 254, respectively. Also monitored are the internal standard methyl ester daughter ions m/z 79 and 81 resulting from parents m/z 256 and 258.

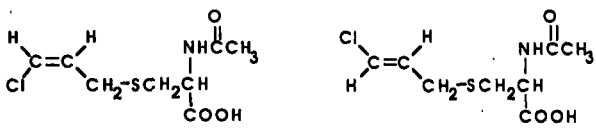

Figure 1. Structures of mercapturic acid conjugates of cis- and trans-1,3-dichloropropene

SAMPLE PREPARATION Urine samples (approximately 4 g) are weighed into glass vials or polypropylene centrifuge tubes, fortified with an accurate amount of a D4-1,3-D NAC internal standard solution and mixed briefly. The samples are then acidified with 1 mL of 1 N HCl and mixed again. Ethyl acetate (5 mL) is used to extract the compounds of interest by vortexing for about 1 minute followed by centrifugation to separate the layers. The organic layer is removed and methylated with 1-2 mL ethereal diazomethane. After evaporation with nitrogen to dryness the residues are reconstituted in 1 mL ethyl acetate for analysis by GC/MS/MS.

ANALYTICAL CONDITIONS Urine extracts were analyzed by GC/MS/MS on a Finnigan TSQ-70 with a Hewlett Packard 5890 GC. Separations were achieved on a 15m x 0.32mm i.d. capillary column coated with a 1μm film of DB-1701. The injector and transfer line were both held at 280°C while the column temperature was ramped after an initial hold at 200°C for 1 minute at a rate of 8°C/minute to 248°C followed by a ramp at 25°C/minute to 280°C (2 minute hold). Helium was used as the carrier gas with a column head pressure of 10 psi. Splitless injections (6 seconds) of 2-3 μL were made with a Hewlett Packard 7673A

autosampler. For analyses involving very low levels of analytes it was necessary to perform a 2 minute splitless injection while holding the column temperature at 50°C followed by a ramp at 15°C/minute to 280°C (1 minute hold). The mass spectrometer was operated in the positive chemical ionization mode using methane as the reagent gas at a pressure of 0.85 torr. Argon was introduced as the collision gas at 0.6 millitorr. The source was operated at a temperature of 150°C. The analysis procedure monitored selected ions m/z 75 (daughter of MH^+ 252), m/z 77 (daughter of 254 - chlorine-37 isotope) and internal standard ions m/z 79 (daughter of MH^+ 256) and m/z 81 (daughter of 258 - chlorine-37 isotope). Scan time was 0.125 second for each ion.

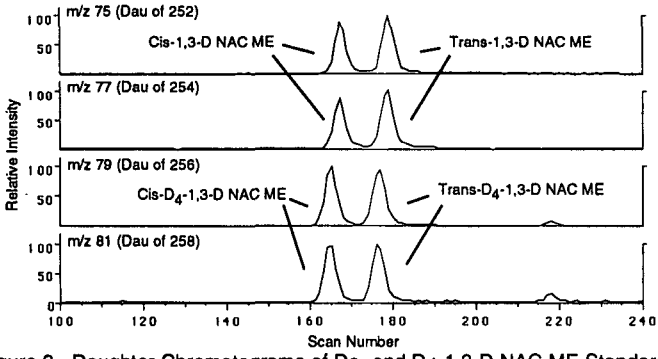

Figure 2. Daughter Chromatograms of D_0- and D_4-1,3-D NAC ME Standards

LIMIT OF DETECTION The detection limit for this method was found to be approximately 1 ng of cis or trans-1,3-D NAC (as the methyl ester) per g urine. Since there are a relatively large number of parameters to optimize on a MS/MS system, sensitivity may vary with sample sets. A detection limit that can be achieved on a regular basis is about 5-10 ng/g.

RECOVERIES The average recovery of cis-1,3-D NAC from fortified control urine was 102.0±5.3% for concentration levels ranging from 0.0018 to 1.37 µg/g urine. The average recovery for trans-1,3-D NAC was 102.7±8.0% for concentrations in urine from 0.0021 to 1.54 µg/g.

Investigations Into the Utility of MS-MS in the Detection of Changes in the Urinary Excretion of Endogenous Substances Following Induction of Drug Metabolizing Enzymes

JJ Vrbanac

Drug Metabolism Research, Upjohn Laboratories
The Upjohn Company, Kalamazoo, MI 49001

Tandem mass spectrometry can be utilized to select (i.e, screen) for compounds with similar structural characteristics. For example, product ion mass spectra of drugs exhibit characteristic neutral losses and product ions that are not only characteristic of the intact drug but also of some metabolites. Likewise, conjugates of drugs (e.g., glucuronides, sulfates, etc.,) can be detected by utilizing specific tandem scan modes with both positive and negative ionization. In the course of utilizing neutral loss scans of 176 daltons following liquid secondary ion mass spectrometry (LSIMS) ionization to detect glucuronide conjugates of a drug thought to be a "mild" inducer of hepatic drug metabolizing enzymes (P-450 cytochromes, UDP-glucuronosyltransferases, etc.), it was observed that there was an apparent increase in glucuronides unrelated to the drug. It was decided to test the following hypothesis: Induction of certain hepatic drug metabolizing enzymes by phenobarbital (PB), and specifically UDP-glucuronosyltransferase-2, will result in increased urinary concentrations of specific glucuronide conjugates in the rat. Three rats received a daily oral doses of 80 mg/kg phenobarbital. Urine samples (24 hour) were collected pre-dose and for 4 days following PB administration. Crude fractions of the pre-dose, 0-24, 24-48, 48-72 and 72-80 hour urine samples were prepared by ODS extraction, water wash and methanol elution, and analyzed by positive ion LSIMS and tandem quadrupole mass spectrometry employing neutral loss scans of 176 daltons. Samples were analyzed by placing 1 µl (out of 40 µl total) of the pooled urine samples on a probe with the 2-HED matrix. An internal standard (*p*-nitro-phenyl-β-D-glucuronide, 1 µg) was also added. The precursor ion mass spectra obtained for these crude urinary extracts were similar except for three precursor ions, m/z 453, 469 and 485, that increased with time after phenobarbital administration. Results (precursors of 176 daltons) obtained for the predose, 24-48 and the 72 to 80 hour samples are displayed in Figures 1-3. The spectra are normalized to the internal standard. Table 1 summaries the data. The three ions observed to increase with time were not observed in the pooled predose sample. However, m/z 453, 469, and 485 increased to 18:1, 12:1 and 6:1 signal to noise ratios in the 72 to 80 hour urine sample, respectively. The data displayed in Table 1 are calculated as the response above the background noise. The trend is identical if response is normalized to the internal standard. These actual magnitudes of the increases are underestimated since the predose sample did not exhibit ion currents at these m/z values. Product ion mass spectra obtained for m/z 452, 469 and 485 were not informative in that only ions representing the loss of the glucuronic acid moiety were observed. Thus, structures could not be assigned with the data obtained.

These data indicate that there is an increased urinary concentration of certain glucuronides following administration of PB. The molecular weights of the aglycones (276, 292 and 308) could not be correlated with known PB metabolites (molecular

weight = 232). In fact, the para-hydroxyphenyglucuronide and the N-glucoside metabolites were not observed. Thus, since the molecular weights observed do not correlate with known major PB metabolites and do not correlate with logical biotransformations, the obsevered glucuronides are apparently of endogenous origin. These observations are not suprizing since PB is an inducer of UDP-glucuronosyltransferase-2. Unfortunately, the product ion mass spectra were not structurally informative. If the observed compounds are of endogenous origin, unrelated to PB, then possible structures for two of the compounds observed are glucuronide conjugates of di- and tri-hydroxyandrostanes (MH^+ = 469 and 485). Future work to address this possibility will employ on-line LC-MS and LC-MS-MS analysis using particle beam and ESI.

PENTAFLUOROPHENYL BORONIC ACID: A NEW DERIVATIZATION REAGENT FOR NCI/MS

J.T. Simpson, S.P. Markey, Yu Ming Pu*, and H. Ziffer*
Section on Analytical Biochemistry, National Institute of Mental Health
and *Laboratory of Chemical Physics, NIDDK, NIH, Bethesda, MD 20892

Introduction

The use of cyclic boronate derivatives of diols has been investigated to enhance the selectivity of the derivatization processes, improve chromatographic properties, or direct mass spectrometric fragmentation. We previously employed hexafluoroacetone and hexafluoroheptanone (HFH) to form cyclic ketals of diols, but found that harsh reaction conditions were required to effect ring closure (1,2). The reaction conditions were incompatible with many of the compounds which we wanted to derivatize, and consequently we have sought an alternative reagent. An appropriately substituted boronic acid was seen as a viable alternative considering the ease of formation of cyclic boronates. Therefore, pentafluorophenyl boronic acid (**FPBA**) was synthesized in order to impart both enhanced electron capture properties and anion stability.

Experimental

The preparation of FPBA has been previously described (3). Briefly, the magnesium Grignard reagent of bromopentafluorobenzene was condensed with tributylborate to form the pentafluorobenzene dibutylborate. The dibutylborate was then hydrolyzed to give FPBA in 46% overall yield.

1,2-Propanediol, *cis* -1,2-cyclohexanediol, methyl 2-methylglycerate, and 3,4-dihydroxyphenylethylene glycol (DHPG) were chosen as model compounds for derivatization. Typical reaction conditions were combining 200 µL of a 2 nmol/µL solution of the diol dissolved in methylene chloride with 200 µL (400 µL for DHPG) of a 2 nmol/µL solution of FPBA dissolved in methylene chloride. The solution was then vortexed briefly and allowed to stand at room temperature for 15 min. An aliquot of the reaction mixture was taken for analysis.

Analytical Conditions

Spectra were obtained on either a Finnigan TSQ-70 operating in single quad mode, scanning Q3, interfaced with a Varian 3400 GC or on a HP-5989 interfaced with a particle beam (PB) LC/MS inlet. The mass spectrometers were scanned from m/z 50 to 750 for GC/EI and NCI/MS, m/z 60 to 750 for GC/PCI/MS and m/z 100 to 750 for PB/MS. The ion source temperature was 150°C (250°C for PB/MS). Methane was used as the reagent gas for all chemical ionization experiments.

Typical GC conditions were ramping from 70°C to 280°C at 30°/min, with the injection port and transfer line at 280°C. An HP-5 column (12 m x 0.2 mm x 0.33 µm film thickness) was used for the analyses. Under these conditions the 1,2-propanediol / FPB derivative eluted at 3.1 min., the *cis* -1,2-cyclohexanediol / FPB eluted at 4.4 min, and the methyl 2-methylglycerate / FPB eluted at 4.1 min. The DHPG/FPB did not elute under these conditions and was analyzed by direct flow injection (no column) PB/LC/MS using toluene at 0.4 mL/min as the solvent.

Results

The pentafluorophenyl boronates (FPB) of the diols formed with quantitative yields at room temperature. The FPB derivatives are stable in methylene chloride, whereas they have been reported to be unstable in tetrahydrofuran (4). Exposure to water or wet solvents resulted in hydrolysis of the derivative. The mass spectra showed intense molecular (or $[M+H]^+$) ions in all ionization modes. The NCI spectra were dominated by the molecular anion and one or two structure specific ions. Of note are the appearance of weak but reproducible ions at higher mass. Some of these ions contain boron isotopes and their origin is under investigation. The PCI spectra of the derivatives were dominated by the $[M+H]^+$ ion while the EI spectra had prominent molecular ions as well as abundant structure specific ions.

The sensitivity of the FPB derivatives appears to be dependant on the structure of the analyte. EI gave the best response for the derivatives tested by GC/MS. The methyl 2-methylglycerate/FPB derivative also showed good sensitivity in NCI, only slightly less than that obtained in EI. The NCI response for 1,2-propanediol/FPB and *cis* -1,2-cyclohexanediol/FPB was an order of magnitude less than that seen in EI. The sensitivity in PCI of these three diol derivatives was roughly equivalent and again, a factor of 10 less sensitive than EI. The DHPG/FPB derivative gave the best NCI sensitivity, 30 to 50 times greater than in either EI or PCI. This may be the result of the addition of a second FPB group on the molecule combined with the aromatic ring present in the system. The NCI spectrum of DHPG/FPB is shown in Fig. 1.

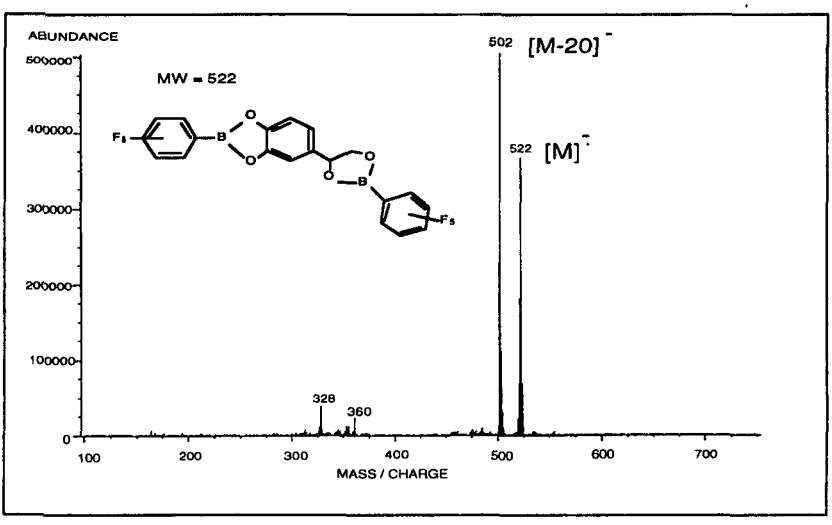

FIG 1: PB/NCI mass spectrum of DHPG/FPB.

Conclusions

Cyclic pentafluorophenyl boronate (FPB) derivatives of diols can be formed readily at room temperature in quantitative yields. The FPB derivatives exhibit good chromatographic properties, with the exception of DHPG, and the expected EI and PCI fragmentation characteristics. The NCI spectra are dominated by the molecular anion and contain weak, high mass, boron containing ions which may be the result of adduct formation. The FPB derivatives show excellent sensitivity in EI and, in the case of methyl 2-methylglycerate/FPB and DHPG/FPB, NCI as well.

FAB MS and MS/MS Analysis of Benzo[*a*]pyrene-Peptide Conjugates

*J. Zaia and K. Biemann, Dept. of Chemistry, MIT, Cambridge MA 02139

Benzo[*a*]pyrene (B*a*P) is a polycyclic aromatic hydrocarbon that is prevalent in the environment. BaP is found in high concentrations in the sediment of polluted harbors and is also found in the air as a combustion byproduct. Exposure to B*a*P is considered to be an initiating event in the growth of cancer. Once in the body, B*a*P is enzymatically oxidized in the liver. Among several oxygenated B*a*P metabolites, the (±)-*r*-7,*t*-8-dihydroxy-*t*-9,*t*-10-epoxy-7,8,9,10-tetrahydrobenzo[*a*]pyrene (B*a*PDE) has been implicated as a DNA and protein binding agent. B*a*PDE reacts with cellular nucleophiles at its electrophilic C-10 position.

Mass spectrometry has played a role in recent studies of B*a*PDE adduction of hemoglobin[1] and serum albumin[2]. One of the primary goals of these studies has been to determine the site of B*a*PDE adduction in the protein sequence. Methods usually involve digestion of the adducted protein with a protease followed by a step to enrich for the adducted peptides. The pyrene chromophore absorbs strongly at 345 nm, allowing for detection of adducted peptides using an HPLC with a dual wavelength detector. To identify the adducted portion of the protein sequence it is desirable for the peptide to be of sufficient size to define a unique sequence. Thus it is important to choose a protease which yields peptides of appropriate size. Since complete sequence information for FAB MS/MS is generally limited to peptides of Mr < 2000 and the B*a*PDE adduct adds 302 Da, the peptide portion should be less than 1700 Da.

The B*a*PDE adduct of angiotensin II was synthesized[2] and the N-acetylated[3] and N- and O-acetylated[2] derivatives of the adducted peptide were prepared. Scheme 1 shows the pathway for the adduct product ions observed in unacetylated and fully acetylated B*a*PDE-peptide CID spectra. In scheme 1A, the adduct ion at m/z 303 loses H_2O and CO to produce the product ions at m/z 285 and 257. In scheme 1B, the adduct ion at m/z 429 loses acetic acid and two ketene molecules to produce the ions at m/z 369, 327, and 285..

Figure 1 shows the CID spectrum of the angiotensin II-B*a*PDE adduct. The spectrum shows a significant increase in the relative abundance of the peptide backbone product ions when compared to the spectra of smaller peptide adducts (not shown). Also present are the adducted a_6, a_7, and a_8 ions (denoted a_n^*) allowing for the unambiguous assignment of the site of the adducted histidine. The CID spectrum of the N-acetylated derivative was very similar to that of the unacetylated spectrum including the presence of the adducted a_n ions. The CID spectrum of the N- and O-acetylated derivative lacked the adducted a_n ions. Acetylation was clearly not necessary for the angiotensin II adduct in terms of ionization efficiency, although the preparation of an N-acetylated derivative could help resolve uncertainties in the interpretation of the spectrum of an unknown.

The positive CID MS/MS spectra of B*a*PDE-peptide adducts are dominated by product ion derived from the adduct but appear to become less so as the size of the peptide increases. It is possible to unambiguously determine the adducted residue for peptides provided that the peptide product ions are sufficiently abundant. Acetylation seems to improve the ion abundance of the smaller B*a*PDE-peptide adducts but is not necessary for a larger B*a*PDE-peptide adduct.

Analysis of Amino Acids by GC-MS: Simultaneous Derivatization of Functional Groups by an Aqueous-Phase Chloroformate-Mediated Reaction

*Jian Wang[1], Zhi-Heng Huang[2]; Douglas A. Gage[2] and J. Throck Watson[1,2]
Departments of Chemistry[1] and Biochemistry[2],
Michigan State University, East Lansing, MI 48824

The criteria for a hypothetical, ideal procedure for amino acid determination by GC-MS are 1) simple reaction conditions with minimal sample handling; 2) derivatization carried out in an aqueous medium; 3) rapid reaction proceeding at room temperature; 4) single GC column with good resolution for the common protein amino acids. Husek [1] developed an ethyl chloroformate reagent for derivatization and analysis of amino acids by GC, which is a good candidate for this ideal. In an aqueous medium, ethyl chloroformate reacts instantaneously with the amino, carboxyl and thiol functional groups to derivatize amino acids to for the N(S,O)-ethyloxycarbonyl ethyl ester.. For the derivatization procedure, see [1].

In our work, we are extending and improving this derivatization method by applying alternate chloroformate reagents and different combinations of derivatization reagents for amino acids prior to analysis by GC and GC-MS. We are also applying this single-step chloroformate derivatization method for analysis of glutathione conjugates by FAB-MS/MS.

A different reaction mechanism for the carboxyl group derivatization is proposed over that suggested by Husek[1]. Previously, Husek suggested that the carboxyl group derivatization is through a decarboxylation of the intermediate "mixed anhydride"[1]. In our experiment, by using an alcohol with a different alkyl group from that in the alkyl chloroformate, the alkyl group in the ester (derivative) exclusively corresponds to that in the alcohol, (and not that in the chloroformate). We suggest that during the course of esterification, an exchange between the alcohol and the intermediate "mixed anhydride" is involved (Figure 1). The derivatization product from the decarboxylation is only a minor part.

From this observation arises an additional and important advantage of this technique--versatility for the preparation of a wide range of esters merely by changing the alcohol component in the reaction medium. A systematic comparative study of a series of amino acid derivatives formed by alkylchloroformates with alkyl alcohol, perfluoroalkyl alcohol, and TMS-alkyl alcohol. has been carried out on GC and GC-MS(EI and CI). From the systems studied, isobutylchloroformate-heptafluorobutanol (iBuCF-HFB), and isobutylchloroformate-trimethylsilylmethanol (iBuCF-TMSMeOH) and isobutylchloroformate-isobutanol (iBuCF-iBuOH) derivatives showed the best sensitivity and separation. (Figure 2) And perfluoro-assisted reagents have the potential for ECNI-MS, which could drastically increase the sensitivity of the analysis. This work is under way. These chloroformate-alcohol combinations provide a new simple and sensitive derivatization method for the analysis of amino acids by GC/MS.

Preliminary study of this single-step derivatization method for the analysis of glutathione conjugates by FAB-MS/MS. The model compound we chose so far is S-

decylglutathione. The MS spectrum of the derivative shows both the amino and carboxyl function groups are derivatized in one step. And MS/MS spectrum of the derivative shows a change in fragmentation and enhancement of **a** [2] ion that results from loss of the glycyl moiety (which agrees with the two step derivatization result by Pearson [3]). The **a** ion can be used for a constant neutral loss scan for screen of the glutathione conjugates in mixture [3]. Systematic work is under way. The preliminary result shows promise for simplification of the derivatization methods for the derivatization/HPLC purification/FAB-MS/MS analysis of glutathione conjugates.

Application of Ionspray LC-MS for the Detection of New Analogues of Dinophysistoxin-3

J.C. Marr[1], T. Hu[1], S. Pleasance[2,3], M.A. Quilliam[3], and J.L.C. Wright[3]. [1]Fenwick Laboratories Limited, Halifax, N.S., Canada, B3H 4M2, [2]Present address: The Wellcome Foundation Ltd., Beckenham, Kent, U.K., [3]Institute for Marine Biosciences, NRC, Halifax, N.S., Canada, B3H 3Z1

Dinophysistoxin-3 (DTX-3) is one of several diarrhetic shellfish poisoning (DSP) toxins that have been detected in shellfish [1]. Unlike the DSP toxins, okadaic acid (OA) and dinophysistoxin-1 (DTX-1), that have been identified in several dinoflagellate species, including *Prorocentrum lima* [2], DTX-3 has only been found in the digestive glands of shellfish [1]. DTX-3 describes a series of DTX-1 derivatives esterified with either a saturated or unsaturated fatty acid group attached at the C-7 position. It has been suggested that DTX-3 may be produced by bioconversion in shellfish, since it has not been found in dinoflagellates [1].

Routine monitoring of shellfish for DSP toxins is generally done using rat or mouse bioassays, but instrumental methods are required for confirmation. The most common method for both shellfish and phytoplankton is reversed phase HPLC with fluorescence detection after derivatization of the extract with anthryldiazomethane [3]. However, due to its high molecular weight and lipophilicity, DTX-3 must be converted back to DTX-1 via alkaline hydrolysis before analysis.

We have recently reported the application of LC coupled with ionspray mass spectrometry (LC-ISP-MS) for the detection of DSP toxins in shellfish samples [4]. Using this technique, it is possible to detect the intact, underivatized toxins in relatively crude extracts. The acyl ester derivatives of DTX-1 (DTX-3), OA, and a new toxin, DTX-2 [5] were separated and detected in a semi-purified fraction obtained from mussel digestive glands using LC-ISP-MS. The most abundant derivatives were those containing the C14:0, C16:0, and C16:1 fatty acid groups (Figure 1). Alkaline hydrolysis of this fraction resulted in conversion of these toxins to their parent molecules (Figure 2).

This is the first report of the direct detection of these compounds. These results show that all known DSP toxins can produce acyl ester derivatives and raises the question of the most appropriate nomenclature for these compounds. A revised nomenclature is suggested that would simplify and clarify the nature of these compounds. For example, the 7-O-acyl derivatives of a specific DSP toxin, such as DTX-1, could be more precisely described as acyl-DTX-1 (instead of DTX-3), acyl-OA, *etc.* and if possible the fatty acid chain length should be specified (e.g. C14:0-DTX-1).

MILD PERIODATE OXIDATION AND CORE-BRANCHING PATTERN ANALYSIS OF O-LINKED GLYCOPROTEIN OLIGOSACCHARIDES

W. Chai, G. Cashmore, M.S. Stoll and A.M. Lawson
MRC Clinical Research Centre, Watford Road, Harrow, Middx HA1 3UJ, UK.

O-linked glycoprotein oligosaccharides are usually released by alkaline/borohydride treatment as reduced alditols. Microscale determination of the GalNAcol core-branching pattern and sequences of 3- and 6-chains of these alditols can be made by a new strategy (1) which includes mild periodate oxidation, dipalmitoyl phosphatidylethanolamine (DPPE) conjugation and TLC/LSIMS analysis. The DPPE derivatives obtained in this way are also suitable for solid phase ligand binding studies on TLC plates.

It was demonstrated that under mild periodate oxidation conditions only the C_4-C_5 diol of the open chain of the 3,6-disubstituted GalNAcol core was cleaved, while diols on the saccharide ring remained intact (1). As 3- or 6-monosubstituted GalNAcol and sialylated alditols contain more than one potential oxidation site, it remains unclear whether conditions can be optimized to produce a single cleavage product. This would allow the oxidation strategy to be applied to mono-substituted GalNAcol core and sialic acid containing structures and hence complete the range of O-linked glycoprotein oligosaccharide alditols that can be studied.

Using a variety of oligosaccharide alditols, the mild periodate oxidation was assessed by characterizing the aldehyde-containing products of the reaction as their DPPE derivatives. This was carried out by direct TLC/LSIMS analysis (2). The distribution of oxidation products was determined from the intensity of fluorescence of sample bands containing the DPPE lipid conjugate following spraying with primulin reagent. Greater than 95% specific cleavage of the C_4-C_5 bond is observed for 3- and 6-monosubstituted GalNAcol. The major sites of oxidation in 4- and 6-monosubstituted glucitols are diols with *threo*-configuration (e.g. C_2-C_3, 92% for 4-substituted, and C_3-C_4, 68% and C_2-C_3, 29% for 6-substituted glucitol). In the case of NeuAc2-6GalNAcol, 60% of oxidation products involve cleavage at the C_4-C_5 bond of the GalNAcol leaving sialic acid intact.

The value of this procedure, for branching pattern analysis of mono-substituted GalNAcol cores of O-linked glycoprotein oligosaccharides, is exemplified by the confirmation of two recently established but less common mono-substituted core-type sugars, GalNAcα1-3GalNAcol (R2) and GalNAcα1-6GalNAcol (N2-2) from human meconium glycoproteins and bovine submaxillary-gland mucin, respectively. After oxidation and DPPE conjugation, the reaction mixture was separated on a TLC plate. Single product bands (bands a and b in Fig 1a and 2a, respectively) are found in each case. Multiple bands in the upper region of the TLC plate are derived from the excess reagent. Mass spectra obtained directly from the TLC bands a and b are shown in Fig 1b and 2b, respectively. In each spectrum, the 203 Da difference between the intense $(M-H)^-$ and the major sequence ions indicates a HexNAc residue. Fragment ions at m/z 835 and m/z 734 are the DPPE linked C_3- and C_6-containing fragments of the core GalNAcol. Direct "methylation analysis" of both bands after solvent extraction showed the presence of GalNAc1- (Fig 3) and fully agreed with the non-reducing terminal structures of R2 and N2-2.

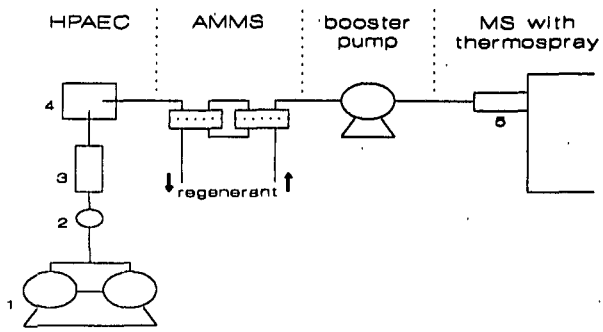
High-performance anion-exchange chromatography (HPAEC) is a powerful method, that is widely used in the analysis and characterization of oligomeric sugars as, for instance, obtained by enzymic degradation of plant cell wall polysaccharides. Identification of unknown oligomers is performed by time-consuming fractionation and purification techniques, followed by characterization by MS and NMR. On-line HPAEC-MS might allow a more rapid characterization of fractions in terms of molecular weight and structure.
The HPAEC-MS system developed features:

- conventional Dionex HPAEC analysis with electrochemical detection of sugar oligomer mixtures, using a mobile phase of 0.1 mol/l aqueous sodium hydroxide and a 0-0.5 mol/l aqueous sodium acetate gradient.
- post-column removal of sodium by a dual anion micromembrane suppressor (AMMS) using sulphuric acid as regenerant.
- dilution and re-pressurization of the solvent for the LC-MS interface.
- Finnigan MAT thermospray LC-MS analysis based on cationization of sugar oligomers by sodium ions.



The coupling is relatively easy to accomplish, given experience with thermospray LC-MS.

The mass spectra obtained under the present conditions are characterized by sodiated molecules, $[M+Na]^+$ at $m/z=M_r+23$ and (with higher DP-values) $[M+2Na]^+$ at $m/z=(M_r+46)/2$. No fragmentation is observed.
Insufficient removal of sodium ions by the AMMS restricts the sodium acetate gradients that can be applied. Up to 0.4 mol/l sodium can be removed by the AMMS. This limits the maximum DP values that can be analyzed. For homologous series these limits are: DP=3 for polygalacturonic acids, DP=5 for α-1,4-glucans, DP=6 for ß-1,4-galactans, DP=9 for α-1,5-arabinans and DP=25 for ß-1,4-xylans.
The system was applied to the analysis of various homologous series of sugar oligomers and to samples obtained by enzymic degradation of plant cel wall polysaccharides. As an example, the results of the analysis a potato arabino-1,4-galactan which was degraded by an endogalactanase are shown below. The larger peaks in the chromatogram were identified as a series of galactose oligomers, and the smaller peaks contain one arabinose next to the galactose units.

ALKALI METAL ION CATIONIZATION OF CARBOHYDRATES

Gary Siuzdak, Conrad W. Hummel,[1] K. C. Nicolaou,[1] and Yoshitaka Ichikawa

The Scripps Research Institute
Department of Chemistry
La Jolla, CA 92037

The multidentate-alkali metal ion complexation of macrocyclic compounds has been examined through a variety of methods; crown ethers, for example, have been shown to form relatively stable complexes with alkali metal ions by X-ray crystallography. Recently desorption mass spectrometry has been used to study such complexation[2,3]. We have attempted to examine the interaction between alkali cations and underivatized neutral sugars through the semi-quantitative capabilities of particle desorption and ion spray mass spectrometry. In this investigation we have examined the alkali cationization of eight underivatized carbohydrates: fructose, glucose, galactose, mannose, maltose, sucrose, tetramaltose, heptamaltose, and a deuterated analog of glucose, 6,6-glucose-d_2.

The positive liquid secondary ion mass spectrometry (LSIMS) performed on the monosaccharides were obtained with a VG ZAB-VSE double focusing mass spectrometer. These experiments were performed on solutions containing two monosaccharides, fructose & 6,6-glucose-d_2, glucose & 6,6-glucose-d_2, galactose & 6,6-glucose-d_2, or mannose & 6,6-glucose-d_2 and equivalent amounts of an alkali iodide salt. The ion spray experiments were performed on the glucose-containing sugars with a PE Sciex Ion Spray MS because of its increased sensitivity for the higher order carbohydrates.

Table I. LSIMS monosaccharide cationization, intensity of the monosaccharide cationized precursor ions relative to [6,6-Glucose-d_2 (**G-d_2**) + Cation]$^+$.

Monosacch. (M)	Glucose	Mannose	Galactose	Fructose
$[M + Li]^+/[G\text{-}d_2 + Li]^+$	1.02	1.65	1.40	1.79
$[M + Na]^+/[G\text{-}d_2 + Na]^+$	0.97	1.54	1.25	1.72
$[M + K]^+/[G\text{-}d_2 + K]^+$	1.03	1.13	1.00	1.01
$[M + Rb]^+/[G\text{-}d_2 + Rb]^+$	1.05	1.00	1.03	0.98
$[M + Cs]^+/[G\text{-}d_2 + Cs]^+$	0.95	-------	0.98	------
Error (+/-)	0.08	0.08	0.09	0.07

The LSIMS relative ion intensity data, obtained when a equimolar mixture of alkali salts was added to the monosaccharides, suggested mannose and glucose had a greater affinity for the sodium cation, although this effect was diminished with galactose and further with fructose. Fructose had the greatest affinity for the lithium cation than any of the other monosaccharides. A significant decrease was observed in the formation of [monosaccharide + cation]$^+$ ion intensities for the cations - potassium, rubidium, and cesium. These results indicate, similar to the crown ether-alkali metal ion

complexation[2], that the monosaccharides were undergoing multidentate binding dependent on the size of the cations. In fact, complexation of sugars has been shown to be dependent on the ionic radius of the cation[4]. However, variations in ion intensity ratios for each monosaccharide suggest that different isomeric conformations, **Table I** and **Figure 1**, result in selective binding of the cations.

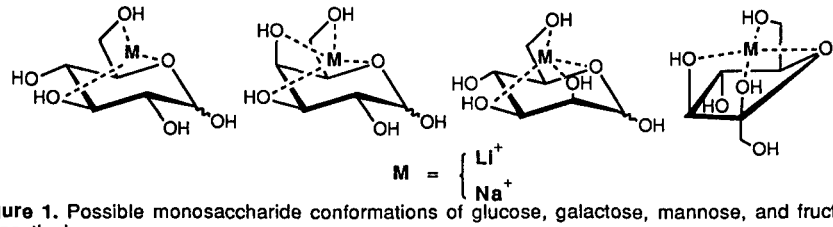

Figure 1. Possible monosaccharide conformations of glucose, galactose, mannose, and fructose, respectively.

Two aspects of carbohydrate-alkali cation binding appear to drive effective complexation, the size of the cation and the number of sites available for complexation. The dependence on the number of binding sites is further enhanced when the larger sugars are considered, a result especially apparent in the ion spray analysis of the glucose containing sugars shown in **Figure 2**.

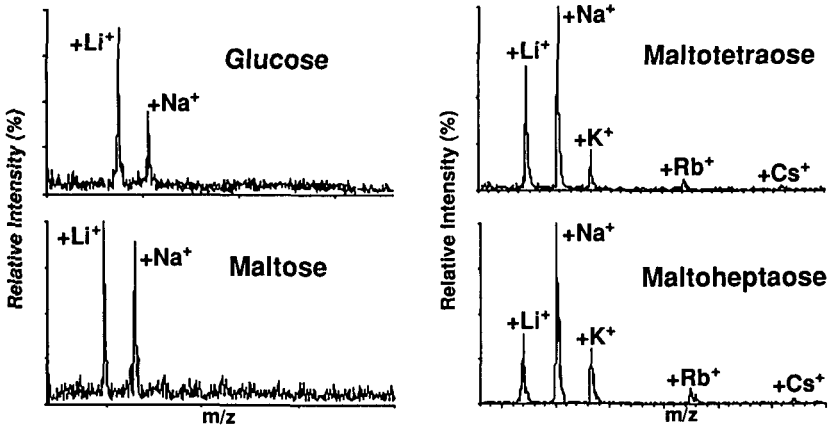

Figure 2. Ion spray mass spectra of the glucose containing sugars (maltose = 2 x glucose, maltotetraose = 4 x glucose, and maltoheptaose = 7 x glucose) analyzed in equivalent amounts of the alkali iodide salts.

Characterization of Phytoalexin Elicitors Derived from Hops (*Humulus lupulus*)

*M.O. Glocker, H. Su, and M.L. Deinzer

Department of Agricultural Chemistry, Oregon State University, Corvallis, OR. 97331.

Developing resistant plant varieties is one way of controlling pests without an over-reliance on chemical pesticides. In order to achieve this goal it is important to obtain detailed knowledge of plant resistance mechanisms and the corresponding chemical compounds that are responsible for this resistance. The identified resistance substances could also be synthesized in order to provide the crop grower with the "natural" pesticide that does not carry the disadvantages recent pesticides might have.

Our investigations deal with the resistance of hops (*Humulus lupulus*) to hop aphids (*Phorodon humuli*). By penetrating the leave tissue the aphid stylet destroys plant cells and so releases enzymes which produce cell wall derived endogenous elicitors [1,2]. Cell wall substances not only have structural functions but also contain informational components [3,4]. Among the plant cell wall components that function as elicitors, the family of oligo-galacturonic acids is of tremendous importance [5,6]. Elicitors trigger a reaction cascade and lead to the production or accumulation of phytoalexins. Elicitation of phytoalexins as a response to infestation by parasites is a commonly accepted resistance model [7,8]. Based on these assumptions we focus on the extraction, purification and characterization of the responsible chemical compounds in hops.

Recently, unsaturated hexa galacturonides isolated from *Ficus awkeotsang* have been reported to bear phytoalexin eliciting properties [9]. Our studies reported here are the second example in which unsaturated hexa galacturonides have been identified and proven to function as phytoalexin elicitors, suggesting that these molecules form a novel class of elicitor compounds.

We prepared cell wall material (CWM) from hop leaves using a procedure that achieves maximum solubilization of starch and cytoplasmic components with minimum loss of the non-starchy cell wall polysaccharides [10,11]. Total hydrolysis of the CWM in either trifluoroacetic acid (TFA) or sulfuric acid confirmed that the obtained material consists only of carbohydrates. Using both the High pH Anion Exchange Chromatography coupled with Pulsed Amperometric Detection (HPAEC-PAD) and colorimetric assays the monosaccharide composition of the CWM was established [12,13]. These results show that the major compound in the obtained CWM is galacturonic acid (see table 1).

Table 1: Monosaccharide composition of hop CWM (variety 64107)

Carbohydrate	% of total sugar
Fucose	0.1
Rhamnose	6.8
Arabinose	14.8
Galactose	12.9
Glucose	16.6
Xylose	8.2
Galacturonic acid	39.5

Partial hydrolysis of the CWM leads to a mixture of oligomers. Separation on a QAE-Sephadex A-25 anion exchange column reveals nine fractions according to colorimetric assays for galacturonic acid and total sugar [12,13]. These results and also HPAEC-PAD of the nine fractions indicate that all but fraction no. 2 consist of galacturonic acid oligomers (see figure 1a).

All fractions were isolated and assayed for biological activity. As a bioassay for elicitor activity we used the soybean cotyledon assay [3,14,15]. Soybean tissues accumulate glyceollin in response to elicitors. The monitored increase in UV absorbance at 286 nm is linearly correlated to the phytoalexin increase in the sample solution [16,17]. Using this assay fraction no. 6 was identified as the sample bearing the greatest activity in phytoalexin elicitation. A lower elicitor activity was detected for fraction no. 7 (see figure 1b).

Figure 1: Ion exchange chromatogram and elicitor activity for the separated elicitor fractions after partial hydrolysis of the hop CWM.

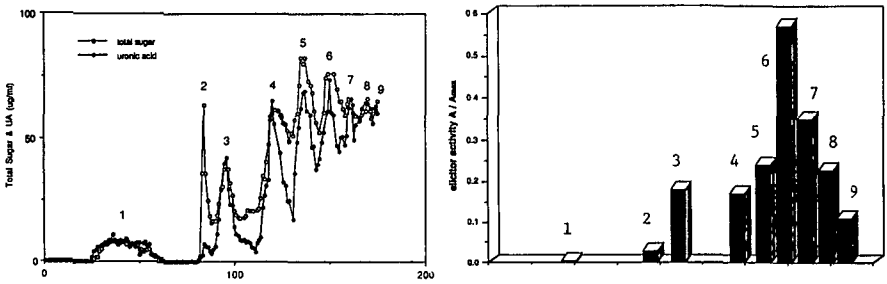

figure 1a figure 1b

The exact degree of polymerisation of the isolated elicitor fractions was unambiguously established by Fast Atom Bombardment Mass Spectrometry experiments (FAB-MS). These experiments revealed that the most active elicitor fraction (fraction no. 6) consists of an unsaturated galacturonic acid hexamer. This structure is represented by the molecular ion peak at m/z 1055 for $[M-H]^-$ (see figure 2). Prominent fragment peaks were observed with 176 mass units lower than the molecular ion for the loss of saturated galacturonosyl residues from the reducing end. A peak being 158 mass units lower than the molecular ion represents the loss of the unsaturated galacturonosyl residue from the nonreducing end.

Figure 2: Negative FAB-MS spectrum of the molecular ion region of the unsaturated hexa galacturonide and its tentative structure.

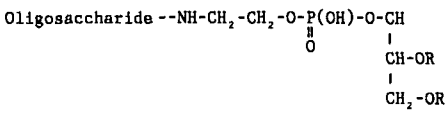
DETECTION OF NEOGLYCOLIPIDS BY MATRIX ASSISTED LASER DESORPTION MASS SPECTROMETRY

A.M. Lawson, W. Chai, [1]J.S. Cottrell, M.S. Stoll and [1]C.W. Sutton,
MRC Clinical Research Centre, Watford Road, Harrow, Middx, HA1 3UJ, UK
and [1]Finnigan MAT Ltd., Paradise, Hemel Hempstead, Herts, HP2 4TG, UK.

INTRODUCTION

Phosphatidylethanolamine derivatives of oligosaccharides have been shown to give high LSIMS-sensitivity molecular ions, together with fragmentation that reflects monosaccharide sequence and branching information (1). The derivatives have the composition:



where R = acyl or alkyl (e.g. palmitoyl or hexadecyl, respectively). The accepted importance of carbohydrate-recognising domains in an increasing number of proteins has given considerable impetus to the value of the neoglycolipid technology for direct ligand binding studies and its combination with structure elucidation by mass spectrometry.

In the present study, matrix-assisted laser desorption has been investigated for the detection of neoglycolipids to assess possible advantages in sensitivity and for the screening of mixtures of oligosaccharides converted to these lipid conjugates as part of the ligand binding overlay strategy.

EXPERIMENTAL

LNFP I and a mixture of malto-oligomers were converted to neoglycolipid derivatives containing dihexadecyl lipid tails (DHPE) and a mixture of oligosaccharides released from IgG glycoproteins were converted to dipalmitoyl-containing neoglycolipids (DPPE).

α-Cyano-4-hydroxycinnamic acid (CHC) was used as matrix for the neoglycolipids and 2,5-dihydroxybenzoic acid (DHB) for native oligosaccharides. Matrix solutions of 10 μg/μl were preprared in 60% CH_3CN and 1 μl loaded onto the target. Solutions of the free oligosaccharides in water or neoglycolipids in $CHCl_3$:MeOH:H_2O (25:25:8 by vol) were added to the matrix solution on the target.

The samples were analysed on a Lasermat (Finnigan MAT Ltd, Hemel Hempstead, UK) using a pulsed nitrogen laser (337 nm). Each pulse of desorbed ions was accelerated to 20 keV/charge and detected at the end of a 0.5 m TOF analyser by a discrete dynode electron multiplier.

RESULTS

The milk oligosaccharide LNFP I, Fucα1-2Galβ1-3GlcNAcβ1-3Galβ1-4Glc, as a DHPE derivative gave an MH^+ ion at m/z 1503 from 5 pmol sample by LD-MS from a CHC matrix. Despite careful desalting, equally intense Na adduct ions were also present which degraded the apparent sensitivity. In negative ion mode the $[M-H]^-$ ion at m/z 1501 was produced at a similar concentration and while this was less sensitive than for the native LNFP I (1 pmol) or other reported oligosaccharides (2), both matrix and solvent remain to be optimized. Equivalent results were obtained with the mixture of malto-oligomers, Glcα1-$(4Glc\alpha1)_n$-4Glc where n = 1, 2, 3 and 5. The multiple salt adducts reduce the available resolution for mixture analysis by LD-MS in +ve mode while the single deprotonated molecular ions in -ve mode were ideal for discriminating individual components.

The spectrum of a mixture of free N-linked biantennary oligosaccharides (20 pmol) released from IgG glycoproteins is shown in Fig 1, individual species each giving a MNa^+ ion. Fig 2 shows the -ve ion spectrum from the same concentration of this mixture as DPPE derivatives from a CHC matrix. The oligosaccharide mixture contains two series of ions: the major series in which the biantennary branches are extended by galactose (i.e. $Gal_{0,1 \text{ or } 2}$ giving m/z 2120, 2283 and 2444) and a minor series which have the same structures but contain a bisecting GlcNAc (i.e. m/z 2326, 2486 and 2650).

CONCLUSIONS

1. The sensitivity of matrix-assisted LD-MS of neoglycolipids is in the low pmol range and approaches that of native oligosaccharides. It is likely that sensitivities will improve under optimized matrix and solvent conditions.
2. The negative charge on the neoglycolipid encourages salt adduction in the +ve ion mode, but gives rise to simple $[M-H]^-$ ion spectra in -ve mode suitable for mixture analysis.
3. Matrix-assisted LD-MS will be of value for screening pmol aliquots of neoglycolipids at appropriate stages in ligand binding experiments, in particular for establishing quantitative derivative formation and liquid chromatographic separation.

A COMPARISON OF THE SCRAPIE AND CELLULAR FORMS OF THE GLYCOSYLATED AND GPI-ANCHORED PRION PROTEIN (PrP)

M A Baldwin, K-M Pan, R Hecker, R Wang*, R Beavis*, B Chait*, N. Stahl, A L Burlingame and S B Prusiner
University of California, San Francisco, CA 94143-0518. * Rockefeller University, New York, NY 10021-6399.

PrP is a GPI-anchored membrane protein expressed in all neuronal cells. The normal cellular protein PrP^C can be converted by an as yet unidentified modification to a pathogenic form associated with prion diseases. Members of this group of fatal neurodegenerative diseases which includes a number of human diseases and scrapie of sheep are unique in being both familial and infectious.[1] Scrapie is a convenient model to study as it can be experimentally transmitted to laboratory animals, the infectious agent apparently being the modified isoform of the protein, PrP^{Sc}. In a comprehensive analysis of PrP^{Sc} isolated from the brains of Syrian hamsters we have established that the amino acid sequence conforms to that predicted from the cDNA and gene sequences. No posttranslational covalent modifications have been identified other than N- and C-terminal processing with the addition of the GPI anchor at the new C-terminus, additional C-terminal processing of a fraction terminating three residues earlier, the addition of N-linked complex carbohydrates at two consensus sequences, and the formation of an *intramolecular disulphide bond between the two cysteine residues not affected by terminal processing.*[2, 3]

The object of the present study is to compare PrP^C with PrP^{Sc} and to ascertain whether the difference between them is covalent in nature or is entirely physical. There is considerable microheterogeneity in the modifications such as the N-linked carbohydrate and the glycan core of the GPI anchor, therefore it is also necessary to determine whether one or other form represents a different subpopulation. We have carried out an analysis of the GPI glycan of PrP^{Sc}, using a variety of methods for analyzing small samples including high resolution CID-MS/MS and ESMS and have identified 6 major glycoforms (Figure 1). These are identical for PrP^{Sc} isolated from hamsters infected with two different strains of scrapie having different incubation times and pathology.[4] PrP^C has been more difficult to purify but in an initial study using impure material we demonstrated by capillary electrophoresis that the C-terminal peptide-GPI anchor from digestion with endoproteinase Lys C had identical electrophoretic mobility to that from PrP^{Sc} (Figure 2). The products from hydrolysis by 50% aqueous HF which cleaves the phosphodiester bonds or from digestion with neuraminidase which removes sialic acid from the glycan were also indistinguishable, suggesting that the GPI's are identical and therefore are not responsible for the different properties exhibited by the two forms.

We have developed mass spectrometric methods that provide characteristic "fingerprint" spectra of the heterogeneous N-linked sugars attached at each site, e.g. the ESMS spectrum of a 75-residue glycopeptide from a PrP^{Sc} digest that contains the first glycosylation site can be deconvoluted by a minimum entropy method to reveal an array of different glycoforms. Comparisons will be made between PrP^{Sc} and PrP^C, analyzing both consensus sites independently for differences in the mass spectra.

Matrix-assisted laser desorption TOF-MS has been used to compare the proteins after the heterogeneous N-linked carbohydrates have been removed enzymatically. Solubilization of these membrane proteins in a solvent compatible with a suitable UV-chromophoric matrix compound is problematical but we have refined the analysis using hexafluoroisopropanol as a solvent for the protein mixed with chloroform/methanol/water containing the matrix, 4-hydroxy-α-cyanocinnamic acid (4-HCCA). Figure 3 shows the spectra of PrP^C and PrP^{Sc} after treatment with the enzymes PNGase F which removes N-linked sugars and PIPLC which removes GPI lipids. Figure 4 shows an expansion of the PrP^{Sc} M^{2+}, indicating that the enzymes reactions are not 100% complete and showing a naturally truncated form. The heterogeneity of the GPI glycan remains but LDMS with calibration with myoglobin as an internal standard gives the measured masses equal within experimental error. It is seen that subsequent treatment with 50% HF removed the entire GPI anchor, leaving only the amino acid chain.

1-glycosylamines are easily prepared on a small scale by the reaction of reducing sugars with saturated aqueous NH_4HCO_3.[1,2] In contrast to the ESMS of the parent sugar these derivatives show high sensitivity in ESMS. The intensity of the MH^+ ion is very dependent on the cone voltage (Fig. 1).

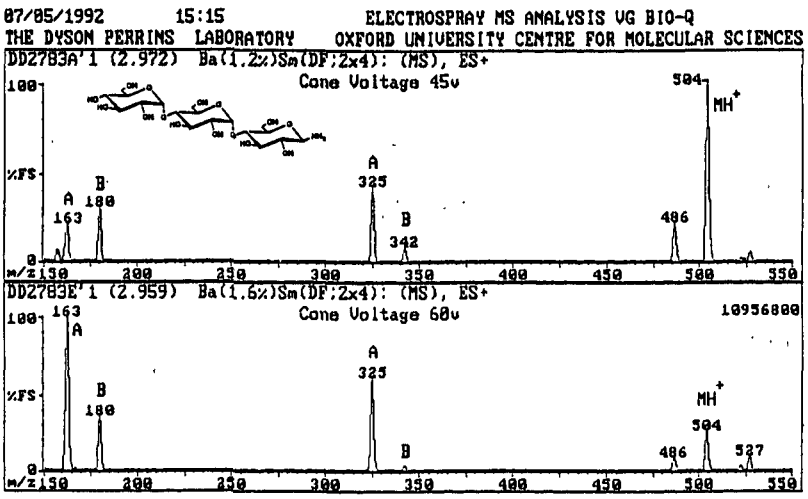

Fig 1. ESMS of Maltotriose-1-glycosylamine

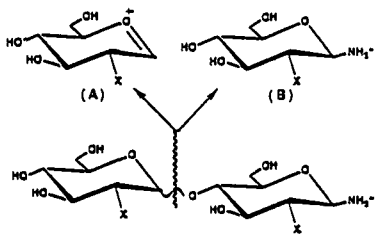
MS-MS analysis using increased cone voltage shows two series of glycosidic bond cleavage ions (Fig. 2) with charge retention by both the ring oxygen (A) and the amino group (B):-



x = OH; NHAc.

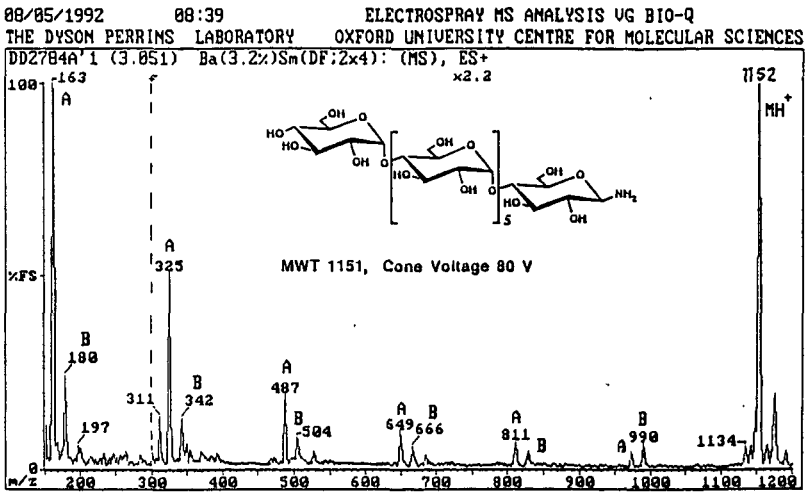


Fig 2. ESMS of Maltoheptose-1-glycosylamine

Two minor ions (ca. 10%) are present in the ESMS spectra at masses above MH^+. These occur at $MH^+ + 18$ and $MH^+ + 23$, the latter is the MNa^+ ion from unreacted starting material and the former corresponds to the MH^+ ion of the hydrate of the ring opened imine.

The major disadvantage of these 1-glycosylamine derivatives is their relatively rapid hydrolysis in the electrospray solvent, ca. 50% in 30 minutes at pH7 for the oligomaltose derivatives and ca. 50% in 60 minutes for the oligo-N-acetylglucosamine derivatives.

Structural Characterization of the N-linked Oligosaccharides of Frog Opsin

Kevin L. Duffin, Joseph K. Welply, Gary W. Lange, Monsanto Corporate Research, Monsanto Company, St. Louis, MO 63198.
Steven Fliesler, Bethesda Eye Institute, St. Louis University School of Medicine, St. Louis, MO 63110.

Opsins (vertebrate visual pigment apoproteins) from a variety of species contain Asn-X-Thr/Ser sequons and oligosaccharides attached to residues 2 and 15 of the polypeptide. N-glycanase treatment of frog opsin and analysis of released oligosaccharide by gel permeation chromatography on BioGel P-4 before and after sequential treatments with purified glycosidases suggested that the major oligosaccharide was composed of a $GlcNAc_3Man_3$ structure. Pronase glycopeptides derived from the intact protein were analyzed by electrospray and tandem mass spectrometry. The electrospray mass spectrum of pronase glycopeptide contains $(M+H)^+$ ions at m/z 1316 and 1357, which correspond to a $Hex_3HexNAc_3$ oligosaccharide attached to the asparagine residue of Ser-Asn and Asn-Lys pronase-derived peptides. Based upon sequence comparisons with other rhodopsins, this would correspond to Asn^{15} of the polypeptide. MS/MS characterization of the $(M+H)^+$ at m/z 1316 yielded fragment ions that confirmed the proposed oligosaccharide sequence. Ions indicative of a carbohydrate located on Asn^2 of frog opsin were not observed.

In an effort to determine whether an oligosaccharide is located on Asn^2, electrospray mass spectrometry was used to mass-analyzed chromatographic fractions isolated during tryptic mapping of frog opsin. Samples containing approximately 100 pmol of various digests of the N-terminal region of frog opsin were dissolved in 25 microliters of water:methanol:formic acid (1:1:0.02, v:v:v). The sample solution was then continuously introduced to the mass spectrometer at a flow of 4 mL/min. A Sciex API III triple-quadrupole mass spectrometer equipped with an atmospheric pressure ion source was used to sample positive ions produced from a pneumatically-assisted electrospray interface. Mass-analysis of sample ions was accomplished by scanning the first quadrupole in 0.1 amu increments from 300-2400 amu in approximately 10 s, and passing mass-selected ions through the second and third quadrupoles operated in the rf-only mode, to the multiplier, which was operated in the pulse-counting mode. Mass spectra of the different sample solutions were averaged over ten scans.

Product ion MS/MS spectra of opsin glycopeptides were acquired by passing the protonated compounds, which had been mass-selected with the first quadrupole, into the second quadrupole where it was dissociated by collision with ultra-pure argon gas. Fragment ions generated by these collisions then were mass-analyzed by the third quadrupole, and detected. The third quadrupole was scanned in 0.1 amu increments from 10 amu up to the mass of the glycopeptide in approximately 10 s. More than 30 scans were averaged for most MS/MS spectra acquired in this study. The argon target gas thickness was maintained at 4.6×10^{14} atoms/cm^2 for these analyses, and a collision energy of 50 eV was chosen by adjusting the DC voltage offset of the collision quadrupole. The first and third quadrupoles were adjusted to obtain unit mass resolution for all mass spectra and MS/MS product ion spectra obtained in this study.

The N-terminal tryptic glycopeptide T-1 eluted from a reversed-phase C-18 column as two major fractions. Amino acid sequencing of the glycosylated and deglycosylated glycopeptide after CNBr treatment together with amino acid composition yielded the sequence:

MNGTEGPNFYIPMSNK

The N-terminal methionine was found to be blocked. The electrospray mass spectrum of the most abundant fraction contained $(M+3H)^{3+}$ and $(M+4H)^{4+}$ that were indicative of glycopeptides with an acetyl group blocking the N-terminus and oligosaccharide composition $Hex_6HexNAc_6$ as the base peak. Other less abundant ion signals in the mass spectrum indicated oligosaccharide heterogeneity consistent with addition of hexose units and loss of a HexNAc unit. The second major LC fraction, which eluted at an earlier retention time, contained the same polypeptide with the oligosaccharide composition $Hex_9HexNac_6Sia$ as the base peak. Again, ion signals indicative of oligosaccharide heterogeneity were present in the mass spectrum (see Figure 1).

To separately determine the oligosaccharide compositions at the two possible N-linked glycosylation sites, Asn^2 and Asn^{15}, chymotrypsin was used to cleave the N-terminal tryptic glycopeptide at the C-terminus of Tyr^{10}. Separated LC fractions containing the chymotryptic

peptides then were mass-analyzed. The C-terminal chymotryptic peptide IPMSNK was found to contain the oligosaccharide $Hex_3HexNAc_3$ as the most abundant carbohydrate, which is consistent with the observed results of the pronase digestion (vide infra). Other less abundant carbohydrates containing one and two additional hexose units also were observed in the mass spectrum. MS/MS analysis of the most abundant species confirmed its oligosaccharide structure (Figure 2) by yielding fragment ions resulting from cleavage of glycosidic bonds. The LC fraction containing the N-terminal chymotryptic glycopeptide Ac-MNGTEGPNFY also was mass-analyzed and found to contain much greater carbohydrate heterogeneity. Mass differences indicative of compositional differences of hexose, hexNAc, and sialic acid were observed in the mass spectrum of this fragment, indicating that the Asn^2 carbohydrates are more heterogenious than those attached at Asn^{15}, and that Asn^2 often has an attached sialic acid-containing oligosaccharide.

CARBOHYDRATE COMPOSITION ANALYSIS OF A GLYCOPROTEIN BY MATRIX ASSISTED LASER DESORPTION MASS SPECTROMETRY

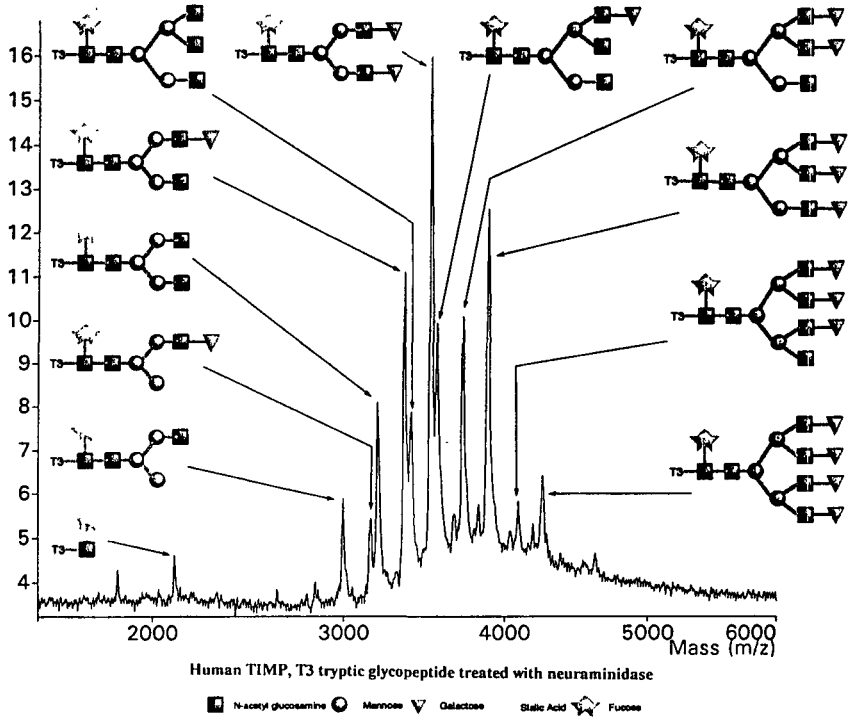
C. W. Sutton, A. C. Poole, and J. S. Cottrell,
Finnigan MAT Ltd., Hemel Hempstead HP2 4TG, UK.
T. Crabbe and A. J. P. Docherty, Celltech Ltd., Slough SL1 4EN, UK

Matrix assisted laser desorption mass spectrometry (LDMS) provides a means of rapidly characterising the carbohydrate structures attached to a glycopeptide by measuring the changes in molecular weight as a sequence of specific glycosidases are used to remove monosaccharide residues. In addition, complete deglycosylation of the intact glycoprotein using PNGase F yields an accurate measure of the total carbohydrate content.

The two N-linked glycosylation sites of Tissue Inhibitor of Metalloproteinases (TIMP) were characterised using the following strategy: The protein was digested using trypsin so as to separate the glycosylation sites onto different glycopeptides. The digest was then fractionated by HPLC and the glycopeptides identified by their characteristic mass distributions. Aliquots of fractions containing glycopeptides were digested with PNGase F so as to confirm the initial identification, and also to provide the mass of the peptide core. Knowing the peptide mass, the carbohydrate composition of all observed glycopeptide peaks could be inferred directly from their molecular weights. Finally, the glycopeptides were treated with a sequence of specific glycosidases and the resulting mass shifts followed by LDMS. Not only did this confirm the composition assignment, but it also enabled the carbohydrate sequence and linkage structure to be determined to the limit permitted by the specificity of the glycosidases.

At first sight, it is surprising that molecular weight alone can be sufficient grounds for assigning composition since there are mass degeneracies even at the monosaccharide level. For example, mannose and galactose residues both weigh 162 Da. Nevertheless, if the known population of naturally occurring N-linked oligosaccharide structures are examined, there are very few mass degeneracies which give rise to ambiguities of composition. The few ambiguities that do occur can be resolved by looking at the compositions of other peaks in the distribution. For example, a peak with a carbohydrate mass of 1664 Da could have either the composition of a hybrid, $Man_5GlcNAc_4$, or a complex, $Gal_2Man_3GlcNAc_4$. But, such a peak will not occur in isolation, it will be one of a series of peaks arising from related structures. The peaks which can only be assigned to one reasonable composition will assist in the identification of the ambiguous peak. Thus, although it is not possible to rigourously deduce compositions from molecular weight, it is possible to guess them with a very high probability of being correct.

The traditional methodology for structural elucidation by sequential glycosidase digestion uses Gel Permeation Chromatography as the analytical tool (A. Kobata et. al. Methods in Enzymology **138** 84-94 (1987)). The advantages of using LDMS are the speed, approximately 5 minutes per measurement, and the low pmol sensitivity, which enabled the entire characterisation to be performed using only 1 nmol of starting material. In addition, the entire population of carbohydrate structures at a particular site could be digested and analysed simultaneously.



Summary

* The optimum strategy for carbohydrate characterisation of a glycoprotein using LDMS is to work with glycopeptides, rather than the intact protein or free glycans.
* For naturally occurring N-linked carbohydrates, composition can be inferred from molecular weight alone.
* For structural elucidation, sequential glycosidase digestion is fast and sensitive when LDMS is the analytical tool. The two glycosylation sites of TIMP were fully characterised using a total of 1 nmol of starting material. Each analysis takes just a few minutes and consumes less than 10 pmol.
* LDMS well tolerates the buffer salts required for glycosidase digestion, intermediate clean-up stages are not required.

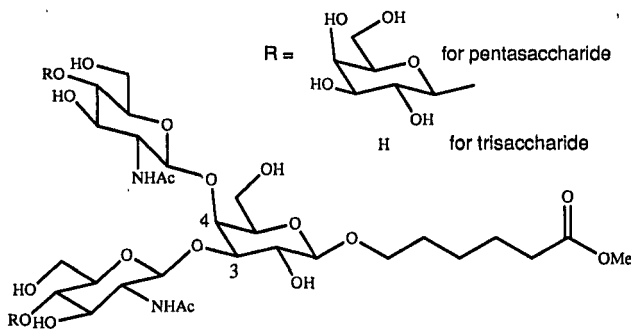
COMPARISON OF THE CID SPECTRA OF A SERIES OF SYNTHETIC BIANTENNARY COMPLEX-TYPE TRI- AND PENTASACCHARIDES

Zamas Lam*, Barbara S. Larsen*, Charles N. McEwen*, Subramaniam Sabesan*, Asjeir Bjarnason¶, Douglas P. Ridge§.
*The Du Pont Company, Experimental Station, Wilmington, DE 19880-0228.
¶University of Iceland, Reykjavik, Iceland. §University of Delaware, Newark, DE.

We sought to understand some of the underlying principles that govern the fragmentation behaviour of branched oligosaccharides. In particular we are interested in the following:

- whether branching patterns can be distinguished by different ionization/desorption techniques or tandem MS experiments
- what role does a proton plays in the fragmentation mechanism,
- what effect does the linkage position have on the fragmentation pattern,
- do the gas phase conformations of oligosaccharides mirror that of the aqueous phase.

ir-LD, FAB, ESI, B/E linked scanning and daughter ion experiments were performed on a series of synthetic complex-type biantennary tri- and pentasaccharides of the general structures: R-(β1→x)-[R-(β1→y)-]-D-galactosyl$_p$-(β1-*O*-5-methoxycarbonylpentyl), where x and y represent all four possible linkage positions — C-2, C-3, C-4 and C-6; R is D-*N*-acetylglucosaminyl$_p$ for the trisaccharides and D-galactosyl$_p$-(β1→4)-D-*N*-acetylglucosaminyl$_p$ for the pentasaccharides.



Although both positive- and negative-ion ir-LD-FTMS gave prominent pseudo-molecular and fragment ions, the intensities of the fragment ions are very similar for the whole series, which made assigning the branching pattern ambiguous. The ESI daughter ion spectra obtained on a triple quadrupole showed different fragment ion intensities for the oligosaccharide series, however, the ion beam was not stable enough for statistically valid comparison.

The FAB unimolecular dissociation B/E linked scanning spectra obtained from two different sector instruments showed similar trend. Three types of fragments were observed: i) loss of the aliphatic aglycon (A) from the reducing end to give the $(M-A)^+$ oxonium ion; ii) loss of one of the

biantennary arms (R) to give the $(M-R)+H^+$ ion; and iii) loss of a biantennary arm to give the R^+ oxonium ion. Three general trends were observed for both series: i) The $(M-R)+H^+$ fragment was the most prominent ion, whereas the intensities of the $(M-A)^+$ and the R^+ ions varied depending on the positions of glycosidic linkage. ii) The 3,4-isomers have more prominent R^+ ions. iii) The 2,6-isomers have more prominent $(M-A)^+$ ions.

The relatively large abundance of the R^+ ion observed with the 3,4-isomers may be explained by the close proximity of the substituents in a 3,4-disubstituted galactosyl$_p$ core; the biantennary arms being in such a rigid conformation has little rotational freedom to distribute excess kinetic energy, and therefore are more likely to undergo fragmentation. If internal motions are the over-riding factors that govern fragmentation, then all the n,6-isomers would be expected give less R^+ ion than other oligosaccharides. However, the R^+ ion intensity for the 3,6- and 4,6-pentasaccharides was approximately twice that of the 2,n-pentasaccharides. Another factor that may govern the intensity of this R^+ ion is the ease of formation and the stability of the $(M+H)^+$ reaction-intermediate-complex. The conformation of the galactosyl$_p$ core is such that the *cis* C-3 and C-4 oxygens can complex with a proton to form a stable five-membered cyclic intermediate. Thus, the higher abundance of the R^+ ion may be a reflection of the greater stability of the precursor complex formed by two glycosidic oxygens. In the case of the 3,6- and 4,6-pentasaccharides, the proton can form two complexes that favor glycosidic cleavage of the *N*-acetyllactosamine arm. The complexes formed, however, are not as stable as in the 3,4-pentasaccharide. This can be attributed to the three following points:

- The 3,6- and 4,6-isomers experience less steric crowding than the 3,4-isomer.
- The 3,6- and 4,6-isomers reaction-intermediates consist of one glycosidic oxygen and one ring or hydroxyl oxygen. The lower basicity of hydroxyl oxygen compared to glycosidic oxygen imposes less stability to the five-membered ring complex.
- Greater rotational motion around C-6 destablizes the five-membered ring.

In the case of the 2,3-, 2,4- and 2,6-pentasaccharides, the C-2 oxygen is *trans* to all the other hydroxyl oxygens, therefore, the proton can form only one five-membered ring intermediate complex.

For the trisaccharide series, however, this stabilization by reaction-intermediate-complexes and dissipation of excess energy *via* internal motions may not be the over-riding factors that govern fragmentation, as equal R^+ ion abundance was observed for the 2,n-isomers and n,6-isomers. This can be attributed to the fact that the *N*-acetylglucosaminyl$_p$ arms of the trisaccharides are less bulky than the *N*-acetyllactosaminyl$_p$ arms of the pentasaccharides. Therefore, the substituent at C-6 of the trisaccharide is less rigid and can undergo greater rotational motion, which may lead to the destabilization of the protonated C-6 and ring oxygen five-membered ring complex. The relative intensities of the R^+ ion for the trisaccharide series were less than that of the pentasaccharide series. This is a further indication that greater rotational motion may be destabilizing all the reaction-intermediate-complexes.

Carbohydrate Structural Characterization by SFC-MS and SFC-CID-MS

Douglas M. Sheeley and Vernon N. Reinhold
Harvard School of Public Health, Boston, MA 02115

Introduction

Improved understanding of the biological role of glycosylation has stimulated significant efforts in carbohydrate structural analysis. However, due to the isomeric complexity of these systems, and the general lack of sensitive detection for glycoconjugates, several times more material is generally necessary for the detailed structural analysis of a carbohydrate than other biopolymers.

SFC-MS has provided an alternative approach for molecular weight profiling of glycoconjugate mixtures (Reinhold, Sheeley et al. 1988; Sheeley and Reinhold 1989). By combining the techniques of pre-column chemistry to introduce greater structural specificity and enhanced detection through reducing-end labeling, significant structural information can be obtained from SFC-MS. However, unambiguous structural assignment is frequently impossible from molecular weight information alone. Sequence and branching must be determined from fragment ions generated either in the ion source or by collision induced dissociation. SFC-MS is especially amenable to combination with CID because of its enhanced sensitivity of detection, low background and concentration of ion current in the molecular ion.

Results

In this study, to evaluate the coupling of SFC-CIMS and CID, a standard oligosaccharide has been analyzed by CID following both FAB and SFC-CI. The resulting spectra are comparable in daughter ions observed, and their relative intensity. In addition, similar daughter ion spectra have been obtained for samples not amenable to analysis by FAB, e.g. TMS derivatives. No losses of TMS and OTMS are observed for this derivative, as is commonly the case in CI. This may be attributable to the low thermal energy of SFC-CI generated ions.

A series of "host-specificity" lipo-oligosaccharide signals isolated from the nitrogen-fixing bacterium *R. leguminosarum* (Spaink, Sheeley et al. 1991) have also been profiled and sequenced by SFC-MS. A crude mixture of these oligosaccharides was trimethylsilylated and profiled by SFC-MS. Figure 1 gives the total ion chromatogram for this analysis, with selected ion plots for each molecular ion projected behind it. SFC-CID-MS of the latest eluting component provides the daughter ion spectrum in Figure 2. A series of oxonium ions resulting from glycosidic bond rupture establish the sequence of the oligosaccharide, and the residue positions of acyl substituents.

The chromatographic resolution and sensitivity of SFC-CIMS can be coupled to CID to provide enhanced structural information. By combining molecular weights and sequence analysis of individual components, SFC-CID-MS may make a significant contribution to characterization of lipophilic glycoconjugates.

Structural Characterization of Protein Anchors by ESI and Collision of Multiply Charged Parent Ions

Bruce B. Reinhold and Vernon N. Reinhold. Harvard University School of Public Health, Boston, MA 02115

Selective processes during eukaryotic cell evolution have resulted in different mechanisms that provide stable association between proteins and the plasma membrane. The more primitive and simplest of structures to accommodate this marriage have been the lipophilic domains of peptides. An alternative structure has been recently described that entails protein C-terminus glycosylation, from which is attached two alkane chains to accommodate membrane solubility. The glycan serves as an interlinking structure that enhances anchor specificity, or as demonstrated in this report, provides an opportunity to induce altered molecular specificity, by anolting different conjugate groups. More than 100 glycosyl-phosphatidylinositol (GPI)-anchored proteins have now been reported. In addition to the trace quantities available, and difficulties in isolating amphipathic materials, protein anchors are characterized by considerable structural heterogeneity. As expected, the carbohydrate and lipid components contribute their own characteristic microheterogeneity, and as mentioned, these glycans appear to be conjugated with additional residues of phosphatidylethanolamine (PEA) and lipophilic groups. Four or five anchors have now been characterized in detail, *T. .brucei* and *cruzi* surface glycoproteins, rat brain Thy-1 glycoprotein, human erythrocyte acetylcholinesterase (E^{hu}AcChEase), and *l:.eishmanla major* promastigote surface protease. Structures studied to date indicate a conserved glycan motif, linking the protein carboxy terminus to an inositol phospholipid, the factual membrane anchor.

For improved detecting sensitivity we have applied electrospray ionization mass spectrometry (ESI-MS) to characterization selected components of the E^{hu}AcChEase anchor, and further report results of intact *T. brucei* anchor analysis, (C-terminus peptide attached to the total anchor). The E^{hu}AcChEases anchor was investigated to localize phosphoethanolamine (PEA) residues following proteinase K and phosphatidylinositol-specific phospholipase C treatment. The digests were chromatographed on anion exchange HPLC and four radioactive spots were detected. The α and β peaks were subjected to analysis by electrospray ionization mass spectrometry (ESI-MS), (β top, next page). Shifts in the glycosidic cleavage, sequence fragments provided residue location of the additional PEA group. The *T. brucei,* peptide attached-anchor, provided an opportunity to observe enhanced CID detail as a function of increasing charge, including details of the branched galactosyl residues, (bottom, next page).

EXTENDING DETECTION LIMITS WITH AN SOLID PHASE INJECTOR, PCI AND FOCAL PLANE DETECTION

Iina J. Koski, Douglas M. Sheeley and Vernon N. Reinhold
Harvard School of Public Health, Department of Nutrition
665 Huntington Ave, Boston, MA 02115

INTRODUCTION

In open tubular column supercritical fluid chromatography (SFC) solutes can be separated with high efficiency. Some of the advantages over gas chromatography (GC) are that thermally labile and high molecular weight compounds can be analyzed. Some of the advantages of SFC over liquid chromatography (LC) are that higher separation efficiencies can be obtained and universal detectors can be used even at trace level detection. When SFC is connected to the mass spectrometer (MS) more information of the sample can be obtained than e.g. with flame ionization detector.

One of the major limitations of trace analysis using SFC-MS has been the sample introduction methods. The internal diameters of the SFC columns are usually 25-50 μm. If large volumes of liquid solvent is injected the column can be flooded, the mobile and stationary phases can be modified. Also large volumes cause resolution losses in the column. Generally less than 0.5 μL volumes are injected.

The objective of this study was to improve the sample introduction method for SFC-MS to be able to utilize the total detection power of MS. The samples were introduced into an open tubular column with a solid phase injector (Figure 1) and detected with a point or a focal plane detector.

INJECTION PROCEDURE

For sample introduction, a sample was loaded onto the platinum wire (30 gauge) of the injector with an on-column syringe after the screw (#1) was rotated out to the sample loading position. The on-column syringe was inserted through a hole in the main body of the injector (#2). The solvent was then allowed to evaporate before introducing the wire into the inlet of the injector. The rate of solvent evaporation could be increased by introducing nitrogen or other inert gas through the mobile phase inlet (#9), which flowed out of the sample inlet and around the wire. After the solvent was removed, the wire was inserted into the injector inlet by rotating the screw (#1) to the closed position. Then the mobile phase was introduced and the chromatographic run was started.

RESULTS

Because in the solid phase injector the solvent is removed from the sample before the chromatographic analysis the solvent does not interfere with the separation. Hence, it was possible to increase the sample volume from 0.2 μL to 10-20 μL without losing the separation efficiency. Absolute and relative peak area reproducibilities of the injection method were evaluated. The relative standard deviations (%RSD) of absolute peak areas were 2.0-4.5% for both 1-μL and 2-μL injections. The %RSDs of relative peak areas were 0.4-1.8% for 1-μL and 2-μL injections. Larger deviations were observed for compounds that had high vapor pressures. The retention time stability was also evaluated. The %RSDs of retention times from 6 subsequent injections were 0.04-0.06%.

The minimum detectable quantity of permethylated maltoheptaose was 83 pmol (S/N = 2 in single ion plot) using the point detector, while even 0.65 pmol (S/N = 8 in total ion plot) could be detected with the focal plane detector (Figure 2). The difference of the minimum detectable quantities

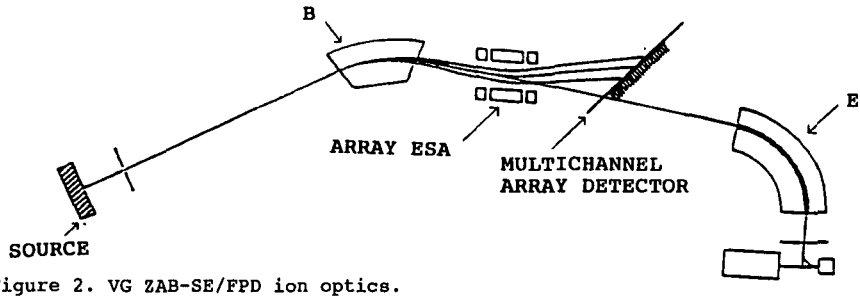

Figure 2. VG ZAB-SE/FPD ion optics.

would have been even greater if the focal plane detector signal could have been monitored in the single ion mode.

CONCLUSION

By increasing the sample volume from 0.2 μL (the sample volume of the commonly used internal sample loop injectors) to 14 μL the concentration of the solutes can be 70 times lower for them to be detected. The minimum detectable quantities using the focal plane detector and positive chemical ionization were over 100 times smaller than with the point detector. Even lower quantities have been detected using PFBAB-labelling (pentafluoro benzyl aminobenzoate) and negative chemical ionization [J.P. Caesar et al., Anal Biochem. **191**, 247 (1990)]. Hence, using these injection and detection systems, large volumes can easily be injected making the trace analysis possible.

Glycoforms of the HIV Envelope Glycoprotein gp120: Analysis of Glycans and Glycopeptides by ESI and SFC-MS

John Caesar, Iina Koski, Bruce Reinhold and Vernon Reinhold
Harvard School of Public Health; Boston, Mass.

Oligosaccharides have received considerable attention for their role in the pathogenesis of the human immunodeficiency virus (HIV). Viral attachment to immunocompetent T cells is mediated through the HIV envelope glycoprotein gp120. Although the glycan structures on gp120 are known to be of the high mannose, complex and hybrid forms in the wild type virus (1,2), there is reason to hypothesize that high mannose glycotypes are sufficient for viral infectivity. Experiments with glycosidase inhibitors showed that if the early events of glycan processing were blocked - thus preventing the appearance of high mannose glycoforms - HIV infectivity was aborted (3). The same study demonstrated that if one blocked further processing of these high mannose sugars to complex glycoforms, viral infectivity was unaffected.

High mannose glycans were also implicated in HIV pathogenesis by the ability of mannose-specific lectins to inactivate in vitro HIV infection (4) and by the observation that a human serum lectin recognizing gp120 also reacted with glycolipid probes synthesized from the high mannose structures purified from gp120 (5). Recently, the mannose-specific lectin Con A was reported to neutralize HIV without interfering with CD4-gp120 binding (6), an interesting result because the glycans on gp120 are not critical for this binding.

Structure-function relationships have been assigned to specific high mannose oligosaccharides for their inhibition of antigen-driven T cell responses (7) as well as stimulation of prostaglandin and cytokine synthesis in vitro (8). The correlation of detailed structure with function in HIV would be enormously helpful in new treatment strategies against AIDS.

We have profiled the glycans from gp120 expressed using a baculovirus vector and the insect cell line Sf9. Despite trace amounts of fucose in the composition analysis, the glycotypes are exclusively high mannose as found by HPLC profiling and supported by ESI and SFC-MS. Complex glycans are absent despite the occurence of the Man 5 glycoform (structure 5-18, shown by SFC-MS) which is the necessary substrate for GlcNAc-transferase I in the processing pathway leading from high mannose to complex structures. This is somewhat surprising because the production of this glycoform (5-18) is apparently inducible by the baculovirus infection process in the related cell line Sf-21AE (9), resulting in the expression of complex glycotypes.

The SFC-MS data suggest the presence of at least 10 different glycoforms. Structures 7-18-AB and 5-13-A (figure 1) are unusual, in that the alpha 1-6 antenna of the trimannosyl core has been trimmed without processing of the alpha 1-3 antenna. The glycoform distribution from SFC-MS is contradicted by the electrospray data, and is probably explained by less efficient extraction of the higher mass compounds in the solid phase injector. The "reversed" order of SFC elution from high to low mass is unexplained.

The analysis of gp120 glycopeptides by LC-ESI-MS (figure 2) indicates that even triply glycosylated peptides can be easily identified (figure 3). Better analysis would be possible after higher mass calibration to afford a larger scan range.

ANALYSIS OF COMPLEX MIXTURES OF REDUCING END DERIVATIZED OLIGOSACCHARIDES BY μHPLC-DYNAMIC FAB MS

James E. Evans, Amit Ghosh and Robert H. McCluer

The Shriver Center, Mass Spectrometry Facility
200 Trapelo Rd., Waltham, MA 02254

INTRODUCTION

Strategies for the analysis of reduced alkyl p-aminobenzoates (ABXE) of oligosaccharides (OS) by HPLC with UV detection and separately by FAB MS for structural determination have been reported by others[1,2]. These derivatives provide improved FAB sensitivity by increasing the surface activity of OS and improving fragment ion production for sequencing. Combined LC-FAB MS methods are expected to improve the efficiency of analysis of complex OS mixtures. We report here on our efforts to utilize combined μHPLC-dynamic FAB, negative ion MS for the analysis of OS mixtures as their ethyl, butyl and octyl (ABEE, ABBE and ABOE) derivatives.

EXPERIMENTAL

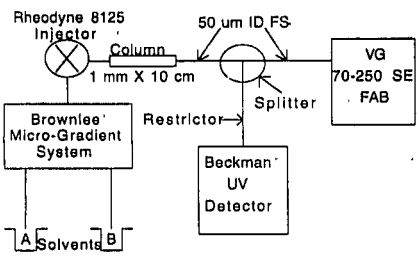
Materials

ABEE and ABBE reagents, OS from corn syrup and individual standards were purchased from Sigma Chemical Co. ABOE reagent was synthesized as described by Poulter[1]. Hypersil ODS reverse phase and Hypersil APS-2 amine μHPLC columns (1 mm X 100 mm) were purchased from Keystone Scientific.

Synthesis of ABXE-OS Derivatives

The OS were reacted with the ABXE reagent in aqueous methanol solution with sodium cyanoborohydride and acetic acid at 80° as previously described[1]. Some reactions were at X10 scale. Aqueous extracts of the reaction mixtures were evaporated and redissolved in 50% methanol for injection.

μHPLC-Negative Ion, Dynamic FAB MS



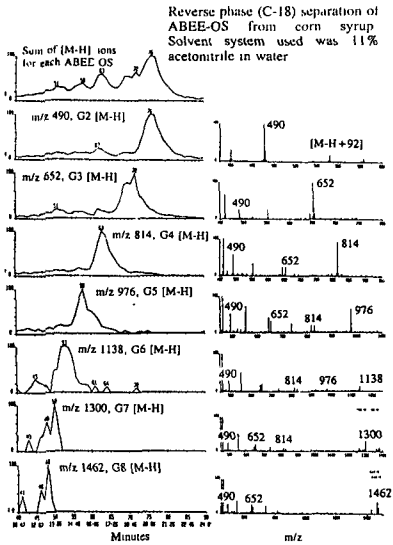
See diagram. For reverse phase HPLC an ODS-Hypersil micro column (Keystone) was used. For normal phase an Hypersil-APS-2 amino micro column was used. The flow rate used was 55 μl/min with a split ratio of 15:1. A clamp was placed on the 0.007" ID X 1/16" PEEK tubing that connects the tee to the UV detector and serves to adjust the split ratio. All solvents contained 2% glycerol matrix. FAB-MS was in the negative ion mode with Xe atoms at 8kV.

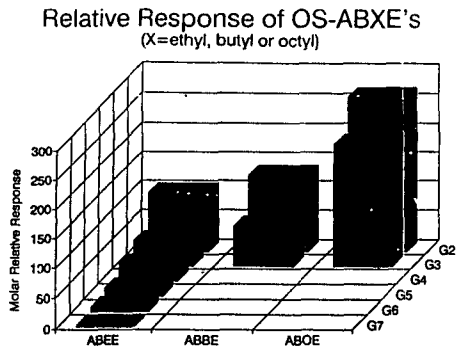
RESULTS

The figure shows the separation and spectra obtained from the C-18 μHPLC-dynamic FAB MS analysis of ABEE-OS from corn syrup. Plots for the $[M-H]^-$ for each OS from G2 to G8 are shown along with the mass spectrum for each. Near base line separation was obtained between each oligomer. Prominent ions resulting from cleavage of glycosidic bonds are seen as neutral losses of 162 amu. Similar results were obtained when the ABBE-OS and ABOE-OS from corn syrup were analyzed.

The graph shows the effect on response obtained by increasing the alkyl chain from ethyl to butyl and octyl and independently increasing the size of the OS from 2 through 7 glucose units.

Detection limits for the ABEE, ABXE and ABOE derivatives of maltose were determined to be 25 pMol, 13 pMol and 4.5 pMol respectively when analyzed by C-18 μHPLC-FAB MS.





CONCLUSIONS

Dynamic FAB-MS sensitivity for ABXE-OS derivatives is shown to improve as X increases from ethyl to butyl and octyl as has been reported for static FAB-MS[1]. We found that sensitivity decreased as the number of glucose units increased in ABXE malto-OS. Near base line reverse phase HPLC separations are obtainable for linear malto-OS. Baseline separations were obtained for ABEE malto-OS using the amino column. But low solubility and FAB-MS sensitivity in the solvent system used limited its application. The chromatographic efficiencies we obtained with any of the ABXE-OS was much less than the efficiencies of which the columns used are capable. We speculate that this may be due to the formation of micelles by these derivatives in the chromatographic solvents we employed.

FAST ATOM BOMBARDMENT AND TANDEM MASS SPECTROMETRY FOR DIFFERENTIATION OF ISOMERIC C-GLYCOSIDIC FLAVONOIDS

Q. M. Li, H. Van den Heuvel, L. Dillen and M. Claeys
Department of Pharmaceutical Sciences, University of Antwerp (U.I.A.), B-2610 Antwerp, Belgium

Flavonoid glycosides are a widespread class of plant metabolites with biological significance. The present work was aimed at the differentiation between 6-C and 8-C glycosidic flavonoids using fast atom bombardment in combination with collisionally activated decomposition (CAD) and linked scans at constant B/E. Daughter ion spectra obtained for $[M - H]^-$ ions were well documented by Becchi and Fraisse[1]. Because $[M + H]^+$ ions were also found to give structurally informative fragmentation, a more detailed investigation on the fragmentation of protonated C-glycosidic flavonoids was performed.

A major problem encountered during the analysis of $[M + H]^+$ ions is sodium salt contamination. Due to the high salt content of isolated glycosidic flavonoids, positive ion FAB/MS generally results in weak $[M + H]^+$ signals, intense $[M + Na]^+$ signals and even di- and trisodiated molecular ion species, whereas negative ion FAB/MS often yields weak $[M - H]^-$ signals. In order to obtain reliable molecular signals in the positive ion mode, we worked out a simple desalting method based on adsorption on mini C18-columns. We also performed experiments aimed at controlling sodium salt contamination during storage of samples, preparation of samples for FAB/MS analysis or collection of HPLC fractions [2].

The daughter ion spectra obtained for the protonated mono-C-glycosides showed differences in abundances for a number of daughter ions. The most distinct differences relate to the loss of molecules of water and the formation of $[M - H_2O]^{+\cdot}$ and ${}^{0,4}X^+_{-2w}$ ions (scheme 1), fragmentations which are most pronounced for 6-C isomers. The nomenclature proposed by Domon and Costello [3] for glycoconjugates was adopted to denote the fragment ions [4]. The mechanisms for the formation of these ions was supported by examining analogous C-pentose and deoxyhexose derivatives, performing MS/MS and parent ion scans and deuterium-labelling. Diagnostic fragment ions of mono-C-glycosides include ${}^{0,4}X^+_{-2w}$, ${}^{0,2}X^+$, ${}^{1,5}X^+$, ${}^{0,1}X^+$ and Y^+ ions (scheme 1). Among these, the ${}^{1,5}X^+$ ion was shown to result from fragmentation of the M^+ ion.

Analysis of asymmetrical 6,8-di-C-glycosylflavones, schaftoside, isoschaftoside and C-6-Rha-8-Glc chrysin, showed that the 6-C and 8-C glycosyl residues each give rise to a group of diagnostic fragment ions. Figure 1 illustrates the daughter ion spectrum obtained for $[M + H]^+$ ions of isoschaftoside. The 6-C-arabinosyl group gives rise to ${}^{0,4}X^+_{6\text{-}2w}$, ${}^{0,2}X^+_6$, ${}^{1,5}X^+_6$, ${}^{0,1}X^+_6$ and Y^+_6 ions, while the 8-C-glucosyl substituent mainly yields ${}^{0,2}X^+_{8\text{-}nw}$ ions (n = 0, 1, 2 and 3). This information can be used to characterise the location of carbohydrate substituents in asymmetrical 6,8-C-glycosidic flavonoids.

Unimolecular Decomposition of Metastable oligosaccharide cations in a Liquid Secondary Ion Source Fourier Transform Mass Spectrometer

Lambert Ngoka and Carlito B. Lebrilla, Department of Chemistry,
University of California, Davis, CA 95616

Structural elucidation of oligosaccharides by mass spectrometry remains one of the most forbidding challenges to the analytical chemist due to a complex linkage and anomeric isomerism, very high polarity, difficulty in distinguishing between individual monosaccharides and (often) high degree of branching. Fourier transform mass spectrometry with an external liquid SIMS ionization source[1] holds considerable promise toward analysis of oligosaccharides.

Spectra of underivatized oligosaccharides obtained on our instrument show strong parent and oligomeric ion intensities with virtually no background noise. The large degree of fragmentation as well as the low background noise may be attributed to metastable decay occurring in the FTMS instrument. In particular, understanding the mechanics of metastable decay of oligosaccharides could facilitate optimization of parameters, or open up new possibilities towards ion/molecule chemistry that could furnish further valuable structural information. Metastable decay of oligosaccharides has never been observed in the FTMS.

Maltohexaose and α-cyclodextrin obtained commercially were used to study metastable decay.

A 5-10 μl sample of approximately 0.50M aqueous solution of the oligosaccharide was deposited on a drop of the matrix (50% thioglycerol in glycerol) on a copper probe tip. This solution was then bombarded with a 10 KV Cs^+ beam and the resultant secondary ions extracted with -268V and injected into the analyzer cell by 119 cm -quadrupole electrodes *operated in the RF-only mode*(1 MHz). *To minimize the decomposition of the protonated* parent in the ion source, a short (i.e. 10 milliseconds) ion production/injection pulse was used. The detect delay time was varied from 1 to 10 milliseconds from the end of the injection pulse. Data was acquired using the Omega data system(Ionspec corporation).

Figure 1 shows the metastable decay of α-cyclodextrin cation. The relative intensity of the protonated parent (m/z 973) decreases exponentially through the first five milliseconds and remains almost constant thereafter. The oxonium ion fragment, m/z 811, resulting from the loss of one saccharide unit, also decreases exponentially to a relatively constant level at five milliseconds detect delay. The decrease in the relative intensities of the m/z 973 and 811 peaks are accompanied by a rise in the intensities of the m/z 325, 487 and 649.

Figure 2 shows the spectra of sodiated α-cyclodextrin with detect delays of 2, 3 and 4 milliseconds respectively. The decay of protonated and sodiated parent peaks, m/z 973 and 995 respectively, are evident. However m/z 973 decays faster than the m/z 995 peak suggesting that the decay rate is characteristic of each ion.

Metastable decay of maltohexaose, maltopentaose, maltotetraose and maltotriose have also been studied. In each case, the behavior is similar to that of α-cyclodextrin . We conclude that metastable decay of the protonated parent is important for explaining the spectral features derived from these compounds.

Metastable decay is further supported by the constancy of the total ion current through 200 milliseconds. Currently, we are investigating the dependence of the size of the oligosaccharide cation and the influence of Li^+, Na^+, and K^+ on the rate constant.

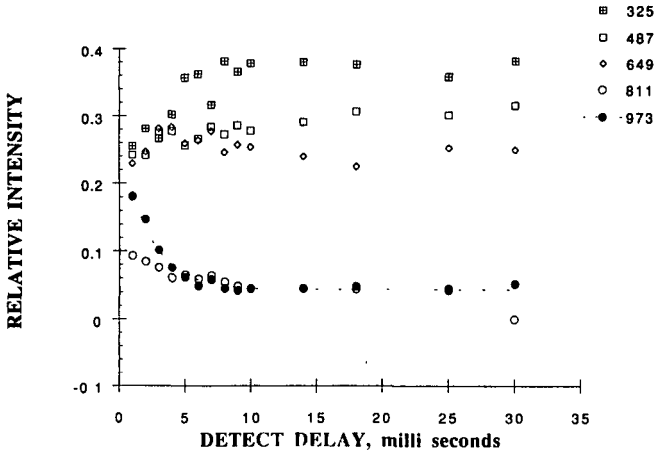

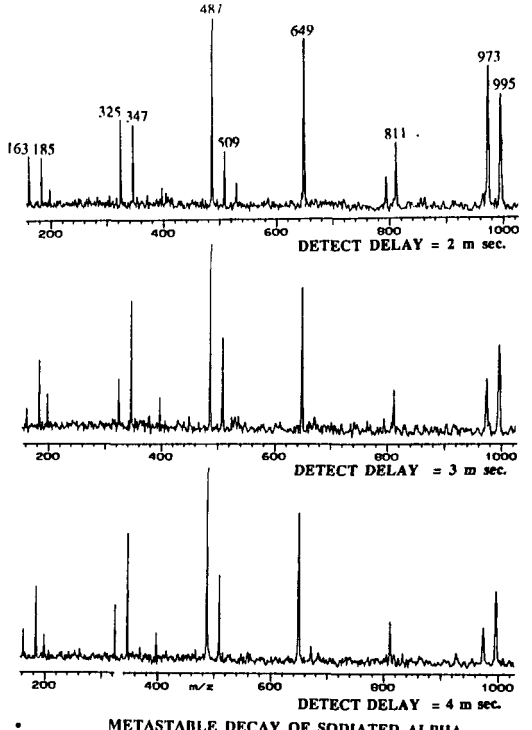

Figure 2 : METASTABLE DECAY OF SODIATED ALPHA CYCLODEXTRIN

ELECTROSPRAY IONIZATION MASS SPECTROMETRY FOR NATURAL AND RADIATION-INDUCED MODIFICATIONS IN HISTONE PROTEINS, *C. G. Edmonds, A. F. Fuciarelli, B. D. Thrall, and D. L. Springer, Pacific Northwest Laboratories, Richland, WA 99352.

The nucleus of the cell is densely packed with DNA and numerous proteins which, at nuclear division, arrange themselves in distinct structures, called chromosomes. A basic subunit of this chromatin structure is the nucleosome consisting of 146 base pairs of DNA wrapped around a core histone octamer. The nucleosome consists of core histones that are lysine and arginine rich proteins which participate in formation of the reversible complex with DNA.

Exposure of nucleosomes to free radicals generated by ionizing radiation results in a number of modifications inducing altered base and deoxyribose moieties and DNA protein cross-links. Acid hydrolysis of irradiated nucleosomes followed by trimethylsilylation and GC/MS has revealed the presence of DNA base-amino acids dimers between thymine and aliphatic (Gly, Ala, Val, Leu, Ile and Thr) (E. Gajewski, A. F. Fuciarelli, and M. Dizdaroglu, Int. J. Radiat. Biol. *54*, **1988**, 445-459), basic (Lys) (Dizdaroglu and Gajewski, Cancer Res. *49*, **1989**, 3463-3467) and aromatic (Tyr) (M. Dizdaroglu, D. Gajewski, P. Reddy, and S. A. Margolis, Biochemistry, *28*, **1989**, 3625-3628,) amino acid residues, but failed to reveal acid-labile species. Additionally, information on the location of these cross-links relative to the amino acid sequence was lost. We have sought to extend these studies employing electrospray ionization mass spectrometry (ESI-MS) of the intact species.

In preliminary experiments, check erythrocyte histone H2B was irradiated in the presence of thymine, the principle cross-linking base recognized in earlier studies, and the products were examined directly by ESI-MS. Following exposure to 5 Gy of ionizing radiation the relative abundance of two unique species were increased by nearly 50% in irradiated samples over background response at the same *m/z*. The first corresponds to a mass increment increase similar to the expected value for thymine-H2B adduct formation (126.1 Da measured, 125.1 Da calculated). The mass increment increase for the second component (140.7 Da) was less easily explained. Additional dose-yield data are needed to confirm the significance of these changes. Further experiments on the intact proteins and on the products of specific proteolysis are being undertaken to confirm and further elucidate the structures of these radiation induced modifications.

The nature and function of naturally occurring covalent post-translational modifications of histones which include acetylation, methylation, phosphorylation, mono- and poly(ADP)ribosylation and ubiquitination is the object of other ESI-MS experiments. Each of these frequently reversible modifications is known to have important associations with alternations in chromatin structure that accompany induced damage and its repair. It is our belief that the temporal and spatial patterns of these modifications, although complex, is distinctly nonrandom and predictably related to cellular responses. We have begun preliminary evaluation of the nature and extent of histone modification by ESI-MS. Using chick erythrocyte histones we observed a number of modifications which are consistent with the known post-translational modifications of histone (Figure 1). Included among these are acetylation, methylation and an array of various combinations of modifying species. Ongoing experiments are being conducted to further define the nature of these modifications, as well as to attempt to understand the relationship between these modifications and cellular behavior.

Work supported in part by Laboratory Directed Research and Development of the Pacific Northwest Laboratory under Contract DE-AC06-76RLO 1830 from the U. S. Department of Energy and the National Science Foundation, Instrumentation and Instrument Development Program (DIR 8908096).

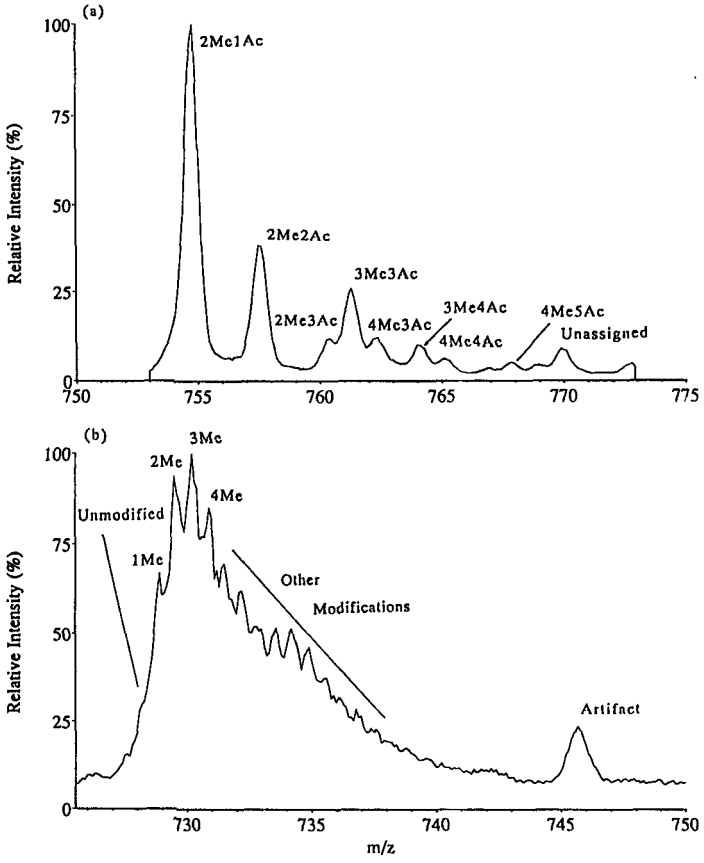

Figure 1. Electrospray ionization mass spectral profiles for the multiply protonated molecular ions of (a) chick erythrocyte histone H3, $(M+15H)^{15+}$, and (b) histone H4, $(M+21H)^{21+}$. Post-translational modifications are infered from differences in measured masses and the mass predicted from the protein gene sequence. Putative assignments are marked (Me = methylation, Ac = acetylation). Where nearly isobaric multiple modifications are possible the least multiplicity of modification is proposed.

Analysis of Cyclosporin A Using Electrospray Ionization and Fast Atom Bombardment

G. McKay, N. Pidskalny and K.K. Midha,
College of Pharmacy, University of Saskatchewan,
Saskatoon, Saskatchewan, Canada, S7N 0W0.

The cyclic oligopeptide cyclosporin A is used as an immunosuppressive agent to prevent rejection of transplanted tissues and organs. A complete understanding of the mechanism of action of cyclosporin A requires detailed knowledge of its metabolism in vivo. To date this metabolism has been shown to be complex with at least 27 different metabolites described (Wallemacq et al, 1989). The majority of these metabolites involve demethylation or hydroxylation at different sites of the peptide as shown in Figure 1. In addition to this metabolic complexity is the fact that cyclosporins are naturally present in a number of different structural forms also designated in Figure 1. FAB mass spectrometry has been very useful in elucidating the molecular weights of these metabolites. In order to evaluate the suitability of electrospray ionization (ESI) in the analysis of these compounds results were compared between FAB and ESI of cyclosporin A.

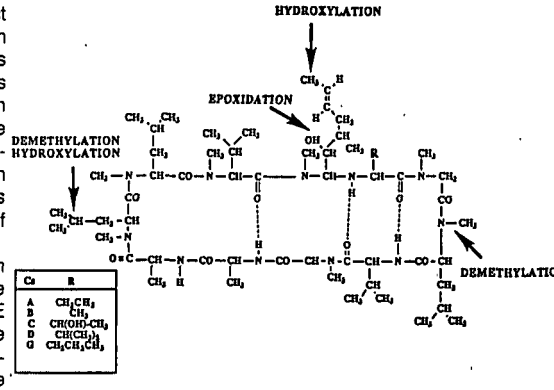

Figure 1. Chemical structure of cyclosporin A and its natural structural analogues
Sites of metabolism are indicated in the figure.

Cyclosporin A was obtained from Sandoz (Basel). FAB mass spectra were obtained on a VG Analytical 7070 HE mass spectrometer from the pure compound dissolved in the matrix 3-nitrobenzyl alcohol and stored in borosilicate glass vials. The accelerating voltage was 5 kV, argon was used as the source of fast atoms accelerated to 7 kV with 1mA emission current. The stainless steel target was loaded with matrix containing 1-2 μg of analyte. The reported spectrum is an average of 10 scans over the indicated mass range. ESI spectra were obtained with a VG Biotech Bio-Q mass spectrometer using cyclosporin A dissolved in 50:50 methanol/water (10 pmoles/μl) in either borosilicate glass vials, polypropylene vials or borosilicate glass vials which also contain 0.01 M NH_4CO_3 to give a final concentration of 10% NH_4CO_3. The capillary voltage was 3.5-4 kV and the cone voltage was set as indicated in the spectra. A constant flow of 4 μl/min of 50:50 methanol/water containing 1% acetic acid was delivered as the mobile phase. Injections of 10 μl of the various solutions was used throughout the studies and all spectra were the sum of 10 consecutive scans collected in the continuum mode. Shown in Figures 2 and 3 are the FAB and ESI mass spectra of cyclosporin A.

Figure 2. FAB mass spectrum of cyclosporin A

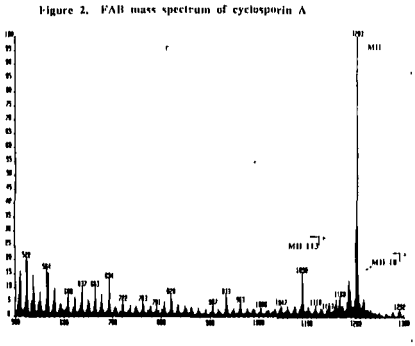

Figure 3. ESI mass spectrum of cyclosporin A stored in borosilicate glass, cone voltage 40V.

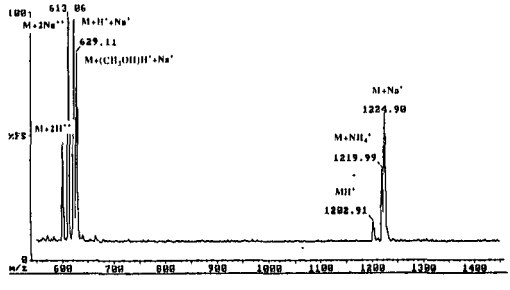

The FAB mass spectrum shows a prominent pseudo-molecular ion at m/z 1203. In addition, diagnostic ions at M-18 and M-133 at m/z 1185 and 1090 respectively are also observed When this same sample was analyzed by ESI mass spectrometry not only was the protonated molecular ion observed but also ions at m/z 1220 and 1225 were also observed and correspond to the ammonia and sodium adduct ions respectively. In addition various doubly charged ions were observed at 602, 613, 624 and 629. The relative intensity of these doubly charged ions was directly related to the cone voltage under which the spectra were obtained and the concentration of sodium or ammonia present in the sample as illustrated in Figure 4 and Table 1.

Table 1 Relative ion intensities in the ESI spectra of Cyclosporin A (CSA) analyzed under different cone voltages.

Sample Conditions	Cone (V)	Relative ion intensities % 602	613	624	629	1203	1220	1225
CSA in borosilicate glass vial	30	9	44	83	27	7	16	100
	40	12	40	68	25	13	10	100
	50	2	15	53	22	25	n/a*	100
	60	9	17	59	5	58	n/a	100
	70	2	7	50	4	45	n/a	100
CSA in borosilicate glass vial plus 10% 0.01 M NH_4CO_3	30	90	72	53	n/a	5	100	61
	40	100	60	50	n/a	30	70	62

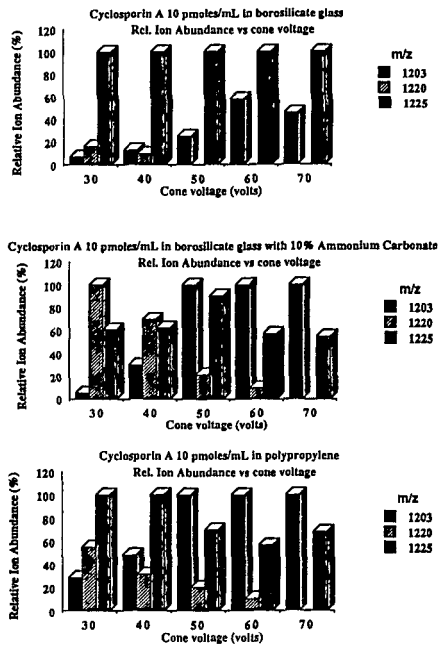
*n/a = not apparent

Figure 4. Influence of cone voltage on the relative intensity of ions originating from the ESI spectra of cyclosporin A



Cyclosporin A is readily examined using FAB and ESI. In the case of ESI the spectra are characterized by not only abundant protonated molecular ions but also by doubly charged ions. A further feature of the ESI spectra is the abundance of adduct ions that arise as a consequence of the ESI technique and the contamination of solutions by sodium and ammonia from the solvents themselves or the vessels in which the samples are contained. Clearly as shown in Figure 3 when samples are dissolved in borosilicate glass vials there is a heavy contamination of cyclosporin A with sodium from the glassware. When cyclosporin A is placed in polypropylene vials there is less contamination with sodium but the relative abundance of ammonia adducts increase (see Table 1 and Figure 4). The relative intensities of ammonia adduct ions, sodium adduct ions and doubly charged ions varies as a function of the concentration of contaminating species and also the operating voltage of the skimmer cone (see Table I and Figure 4). It is essential however that given the subtle differences between metabolites of cyclosporin A as well as the subtle differences between different forms of cyclosporins, prior knowledge of adduct ion formation is critical to avoid confusion between actual adducts and potential metabolites or structural analogues.

Electrospray Ionization of Quaternary Ammonium-Linked Glucuronides and its Comparison to Mass Spectra Obatained by FAB

G.McKay, H.Luo, E.M.Hawes, N.Pidskalny and K.K.Midha
College of Pharmacy, Univ. of Sask. , Saskatoon, SK, Canada, S7N 0W0.

The in vivo metabolism of various aliphatic tertiary amine containing drugs has been recently shown to involve the formation of quarternary ammonium-linked glucuronides (N^+-glucuronides). The direct analysis and identification of these N^+-glucuronides has been hampered due to their physiochemical properties and a general lack of authentic reference compounds. A generalized procedure for their synthesis was developed in our laboratories with direct confirmation of their structure using mass spectrometry under electrospray (ESI) and fast atom bombardment (FAB) modes of ionization. In this regard the application of ESI to the analysis of highly polar pre-charged low molecular weight compounds is somewhat unique while the application of FAB has been previously shown to be very useful. In an attempt to assess their suitability for the analysis of pre-charged quarternary ammonium compounds of relatively low molecular weight we examined 20 different N^+-glucuronides using FAB and ESI.

A variety of tertiary amine containing drugs were used in a generalized synthetic procedure developed in our laboratories for the synthesis of N^+-glucuronides[1]. All of the synthesized compounds were purified using ion exchange chromatography. The isolated glucuronides were characterized using melting point, NMR, HPLC, FAB and ESI mass spectrometry. A list of the compounds analyzed by mass spectrometry is given in Table I.

FAB mass spectrometry was carried out using either a VG Analytical 70SQ or a 70-70HE mass spectrometer. The accelerating voltage was 6kV (70SQ) or 5kV (70-70HE), argon was used as the source of the fast atoms accelerated to 7 kV and 1 mA emission current. The matrix was either glycerol or 3-nitrobenzyl alcohol and 1-2 μg of sample was placed on the stainless steel target. The scan range was 50-800 amu, 2 sec/decade and 5-10, scans were averaged. ESI was carried out on a VG Biotech Bio-Q mass spectrometer with a capillary voltage of 4 kV, cone voltage of 30 volts and 50:50 methanol/water containing 1% acetic acid mobile phase delievered at 4 μL/min. In all cases 10 μL of a 10 pmole/μL solution was injected and ten consecutive scans covering a mass range of 80-800 amu were summed.

Table I Results of FAB and ESI analysis of some N^+-glucuronides

N^+-glucuronide (drug/metab.)	FAB M^+(I%)	FAB Protonated Aglycone(I%)	ESI M^+(I%)	ESI Protonated Aglycone(I%)
Chlorpromazine	495(82)	319(100)	495(100)	319(24)

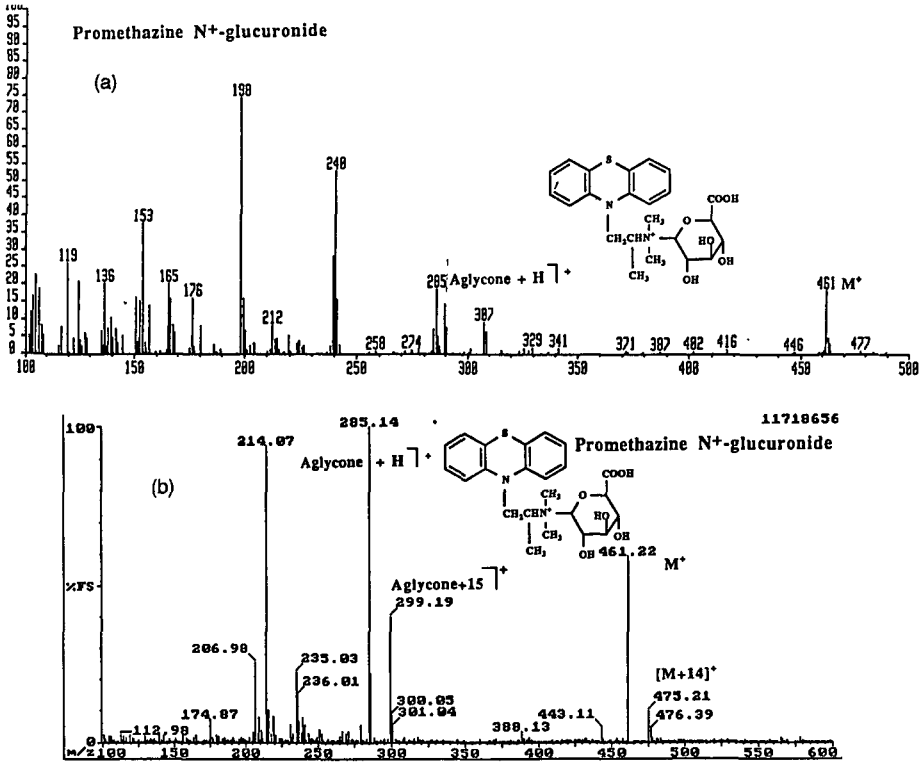
[1] H. Luo et al, in press, J. Pharm. Sci.

As shown in Table I all of the N+-glucuronides examined gave pre-charged molecular ion and protonated aglycone fragment ion data. In this regard the ESI technique consistently gave more intense ions. In addition, both FAB and ESI spectra often demonstrated natriated adduct ions at M+22 mass units. The majority of the sodium in these adducts appears to arise from the borosilicate glass used in preparing solutions of the various analytes. When polypropylene vials are used in place of glassware the intensity of the sodium adducts is greatly reduced (data not shown).

Figure 1 illustrates typical spectra obtained and shows other characteristic ions of FAB and ESI, some of which may be related to the ionization process. As illustrated in Figure 1 the FAB spectra like the ESI spectra show the facile loss of water from the molecular ion. In additiion however, the ESI spectra demonstrated in some cases ions at $[M+14]^+$ and $[\text{aglycone} +15]^+$. Presumably these methylated adduct ions are a consequence of the ionization conditions and solvents employed during the ESI analyses.

Figure 1. Typical FAB (a) and ESI (b) mass spectra of a N+-glucuronide



The results of this study confirm the synthesis of these N+-glucuronides and in the majority of cases represents the first reports on the direct analysis of these compounds. Both FAB and ESI mass spectrometry yield molecular and protonated aglycone ion information. In this regard ESI is somewhat more useful with a greater yield of intact molecular ions in the majority of cases. However, ESI also yields adduct ions which could be confusing when these analytes are isolated from biological matrices. Prior knowledge of the potential formation of these adduct ions should aid in the correct interpretation of these spectra.

The MRC of Canada and Fisons Instruments are gratefully acknowledged.

COMPARATIVE ELECTROSPRAY AND FAB MASS SPECTROMETRIC STUDY OF LIPOPHILIC NEUROPEPTIDE DERIVATIVES

Laszlo Prokai, S.S. Jonalagadda, H. Farag, and N. Bodor
Center for Drug Discovery, University of Florida
College of Pharmacy, Gainesville, FL 32610-0497

Due to the existence of the blood-brain-barrier, the development of strategies for delivering centrally active neuropeptides into the brain is imperative. The hydrophilic, water-soluble peptides cannot cross the brain capillary endothelium which behaves like a continuous lipid bilayer, and transport through this membrane is largely, but not exclusively, determined by the lipid solubility of the compound.

Preparation of lipophilic derivatives of the neuropeptides is part of our brain-delivery strategy [1]. We employ a stepwise, solution-phase method based on a coupling/deprotection sequence (Boc chemistry) to build up neuropeptides with bulky, lipophilic cholesteryl ester function at the C-terminus. As the size and complexity of the molecule increase during the synthesis, the opportunity for synthetic errors, unwanted modifications and cumulative effects arising from incomplete reactions also increase. Sophisticated analytical control of the synthesis is, therefore, imperative.

Desorption ionization mass spectrometry has been our primary tool for confirming the covalent structure of the peptide cholesteryl esters, for the identification of by-products, and determining sample purity--information necessary to perfect the synthetic methods. We have used fast atom bombardment (FAB), and more recently electrospray ionization (ESI) mass spectrometry. In this presentation, we evaluate and compare the potential of these alternative techniques for the analysis of lipophilic cholesteryl esters of selected neuropeptides.

FAB mass spectrometry (KRATOS MS80RFA) for peptides containing the cholesteryl ester portion was sensitive to the selection of the liquid matrix. We could not obtain meaningful spectra using polar matrices such as glycerol, thioglycerol, dithioerythritol/dithiothreitol ("Magic Bullet") that are applicable to the parent peptides. The relatively non-polar 3-nitrobenzyl alcohol (NBA) was used to record the FAB mass spectra. We usually analyze the lipophilic peptide obtained from a coupling reaction after the removal of the Boc-groups (with TFA). It is advantageous, since partial cleavage of the protecting groups occurs during the analysis of the Boc-peptides, which complicates the interpretation. The removal of the nitro group from arginine has also been noted upon analyzing Tyr(Br-Z)-Arg(NO_2) cholesterate (a synthetic intermediate for the brain-delivery system of the opioid-like dipeptide kyotorphin, YR). The FAB mass spectra of the peptide cholesterol esters also exhibit fragmentation (see Figure 1). One of the fragments is the protonated peptide itself [2]. As the number of amino acid residues in the lipophilic peptide increases, the cholesteryl fragment becomes dominant. However, conformation of the peptide sequence is not possible due to the lack of specific fragment ions. In general, the technique is suitable for monitoring the completion of each reaction step. However, identification of minor sample constituents has not been possible due to the high "chemical noise" (matrix).

ESI (VESTEC 200ES) has shown two-three orders of magnitude higher sensitivity than FAB. We found that water is not permitted in the sample solution (precipitation occurs), and a non-polar co-solvent (CH_2Cl_2) should be added to methanol (2-5 % acetic acid is also added) to completely dissolve the lipophilic peptide derivative. With the repeller set to 15-20 V, no fragmentation of the peptide cholesteryl esters was observed (Figure 2). (The removal of NO_2 from the arginine side-chain was also absent). Thus, together with benefit of the lack of background interference, detection of minor sample constituents has been possible. By increasing the repeller potential, fragmentation similar to that observed in the FAB spectrum can be obtained. Because the first generation CID-fragment is principally the protonated parent peptide, dissociation upon further increasing the repeller potential (Figure 3) can be originated in the former ion. This is evidenced by the close similarity of the CID spectrum to that of the protonated enkephalin using the same instrument and collision-induced dissociation in the transport region (skimmer to collimator) of the electrospray interface (Figure 3). Obviously, this approach cannot be used to confirm the covalent structure of the minor sample constituents.

In conclusion, electrospray ionization mass spectrometry has now become our method of choice for monitoring the synthesis with emphasis on deletion or addition of amino acid residues, unwanted

removal of protecting groups. This is due to its versatility ("soft" ionization and CID from the same sample solution without the need for "tuning"--only by increasing the repeller voltage), high sensitivity, lack of background noise, speed, and ease of use. Purity information obtained by the technique is also decisive regarding the suitability of the peptide derivatives to *in vitro* and *in vivo* experiments. We only use FAB mass spectrometry when higher resolution not attainable by our quadrupole system is required, such as for the confirmation of the presence of the bromine in case of the 2-bromobenzyloxycarbonyl (Br-Z) protecting group.

Analysis of Hydrophobic Peptides and Proteins by Electrospray Ionization Mass Spectrometry

A.M. Falick, *P.A. Schindler, and A. Van Dorsselaer+.
Dept. of Pharmaceutical Chemistry and Mass Spectrometry Facility, University of California, San Francisco, CA 94143-0446 and +Laboratoire de Chimie Organique des Substances Naturelles, Université Louis Pasteur, Strasbourg 67084, France.

Introduction

During the last decade mass spectrometry has become an essential tool for the analysis of peptides or proteins. But these analyses have been performed mainly on biopolymers that are soluble in aqueous solutions. Mass spectrometric analyses of very hydrophobic species, such as membrane proteins, have seldom been reported in the literature (1, 2). This is mainly due to the incompatibility between most mass spectrometric techniques and detergents and/or salts which are required to retain such proteins in solution. Nevertheless, the ubiquity and biological importance of membrane proteins make their analysis by mass spectrometry an important goal. Electrospray ionization mass spectrometry (ESIMS) is a powerful tool for the determination of accurate molecular masses of proteins, peptides and other biopolymers (3). Hydrophobic proteins (for example, bacterioopsin) and peptides are in general not soluble in the solutions normally used for ESIMS. We have been developing sample handling protocols and solvent systems that are compatible with instrumental requirements and also are capable of retaining very hydrophobic peptides and proteins in solution, therefore permitting accurate molecular weight measurements to be made on these molecules.

Experimental

The electrospray ionization (ESI) spectra were acquired on a VG Bio-Q mass spectrometer (Fisons/VG, Manchester, UK) with an atmospheric pressure ESI source and a quadrupole mass analyzer with a mass range of 4000. The mass spectrometer was scanned from m/z = 600 to m/z = 2000 in 10 or 20 seconds. The data system was operated as a multichannel analyzer and 10-15 scans were averaged to obtain the final spectrum. The electrospray solvents used were either a chloroform:methanol:water mixture (2:5:2, v:v:v) with sufficient added glacial acetic acid to make the final solution 1% HOAc, or a chloroform:methanol:0.1% aqueous TFA mixture (4:4:1, v:v:v). The flow rate was 2-4 µl/min. Typical sample quantities used were 50-400 pmol per analysis; however the experiments described here were carried out for the purpose of demonstrating feasibility rather than sensitivity.

Results and Discussion

Figure 1 shows the ESIMS spectrum of the A6L subunit of ATP synthase. The measured molecular mass (7964.7 ± 0.2 Da) (Fig. 1) is in very good agreement with the theoretical value (7964.6 Da). In addition to the major series of multiply-charged ions, several minor series are present in the spectrum. The inset shows a +7 ion; the higher mass tail indicates the presence of at least two other components. The mass differences between the molecular masses of these minor components and the major one correspond to oxidation of Met and/or formation of methyl esters. The A6L subunit contains four oxidizable Met residues (1). Esterification of Glu or Asp residues could occur during the purification process since the protein was purified from beef heart by a combination of chromatographic procedures using acidic chloroform/methanol/water mixtures (1).

Figure 2 shows the ESIMS spectrum of the C-terminal portion (C-1) of bacterioopsin. Limited chymotryptic proteolysis cleaves bacterioopsin into two fragments of calculated molecular mass 19,056.3 (C-1) and 7,762.4 (C-2). The experimentally measured mass from this spectrum 19,058 ± 4. is in good agreement with the calculated value. The peak tailing towards higher masses indicates the presence of minor unresolved components of higher mass. The measured mass corresponds to the leading (low mass) edge of this peak.

Conclusion

This work has shown that ESIMS measurement of molecular masses of hydrophobic proteins and peptides can be achieved by using chloroform/methanol/water mixtures as solvents. Samples may be injected in neat formic acid or hexafluoroisopropanol. These solvent combinations are not compatible with all hydrophobic proteins, and we are continuing to explore other solvent systems.

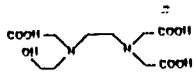
APPLICATION OF ELECTROSPRAY MASS SPECTROMETRY TO THE STUDY OF CHELATORS AND CHELATOR FRAGMENTS IN MIXED HAZARDOUS WASTES

J.A. Campbell, H. Udseth, and R.B. Lucke, Pacific Northwest Laboratory*, Box 999, Richland, WA 99352

INTRODUCTION

Nuclear waste was generated at the Hanford defense complex over its nearly 50 years of operation. The varied chemical operations that have taken place over that period of time have generated a wide variety of chemically heterogeneous wastes. Large quantities of chelators,such as ehtylenediaminetetracetic acid (EDTA), citric acid, and N-(2-hydroxyethyl)ethylenediaminetriacetic acid (HEDTA) have been used in many of the waste processes to complex radionuclides in mixed hazardous wastes.

EDTA



HEDTA

Citric Acid

The presence of organics in the waste tanks, primarily chelators and chelator fragments, has been linked to the production of hydrogen in waste tank 101-SY Also, the organoradionuclides are potentially environmentally more hazardous than either radionuclides or chelators alone due to their enhanced mobility through the soil and possible eventual deposition into the ground water. In addition, many of the chelators can't be analyzed by either gas chromatography/mass spectrometry (GC/MS) or gas chromatography (GC), accepted EPA methodologies, without prior derivatization. However, derivatization may require additional sample handling, may give low or variable recoveries, and often requires the use of hazardous reagents. As a result, we have utilized electrospray mass spectrometry as a potential technique for analyzing chelators and chelator fragments. We have also examined the free acids of the chelators by thermospray mass spectrometry.

EXPERIMENTAL

The mass spectrometer used in the electrospray studies was assembled from Extrel components and is described in detail elsewhere (1) The important features of the instrument are a differentially pumped atmospheric pressure inlet suitable for use with electrospray ionization and a rf only quadrupole for ion confinement while the neutral gas is pumped away by an analysis quadrupole. The sample is introduced through a sheath flow interface previously described (1). The concentration for all samples was approximately 1mg/mL of the free acid. The sample was infused at a rate of 0.2 µL/min through the 50 µm i.d. central capillary. Methanol was used in the sheath at a rate of 3.0 µL/min. The electrospray tip was biased to approximately -4kV, adjusted to optimize the analyte response. The spectra are negative ion single scan spectra and were acquired at a dwell of 50 ms/amu. A HP model 5988A LC/MS was used for the thermospray studies. The source temperature was typically 300° C and the stem temperature was 90° C. The mobile phase was 0.1M ammonium acetate.

RESULTS AND CONCLUSIONS

Figures 1a-d are negative ion electrospray mass spectra of EDTA, ED3A, IDA, and citric acid, respectively.

The base peak in most of the electrospray spectra was $(M-H)^-$, except in the case of EDTA. The base peak in the positive ion thermospray mass spectra was $(M+H)^+$ or $(M+18)^+$. In both cases, the identity of the chelator or chelator fragment can be unambiguously identified based on the mass

spectral data. However, electrospray mass spectrometry has an additional advantage; the small sample size and solvent requirements minimizes waste accumulation. This factor will become extremely important when actual waste samples are analyzed.

Additional studies are underway involving obtaining mass spectra of the complexed chelators, i..e. Cu(EDTA).

Mass Spectrometric Characterization of HIV Proteases

Walter Davidson, Keith McKellop, Gordon Hansen, Roger Dinallo, Richard Ingraham, Peter Kinkade, Chris Pargellis, and Susan Mirando Pav
Boehringer Ingelheim Pharmaceuticals Inc., R & D Center, Ridgefield, CT 06877

Introduction

HIV Proteases are proteins, of about 11Kda molecular weight, with an essential function in HIV viral replication. These proteins are the target of therapeutic drugs designed to inhibit their function. Thus their preparation and purification is of interest. HIV1 protease produced by a t-BOC based synthesis, HIV1 protease produced by recombinant technology, and HIV2 protease produced via recombinant methods were analyzed. Electrospray MS (ESI) has proved of value in the analysis of the several preparations of HIV protease. ESI results are compared with FAB/MS analysis of tryptic digests, particularly in their ability to detect microheterogeneity. Identification of biological precursors, artifacts formed via chemical reaction of the proteases during sample work-up, and autolytic cleavage products was accomplished by ESI.

Discussion

Preparative HPLC fractions from a synthetic preparation of HIV1 protease produced ESI spectra which demonstrated a great deal of heterogeneity, compared with HIV protease prepared via recombinant methods. At each of the 99 steps of the synthesis a small probability of a variety of synthesis errors exists. The overall probability of a molecule being correctly synthesized is low. These errors are not readily detected by FAB/MS analysis of tryptic fragments because they are random. If a molecule has a single incorrect amino acid residue, ten of its eleven tryptic fragments will be correct. Thus the "expected" tryptic fragmentation pattern is reinforced. The spectra of tryptic fragments provide information on the average sequence of the sample and on the location of non-random errors. ESI spectra of the intact protein detect heterogeneity produced by random errors in the synthesis. Preparative HPLC fractions from HIV1 protease synthesized via recombinant technology yielded ESI spectra which demonstrate that several components have been produced and separated. In addition to the desired, unaltered HIV1 protease, components showing a single or double addition of 43 amu were observed. These samples were worked-up with a large excess of urea, which contains isocyanate impurities. The reaction shown below likely accounts for the addition(s) of 43 amu to the protease.

$$\mathbf{HIVR\text{-}NH_2 + NCO \rightarrow HIVRNH(CO)NH_2}$$

HIV2 protease prepared via recombinant technology yielded an ESI spectrum which showed 5 components. The predominant component is the desired HIV2 protease MW = 10719. Two additional components resulted from incomplete cleavage of an N-terminal fusion preceding the proline at position 1. These components had MW = 10790 due to the additional alanine and 10921 due to the additional methionine and alanine. Two other products, of MW = 3772 and 6965, were also observed. This pair of products is consistent with a proteolytic cleavage between residues 37 and 38. The assignment of MW =3772 was confirmed by a high resolution separation of the isotopes in the +3 charge state at m/z = 1258.

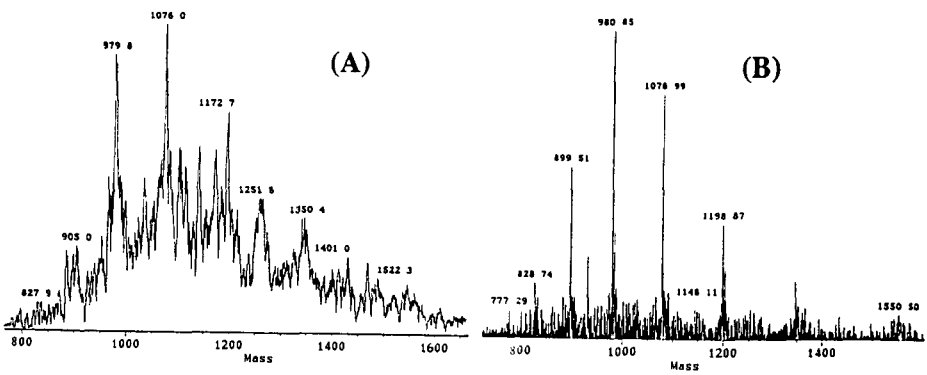
Experimental

All mass spectra were acquired using a Kratos MS80Q double focussing magnetic mass spectrometer. The instrument has been modified by the addition of an electrospray source (Analytica, Branford, CT). FAB mass spectra of the tryptic digests were acquired in raw data mode, with an 8KV Xe primary ion beam, using glycerol/thioglycerol matrix. Electrolytes present in the fractions prepared by HPLC were removed by washing dried fractions with two 50ul volumes of deionized water (HIV protease is insoluble in water). The fractions were dissolved, with sonication, in methanol and an equal volume of water was added. Electrospray spectra were acquired in raw data mode from m/z 1700-550 at 30 sec /decade. Spectrometer control and data acquisition was accomplished using a Kratos (Manchester, UK) Dart data system. This employs a UNIX based operating system. The spectrometer was calibrated with equine cytochrome c. Raw sample and calibration data were transferred and reformatted, via a system developed in-house, to the Macrosoft (Analytica, Branford CT) deconvolution program. This program runs on a PC with an MSDOS operating system. ESI spectra were acquired at 4KV source potential.

Conclusion

Electrospray mass spectra provided valuable information on the amount and identity of impurities in several preparations of HIV proteases. Addition of an electrospray source to an existing magnetic instrument allowed us to obtain this information. Implementation of a data processing and transfer method, which provides access to a sophisticated deconvolution algorithm, provided an excellent capability to analyze this information. ESI allowed the heterogeneity in synthetic HIV1 protease to be observed. FAB MS of tryptic digests did not provide this information. Chemical modifications, which occurred during sample work-up, were observed in recombinant HIV1 protease. Impurities present due to incomplete cleavage of biological precursors and proteolytic cleavage were identified in a preparation of HIV2 protease.

ESI MS of Synthetic (A) and Recombinant (B) HIV1 Protease



Identification of Components In Waste Streams Using Electrospray and Tandem Mass Spectrometry

B. Mason Hughes and David E. McKenzie
Environmental Sciences Center, and
Kevin L. Duffin
Physical Sciences Center
Monsanto Company, St. Louis, Missouri 63167.

Introduction

An important class of compounds which is difficult to analyze using standard environmental analysis protocols, are substituted phenols. The present paper discusses the use of a Sciex API III mass spectrometer with an ionspray interface to detect the anionic forms of various substituted phenol isomers. The mass spectrometric analysis of waste samples from two different chemical processes show a number of anions present in these waste streams. Nitrophenol isomers were shown to be present in these wastes using liquid/liquid extraction followed by capillary GC/MS analysis techniques. The present study involves the use of MS/MS capabilities of the Sciex atmospheric pressure ionization mass spectrometric system for the identification of other substituted phenols which are not amenable to gas chromatography/mass spectrometry. Standard solutions of different substituted phenols and of different waste streams were analyzed. The different MS/MS product ion spectra produced from different isomers were then used to determine which isomers were present in these complex waste mixtures.

Background

The low-level analysis of acidic organic compounds, such as substituted phenols, is difficult since these compounds are not amenable to gas chromatography, and normal HPLC methods that are used may lack specificity. Analysis of complex wastes that may contain a wide range of analytes, requires the use of detection methods which are more specific than HPLC absorption detectors. These more specific detectors should minimize the reporting of false positives for components in the waste streams. Mass spectrometry offers both specificity and sensitivity which may be useful in the analysis of complex wastes from chemical manufacturing.

Experimental

Waste streams and standard solutions were infused into the ion spray nebulization system of the Sciex API III mass spectrometer system. Mass spectra of each sample were recorded. The substituted phenate anion was the major negative ion produced from standard solutions of substituted phenols. Fragmentation patterns (or product ion spectra) from MS/MS experiments of the substituted phenate anions were produced from purchased and synthesized standard solutions of various isomers. Comparison of MS/MS patterns from standards and process wastes, were used to identify the substituted phenols present in the waste streams.

Results

The major reaction paths for two isomers of Cl-dinitro-phenols was shown to involve the losses of NO, NO_2, 2(NO) and 2(NO_2). In addition, Cl^-, NO_2^- and $C(NO_2)_2^-$ were also formed. HPLC

with diode array detection and MS/MS product ion spectra of synthesized 4-Cl-2,6-$(NO_2)_2$-phenol were used to unequivocally identify this compound in a process waste sample and in a concentrated extract from a waste treatment plant which is used to degrade plant wastes.

A minor substituted phenol in the process waste was also identified as 2-Cl-4,6-$(NO_2)_2$-phenol. CID/MS/MS experiments were conducted on the major product ion of the ^{37}Cl-containing anion. The source pressure and orifice voltage were raised so that collision induced dissociation (CID) reactions occurred in the ion source to produce the m/z 145 product ion. This product ion was then selected for further MS/MS reactions. This study showed that the major product ion of 2-Cl-4,6-$(NO_2)_2$-phenate results from the loss of (O-C-NO_2) from the phenate anion. The following table summarizes the product ion spectra measured for two isomers of Cl-dinitro-phenol.

Product Ion Spectra from MS/MS Reactions of ^{35}Cl-$(NO_2)_2$-Phenate Anions

Product Ion Mass	Identity	Relative Intensity	
		2-Cl-4,6-$(NO_2)_2$-phenate	4-Cl-2,6-$(NO_2)_2$-phenate
35	Cl^-	90	100
46	NO_2^-	10	10
63	NO_3^-	<2	15
105	$C(NO_2)_2^-$	<2	10
113	$(O_2N\text{-}C\text{-}NO_2)$-loss	10	5
125	$(NO_2)_2$-loss	5	20
129	$(ON\text{-}C\text{-}NO_2)$-loss	<2	15
141	$(NO\text{-}NO_2)$-loss	<5	10
143	$(O\text{-}C\text{-}NO_2)$-loss	100	<2
157	$(NO)_2$-loss	5	2
159	$(C\text{-}NO_2)$-loss	<2	5
171	NO_2-loss	30	20
187	NO-loss	5	5

Conclusions

Electrospray and tandem mass spectrometry can be invaluable tools for the understanding of complex mixtures containing small acidic organic compounds. This study has demonstrated how this technique can be used to determine exactly which substituted phenol isomers are present in process wastes. This information can be useful in modifying the process, or developing waste treatment approaches which will improve the environmental quality of chemical processes.

Electrospray Ionization and Tandem Mass Spectrometry of Noncovalent Protein Complexes

Joseph A. Loo, Rachel R. Ogorzalek Loo, David R. Goodlett,
Karen J. Light-Wahl, Charles G. Edmonds, and Richard D. Smith
Chemical Sciences Department
Pacific Northwest Laboratory
P. O. Box 999, Richland, WA 99352

Proteins are folded into specific molecular conformations, maintained by noncovalent interactions. Proteins interact with other protein molecules or DNA to form complex structures, accounted for by noncovalent interactions within and between macromolecules. Electrospray ionization-mass spectrometry (ESI-MS) has demonstrated the capability for examining a range of protein noncovalent interactions. In order to better understand the nature of these interactions, we have used ESI-MS and tandem mass spectrometry (MS/MS) to analyze a variety of noncovalently-bound complexes.

A. Protein-Oligonucleotide Complexes

Complexes between proteins and nucleic acids are involved in cell processes that maintain genetic information. Many important enzymatic processes require nucleotide ligands, or coenzymes, binding to the enzyme. ESI-MS experiments indicate the formation of multiply charged complexes between a variety of proteins and mono- and larger oligonucleotides. For example, cytochrome *c* is observed to form 1:1 and 1:2 complexes with pd(AAA); MS/MS of the 12+-charged 1:1 complex yields the complementary 11+ cytochrome *c* molecule and singly-charged pd(AAA) ion pair products. A variety of polypeptides and proteins have been observed by ESI-MS to bind to larger oligonucleotides (up to a 6-mer).

B. Protein-Protein Interactions

Noncovalent interactions between proteins and other polypeptides and proteins are important in a variety of biochemical systems (e.g., antibody-antigen complexes, enzyme-substrate, etc...). Many protein systems are composed of several subunits noncovalently-bound as a complex. Proteins such as carbonic anhydrase (29 kDa) are known to aggregate in solution to form multimeric species. This is reflected in the ESI mass spectra shown in Figure 1.

Ribonuclease A (RNase A, M_r 13 682) is cleaved by subtilisin at the peptide bond between residues 20 and 21 to give S-peptide (residues 1-20, M_r 2166) and S-protein (residues 21-124, M_r 11 534). The separated fragments can reassociate noncovalently with high affinity to yield fully active ribonuclease S (RNase S). The overall dissociation constant, K_D, is *ca.* 4 orders of magnitude greater at acidic pH than pH 7. With the voltage difference between the nozzle and skimmer elements of the atmosphere/vacuum interface (Δ NS) at *+0 V to minimize collisional dissociation*, the ESI mass spectrum of RNase S from a 5% HOAc solution (pH 2.4) shows only multiply charged S-peptide and S-protein ions (Fig. 2). The ESI mass spectrum from a H_2O solution shows predominantly ions for the *intact RNase S complex*, consistent with the trend in K_D values as a function of pH. More studies are necessary to determine the maximum K_D for which ESI-MS can be used to monitor such noncovalent interactions.

C. Cyclodextrin Complexes

Cyclodextrins (CD's) are cyclic polysaccharides made up of 6, 7, and 8 (α, β, and γ, respectively) glucopyranose units. The cavities of CD's are relatively hydrophobic and have an internal diameter of 4.7-8.3 Å. As a result of the differences in cavity size, CD's are useful for the

study of small ligand binding. Binding and formation of *"host-guest"* complexes can be tailored based on substrate size and geometry. As a preliminary study, the formation of the complex between tryptophan and α-cyclodextrin was analyzed by ESI-MS. A singly charged Trp/α-CD complex was observed in ESI mass spectra obtained in H_2O and 5% HOAc solutions. Tandem MS of the complex results in the release of Trp+ in addition to fragmentation of α-CD, indicating a relatively strong complex. More studies are underway to understand the binding of small molecules to CD's.

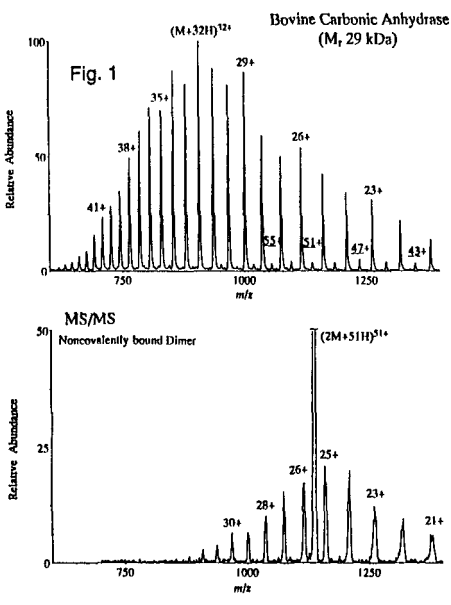
D. Metal Ion Binding

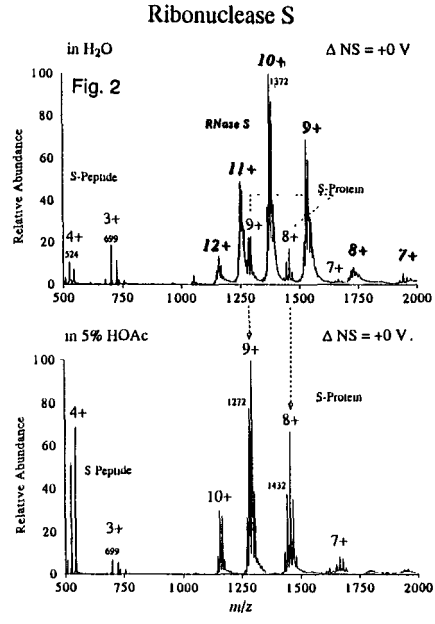
Metal ion binding is an important facet of the function of many protein systems. Calmodulin (17 kDa) and parvalbumin (12 kDa) are proteins whose polypeptide backbones are arranged in a specific orientation for calcium binding. Regulation of enzyme activity has generally been found to require Ca^{2+}. Greater than 3 calcium ions are observed to bind to calmodulin by both positive and negative ion ESI-MS under various pH conditions. Upon the addition of $CaCl_2$, slightly more charging is observed by (+) ESI-MS and slightly less charging is observed in the (-) ESI mass spectrum. Measurement of *m/z* values for calmodulin and several smaller polypeptides with calcium indicate that calcium is in the Ca(II) state.

Carbonic anhydrase is a zinc metalloenzyme containing one essential metal ion bound to a single polypeptide chain. In solution, the zinc ion lies at the bottom of a conical cleft and is tetrahedrally liganded by *histidine* residues. Zinc metal binding to carbonic anhydrase is observed in the ESI mass spectrum.

To better understand the nature of the interactions with zinc ions, ESI-tandem MS results for a variety of histidine-containing peptides with and without zinc were compared. For angiotensin peptides, dissociation of the His - X bond is enhanced in the presence of Zn^{2+}. Further work is ongoing to study the specificity of such peptide interactions with zinc and other metal ions.

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830.





Conformational Changes of Proteins in Solution and in the Gas Phase. An Electrospray and Ion-Molecule Reaction Study

*Rong Feng and Yasuo Konishi
National Research Council of Canada, Biotechnology Research Institute,
6100 Royalmount Avenue, Montreal, Quebec H4P 2R2, Canada

The conformation of a protein in solution can be altered by changing pH, solvent composition and temperature, etc. The conversion from a native state to a denatured one renders the protein biologically inactive, as the tertiary and secondary structures of its polypeptide chain(s) have been partially or completely transformed to random coils. In solution, such structural changes are reversible for some proteins, and not for others. Very little is known about protein conformations in the gas phase, as the effect of solvation is not fully understood. In this study we use electrospray and ion-molecule reactions to probe protein conformational changes in solution and in the gas phase.

A native horse myoglobin consists of a polypeptide chain of 16,951 Da and a noncovalently-bound heme of 616 Da. The electrospray charge-distribution profile of myoglobin in pure H_2O (Fig. 1a), which corresponded to the native state, was drastically different from that in 10% acetic acid (pH ~2) (Fig. 1b), which corresponded to a denatured state. The mass of the acid-denatured myoglobin was 616 Da less than that of the native one in pure H_2O, indicating that in the former heme had been lost because of the destruction of the heme-binding pocket. However, when the pH of the acid-denatured myoglobin solution was raised to ~5, the native-like charge-distribution profile reappeared (Figs. 1c and 2a), although the protein was still heme-less. Interestingly, when the solution pH was further increased to the range of 6 to 8, heme became re-attached to the protein (Figs. 2b and 2c). The re-attached heme could be removed once again either by acidifying the solution, or by mild gas-phase collisions between the heme-bound myoglobin ions and N_2 curtain gas in the atmosphere/vacuum interface region. This reversibility shows that the heme-rebinding at a higher pH is noncovalent in nature, most likely because the functional secondary and tertiary structures (and thus the heme-binding pocket) have been restored from the random coils of the acid-denatured myoglobin.

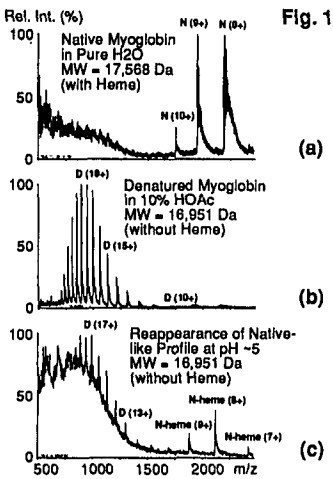


Fig. 1

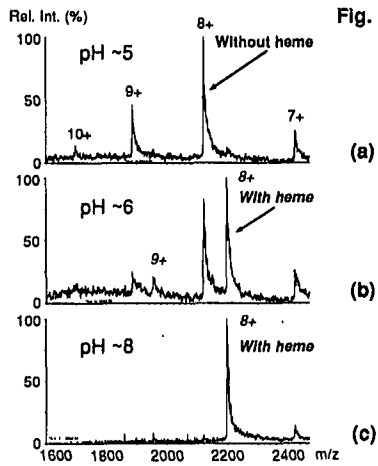

Fig. 2

After charge-transfer reaction with NH_3 gas in the atmospheric region near the instrument sampling orifice, a new charge-distribution profile (Figs. 3b and 3c), which resembled closely to that of the native myoglobin, appeared in the electrospray spectrum of the acid-denatured myoglobin. The gas-phase experiment, in contrast to the one in solution, did not result in the re-attachment of heme. This is consistent with the gas-phase nature of the interaction between myoglobin and NH_3, as in the gas phase heme and the polypeptide chain of the denatured myoglobin are isolated from each other with little chance to reunite. After losing a large number of charges to NH_3, the collision-scattering loss of the acid-denatured myoglobin ions, measured at the MS/MS collision chamber (i.e., the second quadrupole) of the triple quadrupole mass spectrometer, became much smaller than the original ones, pointing to a reduced physical cross-section. Comparing with the gaseous ions from the acid-denatured myoglobin (Fig. 3a), the gaseous ions from the native myoglobin (Fig. 4a), and the pseudo-native ions from the NH_3-deprotonation of the denatured ions (Fig. 3b), were much less prone to loss charges, as evidenced by a higher NH_3 partial pressure required to produce a shift in their charge-distribution profiles and a much smaller degree of shift (Figs. 4b and 3c).

Similar solution and gas-phase phenomena have also been observed with cytochrome c (12.4 kDa) and lysozyme (14.3 kDa), indicating that their conformational changes, like that of myoglobin, are reversible. More importantly, the gas-phase results show that upon charge transfer to NH_3 the extended structures of the acid-denatured proteins shrink back to more compact structures, most likely due to the reduction of the Coulombic repulsions among the charges. The charge-transfer reactivity of the gaseous ions from an acid-denatured protein drops substantially when its charge-distribution profile becomes close to a native profile, indicating that a stable state, possibly a native or pseudo-native state, has been reached. The reactivity difference between the gaseous ions of the native and denatured proteins is difficult to explain on the basis of proton affinities alone, as in both cases the charging sites are Arg, Lys and His residues. More likely it shows that despite multi-charging the conformational differences still exist between these gaseous ions of different solution origins. The fact that the gaseous ions from a native state are much less reactive than the ones from a denatured state suggests that the former have a lower free energy and are thus conformationally more stable.

Structural Characterization of Alkylated DNA Using Electrospray Ionization Mass Spectrometry

*Meg Annan, Roger W. Giese, Paul Vouros; Northeastern University, Boston, MA
David H. Swenson; Louisiana State University, Baton Rouge, LA

Many alkylating agents are potent chemical carcinogens due to their ability to react with nucleophiles such as DNA bases without metabolic activation. In order to understand the chemical basis of carcinogenesis by such agents, it is important to know where on each base alkylation takes place, how the nature of the alkylating agent affects positional selectivity, and which types of modification are more likely to cause cancer. Of fundamental importance, therefore, is the ability to devise a sensitive and specific means of detection and characterization of modified nucleobases. Toward this effect electrospray ionization mass spectrometry (ESI/MS) offers the ability to readily perform analyses at the nucleoside or nucleotide level due to the compatibility of the ESI technique with the polar, thermolabile nature of these DNA subunits.

The work was done on a VG Quattro triple quadrupole mass spectrometer equipped with an electrospray ionization source. All experiments were performed in the positive ion mode using a solvent system of 50/50 $MeOH/H_2O$, 1% acetic acid and a flow rate of 2.0μL/min. A 10μL sampling loop was used for the CID analyses, while a 0.5μL sampling loop was used for the detection work.

The full scan spectra of the nucleobases cytosine, adenine, and guanine show intense molecular ions at m/z 112, 136, and 152, respectively. Furthermore, the spectra of the analogous nucleosides and nucleotides indicate facile loss of the phosphate and/or sugar groups to produce an intense protonated base (BH_2^+) ion. The skimmer voltage can be adjusted to enhance the molecular ion intensity, however, the MH^+/BH_2^+ ratio is typically increased with an accompanying loss in sensitivity.

In terms of structural characterization, the formation of an intense BH_2^+ ion from nucleosides and nucleotides was considered advantageous since fragmentation of the base upon collisional activation would not be in competition with the more kinetically favorable cleavages through the sugar and the glycosidic bond. As shown in Figure 1a, for example, collisional activation of the BH_2^+ ion (m/z 152) from deoxyguanosine produces ions analogous to those observed in the EI mass spectrum of guanine.[1] The effect of ethylation was studied by performing CID experiments on the BH_2^+ ion (m/z 180) from 1-ethyl-deoxyguanosine, N^2-ethyl-deoxyguanosine, O^6-ethyl-deoxyguanosine, 3-ethyl-guanine, and 7-ethyl-guanine. All five BH_2^+ ions exhibit a strong tendency to lose ethylene (C_2H_4). This loss appears to be so facile that it precedes all other cleavages with the exception of the loss of NH_3. The result is a CID spectrum which looks very much like that obtained from unmodified deoxyguanosine and contains very little, if any, information regarding the site of alkylation. This is illustrated in Figures 1a-b. As shown in Figures 2a-d, the methylated analogs produce CID spectra which are characteristic of the site of modification. For instance, the 1-methyl and the N^2-methyl species lose both NH_3 and the analogous methylamine, but the ratio of these ions is vastly different. The O^6-methyl adduct, on the other hand, exhibits a unique loss of MeOH. Finally, the 7-methyl adduct produces ions at m/z 124, 96, 69, and 42 due to sequential losses of CH_2N, CO, HCN, and HCN, respectively, which are displaced by 14 m/z units due to the presence of the methyl group.

Rapid screening of sample mixtures can be performed by using constant neutral loss scanning. For example, screening of a mixture of deoxycytidine, deoxyadenosine, and deoxyguanosine is easily achieved at the level of 30ng per component by monitoring the collision induced loss of NH_3. Finally, ESI affords a sensitive means of detection as evidenced by the 3.5 pg (S/N ration of 4:1) detection limit achieved for the 1-ethyl-deoxyguanosine.

In conclusion, electrospray ionization is a technique compatible with the properties of nucleic acid constituents. It is a technique in which derivatization is not necessary for ionization and volatilization of the analyte. In addition, structural features of certain modified analogs can be probed by CID due to the ability to generate a collision spectrum in which ample cleavage through the base has occurred.

Analysis of Human Calcitonin by Electrospray Ionization Mass Spectrometry

M. Kanai and D. Ma, Finnigan MAT, 2-5-8 Hatsudai, Shibuya, Tokyo , Japan
N. Kobayashi, A. Nakagawa and K. Nakamura, Sankyo Co., Ltd., 1-2-58 Hiromachi, Shinagawa, Tokyo , Japan

As biotechnology has progressed, many protein and peptide macromolecular drugs have recently been developed. As examples, a series of calcitonins (CTs), used in the regulation of blood calcium levels, are currently available for clinical treatment. Having few side effects, human calcitonin (hCT), a single-chain polypeptide (32 a.a.), seems to be an ideal and potent hypocalcemic agent (1). Using hCT as a model, the application of electrospray ionization mas spectrometry (ESI/MS) to quality control and quantitative analyses of polypeptide drugs have been investigated.

Experimental

A Finnigan MAT TSQ700 triple stage quadrupole mass spectrometer equipped with an ESI source was used. The TSQ700 was directly coupled with a micro-capillary HPLC . The ESI source was operated using -4.0kV high voltage, 2-methoxethanol as the liquid sheath and nitrogen as the gas sheath.

A stock solution, hCT dissolved in 0.1% TFA/water at 1nmol/µl was prepared, from which serial dilutions were made. hCT (20pmol/µl) was infused into the ESI source at 1µl/min. for the molecular weight determination and the sequence confirmation experiments using a syringe infusion pump . A CID spectrum was obtained at an energy of 45eV using argon as the collision gas at a pressure of 2.3mTorr.

For the quantitative experiments, a 0.25 mm ID x 10cm C18 capillary column was used. The mobile phase consisted of 0.1% TFA/water (solvent A) and 0.1% TFA/acetonitrile (solvent B), with a linear gradient elution from 0% B to 60% B in 15 min. at a flow rate of 2µl/min. A 0.5µl aliquot of hCT standard solution (40fmol/µl to 20pmol/µl) was injected onto the column and eluted by the linear gradient.

An immobilized antibody column was used for clean-up of biological samples (2). A 0.5mL sample of rat plasma spiked with hCT at the concentration of 3pmol/mL was applied to an immobilized antibody column (0.5mg). The column was washed with 1mL of water twice and 1mL of 20% methanol/water. The analyte was then eluted with 3mL of 95% methanol/water. The eluent was evaporated under N_2 stream and re-dissolved in 50µl of 0.1% TFA/water. A 10 µl aliquot was applied to the micro-HPLC analysis.

Result and Discussion

In the ESI spectrum of hCT, the triply and doubly protonated molecules were observed at m/z 1140.0 and m/z 1708.7 (data not shown). We determined a molecular weight of 3427.4 Da corresponding to the most abundant mass observed for hCT. The CID spectrum of the triply protonated molecule is shown in Fig. 1. A 25 amino acid sequence from the C-terminus was confirmed. We also performed MS/MS of hCT after the reduction of S-S bond. The resulting CID spectrum provided the entire sequence information (data not shown). These results illustrate that ESI/MS and MS/MS are applicable for the rapid quality control of hCT and other polypeptide drugs of this type.

The micro-HPLC-ESI/MS (SIM of m/z 1140) provided good linearity of response in the range of 20fmol to 5pmol without the use of internal standard (Fig. 2). A SIM chromatogram of a spiked sample (3pmol/mL hCT in rat plasma after the clean-up using an immobilized antibody column) is shown in Fig. 3. The recovery of this clean-up method has not been determined. These results demonstrate the prospective application of micro-HPLC/ESI/MS to both qualitative and quantitative analyses of polypeptide drugs in biological fluids.

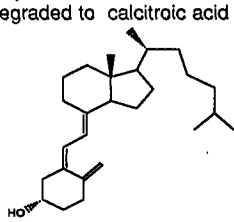
Analysis of Vitamin D and its Metabolites: New Reagents for the Detection of Neutral Molecules by Electrospray Ionization

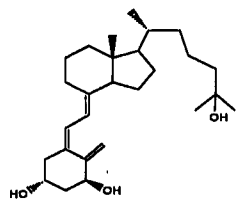
Stephen R. Wilson*, Michael L. Tulchinsky and Yunhui Wu
Department of Chemistry, New York University
Washington Square, New York, NY 10003

Recent reports of subfemptogram sensitivity[1] for electrospray ionization mass spectrometry (ESI-MS) suggest that selective online derivatization methods combined with ESI-MS would provide a powerful new technique for monitoring biological systems. We are exploring the use of this approach for analysis of vitamin D metabolites normally not observable by ESI-MS.

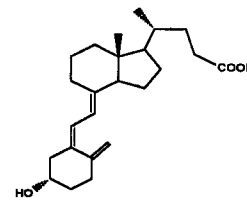
Vitamin D **1** is synthesized in the skin and is metabolized by the liver and kidney to its hormonal form calcitriol **2** (1,25-dihydroxy-vitamin D), a steroid hormone regulating not only calcium metabolism but proliferation and differentiation cells.[2] In addition, vitamin D is degraded to calcitroic acid **3**.[3] Understanding the critical role of vitamin D



1



2

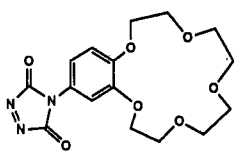


3

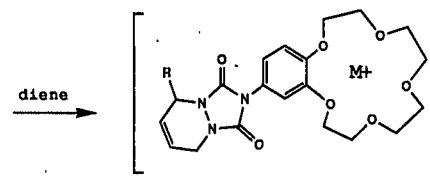
and its active metabolites in various clinical conditions requires methodology for determination of the identity and levels of the compounds in serum. Unfortunately, there is no general method at present which allows determination of vitamin D or its metabolites under physiological conditions (~10^{-9} M). Radioimmunoassay methods for vitamin D compounds lack specificity, so that the best current protocols involve time consuming concentration and isolation by HPLC.[4a,b]

Vitamin D analogs, being uncharged, do not show up in ESI-MS. We have, however, developed several tagging reagents for ESI-MS that (1) are selective for derivatization of the vitamin D triene system, (2) vastly increase their ESI signal and (3) are suitable for online analysis at physiologically relevant concentrations. Only one report has appeared in the literature on the derivatization of a compound to make it more "ESI active".[5]

We have developed new reagents for Diels-Alder derivatization that can convert vitamin D into a chargeable molecule. 4-Phenyl-1,2-4-triazoline-3,5-dione crown ether **4** is a dienophile[6a,b] that introduces a metal binding site into a diene such as vitamin D so that the



4



5

M+Na$^+$ adduct **5** may be detected by ESI-MS. An excellent synthetic route to **4** is available.[7] When a red solution of **4** was allowed to contact vitamin D, instantaneous decolorization indicated formation of the Diels-Alder adduct **6**. ESI-MS analysis of adduct **6** in the presence of $NaClO_4$ is shown in figure 1. Quantitation using crown/vitamin D

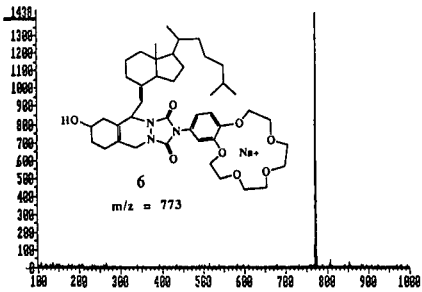


Figure 1. ESI Spectrum of Vitamin D Adduct 6 (5.4x10-4 M in CH_3OH)

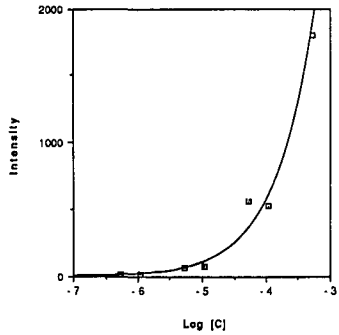

Figure 2. Quantitation of Adduct 6 in CH_3OH

adduct **6** is shown in a plot of ion intensity for the M+Na$^+$ ion (m/z = 773) vs concentration (figure 2). Detection limits with our current system is >1 pmol for adduct **6**. Similar reaction with metabolites **2** (1,25-dihydroxy-vitamin D) and **3** (calcitroic acid) gave adducts showing M+ at m/z 805 and m/z 761 respectively. We have previously reported[8] that related crown ether/metal complexes[9] provide a high yield of M+Na$^+$ ions for detection by ESI-MS.

ESI-MS spectra were obtained on a Vestec Model M-200 ESI-MS instrument[10] spraying at 3-5 µl/min with the following settings: Needle Voltage: 2.0-2.4 kv; ES Chamber Temperature: 45-60°C; Nozzle Voltage: 200 V; Block Temperature. 245-250°C; Lens Temperature: 120°C; Repeller Voltage: 20 V; ES Chamber Pressure: 1.4-1.5 x 10^{-1} torr.

INTRODUCTION:

LSIMS has been shown to be a powerfull method for structural characterization of metal transition complexes, completing and improving the NMR and elemental analysis. Recently we have tested the possibilities of ESMS on a serie of Cu^+ catenates up to 7000 Da (1).

In this work, the possibilities of LSIMS and ESMS for molecular weight and structural determination are evaluated on two metal transition complexes: [3]-catenate and rotaxane. Catenate and rotaxane are transition metal complexes involving a coordination with two phenanthroline chelating one Cu^+. The [3]-catenate formed by three interlocked rings (molecular weight = 2221.6 Da) has both coordination sites of this type. Rotaxane (molecular weight = 2695.8 Da) carries morover a porphyrin complexed with Au^{3+}.

EXPERIMENTAL:

Synthesis: [3]-catenate was synthesized and purified as described previously by Dietrich-Buchecker *et al* (2). Synthesis of the rotaxane is described by Chambron et Heitz (3).

LSIMS. Positive LSIMS was carried out on a ZAB-HF double focusing mass spectrometer (Xenon gun). Resolution was about 2000. The samples were dissolved in CH_2Cl_2 (5 µg/µl).

ESMS. A VG BioQ triple quadrupole (m/z range of 4000, VG BioTech, Manchester, UK) was used to carry out positive ESMS. Extracting cone voltage Vc varied from 40 to 200 volts. The resolution was usually about 600 (10% height). The samples were dissolved in CH_2Cl_2 or in CH_3CN (50 pmol/µl).

RESULTS & DISCUSSION:

LSIMS-spectra of [3]-catenate and of rotaxane displayed a singly-charged pseudo-molecular ion (catenate: m/z = 2135.2; rotaxane: m/z = 2840.3) obtained by loss of one counter-ion and a doubly-charged pseudo-molecular ion (catenate: m/z = 1024.3; rotaxane: m/z = 1347.3) obtained by loss of two

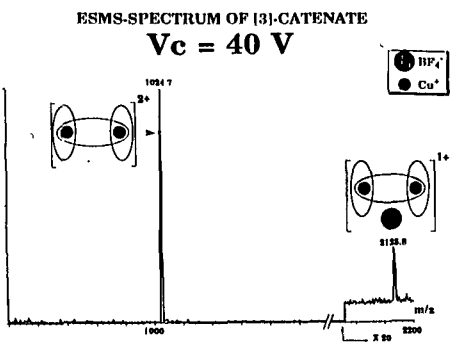

Figure 1

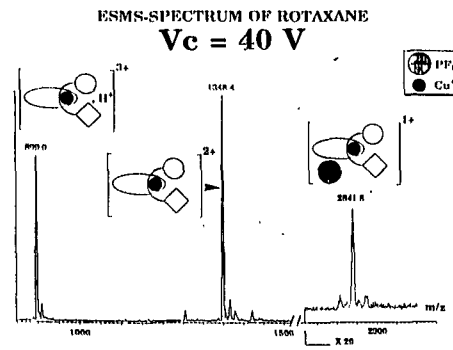

Figure 2

counter-ions. Spectra are characterized by intense fragmentation peaks (catenate: m/z = 585.2, m/z = 1462.4, m/z = 1526.3; rotaxane: m/z = 629.0, m/z = 2064.8, m/z=2126.6). A specific ligand one-reduction in positive mode in case of loss of 2 counter-ions (catenate: m/z = 2048.2, m/z = 1526.3; loss of $2BF_4^-$ rotaxane: m/z = 2694.9; loss of $2PF_6^-$) is observed.

ESMS-spectra (Vc = 40 V) of [3]-catenate (Fig. 1) and of rotaxane (fig.2) displayed singly- and doubly charged pseudo-molecular ions but no fragmentation peaks. In the case of the rotaxane a triply-charged pseudo-molecular ion (m/z = 899.0) was observed corresponding to a protonation of the non coordinating porphyrin. At Vc > 140 V, intense fragmentation of the [3]-catenate was observed (Fig. 3) while no fragmentation was induced for rotaxane (Fig. 4). This difference could be explained by two reasons: (i) a specific molecular topology for [3]-catenate which has been shown to have a fixed conformation by crystallographic and H-NMR studies (the two 27 membered rings are very close; the folding up of the large central ring might be explained by stabilizing π-π interaction between aromatic nuclear) while rotaxe is expected to be flexible, (ii) the counter ions are BF_4^- for [3]-catenate while they are PF_6^- for rotaxane.

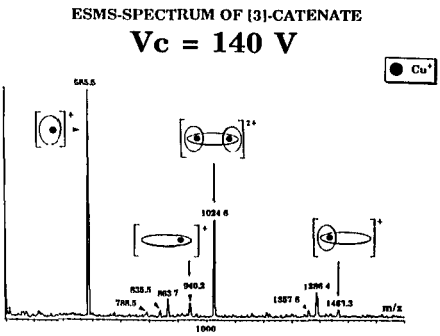

Figure 3

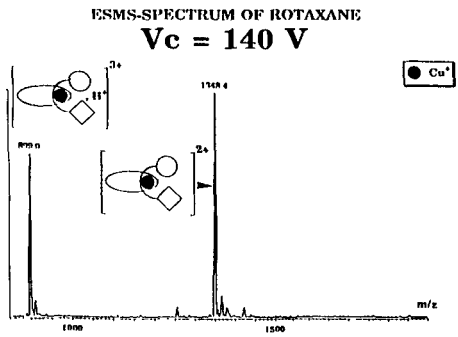

Figure 4

CONCLUSION:

LSIMS analysis of these compounds is characteriezd by several limitations (i) reductions by the matrix (ii) decomposition under high energy particle bombardment., (iii) mass range detection limits.

ESMS has been shown to be a good alternative for the characterization of these high molecular weight coordination compounds and fragmentations could be controled.

Characterization of cyclodextrins and their inclusion compounds by LSIMS and ESMS

O. Sorokine[1], E. Leize[1], J-F. Letavernier[2], J. Ropenga[2] and *A. Van Dorsselaer[1]

INTRODUCTION:

An important analytical work exists about cyclodextrins and their inclusion compounds characterization, using mainly RP-HPLC and NMR. In the case of modified cyclodextrins, accurate characterization is difficult, even when using high resolution NMR. For putative inclusion compounds, analytical methods provide only indirect evidence of the inclusion phenomenon.

In this work we have used ESMS to determinate the number of methylations on modified β-cyclodextrins and also studied inclusions of phenylalanine and hydrocortisone in these methylated cyclodextrines.

EXPERIMENTAL:

Synthesis. Polymethylated cyclodextrins (PMCD) were produced by different synthetic procedures of methylation. Inclusion compounds such as PMCD/phenylalanine and PMCD/hydrocortisone were obtained by mixing phenylalanine or hydrocortisone to PMCD in a 1/1 ratio under controlled conditions.

LSIMS. Positive LSIMS was carried out on a ZAB-HF double focusing mass spectrometer and recorded on a VG 11/250 data system. The samples were dissolved in MeOH (5 µg/µl).

ESMS. A VG BioQ triple quadrupole (m/z range of 4000, VG BioTech, Manchester, UK) was used to carry out positive ESMS. Extracting cone voltage (Vc) varied from 40 to 200 volts. Resolution was about 800. Samples were dissolved in MeOH/H_2O/Formic Acid (50/50/1) at 30 pmol/µl.

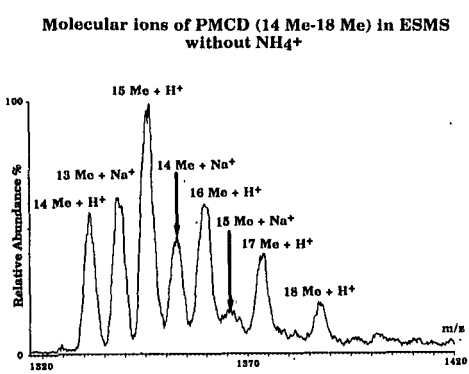

Figure 1: Molecular ions of PMCD (14 to 18 methyl groups) without amonium carbonate.

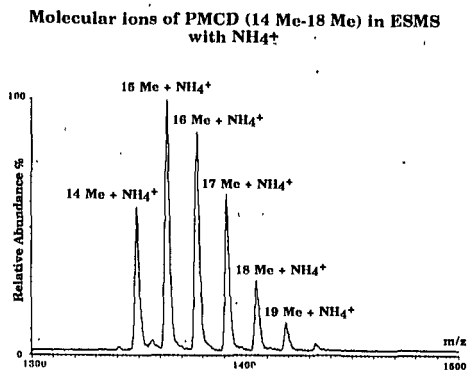

Figure 2: Molecular ions of PMCD (14 to 18 methyl groups) with with amonium carbonate.

ESMS-Spectrum of PMCD/Hydrocortisone inclusion

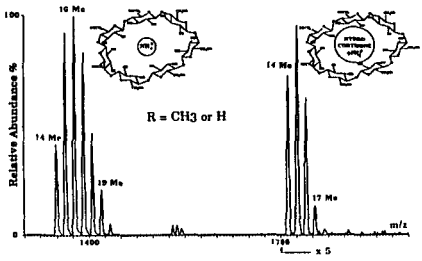

Figure 4: *ESMS spectrum of PMCD with* one molecule of hydrocortison included. One positive charge is given by an additional NH_4^+. Higher methylated forms displayed higher affinity for NH_4^+.

ESMS-Spectrum of PMCD/Phenylalanine inclusion

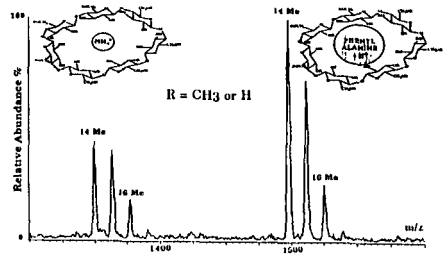

Figure 3: ESMS spectrum of PMCD with one molecule of phenylalanine in presence of amonium carbonate.

RESULTD AND DISCUSSION:

PMCD: In LSIMS we observed peaks corresponding to fragmentations of PMCD and spectrum were complex. In ESMS only $[M+H]^+$ molecular ions were mainly observed but $[M+Na]^+$ molecular ions were also present, which prevented the use of these data for accurate quantitation of the different number of methylations (Fig. 1). When using diluted ammonium carbonate solutions, ESMS produced a single type of molecular ions, $[M+NH_4]^+$ (Fig.2). The quantitation was then possible and several types of PMCD were characterized containing from 14 methylations up to 18 methylations or from 10 Me up to 21 Me. Linearity was verified by mixing, in known ratio, different PMCD preparations with different number of methylation; the intensity of the molecular ions changed linearly.

Inclusion compounds: *These compounds, diluted in a solution containing ammonium ions, were* characterized by ESMS. In the spectra we observed two groups of peaks. The first one consisted of $[M+NH_4]^+$ molecular ions of the PMCD. The second one, corresponded to charged adduct of PMCD/Penylalanine or PMCD/Hydrocortisone (Fig.3 and 4).

CONCLUSION:

ESMS appears to be a very useful method for: (i) Cyclodextrin and inclusion compounds characterization (ii) Control of purity of these compounds (iii) Improvement of methylation and inclusion technology.

Finally, these inclusion compounds are interesting models in the study of non-covalent receptor-ligand complexes by ESMS.

Fragmentation Behavior of Lipid A's in Electrospray vs. Plasma Desorption Mass Spectrometry

Richard B. Cole[1]*, A. Kamel Harrata[1], Linda N. Domelsmith[2]

1. Department of Chemistry, University of New Orleans, Lakefront Campus, New Orleans, LA 70148
2. United States Department of Agriculture, Southern Regional Research Center, New Orleans, LA 70124

Lipid A's are phosphorylated glucosamine disaccharide substructures of lipopolysaccharides comprising part of the outer membrane of gram-negative bacteria. Liberation of lipid A's from parent lipopolysaccharides is achieved via mild acid hydrolysis. Lipid A's are believed to be responsible for the toxicity associated with the inhalation of bacteria-laden dust. Electrospray mass spectrometry (ESMS) and Plasma Desorption mass spectrometry (PDMS) have been used by our group for structural characterization of lipid A's produced by *Enterobacter agglomerans*, a bacterium commonly found in field cotton. Other lipid A's produced by *Salmonella minnesota* and *Escherichia coli* have also been analyzed. No separation of the crude hydrolyzed lipopolysaccharide preparations was performed prior to analyses. Under the conditions employed, each MS technique produced singly-charged ions, enabling direct comparison of results.

Mass spectra were recorded in the negative ion mode (Fig. 1) and in the positive ion mode (Fig. 2) using each ionization technique; a dephosphorylation step was performed prior to positive ion analyses. Results confirm a clear signal-to-noise advantage for ESMS relative to PDMS in both modes. The resolution advantage at higher masses expected of the quadrupole analyzer (ESMS) over the time-of-flight analyzer (PDMS) was also evident. In addition, the ability to promote or minimize collisionally-activated dissociations (CADs) prior to mass analysis in ESMS proved to be quite useful in clearly identifying structurally-informative fragment ions. Ions appearing at low mass (e.g., m/z 1018, 1036) in the negative ion ESMS spectrum of lipid A from *E. agglomerans* (Fig. 1b) originate from CAD processes. These ions are absent from the negative ion PDMS spectrum (Fig. 1a) of the same sample.

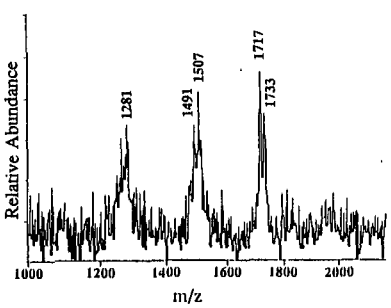

Figure 1a. PDMS negative ion mass spectrum of lipid A from *Enterobacter agglomerans*.

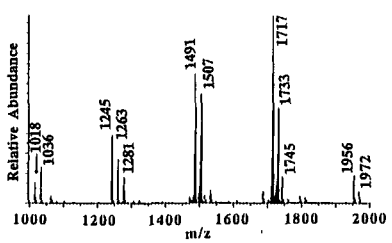

Figure 1b. ESMS negative ion mass spectrum of lipid A from *Enterobacter agglomerans*.

In the positive ion mode, after addition of small amounts of NaCl, all peaks observed in the ESMS spectrum of dephosphorylated lipid A's from *E. agglomerans* (Fig. 2b) could be attributed to sodium-containing ions. All peaks in Fig. 2a have also been assigned to sodium-containing ions except for the peaks appearing at m/z 1008 and 1024. These latter two peaks, which represent oxonium ions (Fig. 3a) characteristic of the distal subunit of lipid A, were found only in the PDMS spectrum. However, sodium-containing hydroxylated analogs of these distal fragments (Fig. 3b) were observed in the ESMS spectrum (i.e., at m/z 1048 and 1064, Fig. 2b).

OPTIMIZED LENS CONFIGURATION STUDIES FOR A TWO STAGE ELECTROSPRAY IONIZATION MASS SPECTROMETER INTERFACE

*Erol E. Gulcicek and Craig M. Whitehouse
Analytica of Branford, Inc. Branford, CT 06405

An extensive lens design study was conducted to improve the performance of a double pumping stage Analytica of Branford Electrospray Ion Source (ESI) interfaced to a 2000 mass range Hewlett Packard quadrupole mass spectrometer. Over a five to ten fold increase in sensitivity from earlier designs was achieved by improving the lens configurations both in the high vacuum ESI MS interface region (stage 3) and in the lower vacuum regions (stages 1 and 2) of the ESI source (Figure 1).

Following systematic approaches were taken to come up with a lens configuration that is optimized for sensitivity, resolution and mass discrimination:

1. Use of the charge particle ray tracing software SIMION (1) to model optimum lens designs in the high vacuum interface stage of the ESI MS, and to experimentally verify or modify the lens stack designs.
2. Optimization of the lens designs empirically in the first two pumping stages of the ESI source where SIMION modeling is not valid.
3. Testing for optimum pressure conditions both in the first and second pumping stages of the ESI source by varying the pumping conditions.

All experiments were done under very similar conditions to compare the performance of the instrument from one set-up to the next. Vacuum in stages one and two was maintained using rotary pumps and stage three was evacuated using a diffusion pump. For the most part of the study, the test molecule was 0.01 μg/μl (9 pm/μl) Gramicidin S (MW 1141.5 amu) in 1:1 Methanol/Water, injected continuously at 1μl/min flow rates. Lower and higher molecular weight compounds (Arginine, Cytochrome C, and Bovine Albumine with MW 174, 12,361 and 66,267 amu, respectively) were also tested for promising lens geometries to confirm the overall lens response as a function of molecular mass.

SIMION was first used to give a preliminary reference on the trajectories of ions for the initial lens configuration; it was then used to improve lens configurations to be tested experimentally. To a first approximation the predictions by SIMION on the original lens configuration as well as on others tested were relatively good and useful. However, predictions were limited by the energy differences of the different molecular ions and by the pressure conditions beyond the conical tip of the second skimmer in high vacuum.

Over 30 different lens configurations were tried experimentally. Figure 2b shows the final lens configuration that gave the best sensitivity and versatility over the original lens configuration shown in Figure 2a. The lens optimization studies in the first and second pumping stages of the ESI source was the most fruitful. The major improvement came when an extra conical lens was put in between two skimmers on Figure 2a. The increase in sensitivity was a factor of 3 to 4. In addition, It was found that replacing the S2 from a 60° to a 90° skimmer did not change the signal much but, instead, reduced the pressure in the 3rd stage appreciably. Further sensitivity improvements were achieved on this lens configuration alone by optimizing the capillary exit lens (EL) to Skimmer (S1) distance and the S1 diameters. When all the parameters were optimized, increase in signal sensitivity of up to a factor of ten from an earlier source has been observed (2).

Figure 4 shows an ESI mass spectrum of 5 fmole/μl Bovine Albumin in 1:1 Methanol/Water and 2% acetic acid. The spectrum is an average of 20 scans 15 seconds each. The flow rate was 5μl/min; total amount of sample consumed for the experiment was 7.5 pmole.

The Coupling of a Versatile Electrospray Source to an External Source Fourier Transform Mass Spectrometer

*Eric Gard, Dale Willard, and Carlito B. Lebrilla
Department of Chemistry, University of California, Davis CA 95616

The design of an electrospray source specifically for the external source fourier transform mass spectrometer is described.(1) The electrospray process involves spraying the analyte from a needle, in the presence of a large potential field, toward a plate containing a small aperture. Upon passing through the aperture the analyte undergoes a free jet expansion into vacuum.(2) The mach disk of the jet is sampled by the skimmer, which transmits the ions through the fringing field of the magnet into the homogeneous region of a three tesla superconducting magnet, which contains the analyzer cell. The instrument is shown below in figure I.

In our design several ideas have been incorporated to couple an electrospray source with an external source FTMS. Since the external source FTMS instrument built in our laboratory already has electron impact and FAB ionization sources, the new source must be replaceable as conveniently as the other sources. The design of the electrospray source allows us to vary the distance between the aperture and the skimmer as well as rapidly change the size of the aperture. It contains a set of einzel lens directly after the skimmer to help collimate the ions, two emmersion lenses which serve to control the kinetic energy of the incoming ions, and a second einzel lense which focuses the ions just prior the injection into the quadrupole ion guide. An expanded view of the source schematic is shown in figure II below.

Pumping is a critical feature of this design because the Ion Cyclotron Resonance(ICR) detection method requires high vacuum conditions . We have addressed this problem by using a roots blower specifically for the electrospray source. This pump in conjunction with the a turbo molecular pump and three cryogenic pumps already in place allows us to proceed from atmosphere (760 torr) to as low as 10^{-8} - 10^{-7} torr between the source and the analyzer cell.

With sample in place (10^{-4} M gramicidin S in methanol/water - 60:40), the present design produces an ion current of **0.25 nA** on the analyzer cell while maintaining an ultimate pressure of 1.5×10^{-7} torr. Initial attempts has not yet produced FTMS signals. The ion currents measured, however, indicate that they are more than sufficient for detection. In addition, the conditions necessary to produce this ion current still produces a very useable pressure in the analyzer cell region. One possible problem with the experiment is the formation of clusters during the free jet expansion. These clusters having sufficient velocities to produce large kinetic energies. A repeller voltage has been placed on the trapping plates of the analyzer cell to determine the kinetic energy of the formed ions. Nearly 100 V is necessary to stop the ions.

Future modifications to the design will include the addition of heated N_2 gas as well as a desolvating capillary to minimize the formation of these large cluster ions.

MAGNETIC FIELD FOCUSSING INTERFACE FOR ENHANCEMENT OF SENSITIVITY IN ELECTROSPRAY IONIZATION MASS SPECTROMETRY

C. J. Harper, V. L. Campbell, D. A. Laude, Jr., Department of Chemistry and Biochemistry, The University of Texas at Austin, Austin, TX, 78712

Electrospray ionization (ESI)/mass spectrometry has enjoyed increasing popularity for high mass analysis of proteins and oligonucleotides that is the consequence of an ionization mechanism which generates multiply charged ions. One important problem with ESI that has impeded its development is that although it is extremely efficient in generating ions, the transfer of ions to the mass analyzer is very inefficient because the ions leave the source with large solid angle and kinetic energy distribution due to charge repulsion. If the ions could be better focussed as a more concentrated, directed ion beam, then ion currents delivered to the analyzer would increase substantially with concurrent increase in sensitivity. To be evaluated here is the possibility that magnetic fields may be used as an alternative or a complement to electrostatic focussing. We have observed that the strong magnetic fields effectively level radial trajectories of electrospray ions to small cyclotron orbits, independent of initial spatial and kinetic energy distributions. The overall ion motion is effectively directed parallel to the magnetic field lines in a more concentrated ion beam. An order of magnitude increase in ion current compared to conventional ion optical assemblies is observed with hundreds of picoamperes delivered to the analyzer. The increase in ion current is expected to improve mass spectral sensitivity by an equivalent amount. Faraday cup measurements were conducted to optimize the interface. Specifically, the importance of magnetic field focussing at the capillary and skimmer exits was determined.

Experimental. The basic experiment to be performed is to measure the magnitude of an electrospray current and its dispersion for a variety of interfaces. The basic electrospray interface consists of a 0.1 mm i.d. blunt-ended electrospray syringe needle positioned 6 mm from a 0.5 mm i.d. x 20 cm desolvating capillary. A Delrin guide assembly is used to center and support the syringe needle and desolvating capillary adjacent to the skimmer. The capillary protrudes several cm from the plug to a distance between 1 and 5 mm from the skimmer. Optimized conditions for efficient formation and trapping of electrospray ions include application of a 3.7 kV electrospray voltage at the syringe needle, a 330V potential at the desolvating capillary which is maintained at 150°C, and between 15V and 0V at the skimmer.

Current can be measured at several points along the ESI interface in the presence of various magnetic fields. Of particular interest is whether magnetic focussing occur s at torr pressures between the capillary and skimmer, or after the skimmer at 10^{-5} torr pressures. The ESI interface is probe mounted and can be inserted into one of two magnet configurations. One set of studies was performed with a solenoidal 3.0T superconducting magnet. A second type of magnet assembly, shown in Figure 1, was also evaluated. This magnet interface is designed to surround the desolvating capillary and skimmer cone. Magnets used are six 0.8 Tesla rare earth cobalt ring magnets (0.75in OD, 0.43in ID x 0.25in width). This particular magnetic field focussing assembly is

Magnet Field Focussing Electrospray Source

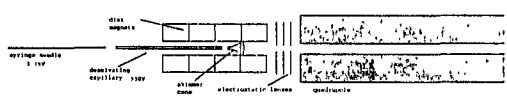

FIGURE 1

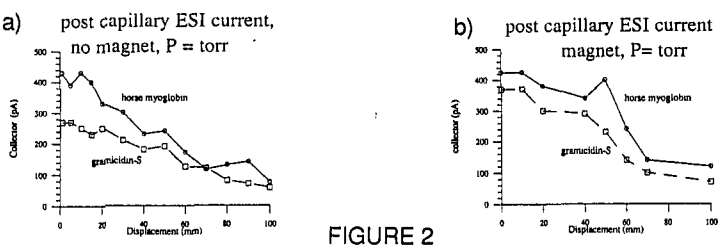

FIGURE 2

advantageous for general purpose ESI because of its small size and cost.

Post-Capillary Spray Collimation. The first region of the ESI interface to be evaluated for magnetic focussing effects is the region between the capillary and the skimmer. One likely problem is the torr pressures in this region as the large number of collisions might tend to offset the effects of magnetic focussing. Another problem specific to magnetic focussing at high pressures is that ions tend to diffuse radially in an ExB drift motion. Even on the time scale of ion transport to the skimmer, the drift may be pronounced. Shown in Figure 2 are current profiles generated as a function of collector displacement from an electrospray source positioned in the bore of the superconducting magnet. The experiment is performed at torr pressures with the skimmer removed. The experiment was also performed in the absence of a magnetic field for comparison. The zero-field profiles for gramicidin-S and myoglobin are shown in Figure 2a. A gradual erosion of the current due to divergence of the spray is observed, with most of the current lost after about 10 cm. Shown in Figure 2b are the analogous current profiles generated in the magnetic field. Although a modest retention of ion current is observed as a function of displacement, the magnitude of initial currents is similar. Given that the skimmer is typically placed within a few mm of the capillary, little benefit is realized from the magnetic field. Shown in Figure 3 is the collimation effect observed with the magnetic disk interface shown in Figure 1. The horse myoglobin current hitting the disks is measured as the spray is displaced into the bore. Aluminum disks are used as a control. The reduced current measured on the magnet disks compared to the aluminum disks is a clear indication that some collimation of the beam does occur which should translate into increased ion current through the skimmer.

Post-Skimmer Spray Collimation. The effect of magnetic fields on the ESI spray after exiting the skimmer was next evaluated. Pressures after the skimmer are typically in the range of 10^{-5} torr and consequently the deleterious effects from collisions are significantly reduced. Comparison current profiles for three different magnetic field environments are shown in Figure 4. In the absence of a magnetic field, a 50 pA current was measured. The current diverged slowly and was measured even out to 30 cm. This is likely because of the skimmer. The profile generated in the fringing field showed a doubling in ion current but dispersion was more rapid because of the diverging magnetic field lines. The most significant profile is for the spray positioned in the bore of a 3.0 T magnet. A major enhancement in both ion current magnitude and collimation of electrospray ions is obtained. Sensitivity improvements are about an order of magnitude and the ion current is retained over the homogeneous region of the magnetic field. Divergence of the beam after 30 cm is due to the divergence of field lines at the edge of the magnet.

High Performance Liquid Chromatography Interface using am External Electrospray Ion Source on a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer

Clifford Watson, John Wronka, [1]Pablo Caravatti, and Frank Laukien
Bruker Instruments, Inc., Manning Park, Billerica, MA 018221 USA
[1]Spectrospin AG, CH-8117 Fallanden, Switzerland

The features of an ideal electrospray (ESI) mass spectrometer include an easy to use interface between the high pressure ESI source and the high vacuum mass analyzer, high mass resolution with high sensitivity and fast mass scanning, known multiple ion detector response for quantitative measurements, unambiguous determination of the charge state for measurement of exact mass and simple MS/MS spectra, exact mass measurements without deconvolution techniques, MS/MS measurements for structural information, and automated sample inlet system such as HPLC or CZE.

The motivation for coupling an electrospray ion source to an Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer equipped with an external ion source was to provide the ease of use of a quadrupole MS along with simultaneous high mass resolution and high sensitivity, stable mass calibration, and MS/MS capabilities offered by FT-ICR mass spectrometry. Additional benefits include the "counting" the charge state from the isotope distribution which in favorable cases can eliminate the need for tedious deconvolution algorithms and simplify interpretation of MS/MS spectra.

An ESI/FT-ICR instruments was constructed that not only incorporates the best features of common ESI-MS systems but offers features not available from common ESI-MS systems. A Bruker/Spectrospin APEX 4.7e external ion source FT-ICR system (4.7 tesla magnet, standard 170 cm^3 cylindrical cell, external ion source operated at ground potential, with two stages of differential pumping) was equipped with a commercially available quadrupole ESI unit. The ESI unit features a 2 stage pump design (500 l/min), 500 micron capillary, counter current N_2 drying gas, with the needle operated at ground potential. The only instrument modification was to remove the standard EI/CI source and install the ESI unit using an adaptor flange to mate to the existing APEX external ion source.

A Bruker LC41 HPLC system (standard analytical grade unit with ChromStar data system, multi piston pump for stable flow, 1 x 250 mm column (20 μl/min flow rate), 4.6 x 250 mm balance column, 5 μl sample injection loop for column, 20 μl injection loop for plug injections) was coupled with the ESI source using a splitter and a fused silica capillary as shown in Figure 1. This system was able to separate a mixture of amino acids, but some form of nebulization to control droplet formation is required for more complex gradient HPLC experiments.

To demonstrate the high resolution feature of this ESI/FT-ICR combination a high resolution mass spectrum of mellitin (from honey bee venom) is shown in Figure 2. The isotopic distribution of the +4 charge state of mellitin, $(M+4H)^{+4}$ was detected at a resolving power of 100,000 as measured at full width half maximum. Even though ionization occurs at one atmosphere, a pressure of 5 to 7 x 10^{-9} mbar can be achieved in the FT-ICR analyzer region. This high mass resolution was achieved because the time domain transient signals for the multiply charged ions were observed to last for over 2 seconds at these pressures.

Additionally MS/MS spectra of multiply charged ions were obtained. The fragmentation could be obtained by either varying the voltage difference between capillary and skimmer, or by using standard MS/MS analysis in the analyzer cell. Combined with the high mass resolution detection, identification of charge of fragment ion is greatly facilitated.

This work has shown that implementation of a high performance ESI FT-ICR is straight forward using commercially available equipment. The combined technique of ESI/FT-ICR offers high performance with the ease of use of a quadrupole ESI MS, and provides high mass resolution and MS^n capabilities of FT-ICR mass spectrometry. The HPLC/ESI/FT-ICR interface displays minimal band broadening, is highly reproducible, and should simplify automatic sample handling. Additional work is planned to include a nebulization interface in the ESI source and continue development of HPLC and CZE applications to include on-line HPLC runs with "real time" MS/MS analysis.

Heating Discharge Needle Increases Electrospray Ion Currents

Xin Zhang and Alfread L. Yergey
NICHD, NIH
Bethesda, MD 20892

(1) Heating Discharge Needle

In bench top measurements similar to that reported previously(1), we observed ion formation from an electrospray discharge needle. As shown in Figure 1, the needle was a 1 cm length of 25 ga hypodermic tubing onto which a conical tip (20° included angle) was machined. The opposite end was fastened into a 2 cm length of 22 ga hypodermic tubing using superglue. A heating cartridge was mounted onto the discharge needle, which was made from a piece of ceramic tubing wrapped with a length of nichrome resistance wire covered with a fiberglass tube.

Using 1:1 MeOH/10^{-4}M aqueous NaCl as solvent at flow rate of 2, 5 and 10 µL/min delivered by a syringe pump, we observed ion currents on a collector plate, spaced 1.6 cm from the spray needle. The observed currents were of the order of 10^{-6} amps. At flow rate of 5 and 10 µL/min, the observed currents were unstable and consisted of a stream of droplets emitted from the Taylor cone at the needle tip. We stabilized the current emitted at the higher flow rate by heating the needle. The current to the collector increased 1.5 to 2-fold as liquid temperature at the needle tip were increased from ambient to about 60°C. During heating, the stream of broken droplets acquired a diffuse conical shape, the fringes of which diminished as temperature was increased. Above about 60°C, the current reached a plateau and liquid was not seen at the needle tip. Little effect of heating was seen at the 2µL/min flow. (Figure 2)

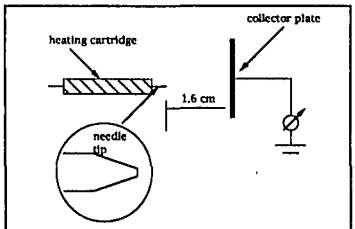

Figure 1. Bench top measurements of ion formation from an electrospray discharge needle with discharge needle heating capability

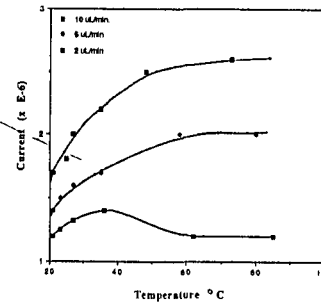

Figure 2. Currents collected with heated discharge needle.

(2) Electrospray Ionization Mass Spectrometry

An electrospray ionization source coupled with a quadruple mass analyzer similar to that previously reported(2), designed and fabricated in our laboratory, is shown in Figure 3. The electrospray of sample solution was generated from the discharge needle. The ions in the spray were transported into the vacuum system through a 30-cm-long, 0.5-mm-i.d. stainless steel capillary, and desolvated by heating the transport capillary up to 120° C. The desolvated ions were sampled through a 90° included angle skimmer with 1.3 mm in diameter, placed at a distance of 3.3 mm (diameter of capillary/capillary-skimmer distance = 1/6.6). The ions were further focused before entering a quadrupole analyzer. Estimated gas flow from the atmospheric pressure source to the vacuum system was 1.6 x 10^3 cc.atm/min. The pressures in the analyzer and at capillary exit were 1x10^{-5} torr and 1.6 torr, respectively.

We tested the electrospray ionization mass spectrometer using 1.6 x 10^{-5} M bovine insulin in MeOH:water:acetic acid = 48:48:4 solution at a flow rate of 1.2 µL/min. The spectrum shown in Figure 4 was obtained for a single scan of 20 seconds, with 6.6 pmole bovine insulin sample actually consumed by the machine.

The performance of the electrospray ionization MS and the consequences of the heating discharge needle for desolvating ions and control of fragmentation remain to be explored and evaluated.

Pyridinium Aldoxime Degradation in an Electrospray Interface as a Function of Skimmer Voltage

E.M. Jakubowski
U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, Edgewood, MD 21010-5425.

INTRODUCTION

Electrospray ionization (ESI) has produced phenomenal results in the picomole analysis of large non-volatile molecules such as proteins and other biological polymers [1,2,3]. Various ESI sources have been designed using different auxiliary means of desolvating the analyte ions. Allen and Vestal designed an ESI interface that employed heat as a means of desolvation [2]. Increased degradation due to the heated source was not experienced with the compounds studied. This design also used a two-stage momentum separator to evacuate the solvent molecules. The separator has three sampling cones that limit and control the movement of molecules and ions into the mass spectrometer. The cone closest to the needle was called the nozzle, followed by the skimmer, and finally the collimator. The collimator determined the ion energy and controlled entry into the quadrapoles. Potential differences between adjacent cones were regulated independently. Studying proteins, Allen and Vestal determined that the potential difference between the skimmer and the collimator could be used to both focus the molecular beam and increase analyte fragmentation. In this interface the pressure in the skimmer-collimator region was between 0.14 to 0.20 Torr which was in the range were significant collisional activation can occur. Maximum signal was seen with skimmer potentials in the range of 15-25 V. Fragmentation was observed above 25 V which was ascribed to collisional activation. Above 30 V a decrease in ion abundance was noted which was attributed to beam defocusing. Other ESI designs have also demonstrated collisionlly induced dissociations (CIDs) but in the nozzle-skimmer region. CID occurred between the nozzle and skimmer because of the use of a single stage separator and were dependent on nozzle to skimmer potential [3].

Certain classes of small molecules (molecular weight < 1000 Da) such as quaternary amines have lacked the necessary volatility to allow gas-phase analysis. LC/MS techniques such as thermospray ionization and particle beam have found some utility in the analysis of very polar compounds. However, there have been some drawbacks to these methods. Sensitivity was in the low ng/mL range for both techniques but may vary greatly dependent on molecular structure especially with thermospray. A group of low molecular weight quaternary amines important in the study of acetylcholinesterase reactivation has been the pyridinium oximes. Both mono- and diquaternary pyridinium oximes have been used with success as reactivators after irreversible cholinesterase inhibition. Thermospray degradation reactions of 2-pralidoxime (2-hydroxyiminomethyl-1-methylpyridinium chloride, 2-PAM) and HI-6 ([4-carbamoyl-2'-hydroxyiminomethyl-1,1'-oxydimethylene-di(pyridinium chloride)]) have been studied in depth and were found to closely resemble established solution degradation reactions for these compounds [4,5]. In general, the pyridinium oximes were thermally labile in the range of temperatures found in the thermospray interface. Analysis of these compounds under ESI conditions has not been previously reported.

This study has reported on the skimmer-potential dependent fragmentation of small thermally labile molecules under ESI conditions of the Vestec interface. Fragmentation between the skimmer and collimator has not been extensively demonstrated for low molecular weight molecules in the Vestec ESI or any other design of ESI interface. A better understanding and control of fragmentation under ESI conditions can be important in the search for structural information. Three monopyridinium oximes were chosen along with three dipyridinium oximes to serve a probes of the ESI interface.

EXPERIMENTAL

A Vestec Corp. (Houston, TX) model 201 single quadrapole mass spectrometer fitted with a 10-kV conversion dynode and a 2000 amu mass range installed with the appropriate interface was used for both electrospray and thermospray

experiments. Vector I (Technivent Corp, St.Louis, MO) software was used for basic instrument control and data acquisition. Direct infusion of sample was performed by a SAGE syringe pump (Orion Research,). Typical electrospray conditions were as follows: chamber temperature=65° C; needle potential=2.75 kV; nozzle potential=175 V; block=250° C; and skimmer potential from 0-50 V. The mobile-phase was 1:1 methanol/water.

The following reagent grade pyridinium oximes were used 2-PAM, ICD301 (1-methyl-2-hydroxyiminomethyl-3-[methylene 3'-butyne ether] imidazolium chloride), ICD467 (1-methyl-2-hydroxyiminomethyl-3-[methylene 2'-nitro-1',2'-dimethylpropane ether] imidazolium chloride), HI-6, TMB-4 (bis[1,1'-trimethylene]-4-hydroxyiminomethyl-1-methylpyridinium dichloride), and MMB-4 (bis[1,1'-methylene]-4-hydroxyiminomethyl-1-methylpyridinium dibromide). The final concentration in mobile phase was 100 ng/uL for each analyte.

RESULTS AND DISCUSSION

The stability of 2-PAM and related aldoximes has been extensively studied for the past 30 years. Degradation as a function of matrix, pH, temperature, and concentration has been described in detail for aldoximes and for 2-PAM in particular [4,5]. The reported degradation products from solution studies were comparable to the ions seen in the thermospray spectrum of 2-PAM. For example, the prominent m/z 110 ion was demonstrated to be the 2-hydroxy-1-methyl pyridinium ion reported [4]. However, at high probe temperatures exceptions existed to the simple breakdown scheme such as the m/z 123 ion which didn't correspond to any of the solution-phase breakdown products. The m/z 123 ion probably represented demethylation of the pyridinium nitrogen followed by protonation. HI-6 solution degradation also resembled its thermospray spectra with the same exceptions noted. Doubly charged ions were occasionally seen when analyzing HI-6 by thermospray but not in great abundance. However, by ESI the same dipyridinium compounds mainly formed doubly charged molecular ions at optimum skimmer potentials. The dipyridinium oximes were less stable than monopyridinium oximes under thermospray conditions (and in non-thermospray studies) most likely due to electrostatic repulsion of the permanent charges. Overall, degradation of the pyridinium aldoximes under thermospray conditions were temperature and matrix dependent. Thermospray produced more fragmentation than ESI when both were operated under optimum conditions. Also, the ESI spectrum of 2-PAM was missing the m/z 110 ion which was very prominent in the thermospray data. The absence of the m/z 110 ion from the ESI data indicated a significant difference from thermospay in the mechanism of fragmentation. Fragmentation in the ESI environment occurred in the gas-phase of the skimmer region at low pressures. In thermospray, the pyridinium aldoximes were in close association with water from the mobile-phase which allowed the bimolecular substitution reaction to occur. At optimum skimmer potentials, usually around 10-15 V, the spectrum would consist of only the molecular ion. The dipyridinium oximes were very sensitive to skimmer potential. Maximum molecular ion abundance for these compounds was achieved at low potentials. As skimmer potentials increased the analyte degradation increased. The molecular ion abundance decreased and breakdown ion abundance increased without a decline in total ion current. This was important to note because changes in skimmer potential can cause defocusing of the electrospray beam. The increase in ion current that occurred initially going from 0-15 V represented ion focusing. As potentials reach 30 V a defocusing of the signal has been reported [2]. Defocusing was not a factor in the decline of molecular ion abundance for the pyridinium compounds.

ELECTROSPRAY IONIZATION AND ION TRANSPORT THROUGH HIGH-PRESSURE CAPILLARIES

Baiwei Lin and Jan Sunner
Department of Chemistry
Montana State University
Bozeman, MT 59717

INTRODUCTION

Electrospray ions can be transported with viscous flow through many kinds of capillaries. A parametric description and quantitative study of this process have been made.

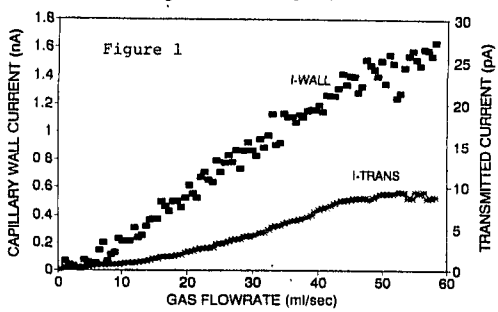
We have studied ion transport through stainless steel, glass, and teflon capillaries as a function of various experimental parameters, such as capillary length and diameter, distance from spray needle to capillary entrance, spray chamber temperature, gas flowrate through capillary, humidity, and capillary temperature. It was found that the most important parameter determining ion transmission is gas throughput. The results are explained with a simple diffusion model where ions diffuse to the capillary wall under laminar flow conditions. The capillary temperature also influences the transmitted ion current.

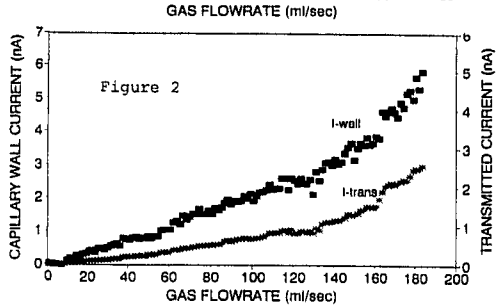
EXPERIMENTAL

Ion transport through capillary was studied with home built equipments. The input, wall, and transmitted ion current of capillaries were collected by KEITHLEY ammeters. Analytes for electrospray are NaOAc and NH_4OAc in the mixture of H_2O/methanol. The effect of nature, charge, and mass of ions has been investigated in a home designed ion transport interface to a quadruple MS (VG-TRIOII). The temperature effect in the transport capillary has been tested by this equipment.

RESULTS AND DISCUSSIONS

Fig. 1 shows the wall and transmitted ion current as a function of gas flowrate through the 2.1 mm ID, 50 ft long metal capillary. The ion transport efficiency (I-transmitted/I-wall) is 0.6 %. Fig. 2 shows the wall and transmitted ion current through the 2 ft long capillary in the same process and the ion





transport efficiency was 35%. The higher ion transport in a short capillary is due to gas throughput. Corona discharged ions were also transferred through the 2 ft capillary. The transport efficiency was 8%, well below that of ESI process. Since the mass of discharged ions is smaller than that of electrospray ions, small ions diffuse to the wall faster and decrease transport efficiency.

Fig. 3 shows the transmitted ion current as a function of ion residence time. The ion transportation follows an ion diffusion model:

$$I\text{-trans} = I\text{-input} * EXP(-at)$$

where a is half life of ions and it relates to the ion diffusion constant. The determined diffusion coefficient is 0.09 cm^2/sec and it is in the conventional diffusion constant range. We expected that the ion lost during transportation is due to the ion diffusion to the wall. Fig. 4 calculates the transmitted ion current from a simple diffusion model in the same condition as experiment. The diffusion constant is also calculated from ion transport efficiency. The calculated diffusion constant is smaller than observed value because we ignored the parabolic flow in long capillaries. In parabolic flow, the high concentration is in the center of tube and so decrease the loss of ions to the wall.

CONCLUSIONS

Electrospray ions can be transported through very long capillaries and the most important effect for ion transport is gas throughput.

Ion lost during transportation is due to the ion diffusion to the wall under laminar flow conditions.

In long capillaries, the observed diffusion constant is larger than that of calculated. The reason is that the parabolic type of flow is dominated in long capillaries and its concentration profile prevents the ion loss to the capillary wall.

A Comparison of a Heated Capillary and a Single-Stage Orifice API Interface for the Determination of Selenium-Containing Anions.

Timothy Wachs* and Jack Henion,
Drug Testing and Toxicology, Cornell University,
925 Warren Drive, Ithaca, NY 14850.

Negative ion atmospheric pressure ionization can be used to detect and determine inorganic and low molecular weight organic anions. Separation by either ion chromatography or capillary electrophoresis can aid these analyses by removing interfering species and by adding important time (retention or migration) information. Unfortunately, low mass chemical noise from the solvent system can cause interferences particularly in highly aqueous systems often required for separation of inorganic ions or small polar molecules.

A comparison study between a single stage orifice type of interface (Sciex curtain gas interface) and a heated capillary nozzle-skimmer interface was carried out. The capillary interface was designed to replace the normal Sciex interface on an API-III triple quadrupole mass spectrometer in order to make direct comparisons between the two systems. The capillary is 0.016 inches inside diameter and is heated to 180-200°C. The skimmer is a standard Sciex skimmer drilled out to 0.023 inches in diameter. The interface is shown below in Figure 1. The standard orifice interface has only one region where the declustering energy can be controlled (between the orifice and the entrance to the mass spectrometer) while the heated capillary interface has both the region between the nozzle and skimmer and also the usual region between the skimmer and entrance to the mass spectrometer. By varying potentials between both of these regions, a finer control of declustering and CID can be obtained.

For this preliminary study, the normal collision gas inlet line was removed and a small (60 L/s) turbomolecular pump attached to the mass analyzer to remove ambient helium that is not pumped by the cryo pumping system.

Because ion chromatography is often done with 100% aqueous or very highly aqueous systems, comparisons were done for selenate anion in water and then in a high level of organic solvent (75% methanol) to determine the differences between the two systems. Since selenate anion can be fragmented by "up-front" CID, conditions were chosen that provided approximately equal abundance of the hydrogen selenate anion (the species seen in the negative ion mode) and its fragment the singly charged selenite anion.

The mass spectra shown in Figure 2 of a 2.3 ng/μL sodium selenate aqueous solution demonstrate the dramatic difference between the two interfaces. In both cases, attempts were made to maximize the ion current due to the analyte. For data not shown, when the same analyte is dissolved in 3:1 methanol:water, there is little difference in the response between the two interfaces and they both show a much better response than in pure water.

Ion chromatography with a Dionex AS4-SC 2 mm Ion Pac column followed by a micromembrane suppressor (Dionex AMMS-II) to remove interferences from the carbonate buffer in the 1:3 methanol:water eluent results in an SIM detection limit of approximately 1 ng Se (as selenate) with a S/N ratio of 5:1.

Other chemical systems were also studied to determine the advantages and disadvantages of the two interfaces. For the identification of an unknown, atmospheric pressure ionization usually only results in molecular weight information. MS/MS systems can provide "clean" mass spectra that can be used for identification. The "up-front" CID possible in the API interface can provide similar spectra to the true MS/MS spectra but without the initial mass analysis in true MS/MS, fragments and background peaks are difficult to distinguish. A study of negative Ion Spray spectra of Acid Red-88 shows a decreased low mass background for the heated capillary interface. By using the heated capillary interface and scanning with mass the potential between the capillary and the skimmer, a CID spectrum can be obtained that closely matches a published MS/MS spectrum (1). Although the same approach can be used with the orifice interface and the same ions are obtained there is still a predominate background, Figure 3. Comparisons were made with large molecules (Cytochrome-C). Only a small difference was observed with the orifice interface being more sensitive.

The heated capillary interface shows distinct advantages for highly aqueous systems, for "up-front" CID studies, and for small molecules. There is no distinct advantage that we have determined for large molecules except perhaps for the investigation of labile complexes. The interface is simple but does require additional pumping for the capillary skimmer region, and an additional high vacuum pump for systems that are pumped by a cryo system

ELECTROSPRAY IONIZATION-ION STORAGE-TIME-OF-FLIGHT-MASS SPECTROMETER

J.G. Boyle, E.E. Gulcicek, C. M. Whitehouse and J.B. Fenn*
Analytica of Branford, Inc., 29 Business Park Drive, Branford, CT 06405
*Dept. of Chemical Engineering, Yale University,, New Haven CT 06520

An Electrospray Ionization source has been coupled to a reflectron time-of-flight mass spectrometer. A previous attempt to integrate these two methods in an axial configuration demonstrated inferior performance due to initial ion energy spread and a consequent loss of mass resolving power (1). In comparison, orthogonally oriented ion source-TOF instruments have shown to be superior in performance, both in terms of resolution as well as effective duty cycle (2-4). By orienting the ion source perpendicular to the field free drift region , the longitudinal energy spread of the ion packet has been substantially reduced, allowing a mass resolving power of over 1000 to be achieved. A significant benefit of the ESI-TOF using orthogonal extraction may be the enhancment of duty cycles as compared to axially oriented pulsing schemes. Long segments of the ion beam can be simultaneously driven into the field free flight tube with a single pulse, the length of which is limited to the diameter of the focusing optics (25 mm). Hence, proper extraction of the supersonic ion beam into the field free drift region allows greater duty cycles and hence higher sensitivities than more standard beam modulation techniques. The instrument has been configured to allow the Electrospray source ion optics to be operated near ground potential, eliminating the possibility of corona discharge and simplifying the pulsing electronics.

Ions are produced externally at atmospheric pressure and injected through differentially pumped transport optics and into an extraction region which holds many of the slowly moving ions between successive pulses (Figure 1). The collimated ion beam, normally at an energy determined by the potential of Skimmer 2, is allowed to "fill" an extraction region between a pulsed lens and a high transmissivity metal mesh. After the extraction region is filled with ions, a time duration dependent upon the gap length and ion velocity, a potential is applied to a pulsing lens for approximately 1-2 μs in order to drive the ions sideways into the acceleration region and the flight tube. Ions were then longitudinally focused using the ion mirror and post-accelerated to -9. kV before detection. The repetition rate can be varied from several hundred to several thousand hertz.

A representative series of spectra using this normal extraction technique are shown in Figure 2, covering approximately four decades of sample consumption. Spectra were obtained using sample concentrations of either 0.01 or 0.1 mg of solute per 1.0 ml of solvent (1:1 methanol:water + 2% acetic acid) and a solvent flowrate of from 0.181- 0.454 μl min^{-1}. The spectrum required the accumulation of ion pulses from the detector for periods of from 30 s to 0.4 s, all at scan rates of 2000 records/s. The spectra exhibit the normal envelope of multiply charged species from the 10^+ ion (1237.1 m/z) through the 17^+ ion (728.1 m/z).

This technique has proven to be a feasible method for the rapid mass analysis of large molecules. Its potential as an on-line technique capable of providing molecular weight data from even the fastest LC or CZE separations (5) is quite promising, given the compatibility of ES with these methods and the scanning speed of the TOF mass analyzer.

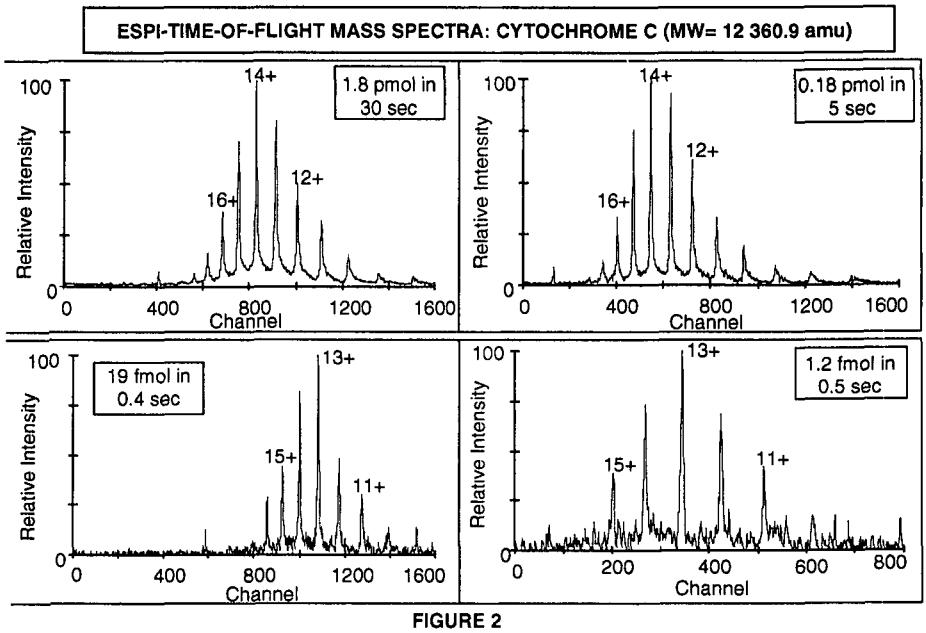

FIGURE 2

The Proper Setting of the Acceleration Voltage in Ionspray-MS Analysis

H. Moser, A. Groeppelin, M. Linder and K. Schellenberg
SANDOZ PHARMA Ltd., Analytical R&D, CH-4002 Basel, Switzerland

Introduction

The analysis of peptides and proteins has been a major reason for the strongly increasing demand for atmospheric pressure ionization mass spectrometers with an electrospray/ionspray interface. This type of ionization is very soft and therefore mostly molecular ions are formed and little or no fragmentation of the sample molecules occurs. For that reason mixtures of several compounds can be analyzed by flow injection. This technique is fast and reliable. It can also be used to check the purity of isolated compounds.

The acceleration voltage determines the velocity and the acceleration of ions in the nozzle/skimmer area of the ion source. The ions accelerated collide with neutrals and three reactions are possible:

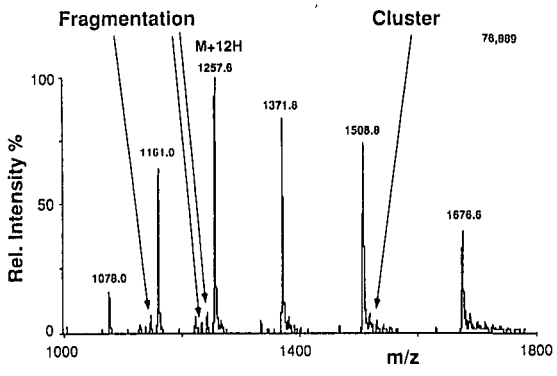
1. Declustering from solvent molecules or salts
2. Fragmentation
3. Loss of charges (protons)

Which one of the three possible types of reaction does happen depends on the setting of the acceleration voltage, the mass of the ions and the number of charges of the individual ions.

Impurity or Fragment Ion?

With the API III mass spectrometer (Sciex) flow injections of peptides and proteins can be done easily. However, interpretation of the mass spectrum is not always easy, especially when the purity of the sample has to be analyzed. Small amounts of the sample often form collisional induced fragments within the ion source. Sometimes clusters and fragment ions can be observed within the same mass spectrum.

Fig. 1: Mass spectrum of hu-interleukin-3, a protein with a molecular weight of 15,080 Da.



Data Analysis

The acceleration voltage cannot always be set in a way that no clusters and no fragmentation can be observed. Parameters like the nebulizing gas pressure and the curtain gas flow do have a minor influence on declustering and fragmentation. The three parameters with a major influence were found to be:

- ☞ Purity of sample (high purity = no cluster formation)
- ☞ Stability of sample
- ☞ Mass of sample (high mass = high acceleration voltage possible)

The best way to distinguish between an impurity present in the sample and a collisional induced fragmentation is to compare the intensity of the ions in question with the intensity of the ions of the main compound. If the ratio of both values remains constant at different charges, the compound is an impurity present in the sample. If the ratio changes with the number of charges the compound is a product of fragmentation.

Multiple injections at different acceleration voltages may be necessary to confirm and to ensure the result.

Conclusions

The proper setting of the acceleration voltage is a delicate balance between the desired declustering of the sample ions and the non-desired collisional induced fragmentation.

A low acceleration voltage is better because less problems with collisional induced fragmentation do arise. But setting of a low acceleration voltage does require a good purity of the sample, preferrably no salts at all being present in the sample.

The three most important factors that influence the setting of the acceleration voltage are the purity, the mass and the stability of the sample to be analyzed. Factors like the nebulizing gas pressure and the curtain gas flow did have a minor influence only.

ELECTROSPRAY MS/MS ON A TANDEM MAGNETIC SECTOR MASS SPECTROMETER FITTED WITH A FOCAL PLANE DETECTOR

Bateman, R.H., Bordoli, R.S., Cashmore, P., Major, H.J., and Woolfitt, A.R., VG Analytical, Manchester, M23 9LE, England.

INTRODUCTION

Electrospray has been shown to be a valuable ionisation technique for the analysis of biomolecules in the picomole and sub-picomole ranges. However, it mainly gives singly and multiply charged pseudo-molecular ions and consequently little structural information. The objective of this work is to investigate the feasibility and utility of MS/MS on a tandem magnetic sector instrument using Electrospray ionisation with a selection of known peptides.

EXPERIMENTAL

All data were acquired on an AutoSpec-T tandem magnetic sector mass spectrometer fitted with a 2048 channel photodiode array detector on MS-2 (Figure 1). LSIMS ion source and a two stage differentially pumped Electrospray ion source were alternatively fitted on MS-1. The Electrospray source was operated at 4kV, at which the mass range of MS-1 is 9000 daltons. The LSIMS source was operated at 4kV for doubly charged ion spectra and at 8kV for singly charged ion data. The gas collision cell fitted in the interface region between MS-1 and MS-2 was operated at ground potential and in the "floated" mode at half the source voltage. In each experiment gas was introduced such as to attenuate the precursor ion by between 65% and 70%.

RESULTS

Figure 1 shows the 8keV Helium CID B/E link scan daughter ion spectrum of the doubly charged pseudo-molecular ion $(M+2H)^{++}$ of Bradykinin (m/z 530.8) acquired on MS-1 using the Electrospray ion source. Predominantly singly charged product ions are observed.

Figure 2 shows the 4keV Argon CID MS/MS daughter ion spectrum of the singly charged ion $(M+H)^{+}$ and the doubly charged ion $(M+2H)^{++}$ of Bradykinin (MW 1059.6), both using the LSIMS ion source. The two spectra are quite similar, the main differences being the addition of the b_6 and loss of the d_5 sequence peaks in the spectrum from the doubly charged precursor ion.

Figure 3 shows the 4keV Argon CID MS/MS daughter ion spectrum of the singly charged ion $(M+H)^{+}$ using the LSIMS ion source, and the doubly charged ion $(M+2H)^{++}$ of ACTH (18-39) (MW 2464.2) using the Electrospray ion source. The two spectra are quite different, the latter possibly now exhibiting predominantly doubly charged products.

CONCLUSION

B/E linked scanning of daughter ions from the first field free region gas collision cell on a double focusing mass spectrometer provide useable data with good signal to noise, whilst MS/MS on a tandem magnetic sector instrument offers improved precursor ion selection with consequent simplification of the daughter ion spectrum. The high energy CID MS/MS spectra of doubly charged ions from LSIMS and Electrospray ion sources are very similar. However, the high energy CID MS/MS spectra of singly and doubly charged ions show small differences in sequence ions for Bradykinin, and large differences for Renin Substrate and human ACTH (18-39).

Performance Evaluation of Electrospray Ionization on a Sector and Quadrupole Mass Spectrometer for the Analysis of High Mass Proteins

J.-M Ding, R.J. Anderegg and D.B. Kassel, Glaxo Research Institute, Res. Triangle Park, NC 27709

Applications of mass spectrometry to biopolymer analysis have been facilitated by the advent of electrospray ionization (ESI). This ionization method has been successfully implemented on both quadrupole, and sector mass spectrometers. Our laboratory was recently equipped with electrospray ionization on both a Sciex API III quadrupole and JEOL SX102 sector mass spectrometer (Analytica of Branford). This research has aimed at evaluating the performance of the respective ESI interfaces for the characterization of biomolecules. Much of our work involves the characterization of both recombinant and novel proteins. Therefore, it was of particular interest to evaluate these ESI interfaces for the analysis of high molecular weight proteins (10 -100 kDa range) A number of proteins spanning this molecular weight range were analyzed, and representative data are presented for the serine proteases, chymotrypsin (Mr=26 kDa) and thrombin (Mr=36 kDa) and the globular proteins, BSA ((Mr=66 kDa) and ovotransferin ((Mr=77 kDa). Our goal has been to establish a set of conditions such that signal/noise, charge state envelope and peak shapes are optimized Instrumental parameters on the Sciex API III evaluated were orifice potential, nebulizer gas pressure and curtain gas flow rate. Instrumental parameters on the JEOL SX102 evaluated were needle/capillary distance, capillary/skimmer 1 potential difference, skimmer 1/skimmer 2 potential difference and counter current nitrogen flow

SCIEX EXPERIMENTAL CONDITIONS.

For the parameter optimization studies the needle position was maintained fixed relative to the orifice plate The orifice potential was varied between 60-120 eV, the co-axial, nebulizer gas (air) pressure was varied between 20-40 psi and the countercurrent curtain gas (N2) flow rate was varied from 0.6 - 1.2 L/min. Temperature of the curtain gas was maintained at 47 °C for all experiments Ion spray voltage was maintained at 4600 eV. A resolution of 1000 was used for all experiments

JEOL SX102 EXPERIMENTAL CONDITIONS:

The electrospray chamber (Analytica of Branford) was set to a needle current, Vn=5000 V; V1=2500 V; V2=2000 V; V3=400 V. Temperature and pressure of the counter-current N2 gas were 200 °C and 20 mm Hg, respectively. The optimum electrospray needle position distance to the capillary entrance was determined to be < 1 cm. The capillary / skimmer 1 distance was optimized for the transmission and stability of high molecular weight proteins and set to 5.2 mm.

RESULTS AND DISCUSSION:

ESI Mass spectra were acquired for chymotrypsin, thrombin, bovine serum albumin (BSA) and ovotransferrin, using both instuments. In general, quadrupole ESI spectra were characterized by both excellent signal-to-noise and narrow peak widths. Sector ESI mass spectra, on the other hand, were of lower signal-to-noise and, especially for the higher mass proteins (> 35 kDa), characterized by substantial peak broadening. Examples of ESI spectra generated for these "high" mass proteins using the two instruments are shown in Figures 1 and 2. The main difference between the two spectra for chymotrypsin and BSA was the broadening of peak widths observed in the sector ESI spectra and this peak broadening affected the signal-to-noise of the sector ESI spectra, especially for the characterization of high mass (> 30 kDa) proteins.

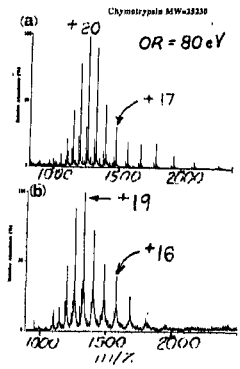

Figure 1 ESI mass spectrum for chymotrypsin using (a) quadrupole and (b) sector mass spectrometers

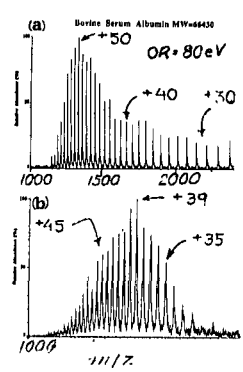

Figure 2. ESI mass spectrum for bovine serum albumin using (a) quadrupole and (b) sector mass spectrometers

The effect of increasing orifice potential (or voltage difference between capillary and skimmer 1) on the quality of ESI spectra of proteins was investigated. Shown in Figure 3a and 3b are the ESI spectra for ovotransferrin acquired using the quadrupole instrument at both low and high orifice potentials. Increasing the orifice potential from 110 eV and 130 eV shifted dramatically the charge state distribution for ovotransferrin. Figure 3b clearly demonstrates a trend towards a bi- (or multi-) modal charge state distribution. Shown in Figures 4 a-b are the ESI spectra for ovotransferrin obtained at different skimmer 1/skimmer 2 potentials. The effect of increasing the potential difference between these skimmer lenses is charge stripping, resulting in a shift of the envelope to lower charge state (and higher mass). Interestingly, we found that upon increasing the distance between these two elements to > 5mm that it was the potential difference between skimmer 1 and skimmer 2 that affected the spectra not the capillary/skimmer potential difference!

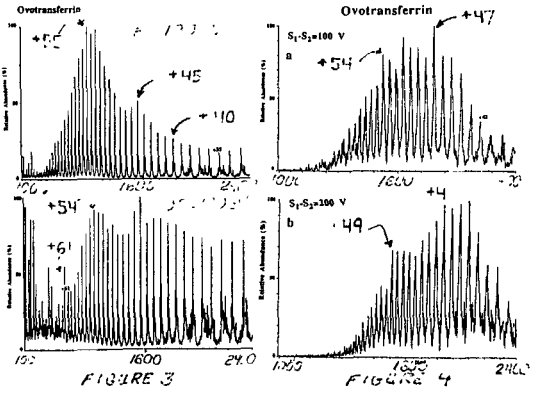

Figure 3 Quadrupole ESI mass spectrum of ovotransferrin using (a) orifice potential = 100 eV and (b) orifice potential = 120 eV

Figure 4 Sector ESI mass spectrum of ovotransferrin using (a) S1/S2 potential difference of 100V and (b) S1/S2 potential difference of 200 V

DISCUSSION.

The peak broadening observed in the sector spectra is assumed to be real (i.e. chemical) and not artifactual. This chemical broadening is believed to be the major factor contributing to the poorer signal-to-noise of the sector spectra for these higher molecular weight proteins because the total ion current is distributed between a greater number of charge-carrying species, such as protein molecular ion adducts, neutral loss products, and ion-molecule reaction products. We believe the major contribution to peak broadening lies in the high energy (relative to quadrupole ESI) and collision cross-section of these higher molecular weight proteins. At lower molecular weights (Mr < 30 kDa), peak widths obtained on the sector more closely parallel theoretical peak widths than those obtained on the Sciex and consequently the signal-to-noise of sector ESI spectra of these lower molecular weight proteins compares quite favorably with Sciex ESI spectra. It may be that there are dramatically different collision cross-sections for 20 kDa *vs.* 70 kDa proteins.

Experiments were performed varying the distance between the capillary and skimmer 1 to investigate the effect on peak broadening and signal/noise character of these proteins.. Whereas quadrupole instruments employing the Analytica of Branford design demonstrate maximum sensitivity at a 3mm distance between the capillary and skimmer 1, the sector gave best results when the distance was increased to greater than 5 mm. A change from 3 mm ---> 5 mm resulted in a pressure drop from 8 x 10-6 torr to 4 x 10-6 torr as measured by the ion source penning gauge. A 2-3 - fold improvement in signal/noise was observed upon increasing this distance.

An additional factor contributing to the peak broadening at high mass was the observation of MeOH and H_2O adducts. This observation led us to investigate the effect of changing the ES needle/capillary entrance distance. However, only the signal-to-noise was affected by varying this distance. The optimum distance between ES needle and capillary entrance was determined to be less than 1 cm.

Accuracy and Precision of Mass Assignments for Proteins Using Electrospray Mass Spectrometry on a Quadrupole and a Magnetic Sector Instrument

*Larry Shampine, Dan Kassel, and Robert J. Anderegg
Glaxo Research Labs, Research Triangle Park, NC 27709

Electrospray ionization mass spectrometry has become an extremely useful method of molecular mass determination for many types of biological molecules. For proteins, spectra contain a series of multiply-charged ions, each of which becomes an independent measure of molecular mass, once the charge state of the ions is determined. Most commercial instruments have software that reports the average mass value and a standard deviation based on these multiple mass measurements.

Our laboratory has electrospray capability on both a sector instrument (JEOL SX-102) and a quadrupole (Sciex API-III), and we undertook this study to determine the data collection conditions that would give us the most accurate mass assignments with the highest precision.

A number of variables were examined, including mass resolution, scan speed and range, the number of ions considered, and data smoothing. Mass resolution settings had little effect on the accuracy and precision of protein mass measurements. Because one is dealing entirely with multiply charged ions, and resolution of the individual isotope peaks is difficult (on the sector) or impossible (on the quad), one is always measuring chemical average masses. As long as sufficient mass resolution is available to separate the protein ions from adducts or interferants, good peak shape can be obtained and good precision and accuracy result. Too high a resolution drastically decreases sensitivity and produces no improvement in the data.

Data smoothing seemed to have little effect on precision and accuracy, although it influenced the sector data more than that from the quadrupole.

The most dramatic effects seemed to be related to scan speed and mass range. For every protein studied, better precision was obtained when only a portion of the mass range was scanned, encompassing a few (3 or 4) multiply charged ions. For example, when a recombinant protein was analyzed using the full mass range and all charge states, an average mass of 19,033.2 +/- 1.6 u was measured. When the same sample was analyzed scanning only a portion of the mass range including the four most abundant ions, the average mass was measured to be 19,032.0 +/- 0.1 u. (Calc. value = 19,031.8) The improvement was not simply related to mass calibration, since when the four most abundant ions in the full-scan data were analyzed separately, the measured molecular mass was 19,034.8 +/- 1.0 u. However, when error (difference between measured and calculated mass) was plotted against m/z, there did seem to be a systematic error, with masses above m/z 1000 being consistently underestimated. We believe this may be related to the reproducibility of the scan, with smaller mass ranges being more reproducibly scanned than larger ones.

Scan speed had a predictable effect on mass assignments. As the speed was increased, the precision and accuracy decreased. On the sector instrument, scan speed was dictated by the signal-to-noise ratio observed for the samples under study. Peak tailing and loss of sensitivity resulted from too fast a scan speed. On the quadrupole, signals were generally stronger, so S/N was less of a concern, but very fast scanning also caused poorer results. The precision deteriorates at

around 1 sec/scan for the full-scan data, and is rather random below 8 sec/scan for the partial scan data. Interestingly, the measured molec. mass tends to increase for both full and partial scan modes as the scan speed increases, overshooting the correct value by several daltons at very fast scans.

Data obtained using electrospray on the sector instrument suggest that the mass accuracy and precision are comparable to or better than those of the quad for proteins below $M_r < 25,000$. For larger proteins ($M_r > 25,000$), the ion envelopes of the multiply-charged ions become quite broad, making mass assignments difficult, and causing a consequent decrease in accuracy and precision. In terms of ease of use, at this time, the quadrupole is much closer to "routine". Only one calibration is needed for all scan ranges and speeds, whereas on the sector, a different calibration is prepared for each mass range and speed. [JEOL recommends the use of protein mass "correction factors" to circumvent the problem of repeated calibration (R. Cody, personal communication)]. Electrospray ionization on the sector is still undergoing development, and its ease of use will improve with time and practice.

In conclusion, on either instrument, the precision of partial scan data is equal to or better than that of full-scan data. The sector shows less dependence in this regard than the quad. For small proteins (< 25,000 da) the sector and quad display comparable results for both accuracy and precision. The average precision on the sector was 0.008 % for full scan and 0.003 % for partial scan data. For the quad, the numbers were 0.011 % and 0.004 %, respectively. The accuracy for both instruments in this mass range is < 2 da error from the calculated mass.

Finally, it should be mentioned that the accuracy portion of this study was hampered by the lack of well-defined standard proteins. Sequence errors as subtle as incorrect amide assignments can throw off the calculated mass by a few daltons, which becomes significant in these experiments. Protein purity and the presence of post-translational modification (particularly glycosylation) can also influence the mass assignment. Recombinant technology may offer the best source of well characterized proteins for use as molecular weight standards.

Comparing the CID Spectra of Large Biomolecules By Electrospray Ionization Using a Quadrupole and Sector Mass Spectrometer,

D.B. Kassel and R.J. Anderegg, Glaxo Research Institute, Research Triangle Park, NC 27709

INTRODUCTION

In our laboratory a combination of techniques are used to sequence peptides and proteins of unknown structure and to confirm sequences for peptides derived synthetically. We have used almost exclusively capillary column LC/Frit-FAB/MS for the sub-picomole sequencing of small peptides derived from protein tryptic digests (< 15 amino acids in length). Primary structure determinations for larger peptides, on the other hand, have required (a) gas phase Edman sequencing or (b) cleavage of the "large" peptide with an appropriate endoprotease and subsequent analysis by LC/Frit-FAB/MS. Although neither of these approaches are particularly labor intensive, they do require a fair amount of analysis time. Cycle times in gas phase sequencing range from 0.5-1.0h per amino acid. Capillary LC/MS runs can take from 10 min - 2h, depending on the complexity of the peptide mixture.

An alternative approach for sequencing larger molecular weight peptides (> 2500 Da) and proteins that has received a great deal of attention is ESI/MS/MS. Hunt and coworkers recently demonstrated the application of this technique to the primary structure determination of some small peptides bound to major histocompatability complex (MHC) class I and II molecules[1]. Smith and coworkers[2], have shown that proteins as large as BSA (66 kDa) can be fragmented to form a series of b_n and y_n ions and have concluded that this approach would be particularly useful in aiding the design of oligonucleotide probes needed for cDNA cloning. The goal of this study was to determine the utility of ESI/MS/MS for providing interpretable and useful CID spectra for large molecular weight peptides and to place in proper context this technique with the proven, reliable and sensitive techniques of Edman sequencing and capillary LC/MS methods already established in our laboratory.

EXPERIMENTAL:

We have electrospray interfaces for both a double focussing sector (JEOl SX102) and triple quadrupole (Sciex API III) mass spectrometer. Both instruments are equipped with collision cells which permit MS/MS (or CID) analyses. Consequently, it has been possible to compare directly the capabilities of the two instruments for providing quality CID spectra for a number of mid-molecular weight peptides and proteins. In specific, we have investigated and compared the efficiency of product ion formation and in a qualitative manner, the interpretability of CID spectra for amylin, a 37 aa protein containing one disulfide bond and the products of cyanogen bromide cleavage of FK 506 binding protein (FKBP), a 108 amino acid peptidyl-prolyl *cis-trans* isomerase. Optimization of the individual instruments for the transmission of product ions was achieved by (a) taking a product ion "survey" scan to establish the most prominent product ions, (b) optimizing CID (He) gas pressure on one of these product ions and (c) optimizing the orifice potential (Sciex) or capillary, skimmer 1 and skimmer 2 potentials (JEOL SX102 ES1) and focus elements CID spectra were recorded at a resolution of 300 for the quadrupole and 1000 for the sector

RESULTS AND DISCUSSION:

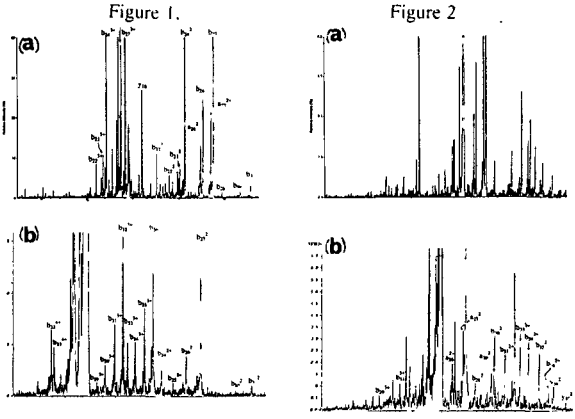
The charge state of the ion selected for MS/MS has a dramatic influence both on the quality and interpretability of CID product ion spectra Figures 1-2 show the CID spectra for amylin obtained from the quadrupole and sector mass spectrometers selecting the 3^+ and 4^+ charge state precursor ions for collisional dissociation Important observations about these spectra were: (1) For the Sciex, the efficiency of product ion formation decreased with decreasing charge state The MS/MS spectrum of the 2^+ ion showed almost no fragmentation (and for this reason the 2+ charge state is not shown). The sector, on the other hand, showed that at lower charge states it was possible to generate numerous product ions of reasonable intensity. (2) The information content also is affected by the precursor charge state selection. In general, the 5^+ precursor ion was found to fragment to a mixture of 4^+ and 3^+ b_n ions, the 4^+ precursor ion fragmented to 3^+ and 2^+ b_n ions, and the 3^+ precursor ion fragmented to almost exclusively 2^+ b_n ions For the Sciex it was the MS/MS spectra of the 3^+ precursor charge state to which amino acid sequences could be assigned most easily In the case of the sector, the 2+ ion gave rise to even a greater b_n ion series $[b_{22}^{2+} \text{--->} b_{17}^{2+}]$ (data not shown).

Figure 1.

ESI/MS/MS of 4^+ Precursor Ion of Amylin using (a) Sciex and (b) JEOL SX102 sector mass spectrometers

Figure 2.

ESI/MS/MS of 3^+ Precursor Ion of Amylin using (a) Sciex and (b) JEOL SX102 sector mass spectrometers



We were particularly interested in determining whether ESI/MS/MS could be used to provide structural information for large peptide fragments generated from chemical (*i e* ,CNBr) cleavage of proteins. As a model we investigated the ESI/MS/MS spectra of CNBr cleavage products of FKBP, a protein found in human T cells. Three of the four fragments gave molecular weights which matched prediction. MS/MS spectra were acquired for each of these three CNBr fragments. From neither the quadrupole nor sector ESI/MS/MS spectra was it possible to sequence more than 50 per cent of the total number of amino acids. MS/MS spectra contained predominantly b_n or y_n ion series and fragmentation was observed only at one end of the molecule (either C- or N-terminus). One CNBr fragment 1 was found to have a MW 75 Da greater than predicted (assuming homoserine lactone formation). It was necessary to treat the quadrupole and sector ESI/MS/MS spectra as unknowns and attempt to determine whether this fragment contained a modified residue or was a contaminant protein peptide fragment. It was possible to sequence a string of 7 amino acids using either of the ESI/MS/MS spectra. The sequence of FKBP was then searched and this 7-mer was indeed found to be associated with CNBr fragment 1. The quadrupole MS/MS spectrum was accompanied by a low mass b_n ion series and this ion series matched with prediction whereas the y_n^{2+} ion series was shifted by 38 Da, corresponding to the 75 Da mass difference between predicted and actual mass. The existence of a b_n ion series enabled the 75 Da discrepancy to be definitively assigned to the C-terminus of the molecule.

It was mentioned that ESI/MS/MS would be placed in proper context with the already established techniques in our laboratory for picomolar and sub-picomolar sequencing. Therefore, capillary LC/MS was evaluated as an alternative to ESI/MS/MS for providing sequence information for the entire FKBP protein. The mixture of CNBr fragments was incubated with trypsin and the resultant peptide mixture was analyzed using capillary LC/Frit-FAB/MS. Importantly, the solution had to be diluted 100x in order not to saturate the capillary column or mass spectrometer detector. Secondly, for greater than 90% of the fragments was it possible to generate complete sequence information!

CONCLUSIONS:

The quality of both the sector and quadrupole ESI/MS/MS spectra were comparable for large molecular weight peptides Product ion spectra were dominated by b_n and y_n type ions Spectra were influenced by the choice of precursor charge state. The sector gave better results with lower charge state precursor ions whereas the quadrupole appeared to yield better results with higher charge state . It was not possible to sequence more than 50% of the amino acids for any of the mid-molecular weight peptides studied It must be concluded that ESI/MS/MS spectra of mid-molecular weight proteins are not particularly informative, especially in light of the well established techniques of Edman Sequencing and capillary LC/Frit-FAB/MS For the analysis of peptides and proteins of unknown structure (and whose concentrations are in the picomole range) the best approach is to (a) characterize the larger peptides by Edman sequencing and/or enzymatically cleave the protein into manageable size fragments and characterize by capillary LC/MS.

INVESTIGATION OF ELECTROSPRAY MASS SPECTROMETRY ON A HIGH RESOLUTION HYBRID INSTRUMENT

Steven R. McGown, John R. Perkins and Kenneth B. Tomer

Laboratory of Molecular Biophysics, National Institute of Environmental Health Sciences, P. O. Box 12233 MD 601, Research Triangle Park, NC 27709

Electrospray Ionization, ESI, has recently become a widespread technique used for the analysis of high molecular weight species. ESI results in ions with multiple charges and this allows the effective mass range of the instrument to be extended beyond the original specifications. The multiply charged species data can be deconvoluted to yield molecular weights. ESI is a gentle ionization technique which can provide molecular weight information on compounds that are not amenable to other types of ionization techniques. While there is the absence of matrix interference found in FAB, there are interfering ion clusters that can become important in dealing with low molecular weight species. On instruments with MS/MS capabilities, daughter spectra can be collected and additional structural information can be determined. ESI sources, first widely used on quadrupoles, have recently become available for sector type instruments as well. We present here data obtained via ESI on a Kratos CONCEPT ISQ hybrid mass spectrometer.

The original factory probe has been modified to provide a coaxial flow system to allow the use of packed capillary LC columns. These columns typically have very low flow rates, 500 nl per minute, and ESI sources require flows of around 2 ul per minute to provide a stable spray. Consequently, a 'make-up' solution consisting of a 50/50 mix of water and methanol with 1% acetic acid was used for the sheath flow.

MASS SPECTRA OF TYR-C-PEPTIDE

CONCEPT ESI (1.7 ng consumed)

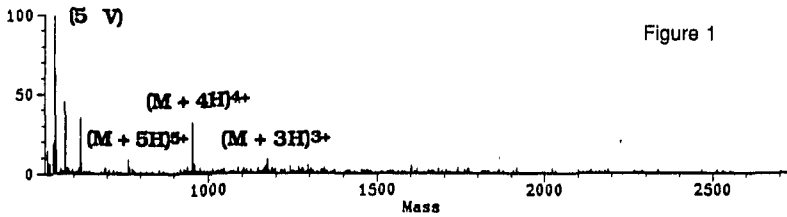


Figure 1

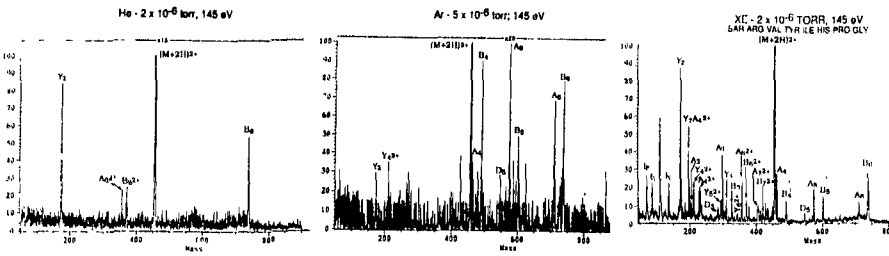
Figure 2

MS/MS SPECTRUM OF THE $(M+2H)^{2+}$ ION OF SAR[1],GLY[6] ANGIOTENSIN II



We Have previously compared the spectra of high molecular weight peptides (M_r ~3500) by coaxial CF-FAB and ESI on a quadrupole(1). Our initial experiments compared data obtained on the CONCEPT ISQ ESI with our previous data. We found the detection limits to be comparable. A spectrum of Tyr-C-Peptide is shown in figure 1.

We then examined instrument parameters affecting MS/MS acquisitions, including the effects of collision gas and collision energy. Upon examination of the data collected at a constant collision energy but, with different collision gases a progression in the fragmentation process was noted. Light collision gases, such as He, yield little fragmentation information while Ar is an improvement and Xe gives the best result (figure 2).

As the collision energy was increased with a given gas, the fragmentation process increases. This increase is less important for small molecules but, it is significant to note the appearance of d fragments (figure 3) at higher collision energies.

A comparison of the MS/MS data for the same compound, but different charge state, i.e. $(M+H)^+$ vs $(M+2H)^{+2}$, shows the fragmentation of the $(M+2H)^{+2}$ species to be superior in yielding fragments and thus, structural information (figure 4).

Electrospray Ionization with Array Detection

Robert B. Cody
JEOL USA
11 Dearborn Road
Peabody, MA 01960

Introduction. Electrospray ionization can provide relatively low detection limits of many compounds. The method produces relatively low ion currents from the analyte and a relatively low chemical background. Therefore the ultimate detection limits are related to the mass spectrometer transmission and the detector sensitivity.

Array detection can improve the performance for magnetic sector mass spectrometers whenever the detection limits are determined by low ion currents. Integration of the ion current combined with simultaneous detection over segments of the mass range should provide a benefit for electrospray ionization.

Experimental: Mass spectra were acquired by using a JMS-HX110 double-focusing magnetic sector mass spectrometer equipped with an electrospray ionization source. The mass spectrometer was operated with an accelerating voltage of 5 or 7 kilovolts with a conventional point detector and a two inch array detector with quadrupole double ion optics.

The array detector was operated at 12% dispersion and 12-13 segments were acquired in 30 seconds and joined to produce the mass spectrum covering a 700-2500 Da range. Samples were prepared by successive ten-fold dilutions in a solvent consisting of 1:1 water/methanol with 2% acetic acid.

Detection Limits: Hen egg-white lysozyme can be detected at concentrations down to 500 amol/ul. A high-quality mass spectrum can be readily obtained with a total sample consumption of 10 fmol.

An interpretable mass spectrum can be easily obtained for a 100 fmol/ul solution of bovine serum albumin (BSA). Smaller quantities produce a detectable ion current, but it becomes increasingly difficult to separate the charge states for the more dilute solutions.

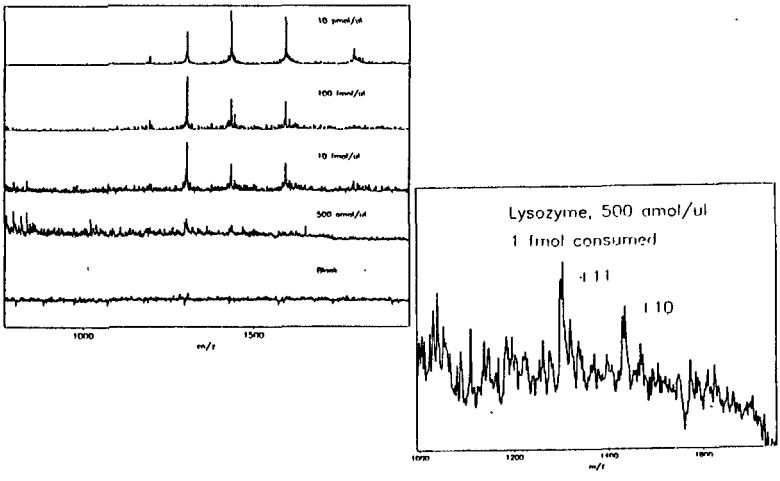
A 20 fmol/ul solution of ubiquitin was analyzed to see if an "unknown" solution can be measured after tune-up with a reference standard such as lysozyme. The ubiquitin solution produced a recognizable mass spectrum despite the presence of low-mass impurities from the sample containers.

Resolution: The array detector can be used to obtain mass spectra with a resolution of approximately 3,000. This resolution value is adequate to identify the number of charges for multiply charges from molecules having masses below ~3,000 Da. Singly and doubly charged ions were identified in the ESI mass spectrum of a mixture poly(propylene glycols) having average molecular weights 1,000 and 2,000. Superior resolution can be obtained with a point detector, although larger sample quantities are required.

Conclusions: Compared to point detection, array detection can provide the expected gain of a factor of ~100 for the analysis of very dilute solutions by electrospray ionization/magnetic sector mass spectrometry. Solutions having concentrations in the 500 attomole per microliter range can be detected, but the ultimate practical limits appear to be in the 10-100 fmol/ul range for relatively pure protein solutions. At these levels, trace contamination from solvents and sample containers can be a problem.

Applications requiring a resolution greater than 3,000 will require the use of a point detector. Dynamic range and data handling considerations suggest that a point detector may be preferred over an array detector for routine LC/MS applications.

Lysozyme· Array Detection



Electrospray ionization/Magnetic sector MS: Calibration, Resolution, and Accurate Mass Measurement

R. B. Cody, J. Tamura, B. D. Musselman
JEOL USA, Inc.
11 Dearborn Road
Peabody, MA 01960

Introduction: Magnetic sector mass spectrometers are commonly used to obtain high-resolution mass spectra and accurate mass measurements for elemental composition determinations. The resolution and mass accuracy of a magnetic sector mass spectrometer was evaluated for electrospray ionization of both large and small molecules. Poly(glycol)s (as positive ions) and poly(glycol) sulfates (as negative ions) were used as reference standards for both magnetic field scans and accelerating voltage scans.

Experimental: Mass spectra were obtained by using a JEOL JMS-SX102 reverse-geometry double-focusing mass spectrometer equipped with an electrospray ionization source (Analytica of Branford). Mass spectra were acquired in profile mode at an accelerating voltage of 5 kV and Hall-effect probe regulation of the magnet current. "Internal calibration" was accomplished by acquiring scans for the analyte, and then replacing the analyte with reference standard without halting the scan.

Small Molecules: Mass accuracies for small molecules were in the low part-per-million range (0.2 to 6.6 ppm at 5,000 resolution) for both magnetic field scans and accelerating voltage scans. These accuracies were sufficient to obtain elemental compositions for both positive- and negative-ion species.

Proteins: The masses were determined for the individual isotopes of the $[M+5H]^{5+}$ species from bovine insulin (avg. M.W. 5733.582). The r.m.s. error for all isotopes was 0.032 u or 5.6 ppm. If only the isotopes having greater than 5% relative abundance are considered, the error is ~2 ppm.

The theoretical average mass of hen egg-white lysozyme is 14305.163. The measured masses for the isotopes of hen egg-white lysozyme ($[M+9H]^{9+}$ species (external calibration, accelerating voltage scan, resolution 10,000) gave an r.m.s. error of 12 ppm (all isotopes). An isotope cluster attributed to water loss was observed at a mass 18.009 u below the lysozyme isotope cluster.

Low-resolution measurements: Low-resolution measurements of large proteins gave comparable mass accuracies (e.g. 2 to 12 ppm for lysozyme). However, low-resolution measurements may be subject to unresolved interferences (adducts and losses), natural isotopic variations and other isotopic interferences (e.g. reduction of disulfide bonds), and data processing considerations (centroid vs. peak top determination). Caution is indicated in assessing the value of accurate mass measurements for unknowns when low-resolution conditions are used.

Electrospray Ionization on a Magnetic Sector Instrument Applied to Samples with Low Molecular Weight

P. Dobberstein, E. Schröder, and H. Münster,
Finnigan MAT GmbH, Barkhausenstr. 2,
W-2800 Bremen, Germany

ESI spectra of polar biomolecules are observed normally in the m/z range 300 to 2000 Da because of the high charge state and therefore many ESI applications have been performed on quadrupole instruments. There is also a big demand for ESI on magnetic instruments, because of their higher resolving power and sensitivity. An ESI source for **MAT 95** and **MAT 900** high resolution instruments has been developed and first results have been reported recently 1, 2).

EXPERIMENTAL CONDITIONS

Although the big interest in ESI was triggered by its ability to analyze large biomolecules, many applications are in the lower mass range (below 1000 Da). In the experiments reported here the source was operated in the negative ion mode because many samples are cation donators.

The Samples have been dissolved in water/methanol 50/50 at a concentration of 40 pmol/µl or lower. In addition to the sample flow of 2 µl/min a sheath flow of isopropanol of 2 µl/min was added to the triple-layered needle assembly 3). A focusing gas flow of several ml/min nitrogen normally increases signal height and stability.

The azo dye **Acid Red 88** (MW 400.05) was used as a tuning and test sample in negative ion mode. A resolution of **R = 8000** at 5% peak height was easily obtained at the [M-Na] peak of this sample.

DETECTION LIMIT

The detection limit for Acid Red 88 at full scans with the **MAT 95** was determined by diluting the sample solution stepwise until the intensity of background ions reached about 1/3 of the most intense sample ions (left spectrum). With the **MAT 900** and the **PATRIC** array detector the spectrum on the right side was obtained. In both cases the sample amount given on the spectra was calculated from the concentration and the scan duration.

2) 12th IMSC, August 26 - 30, Amsterdam, FrM-B06, page 366
3) Hail, M. et al., 39th ASMS Conference, page 556

APPLICATIONS

Under the operating conditions found with the test sample Acid Red 88 two customer samples have been measured.

Sample 1 is another azo dye with the abbreviation **BPT**; it is a contaminant of dyes found in foodstuff and was received from Steve Musser of FDA. Because this sample is also a sodium salt, the same sample preparation as for Acid Red 88 could be applied.

Sample 2 is a Tetrasaccharide with the abbreviation **CSC-I** and was submitted by Hans Schweingruber of Glycomed. In this case the sensitivity is increased if 0.1% of ammonia is added to the sample solution.

Due to the appearance of multiply charged ions in case of these samples the sensitivity is lower than for Acid Red 88. The **detection limits** for full scans (calculated from the scan duration, spectra not shown) are for **BPT 250 fmol** (200 pg) at 6 pmol/µl and for CSC-I **1.2 pmol** (1 ng) at 8 pmol/µl.

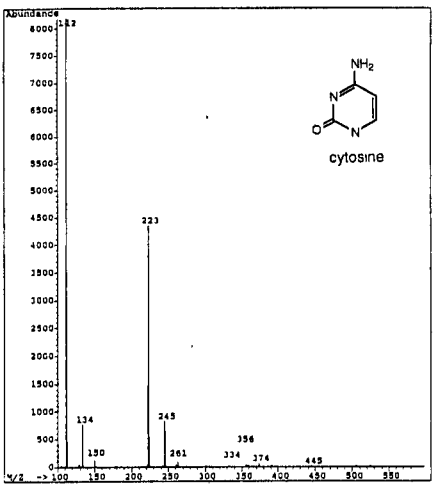
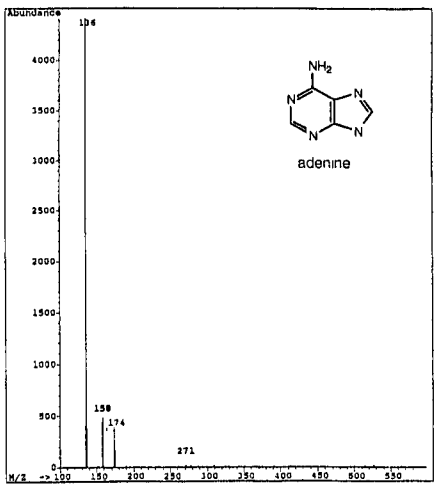
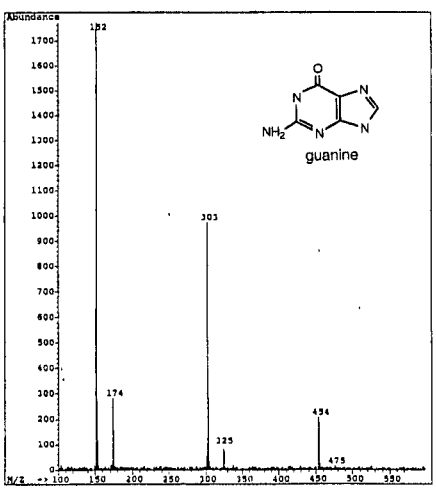
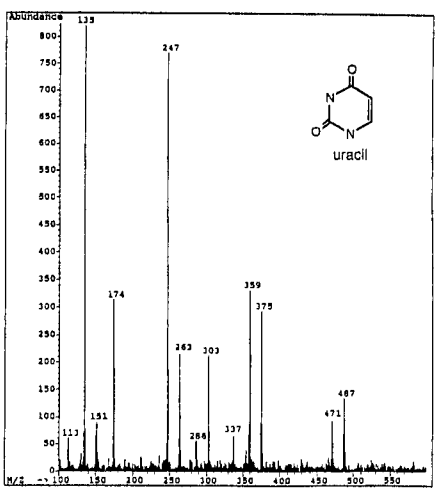
The common nucleic acid constituents (nucleobases, nucleosides and nucleotides) are ubiquitous in nature and represent an important and well-studied class of biochemically active compounds. Unfortunately, the low volatility and thermal lability of these purine and pyrimidine derivatives has historically hampered their analysis by mass spectrometry. For these reasons, we have investigated the use of electrospray mass spectrometry (ES/MS) for the analysis of these compounds.

Shown below are the spectra from the four common RNA nucleobases. The striking diffrences







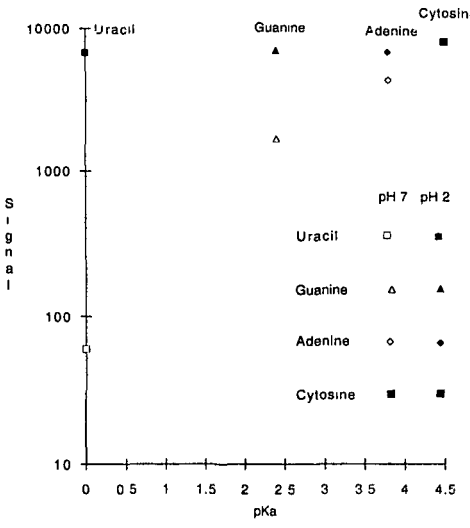


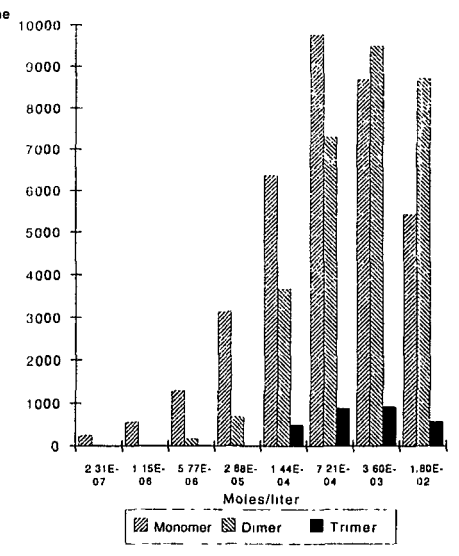
obtained for these seemingly similar compounds prompted an investigation of the chemical and physical properties of the individual species which might account for the observed variations. Focusing first on the differences in absolute abundance of the M + H^+ adducts, we decided to investigate the possible role of pKa. For the protonation of a species in solution, pKa is given by a rearrangement of the Henderson-Hasselbach equation shown below:

$$pKa = pH + \log\frac{[BH+]}{[B]}$$

where [B] is the concentration of the free base and [BH]+ is the concentration of the protonated base in solution. Recognizing that it is in fact a protonated species which desorbs from the droplet in electrospray to yield an ion, it seems reasonable to conjecture that species with higher pka's and thus higher concentrations of protonated bases in solution should yield higher signals in electrospray mass spectrometry. Furthermore, this relationship suggests that the reduced signal from species with lower pka's may be enhanced by lowering the pH of the solvent system used. This is in agreement with the observed experimental results shown below. Here, the intensity of the H+ adduct for each of the four nucleobases is plotted against its pKa, in solutions at pH = 7 and pH = 2. At pH = 7, the signal strength is clearly related to the species pKa. However, when the solution pH is lowered to a value of 2, the signal for the nucleobases with lower pka's increases to the maximum level of the signal from the nucleobase with the highest natural pKa.

Another solution parameter investigated was concentration. Shown below is a plot of the monomer, dimer and trimer species for cytosine vs. concentration spanning a five decade range. The formation of these cluster species seems prevalent among the nucleobases. Clearly, the signal from the monomer increases until a maximum is reached at 7.21 a 10^{-4} M. The dimer and trimer, however, reach a maximum signal at 3.6 x 10^{-3} M. Even though the absolute signal appears to decrease for all species at higher concentrations, the signal from the dimer and trimer continue to increase relative to the monomer throughout the concentration range studied. This behavior implies a solubility dependence as well. The limited solubility of these species may come into play as the concentration increases. The concentration of the solute in solution may be considerably higher at the time of ion desorption, so that a precipitation mechanism could be involved as well. Again, this suggests the important role of solution chemistry in electrospray mass spectrometry.





Environmental LC/MS Applications Utilizing A Benchtop Mass Spectrometer Equipped with Particle Beam

Matthew Dilts, Tom Marecic and Jennifer Duker
Millipore Extrel ™ Pittsburgh PA, 15238

INTRODUCTION

As the environmental industry continues to push for equipment suitable for field testing facilities, the need for smaller more rugged instrumentation is becoming increasingly important. To date most LC/MS instrumentation has been limited to floor standing research grade mass spectrometers. Early LC/MS inlets were designed as additions to research grade mass spectrometers previously in production. Initially, smaller benchtop mass spectrometers were unable to handle the solvent loading associated with LC/MS techniques due to constraints in pumping configurations on the mass spectrometer. Several benchtop mass spectrometers have been recently designed with LC inlet capabilities.

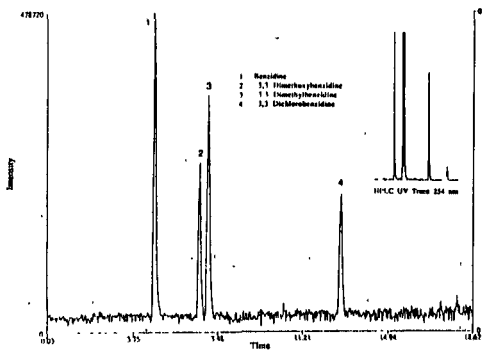
EXPERIMENTAL

This study evaluates the feasibility of utilizing a benchtop LC/MS for the analysis of benzidine compounds in water and wastewater. EPA method 553 was the guideline used for this application. The compounds evaluated were benzidine, 3,3' dimethoxybenzidine, 3,3' dimethylbenzidine, and 3,3' dichlorobenzidine.

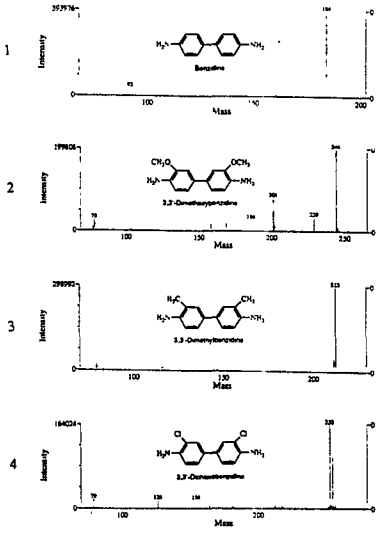
Liquid Chromatography
Waters 600 MS LC pump with a 490 MS detector
Phenomenex Hypersil C18, 4.6 x 125 mm, reverse phase column
0.1M ammonium acetate/ACN, 70/30 to 20/80 v/v, 30 min, linear gradient, 0.5 ml/min
ACN was added post column at 0.1 ml/min, for a total flow rate of 0.6 ml/min

Mass Spectroscopy
Extrel benchmark™ mass spectrometer
ThermaBeam™ particle beam interface

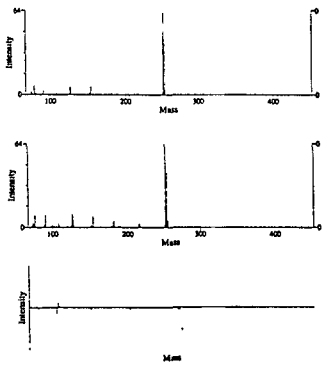
TOTAL ION CURRENT CHROMATOGRAM



EI MASS SPECTRA



3,3'-DICHLOROBENZIDINE REVERSE LIBRARY SEARCH



CONCLUSION

Benzidine compounds were analyzed using a benchtop LC/MS equipped with a ThermaBeam™ particle beam interface. The study was accomplished using standard Waters instrumentation as well as gradient separations, highly aqueous solvents and normal flow rates (0.4 - 1.0 ml/min). The results presented demonstrate the capability to generate EI mass spectra and EI library searchable spectra. Response factors and calibration curves for the compounds were also evaluated.

Infrared Thermal Desorption and Pyrolysis of Soil Contaminants for Mass Spectrometric Analysis

B. Wiezorek(1,2), A. Schiller(1), G. Baykut(1) and K. P. Wanczek(2)
(1)Bruker-Franzen Analytik GmbH, Fahrenheitstr. 4, D-28 Bremen 33,
(2)Inorganic and Physical Chemistry, University, D-28 Bremen 33,
Germany

For detection and analysis of soil contaminants of low volatility extraction methods are employed most commonly(1). These methods need much sample and are time consuming and not suited for rapid and on-site detection.
Thermal desorption and thermal pyrolysis (2) are much simpler and faster. Normally, desorption and pyrolysis products depend upon the kind of soil, the volume of sample pyrolyzed and pyrolysis temperature and time. In most cases, the pyrolysis products contain enough information to identify the original compounds.
The pyrolyzer system is shown in Fig. 1. The infrared radiation source and the pyrolysis reaction chamber are located in the focal axes of the eliptic housing with surfaces of high IR reflectance. One end of the reaction chamber is connected to a carrier gas source, and a controlled flow of the carrier gas can be generated. The solid sample is placed into the center of the reactor in a small boat-shaped container, fixed at the sample insertion rod. A computer controlled electronics unit drives the temperature in the pyrolysis device to a predefined value at a predefined heating rate. The other end of the insertion rod carries the sealing part and the sorbent tube.
A T-tube connected to a suction pump over a valve is mounted into the part which seals the reaction chamber. This gives the opportunity to pump off the pyrolysis products during certain time intervals and to collect only the products generated in a predefined temperature interval.
The desorbed gases are collected in the sorbent tube which contains a Tenax/charcoal combination sorbent. After desorption, the analysis is performed by GC/MS with a Bruker-Franzen quadrupole mass spectrometer MEM with a short column GC (Rtx-200, length 4.5 m).
Soil samples with Lindane and tetrabromomethane contaminations were employed to test the instrument. The detection limits were 0.1 mg/kg for humic soil and 1 mg/kg for clay for both compounds. The quantitative accuracy increases with the number of characteristic ions utilized, a standard deviation of 15% can easily be reached.
The relative intensities of Lindane and tetrabromomethane and their decomposition products are shown in Fig.2. At high temperatures the desorbed quantity increases and an equilibrium between desorption and decomposition establishes.
In humic soil samples contaminants to be detected can be obscured by the many pyrolysis products of the organic compounds of the matrix. This is greatly improved by multiple ion detection.
With real samples and artificial samples contaminated with up to ten compounds, the identification is improved, if characteristic peaks in the mass range above m/e = 150 were found.

The infrared pyrolyzer is capable of processing relatively large amounts of sample. This gives the opportunity of analysis of trace contaminants without requiring an oversensitive analysis equipment. The controlled heating allows the separation of pyrolysis products that are produced at different temperatures.
No solvent is needed for extraction and preconcentration. The speed of the determination is greatly improved. The experiments show that a fast determination of contaminants in different kinds of soil is possible in the low ppm level.

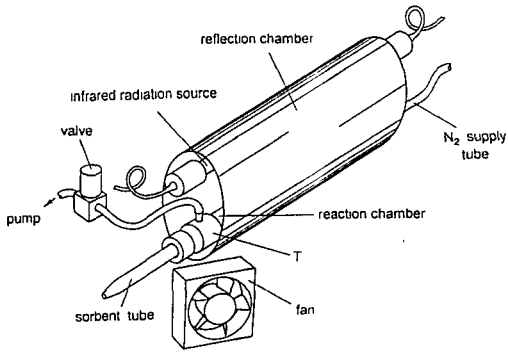


Figure 1 IR pyrolyzer

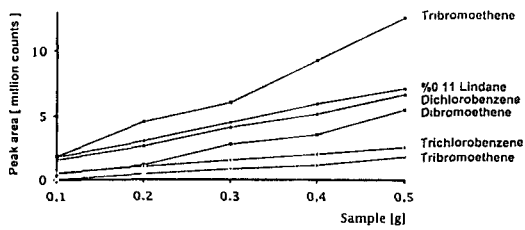

Figure 2 Lindane, tetrabromoethene and pyrolysis products

Multiple ion detection was used for pyrolysis produckts and undecomposed substances
Lindane m/z = 217, 219, 221, tetrabromoethane m/z = 263, 265, 267, 269
dichlorobenzene m/z = 146, 148, trichlorobenzene m/z = 180, 182, 184
tribromoethene m/z = 262, 264, 266, 268,
dibromoethene m/z = 184, 186, 188
Mean of four runs Pyrolysis time 240 s Pyrolysis temperature 250°C

GC-MS and GC-MS/MS Analysis of Samples for Chemical Warfare Agents: Canadian Contribution to the 3rd United Nations Verification Exercise

Paul A. D'Agostino and Lionel R. Provost, Defence Research Establishment Suffield, P.O. Box 4000, Medicine Hat, Alberta, Canada, T1A 8K6.

The possible entry into force of a Chemical Weapons Convention has prompted many countries to consider the difficulties involved in ensuring compliance by all participating nations. Compliance monitoring will be required in the verification of alleged use, the storage and destruction of chemical weapons stocks and to ensure that industrial sites are not illegally producing chemical weapons. The United Nations Conference on Disarmament, realizing that the above scenarios would require the development and use of analytical techniques to ensure compliance, formed a multinational Technical Group on Instrumentation to address the analytical challenges confronting signatory nations. Fifteen laboratories involved in the Technical Group on Instrumentation recently participated in a third round robin analytical exercise designed to evaluate the capabilities and analytical approaches of the laboratories. The samples were typical of an inspection of a military facility and included painted panels, rubber and concrete samples contaminated with low levels of chemical warfare (CW) agents and related compounds that would be scheduled by a Chemical Weapons Convention. Participating laboratories received the samples with no prior knowledge and were asked to document their methods and report, in a semi-quantitative manner, the presence of CW relevant compounds.

Three samples of each matrix type were received and extracted using methods developed in-house for CW agent clean-up (1). Each concrete sample was extracted by ultrasonic vibration for 5 minutes with 15 mL of acetonitrile. The acetonitrile extract was removed and concentrated by nitrogen blowdown to 0.5 mL. Dichloromethane (4.5 mL) was added to the acetonitrile extract (final volume of 5 mL) prior to analysis to improve chromatographic performance. Two mL of this final volume were reduced to 300μL and this concentrate was used for trimethylsilylation. Trimethylsilylation was performed by combining 100 μL BSTFA, 100 μL pyridine and the 300 μL extract in a 1.8 mL glass vial. This sample was heated for 20 minutes at 60°C and analysed immediately after cooling to minimize degradation. Sample extracts were screened by GC-FID and GC-FPD and CW relevant compounds were confirmed by capillary column GC-MS and GC-MS/MS (VG Autospec-Q) under full scanning EI and ammonia CI conditions.

GC conditions: J&W 15 m x 0.32 mm ID DB-1701; 40°C (2 min) 10 °C/min 280°C (5 to 20 min).
MS conditions: EI (8 kV, 200 μA, 70 eV, 2 x 10^{-6} Torr, 200°C, 400 to 40 u at 0.5 sec/decade).
CI (8 kV, 300 μA, 50 eV, 8 x 10^{-5} Torr, 120°C, 400 to 40 u at 0.5 sec/decade).
MS/MS conditions: Daughter spectra (17 eV, 10^{-6} Torr argon, 250 to 50 u at 0.5 sec/scan).

Figures 1 and 2 illustrate GC-MS (EI) chromatograms obtained during analysis (1 μL) of the acetonitrile extract and trimethylsilylated acetonitrile extract of one of the concrete samples.

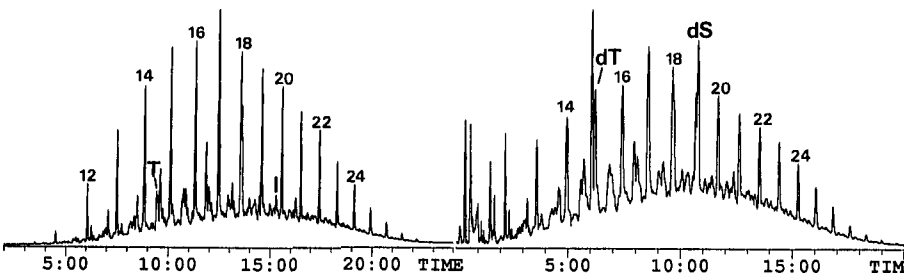

Figure 1: Acetonitrile extract

Figure 2: Trimethylsilylated acetonitrile extract

(T: Thiodiglycol, I: Interference, dT: di-TMS derivative of Thiodiglycol, dS: di-TMS derivative of Thiodiglycol sulfone, Numbered peaks indicate the hydrocarbon number of alkanes extracted from the concrete)

Figures 3 and 4 illustrate the MS data for two degradation products of the sulfur vesicant mustard, thiodiglycol $[(HOC_2H_4)_2S]$ and thiodiglycol sulfone $[(HOC_2H_4)_2SO_2]$, respectively. The EI data for thiodiglycol was similar to published data (2), but the EI mass spectrum of thiodiglycol sulfone was not discernable above the chemical background. Hydrocarbon(s), I, (refer to Figure 1) completely masked this component during EI analysis. The high hydrocarbon content was not ionized during ammonia CI analysis and highly specific detection of these two CW relevant compounds was possible. The molecular weight and presence of these compounds was confirmed by the presence of $(M+H)^+$ and/or $(M+NH_4)^+$ ions (Figure 3a and 4a). GC-MS/MS data were obtained by acquiring the daughter spectrum of m/z 122 (molecular ion) for thiodiglycol (Figure 3b) and m/z 111 (EI fragmentation ion, $[(HO)_2SC_2H_4OH]^+$) for thiodiglycol sulfone (Figure 4b). In both cases the principal daughter was due to loss of H_2O. The use of moderate resolution (1800) in the sector significantly reduced the chemical background and resulted in chromatograms that were considerably less complex than under EI-MS. The EI mass spectra for the di-TMS derivatives of thiodiglycol and thiodiglycol sulfone (Figure 3c and 4c) were similar to published data (2). The molecular weight of each of the derivatives was confirmed during ammonia CI analysis by the presence of $(M+H)^+$ and $(M+NH_4)^+$ ions at m/z 267 and m/z 284 (di-TMS derivative of thiodiglycol) and m/z 299 and m/z 316 (di-TMS derivative of thiodiglycol sulfone) (Figures 3d and 4d).

Only five of the fifteen participating laboratories, including Canada, were able to identify and confirm the presence of the two spiked CW relevant compounds, thiodiglycol and thiodiglycol sulfone, in the concrete samples circulated for round robin analysis. Two additional laboratories reported the presence of both compounds but also reported false positives (e.g., mustard) and/or artifacts with their results. The use of both ammonia CI-MS and MS/MS by Canada resulted in highly specific detection and confirmation of these two compounds during analysis of the concrete round robin samples.

The Analysis of Polychlorinated Dibenzo-P-Dioxins in Soil using Mobile Gas Chromatography Mass Spectrometry

*P. Kowalski, J. Wronka, and F. Laukien
Bruker Instruments Inc., Manning Park, Billerica, Massachusetts 01821

Introduction

The presence of toxic Polychlorinated Dibenzo-P-Dioxins (PCDDs) in the environment is becoming increasingly apparent. Activities such as the incineration of Polychlorinated Biphenyls (PCBs), and the incineration of soils contaminated with PCBs, produce PCDDs which in turn add to the complexity of an already hazardous material. Conventional analytical procedures for the determination of PCDDs in soil are defined within Method 8280 of the SW-846 Test Methods for Evaluating Solid Waste[1]. This low resolution Gas Chromatograph Mass Spectrometer (GC/MS) technique uses Single Ion Monitoring for the determination of PCDDs. Since Method 8280 is performed by only a small number of labs within the US (due to the hazardous nature of the samples and their special requirements for disposal) this analysis tends to be extremely costly.

A simplified and cost effective analytical procedure has been developed for the determination of Dioxins on site using a Mobile Environmental Mass Spectrometer (MEM). The MEM is a duel filament, electron impact ionization, quadrupole GC/MS, with a ruggedized design to allow the quick mobilization into the field providing data on a real time basis. Since the analysis occurs on-site, only a small representative sample needs to be collected, and no residual sample is generated which later needs to be disposed of as a hazardous waste.

Experimental Method of Analysis

The instrument configuration consists of the MEM with a mini-gas chromatograph oven interfaced to the MS ion source. A methyl silicon membrane serves as the separator. The specifications of the selected 3 Meter DB-5 capillary column has an inside diameter of 0.32 mm, and a film thickness of 0.25 um providing ample separation of the Dioxin congeners.

Sample preparation

A simplified micro-extraction of 0.5 g soil sample was performed using 1.0 ml Toluene as an extraction solvent. Following a two minute hand-shake extraction, a 5 ul aliquot of the extract was introduced into the GC oven. This sample introduction was accomplished by first injecting an aliquot of the extract onto a glass wool plug within a glass liner, followed by the insertion of the liner into the heated desorption chamber of the GC oven. Immediate desorption of the sample transfers the analytes onto the capillary column whereby Dioxin congeners are separated prior to detection.

Method of Analyte Detection

Analytes are detected by multiple ion monitoring (MIM). Each congener group is represented by selecting 4 characteristic ions as listed in Table 1.

Table 1 - Multiple Ions Monitored and their relative intensities.

Compound	m/z,Relative Intensity
TCDD	332,100;320,74.9;257,51.9;0,0
PCDD	356,100;354,86.5;358,74.9;293,25.0
HexCDD	390,100;388,85.5;392,74.9;327,25.0
HepCDD	361,100;363,85.5;365,51.9;359,64.7
OCDD	142,100,230,100 ;332,86.5;395,86.5

Results
The selected ions are monitored (SURFACE MONITOR) on a real time basis during a timed experiment lasting up to 400 seconds while a GC temperature profile is completed. A positive identification is determined when the response for all four characteristic ions are detected equally and simultaneously. Interference and reliability criteria are pre-programmed to greatly reduce the possibilities of false positive and false negatives.

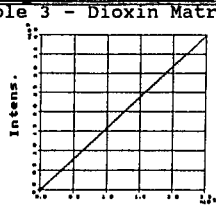
The concentration of the standards for the method detection limit study (see Table 2) and those of the matrix spikes (see Table 3) were calculated by using the equation of a line when the initial calibration curves (see Figure 1) resulted in correlation coefficients equal to 1.00 (PCDD, HexCDD, OCDD). When the correlation coefficients were less than 1.00, (TCDD, HepCDD) the equation for a line of best fit was used.

Compound	ng/ml
2,3,7,8-Tetrachloro Dibenzo-p-Dioxin (TCDD)	165
1,2,3,4,7-Pentachloro Dibenzo-p-Dioxin (PCDD)	40
1,2,3,4,7,8-Hexachloro Dibenzo-p-Dioxin (HexCDD)	101
1,2,3,4,6,7,8-Heptachloro Dibenzo-p-Dioxin (HepCDD)	195
Octachloro Dibenzo-p-Dioxin (OCDD)	6400

Table 2 - Method Detection Limit Study

Compound	Spike Added to Sand	MS(D) Conc	% Recovery
HexCDD	500 ng/ml	631 ng/ml	126
HexCDD	500 ng/ml	631 ng/ml	126

Table 3 - Dioxin Matrix Spike and Duplicate



Concentration (ng/ml)	Intensity
200.00	79
1000.00	566
5000.00	4496
100000.00	158489
250000.00	398107

Figure 1- PCDD Initial Multipoint Calibration Curve

Conclusion
The resulting qualitative and quantitative data support the capabilities of conducting accurate analytical measurements of Dioxins in the field using GC/MS techniques. Typical detection limits range from 40 to 200 parts per billion (except for OCDD whereby fragmentation ions that are 10 % relative to base peak were selected due to the instruments upper mass range of 400 Daltons, and the high boiling point of OCDD). A dynamic range covering 3 orders of magnitude is easily accomplished. Simplified sample preparation, and rapid sample analysis allows for a very high sample throughput, upwards to 50 samples/per day, offering an alternative to conventional methods.

AN INTEGRATED CONCEPT OF AUTOMATED INSTRUMENT CONTROL, QUALITY ASSURANCE AND DATA REPORTING FOR DIOXIN/FURAN ANALYSIS

R. Pesch, R. Schubert, M. Hoehn, H. Pfaff and E. Schroeder
Finnigan MAT GmbH, Barkhausenstrasse 2,
W-2800 Bremen 14, Germany

The identification and quantitation of chlorinated/brominated dibenzodioxins/dibenzofurans in a wide range of matrices continue to present imposeing challenges to the analyst. A growing number of samples have to be evaluated for ever lower concentrations of these compounds. HRGC/HRMS is a proven and well accepted technique which offers the required selectivity and sensitivity. But the lack of automation was the bottleneck for high sample throughput and made quality assurance and quality control very time consuming.

The present paper describes the application of a newly designed instrument control language for automation of a HRGC/HRMS system tailored for dioxin/furan analysis (Fig. 1). Mouse bottom selectable routines guide the user through the MS set-up. They start complete autotune for high resolution at full decreased acceleration voltage as well as algorithms for magnetic and electric calibration. Automatic multiplier gain selection for optimal detection limits is documented in a quality control chart as well as instrument resolution and other important performance parameters.

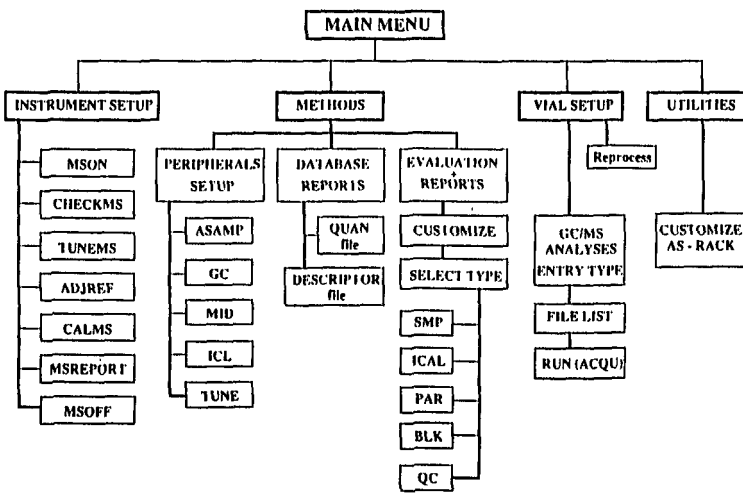

Figure 1

A novel target compound analysis program is used to customize methodes which adjust labority standard working procedures to the system. This fully integrates peripherals like the GC and the Autosampler and gives access to the MS set-up calling predefined MID descriptors and instrument control procedures. This also ensures proper and flexible data evaluation and reporting for different sample types like precision and recovery standards, blanks, samples, etc. Various quality control parameters like isotope ratios, retention time tolerances and the recovery of standards are included. Precision and recovery charts are permanently updated.

A vial set-up menue allows to load the autosampler rack for unattended overnight operation and specifies the sample type for each individual vial entry. The specified method for data evaluation and reporting guarantees complete quality control documentation. Feedback from the data evaluation program ensures that samples are not wasted if specified quality criteria don't fit.

SOLID PHASE EXTRACTION FOR THE ANALYSIS OF PCDDs AND PCDFs IN PULP MILL EFFLUENTS

J. H. Grogan, C. L. Bordies and K. M. Pamidimukkala
Champion International Corporation
West Nyack, NY 10994

There has been a growing concern with the usage and disposal costs of large quantities of toxic organic solvents in laboratories performing environmental analyses. Therefore, there is a definite need to develop alternate extraction methods for the analysis of pollutants from aqueous samples. Solid Phase Extraction (SPE), using minimal amounts of solvents, has in the past been used for the extraction of PCBs and several other organic pollutants. Extraction of chlorinated dioxins and furans by conventional methods require large quantities of solvents. We report here the application of SPE disks for the extraction of polychlorinated dibenzodioxins (PCDDs) or dibenzofurans (PCDFs) at the parts per quadrillion (ppq) level from pulp mill effluents. We have selected a basic extraction stage filtrate and a waste treatment plant (WTP) influent, which has large particulate matter, for the present study. The analysis of native spike samples was performed to demonstrate the precision and recovery of this method.

A one liter sample of an aqueous sample (as received) was spiked with ^{13}C-labelled internal standard (Cambridge Isotopes) and passed through a 90mm solid phase extraction disk supplied by 3M Corp. These disks have 8 μm C18 bonded silica (60A pores) entrapped between two teflon layers. A filter paper was placed on top of the disk to collect any particulate matter in the sample. However, those samples that had a high solid content were pre-filtered. All filter papers, where applicable, were then soxhlet extracted overnight using a 68:32 ethanol/toluene mixture. The aqueous phase was discarded. Two fifteen ml portions of toluene was used to elute the PCDD/F's from the disk. This toluene extract was then added to the soxhlet extract and concentrated down to 200μl after adding column cleanup standard. After reconstitution, the extract was subjected to clean-up procedures and analyzed by high resolution gas chromatograph/high resolution mass spectrometry (HRGC/HRMS) as per the method EPA1613A.

Relative recoveries of the ^{13}C-labelled internal standards and the actual concentrations found from SPE and liquid-liquid experiments are compared for the waste treatment plant influent and extraction stage filtrate in Table 1 and Table 2 respectively. While the recoveries for WTP influent showed excellent comparison for all congeners, the extraction stage filtrate recoveries were very poor. These low recoveries can be attributed to the high pH (pH~11) of the sample. A method validation study was also performed by spiking reagent water with known amounts of the labelled and native PCDD/F's. The results are shown in Table 3 and Table 4. An aqueous filtrate, in one of the reagent blank water SPE experiments, was extracted with methylenechloride to confirm the adsorption efficiency of these disks for PCDDs and PCDFs at very low levels. There were no break through problems encountered with this reagent blank

water sample. However, more experiments with real samples are needed to confirm this observation.

From the data presented here, it can be seen that SPE disks can be used for the extraction of PCDD/F's from pulp mill effluents. The labelled compound recoveries compare favorably with conventional methods and range from 60-100%. The use of SPE disks facilitates ease of extraction, maximize time savings and minimize the use of solvents.

Acknowledgement: We would like to thank Craig Markell of 3M Corporation, St. Paul, MN for supplying the SPE disks and Frank Antonucci, Champion International Corp., for his encouragement and support.

Evaluation of a Method for the Analysis of Chlorinated Phenoxyacetic Acids Using Thermospray LC/MS

*Jeffery S. Hollis, The Hewlett-Packard Company, Dayton, OH. 45459
Alexander B. Schilling, The Hewlett-Packard Company, Naperville, IL. 60566

Introduction:

The forthcoming EPA method for the analysis of solvent extractable non-volatile compounds (SW-846 Method 8321A) recommends the use of thermospray (TS) LC/MS for the identification and quantification of chlorinated phenoxyacetic herbicides. These compounds are found in soil, water, and hazardous waste materials. For an analysis to be productive in the environmental laboratory, the methodology must be evaluated using a variety of commercially available chromatographic materials and shown to retain acceptable reproducibility and sensitivity. Although the method includes the use of MS/MS for qualitative compound identification, the predominant type of MS found in the environmental laboratory is the single quadrupole instrument. Therefore, a study of the method employing standard equipment was conducted.

Experimental:

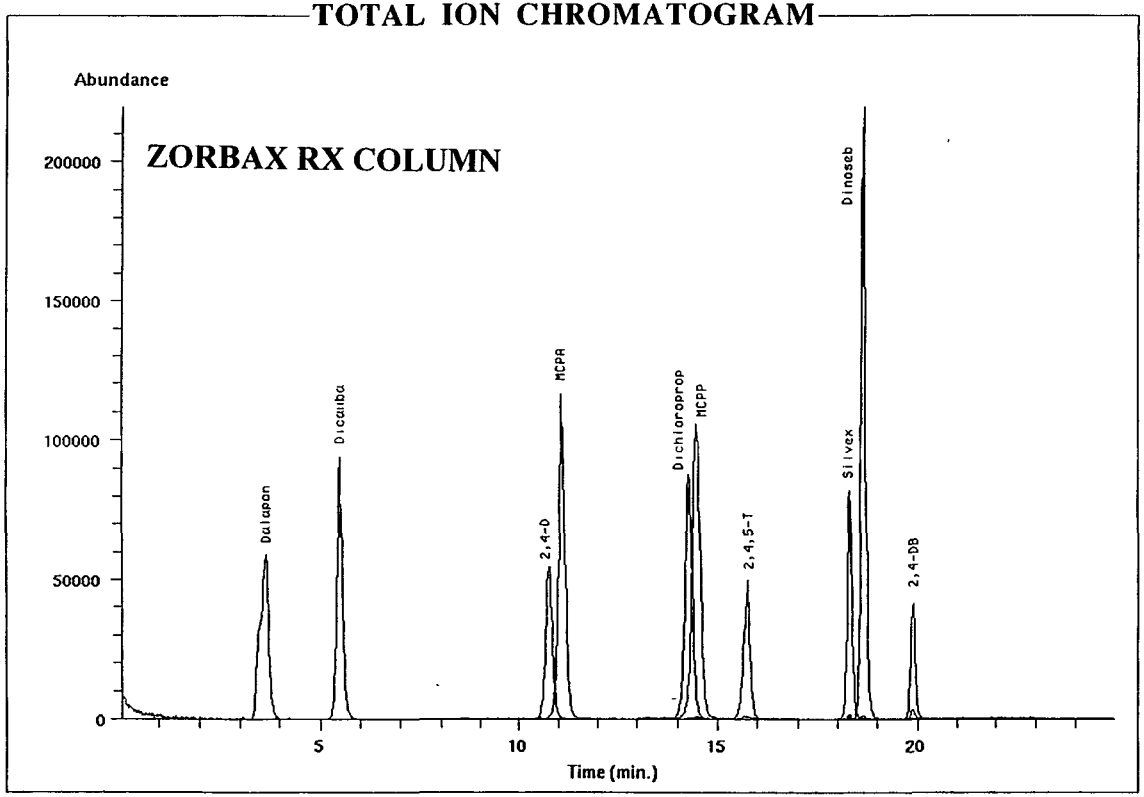
A series of 10 chlorinated phenoxyacetic acid herbicides were analyzed using TS/LC/MS using the proposed protocol outlined in the method. A HP 5989A LC/MS/DS with a thermospray interface and a HP 1090L HPLC with diode array detector were used to chromatograph the compounds. Both negative ion and positive ion modes were used. Three columns were studied; a Hypersil C-18 4.6 x 60 mm, a Supelco LC-18-DB C-18 4.6 x 250 mm, and a Zorbax RX 4.6 x 250 mm. The solvent system used was as follows: Solvent A: 0.1 M NH4Ac pH 4.5, Solvent B: 0.1 M NH4Ac in methanol, gradient elution starting (%A:%B) 50:50, hold 2 minutes then to 40:60 at 12 minutes, then to 10:90 at 20 minutes, hold to 25 minutes, then to 50:50 at 30 minutes. The column was at ambient temperature. Both scan (140-350 amu) and SIM acquisition were used. The thermospray source temperature was 250 C, the fragmentor was 20 V and the discharge electrode was on. A series of 6 calibration levels were run with a 3 uL injection volume. All samples were made up in acetonitrile.

Results and Discussion:

After the initial calibration runs were made, additional standards were run at one week intervals to monitor the stability of the source with respect to continuing linearity of the calibration curve. Some degradation in linearity was observed over these time intervals, however the difference in area counts between successive continuing calibrations was never larger than 30 %. Part of this stability can be attributed to careful adjustment of the pumpout valve to maintain a constant source pressure during all data acquisition and to adjusting the vaporizer temperature to maximize chromatographic peak symmetry instead of signal strength.

Overall, neither positive ion mode nor negative ion mode using scan conditions gave satisfactory sensitivity or linearity, whereas SIM in negative ion mode gave the best detection limits and linearity. The data indicate that by using SIM in negative ion mode this assay can be used on a routine basis for the detection and quantification of the chlorinated phenoxy acids. The use of weekly instrument tuning may have contributed to the slight degradation in linearity therefore more frequent tuning (i.e. on a daily basis) may be required for external standard calibration.

TOTAL ION CHROMATOGRAM



APPLICATION OF GC-MIP-CRIMS TO THE SELECTIVE DETECTION OF A CHLORINATED HERBICIDE (TRICLOPYR) IN GARDEN BEAN LEAVES

Jeffrey T. Morre' and Mehdi Moini
Department of Chemistry and Biochemistry
The University of Texas at Austin, Austin, Texas 78712

Recently we applied the GC-MIP-CRIMS technique to the selective detection of chlorine-containing compounds in complex mixtures (ASMS 91). Here we report the application of this technique to the investigation of the uptake of triclopyr (a chlorinated herbicide) in garden bean leaves.

The herbicide Garlon 4 (Dow Chemical Company), which is the ethylene glycol butyl ether of triclopyr (3,5,6-trichloro-2-pridiny-loxyacetic acid), was applied to garden bean leaves by aerosol spray at a rate of approximately 1/16 lb/acre. After one hour drying time the leaves were removed, rinsed with water, and quick-frozen in liquid nitrogen. The leaves were then lyophilized to total dryness.

500 mg of freeze-dried leaf was ground by a mortar and pestle. The organic compounds were extracted with three 10 mL aliquots of acetone. This solution was then dried under a stream of nitrogen. Samples for normal GC/MS and GC-MIP-CRIMS were derivatized (methylated) and dissolved in hexane. The hexane solution was first dried under a stream of nitrogen gas and then dissolved in 1 mL of hexane. This solution was used for the selective detection of triclopyr in garden bean leaves.

When SO_2 was used as the reaction gas, $H^{35}Cl$ m/z 36 was found to be the most sensitive selective mass chromatogram for chlorine-containing compounds, while CO_2 m/z 44 was the most sensitive mass chromatogram for the non-selective carbon channel.

1) Selective detection of triclopyr in garden bean leaves.

Triclopyr [(3,5,6-trichloro-2-pyridinyl)oxy]acetic acid, $C_7H_4O_3NCl_3$ m/z 255) is the active ingredient in Dow Chemical Company's Garlon 4 herbicide, where it is formulated as its ethylene glycol butyl ether ester. This compound is used mainly as a growth inhibitor in forestry and right-of-way clearance.

2,4,5-trichlorophenoxy acetic acid (2,4,5-T) was used to control brush along roadsides. However, because of environmental considerations (some commercially manufactured 2,4,5-T contained dioxin, a potent mutagen, as a contaminant) the use of 2,4,5-T was banned by the EPA.

As an alternative to 2,4,5-T, researchers are working on some chemicals that would interact with existing phenoxyherbicides such as triclopyr to increase their effectiveness. Both cobalt chloride and ammonium nitrate have been used. Cobalt ions have been known for a long time to

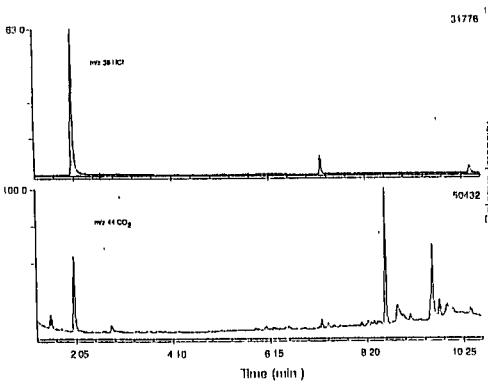


Figure 1

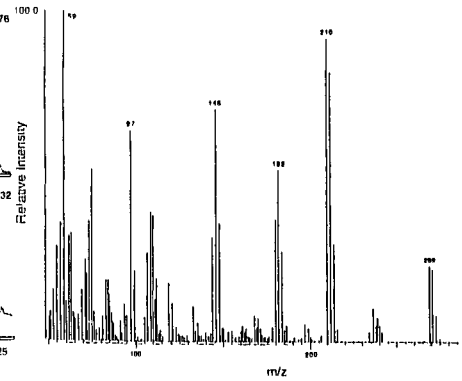

Figure 2

interact rather specifically with 2,4-D and other auxim-like materials both to promote growth at low concentrations and to inhibit growth very markedly at high concentrations.

Although studies have tried to establish a mechanism for this plant growth behavior in the presence of cobalt, the mechanism remains unclear. Some researchers have explained the behavior in terms of enhanced uptake of the herbicide, while others have suggested that the action occurs later, at the herbicide site of action. The purpose of our experiment, using microwave-induced plasma chemical reaction interface mass spectrometry, is to investigate whether cobalt chloride or ammonium nitrate will increase the uptake of triclopyr in garden bean leaves.

A one-microliter solution of triclopyr in hexane was injected in split mode, with the split ratio of approximately 1/10 for p-dichlorobenzene. Results are shown in Figure 1, where the nonselective CO_2 m/z 44 is shown at the bottom, and the selective mass chromatogram for chlorine-containing compounds (HCl, m/z 36) is shown at the top. As is shown in Figure 1, three chlorinated peaks are present in the m/z 36 mass chromatogram. Retention times for the chlorinated peaks were obtained from the x axis. Structural identification of this peak was then obtained by repeating the experiment, MIP-off, and full-scan acquisition mode. Figure 2 shows the mass spectrum obtained at the retention time corresponding to the second observed peak of the m/z 36 mass chromatogram. This mass spectrum is consistent with methylated triclopyr. Figure 3 shows the mass spectrum obtained at the retention time corresponding to the third observed chlorinated peak. This mass spectrum is consistent with the butoxyethyl ester of triclopyr (Garlon 4).

2) Investigation of the uptake enhancement of triclopyr in the presence of cobalt chloride and ammonium nitrate.

Three different organic extracts at two different concentrations (1X and 10X) were obtained by extraction methods previously discussed, one containing herbicide only, one containing herbicide and cobalt chloride, and the last containing herbicide and ammonium nitrate.A one-microliter solution of each organic garden bean extract in hexane was injected in splitless mode. Two masses were acquired: m/z 36 for selective detection of chlorine-containing compounds, and m/z 44 for nonselective carbon-containing compounds

Fig. 4 demonstrates that after a one-hour incubation period, a 5:4 signal ratio (for 1X concentration of herbicide with or without cobalt chloride) was obtained for the peak associated with triclopyr. Fig. 4 shows a 1:2 signal ratio for the 10X solution. Fig. 4 also demonstrates that the addition of ammonium nitrate had no effect on the signal associated with triclopyr at the 1X concentration of herbicide.

The GC-MIP-CRIMS method was applied to the selective detection of triclopyr (a chlorinated herbicide) in garden bean leaves. The results show that at normal concentrations of triclopyr, the amounts of triclopyr in the leaves was slightly more in leaves containing cobalt chloride At concentrations 10 times the normal concentration, in the presence of cobalt chloride or ammonium nitrate, the triclopyr detected in the leaves was half of the amount detected when no additive was used.

DETERMINATION OF TOLUENE DIAMINES IN POLYURETHANE FOAM BY GC/MS

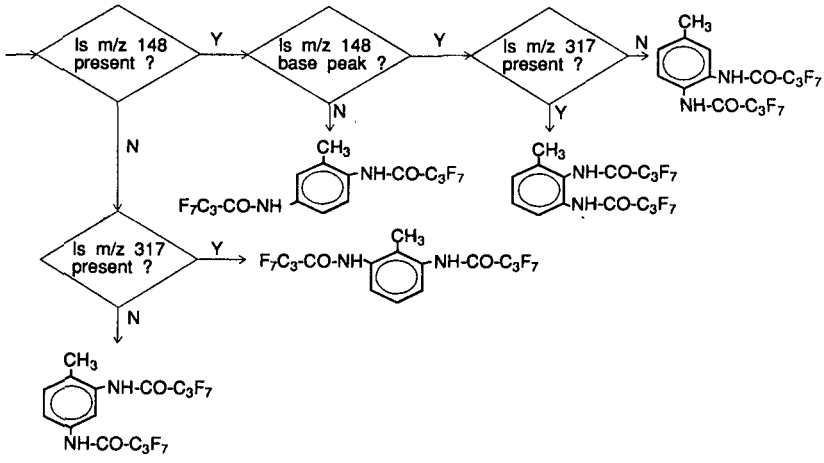
Frank M. Benoit

Environmental Health Directorate, Health & Welfare Canada,
Ottawa, ON, Canada, K1A 0L2.

Polyurethane foam is produced by the reaction of diisocyanate with a diol in the presence of a blowing agent. Toluene diisocyanate (mixture of 2,4- and 2,6- isomers in a ratio of 80:20) and polydiethylene glycol adipate are commonly used in many polyurethane foams. Water reacts with the isocyanate group and is added to the reaction mixture for two reasons: 1. to control the polymeric chain length (converts isocyanate to amine which stops the polymerization) and 2. to enhance the foaming process (release of carbon dioxide). However, this reaction also produces toluene diamines of which the 2,4 isomer is a known toxic material. The analysis of toluene diamines in polyurethane foams is difficult for three reasons: 1. the diamines absorb strongly to various surfaces such as the foam itself, glassware and injection ports which results in poor sensitivity (> 30 ng injected), poor recoveries (10 to 65 %) and poor quantitative reproducibility, 2. the 2,4- and 2,6-toluene diamines coelute with 2,3-dimethyl-6-t-butyl phenol (antioxidant additive), and 3. the mass spectra of the diamines are not very characteristic - the ion pair 121/122 also occurs as minor ions in the mass spectrum of 2,3-dimethyl-6-t-butyl phenol; a reconstructed mass chromatogram of masses 121 and 122 results in the incorrect identification and consequently the overestimation of the true concentration of toluene diamines in polyurethane foams. These problems are eliminated by derivatization of the toluene diamine to toluene di(heptafluorobutyryl) amide by treatment with heptafluorobutyric anhydride (1).

In the course of our analysis of 2,4-, and 2,6-toluene diamines in polyurethane foams we have examined the mass spectra of five isomeric toluene diamines (2,3-, 2,4-, 2,5-, 2,6-, and 3,4-) as well as their heptafluorobutyryl amide derivatives. All five amido derivatives are separable by gc; the mass spectra are less prone to interfering ions because the characteristic ions occur in widely different mass domains. The antioxidant additive does not coelute with any of the amides. The mass spectra of the amides are sufficiently different that identification of the individual isomers is feasible from the mass spectral data alone (Scheme 1). A prominent feature of the scheme is the formation of the ion at m/z 148 which occurs only in those isomers with ortho (2,3-, and 3,4-) or para (2,5-) nitrogen atom orientations and is the base peak in the isomers (2,3-, and 3,4-) with ortho nitrogen atom orientation. In the latter instance the m/z 148 ion is the result of an "ortho effect" wherein the interaction between two adjacent functional groups is rendered possible by the increased chain length of the amido groups compared to the amine functions.

Scheme 1. Identification Scheme for Isomers of Toluene di(heptafluorobutyryl) amides



The derivatization enhances the sensitivity and reproducibility of the analysis and eliminates the problems associated with coelution and incorrect identification of the analytes. The 2,4- and 2,6-toluene di(heptafluorobutyryl) amides are separable by gc and have a limit of detection of ca 40 pg, which is equivalent to 10 pg of the amines, injected, based on quantitation using 2,3-toluene di(heptafluorobutyryl) amide as internal reference standard.

PRELIMINARY INVESTIGATION INTO THE USE OF SUPERCRITICAL FLUID EXTRACTION (SFE) INTERFACED WITH GAS CHROMATOGRAPHY/MASS SPECTROMETRY TO IDENTIFY SPECIFIC MATERIALS IN SHUTTLE AIR

Lily Yang, Thomas F. Limero, and John T. James*

*Biomedical Operations and Research Branch, NASA-Johnson Space Center, and KRUG Life Sciences, Inc., Houston, TX 77058

INTRODUCTION: Early animal enclosure facilities designed for the Space Shuttle's Spacelab have released small quantities of food and fecal particles into the Shuttle cabin atmosphere. Atmospheric debris was collected from a recent Spacelab flight (STS-40) to assess the isolation capabilities of a new animal enclosure facility. Airborne debris typically consists of clothing fibers, human food crumbs, hair, skin, paint flakes and miscellaneous materials. The goal of this study was to develop an analytical method to conclusively identify unwanted rodent materials that could be present in this heterogeneous mixture.

EXPERIMENTAL: A Suprex Supercritical Fluid Extractor SFE/50 was used for extraction. Supercritical CO_2 was pressurized to 370 atm throughout the extraction and the extraction vessel oven temperature was held at 45°C. The depressurized CO_2 effluent was collected into a vial containing 3mL of hexane. The collection vials were changed every 60 minutes and the amount of CO_2 used (mL) was recorded. The hexane solutions were then concentrated to 1.0mL and internal standards, 1,4-dichlorobenzene-d4 and p-terphenyl-d14, were added for the following GC/MS analyses. The sample extraction was complete when a baseline total ion chromatogram was obtained. The GC/MS analyses were performed using a Hewlett-Packard (HP) Mass Spectrometry Detector MSD 5971A interfaced with an HP GC 5890. The GC was equipped with a 30m X 0.25mm I.D. DB-FFAP fused silica capillary column with a film thickness of 0.25μm (J & W Scientific). The GC oven temperature was 75°C for 1.0 min, then was increased at a rate of 4°C/min to 245°C, where it was held for 25 minutes. Samples (1.0μL) were introduced into the GC/MS system using a splitless injection technique. The injector and GC/MS transfer line were at 245°C and 250°C, respectively. The linear flow rate of the helium carrier gas was 34cm/sec measured at a oven temperature of 70°C. Using the full scan mode, a range of mass 34-462amu was scanned at a rate of 1.00sec/scan. The GC/MS system was calibrated by introducing a calibration standard mixture (including 39 compounds) at seven concentration levels. The working calibration curves were verified on each working day by measurement of a daily calibration standard mixture.

RESULTS AND DISCUSSION: This analytical method was evaluated using samples of rat food and rat feces collected from the JSC Animal Care Facility, rodent food bar provided on Spacelab flights, and rodent feces from the STS-40 mission. Total ion chromatograms obtained from the rodent food and fecal extracts are shown in Figure 1. The patterns of the food-bar chromatogram and the feces chromatogram are significantly different from each other, and may serve as "fingerprints" for identifying food and fecal particles. A total of 23 compounds have been identified and quantified in food, feces, or both (see Table 1). Another 18 compounds, including 12-methyltetradecanoic acid (present only in feces), were tentatively identified by mass spectrometry analyses. Compounds found only in feces, such as indole, pentanoic acid and others, may serve as markers for distinguishing

fecal particles. The compound 2,4-hexadienoic acid, present only in the rodent food bar provided on Spacelab, can be a marker for food bar particles as small as 40mg. Together, the GC/MS profiles and the potential marker compounds can be used to identify the food and fecal particles in the airborne debris. Supercritical CO_2 extraction profiles of these animal-related materials (shown in Figure 2) indicate that 90% recovery can be achieved by using 40-150mL of CO_2 at 370 atm and room temperature, depending on the sample size and texture. These results are encouraging for on-line interfacing of SFE and GC/MS. The success with animal-related particulates suggests that the origin of other organic particles in the Shuttle atmosphere can be identified by using this technique.

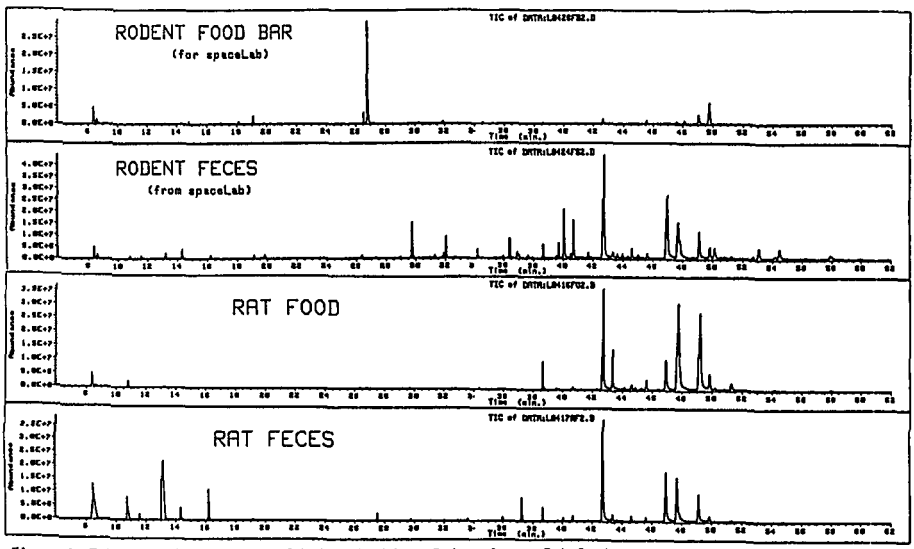

Figure 1. Total ion chromatograms of Rodent food bar, Rodent feces, Rat food and Rat feces (fresh) obtained by the combined technique of SFE and GC/MS.

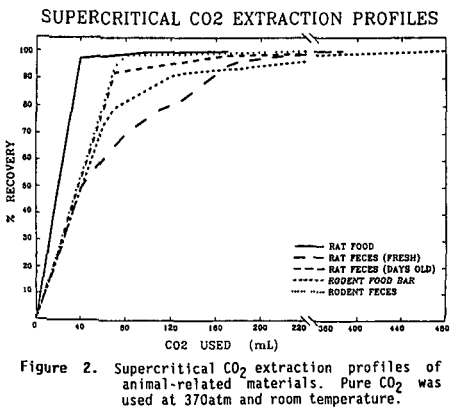

Figure 2. Supercritical CO_2 extraction profiles of animal-related materials. Pure CO_2 was used at 370atm and room temperature.

Determination of Degradation Products of Sulfonated Azo Dyes by LC/MS and GC/MS

Clifton F. Bell[1], Robert D. Voyksner[2], Andrea M. Dietrich[1]

[1]Environmental Engineering and Sciences Division, Department of Civil Engineering, Virginia Tech, Blacksburg, V 24061-0195

[2]Research Triangle Institute, Raleigh, NC

Introduction: Sulfonated azo compounds are one of the most commonly used classes of textile dyes. Dyes present an environmental problem because they can: 1) be difficult to degrade in industrial and municipal treatment systems, 2) cause effluents to violate color standards and 3) produce undesirable by-products. This concern has made necessary the development of methods for monitoring sulfonated azo dyes and their degradation products in water and wastewater, including mass spectrometric identification of these compounds. GC/MS and LC/MS were utilized to characterize a textile mill effluent containing three sulfonated azo dyes: Remazol Black B, Remazol Red RB, and Remazol Golden Yellow 3RA, and to identify degradation products of the dyes resulting from chemical and biochemical reduction.

The term "Remazol" refers to certain dyes which have a vinyl sulfone reactive group. The dye is stored and transported in a sulfato-salt form, but reacts at high pH to form the vinyl sulfone group. This form of the dye can either react with hydroxy groups on cellulose to form a covalent bond, or undergo a competing reaction with water. Hydrolyzed dye can no longer react with cotton.

Methods: GC/MS Analysis: Hewlett-Packard 5890 Series II gas chromatograph with 30 m x 0.25 mm ID DB-5 capillary column and a Hewlett-Packard 5970 Mass Selective detector. Aqueous samples were first extracted into methylene chloride according E.P.A. Method 625. LC/MS analysis: HP5989 Mass Spectrometer coupled to an Analytica Electrospray LC/MS interface.

Results: It was expected that chemical and biochemical reduction of the dyes would result in cleavage of the azo linkages and formation of aromatic amines. One of the reduction products of both the black and red dyes was confirmed by GC/MS to be p-(2-hydroxyethylsulfone)-aniline. The other reduction product of the black dye is hypothesized to be 8-hydroxy-1,2,7-triamino-3,6-naphthalene disulfonic acid but this product appears to be unstable.

GC/MS of the untreated and anaerobically treated dye washwater revealed the presence of p-(2-hydroxyethylsulfone)-aniline as well as over thirty other compounds such as limonene, terpinene, and tributylphosphate. Almost all of these compounds were destroyed by aerobic treatment.

Electrospray LC/MS has confirmed the structure of hydrolyzed Remazol Black B and given clues to the structure of hydrolyzed Remazol Red RB. Negative-ion ES gave stronger signals than positive-ion, and the dye was detected as adducts with sodium.

A Catalytically Enhanced In-line Reduction Method for the Production and Detection of Amines from Azo Containing Dyes as a Method of Dye Characterization in Environmental Samples

Jeffrey T. Keever, Rolf Straub, and Robert Voyksner, Analytical and Chemical Sciences, Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC

The ability to analyze azo containing dyes in environmental samples is strongly hindered by the limited number of suitable analytical methods. These limitations arise as a result of the nonvolatile nature of azo dyes and the complexity of the matrix in which they are often found. Most analytical methods rely upon wet chemical reduction of the azo bonds to produce the characteristic amines of the dyes, followed by subsequence analysis of those amines. The procedures involved are inefficient and costly. A rapid, in-line gas chromatographic/mass spectrometric (GC/MS) method of characterizing wastewaters for the presence of azo dyes has been evaluated.

A palladium/hydrogen catalytic method for the reductive cleavage of azo dyes has been investigated. The technique provides a rapid, economical means of producing the characteristic amines formed by the reductive cleavage of the azo bond found in many commercial dyes. The in-line technique has eliminated all wet chemical reduction steps by catalytically reducing the azo dyes within the heated injector of a gas chromatograph. Subsequent separation by high resolution capillary gas chromatography and detection of the reduced products by mass spectrometry make this a very clean and efficient technique.

The technique was evaluated for the reduction of several azo dye standards. Each standard was analyzed by GC/MS without the presence of the palladium catalyst to assess the chromatographic and mass spectrometric performance. Following the initial evaluation in which single chromatographic peaks representing the unreduced dye were observed, an injection port line containing palladium wire was inserted into the gas chromatograph injector. The dye standards were reinjected, forming the azo dye reduction products that were analyzed by GC/MS.

The results obtained from in-line catalytic reduction of an azo dye standards is presented in Figure 1. It was observed that the catalytic reduction resulted in nearly 100% reduction of the azo bond to form the characteristic amines.

The technique was then evaluated with wastewater extracts. Sample extracts were initially analyzed without the presence of the palladium to characterize the unreduced sample components. Once the unreduced components were characterized, the palladium injector liner was again installed and the wastewater sample reanalyzed. The formation of reduction products was indicated by the presence of new chromatographic peaks not found in the initial analysis are shown in Figure 2. As shown, several toxic amines, including benzidine and chloroaniline, have been identified.

This technique has been shown to be a rapid means of determining the presence of azo containing compounds present in wastewaters. However, characterization of reduction products is useful as an initial screening technique only. Extrapolation of the identities of reduction products to the identities of the parent dye themselves is currently not possible.

Investigation of Metabolic Pathways of Aromatic Amines by Electrochemistry/ Particle Beam/Mass Spectrometry

Jon A. Jones and Richard A. Yost, Univ. of Florida, Gainesville, FL 32611
Douglas W. Kuehl, U.S. EPA/ERL, Duluth, MN 55804

The conversion of a procarcinogen (a carcinogenic compound which requires metabolic activation to produce the carcinogenesis) into the ultimate carcinogen is generally an enzyme-controlled redox reaction. Many aromatic amines are known to be carcinogenic, and the metabolism of these compounds into reactive electrophiles has been attributed to cytochrome P-450 enzymes [1]. A proposed mechanism for the metabolism of aromatic amines is given in Figure 1. Electrochemistry (EC) has been demonstrated as a valid model for the enzymatic degradation of purine compounds, and its combination with mass spectrometry (MS) has been shown to be a useful tool in determining metabolic pathways [2].

In this research, the electrooxidation of aromatic amines is studied by on-line EC/MS using a quadrupole ion trap mass spectrometer (QITMS). The instrumental configuration used is shown in Figure 2. All on-line experiments were conducted using a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) coupled to a prototype Finnigan MAT particle beam (PB) interface. The electrochemistry was conducted using a ESA model 5020 guard cell with a model 173 potentiostat and a model 175 universal programmer (EG&G Princeton Applied Research). An Isco LC-2600 syringe pump was used for sample introduction; mobile phase flow rates were typically 0.10-0.25 mL/min. Cyclic voltammetry is used to determine oxidation potentials for on-line experiments; a cyclic voltammagram of benzidine taken in the guard cell under stopped flow conditions is shown in Figure 3.

A mass chromatogram of m/z 184, from benzidine in 50/50 methanol/water mobile phase, is shown in Figure 4a. The decrease in signal following the application of a +600 mV potential to the EC cell indicates approximately 30% electrochemical conversion of benzidine into other chemical species. As seen in Figure 4b there is an increase in the signal for m/z 305 following the potential pulse corresponding in time to the decrease in m/z 184, although this increase is not as large as the decrease in the m/z 184. The potential of the electrode is plotted in Figure 4c; the change in ion signal is delayed by approximately 30 seconds from the application of a potential to the electrode. The mass spectra corresponding to the sample before and during electrooxidation are shown in Figure 5.

Based on proposed mechanisms for enzymatic oxidation of aromatic amines [1], the m/z 305 ion presumably corresponds to protonated N,N,N',N'-tetramethoxybenzidine oxidation product. Tandem mass spectrometry was performed on this ion; the resulting daughter spectrum is shown in Figure 6. The daughter spectrum shows three daughter ions: m/z 290 from a loss of 15 (- CH_3), m/z 274 from a loss of 31 (- OCH_3), and m/z 262 from a loss of 43. EC/MS on benzidine was also carried out using solvent chemical ionization, with the m/z 33 from the methanol in the mobile phase as the mass-selected reagent ion, to determine if the m/z 305 was a protonated or molecular ion species. The mass spectrum shows the protonated molecular ion for benzidine (m/z 185) and m/z 305, suggesting that the m/z 305 species is a protonated ion in the spectrum of Figure 5. In an aqueous system, which should most closely approximate *in vivo* metabolism, there are no obvious species being formed during the EC. There is a significant decrease in the signal for m/z 184 following the potential pulse, but no other ions show a corresponding increase.

Aqueous EC/MS on aniline and anisidine was not successful, presumably due to inefficient transport of these more volatile compounds at the higher particle beam desolvation chamber temperatures required for water-containing mobile phases. EC/MS was therefore performed with methanolic 0.01 M NH_4OAc, which permits lower desolvation chamber temperatures and therefore more efficient PB transport. The mass chromatograms for each of these compounds show increases in the molecular ion signal during application of the potential to the EC cell, as shown in Figure 7. The mass spectra remain relatively the same throughout the process. The increase in ion signal may be due to electrochemical conversion of the compounds into ionic species which are transported through the PB more effectively, but which are converted back into the starting compounds during thermal desorption/ionization within the ion trap.

The flow rate of mobile phase was found to affect the efficiency of the electrochemical conversion. EC/MS on benzidine in methanolic 0.01 M NH_4OAc was performed at flow rates ranging from 0.05 to 1.0 mL/min. The results indicate the EC efficiency is highest at low flow rates and decreases with increasing flow rate.

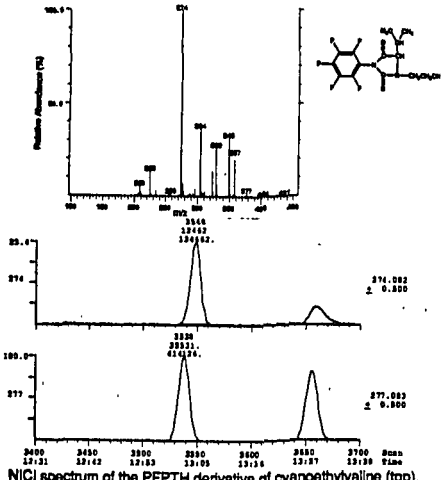
Methods for Quantification of Hemoglobin Adducts from Acrylonitrile, Ethylene Oxide, and 1,3-Butadiene

*M.J. Turner, Jr., S. Osterman-Golkar, J.P. MacNeela, T.R. Fennell
M.S. Bryant, G.A. Csanady, V.E. Walker, and J.A. Bond.
CIIT, Research Triangle Park, NC 27709

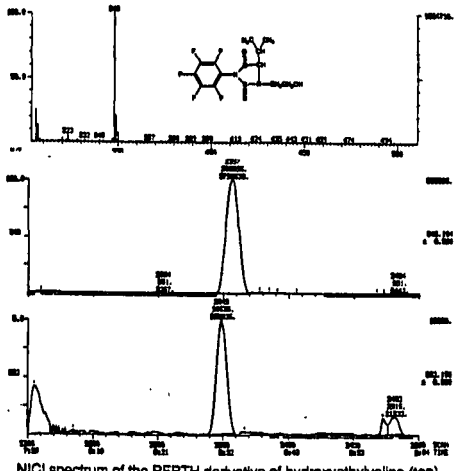
Accurate molecular dosimetry is helpful in estimating risk from exposure to carcinogens. Measuring adducts to hemoglobin has been proposed as a means of determining dose to critical tissues and/or as a surrogate for DNA adduct measurements. Acrylonitrile (ACN), ethylene oxide (ETO), and butadiene (BD) are all known carcinogens in laboratory animals. ETO and ACN can react directly with hemoglobin; BD requires metabolic activation to epoxide(s). Studies have been conducted with these important chemicals to evaluate the use of hemoglobin adducts as a viable dosimeter. Adducts to N-terminal valine were measured since this is a reactive site in hemoglobin and some analytical methodology existed for isolation/detection.

METHODS

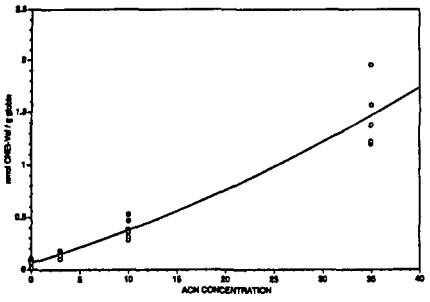
- Globin is isolated from red blood cells using the method of Mowrer, *et. al.* (Tox. Environ. Chem. 11:215 (1986)).
- Internal standards were prepared by reacting $^2H_3$-ACN or $^2H_4$-ETO with the peptide Val-Gly-Gly. The tripeptide was purified and appropriate amounts were added to globin samples prior to derivatization.
- Globin is reacted with an Edman-type reagent, pentafluoropnenylisothiocyanate, forming a thiohydantion derivative (PFPTH) of the modified N-terminal valine. (Törnqvist, *et. al.* Anal. Biochem. 154:255 (1986))
- The valine derivative is chromatographed on a DB-5 capillary column using on-column injection and detected using methane negative ion chemical ionization (NICI) mass spectrometry on a Finnigan 4500 mass spectrometer.



NICI spectrum of the PFPTH derivative of cyanoethylvaline (top). SIM chromatogram of derivatized globin from a rat exposed to ACN (bottom).

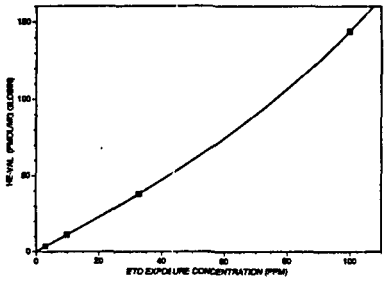


NICI spectrum of the PFPTH derivative of hydroxyethylvaline (top) SIM chromatogram of derivatized globin from a mouse exposed to ETO (bottom).



Rats were exposed up to 300 ppm ACN. The relationship between adduct levels and ACN concentration below 35 ppm approached linearity (graph above). The slope of the dose-response curve was greater at higher concentrations, indicating saturation of some metabolic pathway for the elimination of ACN. Studies measuring hydroxybutenylvaline from BD exposures have indicated that adduct formation is linear with exposure concentration at low levels.

Mice were exposed to 0, 3, 33, or 100 ppm ETO for 6 hr/day for 4 weeks. The graph below shows that the dose-response curve for formation/accumulation of hydroxyethylvaline appears linear below 33 ppm. Again, this is probably due to saturation of a metabolic pathway involved in the detoxification of ETO.



CONCLUSIONS

Advantages of hemoglobin adducts as dosimeters:

- Hemoglobin samples are readily available from experimental animals and human subjects.
- The accumulation characteristics of hemoglobin adducts can can provide an integral measure of dose.
- The sensitivity, specificity, and reliability of the assay should allow measurement from low-level environmental exposures.
- The exposure and/or dose information obtained can be used in pharmacokinetic dosimetry models to help estimate risk from exposure to carcinogens.

Retro-Michael Fragmentation In Tandem Mass Spectrometry of Modified Peptides

C.H. Oberth[1], A.D. Jones[2], T. Shibamoto[1]
[1]Department of Environmental Toxicology
[2]Facility for Advanced Instrumentation
University of California, Davis, CA 95616

Some drugs and xenobiotics are metabolized to reactive electrophiles. These electrophilic intermediates can be then conjugated with polar nucleophiles such as glutathione (γ-glutamylcysteinylglycine, **GSH**). The conjugation by glutathione can occur by one of three pathways: addition to an epoxide, displacement, or Michael addition. The conjugates may be excreted in the bile or feces, or metabolized further to N-acetylcysteine conjugates and then excreted in the urine[1,2].

Several studies[1-5] have demonstrated that fast atom bombardment mass spectrometry (**FAB MS**) and tandem mass spectrometry(**MS/MS**) are powerful techniques for the analysis of thioether conjugates. However, thioether conjugates formed via a 1,4-Michael addition in our laboratory often yield daughter spectra that contain little structural information. For example, the daughter spectrum of N-acetylcysteine conjugated with acrolein consists primarily of a single fragment representing the $[M+H]^+$ of the unconjugated N-acetylcysteine. The N-acetylcysteine/acrolein adduct undergoes a retro-Michael reaction with the charge remaining on the N-acetylcysteine fragment

The importance of retro-Michael fragmentation of various N-acetylcysteine and glutathione conjugates formed by 1,4-Michael addition was evaluated and the names and structures of the conjugates studied are listed on Table 1. Also, the (**GSH/A**) was reduced to the hydroxypropyl'analog (**GSH/P**) or derivatized to an oxime (**GSH/AO**) for the purpose of manipulating fragmentation in MS/MS.

Our data indicate that the N-acetylcysteine adducts of acrolein and 1,4-naphthoquinone(the reduced form) are more prone to retro-Michael fragmentation than their larger glutathione analogs. Table 1 contains some of the relevant daughter ions observed. The site of protonation appears to play a key role in this phenomena. N-Acetylcysteine adducts have fewer sites for protonation in the FAB ionization process, so the likelihood of protonation on the xenobiotic group is greater. Glutathione on the other hand, has multiple sites for protonation along the peptide backbone, and the abundance of b- and y- series daughter ions reflect this.

In addition, the basicity of the xenobiotic group plays a major role in determining how adducts fragment. This is illustrated in the fragmentation behavior of GSH/4-VP. The pyridine group readily becomes protonated and charge directed fragmentation results in a large abundance of retro-Michael-like derived daughter ions.

Modification of the xenobiotic group so that it cannot undergo retro-Michael fragmentation is effective. Reduction of GSH/A to GSH/P inhibited retro-Michael fragmentation and simplified the daughter spectrum. While derivatization to the GSH/AO did not reduce the incidence of the $[GSH+H]^+$ ion, the daughter ion spectrum was more complex and included several internal fragments. The oxidized species of the quinone anologs (N-AcCys/1,4-NHQ•; N-AcCys/1,4-NQ; GSH/1,4-NHQ•; and GSH/1,4-NQ) did not undergo retro-Michael fragmentation.

Because the site of protonation is crucial to the fragmentation process, care should be taken especially when sequencing multply charged peptide conjugates.

PPINICI LC/TSP/MS Techniques for the Characterization of Major and Minor Deoxynucleosides in Fish Liver DNA

Douglas W. Kuehl and Jose Serrano
United States Environmental Protection Agency
and
Sandra Naumann
ASci Corporation
6201 Congdon Blvd.
Duluth, MN 55804

Chemical residues in fish have been successfully used by the U.S. EPA as an indicator of, and monitor for, environmental pollutants that readily bioaccumulate. However, analytical methods must be capable of characterizing electrophilic environmental pollutants, i.e. those chemicals that may react directly, or via metabolic activation, with important biomolecules such as DNA. Our objective was to develop a quality assured standard protocol to generate reproducible data on the composition of DNA constituents, which the U.S. EPA may use in both research and monitoring activities. The protocol is based upon a mild DNA isolation and enzymatic digestion, and product characterization by liquid chromatography/photodiode array ultra violet spectroscopy (LC/UV), and liquid chromatography/thermospray/mass spectrometry (TSP/MS). Rigorous quality assurance/quality control (QA/QC) for both sample preparation and chemical characterization have been developed. The methodology has been applied to the characterization of DNA from liver of three species of fish, brown bullhead, medaka, and rainbow trout, which are known to be sensitive to genotoxicants in vivo. Also characterization of DNA adducts resulting from in vitro reactions with a direct acting electrophile, alkylbromide, have been successful.

Sample preparation involves lysing tissue with SDS, removal of protein-aceous material with proteinase K and organic solvent extraction, removal of RNA by selective hydrolysis with RNase, A, T1, T2, and proteinase K and repetition of the organic solvent extractions, and finally hydrolysis of the resulting DNA with nuclease P1, phosphodiesterase I, and alkaline phosphatase, to deoxynucleosides. Quantification of major deoxynucleosides was done by LC/UV, and confirmed by PPINICI TSP/MS. Identification of DNA-xenobiotic chemical adducts, and their relative amounts, was done by PPINICI TSP/MS, and structural confirmation was done by MS/MS of thermospray ions. Analytes were chromatographed on a RP-C18-HPLC column using both solvent composition and flow rate programming on a Beckman HPLC system. The chromatographic program was: 3% B, 1.2 mL/min, until 3.5 min; then increase flow to 1.4 mL/min during the next 12 min, and increase B to 15% during the next 6 min; then at 9.5 min increase B to 9% during the next 6 min; hold all ending values until 25 min; A = 3% acetonitrile/water, B = 30% acetonitrile/water, in 0.05 M in ammonium acetate and pH adjusted to 6.5. Analyte characterization was done using a Beckman photodiode array UV detector operating at 254 and 280 nm, and a Finnigan-MAT TSQ-70 mass spectrometer with a TSP2 thermospray interface.

Fish liver DNA hydrolysates were found to be free of contamination by protein, free bases, deoxynucleotides, and oligodeoxynucleotides. Contamination by RNA nucleosides was less than 2% (Ado/dAdo). Experimental conditions did not cause m^5-dCyd to deaminate to Thd. The method was found to be capable of determining DNA mole-percent composition to < 1.4% r.s.d. Sufficient sensitivity was observed for PPINICI TSP/MS characterization of major dN in 10^8 cells of fish liver and for characterization of minor DNA-xenobiotic chemical adducts formed during reactions of

direct reacting electrophiles with 50 μg of DNA in vitro. LC/TSP/MS, positive ion-MID, gave a S/N of 10:1 or greater for 10-25 pg dN.

Results of mole-percent composition of DNA from the three species of fish are presented in Table 1. dUrd arises in vivo from spontaneous deamination of dCyd.

	Mole-Percent dN					
Fish	dCyd	dUrd	M^5dCyd	dGuo	Thd	dAdo
Trout	18.31	0.84	1.43	21.36	27.02	31.05
Medaka	16.40	1.50	1.86	20.16	28.12	31.96
Bullhead	14.14	2.22	1.96	22.14	26.36	33.18

Table 1. Deoxynucleoside composition of liver DNA from three species of fish.

Alkylbromide in DMSO was added to a solution containing equal molar amounts of free dN (dAdo, dGuo, dCyd, Thd), or to a solution of fish liver DNA to study the extent of reaction and type of DNA-adduct formed. The reactions were incubated at 37° for 6 hr. dN samples were lyophilized and redissolved in water for analysis. DNA samples were hydrolyzed for analysis. Results are presented in Table 2. The N3 position of dGuo was alkylated the most, and the N7 position of dGuo was alkylated only 50% as much during the reactions of dNs. However the influence of the structure of DNA is clearly seen by the nearly 40X enhancement in the proportion of N7 adducts relative to N3 Adducts.

ANALYSIS OF POWER TRANSFORMER OIL FOR INSULATION DEGRADATION PRODUCTS USING GAS CHROMATOGRAPHY-MASS SPECTROMETRY AND HPLC

Richard B. van Breemen[1], T.V. Oommen[2], and Chien-Hua Huang[1]
[1]Department of Chemistry, North Carolina State University, Raleigh, NC 27695-8204, and
[2]ABB Transmission & Technology Institute, 1021 Main Campus Drive, Raleigh, NC 27606.

Cellulosic insulation materials used in power transformers in combination with liquid dielectric transformer oil degrade as the transformer ages. Furfuraldehyde (2-furaldehyde, **1**) has been reported by Burton *et al.* (1) to be a decomposition product of electrical insulating paper used in transformers. Unsworth and Mitchell (2) have shown that two other paper degradation products, 5-methyl-2-furfuraldehyde (**2**), and 2-acetylfuran (**3**), are present in transformer oil and stable in oil up to at least 80° for 260 days. The concentration of these furan derivatives in transformer oil might be used to indicate the extent of paper insulation degradation in aged transformers. The ability to quantitate these compounds in samples of aged transformer oil and correlate the quantitities of these furans with transformer age would help the power industry replace aging transformers approaching the end of their useful lifetimes without risking catastrophic failure on-line.

Burton *et al.* (1) and Unsworth and Mitchell (2) have reported extraction and HPLC methods for the quantitation of **1** in transformer oil. Dominelli (3) recently reported a more sensitive HPLC assay for all three furans **1-3**. The efficiencies of these and other extraction methods were evaluated, and the HPLC method of Dominelli (3) was compared to the new gas chromatography-mass spectrometry (GC-MS) method developed in our laboratory for the quantitation of compounds **1-3**.

Transformer oil (20 ml) was extracted with 2 ml acetonitrile (or methanol) according to Unsworth and Mitchell (2). A 1 ml aliquot of the acetonitrile layer was removed, mixed with 2 ml water, and applied to a prepacked solid-phase extraction cartridge containing silica derivatized with C18, C8, or C2 (Analtech; Newark, DE). The eluate (3 ml) was collected and saved. The cartridge was eluted with an additional 2 ml of water/acetonitrile (or methanol) (80:20, v/v), and this eluate was combined with the other 3 ml (total volume 5 ml). Alternatively the method of Burton *et al.* (1) was used for sample preparation. In this approach, a mixture of 20 ml oil and 20 ml *n*-pentane was passed through a SEP-PAK silica cartridge (Waters Associates, Milford, DE) and then washed with another 20 ml of pentane. The analytes were eluted from the cartridge with 2 ml acetonitrile (or methanol).

Positive ion electron impact selected ion monitoring (SIM) GC-MS measurements were carried out using a Hewlett-Packard (Palo Alto, CA) 5985B GC-MS, equipped with a J & W 30 m DB-5 capillary column. Following sample injection (1 µl), the GC oven temperature was held at 60°C for 2 min and then increased to 250°C at 8°C/min. Helium was used as the carrier gas at a flow rate of 2 ml/min. The electron energy was 70 eV, and the injector temperature was 230°C. During SIM, the signals of the molecular ion of **1** (base peak) at m/z 96, and the next most abundant ion in the EI mass spectrum ($[M-H]^+$) at m/z 95, were summed together for maximum sensitivity. Similarly, the molecular ion at m/z 110 and $[M-H]^+$ ion of **2** were summed, and the molecular ion of **3** at m/z 110 and the base peak at m/z 95, $[M-CH_3]^+$, were summed.

Compared to methanol, acetonitrile provided higher analyte recoveries for the elution of C18, C8, or C2 cartridges, or for solvent/solvent extraction from transformer oil. Although the use of silica solid-phase extraction cartridges provided slightly lower recoveries than did C18 cartridges, the furan concentrations were higher in the eluate of the silica cartridges because a smaller volume of eluate was required. Therefore, acetonitrile extraction of transformer oil followed by further purification using silica cartridges was used in all subsequent studies.

An example of the GC-MS separation of the three furan analytes **1-3** is shown in Figure 1. GC-MS with SIM surpassed HPLC with UV detection in terms of sensitivity (18 pg vs. 200 pg) and specificity. Next, standard curves were constructed and GC-MS with SIM was used quantitatively to determine the amounts of furans **1-3** in transformer oil samples from oil that was artificially aged in the presence of either hemp kraft paper insulation or pressboard insulation, at 0% or 50% relative humidity, and at 130°C or 150°C for 30 days. The results of these measurements are shown in Table 1.

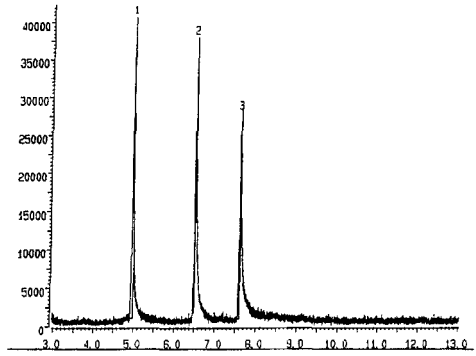

Figure 1. Computer reconstructed total ion chromatogram showing GC-MS separation of 100 ppm of (1) 2-furfuraldehyde, (2) 2-acetylfuran, and (3) 5-methyl-2-furfuraldehyde.

Table 1

Type of Insulation	Relative Humidity	Incubation Temperature	Furan Derivative (ppb) 1	2	3
Hempkraft	0%	130 °C	26±2	ND[a]	ND
"	"	150 °C	124±8	ND	ND
"	50%	130 °C	83±4	ND	ND
"	"	150 °C	125±26	57±3	48±5
Pressboard	0%	130 °C	407±38	ND	ND
"	"	150 °C	5.5±0.6[b]	257±21	57±4
"	50%	130 °C	49±7[b]	447±1	310±6
"	"	150 °C	86±6[b]	1.0±0.1[b]	2.0±0.2[b]

[b]oil concentration in ppm

GC-MS with SIM was shown to be highly specific and sensitive technique for the quantitation of furans **1-3** in aged transformer oil samples. GC-MS with SIM surpassed HPLC with UV detection in terms of sensitivity and specificity. GC-MS was faster and required approximately 20 min per analysis compared to 60 min for each HPLC analysis. The concentration of the three furan derivatives increased as the temperature of incubation of the oil and cellulosic insulation increased, and as the moisture content of the oil and insulation increased. 2-Furfuraldehyde, 2-acetylfuran, and 5-methyl-2-furfuraldehyde in oil samples taken from transformers in use and from failed transformers will be used in subsequent studies to correlate the concentration of these analytes with the extent of decomposition of transformer insulation.

Detection of organohalides in blue marlin (Makaira nigricans) liver by electron capture negative chemical ionization (ECNCI) GC-MS and GC with an electrolytic conductivity detector (ELCD).

Ellen Harvey and John Greaves

Virginia Institute of Marine Science,
College of William and Mary,
Gloucester Point, VA 23062.

Billfish are an important commercial and sport fishery. The blue marlin, Makaira nigricans, is a particularly important fraction of the commercial catch. Billfish are a very wide ranging group of species that are pelagic and are at the top of the food chain. As such they can be expected to be subject to accumulation of organohalogenated pollutants through biomagnification. The pelagic niche indicates that point source contributions of organohalogens are unlikely. There have been no studies reported in the literature on the presence of these compounds in blue marlin or any other billfish species. It was therefore the objective of the present research to determine the identities and to quantify organohalogens in blue marlin liver samples.

Blue marlin liver samples were obtained from 9 female specimens caught off Puerto Rico, August 23-25, 1991. The fish were 137 ± 29 kg and 219 ± 24 cm long measured as lower jaw fork length. Estimated age were <10yrs. The liver samples were lyophilized, internal standard added (500ng decachlorobiphenyl) and approx 10g material Soxhlet extracted with dichloromethane (DCM) for 48h. A subsample of the extract was removed and lipid content determined gravimetrically. After volume reduction sample clean-up was by gel permeation chromatography (60g Biobeads S-X3 column, 5ml/min flow rate 1:1 mixture of DCM and cyclohexane, 130--250ml fraction retained) and Florisil chromatography (10g, pre-extracted, activated, column dry-packed and rinsed with hexane immediately prior to use, elution solvent 50ml 15% DCM in hexane, adapted from ref. 1). Samples were reduced in volume, solvent exchanged into hexane and a surrogate standard (1.4ug pentachlorobenzene) added immediately prior to analysis by GC-ELCD and ECNCI-GC-MS, methane = moderator gas. The GC-MS was an Extrel ELQ 400-2 quadrupole system and was used in the full scanning mode. Identifications were by GC-MS and quantification by GC-ELCD. Appropriate blank samples, (pre-extracted sand, a chicken egg to represent lipidous material and a glassware blank) were analysed in the same manner.

A wide range of organohalogens were observed. These included: industrial pollutants such as PCB; biocides including DDT and metabolites, hexachlorobenzene, chlordane, toxaphene, mirex; and combustion products such as dibenzofurans and octochlorodibenzo-p-dioxin. There were other currently unidentified chlorinated compounds. In addition there were numerous brominated compounds some of which were polybrominated diphenyl ethers, others are currently unidentified although one of the latter has also been reported as occurring in bottlenose dolphins from the Atlantic (2). The PCB congeners observed were similar to those seen in other environmental specimens and were mostly those encountered in Aroclor 1260. Congeners monitored were: 149/118, 153, 187, 183, and 170/190. Congener 180 was present but coeluted with a polybrominated diphenyl ether. Examples of typical PCB concentrations were: congener 138 = 4.9 - 100 ng/g liver dry weight or 26 - 420 ng/g extractable lipid; congener 153 = 7.2 - 170 ng/g liver dry weight or 38 - 710 ng/g extractable lipid. An estimate of the range of total PCB concentration, based on the contribution of the monitored congeners to Aroclor 1260, was 38 - 970/g liver dry wt. or 200 - 4000 ng/g extractable lipid. Total DDT + metabolites ranged from 17 - 270 ng/g liver dry wt.or 90 - 1100 ng/g lipid. Mirex concentrations were 2.2 - 51 ng/g liver dry wt. or 12 - 240 ng/g lipid. No organochlorinated compounds were encountered in any of the blank samples. The detection limit for individual compounds was <0.2ng/g sample. Recovery of the

internal standard, DCB, was 66 - 81 % with the blanks being within the same range as the samples. For the brominated compounds concentrations were more difficult to estimate because of the inability to identify some of the compounds and because of uncertainty over the number of bromine atoms present in each. It was, however, apparent that the brominated compounds represented a substantial portion of the organohalogens present in these samples.

These results are the first report on the occurrence of organohalogens in blue marlin, and, to the authors' knowledge, in any species of billfish. The organochlorinated compounds identified were typical of those encountered in environmental samples. It is unknown whether the concentrations observed are toxicologically significant to this species. Organobrominated compounds comprised a larger than expected component of the pollutant burden. Brominated diphenyl ethers have been typically used as flame retardents. There has been a prior report of contamination with brominated diphenyl ethers in a localized area (3). There has also been a report of naturally produced brominated diphenyl ethers but these are derivative forms (4). Little attention has been paid to brominated organic compounds but their presence in a wide ranging pelagic species suggests additional investigations are required

THE DETERMINATION OF ORGANIC VOLATILES IN THE VAPOR PHASE OF MESQUITE WOOD CHIP SMOKE AND MESQUITE CHARCOAL BRIQUET SMOKE BY THERMAL DESORPTION GAS CHROMATOGRAPHY - MASS SPECTROMETRY

V. Santillan and M.E. Castro*, Department of Chemistry, Texas A&I University, Kingsville, Tx. 78363

INTRODUCTION

Mesquite wood and mesquite charcoal briquets are very popular fuel sources in South Texas for outdoor grilling. The popularity arises from the unique flavor that mesquite imparts on various grilled meat products. Mesquite flavor can be acquired if the smoke produced from the combustion of the mesquite fuel source is adsorbed by the grilled meat product. In this study, the gas phase of mesquite wood smoke and mesquite charcoal briquet smoke was analyzed for volatile organics which may be possible flavor components of mesquite. The volatile organics were collected on an adsorbent tube and subsequently analyzed by thermal desorption gas chromatography - mass spectrometry. Volatile organics identified in both mesquite fuel sources were phenols, aromatic hydrocarbons, nitrogen heterocyclics, furans, and carbonyls.

EXPERIMENTAL

The glass adsorbent tubes used in this study were 11.5 cm X 6 mm o.d. X 4 mm i.d. packed with 250 mg of Tenax TA. A 37 mm glass fiber filter, type AE, in a polystyrene filter cassette blank was placed onto the inlet of the adsorbent tube and the outlet of the adsorbent tube was connected to a Dupont P125 personal air pump. The mesquite smoke source was generated by placing about 1 kg of the fuel source over an electric probe in an open outdoor grill. Household current heated the probe igniting the mesquite fuel source. The vapor collection system was placed about 1 foot from the mesquite smoke source; samples between 2 and 6 liters of air polluted with the mesquite smoke was collected.

The thermal desorption unit used in this study was a 4460A concentrator system from O.I. Analytical. The concentrator system was interfaced with a Hewlett Packard Model 5890 GC, which itself was interfaced with a Hewlett Packard Model 5970 mass selective detector controlled by a Chemstation. The GC column used throughout the study was an HP-5 50 m X 0.2 mm, 0.33 micron film.

Analysis was conducted by placing a sample tube on the heated block (300 degrees Celsius) of the thermal desorption unit. The collected organics were thermally desorbed into a He carrier gas stream (15 ml/min for 11 minutes) which transferred the organics to a second more narrow trap (stainless steel, 30.5 cm X 3.2 mm o.d. X 2.7 mm i.d., packed with Tenax/silica gel/charcoal) for rapid transfer to the GC - MS. The organics were thermally desorbed from the second trap at 250 degrees Celsius for 5 minutes. Operating parameters for the GC - MS system are depicted on both chromatograms (Figures 1 and 2).

RESULTS AND DISCUSSION

The main classes of compounds identified were phenols, aromatic hydrocarbons, furans, nitrogen heterocyclics and carbonyls. The major component identified in the mesquite wood smoke samples (Figure 1) was 3,5 dimethyl - 1H pyrazole (RT: 11.2 min.); it comprised about 27% of the sample. The most abundant phenol identified was 4 - methoxy phenol, 10.32% (RT: 16.9 min.), followed by phenol, 3.58% (RT: 14.5 min), 4 - methyl guaiacol, 2.36% (RT: 18.8 min), methyl phenols (RT: 16.1 min and 16.4 min), 1.90% and 1.67% respectively, 4 - ethyl guaiacol, 0.76% (RT: 20.2 min), and dimethyl phenol, 0.62% (RT: 17.8 min). The most abundant furan identified was 2 - methyl furan (RT: 5.5 min); it comprised about 4.9% of the sample collected. Other furans identified were 2,5 dimethyl furan, 1.78% (RT: 7.8 min) and benzofuran, 0.51% (RT: 15.1). Of the carbonyls identified, 5 - methyl furfural (RT: 14.3 min) was the most abundant comprising about 2.57% of the sample. Other carbonyls identified were cyclopentanone and 2 - furanyl ethanone. The most abundant aromatic hydrocarbon identified was toluene, 4.19% (RT:9.4 min), followed by benzene, 3.20% (RT: 6.8 min). Other hydrocarbons identified were ethylbenzene and xylenes. Only one pyrrole was identified, 1 - methyl - 1H - pyrrole (RT: 8.7 min); it comprised about 1.18% of the sample.

In contrast to the findings in the mesquite wood smoke samples, the major components in the mesquite charcoal briquet smoke samples (Figure 2) were toluene and benzene comprising 16% and 20% of the sample respectively. The minor components consisted of some which were identified in the mesquite wood smoke such as 2 - methyl furan, 1 - methyl - 1H - pyrrole, 3,5 - dimethyl 1H - pyrazole, phenol, and 4 - methoxy phenol. Additional components identified in the mesquite charcoal briquet smoke samples were naphthalene, 3.61% (RT: 18.9 min), 1 - methyl naphthalene, 1.28% (RT: 20.8 min) and 2 - ethenyl naphthalene, 0.61% (RT: 22.2).

Many researchers have concluded that phenols are the major contributors to wood smoke aroma. The major phenols which have been identified in wood smoke are phenol, guaiacol, syringol, and 4 - methyl guaiacol (1). According to some researchers, furans tend to soften

the smoky aromas associated with the phenolic compounds. Nitrogen heterocyclics and carbonyls have also been found to contribute to the wood smoke flavor (1,2); however, in this study few carbonyls were identified.

CONCLUSIONS

All organic compounds identified have been previously identified in other wood smoke (1,2). Identification of compounds was accomplished through library searches with the HP computer system. The low detection of carbonyls may have resulted from the lower detection limit of C_6 for the Tenax adsorbent. Those carbonyls identified had at least five carbon atoms; those which have been identified are generally of low molecular weight. Low breakthrough volumes for carbonyls may also account for the low detection. Guaiacol and syringol were the two major phenols not identified in this study. The absence of guaiacol may be due to its further decomposition to phenol and cresols. This may have also been the case with syringol. The two nitrogen heterocyclics identified, 3,5 - dimethyl 1H - pyrazole and 1 - methyl 1H - pyrrole probably resulted from the nitrogen content of the wood, both which may contribute significantly to mesquite wood smoke flavor (2).

Naphthalene compounds were the only polyaromatic compounds (PAC) identified in this study. It is possible that in the combustion of the briquets, higher temperatures were reached since the briquets had become self igniting; this was not observed for the wood chips. Combustion at higher temperatures would increase the tendency of formation of such compounds. Naphthalene is one of the lowest molecular weight polyaromatic hydrocarbons; therefore it has a greater probability of being in the vapor phase than higher molecular weight PAC. High molecular weight organics are usually adsorbed on particulate matter. The particulate fraction of the mesquite smoke was not studied.

Identifying volatile organics in wood smoke is quite difficult, but it has become much easier with the use of gas chromatography - mass spectrometry. The characteristic flavor associated with mesquite wood and other woods has yet to be resolved due to the numerous factors that can influence smoke composition. Still, there is something unique about mesquite wood and other woods, that give grilled meat products a unique flavor. Whether the combination and relative amounts of the compounds detected is characteristic of mesquite flavor requires much more research.

Evaluation of Various Derivatives for the Mass Spectral Confirmation of Glyphosate

*W. Miles, N. Snider, G. Malis
Agriculture Canada, Central Experimental Farm,
Ottawa, Ontario, Canada, K1A 0C6

Introduction

Glyphosate (GLP), N-(phosphonomethyl)glycine is a broad spectrum, nonselective, post-emergence herbicide which has become the largest selling weed killer in the world. Although its mammalian toxicity is relatively low (LD_{50}=1568 mg/kg) there are concerns about its effect on nontarget organisms and its use in areas where significant amounts can reach groundwater or other sources of drinking water. Due to its high polarity and structural similarity to naturally-occurring compounds like amino acids, determination at residue levels is very difficult. The present work was undertaken to develop a sensitive and specific method for the confirmation of Glyphosate using mass spectrometry.

Methods

Oxygen negative chemical ionization was done on a Finnigan 4500 quadrupole mass spectrometer equipped with a Townsend discharge source. All other mass spectra were obtained from a Finnigan MAT 90 using either the thermospray (TSP) probe or a Varian 3400 GC for sample introduction. TSP conditions for underivatized glyphosate were a mobile phase of 33% 0.2 M NH_4OAc, 33% H_2O and 33% MeOH with a flow rate of 1.2 ml/min and source 300°C. For the derivatives it was 40% NH_4OAc, 40% H_2O, 20% MeOH, flow 1.2 ml/min, source 300°C. GC/MS conditions were 30M DB-1301, 0.32mm ID capillary column, pressure 5 psi, source 200°C.

Results and Discussion

Because of Glyphosate's low volatility and high polarity, LC/MS was investigated as a potential method of analysis. Thermospray gave M+18 ions in positive and M-1 ions in negative mode but the low mass would be prone to interference from sample matrix and the sensitivity was poor (detection limit ≈ 1μg).

Derivatization was then tried to increase the molecular weight and improve sensitivity. A variety of reactions were investigated and the best sensitivity was obtained from the butyl esters reacted with fluorinated anhydrides. These gave molecular weight information by negative TSP but detection limits in the low nanogram region were judged inadequate and the derivatization is a tedious two step reaction.

Since TSP required derivatization to be of any use, GC/MS was investigated because of its greater potential sensitivity and ease of operation. The method of Deyrup et al.[1] (Figure 1) offered a single step reaction giving a volatile product suitable for GC/MS. Figure 2 shows the EI spectrum of this derivative and its detection limit. The extensive fragmentation is ideal for confirmation of identity. In order to further increase

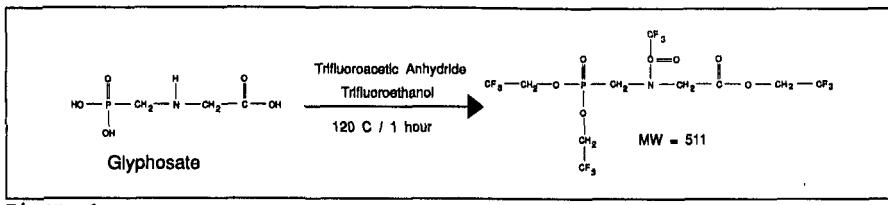

Figure 1

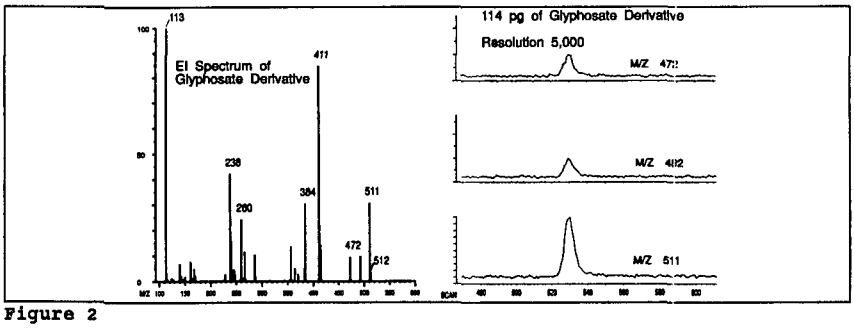

Figure 2

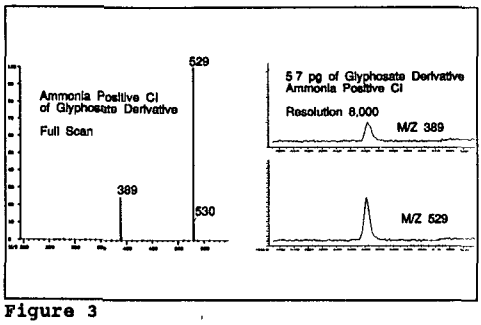

Figure 3

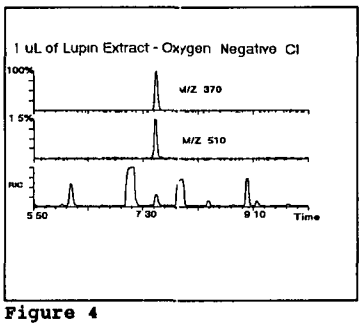

Figure 4

sensitivity, CI was investigated. Figure 3 shows detection levels in the low picogram range for ammonia positive CI with molecular weight information. Similar detection levels and molecular weight information are available with oxygen negative CI.

An additional benefit came from using a volatile derivative. The present ion exchange column clean-up method gives, in some cases, extremely dirty extracts which would quickly contaminate a capillary GC system. It was discovered that the derivative is sufficiently stable to be steam distilled and by use of a combined steam distillation/extraction apparatus, a clean sample with minimal work-up can be obtained. Figure 4 shows the chromatogram of a Lupin extract after steam distillation.

Conclusions

The TFAA/TFE derivative of glyphosate is easily prepared in a one step reaction, gives excellent sensitivity in chemical ionization, has high selectivity by capillary GC and its stability and volatility allow the use of steam distillation as a clean-up method.

Future

Deuterated glyphosate will be used as an internal standard to correct for losses in work-up and improve the accuracy of the method.

FT/ICR Mass Calibration Law, Including Relativistic and Image Charge Effects

Michael V. Gorshkov[§] and Alan G. Marshall[†]

Depts. of Chemistry (and Biochemistry[†]), The Ohio State University, 120 W. 18th Avenue, Columbus, OH 43210

[§] Visiting scientist from the Institute of Energy Problems of Chemical Physics, Russian Academy of Sciences, Leninsky Prospect 38, Moscow 117829, RUSSIA

Accurate mass measurement is extremely important for establishing chemical formulas of new or unknown compounds and for highly specific trace analysis. From the outset, it was clear that mass calibration of FT/ICR mass spectra is potentially highly precise because ICR orbital frequency can be measured with ultrahigh accuracy [1]. ICR mass accuracy at the 0.01 ppm level was achieved in 1984 for $^{28}Si^+$ mass measurements [2]. Recently, the $^{32}S^1H_4^+/^{12}C_3^+$ isotopic doublet ($m_2 - m_1 = 0.0034$ u) has been resolved at m/z 274 in a crude oil distillate [3]. The use of a superconducting solenoidal magnet with high homogeneous magnetic field (3-7 tesla) has led to routine mass measurement accuracy at the ppm level [4]. The most generally used mass calibration law is the one introduced by Ledford *et al.* [5]:

$$m = \frac{a}{\nu} + \frac{b}{\nu^2} \qquad (1)$$

in which the values of the constants, a and b, are determined empirically by measuring the ion cyclotron orbital frequency, ν, for at least two reference masses. Eq. 1 can be derived from Lorentz equation, taking into account the ICR orbital frequency shift arising from a quadrupolar trapping potential and space charge modeled as an axially symmetric ellipsoid of revolution. Mass accuracy may be further improved by (a) use of an elongated or screened trap, (b) ejection of unwanted ions, and/or (c) extrapolating to zero number of ions. However, even with these precautions, an ion cyclotron orbital radius-dependent systematic error remains (see Figure 1). Two components of that error are: (a) relativistic increase in ion mass with increasing ion velocity, and (b) force on an ion packet to due image charge induced by those ions on the electrodes of the trap. The measured ion cyclotron orbital frequency, ν, may thus be expressed as

$$\nu = \nu_c - \nu_m - \delta\nu_{space} - \delta\nu_{relativistic} - \delta\nu_{image} \qquad (2)$$

in which ν_c is the unshifted ICR orbital frequency in the limit of zero trapping potential and zero ion velocity, ν_m is the magnetron frequency (i.e., frequency shift due to trapping potential), $\delta\nu_{space}$ is the shift due to space charge, $\delta\nu_{relativistic}$ is the relativistic shift, and $\delta\nu_{image}$ is the shift due to image charge. For an infinitely elongated cylindrical trap, with ion charge distribution modeled as an infinitely extended line along the magnetic field direction (z-axis), it can be shown that [7]

$$\delta\nu_{rel} = C_1 \nu^3 r^2 \;; \qquad \delta\nu_{image} = \frac{C_2}{r_{trap}^2 - r^2} \qquad (3)$$

in which r and r_{trap} are the radii of the ICR orbit and the trap itself, and C_1 and C_2 are dimensional constants. Eq. 3 leads to a new mass calibration law:

$$m = \frac{a}{\nu} + \frac{b}{\nu^2} + c\nu \qquad (4)$$

in which the constant, b, accounts for magnetron motion, space charge, and image charge effects, and the constant, c, accounts for the relativistic effect. All three terms in Eq. 4 generally vary with ion cyclotron orbital radius. At large radius, the relativistic term dominates for light ions in low abundance (Figure 1A), whereas the magnetron effect can dominate for heavy ions in low abundance (Figure 1B). Space charge and image charge effects both increase with number of ions (Figure 2A-C, in which the number of ions is roughly proportional to the electron ionization period).

A Two-Electrode Ion Trap for FT/ICR Mass Spectrometry

Jarrod A. Marto, Lutz Schweikhard, and Alan G. Marshall†#

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 W. 18th Ave., Columbus, OH 43210

Fourier transform ion cyclotron resonance (FT/ICR) mass spectrometry is conventionally conducted with ion traps consisting of 3 to 6 or more electrodes. In this work, we report the construction and experimental test of a recently proposed[1,2] two-electrode trap. Each electrode is a hyperboloid of one continuous sheet, in a modified Penning arrangement: it is as if the two "end caps" are pushed to the center of the trap until they merge to become a continuous hyperbolic "core" or "spool" electrode, enveloped by the usual hyperbolic "ring". Excitation and detection of the cyclotron motion is performed in "parametric" mode, at a resonance frequency, $\omega_{para} = (\omega_+ - \omega_-)$, in which ω_+ and ω_- are the ICR orbital and magnetron frequencies. The trap geometry is shown in Figure 1.

The measured ICR orbital frequency in the two-electrode trap varied linearly with trapping voltage; the observed slope of -332.2 Hz/V is in excellent agreement with the calculated value of -334.1 Hz/V. The exactness of the quadrupolar potential was evaluated by observing the shift in ICR frequency as a function of ICR orbital radius. Over a wide range of excitation amplitude, represented as the product of excitation rf voltage (peak-to-peak) and excitation period, the ICR orbital frequency for benzene ($C_6H_6^+$) changed by a maximum of 13 Hz, a value which compares very favorably to our prior results for conventional hyperbolic and cubic ion traps (see Fig. 2).[3] .

In the two-electrode trap, ions are necessarily formed off-axis;thus, space charge effects are minimized, because the ions' magnetron drift will carry them around the cell annulus as they are formed. The ICR orbital frequency was determined as a function of the number of ions formed, in order to reveal space charge effects. As seen in Figure 3, the ICR frequency is virtually constant with number of $C_6H_6^+$ ions, varying by only 5 Hz over an ion formation period (i.e. electron beam duration) of 5-3000 ms. Again, these results compare favorably with those from both hyperbolic and cubic traps utilizing on-axis ionization.[3] In addition, both the radial and axial ejection characteristics of the two-electrode trap were investigated. In each case, the two-electrode trap behaved similarly to both hyperbolic and cubic ion traps.

Considering its near-perfect quadrupolar potential and "immunity" from space charge effects, the two-electrode trap should provide excellent mass accuracy. A comparison of mass calibration data (not shown) for several ionic fragments of perfluorotri-n-butylamine showed the two-electrode trap to be superior to both hyperbolic and cubic ion traps for accurate mass determinations. This work was supported by NSF (CHE-9021058) and The Ohio State University.

Image Charge-Induced Ion Cyclotron Orbital Frequency Shift for Orthorhombic and Cylindrical FT/ICR Ion Traps

Xinzhen Xiang, Peter B. Grosshans, and Alan G. Marshall†

Department of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, Ohio 43210

One of the most unique features of Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR/MS) is its capability of highly precise and accurate measurement of ionic mass. FT/ICR mass measurement errors at the sub-ppm level over a wide mass range have been reported by several research groups. In the presence of a quadrupolar electrostatic trapping potential and a homogeneous magnetic field, there exist three independent periodic motions: the ion cyclotron orbital motion at frequency, ω_+; magnetron motion at frequency, ω_-; and trapping oscillation at frequency, ω_z, interrelated according to

$$\omega_\pm = \frac{\omega_c}{2} \pm \sqrt{\left(\frac{\omega_c}{2}\right)^2 - \frac{\omega_z^2}{2}} \qquad [1]$$

At a higher level of precision, magnetic field inhomogeneity, higher than second-order terms of the electrostatic trapping potential, Coulomb repulsions between ions of like charge and like or unlike mass, and relativistic frequency shifts must be incorporated.

In addition, a coherently orbiting ion packet induces on the ion trap electrodes an image charge whose image electric field shifts the ICR orbital frequency. Prior workers have calculated the image charge produced by a point charge on pair of grounded parallel plates [1] or a conductive sphere [2,3], or the induced image charge resulting from charge distributed uniformly along the central axis of a conductive cylinder extended infinitely along the direction of the applied magnetic field [4]. Although qualitatively useful, none of these approaches realistically models an actual ICR ion trap, which typically consists of six electrodes in tetragonal or cylindrical arrangement.

In this work, we calculate the image charge induced by an ion on a finite-dimension orthorhombic or cylindrical trap. We solve Poisson's equation for the geometry under consideration, and compute the surface charge density induced on the conductor from the potential inside the trap, which is in turn obtained by Green's function methods [5]. Next, we employ a formula for the inward pressure exerted on a differential element of induced surface charge by the point charge; integration of this pressure over the entire interior surface of the conductor yields the net force on the conductor due to the point charge. By Newton's second law, that force must be equal and opposite to the net force exerted on the point charge by the conductor. Finally, the radial electric force on an ion is incorporated into the Lorentz force equation to determine the magnitude of the image charged-induced ion cyclotron orbital frequency shift as a function of the ion position. Figure 1 shows the calculated cyclotron frequency shift *vs.* cyclotron orbital radius for cubic (left) and cylindrical (right) traps, and Figure 2 shows the cyclotron frequency as a function of ion axial position for cubic (left) and cylindrical (right) traps. The frequency shift increases dramatically as the cyclotron radius approaches the trap boundary. For a cubic trap, the mass-independent frequency shift at ICR orbital radius equal to half the trap radius is ~10^{-5} Hz for one ion. Thus, image charge-induced frequency shifts in the ppm range can be expected for typical ICR experiments involving 10^3-10^5 ions at low mass-to-charge ratio ($60 \le m/z \le 600$), whereas the shift can increase to ~1 u for 100,000 singly-charged ions at $m/z = 3000$ at 3.0 tesla. The image charge-induced shift for a cylindrical trap is higher than for a cubic trap of comparable size. Implications for mass calibration are discussed. This work was supported by NSF (CHE-9021058), N.I.H. (GM-31683), and The Ohio State University.

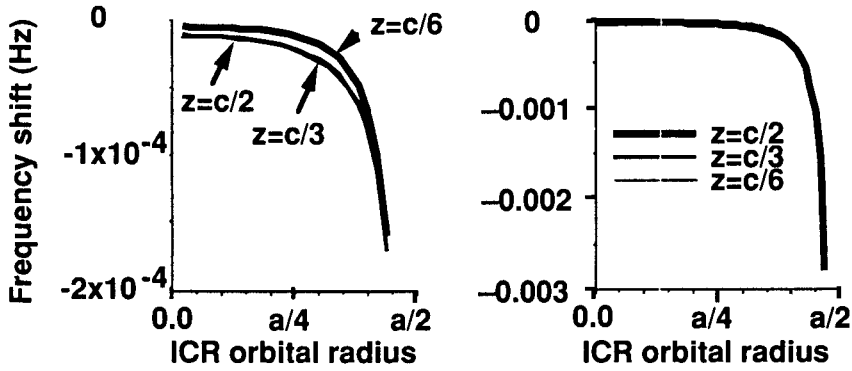

Figure 1. Calculated image charge-induced ion cyclotron orbital frequency shift as a function of ion radius for cubic (left) and cylindrical (right) ion traps, at each of three axial positions (z = c/6, c/3, and c/2), in which z = c/2 is the trap midplane.

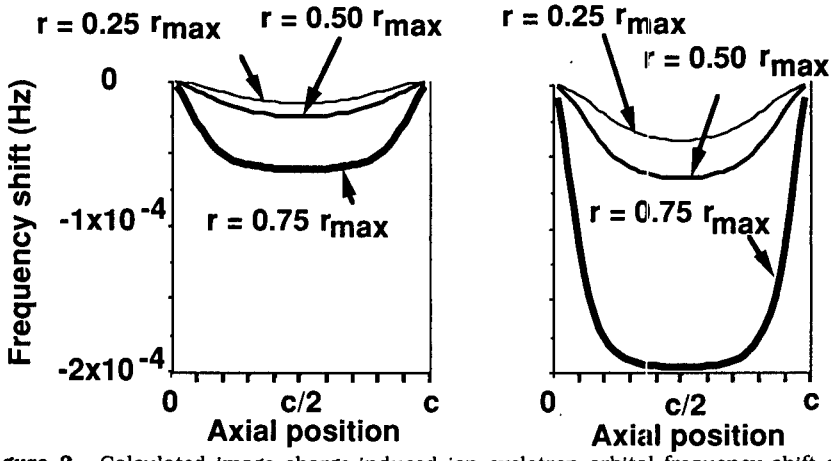

Figure 2. Calculated image charge-induced ion cyclotron orbital frequency shift as a function of axial position for cubic (left) and cylindrical (right) ion traps, at each of three radial positions (r/r_{max} = 0.25, 0.50, and 0.75). (Same vertical scale in both plots)

Linearized FT/ICR/MS Excitation and Detection with a Cubic Ion Trap

Ruidan Chen, Peter B. Grosshans, Patrick A. Limbach, Shenheng Guan and Alan G. Marshall†

Departments of Chemistry (and Biochemistry†), The Ohio State University, 120 West 18th Avenue, Columbus, OH 43210

Addition of "guard rings" connected by a purely resistive voltage-divider network provides for very nearly uniform rf excitation electric field in Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR/MS).[1] By the principle of electrostatic "reciprocity", the same electrode arrangement should provide for near-perfect linear detection as well. However, purely resistive coupling can result in dissipation of ICR signal power through the resistors, with consequent reduction in the observed ICR signal. A design for a finite ion trap which uses only one pairs of plates to linearize simultaneously the excitation electric potential field and the differential charge induced between them has been presented previously.[2] Here, we show that a one-inch cubic ion trap, designed and constructed with a series of adjacent guard rings connected by RC (rather than purely resistive) networks, provides both linear excitation and linear detection (see Figure 1). A relay switch provides for switchover between excitation and detection events, with minimal insertion loss and virtually complete isolation between the excitation and detection channels. The RC components are bakeable, and no significant chemical background is introduced by the additional circuit components.

Experimentally, we observe that: (a) harmonics and sidebands are completely eliminated from the FT/ICR mass spectrum (see Figure 2); (b) the response of the detector is highly linear (e.g., linear increase in mass spectral peak height for $C_6H_6^+$ with increasing excitation amplitude or period), over a wide range of experimental conditions; (c) z-ejection is virtually eliminated, as evidenced by the ICR orbital radius-independence of relative peak heights of ions of different mass-to-charge ratio (see Figure 3); moreover, pre-irradiation at twice the trapping frequency produces virtually no z-ejection compared to that obtained with a conventional cubic trap.

The presently reported experimental results demonstrate the validity of the linearized trap design, and open up several future research directions.[3] For example, with a linearized trap, ion relative abundances may be determined quantitatively; ions are excited to much more uniform orbital radius (and thus more uniform kinetic energy for C.I.D. or MS/MS experiments); radial loss of ions during excitation is minimized; and analysis of peak splitting and other lineshape anomalies is greatly simplified.

We thank T. L. Ricca and T. Hickey for their help in the trap design. This work was supported by NIH (GM-31683), NSF (CHE-9021058), and The Ohio State University.

Stored Waveform Ion Modulation (SWIM) for Two-Dimensional FT/ICR Mass Spectrometry

Charles W. Ross III, Shenheng Guan, Peter B. Grosshans, Tom L. Ricca‡ and Alan G. Marshall†

Department of Chemistry (Department of Biochemistry†; Campus Chemical Instrument Center‡), The Ohio State University,
120 West 18th Avenue, Columbus, OH 43210

Fourier transform ion cyclotron resonance mass spectrometry (FT/ICR/MS) offers high resolution, wide mass range, and the ability to manipulate trapped ions for collision-induced dissociation, MS/MS, and determination of ion-neutral reaction pathways, kinetics, equilibria, and energetics. However, establishing a given ion fragmentation or reaction pathway optimally requires isolation of that ion (e.g., by ejection of ions of all other m/z) followed by a reaction period and then broadband excitation/detection of the various product ions. Thus, the FT multiplex advantage is available for the product ions, but not for the various possible parent ions.

Two-dimensional FT/ICR/MS, introduced by Pfändler *et al.*,[1,2] can potentially identify simultaneously *all* ion-neutral reactions in a single automated experiment. The familiar one-dimensional mass spectrum appears as peaks rising out of the plane of the paper along the diagonal of the two-dimensional display. Off-diagonal peaks result from forward (on one side of the diagonal) and reverse (on the other side of the diagonal) ion-neutral reactions. In the original 2D-FT/ICR/MS experiments, the speeds of primary ions of various mass-to-charge ratios are modulated by use of two excitation pulses whose time-separation forms the time-scale for the second dimension of Fourier transform. The abundances of secondary ions following a fixed delay period (reaction time) after the two-pulse excitation are then modulated at the same modulation frequencies as the primary ions from which they came.

Here we show that parent ion cyclotron orbital radii (and thus parent ion speeds, hence the relative abundances of product ions formed by ion-neutral reactions of those parent ions), may be modulated by applying a series of sinusoidal *single*-pulse excitation magnitude-mode stored inverse Fourier transform waveforms of increasing frequency over a given bandwidth (Figure 1). This approach was originally proposed by Williams and McLafferty,[3] and we are now able to report its first experimental implementation.

We have applied the new stored waveform ion modulation (SWIM) 2D-FT/ICR technique to two chemical systems (acetone and pyrrolidine/3-methylpyridine). Figure 2 shows the ion-molecule reactions of pyrrolidine and 3-methylpyridine with a reaction period of 150 ms. Ten transients were coadded for each of the 512 4K time domain data sets acquired. The off-diagonal peaks allow for the simultaneous identification of five ion-molecule reactions from this single automated experiment. (The off-diagonal connectivities are seen much more clearly in an enlargement of the 2D array—not shown.) This work was supported by NIH (GM-31683), NSF (CHE-9021058) and The Ohio State University.

Methyl Guanine Isomer Differentiation Using Ion/Molecule Reactions and Collision Activated Dissociation in a Fourier Transform Mass Spectrometer.

*B.D. Nourse, R.L. Hettich and M.V. Buchanan
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120*

The development of techniques for structural characterization of DNA adducts is essential in fully understanding their biological effects. Because biological activity depends on the isomeric structure of the adduct, it is necessary to not only establish the identity of the adduct, but also to determine the position of the adduct attachment to the nucleoside and the sequence position of the modified nucleoside in an oligomer. In the present study, laser desorption-ionization, collision activated dissociation (CAD) and ion/molecule reactions have been employed in the Fourier transform mass spectrometer (FTMS) to determine the site of methyl alkylation to guanine.

Laser desorption-ionization of guanine and 1-, N^2-, 3-, O^6-, 7-, 8- and 9-methyl guanine (see Figure 1 for numbering system) gives abundant protonated molecular ions. Differentiation of the isomers has been accomplished by monitoring gas phase hydrogen/deuterium (H/D) exchange reactions of the $(M+H)^+$ ions with D_2O. The results from this study are summarized in Table 1. The first column represents the number of H/D exchanges observed for each isomer. The second column shows the reaction time at which the ion signal ratio of $(M+H)^+$ to $(M+D)^+$ is 1:1, which can be qualitatively related to the rate of the first H/D exchange process. With the exception of 1- and 9- methyl guanine, complete isomer differentiation can be made either by comparison of the number of exchanges observed, the rate of the first H/D exchange or a combination of both.

The number of H/D exchanges observed in each case can be explained if one assumes position 7- as the most probable site for protonation, with positions 3- and O^6- as the next most likely sites of protonation [1-3]. Upon analysis of the resonance structures for these protonated species, a total theoretical number of H/D exchanges varies from 2 to 5 (for guanine) depending on the site of protonation; the number of H/D exchanges possible changes, as expected, upon methylation of a particular site. H/D exchange experiments

Guanine

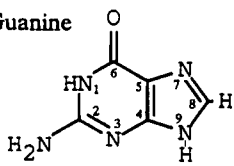

Figure 1

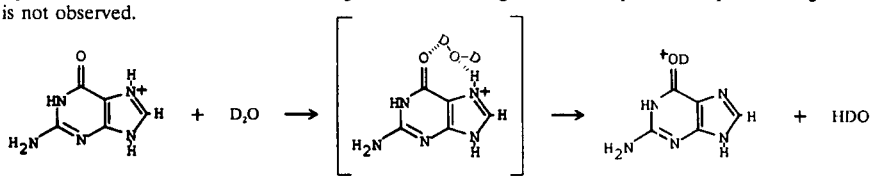
Table 1
Hydrogen/Deuterium Exchange Results For The Reaction of D_2O With The Methyl Guanine Isomers

Isomer	Experimental # H/D Exchanges	Rxn. Time (sec.) when $[(M+H)^+]:[(M+D)^+]$ is 1:1
Guanine	3	0.4 ± 0.2
1-Methyl-guanine	2	0.3 ± 0.1
N^2-Methyl-guanine	3	0.7 ± 0.1
3-Methyl-guanine	1	2.5 ± 1.0
O^6-Methyl-guanine	1	6.0 ± 1.0
7-Methyl-guanine	2	6.3 ± 1.7
8-Methyl-guanine	3	0.4 ± 0.1
9-Methyl-guanine	2	0.2 ± 0.1

are believed to occur through a concerted reaction mechanism (Reaction 1) for guanine and 1-, N^2-, 3-, O^6-, 8-, and 9-methyl guanine. The slower reaction rates observed for 3-, O^6- and 7-methyl guanine are attributed to structural differences which influence the most probable site(s) of protonation and, thus, the mechanism for exchange. For example, in the case of 7-methyl guanine, the methyl group is blocking the most probable site of protonation; therefore, the concerted mechanism illustrated in Reaction 1 is not available, hence, the H/D exchange reaction is expected to be slower. For 7-methyl guanine, both proton abstraction and deuterium cation attachment are believed to occur at positions 3- and O^6-, which results in a total of two H/D exchanges, as observed. All of the experimental data gives evidence that the N^2- and 8- position hydrogen atoms are not involved in the H/D exchange processes. For example, upon comparison of N^2- and 8-methyl guanine with guanine, all show the same number of and rate of H/D exchange. If the N^2- and 8- position hydrogen atoms were involved in H/D exchange, one less exchange would be expected compared with guanine; this is not observed.



Reaction 1

Further isomer distinction can be obtained upon analysis of the CAD spectra for the barium adduct ions, $(M+Ba-H)^+$. The CAD spectra show at least one unique CAD fragment ion, or group of ions, for each of the seven isomers; a selected portion of the experimental results is shown in Table 2. The high resolution and accurate mass measurement capabilities of the FTMS allow for determination of the identity of each neutral loss as well as the empirical formula for each CAD fragment ion. O^6-Methyl guanine (Table 2), for example, shows neutral losses of CH_3NH_2 and CH_3OH upon CAD of the barium adduct ion while 8-methyl guanine shows losses of NH_3 and H_2O.

Table 2

CAD Spectra for the Barium Adduct Ion ($(M+Ba-H)^+$) of Guanine and Selected Methyl Guanine Isomers.

Ion	Guanine	1-Methyl guanine	O^6-Methyl guanine	8-Methyl guanine
Ba^+	X	X		X

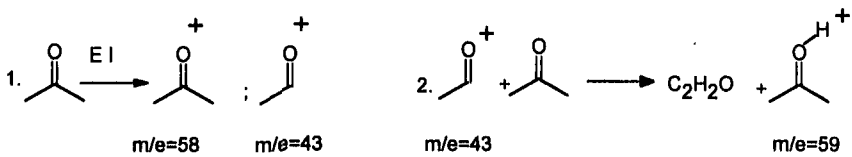
Study of Nonmetal Fluoride Ion-Molecule Reactions by ICR Spectrometry

M.Paul and K.P. Wanczek,

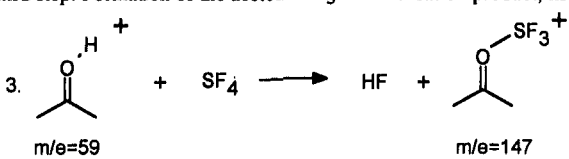
Inorganic Chemistry, Universtity Bremen, D-28 Bremen 33

Reactions of SF_4 and BF_3 are studied with ketone, aldehyde alcohol and amine. All experiments are performed on a modified CMS 47 ion cyclotron resonance spectrometer equipped with a 7 tesla superconducting solenoid magnet and a 192K ASPECT 3000 micro computer. For the study of the reactions we designed a computer (IBM compatible 386) controlled pulsed inlet system.The inlet system allowes to pulse up to six separate neutral compounds into the ICR-cell. The pressure for each sample can be varied with in the range of 10^{-9} - 10^{-5} mbar. The pulse length can be varied within the necessary reaction time. Fig. 1shows the pressure pulse (1st acetone,2nd SF_4) for the reaction of acetonium ions and SF_4. The reaction path of SF_4 with acetonium is proved by double reconance experiments and isotopic labelling of actetone.

First step: Formation of the ion m/e=43. Second step: Generation of the acetonium ion, m/e=59.



Third step: Formation of the acetone-SF_3^+ condensation product, m/e=147.



Similar reactions are found with other ketones, as example cyclohexanone, butadienone and 1,1,1 trifluoroacteone. Diketones like acetylacetone and 1,1,1-trifluoractetylacetone show also condensation reactions.

The reaction of aldehyde ions with SF_4 show a similar mechanism. We observe condensation of protonated aldehyde and molecular ion. Alcohol and amine show no condensation but adduct formation. In Table 1 presents experimental results of the observed reactions.

Further we modified the degree of fluorination of acetonium ions to get information about the reaction mechanism. With the aid of AMPAC 1.0 program charge sites and formation enthalpies of the fluorinated acetonium ions are calculated. Calculated formation enthalpies are compared with experimental results[1]. By increasing degree of fluorination the positive charge of the carbonyl carbon increases. Aetone derivatives with up to three fluorine atoms show condensation reaction. At higher fluorination no condensation reaction is observed.

From our results we propose the reaction of SF_4 and BF_3 as highly **selective** for alcoholes, aldehydes, ketones and amines. The reactions can be utilized for the recognition of these groups.

Tab.1 **Condensation** reactions with SF_4 **Adduct formation** with SF_3^+

Name of ion		SF_4	Neutral		SF_3^+
Propanal	$CH_3CH_2CHO^+$	+	Propanal	CH_3CH_2CHO	-
Propanalium	$CH_3CH_2CHOH^+$	+			
Diethylamonium	$(CH_3CH_2)_2NH_2^+$	-	Diethylamin	$(CH_3CH_2)_2NH$	+
Propanolium	$CH_3CH_2COH_2^+$	-	Propanol (2)	C_3H_7OH	+
Acetonium	$CH_3COCH_3\text{-}H^+$	+	Acetone	CH_3COCH_3	-

Simultaneous Detection of Cl^+ and Cl^- Ions in One FT-ICR Cell through Single Mass Scanning

Y. Wang and K. P. Wanczek
Inorganic Chemistry, NW2, Bremen University,
D-2800 Bremen 33, Germany

FT-ICR mass spectrometer possesses the advantage of high mass resolution and multichannel function. However, it does not have the capability of detecting ions with same mass but different charges through single mass scanning because it cannot simultaneously store positive and negative ions.

On the basic of the previous works of storing the positive and negative ions in one FT-ICR cell, the method and technique of measuring Cl^+ and Cl^- ions are studied. With the calculation, the mass difference for the same mass number but different charges is two electrons mass

$$m_{[A^-]} - m_{[A^+]} = 2m_e = 0.00109716\,\text{amu}$$

and corresponding cyclotron frequency for positive ions is ω_0^+, for negative ions is ω_0^-,

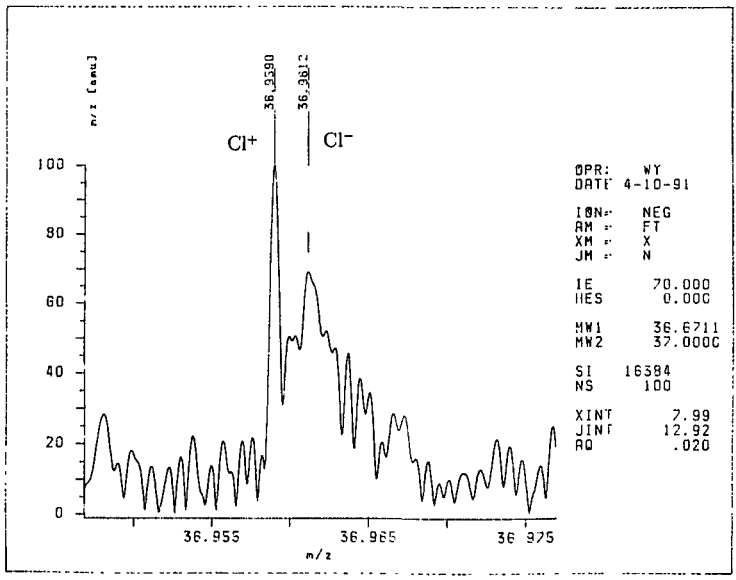
$$\omega_0^+ \approx \omega_c^+ - \frac{E_0}{B_0}$$

$$\omega_0^- \approx \omega_c^- - \frac{E_0}{B_0}$$

$$\omega_c^\pm = \frac{qB_0}{m_{[A^\pm]}}$$

where E_0 is the electric field and B_0 the magnetic field in the cell.

The experiments were performed with Spectrospin CMS 47 FCR spectrometer. The mixed gas material CH_2Cl_2 and C_2Cl_4 are selected as testing samples. Experimental results show that there are voltage condition for Cl^+ and Cl^- ions to be stored simultaneously in the cell. Fig. 1 shows the mass spectrum of Cl^+ and Cl^- ions.



A Method of Rate Constant Measurement in FT-ICR Pulsed Valve Experiments

Yi Lin, G. R. Nicol, D. P. Ridge, Department of Chemistry and Biochemistry, University of Delaware, Newark, Delaware 19716

Introduction Sample introduction through a pulsed-valve in FT-ICR is particularly useful in characterizing the reactivity of gas phase ions. However, rate constant measurements using the pulsed valve technique are complicated by the pressure changes which occur rapidly after the opening of the pulsed valve. As the valve opens, the pressure in the reaction chamber typically climbs immediately to ca. 10^{-6} Torr. Over a decay time of ~ 0.4 sec, the pressure in the reaction chamber drops to $\leq 1 \times 10^{-8}$ Torr. We describe here a method to overcome that complication.

Experimental The experiments were done using an FTMS 2000 (Extrel, Madison, WI) dual cell FT-ICR instrument. The pulsed valve inlet consists of a pair of solenoid operated valves connected by a stainless steel tube 1/2" long and 1/4" O.D. The tube serves as a reservoir that fills from a ca. 100 cm^3 storage volume when the first valve opens. The tube-reservoir then empties into the analyzer vacuum chamber when the second valve opens. The first valve is opened for 15 ms and after a 15 ms delay the second valve is opened. This gives reproducible injections of gas into the high vacuum system. The pressure in the storage volume is measured using a Convectron (Granville Phillips, Boulder, CO) gauge.

Kinetic Analysis The procedure is illustrated for the reaction of Re_2^+ with cyclohexane,

$$Re_2^+ + C_6H_{12} \rightarrow Re_2C_6H_6^+ + 3H_2 \qquad (1)$$

Re_2^+ was formed by 70 eV electron impact on $Re_2(CO)_{10}$ in the source and transferred into the analyzer. The number density of c-hexane, n(t), is time dependent after the pulsed valve opens. The concentration of the reactant ion, $[R^+]$, is related to the time dependent number density of the neutral, n(t), by

$$d[R^+]/dt = k\,[R^+]\,n(t) \qquad (2)$$

where k is the reaction rate constant. Integrating (2) gives (3)

$$\mathrm{Ln}([R^+_n]/([R^+_n]+[P^+_n])) = k\int_0^{t_n} n(t)dt \qquad (3)$$

where $[P^+_n]$ and $[R^+_n]$ are the reactant and product ion concentrations at time t_n, t = 0 is the time that the pulsed valve opens and $t = t_n$ is the time at which the ions are excited for detection. The ratio of the ion concentrations is taken as the ratio of the ion signal intensities, $R_n^+/(R_n^+ + P_n^+)$, such as those plotted in Fig.(1). Thus the left hand side of Eq.(3) can be determined at each value t_n of the reaction time t. If the integral of n(t) on the right hand side of Eq.(2) can be determined for each t_n, the rate constant can be determined from a plot of Ln $[(R_n^+/(R_n^+ + P_n^+)]$ against the integral of n(t).

Pressure Profile Determination The sequence in Fig.2 is used in determining the time dependent density of the reactant neutral. The time dependent number density n(t) is sampled by determining the total ion signal $I(t_n)$ in spectra resulting from pulsing the electron beam on at various delay times t_n after opening the valve. Reactant gas is admitted to the analyzer region when the pulsed valve opens. After a variable delay, the electron beam is turned on for 0.005 s, ionizing the reactant gas. The delay time between opening the valve and the electron beam pulse is typically varied in 0.03 s intervals from 0 to 0.4 s. The number of ions formed at each delay time was taken as proportional to the total ion signal of a spectrum obtained 2 seconds after the electron beam pulse when the gas admitted by the pulsed valve has been pumped away. The total ion signal, I(t), at each sampling time t_n is plotted against t_n for cyclohexane shown in Fig.3. The $I(t_n)$ are fit to an analytic function to give I(t) which can be integrated to give a kinetic variable comparable to pressure at fixed time or time at fixed pressure. The neutral number density n(t) is related to I(t) by $n(t) = (B/\sigma)I(t)$, where σ is the ionization cross section of reactant gas and B is an instrumental sensitivity factor proportional to the electron beam current, the cell length, the excitation voltage and the amplifier gain. Substituting $n(t) = (B/\sigma)I(t)$ gives

$$\ln\frac{[R_n^+]}{[R_n^+] + [P_n^+]} = (B/\sigma)k\int_0^{t_n} I(t)dt = (B/\sigma)kH(t_n) \qquad (4)$$

where $H(t_n)$ is the integral of the total signal I(t). To obtain the rate constant from such an exponential decay the ionization cross section of the neutral and the overall sensitivity of the instrument must be known. The latter can be determined by examining a reaction of known rate constant.

Test of the Method From Eq. (4) a logarithmic plot of the fraction of R that remains after time t_n vs. $H(t_n)$ should thus be linear with a slope Bk/σ. This is illustrated for the reaction of Re_2^+ with cyclohexane in Fig.(4). The data in Fig.(4) are equivalent to data obtained at fixed pressure and variable reaction time in the sense that a linear logarithmic plot indicates that all the ions react with a single rate constant. The linearity of the plot indicates not only that all the ions react with a single rate constant, but also that the present method of analysis is correct.

Figure 1 Relative intensity of Re_2^+ vs. time after opening the pulsed valve to admit c-hexane.

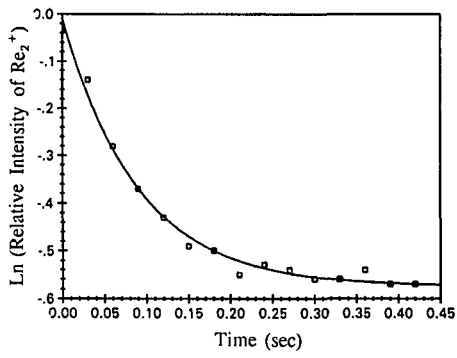


Figure 2 Experimental sequence used in determination of the total intensity I(t).

Time (sec)	Functionality
2	Clean up the analyzer cell
0.015	Pulsed valve open
0 ~ 0.4	Variable delay, pressure changing
0.005	Beam time for ion formation
2	Delay time
0.005	Ion detection

Figure 3 c-Hexane pressure profiles as indicated by the total ion signal intensity I(t) vs. time after pulsed valve opens. Electron beam current, energy and pulse duration are 2 μA, 70 eV and 5 msec.

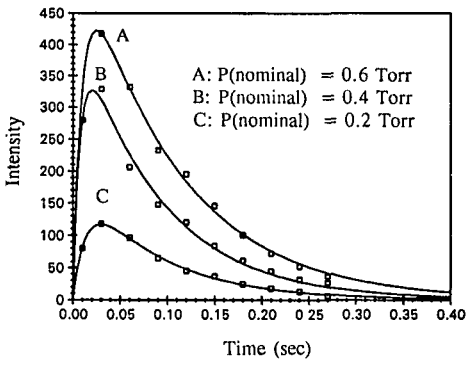

Figure 4 Relative intensity of Re_2^+ vs. $H(t_n)$ after opening the pulsed valve to admit c-hexane.

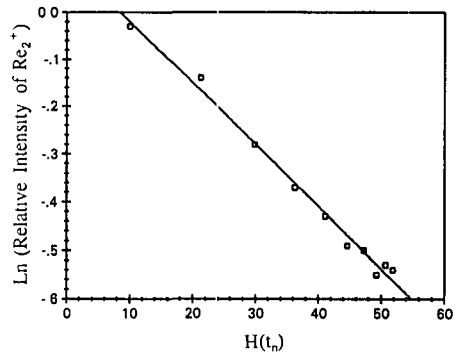
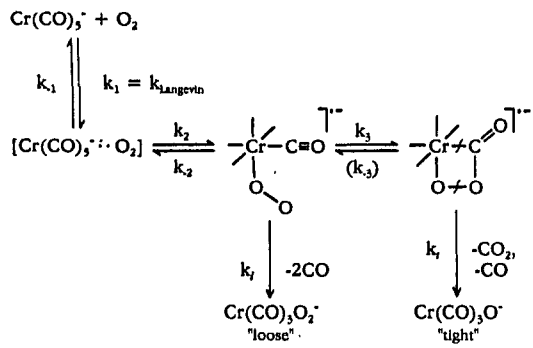


Reactions of Vibrationally Excited Chromium Pentacarbonyl Anion with Molecular Oxygen

*Brian T. Cooper, Kimber L. Wilson, and Steven W. Buckner
Department of Chemistry, University of Arizona, Tucson, AZ 85721.

The reactions of $Cr(CO)_5^-$ with O_2 have been the subject of a number of recent Fourier transform ion cyclotron resonance mass spectrometry (FT-ICR)[1,2] and flowing afterglow (FA)[3] investigations. The primary reaction products are found to be $Cr(CO)_3O_2^-$ and $Cr(CO)_3O^-$, and a mechanism similar to that shown in Scheme I is typically invoked to account for these branching pathways.

Scheme I:



Bricker and Russell[1] noticed in their FT-ICR experiments an "unusual temperature dependence" of the primary reactions, reporting an order-of-magnitude increase in the rate when the inlets were heated and ultimately attributing this enhanced reactivity to a high-energy, high spin state of $Cr(CO)_5^-$ that forms upon ionization of thermally decomposed $Cr(CO)_6$. This notion is further supported by the much smaller increase in rate they observed for the translationally excited reaction.

In this paper, FT-ICR is used along with near-infrared Nd:YAG laser photoexcitation to study the effect of vibrational (as opposed to the hypothesized electronic) excitation of $Cr(CO)_5^-$ on its reactions with O_2. Power dependence studies and collisionless relaxation experiments show that $Cr(CO)_5^-$ absorbs 1064 nm radiation (perhaps through a ligand-field transition), and internally converts to a vibrationally excited ground electronic state that will only dissociate to lose a carbonyl upon timely absorption of a second photon. If the cross sections for absorption of the first and second photon are equal or nearly so, the fraction of remaining $Cr(CO)_5^-$ ions that have absorbed one photon (and are thus vibrationally excited) can be estimated from the extent of dissociation using a Poisson distribution. This source of highly excited ions proves to be a useful tool for investigating the internal energy dependence of these reactions. Two such experiments and their results are shown on the next page.

Future work in this area includes the development of the red (visible) and near-infrared photochemistry of an assortment of metal carbonyl species. The internal energy dependence of related ion-molecule reactions will be studied by the same technique for several other ions already known to undergo two-photon dissociation.

(3) Lane, K.; Sallans, L.; Squires, R.R.; *J. Am. Chem. Soc.* **1984**, *106*, 2719.

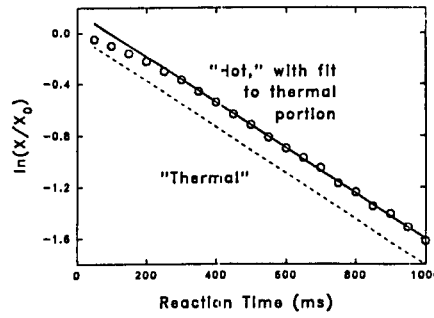

Figure 1: "Return to Overall Thermal Rate" Experiment: Kinetic plot (open circles) for the "hot" reaction of $Cr(CO)_5^{-*}$ (initially ~45%) and $Cr(CO)_5^-$ (initially ~55%) with 1.2×10^{-6} Torr O_2. The best fit to the "thermal" data (dashed line) is included for comparison with the fit to the thermal part of the hot reaction (solid line). Note that the reaction slows down as the average $Cr(CO)_5^-$ internal energy increases, due to a decrease in the lifetime of the collision complex as the rates of the back reactions increase (see Scheme I).

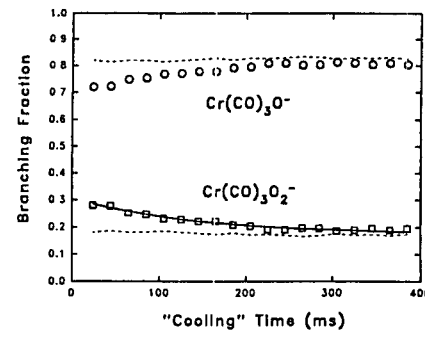

Figure 2: "Return to Thermal Branching Ratio" Experiment: The branching fraction of the two primary reaction products (determined in this case after a constant reaction time of 20 ms) is measured as a function of the time allowed for the hot ions to "cool" before the starting time of the reaction is defined by ejection of any product ions that have formed in the meantime. A first-order "relaxation rate constant" can be found at each pressure by fitting (solid line) the characteristic curve to an exponential. (The O_2 pressure for this plot is 1.2×10^{-6} Torr; radiative relaxation is probably somewhat significant.) The shift in branching ratio identifies $Cr(CO)_3O_2^-$ as the kinetically favored product (formed through a "loose" transition state) and $Cr(CO)_3O^-$ as the thermodynamically favored product (formed through a "tight" transition state), as shown in Scheme I.

Table I: Internal Energy Dependence of the Primary Reactions of $Cr(CO)_5^-$ with 1.2×10^{-6} Torr O_2

$Cr(CO)_5^-$ Internal Energy	$k_{obs'd}$ (s^{-1})		
	k_{eff} (both paths)	$e_i k_i$ (-2CO)	$e_i k_i$ (-CO_2, CO)
"thermal"	1.76 ± 0.02	0.31 ± 0.01	1.45 ± 0.02
"hot"	0.35 ± 0.10	0.11 ± 0.08	0.24 ± 0.07
thermal/hot	5.0 ± 1.4	2.8 ± 0.8	6.0 ± 1.8

(Note: the overall *bimolecular* rate constant measured for the thermal reaction is $(5 \pm 1) \times 10^{11}$ cm^3 $molecules^{-1}$ s^{-1}; first-order rate constants are presented here for the sake of simplicity)

Oak Ridge National Laboratory, P.O. Box 2008, Oak Ridge, TN 37831-6365

INTRODUCTION

Matrix-assisted laser desorption (MALD), which has been proven to be an effective ionization technique for biological molecules, has been implemented on a quadrupole ion-trap mass spectrometer (ITMS). In the instrumental configuration used for this work both the sample probe and laser beam are brought through holes in the ring electrode, thereby enabling MALD generated ions to expand directly into the ion-trap cavity. This *in situ* is approach is advantageous because the entire distribution of ion trajectories and kinetic energies are made available for trapping. In the case of external ion injection, ion focusing lenses can only be expected to channel a portion of the distribution of species into the ion trap. On the basis of detection limits alone, *in situ* generation of MALD derived ions proves to be an effective instrumental approach. For example, detection limits in the single-unit femtomole regime have been achieved for small polypeptides such as leucine enkephalin, bradykinin, and neuromedin U-8. One limitation that currently exists is an unanticipated drop in sensitivity and resolution as the mass/charge ratio for ions approaches 6000 (Table 1). The drop in sensitivity might be due in part to an upward shift in ion kinetic energy distribution leaving fewer ions with the proper range of kinetic energies for trapping. This kinetic energy shift is a consequence of the MALD process resulting from gas dynamic acceleration of species with higher molecular weights. Further studies reveal that this concomitant drop in sensitivity and resolution is also a manifestation of certain ITMS parameters.

EXPERIMENTAL

Experiments were performed using a Nd:YAG laser (Quanta-Ray, DCR-2A) and a Finnigan ITMS. The Q-switched, frequency-quadrupled output (266 nm) from the laser was first directed through a 3-mm aperture and attenuated before it was finally focused with a 45-mm focal length lens into the ITMS. Modifications to the ion trap ring electrode included drilling two horizontally aligned holes that permitted the laser beam to pass radially through the trap cavity. MALD was performed *in situ* by inserting the sample probe through the hole opposite the impinging laser beam. Typical laser power densities at the probe surface were estimated to be 1×10^6 W/cm^2. To aid high-mass measurement, the standard ITMS detector was replaced with a high-voltage conversion dynode unit from a Finnigan TSQ-700. The dynode of the replacement detector was operated at -10 kV. The uncorrected, static bath gas (helium) pressure in the vacuum housing was typically 1.0×10^{-4} Torr.

RESULTS AND DISCUSSION

To gain further insight into the MALD/ITMS combination, the action of capturing ions (referred to as "trapping") was distinguished from storing ions once their trajectories had been stabilized via collisionally cooling (referred to as "storage") by temporal separation of the processes.

The effect of rf trapping level during laser desorption was studied for several polypeptides by holding the rf level during and 5 ms after desorption at a range of values that corresponded to a low-mass cutoff of 50 to 600 m/z. The rf amplitude was then either raised or reduced to a storage level of 2308 V (low-mass cutoff = m/z 200) over a 15 ms period, and the mass spectrum was subsequently obtained. Results were taken with the mass range extended by a factor of 5 by resonance ejection. Plotted in Fig. 1 are signals for $[M+H]^+$ ions of neuromedin U-8, neurotensin, and melittin. The increase in ion signals at some rf trapping level might be explained in terms of minimum pseudopotential well-depth (D_r) requirements. From the results obtained by Beavis and Chait for the kinetic energy of MALD generated ions, gas dynamic acceleration of the laser-induced, free-jet expansion imparts a most-probable velocity of approximately 750 m/s to analyte ions [1]. If the upper kinetic energy limit for trapping MALD derived ions is assumed to be equal to D_r, then calculations (r_o = 1 cm, V_Ω = 7500V, Ω = 1.1 MHz, ion velocity = 750 m-s^{-1}) yield a high-mass limit of m/z 9830 for MALD/ITMS. However, for each of the curves the ion signal falls off at higher rf trapping levels. This behavior is inconsistent with an argument for increased well-depth with rf trapping level; such reasoning would predict a plateau for ion signals above some rf level. A possible explanation is that as the rf level is raised, the effective trapping volume decreases. This phenomenon has been previously demonstrated with electron ionization and photoionization of vapor-phase species, which showed a reduction in the number of ions formed as the rf level was increased [2].

The dependency of ion signal (neurotensin $[M+H]^+$) on rf storage level was studied in the second group of experiments. For these experiments the rf level during and 15 ms after desorption was held at 2308 V (low-mass cutoff = m/z 200). The rf amplitude was then reduced to a specified storage level over a period no shorter than 5 ms. As shown in Fig. 2 the ion signal for neurotensin fell sharply when the rf storage level was brought below 856 V (low-mass cutoff = m/z 75). Similar analyses to those results shown in Fig. 2 were made for ions with a range of m/z values, with the exception that the initial rf level was adjusted to be sufficiently above the ion storage drop-off level for each particular m/z. In Fig. 3 the desorbed ion signal drop-off point is plotted as a function of the ion-storage rf level. A theoretical upper mass limit of 17,600 m/z, corresponding to a sustained low-mass cutoff of 650 m/z (V_Ω = 7500V, Ω = 1.1 MHz, r_0 = 1 cm), can be linearly extrapolated from the plot. These data are significant because they demonstrate the existence of a variable, upper m/z limit that is a function of the fundamental rf amplitude. However, detection limits and resolution were found to significantly degrade before the projected upper limit for ion storage could be experimentally approached.

Table 1. Detection limits for several polypeptides

Polypeptide	Molecular Weight	Detection Limit	Polypeptide	Molecular Weight	Detection Limit
Leucine Enkephalin	555.6	4 fmol	Neurotensin	1672.9	15 fmol
Bradykinin	1060.2	1 fmol	Melittin	2846.5	90 fmol
Neuromedin U-8	1111.3	6 fmol	Bovine Insulin	5733.5	17 pmol

MATRIX-ASSISTED LASER DESORPTION OF PEPTIDES COUPLED WITH CID IN A QUADRUPOLE ION TRAP

D.E. Goeringer, D.M. Chambers, S.A. McLuckey, G.L. Glish
Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831

Since its introduction [1], matrix-assisted laser desorption (MALD) ionization coupled with mass spectrometry has experienced rapid application development [2,3]. This activity is due in part to current demands in analytical biotechnology for techniques that provide molecular weight and structural information and to the ease in which MALD can be implemented. Mass analysis of MALD-derived ions has been carried out most often with time-of-flight (TOF) mass spectrometers due primarily to their inherent compatibility with pulsed ionization techniques and high mass range. Although the compact ion packet produced by MALD is well-suited for TOF mass analysis, the kinetic energy spread of such ions is detrimental to high resolution measurements. Another drawback of the TOF instrument is its limited ability to perform tandem mass spectrometric analysis which is useful for obtaining ionic structural information. The quadrupole ion trap mass spectrometer (ITMS), which is also intrinsically suited for use with pulsed ionization methods, has several attributes that make it attractive for implementation with MALD such as high sensitivity, high mass range, and high mass resolution. Another particularly appealing feature of the ITMS is its capability for producing structural information via multi-step, tandem-in-time mass spectrometry which is demonstrated in this paper for polypeptide ions formed via MALD ionization.

Fig. 1 shows a MALD-MS/MS spectrum for leucine-enkephalin (10 pmol sample) obtained with the ion trap. The fragment ions are identified using Roepstorff nomenclature. Conventional single-frequency resonance excitation was used to effect CID of the $[M+H]^+$ ions (m/z 556) which were generated from a nicotinic acid matrix using 266 nm laser radiation. The MS/MS efficiency, which was difficult to measure accurately due to relatively large fluctuations in the parent ion signals, was about 95%. MALD-MS^n spectra for bradykinin (100 pmol sample, nicotinic acid matrix, 266 nm radiation) are shown in Fig. 2. The m/z 904 ion was the most abundant product ion seen following CID of the $[M+H]^+$ parent ion (m/z 1161). The MS^3 and MS^4 spectra contain additional product ions similar to those seen from low-energy CID on a BEqQ instrument [4]. This is a general observation in the ITMS which is presumably due to the fact that internal energy deposition in the initial MS/MS stage with the ITMS is somewhat lower than in the BEqQ. Because single-frequency excitation is generally used, product ions fall out of resonance and subsequently are not kinetically excited. When this is combined with the relatively slow nature of ion internal energy deposition during resonance excitation, ion trap CID frequently produces only a few different product ions. Therefore, structural information inherent in the MS/MS spectrum may be limited. The use of single-frequency excitation for CID has other ramifications for tandem mass spectrometry in MALD/ITMS. The parent (and subsequent target) ion mass/charge must be known to be collisionally activated. Because the exact secular frequency is also dependent on the number of ions stored in the ion trap, tuning of the excitation frequency is required to optimize CID. The latter characteristic is particularly relevant to MALD/ITMS as the shot-to-shot variation in the desorbed ion number can often be large. Thus, although the ion trap is capable of multiple stages of CID, it may be undesirable to be forced to resort to MS^n with its added complexity.

We have found that the use of a random noise signal for resonance excitation reduces many of the aforementioned limitations associated with single-frequency CID in the ion trap [5]. The technique is simple to implement and has been used successfully with a wide variety of ions generated by electron ionization, chemical ionization, glow discharge ionization, and electrospray ionization. We have now implemented random noise CID in the ion trap for ions generated via MALD ionization. Fig. 3 shows an MS/MS spectrum for protonated bradykinin acquired via random noise CID. Although only one stage of tandem mass spectrometry was performed, extensive structural information similar to that acquired from the single-frequency MS^n spectra (Fig. 2) was obtained without the need for frequency tuning. These results indicate that MALD ionization coupled with CID/tandem mass spectrometry in the ion trap extends the utility of MALD mass spectrometry beyond molecular weight determinations to structural analysis.

Analysis of Spiperone in a Biological Matrix using Laser Desorption/Quadrupole Ion Trap Tandem Mass Spectrometry

*Rafael R. Vargas and Richard A. Yost, Department of Chemistry, University of Florida, Gainesville, FL 32611
Mike S. Lee, Sandra L. Moon, and Ira E. Rosenberg, Bristol-Myers Squibb, Pharmaceutical Research Institute, Wallingford, CT 06492

The purpose of this research is to develop a laser desorption/quadrupole ion trap mass spectrometry (LD/QITMS) technique to detect and determine drug compounds in complex biological matrices. Previously, the use of a single stage of mass spectrometry limited the applicability of this approach for trace-level monitoring of molecular species in complex matrices such as tissue. Tandem mass spectrometry is a powerful and widely accepted method for trace mixture analysis. The quadrupole ion trap mass spectrometer (QITMS) can efficiently perform multiple stages of mass spectrometry (i.e. MS^n) and the pulse/scan method of the QITMS is particularly suited for a pulsed laser desorption technique. Ion traps have also been shown to be extremely sensitive mass spectrometers. Furthermore, the QITMS can trap and store ions of a wide range of masses from a pulsed laser desorption event; in contrast, quadrupole mass spectrometers (and other scanning instruments) are unable to obtain spectra over a wide mass range for a pulsed ionization event.

The LD/QITMS configuration and scan function is shown in **Figure 1**. Laser desorption was performed on spiperone in a Matrigel membrane with no addition of a UV-absorbing matrix (**Figure 2**). Laser desorption was then performed on spiperone in Matrigel using a UV-absorbing matrix (**Figure 3**). In this case, an acidified sinapinic acid matrix was used. The molecular ion yield for the protonated ion and the metal cation adducts (i.e. Na^+ and K^+) appear with the use of matrix-assisted laser desorption (MALD). MALD was also found to increase the length of the ion signal. The $(M+H)^+$ ion yield from spiperone was found to be proportional to the concentration of the matrix modifier, trifluoroacetic acid.

In Matrigel mixtures, the molecular ion yield from spiperone was not as abundant as in previous experiments where no Matrigel membrane was present. The mass spectra obtained for MALD/QITMS was found to change during the sequence of laser pulses with a change in mass resolution and ion abundance. Peaks for the $(M+H)^+$ and $(M+Na)^+$ ions of spiperone in Matrigel were determined to a sampling amount of 9 ng (average of 3 laser shots.) This amount was obtained from the sampled laser spot area of 0.13 mm^2 in a 0.5 μL sample of a 880 ppm spiperone in Matrigel mixture.

The results obtained in these preliminary studies demonstrate the potential of laser desorption/quadrupole ion trap mass spectrometry for achieving a highly sensitive and selective trace-level imaging technique for compounds in complex biological matrices such as tissues.

Matrix-Assisted Laser Desorption in the Ion Trap Mass Spectrometer

Vladimir Doroshenko, Timothy Cornish and Robert J.Cotter
The Johns Hopkins University School of Medicine
Baltimore, MD 21205

Introduction

Quadrupole ion trap spectroscopy has been shown to be a promising technique for protein sequencing and biomolecular structural analysis allowing the possibility of MS^n experiments. The use of matrix-assisted laser desorption (MALD) to generate large molecular ions with quadrupole ion trap mass detection would be a combination of significant interest to biochemists. Previous studies in our lab on direct laser desorption experiments within the ion trap detector (ITD) cavity (Heller, Lys, Cotter, Uy: *Anal.Chem.* 61,1083,1989) demonstrated the potential usefulness of this configuration. In this work we present the initial results of the MALD experiments within the ITD cell.

Experimental

The Finnigan MAT Series 700 ITD was supplied with two additional vacuum ports for the insertion of the sample probe inside the ITD cavity and the introduction of the focussed laser beam through the central ring ITD electrode. The stainless steel probe tip was installed to rest flush with the inner edge of the electrode. A Nd:YAG laser (Quantel) operating at 266 nm modified in order to synchronize it with the ITD was utilized in this work. In order to maintain stable laser output power, the laser flashlamp firing frequency was adjusted to the main ITD scan frequency of 8 Hz so that the laser head thermal regime remained the same when the transfer took place from the free flashlamp firing to the ITD control (see Figure 1a). The laser was triggered by the gate signal normally used to control the electron gun. The storage time (see Figure 1b) was adjusted between 5-10 ms. The laser pulse was synchronized with the RF voltage phase (see Figure 1c). An additional trigger was installed in the laser electronics, and activated by the RF synchropulse from the ITD to turn on the laser Q-switch when the laser was ready for firing. The accuracy of the RF and laser pulse synchronization was about 30 ns. There were two modes of operation of this modified setup: 1) the laser pulse ionization is repeated with the frequency 8, 4 or 1.6 Hz provided by the available laser electronics, or 2) ionization is produced by single laser shots. Additional software was written to average the mass spectra in the repetitive mode of operation. The output from the multiplier was recorded with a digital oscilloscope and processed with a 386 PC using in-house developed software (TOFWARE).

Results and discussion

Several typical spectra obtained in the MALD experiments are presented in Figure 2. The width of the main peaks is not limited by the resolution capability of the instrument. There appears to be a dependence on the shape and width of MALD peaks with the RF phase when the laser fires. The shape of the main peaks is frequently asymmetric and often appears as a pair of peaks. The relative intensities of these peaks depend on the phase φ of the laser firing relative to the RF voltage. This phenomenon is not always observed, however. It may be due to other uncontrolled experimental parameters such as the precise location of probe tip relative to the ring electrode. Possible explanations include the non-uniform geometry of the ion trap cell, the participation of the negative ions formed and trapped under the MALD conditions, and space charge effects.

Axial Introduction of Laser-Desorbed Ions into a Quadrupole Ion Trap Mass Spectrometer

Aubrey McIntosh, Tracy Donovan, and Jennifer Brodbelt*
Department of Chemistry and Biochemistry, University of Texas
Austin, TX 78712-1167

The developments in thermal and matrix-assisted laser desorption/ionization mass spectrometry over the past decade have demonstrated its importance for the sensitive determination of increasingly high molecular weight biomolecules and other involatile materials. The combination of laser desorption with a quadrupole ion trap mass spectrometer may offer some advantages for development of an ultra-sensitive analytical technique with greater flexibility for ion-molecule reactions of laser-desorbed species. We report herein the design of a pulsed infrared laser desorption technique in conjunction with a quadrupole ion trap mass spectrometer (QITMS) that is distinguished by external ion formation and axial introduction of ions without auxiliary injection optics. The method employs a fiber optic laser probe interface that alleviates the need for strategically placed optical windows in a mass spectrometer, and often can provide superior versatility and portability to a conventional optical assembly. The laser desorption method is demonstrated to be useful for several types of experiments, including desorption of organic ions and ion-molecule reactions of selected desorbed cations and anions. The effects of several parameters, including buffer gas pressure, ion storage time, and the trapping voltage, on the effectiveness of ion storage and detection are also described.

The laser desorption probe consists of a rotatable stainless steel sample tip which is mounted via a screw mechanism on a 3/8" stainless steel probe shaft. The 3/8" probe is sealed to a 1/2" probe shaft by a swagelok fitting. The 1/2" probe fits the standard solids probe port of a Finnigan Ion Trap Mass Spectrometer (QITMS) (see Figure 1), and the probe is admitted through a bellows valve vacuum interlock. Along the side of the sample tip is mounted a fiber optic guide tube which directs the fiber optic to point at the sample tip. The fiber optic is also admitted through the probe shaft and externally sealed by a 1/8" Swagelok fitting. The sample probe and fiber optic are positioned orthogonally to the cylindrical symmetry axis of the ion trap assembly. This end-cap is actually a second detector-type end-cap electrode, and thus it has multiple holes for improved transmission of laser desorbed species. In the laser desorption configuration, there is no filament assembly, and the fiber optic probe is about 1 cm from the end-cap electrode. The plume of desorbed material emitted from the surface is aligned directly on-axis with the holes in the end-cap electrode. A Nd:YAG laser operated in the Q-switch mode at both 532 and 1064 nm provides the desorption pulse, and power densities are adjusted from 2×10^6 W/cm^2 to 2×10^8 W/cm^2 depending upon the desired type of laser desorption. This results in typical pulse energies of 7-20 mJ as measured at the outlet end of the fiber optic (600 um core, teflon clad). The laser beam is focussed into the fiber optic by a single 80 mm focal length lens.

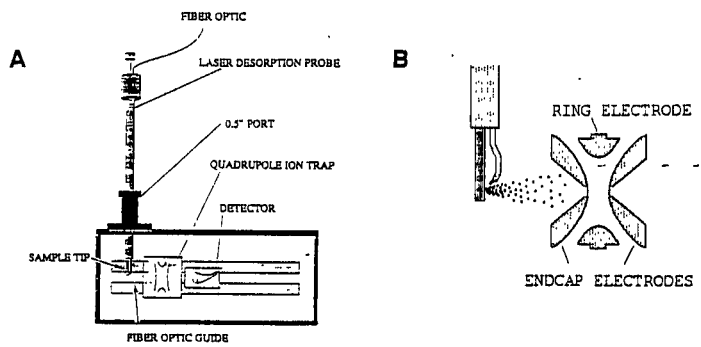

FIGURE 1. (A) Fiber optic laser desorption interface. (B) Detail of sample tip orientation.

The optimal position of the probe relative to the end-cap electrode required alignment of the probe surface with the transmission holes in the end-cap. After each laser pulse, the primary plume of desorbed material is ejected 90 ^{o} from the sample surface. Thus, this plume was aligned to directly pass through the end-cap electrode. A high buffer gas pressure was found to assist in trapping of the desorbed species, and typically 1 - 4 mtorr helium was introduced depending on the sample. Presumably, the high helium pressure enhances collisional damping of the translational energies of the desorbed species, so that they may be trapped upon admission through the end-cap holes. Related to the kinetic energy damping effect as influenced by the helium pressure is the storage time prior to detection in which ions may undergo considerable additional collisional cooling as they reside in the ion trap. When a high helium pressure is used (i.e. 2 mtorr), a long storage time offers modest advantages for effective ion trapping, however, at the lower helium pressures (i.e. $\leq$ 1 mtorr), it appears that a delay of 100-400 ms affords a five-fold enhancement of ion detection (likely because ions have time to undergo kinetic cooling to the center of the trap and thus are more effectively ejected and detected during the analytical scan). Additionally, different types of ions (fragment ions vs. cation-attached molecular species) are enhanced as the delay time is varied. Depending on the combination of pressure and cooling time used, these conditions correspond to an ion undergoing from 1000 - 5000 collisions prior to detection. Finally, the amplitude of the rf voltage applied to the ring electrode during the laser desorption pulse and ion cooling interval has a dramatic effect on the storage and detection of ions. When the rf voltage is less than about 100 V_{0-p} or greater than 1000 V_{0-p} during this period, the trapping of ions is quenched. Apparently, at very low voltages (< 50 V_{0-p}), the trapping field strength is insufficient to retain laser desorbed species. At rf voltages > 1000 V_{0-p}, desorbed ions apparently can not penetrate the potential barrier to the quadrupole field or become too highly energetic to be retained in the trapping field.

Several different types of laser desorption experiments can be performed with the fiber optic interface depending on the laser power densities and types of samples. For example, at low power densities (6 x 10^6 W/cm^2), alkali metal ions and halide ions are formed from desorption of any salt applied to the probe tip. These ions can be trapped, and be used for subsequent cation or anion attachment experiments with organic substrates introduced into the vacuum chamber. At moderate power densities (10^7 W/cm^2), organic ions are formed and can be trapped. Often these are alkali-metal ion attached species. At the highest power densities (10^8 W/cm^2), metal ions can be desorbed from the stainless steel sample tip or from foils attached to the tip, and these can be trapped to react with neutral substrates. In all cases, both positive and negative ions may be formed and analyzed.

At moderate laser power densities, organic ions are formed by laser desorption-ionization. With the mass range extension mode of operation (i.e. application of a supplementary ac voltage of 29 V_{p-p} at 150,000 Hz across the end-cap electrodes), the largest molecule that has been analyzed is Gramicidin S, $(M + K)^+$ at 1180 dalton (Figure 2). As another example, the laser desorption spectrum obtained for leucine-enkephalin is unusual in that both protonated and various cationized forms are observed (Figure 3).

Effects of Collisional Cooling on Ion Detection in a Quadrupole Ion Trap Mass Spectrometer

Hui-Fen Wu and Jennifer S. Brodbelt*
Department of Chemistry and Biochemistry
University of Texas
Austin, TX 78712-1167

Many developments in quadrupole ion trap mass spectrometry stem from the operation of the ion trap in the mass-selective instability mode, in which the application of a radiofrequency voltage to the ring electrode controls the storage and ejection of ions. Ions that achieve stable oscillating trajectories within the quadrupole field may be stored for long periods (> 1 s). Increasing the rf field causes destabilization of the axial motion of ions, resulting predominantly in axial ejection of ions through holes in the end-cap electrodes. These ions may impinge on an external electron multiplier and be detected. The storage and detection of ions is optimized by operation of the trap with a high background pressure (1 mtorr) of an inert buffer gas, typically helium. Multiple collisions between analyte ions and helium neutrals damp the kinetic energies of ions and effectively collapse the ion cloud to the center of the trap, ultimately resulting in more efficient detection and resolution of the ion signal. Ion extraction is directly related to the position of ions in the trap prior to ejection, and it has been estimated that the most effective external detection occurs for ions located within a 2 mm cylinder in the center of the trap. From an analytical perspective, an understanding of collisional effects is important for the control and optimization of experiments which involve selective activation of ions, injection of ions from an external source, and ion/molecule reactions at variable pressure.

All experiments were performed in a Finnigan quadrupole ion trap mass spectrometer. The typical radiofrequency scan program used to investigate collisional cooling is shown in Figure 1. The electron ionization interval is typically 2-5 ms, and then the selected ion of interest is isolated by application of appropriate dc and rf voltages to eject all other ions. The interval labelled "cooling period" represents the period in which ions are stored at a constant rf voltage level prior to detection. During this interval, the kinetic energies of ions are collisionally damped. The mass spectrum is then recorded by using the mass-selective instability mode to eject ions from the trap into an electron multiplier. Compounds were introduced via a leak valve to nominally 8 x 10^{-7} torr. Pressures were measured by a Granville-Phillips ionization gauge attached to the vacuum chamber, and all reported helium pressures were corrected for the gauge sensitivity (0.13).

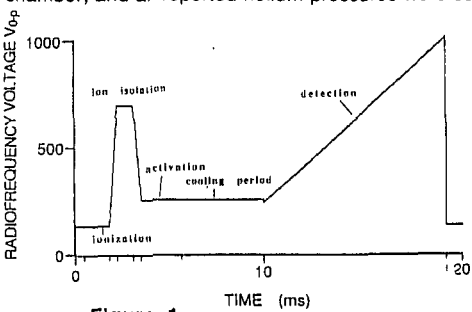

Figure 1

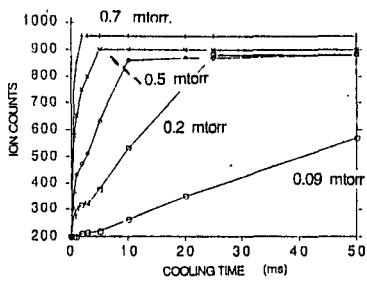

Figure 2

The effects of the specific parameters on collisional cooling and detection of ions are evaluated in the following sections.

i. Effect of Buffer Gas Pressure

The ion current of benzene molecular ions was recorded as a function of cooling time at five different helium buffer gas pressures. Benzene ions were formed, apex-isolated, and then cooled at q_z = 0.4. These results are shown in Figure 2. For the experiments at low helium pressures, the ion current increases dramatically with time. This result indicates that under low pressure

conditions without cooling intervals, the quadrupole ion trap is *filled* with many more ions than are ultimately *detected.* However, with the addition of an appropriate cooling interval, the trap can operate very effectively *even at low helium pressures.*

First-order rate constants for collisional cooling at various pressures were calculated from a secondary study of time-dependent cooling, and the rate constants are plotted as a function of pressure in Figure 3. The near linear increase in collisional cooling rate indicates that the total number of collisions for maximization of the ion signal remains relatively constant (i.e. about 50-100 collisions).

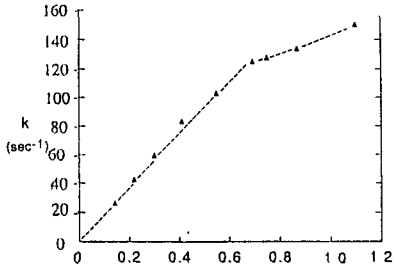

Figure 3.

q_z	Ion Current (Arbitrary Units) Without Cooling	With 100 ms Cooling
0.2	65	170
0.3	65	220
0.4	65	245
0.5	65	255
0.6	65	265
0.7	65	265
0.8	65	200

Table 1.

The rationalization for the collisional cooling phenomena is that at lower helium pressures and at low storage times, ions which pass the outskirts of the diffuse ion cloud during the analytical scan may more likely be accelerated into an end-cap electrode than through one of the end-cap holes. The end-cap holes are small perforations concentrated in the center of the electrode, and one can imagine that only ions positioned nearly on-axis will pass through a hole and strike the external detector. When the storage interval is increased, the diffuse ion cloud has sufficient time to contract due to collisional reduction of ion kinetic energies and damping of motion, and thus more ions are aligned for successful ejection and detection.

ii. Effect of q_z

The q_z value is defined by the radiofrequency voltage used to create the quadrupolar field in which ions are trapped. For these experiments, helium was admitted to only 0.1 mtorr to maximize the appearance of collisional cooling effects. The ionization time was adjusted to 10 ms (at q_z = 0.2) to establish a sufficient detectable ion signal in the absence of cooling. The benzene ions were stored at a range of rf levels corresponding to q_z = 0.2 to q_z = 0.8. The ion currents measured before and after a 100 ms collisional cooling period are shown in Table 1. There is an overall increase in detected ion current as q_z increases, until a significant drop occurs at q_z = 0.8. The increasing portion of the trend is rationalized by considering two factors related to q_z. First, the initial benzene kinetic energies are greatest for higher q_z values, and thus the ion cloud requires the most cooling to ensure effective ejection of ions from the center of the trap. Upon cooling, the ion cloud collapses to the center and results in a more concentrated ion population. Such ion cloud focussing effects are much less important for the lower q_z values in which the ions have lower initial kinetic energies prior to any collisional cooling, and thus the addition of a 100 ms cooling time will have little overall effect on the detected ion current at low q_z values. Second, the number of ions that can be trapped is greatest at the largest q_z values , and collisional cooling should maximize the storage capabilities at higher q_z values.

Collisional cooling plays a significant role in the efficient storage and detection of ions;however, it is not necessary to operate the quadrupole ion trap with 1 mtorr helium buffer gas. Lower pressures (< 0.5 mtorr) are suitable when an appropriate collisional cooling period is added to the scanning program. The cooling period allows focussing of ions to the center of the trap prior to detection.

Separation of Isobars at Low Mass on a Modified ITD800 Ion Trap

Steven E. Young, SRI International, Menlo Park, CA 94025

Previous work by others[1,2] has concentrated on obtaining unit mass resolution at high mass, while our objective is to separate low mass isobars.

A Finnigan ITD800 ion trap was modified by placing the trap portion in a separate vacuum chamber pumped by a 6" diffusion pump. The end caps were isolated from the three mounting studs with .002" sleeves of Kapton polyimide film and the nuts by washers of .003" Kapton film. This film is rated to 400°C and has a dielectric strength in excess of 10 KV at this thickness.

For axial modulation, a balun coil is necessary between the end caps and the frequency generator in order to remove the common mode rf component at 1.1MHz as shown in Figure 1. T1 is a broadband unbalanced to balanced transformer with a 1:4 impedance match[3]. T2 and T3 both reduce common mode rf pickup and effectively ground the end caps at DC. The balun is driven with a Rockland 5100 frequency synthesizer or an Exact model 126 sweep generator.

The rf drive circuitry was modified by the addition of CMOS analog switches and precision resistors to allow a slow scan function similar to that used by Kaiser *et. al.*[2]. This effectively slows the rf scan by a factor of 2,5,10,20,50,100,200 or 500 and narrows the mass range covered by a corresponding amount. Standard ITDS software with the AGC turned off was used which allows a maximum of 16 averages per spectrum. Spectra of the samples were taken with 256 averages by collecting raw data on a Tektronix 2430A digital oscilloscope. At slow scans of 100 and greater, it was found that the first scan of a microscan sequence would have the data shifted to the right. A gating circuit was developed that allowed data acquisition on only the 2nd through 16th microscans when N=16.

Figure 2 shows the separation obtained for the isobars $^{131}Xe^+$ and $C_3F_5^+$ of FC-43. (Δm=87mmu) at a slow scan factor of 200 with an axial modulation frequency of 390,971 Hz at 2.4 Vpp. Figure 3 shows the separation of the isobars N_2^+ and $C_2H_4^+$ at m/z 28 . The slow scan factor of 100 was increased to 140 by sweeping the axial modulation frequency up with a nominal frequency of 380 KHz at an amplitude of 300 mVpp.

As the slow scan factor becomes larger, the range of axial modulation amplitudes that yield good spectra becomes smaller. In general, the absolute amplitude of the axial modulation must be decreased for slower scans because the ions are exposed to the modulation for a longer period of time before undergoing resonance ejection.

Electron Energy in a Quadrupole Ion Trap Mass Spectrometer

Randall E. Pedder*, Jodie V. Johnson**, and Richard A. Yost**

**Chemistry Dept., University of Florida, Gainesville, FL 32611

In a conventional electron ionization (EI) source, electrons injected into the ion source all experience essentially the same **static** electric field. However, in a quadrupole ion trap mass spectrometer (ITMS), electrons are injected into the ion trap over many cycles of the ring RF voltage, resulting in a wide range of electron energies. The purpose of this research is to characterize (via simulations and experimental) (1) the effects of the ring RF and DC voltages on the electron energy, (2) the effects of He^+ and $N_2^{+\cdot}$ charge exchange on the EI spectra, and (3) the possibility of generating thermal electrons for performing electron-capture negative chemical ionization (ECNCI) in the ITMS.

Experimental. A BASIC computer program (HyperIon[1]) was used to calculate the trajectory and energetics of an electron injected into a quadrupole ion trap under various experimental conditions corresponding to operation of the Finnigan MAT ITMS: 1 cm ring radius, 1.1 MHz drive frequency applied to the ring electrodes, and 12.5 volts filament potential. Simulation results were verified using a Finnigan MAT ITMS configured with a Selected Mass Storage module for DC potentials. A scan function was utilized which had an ionization period followed by a "cooling period". The $Int(91^+)/Int(92^+)$ ratio resulting from ionization of n-butylbenzene (nBB) was used as a measurement of the energetics. Simulations and experiments were made with and without DC voltage applied to the ring electrode.

Electron Trajectory and Energy as a Function of RF Phase Angle. The trajectories and energies of 12.5 eV electrons injected into a quadrupole ion trap vary as a function of the applied RF phase angle. With RF phases (e.g., 180°) corresponding to applied potentials more negative than the filament potential (-12.5 V), electrons are repelled by the trapping field and strike the filament endcap. For those cases where there are either small incident angles or trapping field potentials which are slightly more positive than the filament potential (e.g., 90°), the electrons traverse the trapping field, striking the exit endcap. For those cases where there is significant positive field potential, the electrons are seen to traverse the trap, ultimately attracted to the ring electrode. The electron energy of the injected ions is a function of the Rf phase angle also and can be related to their trajectories. Those electrons which strike the ring electrode have a maximum kinetic energy equivalent to the applied potential, and those electrons which strike the exit endcap have a maximum kinetic energy which is slightly more than ½ of the applied ring potential. The segmentation in the plots in Figure 1 correspond to this transition of striking the ring electrode or striking the endcap electrode.

Electron Energy as a Function of RF Phase Angle. The relationship between electron energy and applied ring voltages is a simple one: $\mathbf{Energy_{max} = Energy_{init} + DC + RF\cos\Theta}$, which maximizes at $\Theta=0$. While DC voltage has an effect on electron energy, for typical applications, during ionization the magnitude of the RF voltage far exceeds any applied DC voltage. Thus, RF voltage has the dominating effect on electron energy. Experimentally, variation of the DC voltage had no significant effect on the $Int(91^+)/Int(92^+)$ ratio. However, Figure 2 shows that the intensity nBB ions exhibits a fairly sharp maximum at the m/z 18 low mass cutoff, with the intensity tapering off at higher RF voltages. This effect corresponds well with the cross-section measurements[2] of electron ionization of acetylene. From the correlation of these two sets of data, one could infer that the **effective** electron energy is $\mathbf{Energy_{eff} = E_{init} + 0.44 * (DC + maximum\ RF)}$. Electron ionization mass spectra obtained using a quadrupole ion trap represents an aggregate of ions resulting from electron ionization with a wide range of electron energies. This aggregate effect would be expected to make the apparent ionization cross-section slightly larger than would be predicted from static electron energies.

Evidence for Charge Exchange in "Electron Ionization" Spectra. If only "conventional" EI were occurring in the ion trap, the $Int(91^+)/Int(92^+)$ ratio would be expected to maximize at 1.5 as experimentally determined in a conventional quadrupole mass spectrometer (Finnigan MAT TSQ70) for electron energies greater then 35 eV. However, with increasing RF voltage during ionization, the $Int(91^+)/Int(92^+)$ of nBB steadily increases to a maximum of approximately 2.5. To determine if charge exchange were occurring with $He^{+\cdot}$ and/or $N_2^{+\cdot}$ (leading to more energetic spectra), the pressure of helium was varied in the trap and spectra were obtained with and without resonant ejection of the $N_2^{+\cdot}$

ions. As shown in Figure 3, at low pressures of helium buffer gas, the $Int(91^+)/Int(92^+)$ remains relatively constant and offset from the 1.5 value obtained with conventional 70 eV EI. If N_2^+ is resonantly ejected from the ion trap during ionization, then the $Int(91^+)/Int(92^+)$ ratio agrees well with that of 70 eV EI. With increasing helium buffer gas pressure, the $Int(91^+)/Int(92^+)$ ratio increases. As the effect of $N_2^{+\cdot}$ is accounted for by resonant ejection, this is presumably due to contributions from He^+ charge exchange.

Evidence for Electron Capture Negative Chemical Ionization in Electron Ionization" Spectra. As indicated in Figure 1, during each cycle of RF voltage, there occurs two RF phase angles which willyield a ring voltage of -12.5 V which increases the possibility of producing thermal electrons from the 12.5 eV injected electrons. At these phase angles, the injected electrons travel the greatest distance and have the maximum residence time, thus increasing the likelihood of ECNCI occurring. Due to its high electronegativity and sensitivity in ECNCI, perfluorotributylamine (FC43) was used to probe for thermal electrons and ECNCI. In conventional ECNCI, FC43 produces abundant 452^- and 633^- ions while under EI conditions it produces characteristic 414^+ and 614^+ ions. With "EI"at an RF low m/z cutoff of 10, ions were easily detected at these m/z values. With an increase in the storage RF to a low m/z cutoff of 270 and application of DC voltage, it was possible to obtain spectra (Figure 4) containing just negative ions due to ECNCI (Spectrum B), containing largely EI positive ions (Spectrum C), and containing both polarities of ions ("EI"Spectrum A).

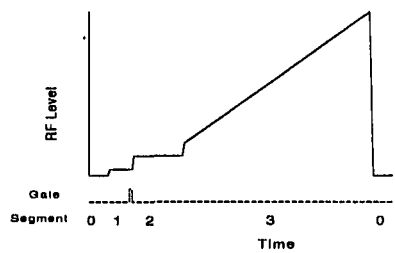
HIGH KINETIC ENERGY CHEMICAL IONIZATION IN THE QUADRUPOLE ION TRAP

R. Cameron Dorey,Chem. Dept., Univ. of Central Arkansas, Conway, AR 72035
James P. Freeman, Natl. Center for Toxicological Research, Jefferson, AR 72079

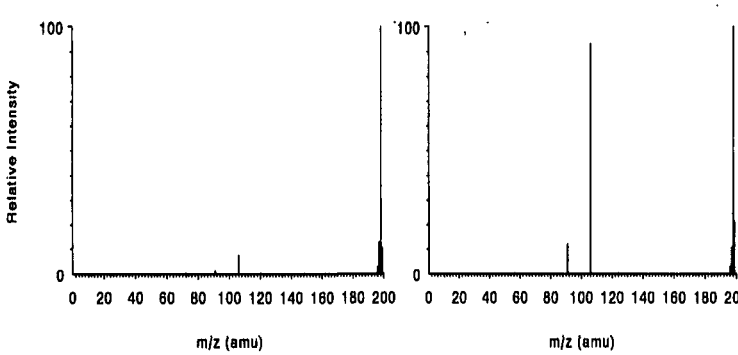
Chemical ionization mass spectrometry in the quadrupole ion trap occurs with the reagent ions at high kinetic energy. Theoretically, these ions can reach over 7 eV kinetic energy, but the buffer gas lowers this limit substantially. This excess energy can be transferred to the analyte ion formed by proton transfer, causing fragmentation. This is an example of endothermic reactions which have been shown to occur in the collision cells of tandem mass spectrometers.

The extent of fragmentation is found to be strongly dependent on the "reaction level" of the CI scan (below, segment 1: ionization of reagent, 2: reaction, 3: analytical scan, 4: reset).

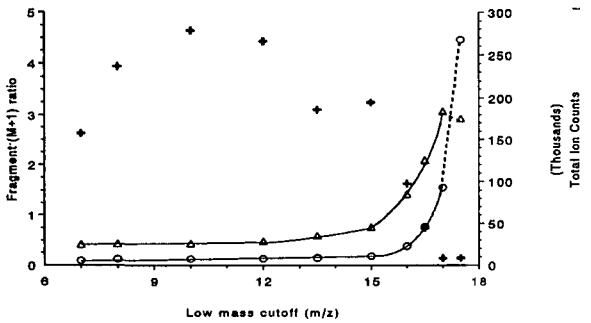


Experiments were performed using ammonia CI on a Finnigan ITD, Model 800.

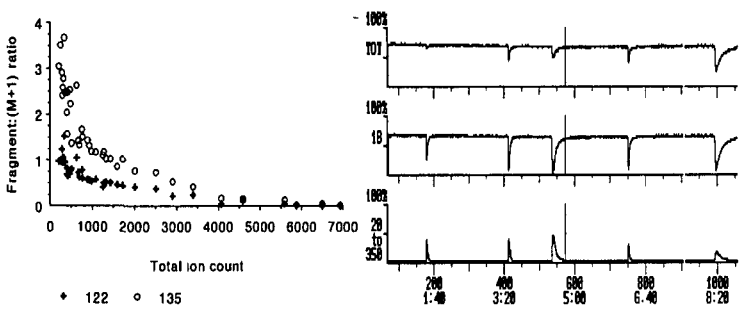
A high reaction level increases fragmentation as shown in the ammonia CI mass spectra of dibenzylamine at 7 amu and 15 amu:



Para-methoxyphenethylamine (p-CH_3O-Ø-$CH_2CH_2NH_2$, MPEA) was used as a probe of fragmenatation vs reaction level in ammonia CI, and it was found that at levels above 15 amu, fragment ion intensity (m/z 122 (O) and 135 (Δ)) increased dramatically, while the total ion count (+) fell. These results are explained by (1) the addition of kinetic energy to an exothermic reaction (proton transfer from ammonium ion to MPEA) which decreases the extent of reaction, and (2) distribution of the energy into vibrational modes of the analyte ion to cause fragmentation.



The extent of fragmentation is also found to be inversely dependent on the concentration of the analyte (high mass) ion in the trap. This is due to space-charge expulsion of the higher energy reagent ions, which are travelling *closer to the edges of the trap, and are easily lost.* Automatic Reaction Control, which tries to control the total number of ions in the trap, can lower this dependence, but not eliminate it. If the total number of ions during a chromatogram is monitored, it will drop during elution of a peak, because of a higher-than-expected drop in reagent ion concentration in the trap.



The Design of a Tandem Ion Trap/Time-of-Flight Mass Spectrometer

S. M. Michael, M. Chien and D. M. Lubman, Department of Chemistry
The University of Michigan, Ann Arbor, MI 48109

The goal of this work has been to interface an ion trap storage device as a front end source for a time of flight mass spectrometer. This device combines the ion storage of the trap with the relatively high resolution and speed of the TOF to produce a hybrid instrument with unique capabilities. The design of an ion trap/time-of-flight device is described in which ions are initially produced by resonance enhanced multiphoton ionization (REMPI) in the ion trap, stored between several hundred μsec up to several seconds and then pulsed out into a time-of-flight device for mass analysis. The ion trap is an RF quadrupole trap which operates in the total storage mode, i.e. with the DC voltage = 0 on the end caps and RF voltage on the ring electrode. The stored ions are ejected into the time-of-flight device using a -150 V DC pulse on the exit end cap which causes the ion trajectories in the trap to become unstable. The ions are mass analyzed using either a linear or reflectron TOF. In the linear mode the resolution is 240 while in the reflection mode a resolution of 1300 is achieved. In addition, it is shown that ion storage enhances the resolution of the device by narrowing the spatial distribution of the ions towards the center of the trap.

The experimental setup is shown in Figure 1. It consists of a differentially pumped reflectron time-of-flight mass spectrometer interfaced to an RF only quadrupole ion trap source and a liquid injection sample source. A liquid injection sample source was used to deliver the sample, dissolved in a solvent, through a heated stainless steel tube to the first vacuum chamber. In this chamber, pumped to ~ 150 mtorr, the sample and solvent are vaporized, most of the solvent is removed and the sample passed through a skimmer cone to the ion trap region. The resulting pressure in the trap is ~ 10^{-2} Torr. In the ion trap the sample is ionized by 266 nm laser radiation. The resulting ions are then stored in the trap until the RF trapping potential is shut off and subsequentially a DC extraction pulse is applied to the exit endcap of the ion trap. Upon leaving the trap, the ion packet enters a field free drift region ~ 2 m long in a reflectron TOF and is detected by a dual 40 mm microchannel plate detector.

In Figures 2 and 3 are shown typical results obtained using the IT/reTOF. In figure 2 a sample of aniline has been ionized via 266 nm radiation. An RF potential of 310 V at 1.1 MHz is applied to the ring and the ions stored for ~ 100 μsec. The RF is switched off and the ions are then ejected by a -150 V DC pulse applied to the extraction endcap and are detected in the reTOF. Figure 3 shows an expanded version of the m/z 93 ion peak which illustrates a peak FWHM of 16 ns. This provides a resolution of greater than 1300. The resolution is found to increase substantially

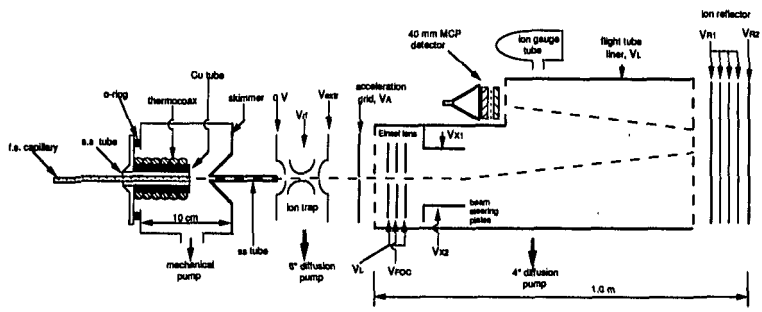


Figure 1. Ion Trap/Time-of-Flight Device

compared to the case when there is no trapping. A trapping time up to 2 sec has been achieved using this set-up. In addition, the RF power supply associated with this device can operate over a frequency range of 800 - 1.3 kHz and up to an RF 400 V_{pp}. The DC draw out voltage can operate up to -450 V; however, -150 V was found to provide the best resolution and sensitivity. A sensitivity measurement down to 50 femtomole was performed for benzene using REMPI in the IT/reTOF detector.

Structural Determination of Secondary Ions using Matrix Isolation Infrared Spectroscopy ------ Ion Decomposition Products

X.K.Zhang* J.M.Parnis and R.E.March

Chemistry Department Trent University Peterborough ON Canada K9J 7B8

**Registered at Queen's University Kingston ON Canada K7L 3N6*

Introduction

The objective of this project is to obtain the matrix-isolated infrared spectrum of the secondary ions, that is, the products of the ion/molecule reactions. A novel instrument has been constructed and installed recently in our laboratory, employing a quadrupole ion trap to produce and store secondary ions in an "isolated" chemical environment [1], a cryostat assembly to allow ionic and neutral molecules to be stabilized in an inert gas matrix, and a Fourier Transform Infrared Spectrometer to obtain infrared absorption spectra of ions which have been ejected and entrained in the inert gas solid.

Instrumentation

The experimental arrangement consists of a differentially-pumped quadrupole ion trap coupled to a closed-cycle He cryostat system (Fig.1). Ions created inside the ion trap undergo ion/molecule reactions, the secondary ions thus formed are ejected resonantly onto a CsI window, where they co-condense with an excess of argon at 12 K. As a result, the secondary ions are expected to be effectively frozen and isolated in the surrounding Ar matrix. Vibrational spectra of matrix-isolated species are obtained with a FTIR spectrometer.

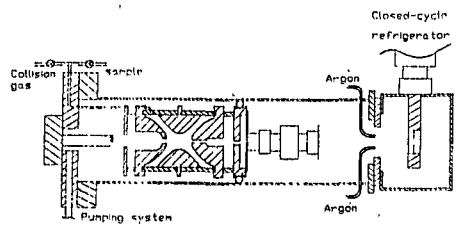

Fig.1 Diagram of ion trap and cryostat assembly.

Experiment and Results

Acetone (and d_6-acetone) was ionized by conventional electron impact and underwent self-chemical ionization within the ion trap; the product species consisting of mainly protonated acetone were co-condensed in the Ar matrix. The infrared spectra obtained thus show several new features which are not observed in the spectra of neutral acetone. The difference spectrum obtained by subtracting the neutral acetone spectrum from the ionized acetone one with an appropriate factor is shown in Fig.2. Among the new features, there are no absorptions that have been assigned definitely to protonated acetone. However, some of the observed features have been assigned to neutral product species, such as CO, C_2H_2O, CH_4, probably C_2H_2 and H atoms.

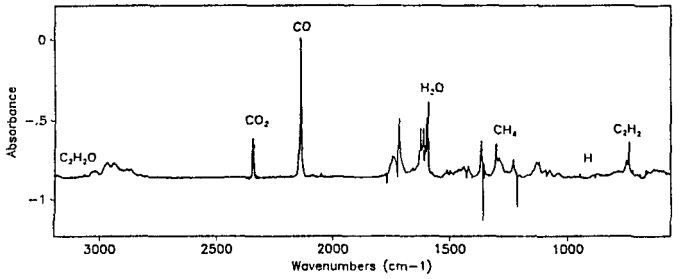

Fig.2 The difference spectrum by subtracting infrared spectrum of neutral $(CH_3)_2CO$ from infrared spectrum of ionized $(CH_3)_2CO$ with an appropriate factor.

Substitution of d_6-acetone for acetone gave the isotopically-shifted frequencies.

Conclusions and Outlook

Ab initio calculations predict that the perturbed C=O stretching vibration of protonated acetone should show a red shift of about 200 cm^{-1} with respect to that of free acetone at 1721 cm^{-1}. However, no significant absorption peaks were detected in that region. Instead, several very broad and weak absorptions were observed, which were not observed in un-ionized samples. These severely broadened spectral features may result from strong ion-induced dipole interactions between the ion and the surrounding matrix support material. Such an effect may be due to the similarity of the ionization potentials of protonated acetone and argon [2,3].

Identification of the neutral species obtained from the decomposition of ionized or protonated acetone is of considerable interest, since these fragments shed light on the various pathways proposed for these processes. Several obstacles have been included in the design of the instrument to prevent any neutral decomposition products, created in the vicinity of the filament, from flowing through the trap and reaching the cold window. Therefore, it is reasonable to assume that some of the observed neutral products are due to decomposition of energized $(CH_3)_2COH^{\bullet}$ radicals formed following electron capture by protonated acetone. Electron capture could conceivably occur in the ion trap or following abstraction of an electron from an impurity such as $OH^{\cdot}$, during the formation of the matrix. The product, $(CH_3)_2COH^{\bullet}$ could be formed with sufficient energy to induce fragmentation, to form CO, C_2H_2O, CH_4, C_2H_2 and $H^{\bullet}$, all of which have been detected.

A SIMULATION STUDY OF MASS-SELECTIVE ISOLATION IN THE QUADRUPOLE ION TRAP

F.A.Londry and R.L.Alfred, Department of Physics, and R.E.March and M.Tkaczyk, Department of Chemistry, Trent University, Peterborough, ON, Canada K9J 7B8

INTRODUCTION

As the isolation of a single ion species within a quadrupole ion trap is of comparable significance in mass spectrometry to purification of a compound, the examination of ion trap function by this laboratory using simulation methods [1] has been extended to ion isolation [2]. Single ion trajectories have been calculated for two scan functions corresponding to two processes of ion isolation [3,4].

ION ISOLATION

Ion isolation in the ion trap can be effected readily by two basic methods, **concurrent** [5] and **consecutive** [6], each of which is discussed here. Simulation of these methods followed the "trajectories" of the working points within the stability diagram as shown in Figures 1 and 2, respectively.

FIGURE 1. CONCURRENT ISOLATION

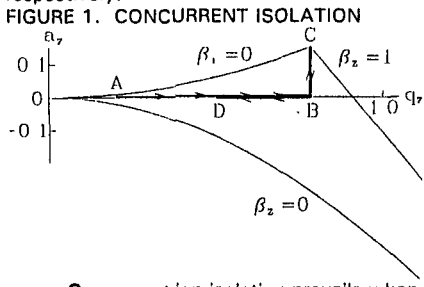

FIGURE 2. CONSECUTIVE ISOLATION

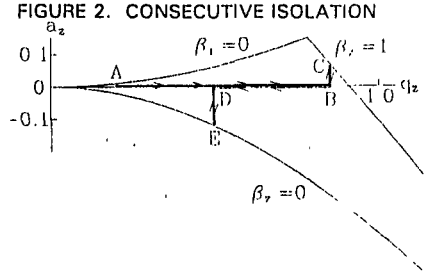

Concurrent ion isolation prevails when ion species of lower and greater *m/z* values are lost from the ion trap at the same time; isolation is achieved by manoeuvering the working point of the ion species to be isolated to the vicinity of the upper apex of the stability diagram. Trajectories of low *m/z* ions and high *m/z* ions become unstable axially and radially, repectively.

Consecutive ion isolation is wrought by moving the working point of the ion species to be isolated close to the $\beta_z = 1$ and $\beta_z = 0$ stability boundaries in turn; the trajectories of low and high *m/z* ions, respectively, become unstable axially. This method has been applied [6] to the isolation of $[M\text{-}H]^+$ ions, *m/z* 207, formed from chalcone (2-propen-1-ona-1,3-diaphenyl). In our simulation study, the order of ejection of *m/z* 206 and 208 ions is unimportant but this is not so in practice.

Boundary-Activated Dissociation (BAD)

With the working point close to a stability boundary, ions absorb r.f. power; secular excursions and kinetic energy increase. Though the trajectory remains stable, the ion may collide with an electrode or with helium and fragment. Thus it is convenient to visit the $\beta_z = 1$ stability boundary first at which low *m/z* ions are lost so that, near the $\beta_z = 0$ stability boundary, high *m/z* ion loss is accompanied by the formation of fragment ions. Resonant excitation is obviated by BAD [7,8].

RESULTS AND DISCUSSION

Neighbouring ion species are lost rapidly from the ion trap as trajectories become unstable. Thus the duration of the visit of the working point of, e.g., *m/z* 207 to the stability boundary vicinity may be brief and, perhaps, should be; vide infra.

We have focused upon the temporal variations of ion radial and axial excursions and ion kinetic energy at point E in Fig. 2.

Simulations were made for ten subject ions at both $P_{He} = 0$ and at 0.7 mTorr of helium. The initial position, R, for each ion designated as "warm" was restricted to $0.01 < R < 1$ mm; initial kinetic energy, T, restricted to $0.05 < T < 0.3$ eV; thus mimicking a collisionally-focused ion. However, at $P_{He} = 0$, five of the ions were lost axially at point E and, at $P_{He} = 0.7$ mTorr, three ions were lost. Thus each of the ten original ions was subjected to a cooling period of 1000 μs with an

ambient P_{He}=15 mTorr. Each ion had ca. 250 collisions at which point the ion has been cooled as much as possible. The co-ordinates and velocities of the "cool" ions were taken as initial conditions for the subsequent simulations of the ion isolation process. At P_{He}=0, no "cool" ions were lost at point E but, at P_{He}=0.7mTorr, one "cool" ion previously confined was lost. Clearly, ion retention at point E is dependent upon ion kinetic energy maxima as is shown in Table 1 for "warm" and "cool" ions and for both the collision-free and collisional systems.

TABLE 1: Kinetic energy maxima at the working point E for "warm" and "cool" ions both with and without collisions with helium atoms.

ION	WARM[a]		COOL[b]	
	P_{He}=0	P_{He}=0.7mTorr	P_{He}=0	P_{He}=0.7mTorr
	E[e] (/eV)	E[e] (/eV)	E[e] (/eV)	E[e] (/eV)
Alf	55.0	110.0[d]	8.0	11.0
Bob	15.0	6.0	1.4	1.8
Cam	140.0[d]	-[f]	37.0	0.8
Dot	3.4	12.0	2.3	118.0[d]
Els	130.0[d]	130.0[d]	99.0	70.0
Fil	14.0	12.0	4.6	15.0
Guy	110.0[d]	70.0	0.3	20.0
Hen	115.0[d]	7.0	8.0	9.0
Ian	110.0[d]	-[f]	4.2	8.0
Jan	27.0	110.0[d]	0.8	80.0
Range (/eV)	3.4-140.0	6.0-130.0	0.3-99.0	0.8-118.0
Average (/ev)	72	57	14	34

[a] Initial position, R, restricted to 0.01<R<1 mm; initial kinetic energy, T, restricted to 0.05<T<0.3 eV.
[b] Ions created initially at random and subjected to *ca.* 250 collisions
[c] Maximum radial excursion.
[d] Maximum axial excursion.
[e] Axial excursions exceed the physical dimensions of the ion trap.
[f] Ion lost at the working point C.

CONCLUSIONS

Ions with unstable trajectories are lost rapidly.

While the trajectories of ions undergoing isolation remain stable throughout, the trajectories may exceed the physical limits of the ion trap. Ion retention is enhanced by collisional pre-cooling, minimization of the time during which the working point is in the vicinity of a stability boundary, and pressure of helium buffer gas.

For Boundary-Activated Dissociation, the energy-dampening conditions described above must be relaxed to a compromise position.

The retention of ions is largely unimpaired as the working point approaches to within 0.3 Da/charge of a stability boundary.

Effect of Experimental Parameters on Effective Ion Temperatures in a Quadrupole Ion Trap

K.J. Hart, S.A. McLuckey and G.L. Glish
Oak Ridge National Laboratory, P.O. Box 2008
Oak Ridge, TN 37831-6365

The "effective temperature" of ions stored in the quadrupole ion trap has been studied using ion/molecule chemistry in this and other research groups. Parameters that have been examined in detail are the helium buffer gas pressure and q value during the reaction period. We have investigated the effect of these parameters as well as trap temperature and number of stored ions on the rate constant and product distribution of the phenylium/methane system, a reaction of interest in our laboratory. Phenylium ions react with methane to form two ions at m/z 91 (benzyl) and m/z 93 (presented elsewhere [1]). The m/z 93 ion arises from collisional stabilization of the phenylium-methane complex. The dependence of the rate constant and the ratio of m/z 93 and m/z 91 product ions on the parameters mentioned are presented here. Unfortunately, the temperature dependence of this reaction is not independently known. Thus, it is difficult to assign an "temperature" in absolute terms for this system.

All experiments were carried out on a Finnigan MAT Ion Trap Mass Spectrometer (ITMS). Phenylium ions were generated by EI of chlorobenzene [p = 6.6 x 10(-8) torr] and allowed to react with methane [p = 7.5 x 10(-6) torr]. The trap conditions used for the experiments presented here are summarized in Table 1. The m/z 77 reactant ions were isolated by applying appropriate rf and dc voltages to the ring electrode. Rate constants were determined using the first order rate equation: $[m/z\ 77]_t = [m/z\ 77]_0\ e^{-k[CH_4]t}$. The abundance of non-reactive m/z 77 (< 10%), determined by examining the m/z 77 abundance for t > 100 ms, was subtracted from the m/z 77 abundances used to calculate the phenylium / methane rate constants. A low number density of chlorobenzene molecules and a relatively large number density of methane were maintained in the trap to minimize the effect of the competing reaction: $C_6H_5^+ + C_6H_5Cl \rightarrow C_{12}H_{10}, C_{12}H_9$. The neutral number density was determined by the methane proton transfer reaction assuming a rate constant of 1.1×10^{-9} $cm^3 molecule^{-1} s^{-1}$. All other gas pressures were measured using a Granville-Phillips ionization gauge and corrected using an ionization probability table.

Helium is used as a buffer gas to collisionally "cool" ions stored in the trap. The net effect is to damp the kinetic energies of the ions such that the ion cloud collapses to the center of the trap, thus yielding greater detection efficiency and ion resolution. Helium appears to rapidly "cool" the kinetic temperature of the phenylium ions as shown in Figure 1 since the rate constant for the reaction is 3 times faster when helium is present in the trap. There does not appear to be much affect of helium pressure in the pressure range normally used in the trap (approximately 1 mtorr). Increasing the helium pressure steadily increases the 93/91 ratio (i.e. collisional stabilization of m/z 93) throughout the pressure range studied as shown in Figure 2.

The trap temperature determines the temperature of the neutral species (i.e. helium and methane) in the trap. For the phenylium / methane reaction, the rate constant and 93/91 ratio both decrease with increasing neutral temperature as shown in Figures 3 and 4. The rate is decreased by approximately 70% over the available temperature range for the trap. The decrease in the 93/91 ratio is consistent with increased internal energy of the methane molecules.

A relatively small effect has been observed with a large number of stored ions but this effect was difficult to measure owing to a increasing percentage of unreactive m/z 77 with increasing ionization time. The effect of number of stored ions was investigated by increasing ionization time at a fixed chlorobenzene pressure. The phenylium ion temperature also increased at q values close to q_{cutoff} for m/z 77 during the reaction period (≈ 20% decrease in k @ q = 0.825). The effect observed for q value is consistent with the "heating" effect near the edges of the stability diagram reported elsewhere [1].

Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

The following generic equation can be used to determine the number of analyte (A) ions formed in EI and CI experiments:

$$A^+ = I_o(1-e^{-\beta[A]})$$

In EI, I_o is the number of ionizing electrons and β is the product of the ionization cross-section and the path length. In CI, I_o is the number of reagent ions and β is the product of the reaction rate constant and the reaction time. In typical beam instruments, the only variable in the equation that is easily changed is the number of ionizing electrons, which is achieved by changing the emission current. In a quadrupole ion trap the number of ionizing electrons can also be changed by varying the length of the ionization pulse. In CI experiments on an ion trap, the reaction time can be readily varied as well, whereas most beam instruments have a set reaction period. EI experiments on a beam instrument and an ion trap are similar, but there are fundamental differences in the CI experiment. First, the reagent gas pressure is several orders of magnitude lower in the ion trap experiment. More importantly, I_o is a couple of orders of magnitude lower in the ion trap. This can be partially compensated for by increasing the reaction time, though this is limited because the number of reagent ions continually decreases in the ion trap experiment. New reagent ions, however, are continually being generated in the beam instrument.

To evaluate the relative sensitivities of the two ionization methods, we studied two compounds on the Finnigan-MAT TSQ 700 (beam) and the Finnigan-MAT ITS-40 (ion trap). Varying levels of benzophenone and N,N-dimethylaniline were injected onto a Varian 3400 GC coupled to the instruments. The ionization time (EI) and the reaction time (CI) were varied on the quadrupole ion trap experiments. The EI and CI experiments on the TSQ 700 were carried out without any parameters being changed. Methane was the CI reagent gas on both instruments.

On the quadrupole ion trap, as the ionization period was increased for 160 pg of benzophenone, the response increased linearly as shown in Figure 1. In Figure 2a, the benzophenone molecular ion response is plotted for two ionization times, 1 ms and 10 ms. A ten-fold increase is observed across most of the range. The response of the higher analyte level begins to tail off because of space charge effects in the ion trap. This effectively reduces the dynamic range available and reduces sensitivity. In Figure 2b, a corresponding plot for CI shows a ten-fold increase in the response of the protonated molecule of benzophenone when the reaction time is increased from 10 to 100 ms. To overcome problems of space charging, the AGC and ARC scan functions were used to obtain good sensitivity without compromising dynamic range for comparing EI and CI sensitivities and detectability. In Figure 3a, the ITS-40 data shows the response for both the molecular ion and protonated molecule of N,N-dimethylaniline using the AGC and ARC scan function. The sensitivity (slope) of the two are nearly equal, but provided that the background is the same, the line with the higher intercept should give the better detection limit. Hence for N,N-dimethylaniline, EI would give lower detection limits than CI on the ion trap by a factor of 10 when comparing molecular species. This is in contrast to the result obtained on the TSQ 700 as shown in Figure 3b, where CI has the higher intercept. Data for benzophenone also shows EI detection limits about 50 times better when comparing molecular species and about 100 times better when looking at the total ion current.

In summary, EI experiments on the quadrupole ion trap showed linear response as a function of the ionization time as the number of ions, I_o, increases proportionally with ionization time. EI data predicts better detection limits over CI for benzophenone and N,N-dimethylaniline. CI detection limits on the ion trap appear to be hindered by the lower number of reagent ions.

Modeling of Ion Trap Mass Spectrometer Operation Using Potentials Calculated from Accurate Electrode Geometries

S. E. Buttrill, Jr.
The Edward L. Ginzton research Center
Varian Associates, 3075 Hansen Way K-407, Palo Alto, CA 94304-1025

INTRODUCTION: Commercial ion trap mass spectrometers all operate in the consecutive mass instability scanning mode. Second generation systems obtain improved sensitivity and resolution by using axial modulation, which is the application of a low amplitude rf waveform across the end caps of the ion trap in addition to the high amplitude trapping rf applied to the ring electrode. The theory of the ion trap mass spectrometer operation is almost all derived from the equations for ion motion in an ideal quadrupole potential. The solution of the Mathieu Equation gives us the stability diagram, which allows us to explain qualitatively the consecutive mass instability scan and other features of the ion trap operation. However, there is no theory which can predict the lineshape or mass resolution to be expected, either with or without axial modulation.

Franzen [I.J.M.S.I.P. **106** (1991)63-78] has shown that the addition of higher order multipole components to the pure quadrupole field can dramatically change the amount of time required for an ion to be ejected. Therefore a useful treatment will have to use realistic potentials if it is to be able to reproduce the features of commercial ion trap mass spectrometers.

METHOD: SIMION Version 4.02 was used to compute the potentials in the ion trap and integrate ion trajectories through them. The electrodes are represented by a square grid of potential points on 0.25 mm centers. The electrode array was carefully constructed to match the geometry of the actual trap electrodes, including the shape at the edges. SIMION assumes perfect cylindrical symmetry, but we can still represent and see the effects of holes in the electrodes, the presence of the ion multiplier potential, and electrode edge effects.

SIMION was modified to eliminate storage of the detailed ion trajectories (to avoid filling the hard disk). The maximum number of integration steps was increased to 2,000,000 and the marker file feature was modified to be always available and to include the complete initial and final conditions for each ion.

For most of the work, a set of 60 trajectories was used with a starting energy of 0.05 eV (500 K) and a uniform distribution in position and direction. A set of Lotus 123 Rel. 3 spread sheets and macros was used to convert the marker files into plotted results.

RESULTS: Peak shapes both with and without axial modulation are modeled well. Figure 1 shows an example of the predicted peakshape and resolution without axial modulation at m/z 500 and 501. A total of 240 trajectories were used for each of the peaks. The shapes of the peaks would be a better match for those observed experimentally if they were smoothed to account for the filtering effect of the limited electrometer bandwidth.

In the Varian Saturn II, axial modulation is applied at β=0.925 corresponding to a frequency of 485 kHz. The optimum level is usually 2 to 4 volts zero-to-peak. Axial modulation improves both the mass resolution and ion storage capacity of the trap. It also causes a shift in the apparent mass of the peak, and this shift is amplitude dependent. Figure 2 compares the peak shift measured with the peak shift predicted by the trajectory calculations. For this comparison, the axial modulation rf was measured directly off of the end cap electrode using a digital storage oscilloscope. The excellent agreement confirms that our approach is capable of producing useful predictions of ion trap performance for aspects of trap operation which are not presently treatable by any analytic theory.

CONCLUSIONS: (1) Using actual electrode geometry, trajectory calculations accurately predict ion trap mass resolution and peak shape. (2) The peak shifts and resolution improvement produced by axial modulation are quantitatively reproduced by the trajectory calculations.

ACKNOWLEDGEMENT: This work would not have been feasible without the SIMION program and source code supplied by David Dahl of the Idaho National Engineering Laboratory.

Large Scale Simulation of Resonant Ejection in the Quadrupole Ion Trap Mass Spectrometer

Randall K. Julian Jr., Hans-Peter Reiser, R. Graham Cooks, Purdue University, West Lafayette, IN 47907

Simulation of ion trajectories within the quadrupole ion trap mass spectrometer is used as a method for determining optimum operating conditions and for studying the effects of individual operating parameters on the mass spectra obtained. To provide the simulation with a more accurate electric field model, coordinates were obtained from the actual ITMS electrodes and equations were fit to describe the ring and endcap surfaces as shown in the following equations:

$$Ring: \frac{r^2}{b_r^2} - \frac{z^2}{a_r^2} = 1 \qquad Endcap: \frac{z^2}{a_e^2} - \frac{r^2}{b_e^2} = 1$$

For the ITMS a_r = 0.7341, b_r = 0.9956, a_e = 0.7825 and b_e = 1.0838. The simple geometric derivation gives $z_0 = a_r = a_e = 0.7071$ and $r_0 = b_r = b_e = 1$. The measured values for z_0 and r_0 are 0.78105 cm and 1.000 respectively.

To a first approximation the ring and the endcaps follow equipotential surfaces for a pure quadrupole field for the value of r_0 and z_0 used. The equations for the electric field must now include z_0 as presented by Knight [1]. Deviations from these equipotential surface are shown in the asymtopes in Figure 1. Field distortions created by this geometry produce higher order even field components, the largest of which is the octopole term. Using the terminology given by Franzen et. al. [2] the ITMS electrodes have a value for Θ (r_0^2/z_0^2) of 1.839 for the ring and 1.918 for the endcap. The octopole term gives rise to the "black holes" or "canyons" observed by several investigators at $\beta_z = 0.5$, $\beta_z + \beta_r = 1$ and $\beta_r = 0.5$ [3,4,5]. Simulations were performed ignoring these higher order fields using the pure quadrupole term and a pure dipole to approximate the resonance ejection field. The aim of the simulation was to determine the ring RF voltage needed for ion ejection. These simulations are compared to experimental spectra in Figure 2. The ejection ring voltage for the experimental data was measured by connecting a high voltage probe the ring electrode and retuning the L-C circuit.

The simulation has also been expanded to include buffer gas collisions. Collisions are taken to occur at random, based on the collision probability determined from the mean free path of the ion in thermal buffer gas. A collision reduces the velocity of an ion by a random amount ranging from zero to the ratio: $(m_{ion} - m_{gas})/(m_{ion} + m_{gas})$. Simulation of mass selective stability scan in the presence of 1×10^{-3} torr of He buffer gas results in peak broadening without a substanial change in the RF voltage needed for ejection. This suggests that buffer gas collisions improve resolution by improving trapping efficiency, but reduce resolution during the ejection process.

A simulation study has been performed investigating mass range extension factors which produce a fixed RF/AC phase angle. The study concludes that ions are ejected only at a specific RF/AC phase relationship and by choosing the AC frequency such that there is a fixed phase relationship between the RF and the AC more control is gained over the ejection process. It is shown that not all phase angles are optimum, most producing very poor resolution, while a carefully chosen phase angle can dramatically improve resolution. Figure 3 compares the resolution obtained from an arbitray choice of the AC frequency a) compared to choosing an AC frequency with a fixed phase relationship and a specific initial phase angle.

Factors Affecting Mass Measurement Accuracy in the Quadrupole Ion Trap

Kenneth Morand, Hans-Peter Reiser, Jon D. Williams, Randall Julian and R. Graham Cooks, Department Of Chemistry, Purdue University, West Lafayette, Indiana, 47907-1393

Operation of the quadrupole ion trap for mass-to-charge (m/z) range extension is effected by the application of a low voltage dipole signal of appropriate frequency to the endcap electrodes.[1] However, it has been observed that there is a substantial mass shift $[(m/z)_{measured}-(m/z)_{theoretical}]$ associated with the resonance ejection method, the magnitude of which is dependent upon the amplitude of the applied signal.[2] Furthermore, for a constant amplitude, the magnitude of the shift varies from high to low m/z ratio ions.[2] This has a profound effect upon the mass measurement accuracy since the m/z ratio at which an ion will be detected may not be determined by a simple extension of the m/z range and requires that calibrants such as cesium iodide and cesium fluoride be used in order to assign the mass-to-charge for unknown ions. Recent results using a split probe tip and internal calibrants demonstrate mass accuracies of better than 0.007% for the protonated molecular ion of gramicidin S.[3] This was accomplished using a peak matching procedure such that analyte and calibrant ions of differing m/z ratios are brought to an identical point in the mass analysis scan. Although the use of internal and external calibrants does allow sufficient m/z assignment, mass shifts are of fundamental interest.

The oscillatory motion of an ion confined in quadrupole ion trap may be simulated by the simple movement of a mass attached to a spring. During resonance ejection, this motion is modified by the application of a dipole-forcing function allowing the ion to absorb energy and hence increase its trajectory path. Assuming an appropriate dampening or restoring component, this leads to the following equation defining the displacement of an ion due to an applied force.

$$u=\frac{F_o}{\sqrt{m^2(\omega_o^2-\omega^2)^2+c^2\omega^2}}\cos(\omega t-\delta)$$

where u is the displacement of the ion from its resting position, F_o is the applied force and is equal to eV/z_o, m is the mass of the ion, c the dampening factor, ω_o the resonant angular frequency of the ion and ω is the applied angular frequency equal to $2\pi f$.

Clearly from this equation, the magnitude of the displacement will be dependent on (1) the amplitude of the voltage applied in the forcing function, (2) the mass-to-charge of interest when the applied force is constant, (3) the proximity of the applied frequency to the resonance frequency of the spring/mass combination and (4) the magnitude of the dampening factor. This suggests that ions which are resonantly excited may be ejected earlier than predicted during mass-range extension if one of the above criteria are satisfied.

This study concludes that long range mass shifts $|(m/z)_{measured}-(m/z)_{theoretical}|$ associated with resonance ejection in the quadrupole ion trap mass spectrometer may be accounted for by energy absorption at off-resonance frequencies during the radio frequency voltage scan. Results from a variety of experiments show that mass shift is in good agreement with those predictions by the pseudo-potential well model. In addition, short range space-charge effects due to ion m/z proximity are shown to account for mass shifts during the co-injection of cesium fluoride and substance P.

UTILIZATION OF BUFFER GAS MIXTURES FOR ION INJECTION, ACTIVATION AND DISSOCIATION IN THE QUADRUPOLE ION TRAP

*K.A. Cox, K.L. Morand and R.G. Cooks, Purdue University, Department of Chemistry, West Lafayette, IN, 47907

Traditional operation of a quadrupole ion trap mass spectrometer with desorption ionization capabilities involves the injection of low energy ions desorbed from a probe tip and cooling these ions to the center of the trap through collisions with helium buffer gas. Collision-induced dissociation (CID) can then be performed by resonantly exciting an ion at its fundamental frequency, inducing accelerated collisions with the helium gas. This method has been widely used with great success in dissociating ions which require low internal energies to fragment.[1] The presence of small amounts of a heavier mass target, in addition to helium, results in differences in the trapping efficiency upon injection as well as the energy deposited upon CID and the stability of the parent. The experiments described here examine these parameters for three different systems: CsI cluster ions, $C_{60}^{+\cdot}$ and the peptide, leucine enkephalin.

Since the target gas is present in the ion trap throughout the scan, the effects of target gas upon injection as well as during CID are investigated. Previous reports of the use of heavier targets in the ion trap revealed a loss in signal intensity when compared to using helium alone.[2] A systematic study involving Cs^+ and two CsI cluster species in the presence of helium buffer and small amounts of Ar, Kr and Xe, respectively, reveals a strong interdependence between the mass of the ion and the mass and pressure of the target (shown in Figure 1 for the $Cs(CsI)_{31}^+$ cluster). Higher pressures or heavier targets result in a dramatic decrease in the injection efficiency of the lighter ions. However, as the cluster size increases, the injection efficiency is actually enhanced at higher target pressures and with more massive targets.

In addition to enhanced stability, the presence of the larger noble gas species also provides more massive targets for collisions during CID and hence provides access to more energetic fragmentation pathways. In the well-characterized pyrene system, previous studies showed that more energetic pathways are accessed and higher dissociation efficiencies achieved when a small amount of argon is present.[3] CID can also be performed at much lower q values (≤ 0.1) allowing a wider range of fragment ions to be recorded. The heavy buffer gas prevents ejection of the parent and fragment ions due to scattering so that very high mass cluster ions can be effectively dissociated. Figure 2 shows CID spectra for $Cs(CsI)_{31}^+$ at q = 0.074 in the presence of a) helium alone (1.2×10^{-3} torr) and b) helium (1.2×10^{-3} torr) and xenon (1.0×10^{-4} torr).

CID of the fullerene, $C_{60}^{+\cdot}$, shows no fragmentation in the presence of helium alone. However, when 2.2×10^{-3} torr Ne is added, consecutive C_2 losses down to $C_{32}^{+\cdot}$ are observed (Figure 3).[4] This is believed to be the smallest stable intact carbon cluster of geodesic structure.[5]

While peptides are vastly different chemical systems to the ones described above, CID of the small peptide, leucine enkephalin (m/z 556), reveals similar trends. It has been demonstrated that the relative abundance of the y_2/b_3 fragment ions can be used as a gauge to monitor energy deposition.[6] Figure 4 uses this measure to show qualitatively that more energy can be deposited at low CID voltages when heavy targets are present.

In conclusion, the experiments described here illustrate two aspects of the behavior of heavy gases in the ion trap. The larger mass targets aid in cooling extremely large ions upon injection, resulting in enhanced trapping efficiency. During CID, this enhanced stability allows ions to be dissociated at very low q values. In addition, the more massive targets allow higher energy collisions to take place during CID, providing access to more energetic pathways.

Negative Ion Fragmentation Pathways in 2,4,6-Trinitrotoluene

M L Langford and J F J Todd

The Chemical Laboratory, University of Kent, Canterbury, Kent CT2 7NH, UK.

Introduction

The isomer 2,4,6-trinitrotoluene (2,4,6-TNT), has widespread applications as an explosive in both military and non-military fields. Many properties of this substance, and the fragmentation pathways of the molecular ion, have therefore been studied extensively.

The present study examines the cascade fragmentation routes formed by the dissociation of negatively charged 2,4,6-trinitrotoluene. Many of the devices which have been designed to detect explosives depend on the high electron affinity, and thus the high probability of negative ion formation, of compounds such as TNT. The TNT molecular anion is, however, easily fragmented even in soft ionisation ion sources. A complete knowledge of the fragmentation paths produced by the dissociation of $(TNT)^-$ may therefore enable the detection of TNT by the identification of negative fragment ions and may increase the detection limits of this explosive material.

Experimental

All experiments were carried out on a Finnigan MAT. Ion Trap Mass Spectrometer (ITMS) which was fitted with an Air Sampling Glow Discharge (ASGDI) source. A few grains of 2,4,6-trinitrotoluene were placed just outside the source aperture and air was drawn over the sample into the source. A voltage was applied across the electrodes causing a spontaneous glow discharge to occur between the plates. A proportion of sample molecules drawn into the discharge initially suffer fragmentation and then capture an electron from the discharge electron swarm to form a stable negative ion.

Negative ions produced in the glow discharge were directed into a quadrupole ion trap by a series of lenses. The application and manipulation of applied RF voltage and DC voltages is controlled by the construction of a scan function. This was defined using ITMS software to enable MS/MS/MS experiments to be performed in the ion trap.

Results

The isolation and dissociation of the negatively charged molecular ion, M^-, led to the production of two fragment ions with the masses 197 and 210 a.m.u. The isolation and dissociation of the daughter ions reveals that the two ions initiate two completely separate fragmentation pathways as is illustrated in Figure 1. Branch A is initiated by the loss of a NO fragment and appears to be the main fragmentation channel for the M^- precursor. The major channel for the dissociation of this ion appears to be the loss of a further NO fragment and 2(NO) fragments. Fourth generation ions were found at m/z 109 (M-2(NO)-CO), 137 and 139 ((M-2(NO)) and 91. Branch B was initiated by the loss of an OH fragment and is probably a manifestation of the *o*-effect where an oxygen atom from an ortho nitro group is lost together with a hydrogen from the methyl group. Many of the fragmentation processes in this latter branch were difficult to apportion and remain unassigned.

The negative-ion mass spectrum of TNT vapour in air, which was obtained using the above apparatus, contains many ions which do not appear in the fragmentation tree. These are due to the formation of stable negative ions in the ASGDI source following neutral-neutral interactions involving atmospheric molecules. Additional peaks in the mass spectrum indicate the formation of clusters involving some of the dominant atmospheric negative ions.

APPLICATIONS OF THE PEPTIDE SEQUENCING ALGORITHM NEWPS TO FAST ATOM BOMBARDMENT AND ELECTROSPRAY MASS SPECTRAL DATA

Marshall M. Siegel

American Cyanamid Co., Medical Research Division, Lederle Laboratories, Pearl River, NY 10965

SUMMARY

The peptide sequencing algorithm NEWPS has been designed as a robust system for predicting the most likely peptide sequences based upon data obtained in the FAB/MS/MS, ES/MS/MS and cone discharge ES/MS modes. The algorithm is a significantly revised version of one described at the 39th ASMS Conference Proceedings (pp. 1121-2) and is described in the accompanying flow diagram. The robustness of the algorithm is derived from a unique scoring system used to find the most likely partial peptide sequences. Backtracking and feedback methods were used to enhance the speed of the algorithm.

ALGORITHM

A) *DATA INPUT:* Required input for the programs are: (i) molecular weight of the peptide, (ii) charge of parent ion, (iii) observed spectrum: fragment ion masses and intensities, (iv) N-terminating group, (v) C-terminating group, (vi) program control parameters, and, (vii) amino acid residue Look-Up Tables.

When the parent ion in a MS/MS experiment is multiply charged or in cone discharge experiments of multiply charged ions, the observed ions can have a variety of possible charges. For each possible charge, the singly charged masses for each ion are computed. This set of singly charged masses becomes the input data set to be analyzed.

The aa residue Look-Up Tables are of two types: (1) aa residue fragment ion masses, and, (2) mass changes upon fragmentation for each individual aa residue. Separate tables were prepared for N- and C-terminal fragmentation processes. The tables were tailored to the type of data being analyzed and the list of amino acids considered. The Look-Up Tables for high energy FAB/MS/MS data included all the known fragmentation processes (a,b,c,d,v,w,x,y,z) and the masses were expressed as nominal masses. The Look-Up Tables for low energy ES/MS/MS and cone discharge/ES/MS also included the known fragmentation processes (a,b,c,x,y,z) and the masses were expressed as chemically averaged exact masses.

Often sequence ions corresponding to an aa are absent from the mass spectra of a peptide. Such peptides cannot be sequenced when sequencing is performed one aa at a time. Gaps of single aa's in the aa squence are spanned by preparing the Look-Up Tables with both single and pairs of amino acids. When single aa's fail to sequence, pairs of aa's are searched in the Look-Up Tables to extend the sequence, however, the order of each aa in the pair is unknown.

B) *SEQUENCING DETAILS:* The sequencing can begin from either the N- or C-terminus and from either the high or low mass end, all being mathematically equivalent For the following discussions, sequencing will be described beginning from the N-terminus and from low to high mass.

1- Since fragment ions can arise from either the N- or C-terminus, all the possible fragment ion masses are mathematically recomputed as both N-terminus and C-terminus fragment ions where the C-terminus fragment ion masses are re-computed from the N-terminus side. Hence, each mass of the input data set has two corresponding recomputed mass values, all expressed a N-terminus ions. All the possible recomputed ion masses, including the molecular weight of the peptide minus the mass of the C-terminating group, are sorted from lowest to highest mass after subtracting from each the mass of the N-terminating group. Each of these masses are referred to as a "reconstructed ion mass (RIM)".

2- The lowest RIM value is searched in the appropriate N- or C-terminus Look-Up Table of aa residue fragment ion masses for a match and the corresponding amino acid residue is noted. All other fragment ions associated with this amino acid residue are noted by searching the appropriate N- or C-terminus Look-Up Table of mass changes upon fragmentation. All the interpreted RIM values and their sequence ion types are noted in the array MIONFLAG together with the aa residue This lowest RIM value is now considered to arise as a "bad ion", namely a non-sequence ion arising either from the peptide or from any other possible source.

3- The next highest RIM value is analyzed as described in 2. This process is repeated until the mass difference between the highest and lowest RIM values is greater than the highest mass in the appropriate fragment ion mass Look-Up Table. During each of these loops, a number of aa's are interpreted as the first possible aa of the sequence with each of their corresponding MIONFLAG arrays. The collection of these aa answers and their MIONFLAG values constitutes the ANS(WER) file for the first cycle.

4- The masses of the aa's of the previous ANS(WER) file are now considered to be the N-terminating masses of a growing peptide. Steps 2 and 3 are repeated starting from the first non-interpreted RIM values appearing in each of the MIONFLAG arrays, thereby, extending the aa sequence. This process is repeatedly cycled until the mass of the sequenced aa residues is equal to or greater than the MW residue mass of the peptide.

5- SCORING- During each cycle a score is assigned to each of the aa sequences which is based upon the sequence ion information stored in each MIONFLAG array. The numbers of each of the interpreted sequence ion types (a,b,c,d,v,w,x,y,z) are counted. The score is the sum of each number raised to the 1.5 power plus the number of internal acyl and immonium ions normalized by the number of aa's in the sequence also raised to the 1.5 power. This scoring procedure is robust because data having the largest number of similar sequence ion types, a common feature of many MS/MS peptide spectra, are ranked highest as well as those data which have dissimilar sequence ions but an abundance of them. All aa sequences are ranked by their scores and a preset number of the highest scoring sequences are stored in the ANS(WER) files for processing in the next cycle.

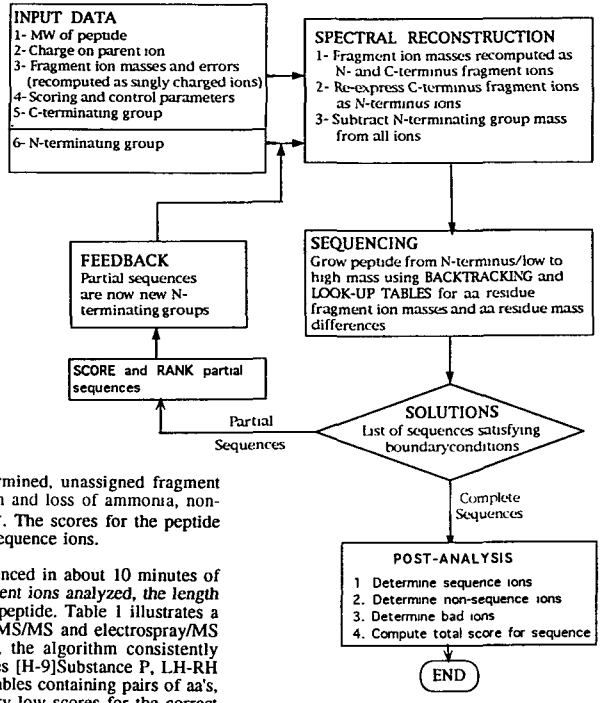
b) The FAB data kindly supplied by A M Falick, University of California, San Francisco and the ES data kindly supplied by J Loo, Battelle Pacific Northwest Laboratories, Richland, Washington
c) ACTH = (RP)VKVYPNGAEDESAEAFPLEF d) Angiotensin I = IDRVYLHPFHL
e) LH-RH = pGlu-HWSYGLRPG-NH_2 f) [Gln8]-LH-RH = pGlu-HWSYGLQPG-NH_2
g) Lys-Bradykinin = KRPPGFSPFR h) [H-9]Substance P = RPKPQQFFGLM-NH_2



C) *POST-ANALYSIS:* For each peptide sequence solution, all sequence ions are determined, unassigned fragment ions are analyzed for internal acyl fragment ions, internal immonium ions, dehydration and loss of ammonia, non-sequence low mass fragment ions and non-sequence neutral losses from the $[M+H]^+$. The scores for the peptide solutions are computed and ranked as described above for sequence ions and the non-sequence ions.

D) *RESULTS:* Using the above described methodology, 50 fragment ions can be sequenced in about 10 minutes of CPU time on a VAX computer. The analysis time is a function of the number of fragment ions analyzed, the length of the Look-Up Tables and the number of partial sequences analyzed, i.e , size of the peptide. Table 1 illustrates a number of examples of peptides sequenced by the NEWPS algorithm. In all the FAB/MS/MS and electrospray/MS examples where sequence ions are present in the spectra for all the predicted aa's, the algorithm consistently sequenced the peptides in a reliable fashion. In the electrospray/MS modes, the peptides [H-9]Substance P, LH-RH and [Gln8]-LHRH were each missing sequence ions for one aa. When using Look-Up Tables containing pairs of aa's, the LH-RH peptides gave the correct sequence. The [H-9]Substance P sample gave very low scores for the correct sequence requiring the cut-off number of analyzed subsequences to be abut 1500 answers. Since lower scores are generated when pairs of aa's are found vs. single aa's, highest scoring is maintained during the analysis if a missing aa residue occurs during the end the sequence rather than the beginning of the sequence. In the LH-RH examples, the sequence information for the last analyzed aa produced a proper sequence while in the Substance P case the sequence information was missing for the fourth aa analyzed. If in this latter case sequencing was performed from the C- to N-terminus, so information was missing from the eigth aa analyzed, a higher scoring sub-sequence should be found.

CONCLUSION

The procedures described above were found to rapidly sequence peptides from a variety of FAB and ES mass spectral data. In most cases studied to date, the correct answer was always one of the top ten candidates when sequence ions were present for each aa.

QUICKPEP: AN OPTIMIZED ALGORITHM FOR PEPTIDE SEQUENCING BY LOW RESOLUTION MS AND MS/MS

D. Zidarov, D. Faubert, P. Thibault and M. J. Bertrand

University of Montreal, Montreal, Canada, H3C 3J7

The interest of mass spectroscopists in the area of peptide sequencing has been intensified in the last decade by the introduction of desorption-ionization techniques. Methods for peptide analysis have been developed using conventional mass spectrometry (MS) with ionization by FAB/LSIMS and PDMS, and more recently using tandem mass spectrometry (MS/MS) with FAB/LSIMS, thermospray (TSP) and electrospray (ES) ionization. Because of the complexity involved in determining the amino acid composition and sequence of peptides several computer programs have been developed to assist in the interpretation of mass spectral data. Our recent interest in the characterization of proteins by enzymatic cleavage with LC/MS/MS analysis of the residual peptides has lead us to extend our peptide sequencing package "PEPTIDE" to include the use of nominal masses by the addition of the algorithm "Quick-Pep" which is designed to process MS or MS/MS data acquired on quadrupole or sector instruments and generated by commonly used ionization techniques. Another objective of the program was the optimization of the speed of execution so that it would allow almost "on-line" sequencing during LC-MS/MS analysis.

In order to handle data acquired in several types of mass spectral experiments (MS, MS/MS) using different ionization techniques and to optimize the speed of execution the methodological approach on which Quick-Pep is based privileges speed and flexibility. Flexibility is needed to allow the use of many mass spectral techniques, and speed is necessary to treat the considerable amount of data generated by LC-MS analysis Thus, the program can be considered as having two distinct modules: the input module and the analytical module. The input module ensures that flexibility is achieved while the analytical module is dedicated to rapidly produce reliable identification data.

The input module can be described in terms of three different classes of input each fulfilling a specific role. The first category of input is concerned with the actual data required to conduct the sequence analysis from the spectrum. These data include the nominal mass of the peptide, the mass/intensity list, the type of C-terminal function and the amino acid base. Amino acids can be discarded or added to the base. The second category of input regards the type of mass spectral and ionization techniques that were involved in obtaining the data The information required in concerned with the use of a filtering routine to remove matrix or background interferences, the type of ion series that should be used for scoring and the method selected for sequence construction Filtering of the spectrum is very useful if not essential in almost all cases while the nature of the matrix is limited to LSIMS/MS analysis. The type of ion series used for scoring is intimately related to the mass spectral and ionization techniques used (MS, MS/MS, FAB, ES etc) and can even be user defined. The method used for sequence construction is related to the ionization method and to the speed of execution. Finally, the third category of input includes optional information such as exact mass, isotopic ratio, amino acids present in the structure and enzymes used to digest. This last category is used to increase the quality of the sequences generated by serving mainly to decrease the list of candidate-sequences. Thus, the input module is used to offer the necessary flexibility and to favor the speed of sequencing by providing the analytical module with the appropriate information.

The analytical module involves the computer algorithm that is responsible for sequence determination and speed of execution. This module is based on the extension algorithm and its rationale is design to favor speed of execution at every step The program initially generates subsequences of up to three amino acids that must be in agreement with the mass spectrum and tries to extend the subsequences by adding an additional amino acid while using a step by step dual scoring procedure, that was described previously and used in 'PEPTIDE". The procedure is based on the intensities of predicted ions and on consecutive sequence ions found within a given fragmentation pattern. This scoring system provides a fairly high resolution in the score which is required in order to establish the most probable candidate-structures. The algorithm tries to generate full sequences, however, it will generate subsequences should no full sequence be found as can be the case in electrospray ionization.

In order to evaluate the efficiency of Quick-Pep with regards to speed and its ability to succesfully analyze data generated by multiple mass spectral techniques, several peptides were analyzed using conventional LSISM/MS, LSIMS/MS/MS, ES/MS/MS and data obtained was processed by Quick-Pep Initial experiments were conducted in LSIMS/MS where it is essential to use a powerful spectrum filtering routine in order for identification to be successful Using this filtering routine, the results obtained for several peptides analyzed by LSIMS/MS are shown in Table 1.

It can be seen from the data presented that most peptides analyzed are correctly identified as the most probable candidate-sequence within tens of seconds At higher masses (>1600 Da) the algorithm fails and this is due to the lack of observed sequence ions which are either lost in the background (S/N<2) or simply not present It is, threrefore, imperative to use a powerful background treatment routine in order to correctly identify peptide analyzed by LSIMS/MS. Typical results obtained by Quick-Pep for LSIMS/MS/MS analysis of parent-molecular $(M+H)^+$ ions reveal that the algorithm is, most of the time, able to correctly identify the peptides analyzed after filtering of the raw MS/MS data, acquired in the MCA mode. The algorithm was also used in order to identify CA spectra generated from $(M+2H)^{+2}$ ions that are produced by electrospray ionization of medium range molecular weight peptides Figure 1 shows the ES/MS/MS spectrum of angiotensin I, which was correctly identified as the most probable candidate-structure by Quick-Pep. Interestingly, the $(M+2H)^{+2}$ spectrum of some peptides lack some sequence ions because of the presence of a very basic residue in the structures The special provisions built-in Quick-Pep to deal with this type of situation reveal that in such cases the program will complete the most probable subsequences found by providing the amino acid complement Thus, the evidence presented demonstrates that the program can be used succesfully with most mass spectral and ionization techniques that are used in the characterization of proteins by enzymatic digest and that it really combines characteristics of speed and mass spectral flexibility

Some less-common fragmentation processes from collision-induced dissociation of peptides

*K.M. Downard, I.A. Papayannopoulos and K. Biemann
Dept. of Chemistry, Massachusetts Institute of Technology, MA, 02139

Collision induced dissociation of peptides within a tandem mass spectrometer is well-established as a sensitive and reproducible approach to peptide sequencing. Peptides have been shown to dissociate along predictable fragmentation pathways often accompanied by hydrogen rearrangement.[1,2] Of the six major ion types produced by the fragmentation of a linear peptide backbone, c_n ions have received relatively little attention. Whilst these ions are generally observed in low relative abundance in CID spectra, they can nevertheless provide valuable sequence information, particularly in regions of a CID spectrum where few other fragments are observed. By studying the many hundreds of CID peptide spectra recorded in our laboratory, it has been possible to determine sequence-related prerequisites under which c_n ions occur. In addition, the dependence of internal fragment ions and neutral losses from amino acid side chains on particular amino acid sequences has been investigated. The rapid retrieval and inspection of CID spectra with a specified sequence or subsequence, or which contain a particular modification, has been facilitated by a computer program (CIDSEQ) especially written for this purpose.

A c_n ion is formed by cleavage of a N-C bond of a peptide backbone such that the N-terminus retains the charge and a hydrogen is transferred from the neutral C-terminal portion. C_n cleavage has been found to occur preferentially adjacent to specific amino acid residues (T>W>K>S>Q>N>C>D>Y>F>L>R>P>G>H>E>A>V>I>M, corrected for cleavage adjacent to the C-terminus) indicating that hydrogen transfer occurs from the side chain of the adjacent amino acid. The effect of c_n ion formation on the nature of the adjacent residue is illustrated dramatically in the CID spectra of two protonated hexapeptides ARVTAL and ARVVAL (Figures 1a and 1b respectively).

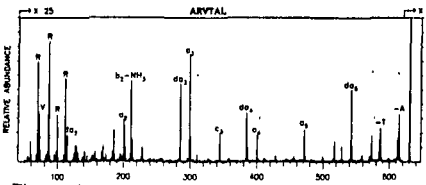

Figure 1a

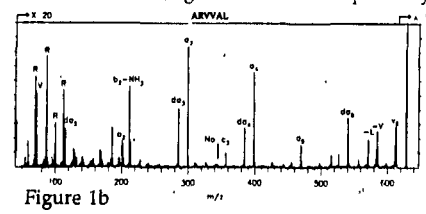

Figure 1b

Figure 1a shows an abundant c_3 ion (*m/z* 344), produced by hydrogen transfer from the adjacent threonine residue. This ion is effectively absent from the CID spectrum of protonated ARVVAL (Figure 1b) where threonine is replaced with valine.

As evidenced from the spectra of Figure 1, CID spectra of peptides with arginine at position 2 show abundant fragments corresponding to b_2-NH_3 ions. This observation is a general one, and is illustrated further in the CID spectrum of protonated Angiotensin I (Figure 2a) where a b_2-NH_3 ion (*m/z* 255) is seen as a fragment of 50% relative abundance. When the N-terminus is acetylated, as in the case of N-acetyl angiotensin I (Figure 2b), the intensity of this ion is dramatically reduced (*m/z* 297, 5%) and an additional ion corresponding to b_2-CH_3CONH_2 (*m/z* 255, 10%) is observed. Similarly, the CID spectrum of protonated N-methyl angiotensin II shows ions corresponding to losses of methylamine (*m/z* 197) and ammonia (*m/z* 211) from the b_2 fragment.

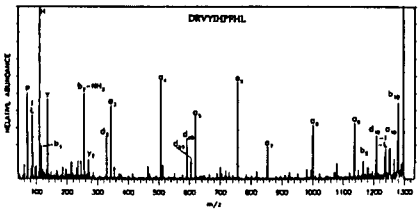

Figure 2a

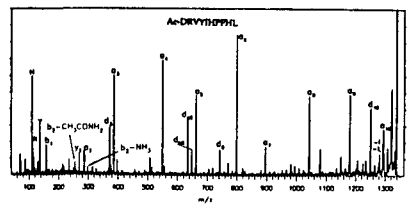

Figure 2b

These results suggest that the loss of ammonia occurs from both the N-terminus and the side chain of arginine through competing processes. However, the loss of ammonia from the N-terminus is clearly dependent on the nature of the arginine side chain, since b_2-NH_3 ions are only observed in CID spectra of peptides which contain arginine (and in some cases glutamine) at position 2. The mechanism below (Figure 3) has been proposed to account for these observations where the loss of ammonia and a substituted amine is rationalised through a common intermediate.

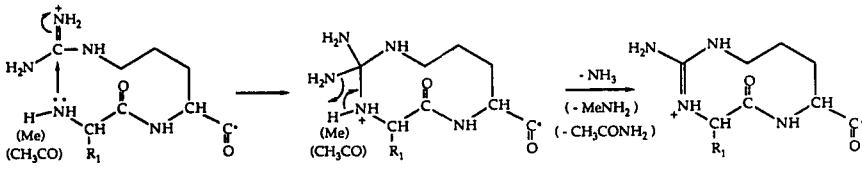

Figure 3

Internal fragment ions are another type of less-common fragment seen in CID spectra. These ions are produced by the cleavage of two bonds within the same peptide molecule, the first a y_n cleavage at one residue and the second a b_n cleavage at another residue toward the C-terminus.
Cyclic peptides are ideal systems for studying the occurence of internal fragment ions since CID fragments can only be produced by cleavage of two bonds of the backbone, the first resulting in the formation of a linear peptide. We have observed that cyclic peptides which contain proline show a propensity to undergo y_n cleavage at this residue. Internal fragment ions are consequently produced by further cleavage of the peptide backbone toward the N-terminus. A similar propensity for y_n cleavage at proline has been observed in CID spectra of linear peptides. Here, abundant fragment ions are commonly detected which correspond to internal fragment ions with proline at their N-terminus. Amino acid sequence-related prerequisites have been described for several types of less-common CID fragment ions. Whilst these ions are generally of low relative abundance in CID MS/MS spectra, they can provide valuable sequence information useful to correctly determine a peptide's primary structure. A knowledge of these prerequisites permits potential ambiguities which arise in both the manual and computer-aided interpretation of CID spectra to be overcome.

Alternative Edman Reagent for Electrospray Detection of Thiohydantoin Amino Acids

K. A. N. Dharmasiri[1], Z. H. Huang[2], and J. Throck Watson[1,2]
Departments of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing, MI 48824

For over 25 years, the Edman degradation procedure has been the principal method to determine the primary structure of peptides and proteins. In conventional Edman degradation methodology, the resulting phenylthiohydantoin (PTH) amino acids are separated by HPLC and detected by UV absorption. The detection limits are in the low picomole for an automated peptide sequenator. In this work, we are modifying Edman reagents in order to produce thiohydantoin products that are amenable to electrospray ionizationmass spectrometry (ESI). The response of thiohydantoin (TH) amino acids during ESI can be increased by incorporating basic or ionic sites into the Edman reagent; with the latter approach, the detection limits can be lowered to the femtomole level[1].

In our laboratory, we have synthesized new Edman reagents having a pyridyl group as the basic site for enhanced detection of the TH amino acids. The isothiocyanates can be prepared using an amine with di-2-pyridyl thiocarbonate (DPT) as the isothiocyanate functional group transfer agent in methylene chloride at room temperature[2]. These isothiocyanates can be identified using their characteristic reaction with sodium azide and dimethyl formamide. We have characterized these reagents and TH amino acids by EI and FAB, and we investigated their response by ESI-MS. The FAB-CAD-MS/MS spectrum of 3-pyridyl methyl thiohydantoin valine is shown in figure. 1.

We investigated a modified Edman reagent that was originally proposed for post column fluorescent derivatization of PTH amino acids. This modified phenylisothiocyanate (PITC) is substituted in the 4-position of the phenyl ring with a t-BOC-aminomethyl moiety. In the acid-cleavage step of the peptide sequencing procedure, it is converted to a free amino terminal. This reagent gives a repetitive yield similar to that of PITC[3]. The ESI-MS spectrum of 500 fmole aminomethyl phenyl thiohydantoin Asp is shown in figure 2.

These new derivatives can be detected at the subfemtomole level using electrospray ionization mass spectrometry.

DISTINGUISHING LEUCINE/ISOLEUCINE AND IDENTIFYING ASPARTIC ACID AND GLUTAMIC ACID IN PEPTIDES BY PLASMA DESORPTION MASS SPECTROMETRY

Rong Wang and Robert J. Cotter
Department of Pharmacology and Molecular Sciences
The Johns Hopkins University School of Medicine, Baltimore, MD 21205

One of the features of plasma desorption mass spectrometry (PDMS) is that molecular ions are the predominant ions in the spectra of peptides and proteins. Thus, the technique has been particularly useful for "*mass mapping*" of unfractionated enzymatic digests. We[1] and others[2-7] have found that PDMS also can provide whole or partial peptide sequence information, although the fragment ions are very weak. In contrast with fast atom bombardment (FAB) and collision induced dissociation (CID) tandem mass spectrometry, PDMS spectrum is much easier to interpret. Here, we are reporting a sensitive and simple method to distinguish leucine and isoleucine isomers by using side-chain specific fragment ions (Δ15 for leucine and Δ29 for isoleucine) in PDMS. Similarly interesting is the loss of carboxyl group related species from the side-chains of aspartic acid and glutamic acid residues.

Fragment Ions Observed in PDMS. All of the PDMS spectra were obtained on a BIO-ION Nordic (Uppsala, Sweden) BIN-10K plasma desorption time-of-flight mass spectrometer, equipped with a 10 μCi $^{252}Cf_{98}$ ionization source. The positive ion PDMS spectrum of parathyroid hormone fragment (39-68, human) is shown in Figure 1. This is a 30 amino acid peptide, APLAPRDAGSQRPRKK EDNVLVESHEKSLG, with a molecular weight of 3285.81 Da. 1 nmole of peptide was applied to the nitrocellulose sample foil. The spectrum was acquired with an accelerating voltage of +18 kV for 2 million primary ion counts.

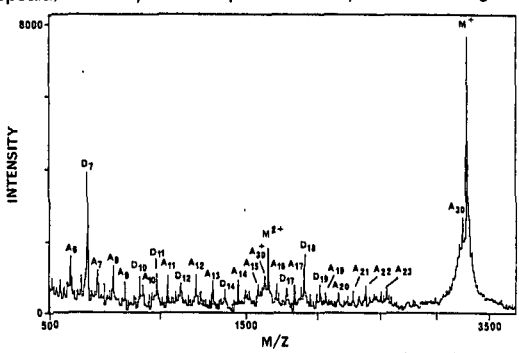

Figure 1. Positive ion PDMS spectrum of parathyroid hormone fragment (39-68, human).

As in other peptide PDMS spectra, we observed very intense molecular ions. Peaks at *m/z* 3286.5 and 1644.0 are $[M+H]^+$ and $[M+2H]^{+2}$, respectively. Fragment ions were also observed between *m/z* 500 and 2600. Their measured *m/z* values were compared with the values calculated for expected fragment ions, and are summarized in Table 1. The fragment ions observed in Figure 1 appear to be exclusively the N-terminal A_n (or A_n+1) sequence ions (A_6 - A_{23}) and some D_n side chain fragment ions.

Sequence vs. Side-Chain Fragmentation. The Positive ion PDMS spectrum of Angiotensin I, DRVYIHPFHL, shown in Figure 2, also exhibits a series of peaks, which reflect the amino acid sequence of the peptide. In this case, about 80 pmoles peptide was applied to the nitrocellulose sample foil. Sequence

ions, A_n, were observed from A_3 to A_{10}, and are denoted in Figure 2. Three side-chain fragment ions, D_3, D_5 and D_{10}, were observed. In contrast to Figure 1, this spectrum shows much weaker fragmentation and has less side-chain cleavage. However, the side-chain fragment ions are amino acid residue specific and sequence information is clear.

Distinguishing Amino Acids with Branched Side-Chains. Angiotensin I has valine at position 3, isoleucine at position 5 and leucine at position 10. Valine has the same branched structure as leucine (*e.g.* two methyl groups) in contrast to isoleucine which has a methyl and an ethyl group. Fragment ions corresponding to the loss of the methyl group from valine (D_3) and leucine (D_{10}) were observed in the spectrum as well as the loss of ethyl group on isoleucine (D_5). These are the only D_n ions observed in the spectrum. Similar results were observed for several other peptides containing these three amino acid residues. With the exception of the D_{10} ion, the side chain cleavages observed in the spectrum of angiotensin I have almost the same intensities as those of their corresponding A_n ions (here, A_3, A_5, A_{10} ions). The lower intensity of D_{10} ion may be due to the fact that it is C-terminal residue. These spectra also indicated that branched amino acid residues tend to lose the large branch rather than the small branch, in this case, the ethyl group in the leucine residue. These results demonstrate that PDMS can be used to identify and distinguish amino acids with branched side-chain structures in the peptides.

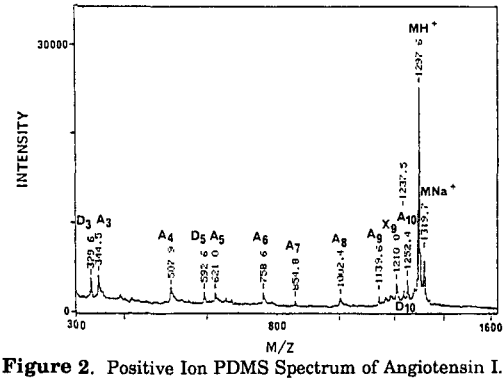

Figure 2. Positive Ion PDMS Spectrum of Angiotensin I.

Identifying Aspartic Acid and Glutamic Acid Residues in Peptides. Two very intense peaks occur at *m/z* 650.2 and 1903.0, respectively in Fig.1. Both are D_n ions (D_7 and D_{18}) occurring as side chain cleavage of aspartic acids. The mass difference between A_7 and D_7 is 45.0 corresponding to loss of the carboxyl group. In contrast, the glutamic acid residue gave relatively weak D_n ions (D_{17} and D_{23}). This discrimination in fragmentation may caused by the interaction of charges between the side chain and peptide backbone. There is one CH_2 less in the side chain of aspartic acid than the glutamic acid, so that the carboxyl group of aspartic acid is closer to the peptide backbone. However, combined with the mass difference of 45 amu between A_n and D_n ions, the difference in intensity of the fragment peaks enables one to easily recognize both aspartic acid and glutamic acid residues.

The results of this study demonstrated that PDMS can be used to identify and distinguish amino acids with branched side-chain structures and aspartic acid and glutamic acid residues in the peptides by observing specific fragment ions corresponding to the side-chain cleavage.

Cleavage of Skeletal Bonds in Enkephalins: A Comparison of the Thermal Degradation of Pentapeptides vs. Collisionally-Activated Dissociation (CAD) of Protonated Molecules

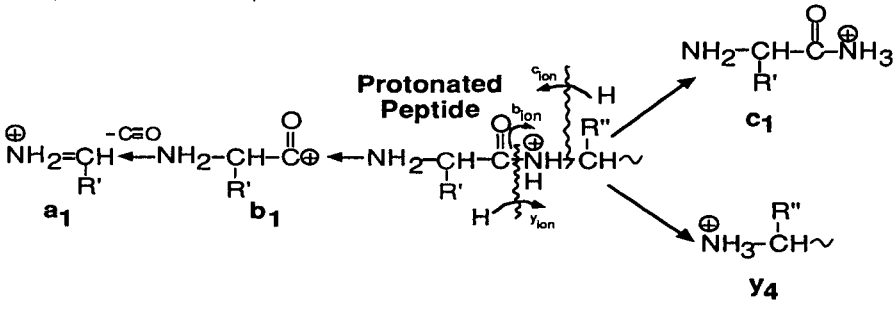
Huaiqin Wu*, Jason C. Rouse, Keith A. Leali, John Allison
Department of Chemistry, Michigan State University, East Lansing, MI 48824

The interpretation of a fast atom bombardment (FAB) mass spectrum of a peptide most often relies only on the presence or absence of ion current at a particular m/z value, but not the magnitude of the signal. The unimolecular dissociation pathways of protonated peptides in FAB are not well understood since there exists many basic sites within peptides where charge-induced and/or remote-site chemistry could occur. This study is an attempt to characterize the formation of fragment ions and correlate their structures, relative intensities, energetic stabilities, and estimated reaction enthalpies. The fragmentation pathways are examined by considering the relative abundances of skeletal bond cleavages and estimated enthalpies of fragmentation. The cleavage of various skeletal bonds in the pentapeptide methionine enkephalin was compared using thermal degradation, FAB, metastable decomposition, and single-collision high-energy CAD.

The thermal degradation technique employed was K^+ ionization of desorbed species (K^+IDS). K^+IDS represents an ideal low energy model for remote-site chemistry because the decomposition products are generated before K^+ ionization occurs. Thermal degradation of methionine enkephalin and its derivatives, CH_3CO-Met-Enk and CH_3CO-Met-Enk-OCH_3 each show unique fragmentation patterns where the lowest energy pathway always dominates. It was found that homolytic cleavages do not occur, reflecting the fact that greater than 80 kcal/mol is required. Lower energy 1, 2-eliminations (requiring 20 - 30 kcal/mol) about the amide bond also do not occur, as indicated by deuterium labeling experiments. The dominant low energy degradation pathway for underivatized methionine enkephalin is the formation of stable [cyclo b-H] and [y+H] neutrals (ΔH_{rxn} =0 to -10 kcal/mol). This process involves formation of a cyclic intermediate, through a favorable secondary interaction (i.e. dipole-dipole) between the terminal amine and an amide bond, through which a H atom shift occurs. For CH_3CO-Met-Enk, formation of [$b_{3,4}$+OH] neutrals becomes the low energy pathway because the N-terminal H atom shift is sterically hindered.

The thermal degradation of methionine enkephalin was compared to the processes that lead to the ions observed in FAB. Mechanisms for the formation of peptide sequence ions in FAB cannot be written unless the structure of the protonated molecule is known. If an amide bond is protonated, simple mechanisms can be written to explain the formation of **a**, **b**, **c**, **y**, and **z** ions. If the carbonyl group is protonated at the oxygen, the formation of the sequence ions is not obvious. We use standard charge-site initiated mechanisms and assume **a** ions come from **b** ions through the loss of CO, **b** ions are a result of a simple inductive cleavage of the amide bond, and **c** and **y** ions occur through cyclic intermediates since favorable secondary interactions (i.e. charge-dipole) facilitate the shift of a H atom to the fragment ion. If inductive cleavage of the NH-CHR bond occurs, then **z** ions are formed; the energy required is estimated to be 69 kcal/mol. Once the mechanisms and structures are established, the relative abundances of the ions indicate which pathways dominate. Reaction

enthalpy data suggests that **b**, **c**, and **y** ions are the result of three competitive processes. Some of these processes are influenced by side chains and steric effects. The sum of the relative intensities of **a**, **b**, **c**, and **y** ions that evolve from protonating a particular residue indicate the extent to which that amide nitrogen is protonated. However, the kinetics which are influenced in part by internal energy content, dictate the amount of fragmentation that occurs and which pathway(s) dominate. When the amide bond in the glycine residue of methionine enkephalin is protonated in FAB, an $\mathbf{a_1}$ ion is dominant. This indicates that the internal energy transferred to this site from protonation is high, and enough energy for complete conversion of $\mathbf{b_1}$ ions to $\mathbf{a_1}$ ions is available. No other significant competitive processes occur because secondary interactions that must occur to form **c** and **y** ions are not favorable. If the amide bond of the methionine residue is protonated, a competition exists because the relative intensities of $\mathbf{y_1}$: ($\mathbf{a_4}$ + $\mathbf{b_4}$) : $\mathbf{c_4}$ are 65% : 28% : 7%, respectively. At the amide bond of the 2nd glycine residue, a competition also exists leading to $\mathbf{y_3}$: ($\mathbf{b_2}$ + $\mathbf{a_2}$) : $\mathbf{c_2}$ are 10%: 70% : 20%, respectively. These distributions clearly indicate that a unique competition for forming low energy ions exists at each amide bond since a different sequence ion dominates from each bond. In the metastable decomposition spectrum of methionine enkephalin, the relative abundance data is inverse to FAB abundance data. For example, the $\mathbf{a_1}$ and $\mathbf{y_1}$ ions are low intensity in the metastable spectrum, but in the FAB spectrum, they are major fragments. Likewise, the $\mathbf{b_4}$ and $\mathbf{y_{n>1}}$ ions are of much greater intensity in the metastable spectrum than FAB. In FAB, the protonated molecules with high internal energy unimolecularly dissociate readily to form the ions observed in the primary FAB spectrum. The protonated molecules with little excess energy may undergo metastable decomposition or remain intact. The ions observed for the two processes are due to the available kinetic pathways which reflect the initial internal energy. The metastable ions would most likely parallel thermal degradation data, however, more fragmentation is observed in the metastable spectrum because there are multiple protonation sites on the molecule which introduce a variety of low-energy options. A "true" single-collision, high energy CAD spectrum, with the metastable ion contribution subtracted out, was reported by us. The types of sequence ions obtained parallel those in the FAB spectrum. However, the intensities are altered because CAD is performed on only those protonated molecules that do not fragment during the FAB experiment. This study represents one of the first attempts to use thermodynamic data to support the fragmentation of peptides using desorption/ionization techniques.



C-Terminal Sequencing Of Peptides Using Electrospray Mass Spectrometry

Kenneth J. Rosnack and Justin G. Stroh
Pfizer Inc, Groton, CT 06340

N-terminal sequencing of peptides via Edman degradation is the most common form of sequencing analysis performed today. Mass spectrometry is useful for sequencing peptides that are resistant to Edman degradation and usually involves digestion of the peptide with enzymes followed by LC/MS (off-line or on-line) and MS/MS. Electrospray ionization is very useful in this regard. However, difficulties often arise in sequencing the peptide near the C-terminus via mass spectrometry. A possible method for C-terminal sequencing using mass spectrometry was first proposed by Caprioli using carboxypeptidase enzymes which cleave single amino acids off the C-terminus of peptides and proteins. Standard biochemical methods using carboxypeptidase digestion involve analyzing the single amino acids that are released during the course of the experiment which require knowledge of the kinetics of the amino acid cleavage. On the other hand, carboxypeptidase digestion with mass spectral analysis requires no knowledge of enzyme kinetics since one observes not the amino acids that are released but rather the peptide that remains after digestion. Therefore, somewhat complex mixtures of peptides can be observed simultaneously since the individual peptides are identified by their molecular weight.

Certain amino acids are cleaved rapidly by carboxypeptidase enzymes, while other amino acids are cleaved quite slowly (especially glycine and serine). The development of an on-line reactor vessel allows us to continuously monitor those enzymatic cleavages that are rapid. When a slow cleavage (gly or ser) is encountered, the reactor flow can be turned off until that particular amino acid is clipped and then the reactor flow can be turned on again.

The reactor is simple in design. A 750mm length of 320μ fused silica tubing is placed in a 37°C constant temperature bath (total volume = 60μL). 50μ tubing is connected to the entrance and exit of the reactor (for low dead volume). Flow is produced from a Harvard syringe pump at a flow rate of 300nL/min. Samples are dissolved in 0.1% acetic acid at 10pmol/μL. Carboxypeptidase P was added at a concentration ranging from 50:1 to 100:1 substrate:enzyme. A sheath liquid of 2-methoxyethanol with 0.1% TFA flowing at 1.5μL/min is added to the sample solution at the electrospray capillary tip, which lowers the pH sufficiently to produce stable and intense electrospray mass spectra.

Glucagon (shown in Figure 1) was digested and we were able to determine the first 23 amino acids. In our analysis of apomyoglobin (Figure 2) we were able to sequence the first 29 amino acids. Finally, we analyzed an in-house unknown and determined the partial sequence to be R-G-R.

The advantages of the technique described here are that one can continuously monitor the enzymatic digestion, "high mass" peptides can be analyzed, and the experiment can be performed on picomolar amounts of material. The disadvantages are that not all peptides work, solubility of the peptide at acidic pH is required, cleavage of Gly and Ser are slow, and salts are not tolerated.

Disulfide Bond Assignment of Endothelin-1 and Analogues by Ionspray Mass Spectrometry

Mark S. Bolgar and Gerald C. DiDonato
The Bristol-Myers Squibb Pharmaceutical Research Institute, Princeton NJ 08543-4000

The general strategy employed for the assignment of disulfide bonds is cleavage of the peptide backbone in between each cysteine residue. The resultant mixture contains disulfide linked peptides, peptides containing no cysteine residues and therefore no disulfide linkages, and possibly uncleaved or partially cleaved peptide. For small peptides the mixture has been successfully examined directly by FAB mass spectrometry without any chromatographic separation. This is a very rapid analysis but has three major limitations: 1) Disulfide bonds tend to reduce during FAB analysis resulting in low signal for the disulfide bound peptides. 2) The signal of hydrophilic peptides can be reduced or completely suppressed by other components in the mixture. 3) Reagents or buffers remaining from the cleavage steps may also suppress ionization.

Ionspray mass spectrometry is well suited to the analysis of disulfide linked peptides because disulfide bonds are not reduced during ionization . Additionally mixtures can be resolved chromatographically and detected by ionspray-MS. Using ionspray in conjunction with enzymatic and chemical cleavages the disulfide bonds have been assigned for endothelin-1 and analogues . Endothelin-1 (ET-1) is a potent vasoconstricting 21-residue peptide with cysteine residues in the 1, 3,11 and 15 positions. This allows for three possible disulfide isomers: 1,3/11,15; 1,11/3,15 and 1,15/3,11. Endogenous ET-1 is the 1,15/3,11 disulfide isomer.

The method employed for disulfide bond determination is a modified version of that reported by Ishibashi[1]. Disulfide isomer 1,3/11,15 can be readily distinguished from the other two isomers via cleavage after Lys^9 with trypsin. Disulfide isomer 1,3/11,15 is cleaved into two new peptides each with an intramolecular disulfide bond. The other two isomers are cleaved into a single new peptide with two chains linked via disulfide bonds. The two remaining isomers 1,11/3,15 and 1,15/3,11 are distinguished from each other by chymotryptic cleavage after Tyr^{13} and Edman cleavage of the N-terminal Cys. Isomer 1,11/3,15 is converted to single new product containing three peptide chains linked via disulfide bonds. Isomer 1,15/3,11 is cleaved into two new products, one containing an intramolecular disulfide bond and the other containing a intermolecular disulfide bond.

The product obtained from the tryptic digest of commercially available ET-1 was examined by ionspray LC-MS. In addition to uncleaved ET-1 one other product was obtained. The molecular weight was 2510, indicating cleavage of the peptide backbone resulting in a product with two peptide chains linked via disulfide bonds. This result indicates that this is not the 1,3/11,15 isomer and is either the 1,11/3,15 or the 1,15/3,11 isomer. Differentiation of the two remaining isomer possibilities is performed starting with uncleaved peptide. The trypsin cleavage is only required to distinguish the 1,3/11,15 isomer. ET-1 was coupled with phenylisothiocyanate, cleaved after Tyr^{13} with chymotrypsin and then the Edman cleavage carried out with neat TFA. The product obtained was examined by ionspray LC-MS. Two components are seen in the LC total ion chromatogram (Figure 1). The mass spectrum of the peak at 4.7 minutes indicated MW 1497.6, which is consistent with residues 2-13 of ET-1 which contain a disulfide bond between Cys^3 and Cys^{11}(Figure 2). The mass spectrum of the peak at 7.8 minutes indicated MW 1314.3 which is consistent with ET-1 residue Cys^1 linked to ET-1 residues 14-21 via a disulfide bond to Cys^{15}(Figure 3). These results that indicate the original peptide contained disulfide bonds between Cys^1 and Cys^{15} and between Cys^3 and Cys^{11} The mass spectrum contains ions only for the disulfide bridged peptides, no ions are observed that correspond to any disulfide reduction products.

While maintaining the disulfide bonds is useful for molecular weight determination of peptides containing intermolecular disulfide bonds, no molecular weight information is available for the individual peptide chains. This information can be obtained through high energy CAD-MS of the intermolecular disulfide containing peptides [2].

Automated LC/MS/MS Analysis of Peptide Mixtures Using Capillary HPLC and Electrospray Ionization on a Triple Sector Quadrupole Mass Spectrometer

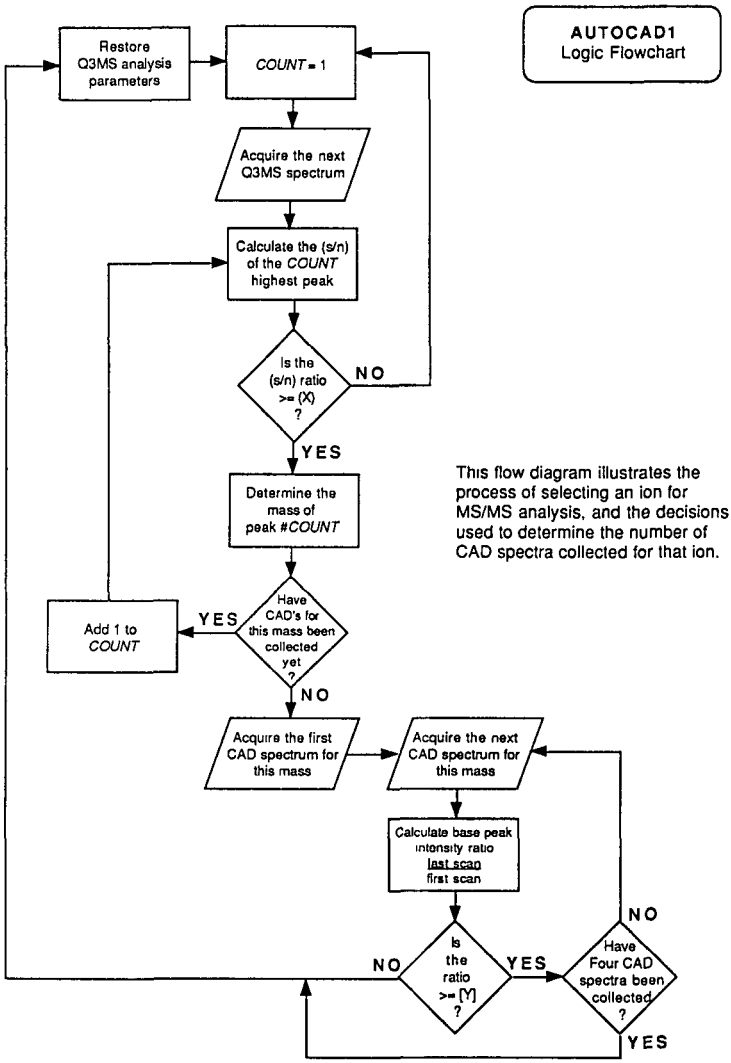
D.C. Stahl, P.A, Martino, K.M. Swiderek, M.T. Davis, and T.D. Lee., Division of Immunology
Beckman Research Institute of the City of Hope, Duarte, CA 91010

The structural characterization of peptides and proteins isolated in minute amounts demands the most efficient use of available sample. The goal of this research was to develop methodology that would provide molecular weight and sequence information on picomole amounts of peptides derived from the digest of a protein with an endoprotease. By coupling capillary HPLC to a quadrupole mass spectrometer via an electrospray interface, it is possible to determine molecular weights for components in the mixture. With tandem (MS/MS) quadrupole systems, it is also possible to obtain fragment ion spectra of individual peptides, and thus obtain sequence information. Previously, at least two HPLC runs were needed to obtain MS/MS spectra. The first run would identify the ions of interest. In subsequent runs, the instrument would be programmed to switch to MS/MS mode at specified times to collect collision activated dissociation (CAD) spectra of selected ion precursors.

We have written two programs (AUTOCAD1 and AUTOCAD2) using Finnigan MAT instrument control language (ICL) that fully automate the collection of MS/MS spectra on a TSQ-700 mass spectrometer. These programs eliminate the need for a first LC/MS run because data is analyzed in real time, and the instrument is switched into MS/MS mode whenever an ion of interest is observed. At the end of each scan, the base peak intensity and signal to noise ratio (s/n) are determined. If either of these parameters falls below a minimum preset value, no ions are selected for MS/MS analysis and the next scan is acquired. If the base peak criteria are met, the mass of the base peak ion is compared with a user list of masses. The difference between the two programs is the treatment of the user list. AUTOCAD1 ignores ions found in the user list. In AUTOCAD2, only ions found in the user list are selected for CAD MS/MS analysis. If the base peak in a spectrum is rejected, the next most intense peak in the spectrum is considered. This process continues until an ion is found that meets the criteria for CAD analysis, or until the s/n falls below the minimum value. A maximum of four MS/MS scans are collected for each selected ion. Fewer than four scans are collected if the signal falls below a certain level. This reduces the risk of missing molecular ions when collecting MS/MS spectra for an earlier eluting component. With AUTOCAD1, ions selected for MS/MS analysis are written to the user list. This allows coeluting components missed the first time to be picked up in a subsequent run.

The programs were tested on a 10 picomole mixture of peptides from an endo Lys C digest of cytochrome c. In a single LC/MS run, molecular weights were determined for all 14 known peptides with masses greater than 500 amu. At the same time, MS/MS spectra were collected for 13 of the 14 components, and for three other ions resulting from impurities in the sample. The MS/MS spectra could be grouped in three basic categories. A few of the spectra had enough information to define the entire sequence. An equal number were largely uninterpretable. Most spectra contained sufficient information to confirm an expected sequence or yield partial sequence information. MS/MS spectra also served to define the charge state of the selected ions.

Using an efficient program to analyze spectra at the end of each scan, it is possible to automatically select ions "on the fly" for MS/MS analysis during the course of an LC/MS run. This automated MS/MS procedure yields typical "electrospray spectra" containing an abundance of sequence information. This makes it possible to rapidly characterize small amounts of complex mixtures. Improved methods of data analysis and spectral interpretation are needed to handle the enormous quantity of data produced using this methodology.



This flow diagram illustrates the process of selecting an ion for MS/MS analysis, and the decisions used to determine the number of CAD spectra collected for that ion.

Sequence Analysis of a Sexual Receptivity-Terminating Factor in the Corn Earworm Moth and Peptides Associated with the Class I MHC Molecule, HLA-B7

W.M. Bodnar, D.F. Hunt, J. Shabanowitz, and H.P. Michel
Department of Chemistry, University of Virginia, Charlottesville, VA 22901
T.G. Kingan
USDA ARS, Insect Neurobiology and Hormone Lab, Beltsville, MD 20705
E.L. Huczko and V.H. Engelhard
Department of Immunology, University of Virginia, Charlottesville, VA 22901

In the corn earworm (Helicoverpa zea), as in many other species of moth, mating is mediated by a pheromone biosynthetic activating neuropeptide (PBAN) (1) that stimulates production and release of species specific sex pheromones by the female. When the appropriate level of pheromone has accumulated in the pheromone gland, the female begins her "calling" behavior in which she extrudes her ovipositor and fans her wings to disperse the pheromone. A so-called sexually receptive female will then accept a mate if he attempts copulation. As a result of mating, production of the pheromone decreases dramatically and female receptivity to the sexual advances of pheromone-primed males declines markedly. Here we report the structural characterization of a soluble pheromonostatic factor (PSF), isolated from male accessory glands, which, when transferred with sperm during mating, is responsible for the decline in sexual receptivity.

Sequence analysis by a combination of microcapillary HPLC/ electrospray ionization tandem mass spectrometry and Edman degradation indicates that the factor is a basic, 57 residue peptide having a protonated average mass of 6,628 Da. The complete sequence has been determined and is presented in figure 1. The molecule contains a blocked amino-terminus (pyro-Glu), a mixture of Asn and Asp at position 6, Met-sulfoxide at position 28, a disulfide bond between Cys-42 and Cys-54, and an amidated carboxy-terminus. These features highlight the benefit of ESI MS/MS over classical Edman sequencing.

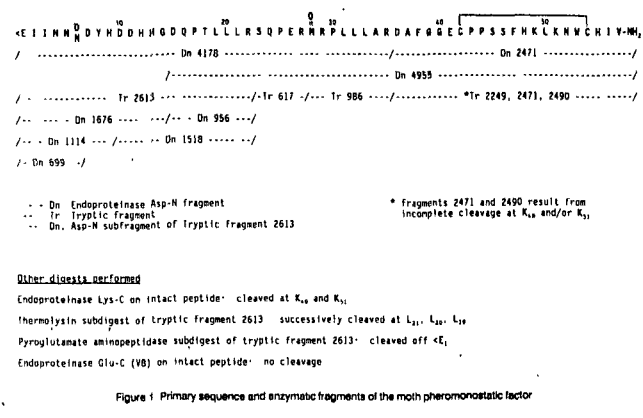


Figure 1 Primary sequence and enzymatic fragments of the moth pheromonostatic factor

Also reported here are results of an effort to characterize the structures of peptides presented to the immune system in conjunction with the human class I major histocompatibility complex (MHC) molecule HLA-B7. Peptides derived from the degradation of intracellular proteins, both self and foreign, are transported to the cell surface via complexation with a class I MHC molecule. Cytotoxic T lymphocytes (killer T-cells) screen MHC-bound peptides on the cell surface and determine the fate of the cell. If non-self peptides such as fragments of viral proteins are identified, the killer T-cell secretes proteins which cause lysis of the infected cell. Once virus particles are released into the extracellular medium they are bound by antibodies and eliminated by the immune system.

On the order of a thousand normal cellular peptides have been extracted form HLA-B7 at the low to sub-picomole level. Complete sequences have been obtained for 14 peptides (Table 1) and partial sequences determined for several others (not shown). Sequence information was obtained from CAD analysis of $(M+H)^+$ and $(M+H)^{2+}$ ions and their derivatives (manual Edman degradation, N-acetylation, and esterification). The peptides sequenced thus far vary in length from 9 to 11 residues and show a sequence motif that differs from those displayed by the class I molecules HLA-A2.1 (3) and HLA-B27 (4). Synthetic peptides corresponding to the 14 sequences determined are being prepared in order to confirm these assignments In most cases, HLA-B7 peptides contain Pro or Val at position 2 and Leu at position 9. To identify possible precursor proteins for these peptides, gene and protein databases were searched, and the 6 matches obtained are described in Table 1. Development of an effective assay to test HLA-B7 peptides for stimulation of cytotoxic T-cell activity is currently underway.

Peptide $(M+H)^+$	Sequence	Source Protein
838	APATPTAPX

Sequence and Functional Characterization of Peptides Associated with the Class I MHC Molecule, HLA-A2.1

A.L. Cox, H. Michel, J. Shabanowitz, D.F. Hunt, Department of Chemistry, University of Virginia, Charlottesville, VA 22901; R.A Henderson, N. Sevillir, V.H. Engelhard, Department of Microbiology and Beirne Carter Center for Immunological Research, University of Virginia School of Medicine, Charlottesville, VA 22901; K. Sakaguchi, E. Appella, Laboratory of Cell Biology, National Cancer Institute, NIH, Bethesda, MD 20892

A complex mixture containing more than a thousand peptide fragments derived from viral or normal cellular proteins is displayed on the surface of nucleated mammalian cells in association with major histocompatibility complex (MHC) class I molecules. Peptides formed by degradation of cytosolic proteins are transported into the endoplasmic reticulum and complexed with class I molecules. The presentation of peptides from viral or foreign tissue origin with class I molecules stimulates cytotoxic lymphocytes to lyse the infected or transformed cells.

This report describes the use of microcapillary HPLC in conjunction with electrospray ionization/tandem mass spectrometry on a Finnigan triple quadrupole instrument (1) to determine the primary structures of peptides isolated at sub-picomole level from the class I HLA-A2.1 molecule. Figure 1 shows a collision activated mass spectrum of peptide $(M+H)^+$ ions at m/z 1121, a peptide which was eluted from two types of A2.1 positive cells.(2) Table 1 shows a partial list of the more than 200 peptides extracted from the HLA-A2.1 molecule. All of the peptides were present only in extracts of HLA-A2.1 positive cells, and peptides synthesized to match the determined sequences were able to compete with antigenic viral peptide for binding to this molecule. All of the peptide sequences were distinct from those previously reported for another class I molecule, HLA-B27.(3) All peptides are 9 residues long, contain Leu/Ile at position 2, hydrophilic residues at positions 1 and 8, and a hydrophobic alkyl side chain, usually Val, Ile/Leu, at position 9. These features define a unique structural motif for peptides bound to HLA-A2.1, and by comparison with the peptides bound to HLA-B27, emphasize the specificity with which different class I molecules bind peptides.

Sequences of three of these peptides were identified in normal cellular proteins with intracellular locations, providing evidence that such proteins are processed and presented in the same way as viral proteins. The enhanced knowledge of peptide-MHC interactions and of the cellular processes that regulate formation of these complexes provided by this research should allow direct identification of peptides that are alloreactive T-cell epitopes. This same methodology should also facilitate identification of peptide antigens associated with viral infection, cellular transformation, and autoimmunity.

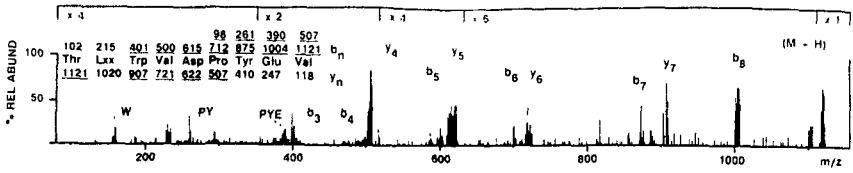

FIGURE 1 Collision-activated dissociation (cad) mass spectra recorded on the ion at m/z 1121 using 100-300 fmol of material from 2 x 10^6. Predicted masses for fragment ions of types b and y are shown, respectively, above and below the deduced amino acid sequence. Ions observed in this spectrum are underlined. This sequence corresponds to an amino acid sequence encoded by the gene TIS21.

TABLE_1 Partial list of peptides presented by HLA-A2.1. Peptides were extracted from C1R-A2.1, C1R and JY cell lines and isolated by using a PA2.1 mAb affinity column. C1R cells do not express HLA-A2.1 Or any other class I molecule, and thus functioned as a control in this experiment. C1R-A2.1 Were derived from C1R cells and were transfected so that they express HLA-A2.1. C1R-A2.1 Cells differ from C1R cells only with respect to expression of A2.1. *JY cells are naturally homozygous for A2.1 And* differ from C1R and C1R-A2.1 In the expression of other class I molecules. Signals for peptide (M+H)+ and (M+H)++ ions observed in the three samples are *summarized in the table. Synthetic peptides, corresponding* to sequences 8 and 14, doped into the sample matrix at the 1 pmol level afforded ion signals at the 60-70 x 10^5 level. Background noise produced a signal at the 1.0 x 10^5 level across the mass range and defined the limit of detection (2/1, S/N) as 30-35 fmol. A (-) in the table indicates that the signal obtained was equal to or below background. Leu and Ile, two residues of identical mass, cannot be distinguished on the triple quadrupole instrument and are designated by the letter, X, in the sequences. Database matches identified the protein sources for peptides 4, 8, and 14, 19 as IP-30, RNA helicase p68, protein phosphatase 2A and TIS-21 respectively.

Sequence Analysis of Peptides Presented by Class II MHC Molecules.

H. Michel, T.A. Dickinson, J. Shabanowitz, T.A. Davis, A.L. Cox, and D.F. Hunt, Department of Chemistry, University of Virginia, Charlottesville, VA 22901; K. Sakaguchi and E. Appella, Laboratory of Cell Biology, National Cancer Institute, NIH, Bethesda, MD 20892; A. Sette and H.M. Grey, Cytel Corporation, San Diego, CA 92121

Recognition of peptide fragments by T-lymphocytes is a central event in the immune response to foreign proteins. Peptides are presented to the immune system in association with either class I or class II molecules of the Major Histocompatibility Complex (MHC). Peptides that are derived from the degradation of cytosolic proteins and transported into the endoplasmic reticulum are found in complexes with MHC class I molecules. In contrast MHC class II molecules bind peptides derived mainly from exogenous proteins that enter the cell by phagocytosis, endocytosis, or internalization of part of the membrane. These exogenous proteins are processed in acidic vesicles and the resulting fragments associated with class II molecules are transported to the cell surface and recognized by helper T-cells.

We used microcapillary HPLC in conjunction with electrospray ionization/tandem mass spectrometry on a Finnigan triple quadrupole instrument (1) for the analysis of complex mixtures of peptides presented by murine class II molecules. The use of this methodology for the analysis of peptides presented by human class I MHC molecules has already been described (2). This methodology defines the approximate number, quantity, and molecular mass of individual peptides associated with the class II molecules. Sequence information can be obtained at the low- or subpicomole level by the process of collision activated dissociation on the triple quadrupole mass spectrometer. Class II molecules were purified from cells of the murine B-cell lymphoma A20-1.11 by affinity chomatography. Peptides were released from the class II molecules on treatment with acid, separated from protein by filtration through an Amicon filter, and fractionated by narrow bore reverse phase HPLC. Aliquots of these HPLC fractions were then further fractionated by microcapillary HPLC and analyzed on the mass spectrometer. From our results we conclude that between 650 and 2000 different peptides are associated with the class II molecule I-A^d. A mixture of similar complexity was also obtained from the class II molecule, I-E^d.

In figure 1 is shown a collision activated dissociation mass spectrum recorded on the $(M+2H)^{+2}$ ions (m/z 838) on one peptide associated with the class II molecules I-A^d. The peptide found are residues 52-68 in the α-chain of the MHC class II protein I-E^d. Another peptide with the same origin, residues 52-57 has also been found. Complete sequences for nine I-A^d peptides are shown in table 1. Complete sequence information for these nine peptides has been obtained by either automated Edman degradation or by the process of collision activated dissociation. The origin of two peptides is mentioned above. Four of the peptide sequences appear in mouse apolipoprotein-E, a seccretory protein found in high abundance in the extracellular medium. One peptide is derived from mouse cystatin-C, a secreted inhibitor of cysteine proteinases. One peptide is derived from the cell surface receptor for transferrin. One peptide is derived from the class II invariant chain (Ii). All peptides contain at least one sequence motif (underlined in table 1) previously described as crucial for I-A^d binding (3). Six of the nine peptides were tested for binding to purified I-A^d by using the corresponding synthetic peptides. All six synthetic peptides bind strongly to the I-A^d molecule. Three of the peptides bind with a several fold higher affinity than the reference peptide, ovalbumin 323-339.

Recently, sequences for twelve 13-17 residue peptides eluted from class II I-A^b and I-E^b molecules have been determined by a combination of HPLC Chromatography and automated Edman degradation (4). We find that the complexity of the peptide mixture associated with class II molecule, I-A^d, is at least two orders of magnitude greater than that described for I-A^b. Peptides associated with most class I as well as class II MHC molecules form rather complex mixtures. The combination of the resolving capability of a reverse phase microcapillary column with the high sensitivity of the triple quadrupole mass spectrometer is ideal for the analysis of these highly complex mixtures

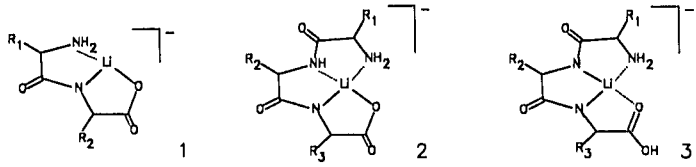
Anionic Lithium-Bound Peptides and Peptide Dimers: Structure and Fragmentation

Peifeng Hu and Michael L. Gross

Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304

By using alkaline matrices (MOH in glycerol), alkali metal ions form metal bound-peptides $[pept + M^+ - 2H^+]^-$ and peptide dimers $[2pept + M^+ - 2H^+]^-$ under FAB. This shows that alkali metal ions are able to deprotonate peptides intrinsically although interactions of this nature cannot be detected in solution[1].

Alkali-metal-bound dipeptides have a structure in which the C-terminal COOH and the amide NH are deprotonated (structure 1). Collisionally activated decompositions of these complexes are consistent with the assignment. Major fragmentations include the loss of the metal ion along with a portion of the C-terminus and the formation of C-terminal ions, x_1, y_1, and that of NH_3 loss (see Figure 1a).



Alkali-metal-bound tripeptides have two structures (2 and 3) because deprotonation may take place at different sites among the three acidic groups (COOH, two amide NH groups). Upon CA, structure 2 forms y_2, O and P ions (see Figure 1d, CAD spectrum of Li^+-bound GPA, which may only have structure 2). Structure 3 mostly undergoes fragmentation by losing H_2O. For peptides containing aliphatic amino acids, the loss of H_2O dominates the CAD of their alkali metal complexes (Figure 1b). It, however, is misleading if the relative population of the two possible structures are assessed on the basis of the relative abundances of water loss (representing structure 2) with respect to those of y_2, O, and P ions. The water loss appears to be more facile than other fragmentations. This can be seen in the CAD of Li^+-bound GFA (Figure 1c).

As we described before[2] an abundant z_n - H is formed when phenylalanine is the *nth* amino acid of the peptide in the CAD of alkaline earth metal bound peptide dimers. The stabilization of the product ion by the phenylalanine side chain renders this fragmentation favorable. Now that the formation of z_2 - H ion from structure 2 is favorable the water loss from structure 3 is no longer dominant. It is virtually less competitive. Based on these observations, the two structures of alkali metal bound tripeptides are considered to have similar populations in the structure composite. The implication is that the alkali metal ions bond peptides via both nitrogen ligands and oxygen ligands.

Alkali metal ion bound peptide dimers decompose principally to form deprotonated peptides. This is in contrast to the formation of metal-bound peptides from doubly charged metal (transition and alkaline earth) bound peptide dimers.

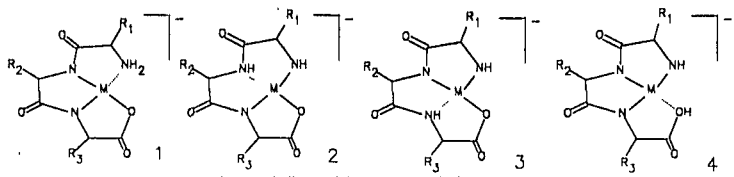
A comparison of ion structure and CAD fragmentation of transition metal bound-peptides and peptide dimers with alkaline earth metal-bound counterparts

Peifeng Hu and Michael L. Gross

Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska-Lincoln, Lincoln, NE 68588-0304.

Doubly charged transition metal ions (Mn, Fe, Co and Ni) complex with peptides to form anionic metal-bound peptides [pept + M^{2+} - $3H^+$]$^-$ and peptide dimers [2pept + M^{2+} - $3H^+$]$^-$. These complexes formally are identical to those of alkaline earth metal ions we reported before[1,2]. They, however, show distinct fragmentations in collisionally activated decomposition (CAD). The differences in the CAD of complexes of different metal groups reflects the intrinsically different coordination properties.

Transition metal-bound tripeptides fragment upon CA by losing portions of both the N-terminus (x_2 and y_2 ions) and the C-terminus (losses of CO_2 and H_2CO_2, see Figure 1). This is in direct contrast to the CAD of alkaline earth metal bound tripeptides, which exclusively fragment to form x_2 and y_2 ions[1,2]. The loss of CO_2 and H_2CO_2 requires that the complex has an protonated C-terminus COOH. This implies that transition metal ions deprotonate amine readily and the transition metal-bound tripeptide exists as a structure composite (structure 1-4). The observation is interpreted to be a result of high nitrogen affinity of transition metal ions. The formation of transition metal-bound dipeptides discussed below supports this intepretation.



Transition metal ion-bound dipeptides may only have a structure in which the peptide is deprotonated at the C-terminal COOH, the amide NH and the N-terminal amine group. The major fragmentations of these complexes include a loss of CO_2 from the C-terminus, a loss of an imine to form x_1 ion or both. The metal ion can also be lost, such as in the formation of the ion marked as **O** in Figure 2a-2b. Cobalt induces x_1 + 2H formation. The x_1 ion is only weakly formed. Fe^{2+}-complexes produce x_1 + 2H along with x_1 ion.

Transition metal-bound dipeptide dimers appear to have a similar structure as that of alkaline earth metal complexes. The metal ion binds to a doubly deprotonated peptide and a singly deprotonated peptide (at C-terminus).The decompositions upon CA show charateristic features (Figure 2c). Alkaline earth metal-bound peptide dimers produce abundant peptide chain fragments. The difference may be explained by the following: 1) Transition metal ions favor nitrogen ligands in coordination. In the dimeric complexes, two of three ionic binding ligands are oxygen ligands; 2) transition metal ions assume octahedral geometry when involved in six coordination. This cannot be satisfied in dimeric complexes.

RAPID HIGH SENSITIVITY PEPTIDE MAPPING BY LC-MS

*Kuldip Mock, Mark Hail, Iain Mylchreest, Joe Zhou, Ken Johnson, and Ian Jardine
Finnigan MAT, San Jose, CA 95134

INTRODUCTION

An ideal system for peptide mapping of proteins includes automated protein digestion and injection onto a dedicated HPLC optimized for peptide and glycopeptide separation; on-line UV detection; on-line high efficiency soft ionization with MS analysis, including molecular weight and fragmentation information; high sensitivity detection; automated recording and interpretation of data including automated search algorithms for predicted peptide molecular weights and significant fragments. Toward such a complete system, we have coupled a new HPLC, which has been specifically designed for optimized analysis of peptides and proteins on 1mm i.d. HPLC columns to an electrospray single quadrupole mass spectrometer. The HPLC allows fast separation of protein digests with UV detection at the low pmole level. A 2 μL/min portion of the effluent is passed into a high sensitivity electrospray MS system. The electrospray source allows for molecular weight associated ions (MH^+, MH_2^{2+}, MH_3^{3+}, etc.) to be generated as well as collision induced dissociation of these ions before MS analysis. The quadrupole m/z range is 2000 which is sufficient for peptide mapping analysis by electrospray. After LC-MS runs, with or without partial fragmentation, the data generated are largely interpreted by identification of predicted peptides, incompletely digested peptides, unusual peptide cleavages, and so on, using appropriate integrated software (PEPMAP™, PEPMATCH™). Examples of peptide mapping at the low pmole level using this integrated system will be shown (e.g. of the proteins, tissue plasminogen activator, and human growth recombinant hormone.

EXPERIMENTAL

Materials: Tryptic digests of native recombinant human growth hormone and reduced carboxymethylated tissue plasminogen activator were analyzed.

Chromatography: The HPLC used in this work consisted of a Michrom (Pleasanton, CA) capable of delivering linear reproducible gradients at low flow rates (e.g. 50 μl/min). All chromatographic separations were accomplished using a Reliasil 150 x 1 mm i.d. column packed with a C18 stationary phase. The mobile phase A consisted of water containing 0.1% trifluoroacetic acid. Mobile phase B was acetonitrile containing 0.085% trifluoroacetic acid. The column effluent was split at a ratio of 25:1 to give a flow rate of 2 μl/min into the mass spectrometer.

Electrospray mass spectrometry: Experiments were conducted on a Finnigan MAT SSQ®710 single stage quadrupole mass spectrometer fitted with a 20kV post-acceleration detector and an electrospray interface (ESI) - figure 1.

Collisionally-activated dissociation spectra of peptides were generated between the capillary and the skimmer. The voltages were increased from 36 to 100 on the capillary lens and to 195 from 136 for the tube lens.

RESULTS AND DISCUSSION

Figure 2 shows ESI/LC/MS of human growth hormone tryptic digest at 26 pmoles loaded on the LC. A half-hour separation accounted for most of the tryptic fragments (16 out of the expected 21) of human growth hormone.

After LC-MS the data generated are interpreted using integrated software (PEPMAP™, PEPMATCH™). Results of the pepmap chromatogram search are detailed in figure 3. Using this, it was possible to rapidly locate the disulfide-bridged peptides, two in the case of human growth hormone (T_6-T_{16}, T_{20}-T_{21}) and an incompletely digested fragment (T_{18}-T_{19}).

Figure 4 is a source-CAD spectrum of tryptic peptide T_{11} from human growth hormone, obtained from an on-line ESI/LC/MS experiment. Tissue plasminogen activator, a 527 amino acid glycoprotein, was also tryptic mapped.

CONCLUSIONS

1. Routine LC/MS peptide mapping on a single stage quadrupole mass spectrometer
2. Accommodate full LC gradients including trifluoroacetic acid
3. UV trace is acquired directly on the data system on the mass spectrometer
4. Sensitivity is excellent
5. Automated peptide matching, deconvolution, and in particular, peptide mapping to confirm amino acid sequences. Confirmation and correct configuration of disulfide bonds and presence of glycosylation
6. Source collisionally-activated dissociation works well, with good sensitivity. Different solvent systems can influence CAD. This requires further investigation.
7. Ideal set-up, 1/25 of sample consumed and the rest fraction collected for further analysis (e.g. Edman sequencing)

Amino-Terminal Quaternary Ammonium Derivatives of Peptides Alter Fragmentation by Electrospray Ionization/Low-Energy Collisionally Activated Dissociation.

John T. Stults
Protein Chemistry Department, Genentech, Inc.
460 Point San Bruno Blvd., South San Francisco, CA 94080.

Peptide sequencing by tandem mass spectrometry is an important technique in protein chemistry. The recent introduction of electrospray ionization adds another tool to the expanding repertoire of biological mass spectrometry. Efforts to determine the sequences of peptides, using electrospray ionization and low energy collisionally activated dissociation, are not universally successful. One of the chief problems is the lack of complete ion fragmentation series, especially for large peptides or for peptides which contain a basic amino acid at a site other than the N- or C-terminus. In addition, the CAD spectra of the doubly-charged precursor ions of tryptic peptides frequently show a significant series of ***y*** ions, but few of the corresponding ***b*** ions.

To address this problem, peptide derivatives were prepared in which a quaternary ammonium group is added to the α-amino group. These derivatives have been shown to produce extended ion series in peptide high-energy CAD daughter spectra (1-3). The peptides are modified by a two step procedure (4). An iodoacetyl group is first added at pH 6, conditions in which the α-amino group reacts with high specificity over other amino groups. A dimethylalkyl amine is subsequently added to form the quaternary ammonium derivative. In this work, the dimethylhexylammonium acetyl (DMHA) peptides were formed. The derivatives were purified by RP-HPLC prior to analysis. Spectra were acquired with a Sciex API-3 triple quadrupole mass spectrometer. Ions were formed by pneumatically-assisted electrospray ionization (Ionspray) from approx. 10 pmol/μl solutions, flowing at 1.5 μl/min. The collision energy (laboratory frame) was 90-150 eV, with argon as the collision gas.

Figure 1 shows the CAD spectrum of the tryptic peptide T49 (DVPGVYTK, M_r 878.0) from recombinant tissue plasminogen activator (tPA). Only a partial series of ***y*** ions is observed. Figure 2 shows the CAD spectrum of this peptide following derivatization, the DMHA-T50 peptide (Mr 1048.3). A complete series of ***a*** ions is observed. The C-terminal ions are completely absent.

From these and other spectra obtained for this study, several observations were made:

- A strongly basic C-terminal residue (Arg, but not Lys) may yield a few abundant ***y*** ions, but only at higher masses.
- Fragmentation is weak immediately to the C-terminal side of prolines.
- The fragmentation of the DMHA-peptides requires higher energy than for underivatized peptides. If a basic residue is near the N-terminus, the energy required appears to be even greater.
- Unlike the case for high-energy collisions, the derivatization does not increase the size of peptide that may be sequenced.
- The signal strength for the precursor ion of the DMHA-peptide is lower than for its underivatized counterpart by a factor of 2-5.

The differences observed between derivatized and underivatized peptides may shed some light on the mechanisms involved in low-energy CAD of doubly-charged precursor ions. The paucity of C-terminal fragments from the doubly-charged precursors of the DMHA-peptides suggests that proton-stripping is an important process. If this is the case, it remains unclear why the singly-charged precursor is seldom observed in these CAD spectra. One explanation is that fragmentation in low energy CAD occurs mainly at the site of protonation, which is supported by the evidence that charge-remote fragmentation is normally observed only for high-energy processes. Thus, the proton cannot be localized to the basic C-terminal residues. The data presented here further indicate that the proton must be lost in the fragmentation process.

Regarding the analytical utility, these results indicate that low-energy CAD spectra from fixed-charge derivatives of peptides yield complementary information to that from the underivatized species. The strong a_1 ion may prove useful for determination of the N-terminal residue, which is frequently difficult to determine from the underivatized peptide. In some cases, the ability to determine the peptide sequence is improved.

TANDEM MASS SPECTROMETRY OF THE S-PALMITYLATED PEPTIDE VTTLCCGKNP FROM THE C-TERMINAL REGION OF BOVINE RHODOPSIN

D. I. Papac, K. R. Thornburg, E. E. Büllesbach†, R. K. Crouch* and D. R. Knapp
Departments of Pharmacology, Biochemistry†, and Ophthalmology*
Medical University of South Carolina, Charleston, SC 29425

Introduction

Bovine rhodopsin is the prototypical G-protein coupled receptor whose structure is the basis for the structure of all the other G-protein coupled receptors. Bovine rhodopsin has been shown to be labeled with tritiated palmitic acid (1). In 1988, Ovchinnikov *et al.* reported that the peptide containing residues 318-348 from bovine rhodopsin was the site of palmitic acid attachment (2). Although the palmitylated peptide, residues 318-348, could not be isolated; Ovchinnikov *et al.* concluded that cysteines 322 and 323 were palmitylated. That same year Karnick *et al.*, using site directed mutagenesis, concluded that the presence of palmityl groups on cysteines 322 and 323 was not essential for transducin activation (3). This uncertainty in the site and nature of the palmitic acid bonds prompted us to use mass spectrometry to identify the sites of palmitylation in bovine rhodopsin.

Methods

Rod outer segments were isolated from 100 frozen bovine retinae using the method of Papermaster and Dreyer (4). Membrane bound rhodopsin was cleaved with thermolysin using an enzyme/substrate ratio of 1:20. The major thermolytic fragments, F1 and F2, were carboxymethylated with iodoacetic acid without prior dithiothreitol reduction, and separated on a Sephadex LH-60 column equilibrated with formic acid/ethanol (3:7). The F2 fragment was dissolved in 70% formic acid and cleaved with a 500-fold molar excess of CNBr. The CNBr peptides of F2 were separated using a cyano column (Brownlee, 2.1 x 30 mm, 5µm particle size) with a nonlinear gradient of 0.1% aqueous trifluoroacetic acid and acetonitrile/n-propanol (2:1) containing 0.078% trifluoroacetic acid. The eluent was monitored at 214 nm. The preparation of a reference palmitylated peptide is outlined in figure 1. The protected peptide shown at the top of figure 1 was prepared using Fmoc chemistry on SASRIN resin with an Applied Biosystems Inc. 430A Peptide Synthesizer. The trimethylammonium acetyl derivative was prepared as described by Vath and Biemann (5). The methyl ester was prepared with 2 N methanolic HCl. Mass spectra were recorded on a JEOL HX110/HX110 mass spectrometer. Samples were ionized with 18 kV cesium ions from a glycerol/mNBA alcohol matrix (1:1). Single stage analysis was performed with an accelerating voltage of 10 kV and a resolution of 1500. The MS/MS experiments were performed with the collision cell operated at 3 kV filled with helium sufficient to attenuate the ion current of the C-12 parent peak by 70%.

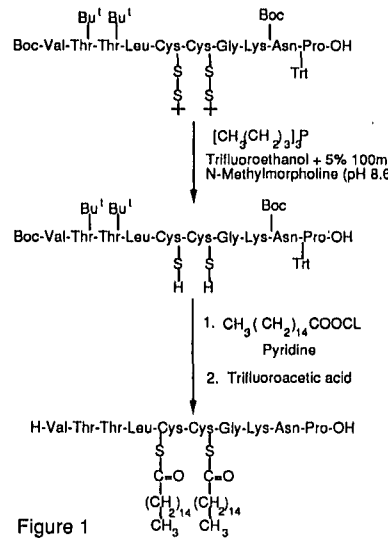

Figure 1

Results

Membrane bound bovine rhodopsin was cleaved with thermolysin to generate two large fragments; F1, residues 1-240, and F2, residues 241-327 which were separated by size-exclusion chromatography. F2 was further cleaved with CNBr and separated by reversed-phase HPLC (Fig. 2A). A peptide fraction was collected from the HPLC which had the same retention time (67.8 min) as the synthetic standard (Fig. 2B). LSIMS analysis of both the synthetic peptide and the isolated peptide produced a molecular ion with m/z of 1511.7 Da. The calculated molecular weight for the bis-palmitylated peptide (VTTLCCGKNP) from bovine rhodopsin is 1511.9 Da. Proof for the location of the palmityl groups was provided by MS/MS. Figure 3 is the MS/MS spectrum for the isolated peptide. A sufficient number of fragment ions were present to show that the palmityl groups were attached to the two cysteine residues. To facilitate interpretation of the MS/MS spectra of the palmitylated peptide, various derivatives of the peptide were prepared. The methyl ester derivative (MH^+ = 1526.9 Da), trimethylammonium acetyl derivative (MH^+ = 1610.9 Da) and the myristylated peptide (MH^+ = 1455.9 Da) were prepared and analyzed by MS/MS. A common feature of all the MS/MS spectra for the various peptides was that the most abundant fragment ions were generated by cleavage of the fatty acyl groups on either side of the sulfur atom.

Conclusion

We have shown that bovine rhodopsin is palmitylated on cysteines 322 and 323 as first suggested by Ovchinnikov *et al.* (2).

Characterization of the Gramicidin and Tyrocidine Fractions of the Tyrothricin Complex from *Bacillus brevis* using Liquid Chromatography and Mass Spectrometry.*

Xue-Jun Tang, P. Thibault and R.K. Boyd. Institute for Marine Biosciences, National Research Council, 1411 Oxford Street, Halifax, Nova Scotia B3H 3Z1, Canada.

Tyrothricin, the peptide fraction from the fermentation broth of *Bacillus brevis*, was the first antibiotic used in clinical practice. It was shown to contain a neutral fraction (the gramicidins[1]) comprised of a mixture of linear peptides, plus a basic fraction (the tyrocidines[2]) consisting of cyclic peptides. The tyrocidines are not amenable to sequencing by orthodox Edman-type strategies, and primary structures of five compounds (tyrocidines A-E) have been established[2] by classical methods of organic structure determination. More recently, Barber *et al.*[3] applied techniques of tandem mass spectrometry to the crude tyrothricin complex, and succeeded in establishing an additional 5 new structures (one of the structures claimed[3] to be new, and christened tryptocidin C, is in fact identical to the previously known[2] tyrocidine D).

In the present work, LC-MS analysis of the tyrothricin complex, using ionspray ionization, demonstrated sufficient complexity (*e.g.* Figure 1) of the tyrocidine fraction that it seemed unlikely that on-line LC-MS-MS techniques would suffice. Accordingly fractionation by preparative HPLC, resulting in 32 purified fractions (some of which were still mixtures) were subjected to MS-MS analysis of the $(M+2H)^{2+}$ ions of the constituent peptides using flow injection (*e.g.* Figure 2). In all 18 new cyclic tyrocidine analogues, in addition to the 10 already known[2,3], have been thus characterized. In addition, several other compounds could be only partially characterized. All 28 components may be regarded as derived from tyrocidine C *via* amino acid substitutions at one or more of just 5 of the 10 residues (see below -- the numbering system is arbitrary). Distinction of Leu from Ile was not possible under the low-energy CID conditions used (SCIEX API III triple-quadrupole), and the nature of the residue labelled (Trp+28), for convenience, is wholly unknown at present.

The linear gramicidins (*not* related to gramicidin S, which is in fact closely related to the tyrocidines) are pentadecapeptide ethanolamides[1] in which the N-terminus (either Val or Ile) is formylated; they may be regarded as hexadecapeptides in which the C-terminal glycine has been reduced to a primary alcohol. Six linear gramicidins were known previously[1], and the present work has demonstrated the presence of 3 new components which are homologues of Val[1]-gramicidins A, B and C, with the additional methylene in the C-terminal alkanolamide.

Investigation of Fragmentation Mechanisms of Doubly Protonated Tryptic Peptides.*

Xue-Jun Tang and R.K. Boyd. Institute for Marine Biosciences, National Research Council, 1411 Oxford Street, Halifax, Nova Scotia B3H 3Z1, Canada.

Tryptic peptides, with a highly basic Arg or Lys residue at the C-terminus, form abundant $(M+2H)^{2+}$ ions under electrospray/ionspray ionization. These doubly-protonated peptides readily fragment [1-6] to give abundant sequence information. The fragment spectra are dominated by y" ions, with usually much less intense a and b ions. The combined masses of each (y_i" plus b_{n-i}) complementary pair account for the mass of the $(M_n+2H)^{2+}$ precursor; this would suggest a charge-separation mechanism, despite the unequal intensities of the y" and b products. Figure 1 shows a comparison of the MS-MS fragment spectra of $(M+H)^+$ and $(M+2H)^{2+}$ ions from the tetrapeptide GGYR. Apart from the dominance of the y" fragments from $(M+2H)^{2+}$, this Figure illustrates the more facile fragmentation of the doubly-protonated form and also the formation of doubly-charged fragment ions assigned as $(y''')^{2+}$ (labelled as Y^{2+} on the spectrum).

MIKES investigations, intended to demonstrate charge-separation *via* characteristically broad peaks in complementary pairs characterized by a common value for the k.e. release, were unfortunately inconclusive. This was due in part to low signals for $(M+2H)^{2+}$ using LSIMS ionization, even for the pre-formed peptide dihydrochloride [6]. Broad peaks interpretable as y" fragments were observed at the high-mass end of several MIKE spectra, but the complementary low-mass b fragments were not observed, possibly due to extreme instrumental discrimination.

The possibility of a dissociative charge exchange mechanism, proceeding *via* a hypervalent $(M+2H)^{+\cdot}$ intermediate, was discounted on the basis of failure to observe the required cation from the collision gas despite an exhaustive search, and also by the fact that all $(M+2H)^{2+}$ ions studied showed at least one intense fragmentation reaction, plus others less intense, in the absence of collision gas. Another possibility which would not require equal intensities of y" and b fragments would involve initial expulsion of one proton, followed by "conventional" fragmentation of the $(M+H)^+$ intermediate; however, no trace of this (normally stable) species was found, and some reactions of $(M+H)^+$ precursors were entirely absent from the spectra of their $(M+2H)^{2+}$ counterparts, *e.g.* intense (y"-17) fragments from $(M+H)^+$ if M contained Arg at the C-terminus.

By default, the only possibility appears to involve direct charge-separation of $(M+2H)^{2+}$ to complementary (y"+ b) pairs. The low intensity of the b fragments must reflect an intrinsic instability and consequent facile fragmentation to low-mass immonium ions and similar fragments. This was investigated by MS-MS-MS experiments in which y", b and a fragments were induced by collisions in the de-clustering region of the ionspray interface, and then subjected to conventional low-energy MS-MS as a function of (argon) target thickness. These results are shown in Figure 2, and indeed the y" ions are much more resistant to CID than are the a and b ions.

None of the foregoing addresses detailed mechanistic questions. A series of experiments, involving monoacetylation of these tryptic-like peptides, strongly indicated that the extra protons in the non-reactive $(M+2H)^{2+}$ ions are localized on the N-terminus amino group and on the sidechain of the basic C-terminus residue. Facile fragmentation to (y"+b) pairs requires activation and migration of one proton plus one H-atom to the site of amide cleavage, reminiscent of recent work [7] on $(M+H)^+$ ions.

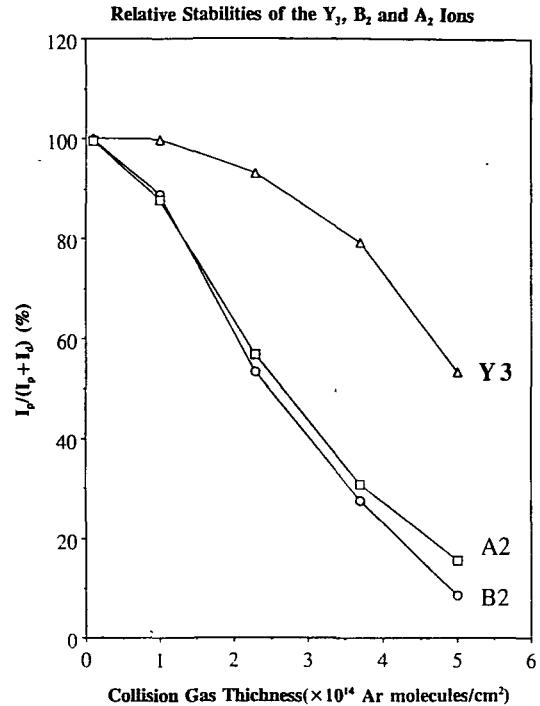

Fig. 2 The relative stabilies of y_3'', b_2 and a_2 ions from peptide YIGSR. These precusor ions were produced by CID in the de-clustering region of the ionspray interface. Five fragment ion spectra of each precursor were obtained by CID in RF-only collision cell with different argon collision gas thicknesses. The Lab. frame energy is 70ev for the singly charged precursors. I_p is the intensity of precursor ions and I_d the summed intensities of all fragment ions in each spectrum.

Fragmentation in the LSIMS Daughter Ion Spectra of Bicyclic Lactam Bridged GnRH Analogs Analyzed with the Computer Program AMASS.

A. G. Craig, S. C. Koerber, J. Porter and J. E. Rivier
The Clayton Foundation Laboratories for Peptide Biology, The Salk Institute, P.O. Box 85800, San Diego, CA 92186-5800.

Folding of peptides can be induced and stabilized through the introduction of internal bridging elements (1). We recently synthesized several highly potent GnRH antagonists possessing two lactam bridges (2). The procedure for cyclizing these compounds typically involved formation of one bridge while the peptide was retained on the resin, during solid phase peptide synthesis (SPPS) while the second bridge was formed in solution after removal of the peptide from the resin. Using these procedures we carried out the synthesis of (cyclo 1-8,4-10) Ac-DGlu-DCpa-DPal-Asp-Arg-DNal-Leu-Lys-Pro-Dpr-NH_2 (**1**) and the corresponding {$LGlu^1$} GnRH analog (**2**) (see reference (1) for amino acid abbreviations). Each synthesis unexpectedly resulted in two closely related peptides which could be resolved and purified using HPLC (labeled **1a**, **1b** and **2a**, **2b**). These analogs had remarkably similar LSIMS mass spectra. Elevated temperature HPLC (60°C) indicated that **1a** and **1b** or **2a** and **2b** were not in a conformational equilibrium. All four compounds were found to have different optical rotations and slightly different biological potencies in vitro and in vivo. The possibility of racemization of a residue occurring during SPPS or cyclization was discounted on the basis of two results. Firstly, the synthesis of the monocyclic peptide of each bridge resulted in only one major product. Secondly, co-injection on HPLC of **1a**, **1b**, **2a**, **2b** indicated four unique peptides.

In the absence of alternative explanations we decided to investigate the unlikely hypothesis that the cyclization steps resulted in two structural arrangements. This is shown schematically in Figure 1. In order to exclude this possibility, we used the recently developed computer program AMASS (3) to search for all possible fragment ions formed by one or two bond cleavages within these bicyclic GnRH analogs. Based on the comparison of each list of possible fragment masses, we identified three (811.5, 827.4 and 968.5 Da) which would be characteristic for one or the other structural arrangement. For example the $\{(b_2) + (x_2)\}$ or $\{(c_2+1) + (y_2+2)\}$ structures (described using a proposed nomenclature scheme (4)) from the 1-10, 4-8 structural arrangement would correspond to the 811.5 and 827.4 Da fragment ion respectively while the $(p(\chi_1)_8/y_8+2)$ structure would correspond to the 968.5 Da fragment ion from the 1-8, 4-10 structural arrangement. While neither CID - daughter ion spectra of **2a** and **2b** contained ions in the region 804-817 or 819-830 Da, both spectra contained the m/z 966.4 fragment ion. We interpret these results as a confirmation of the presence of the desired bridges (i.e. 1-8, 4-10). We therefore proposed that in each synthesis either 2a or 2b (or 1a or 1b) was the result of the formation during the cyclization (i.e., 1-8) of an iso-γ-glutamic residue in position 1 .

Using the program AMASS and the CID daughter ion spectra we were able to confirm the structural arrangement of a complex GnRH analog.

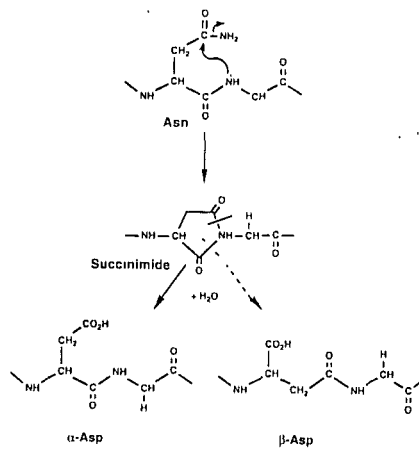
Differentiation of α- and β-aspartic Acids in Isomerized Peptides by Tandem MS

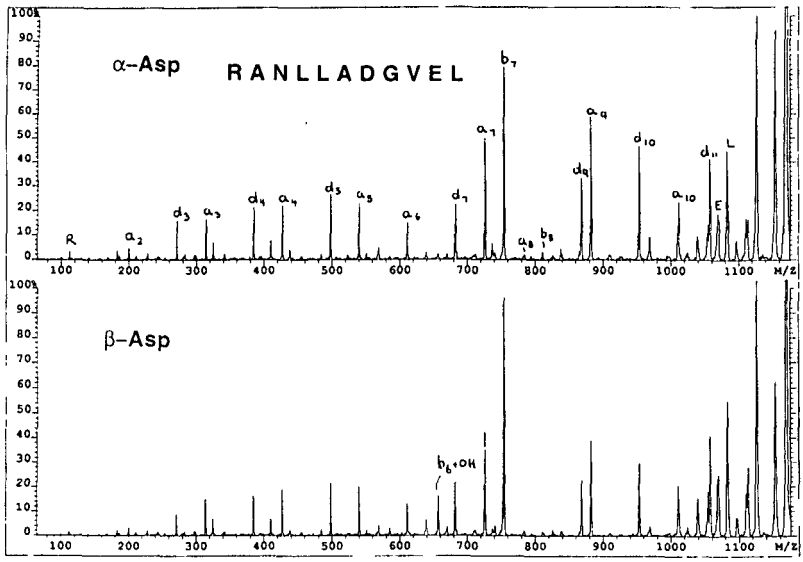
Mark F. Bean and Steven A. Carr
SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

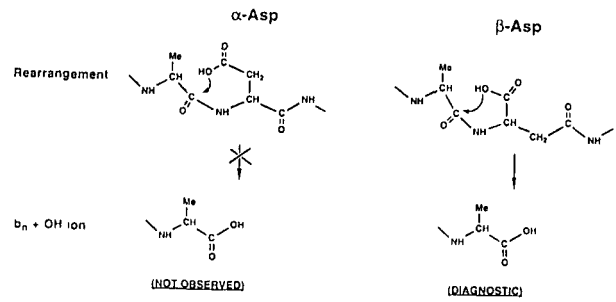
Aspartyl isomers can result from deamidation of asparaginyl (Asn) residues in peptides and proteins and is frequently observed in proteins exposed to alkaline conditions during isolation. Deamidation in proteins proceeds via a cyclic imide (succinimide) when the amino acid C-terminal to Asn is Gly, Thr, or Ser. The succinimide can then reopen to either α- or β-Asp (Fig. 1). Isomerization of aspartic acid might also occur during peptide syntheses such as the common RGDS sequence. Loss of protein or peptide activity can be attributed to such deamidated or isomerized products, and mass spectrometric methods are one attractive means of aspartyl characterization because of their speed and sensitivity. They cannot be used in a quantitative fashion when mixtures of α- and β-isomers are present.



The approach we have taken is high-energy CID product-ion tandem MS analyses because the side-chain cleavages of peptides commonly observed by this method looked promising for distinction of the different length side chains of the two aspartyl isomers. This was not as straight forward as we expected. For natural and synthetic tumor necrosis factor (TNF) peptides with basic amino acids at the C-terminus (tryptic fragments), we did indeed observe the expected **v**- and **w**-ions for the α-Asp peptide and the **v**-ion for the β-Asp isomer. Unfortunately, the diagnostic α-Asp sequence ions were of very weak intensity and appeared to overlap with interfering signals. After methyl esterification, the diagnostic ions were clearly observed for both peptides.

In the case of peptides with a basic N-terminal residue, a signal corresponding to the side-chain cleavage **d**-ion was seen for the α-Asp isomer. Nevertheless, a signal with the same m/z results from decarboxylation of an **a**-ion like fragment of the β-isomer. There was a signal observed uniquely in the spectrum of the β-Asp sequence but of a nature that we had not previously experienced (Fig. 2). It corresponds to a **b**-ion cleavage N-terminal to the β-aspartyl with addition of water, analogous to the C-terminal hydroxyl rearrangement ions commonly observed in high-energy tandem MS of cationized peptides or under low-energy CID conditions (Fig. 3). We have looked at other sequences and observed the same ion for the β-aspartyl isomer only. Papayannopoulos and Biemann have also recently reported the same observation[1].





The marked difference in ion intensities noted in tandem MS spectra of isomeric aspartic acid containing peptides with no basic residues appears to be insufficient to distinguish the isomers. We have explored terminal derivatizations with basic moieties to induce the diagnostic fragment ions. C-terminal derivatizations have the advantage that diagnostic ions can be observed for both isomers; however, the total ion current is distributed over an unnecessary number of fragmentation pathways so that the required diagnostic ion signals may be too weak to be useful. Moreover, C-terminal derivatizations run the risk of modification of all carboxyl groups. N-terminal derivatizations can be pH controlled to prevent alkylation of lysine and result in a clear **a**- and **d**-ion series of marked intensity. Although diagnostic ions are only observed for the β-Asp isomer, this is the very isomer that one is most interested in detecting. We have been using a methodology developed by Stults and Wetzel for this purpose[2].

Sequence-Specific Fragmentation of Cystine-Containing Peptides and Proteins

David M. Bunk and Ronald D. Macfarlane
Department of Chemistry, Texas A&M University
College Station, TX 77843-3255

The presence of a disulfide bond in the polypeptide chain of a peptide or protein limits the amount of sequence-specific fragmentation that is observed by mass spectrometry. A disulfide cross-link between two cysteine residues (a *cystine*) creates a loop in an otherwise linear polypeptide chain; to observe the sequence-specific fragment ions of the amino acid residues within the loop, fragmentation must occur at two bonds, an amide bond along the polypeptide chain and a bond along the disulfide. This two-bond cleavage requires more energy and is consequently less probable than a fragmentation requiring the cleavage of a single bond.

We have previously demonstrated that the excitation energy inherent to ^{252}Cf-PDMS is sufficient to produce sequence-specific fragmentation of peptides (1,2) as well as intact proteins as large as 29 kDa (3). To compliment these studies, we examined the influence of intra- and inter-chain disulfides on the fragmentation of peptides and proteins in PDMS.

Experimental. Prior to PDMS analysis, all peptides and proteins were purified by RP-HPLC. Approximately 200-250 pmol of sample was used for PDMS. Nitrocellulose (100 $\mu g/cm^2$) was used as the sample substrate. Mass spectra were acquired for 720 min using a linear ^{252}Cf-PD mass spectrometer with a 52-cm-long field-free region. The *in situ* reduction with dithiothreitol was performed using the method of Chait and Field (4).

Results and Discussion. Our first studies examine the fragmentation of cystine-containing peptides. The PD mass spectrum of [arg^8] vasopressin, a small peptide (9 residues) containing a single intra-chain disulfide, contains intense fragment ions from regions of the peptide outside the loop created by the cystine residue. There are also fragment ions originating from residues within the cystine loop of the peptide. These cystine loop fragment ions are lower in intensity than the fragment ions originating outside the cystine loop. After the [arg^8] vasopressin sample was reduced by *in situ* treatment with DTT, the PD mass spectrum of the reduced peptide was obtained. The spectrum of the reduced peptide contained all of the fragment ions found in the spectrum of the spectrum of the oxidized peptide, but the intensities of the fragment ions originating between the two cysteine residues of the reduced peptide (the cystine loop fragment ions of the oxidized peptide) were increased nearly 5-fold by the reduction. This result demonstrates that the cystine residue in the oxidized peptide hinders fragmentation but does not prevent it. The masses of the cystine loop fragment ions of oxidized [arg^8] vasopressin were observed at the same values as those of the reduced peptide, suggesting that fragmentation of the cystine loop of the oxidized peptide is occurring with concerted disulfide bond reduction. The masses and peak shapes of the molecular ions and the a_5 fragment ion (which contains the entire cystine loop) of oxidized [arg^8] vasopressin indicated that reduction of the oxidized peptide sample had not occurred.

The fragmentation analysis of two larger peptides, a somatostatin-28 analog and atrial natriuretic peptide, yielded many of the same results observed for [arg^8] vasopressin. The PD mass spectra of both of these larger cystine-containing peptides contained fragment ions from reductive cleavage of residues within the cystine loop. Unlike the spectra of oxidized and reduced [arg^8] vasopressin, the spectra of the two oxidation states of these peptides displayed obvious differences in the overall fragmentation patterns. For both oxidized peptides, a bimodal partition of fragment ions is observed: a cluster of low-mass fragment ions from one side of the cystine loop region, and another cluster of high-mass fragment ions from the other side of the loop region. When the disulfide was reduced, a more normal and continuous distribution of fragment ions is observed. For the somatostatin-28 analog and atrial natriuretic peptide, the intensity of the mid-mass fragment ions of the reduced peptide was enhanced at the expense of the high-mass fragment ions. This fragmentation behavior suggests that the presence of the cystine loop region in a peptide affects the partitioning of fragmentation.

For proteins, disulfide cross-links appear to be a more substantial barrier to fragmentation than for peptides. The fragmentation pattern of native lysozyme contains only a few weak fragment ions due to disulfides near both the N- and C-terminus. After reduction, the PD mass spectrum of this protein contains a large abundance of both N- and C-terminal fragment ions. The spectrum of native α_2-interferon contains only C-terminal fragment ions because a disulfide cross-links that N-terminal region of the protein. After reduction, the fragmentation pattern of the reduced protein, shown in Figure 1, contains numerous N-terminal fragment ions intersperse among the C-terminal fragment ions that are observed for the native, oxidized protein.

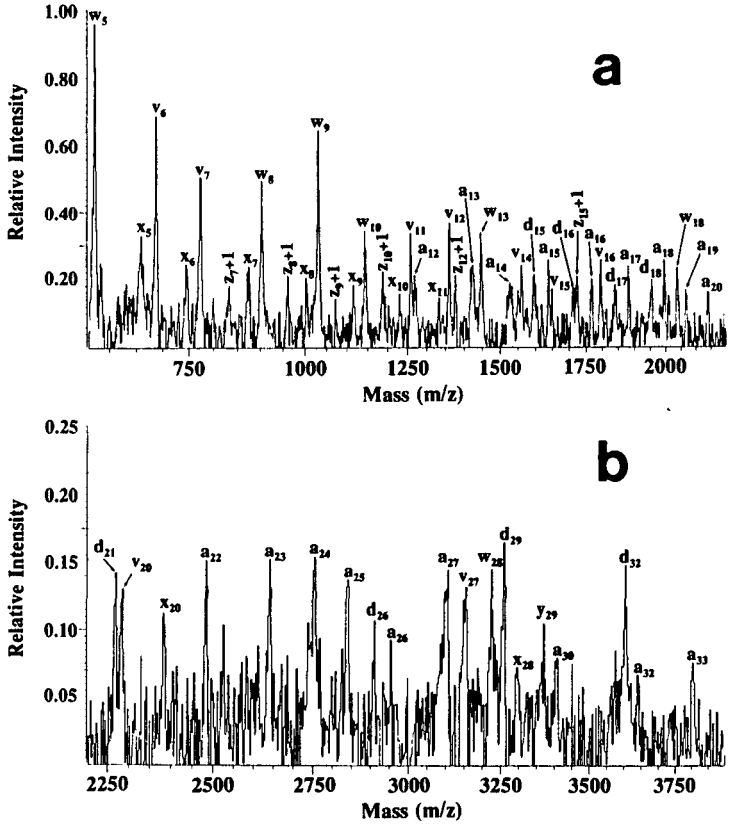

Figure 1. Positive ion PD mass spectrum of reduced α_2-interferon (**a**) in the range m/z 550-2200, and (**b**) in the range m/z 2200-3900.

An Investigation of Dipeptides Containing Polar and Non-Polar Side Groups by Curie-point Pyrolysis Tandem Mass Spectrometry

Alexander S. Noguerola, B. Murugaveri, and Kent J. Voorhees
Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, CO 80401

Limited studies have been done on pyrolysis electron ionization mass spectrometry (Py-MS) of dipeptides[1,2], although there is considerable literature on their electron ionization (EI) mass spectra[3,4,5,6]. Most of the EI studies, however, are on derivatized compounds which can have fragmentation pathways significantly altered from the underivatized dipeptides. Two general pathways for dipeptide fragmentation have been commonly proposed or stated: either dipeptide cleavage or dipeptide cyclization and then cleavage. Isotope labelling has been often used as evidence to support these postulated fragmentation pathways.

Eight dipeptides have been analyzed to determine dipeptide fragmentation mechanisms in Curie-point pyrolysis tandem mass spectrometry. Results (see Table I for major peaks) show that fragmentations of dipeptides follow two general pathways, one involving direct cleavage of the dipeptide, and the other involving cyclization of the dipeptide. Figure 1 illustrates the loss of water and cyclization of the dipeptide for phenylalanyl-leucine and leucyl-phenylalanine plus the electron ionization fragmentations involving the cyclized dipeptide. Unique products and strong changes in relative mass spectral peak intensities arise, depending on constituent amino acid residues and their sequence. Also, the length and nature of the side groups strongly direct fragmentation.

Table I. Major Peaks in Spectra of Several Other Dipeptides

Dipeptides	MW (u)	Major Peaks (m/z)
leucyl-phenylalanine	278	260, 204, 169, 141, 120, 113, 103, 91, 86
phenylalanyl-leucine	278	260, 204, 187, 169, 141, 120, 113, 103, 91,86
methionyl-valine	248	248, 230, 187, 169, 156, 141, 113, 85, 72, 61
methionyl-serine	236	236, 218, 157, 144, 131, 114, 113, 85, 75, 61
seryl-methionine	236	218, 157, 144, 126, 114, 113, 85, 75, 61
methionyl-glycine	206	206, 188, 131, 114, 104, 85, 76, 61
alanyl-phenylalanine	236	218, 127, 99, 91, 71
valyl-methionine	248	248, 230, 187, 169, 156, 141, 113, 85, 72, 61

The isobutyl group on leucine was loss via a six-membered rearrangement while the phenyl was lost by a radical cleavage. In the dipeptides that contained methionine, the side chain cleavage occurred again via a six-membered rearrangement. This reaction occurred with all dipeptides that contained a γ-hydrogen on the side group. Previously[3], the loss of the side chain had been postulated to occur after the breakup of the cyclized dipeptide.

The direct dipeptide cleavage reaction was observed for all dipeptides investigated. Figure 2 shows the reaction for methionyl-leucine. Daughter-ion experiments verified the direct cleavage reaction for the eight dipeptides.

A problem associated with Py-MS results is the ability to differentiate between the ions due to pyrolysis products and those from electron ionization fragmentations. With the exception of the dehydration product, the tandem MS results have shown that the ions in this study are a result of electron ionization. Resolution of the genesis of the dipeptide dehydration product will have to be determined by using the same experimental approach with a soft ionization technique.

Size and Frequency Effects on RRKM Rates of Decomposition of Model Oligo/Polypetides

Lawrence L. Griffin[a] and David J. McAdoo[b]
a Department of Marine Sciences, Texas A&M University, Galveston, Texas 77553
b Marine Biomedical Institute, University of Texas Medical Branch, Galveston, Texas 77550

The use of mass spectrometry to characterize macromolecules is growing dramatically due to the development of techniques for generating large ions in the gas phase. Structural information for such ions is limited because larger ions do not fragment readily. Statistical rate theories suggest that fragmentation should slow with ion size since internal energy must be distributed over increasing numbers of degrees of freedom and hence will be concentrated less often in the reaction coordinate.

We investigate the effects of size on RRKM/QET rates of a model N-terminal peptide cleavage for a homologous series of poly-alanine-glycine ions ranging from AG2 (A.G.A.G, MW: 0.27 kDa, 105 degrees of freedom) to AG800 (MW: 102.4 kDa, 40,803 degrees of freedom). We have computed RRKM rate constants with two sets of model vibrational frequencies for AG2, AG16, AG107, AG401 and AG800, assuming a critical energy of 100 kJ/mol, and for these and others in the series with the first set of model frequencies at lower critical energies .

For our original model ions we assume that normal modes of a molecular ion or transition state are reasonably approximated by the set of all individual bond stretches plus bending modes associated with individual structural units in each peptide residue. The frequencies for each residue's modes are selected from values associated with analogous regions of small molecules and ions and are degenerate over each GA (glycyl-alanyl) structural unit of A..$(GA)_{N-1}$..G for AGN.

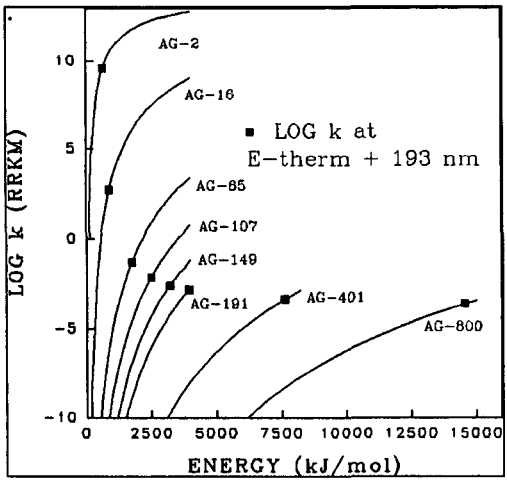
Our second set of frequencies is intended to mimic the effect of larger numbers of cooperative modes (with lower frequencies) for larger ions. We apply a series of reduction factors (based on amplitude), to modes formally associated with each GA unit, sequentially to units more-and-more to the interior of the linear sequence of residues. Both sets of frequencies neglect side-chain interaction and H-bonding along the peptide backbone. The assumed values are employed to investigate whether RRKM computations will produce a decline in decomposition rates for a set of related polymeric ions.

Rate constants are computed with a modified version of the RRKM program of Bunker and Hase (QCPE 234) using Whitten-Rabinovich semiclassical state counting. We also have computed the thermal energy content of ions using both sets of vibrational frequencies. RRKM rates are determined at energies which range from twice the assumed threshold to the sum of thermal energy plus the energy of the 193 nm photon (which might be employed in photodecomposition experiments).

The resulting rate constants for the original sets of frequency values are reported in the figure below. Expected RRKM ion lifetimes (at E-therm + 193 nm) are reported in the Table for both the original and the lower frequency models.

Our RRKM computations predict that larger ions should not fragment on a mass spectrometry time scale (10^{-6}s to 10^{-5}s). Lower frequencies result in lower rates at a given energy for a given ion. This is effect is partially compensated for by an increased thermal energy content with lower frequencies (E-298K + 193 nm: 894 vs. 898 kJ/mol for AG16, low vs original; 23948 vs 14568 kJ/mol for AG800, low vs original), but for larger ions the set of lower-valued modes produces dramatically lower rates at near thermal energies.

MODEL WITHOUT LOW FREQUENCIES



LOG ION LIFETIMES (s)
FOR AG-N
AT E-298K + 193 nm

N	orig.	low freq.
16	-2.70	-2.56
107	2.16	3.01
401	3.36	5.66
800	3.61	7.02

With either set of model frequencies, ions AG8 (MW: 1.04 kDa) and larger should, at energies E-298K + 193 nm, have RRKM lifetimes longer than 10^{-5}s, if the critical energy is 100 kJ/mol. This prediction agrees reasonably well with 1.5 kDa as a rule-of-thumb molecular weight upper limit for observation of fragmentation of polypeptide ions via collision-induced dissociation. Further computations show that an increase (above E-298K) in internal energy by absorption of up to nine 193 nm photons will not reduce RRKM ion lifetimes for ions as large as AG107. Thus with E_0 = 100kJ/mol, impractically large amounts of energy would be required for fragmentation of our ions.

We examine the effect of critical (or "activation") energy in two ways. 1) RRKM rates are determined for all original-model ions, but with a critical energy of 0.1 eV (9.65 kJ/mol). For all ions all rates are above $10^{10}s^{-1}$. Thus mean lifetimes of 10^{-1}s or shorter are indicated. 2) Rates at E-298K + 192 nm are computed for representative original-model ions through AG800 for a series of E_0 values from 0.1 eV through 200 kJ/mol. Rates decay exponentially with E_0; this is concordant with the Arrhenius rate relationship. The slope of Log k vs E_0 increases with ion size, but for $E_0 \leq 35$ kJ/mol a significant fraction of all original-model ions would decompose in the ion source.

-CONCLUSIONS-

The similarity of ion size vs mean lifetime (with a "reasonable" E_0) of our model ions to experimental size limits for polypeptide fragmentation suggests that RRKM/QET theory can be valid for (at least semiquantitative) studies of polymer fragmentation. We show that it is impractical to add enough energy (via collisions or photodecomposition) to induce framentation unless the reaction has a low critical energy. We suggest that fragmentation might be induced by ion-molecule reactions which have a low critical energy. These reactions preferably would be exothermic.

Fragmentation of polypeptides containing proline residues by ES-MS and LSIMS

*M. Jaquinod, F. Bitsch, K. Klarskov and A. Van Dorsselaer.
Laboratoire de Spectrométrie de masse Bio-Organique, URA31,
Louis Pasteur University, 67008 Strasbourg Cedex, France.

Introduction: Sequence informations are obtained from fragmentations of peptides in both LSIMS and ESMS from source spectra. We have already shown that in LSIMS peptides containing prolines usually exhibite larger fragmentations at the level of prolines than for the other amino acids on source spectra up to 7 KDa (1,2). These fragments are usually of the Y or B type (1,2,3). It was shown that peptides <1 kDa containing prolines yield spontaneous and collisionally activated fragmentation leading to the formation of Y or Y" ions (3, 4).

In this study we have evaluated the possibility of obtaining preferential peptide bond cleavages at the level of prolines on peptides up to 6000 Da in ESMS. Several peptides were synthetised with prolines adjacent to different amino acids in order to determine if this preferential cleavage is obtained for all common amino acid connected with prolines. These fragmentations were produced using different conditions: (i) fragmentation by high Vc sampling cone voltages (ii) MS-MS and collision activated decomposition with cold (low Vc) and warm (high Vc) ions .

Experimental: ESMS spectra were obtained using a VG BioQ (VG BioTech). For CAD MS/MS, argon was used as collision gas. For LSIMS, spontaneous fragmentation (thioglycerol matrix) were obtained on a ZAB-HF

Results and discussion: With LSIMS we have noticed that all peptides with X-Pro combination yielded fragmentation ions. Fragmentation observed by LSIMS were generally of B, Y", A and X types .

With ESMS multiply charged ions also yield large fragments corresponding to a preferential cleavage on the N-terminus side of prolines. These fragments were also of Y and/or B type. The intensity of these proline specific fragmentations were determined by the voltage applied on Vc (Fig.1, 2). Intensity of fragmentation at proline bond was also shown to depend on the nature of the amino acid residue (X) adjacent to the proline on the N-terminus side (X-Pro-). For Pro-Y sequence, with basic residues (Arg, Lys, His) at C-terminus side of prolines, peptides give also source fragmentation ions under hight Vc. For acidic amino acids (X=Asp,Glu), fragmentations at X-Pro bonds were generally particularly intense . For basic residues (X=Lys, Arg, His) fragmentation at X-Pro bonds was not observed. Peptide containing proline showed inCAD-MS/MS that fragmentation occuring at prolines were more intense in case of more higher Vc (warm ions).

Poly-Pro peptides (Pro_{10} to Pro_{20}) displayed protonation ofthe amide bonds (since multiply charged ions were observed) (Fig.3). Poly-Pro peptides show the possibilities to form fragment ions resulting from multipoint cleavage of the peptide backbone corresponding to type (Bx,Yy') or (Bx,Xy) in higher abundance than internal fragment observed by the other ionization techniques (Fig.4).

Conclusion: This work showed the possibility of nitogen of proline ring, and fragmentation in the ES interface leading to the formation of Y, B and internal fragments (Bx, Yy).(Bx, Xy). The presence of a basic residues at the N-terminal position of proline residues probably involve in the lack of fragmentation by repulsion effect or inhibition of proton migration.

CHARGE PROMOTION OF LOW ENERGY FRAGMENTATIONS OF PROTONATED PEPTIDES

Simon J. Gaskell, Odile Burlet, Kevin D. Ballard and Ralph S. Orkiszewski
Baylor College of Medicine, Houston, TX 77030

It is generally considered that low energy decompositions of gas phase peptide ions predominantly occur proximal to a site of charge. If this premise is correct, then the generation of extensive sequence data by low energy CAD of biopolymers such as peptides is dependent upon a multiplicity of possible sites of charge location. Structural features or derivatization strategies which diversify or restrict the site of charge location are then expected significantly to affect patterns of fragmentation via low energy processes.

Here we report three series of experiments which address this issue.

1. Modification of charge distribution via intra-ionic interactions. The low energy CAD product ion spectrum of the protonated octapeptide, GFLCGHYR, shows a poor yield of diagnostic fragment ions. The most prominent product ion is Y_1'', representing cleavage of the peptide bond adjacent to the C-terminal arginine residue. The corresponding spectrum of the oxidized analogue, in which the cysteine residue is converted to cysteic acid, shows, in marked contrast, an abundant series of Y_n'' ions defining the peptide sequence. A comparison of native and oxidized forms was also made for the truncated peptide, GFLCGHY, which was prepared by enzymic removal of the C-terminal arginine residue. Only minor differences were observed between the spectra of the native and oxidized analogues. These and other [1] data suggest that intra-ionic interaction between the arginine and cysteic acid side-chains reduces the preponderance of the arginine residue as the site of protonation. A precursor ion population heterogeneous with respect to the site of charge then promotes a multiplicity of fragmentation pathways.
2. Low energy decompositions of pre-charged derivatives. Several peptides have been converted to N- or C-terminal derivatives incorporating a pre-charged triphenylphosphonium group.[2] Figure 1 compares the low energy CAD product ion spectra of the protonated peptide, SIGSLAK, and of its C-terminal pre-charged derivative. It is clear that the formation of the derivative is detrimental to the yield of structurally informative fragments following low energy CAD; the product ion spectrum is dominated by fragments associated with the derivative group and peptide sequence ions are of very low abundance. Similar results have been obtained for other peptides incorporating a pre-charged group at either terminus, indicating that the incorporation of a fixed site of charge reduces the propensity for multiple diagnostic fragmentations.
3. Low energy CAD of doubly charged ions. Figure 1 also includes the low energy CAD product ion spectrum of the protonated, pre-charged derivative of SIGSLAK. In this instance, the doubly charged precursor ion incorporates a fixed site of charge (at the C-terminal derivative group), together with a proton which may be located at any of a number of sites. The yield of peptide sequence ions is markedly improved by protonation of the pre-charged derivative; in particular, fragmentations remote from the pre-charged group are favored. Product ions associated with the derivative group are of reduced relative significance.

It is concluded that the promotion of multiple diagnostic fragmentations by low energy CAD of peptides is contingent upon a precursor ion population which is heterogeneous with respect to the location of charge. Native or introduced structural features which lead to a single preponderant site of charge are detrimental to the generation of informative product ion spectra under low energy CAD conditions.

FAB-CAD-MS/MS of Ethyl-Triphenylphosphonium Derivatives of Modified Peptides

D.S. Wagner[1], T.J. Nieuwenhuis[1], Y.S. Chang[2], D.A. Gage[2], J.T. Watson[1,2], Departments of Chemistry[1] and Biochemistry[2], Michigan State University, East Lansing MI 48824.

Identification and location of posttranslational modifications in proteins remains one of the important contributions of mass spectrometry to the field of biochemistry (1-3). Many conventional techniques often require sample manipulation and harsh conditions, causing the loss of the modified group. Although FAB-MS/MS has been successful for this application, the approach suffers from several disadvantages: *i)* poor ionization efficiency of some modified peptides requires large amounts of sample (0.5-2 nmol) for analysis and *ii)* often the modification interferes with fragmentation, resulting in incomplete sequence analysis and the inability to determine the site of modification.

Preliminary experiments have been performed to characterize posttranslationally and chemically modified peptides by FAB-CAD-MS/MS (using linked scanning at constant B/E) after derivatization with the ethyl-triphenylphosphonium (TPP) moiety (4). The peptides used in the study include a phosphorylated peptide, a peptide containing a disulfide bridge, a backbone modified peptide (5), a cyclic peptide and a lipoidal peptide derivative (6).

N-terminal derivatization was accomplished by dissolving the peptide (0.1-2 nmol) in a pyridine/acetonitrile (1:1 v/v) mixture. Vinyl-TPP was added in a ten-fold molar excess. The sample was vortexed and reacted 3 hrs at 37°C and then the solvents were removed under a nitrogen stream. Derivatization of the C-terminus was performed by reacting the peptide with a ten-fold excess of 2-aminoethyl-TPP and EDC coupling agent in a dilute, aqueous TFA solution (pH 5). The reaction mixture was warmed to 37°C for 3 hrs and then lyophilized to dryness. Approximately 100-500 pmol of derivatized peptide and 0.5-2 nmol of the underivatized peptide were used for analysis. The experiments were performed on a JEOL HX-110 double-focusing instrument.

The preliminary results indicate that derivatization with ethyl-TPP moiety increases the detectability of posttranslationally and chemically modified peptides by at least an order of magnitude. This was most evident from the analysis of the lipoidal peptide, where the C-terminal derivative was readily detected. The underivatized peptide could not be detected under identical conditions.

The results also indicate the ethyl-TPP derivatives generate simplified FAB-CAD-MS/MS spectrum, containing only N- or C-terminal fragment ions, depending on the location of the charged moiety. The Ethyl-TPP derivatized peptides also provide superior sequence information and aid in the location and identification of the modification. As an example, the FAB-CAD-MS/MS spectrum of the backbone modified peptide HPFHLΨLVY (containing a reduced carbonyl group at Leu^5) (Figure 1) can be compared to the N-terminally derivatized peptide (Figure 2). The spectrum of the underivatized peptide displays good fragmentation, but a complete or overlapping ion series needed to deduce the amino acid sequence is not present. In contrast, the CAD spectrum of the N-terminal derivative displays a complete series of a_n ions, thus determining the primary sequence. In addition, an intense peak at m/z 921 represents an unusually prominent c_5 ion at the reduced carbonyl site, clearly indicating the site of modification. No other c_n fragments are observed in the mass spectrum.

In the case of the cyclic peptide, the ethyl-TPP derivatized peptide did not fragment efficiently under CAD conditions, while the protonated peptide fragmented extensively, producing mainly internal ions. This indicates that ring cleavage of cyclic peptides requires a charge to be located on the ring. Because TPP derivatives contain a fixed charge, they may not be useful for the sequencing cyclic peptides.

Upon CAD analysis, neither the underivatized nor the C-terminal ethyl-TPP derivatized peptide of the phosphorylated peptide generated the necessary fragments to determine the amino acid sequence; however, both species indicate the presence and the relative position of the phosphate group. Although a complete amino acid sequence could not be determined, signal enhancement due to the ethyl-TPP derivative improved the detectability of the phosphopeptide by at least an order of magnitude.

FAB-CAD-MS/MS spectra for the peptide containing a disulfide bond indicated that the N-terminally derivatized peptide generated superior fragmentation over the underivatized form. However, fragmentation was interupted at the cysteine residue linked by the disulfide bond. The CAD of the reduced underivatized peptide does not generate a complete or overlapping series, while the N-terminally derivatized peptide produced a complete series of a_n ions, from which the sequence was determined.

These results are encouraging and further studies on derivatization of posttranslationally and chemically modified peptides will be performed.

A Novel Derivatization Method for Peptides to Increase Information Content of Liquid Secondary Ion Mass Spectra

Jeffrey P. Kiplinger, Leonard Contillo,and W. Lee Hendrick; Pfizer Central Research, Eastern Point Rd., Groton, CT 06340

Introduction. It is well known that derivatization of peptides can be useful in producing better LSIMS or FAB spectra. Esterification at the C-terminal, for example, increases the hydrophobicity of a peptide and helps it ionize more efficiently. Derivatization at either terminal with aromatic groups helps to direct fragmentation and provide more easily interpreted sequence information. This work was directed toward developing a derivatization process to enhance both sensitivity and structural information in FAB or LSIMS spectra which is fast and easy to use. Peptides are reacted with pentafluorobenzoyl fluoride (PFBF) to acylate with one or more pentafluorobenzoyl (PFB) groups. The reaction is indeed simple and takes place in a single vial, and the reaction mixture may be immediately analyzed in the mass spectrometer. It provides good increases in signal/noise for MH^+ and $(M-H)^-$ ions under +ve and -ve conditions, and enhances backbone fragmentation, usually in a single ion series to aid in sequence assignment.

Experimental. Peptides were purchased from Sigma, and were subjected to preparative HPLC purification and lyophilization before use. The PFBF reagent was synthesized separately, and prepared as a stock solution for use as required. **Synthesis of PFBF**: 10.0 g pentafluorobenzoic acid (Aldrich) dissolved in 141 ml ether, cooled under N_2 to 0°C. A solution of 5.8 ml morpholinosulfur trifluoride (Aldrich) in 47 ml ether was added dropwise over 1/2 hr with stirring at 0°C. Reaction allowed to warm to r.t., the ether was evaporated, and the residue distilled under vacuum. Fraction collected at 40°C-58°C/22 mm was dissolved in hexane and filtered through celite. Evap. of hexane yielded 1.9 g colorless liq. (d = 1.627 g/ml) PFBF. **Prep. of PFB derivatives**: Typically, 0.1 µmoles of peptide in water were placed in a polypropylene vial. 10 µl (1.2 µmoles) of a stock PFBF solution (16 µl in 1 ml acetonitrile) and 10 µl (2.2 µmoles) of a stock triethylamine solution (33 µl in 1 ml acetonitrile) were added, the solution was shaken and analyzed directly. The acylation takes place at the unblocked N-terminal amine group, at the free amine group of lysine, and at the phenolic -OH of tyrosine. The -OH groups of serine and threonine react slowly or not at all, and arginine and histidine do not appear reactive. These conclusions are easily verified by examination of the spectra. **Mass Spectrometry**: All experiments were carried out using a Kratos Concept 1-S spectrometer using Cs^+ LSIMS ionization. The matrix was magic bullet for both +ve and -ve experiments, and the gun was operated at 16 keV primary ion energy in either case.

Results - Sensitivity Enhancements. We expect some enhancement in MH^+ intensity on derivitization due to the increase in hydrophobicity. Figure 1 shows a reaction of a small peptide with 0.2 eq of PFBF. Assuming complete reaction, no more than 1 in 5 peptide molecules may be derivatized, yet the combined intensities of the mono- and diacylated products is ~35% of the underivatized intensity. The -ve spectrum of the same solution in Figure 2 shows an even greater S/N enhancement, as we expect from derivatization with such a highly electron-withdrawing group.

Results - Enhanced Sequence Information. Figure 4 illustrates the substantial increase in fragment ion yield, as well and the simplification of the spectrum, that may be expected on PFB derivatization. Note that while the yield in the PFBF reaction is limited to 20% by addition of only 0.2 eq PFBF, the fragments produced are all from the b and a series (C-terminal losses) and are all from the derivative. No fragments of significance from the non-derivatized material are observed. Figure 6 shows the spectrum from the near-complete derivatization of Leu-Enkephalin, which acylates at Tyr as well as at the N-terminal amine. The fragments are all from the b series from the diacylated derivative, and their yield is greater than the intensity of the MH^+ ion.

Conclusions. The PFB group provides a pleasantly large S/N enhancement in negative ion mode, and some enhancement in +ve mode. The greatest benefit seems to be the very dramatic increase in fragment ion yield and the directed nature of the fragmentation reactions (toward N-terminal fragments only). The greatest strength of the method lies in its simplicity and

speed. Although there are many different analytical methods for getting more sequence information from peptides, this one can be carried out at the spectrometer console in a few moments.

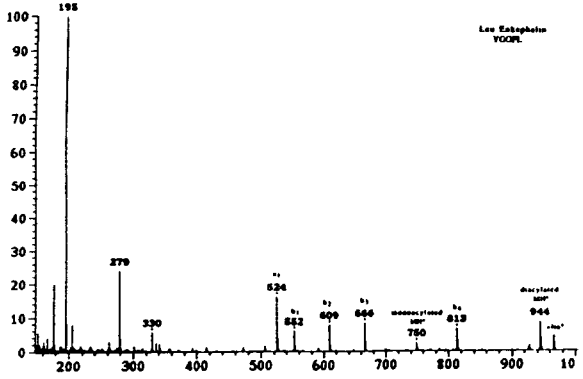

Figure 6. The spectrum of the di PFB derivative of Leu Enkephalin The underivatized material shows a strong protonated molecule, but no fragmentation. The diacylated derivative shows a complete b series af fragments, with greater intensity than the protonated molecule

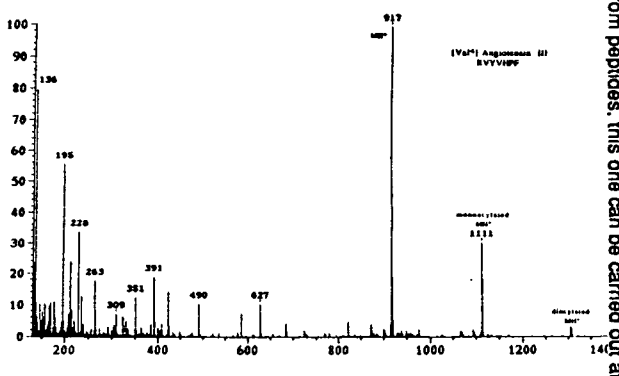

Figure 1 Positive ion LSIMS spectrum of [Val⁵]-Angiotensin III reaction mixture, illustrating relative intensities of the MH⁺ ions of the underivatized peptide (917), the monoacylated PFB derivative (1111), and the diacylated derivative (1305)

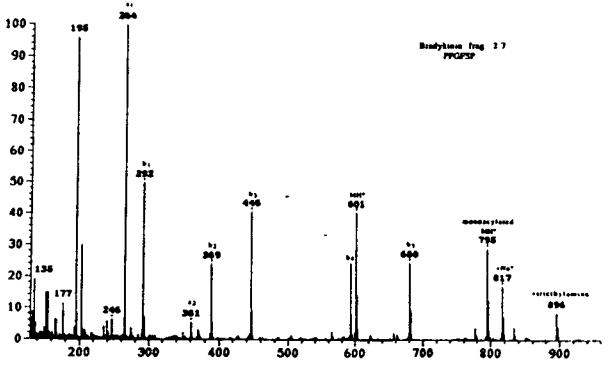

Figure 4 This reaction mixture is estimated to contain 80% underivatized Bradykinin frag 2-7 and only 20% of the PFB derivative Note, however, that the b series fragments from the derivatized material dominate the spectrum, especially the a_1/b_1 pair with a mass difference of 28 u

IDENTIFICATION OF SULFATE CONJUGATES OF β-ADRENERGIC DRUGS BY FABMS AND MS/MS

Kevin L. Schey, Kelly R. Thornburg, U. Kristina Walle, and Thomas Walle
Dept. of Pharmacology, Medical University of South Carolina, Charleston, SC 29425

β-Adrenergic drugs represent an important class of drugs used to treat a variety of conditions including asthma and many cardiovascular diseases. Structurally, the β-adrenergic agonists are similar to catecholamines with the addition of alkyl substituents to the amino nitrogen. The principle metabolic pathway for elimination of these drugs in humans is sulfate conjugation [1], a pathway which recently has received much attention as it shows significant stereoselectivity for these racemic chiral drugs [2].

The structures of some sulfate conjugates of β-agonist drugs have been deduced using indirect methods. Recently tandem mass spectrometry (MS/MS) has been used to examine the structure of a catecholamine sulfate conjugate [3]. We present here MS/MS experiments used to provide direct structural information on sulfate conjugates of a variety of β-agonist drugs produced by a human tissue cell culture.

Cultures of human liver HEP G2 cells were incubated with various β-agonist drugs for 48 hrs [4]. The metabolites were isolated from the cell culture medium by reversed-phase HPLC. Fractions of sulfated material (indicated by ^{35}S labelling) were collected, lyophilized and then resuspended in deionized water before mass spectral analysis. Tandem mass spectrometric analysis was carried out on a JEOL HX110/HX110 tandem mass spectrometer. Ionization was accomplished by liquid secondary ion mass spectrometry (LSIMS) with a glycerol or thioglycerol matrix.

Isoproterenol, the prototypical β-agonist, has a catechol ring and therefore is susceptible to both sulfation and O-methylation. Both the sulfated and the sulfated, methylated products were isolated by HPLC and mass analyzed. The positive and negative product ion spectra for sulfated isoproterenol shown in Figure 1. These results represent the first direct structural information obtained on the sulfate conjugates of isoproterenol. The observed fragmentation patterns are also found in most of the β-agonist spectra and are summarized below:

- loss of H_2O, SO_3, and combinations in (+) and (-) ion modes.
- loss of neutral C_nH_{2n} (-), C_nH_{2n+2} (+), $NH_2C_nH_{2n+1}$, $CH_3NHC_nH_{n+1}$ in (+) and (-) ion modes.
- loss of radical $CH_2NHC_nH_{2n+1}$.
- combinations of the above losses.
- SO_3^- and HSO_4^- in (-) ion mode.
- side chain ion $CH_2NHC_nH_{2n+1}^+$ in (+) ion mode

Ritodrine is a β_2-agonist used to relax the uterus. Its unique structure provides the possibility of having two different sites of sulfation and, indeed, two sulfated products were isolated using HPLC. Negative ion MS/MS data shown in Figure 2 indicates that the two products are sulfated on opposite ends of the molecule as drawn on the spectra.

LSIMS and MS/MS analysis provided, for the first time, direct structural information on sulfate conjugated β-agonists isolated from a human tissue cell culture. Our data suggest that negative ion MS/MS provides more structural information than positive ion MS/MS. This systematic study revealed that predictible fragmentation occurs along the side chain which should be useful for structural identification of unknown β-agonist metabolites. In addition, we have shown that sulfation occurs on the ring hydroxyl groups for prenalterol (not shown) and ritodrine, suggesting that this is likely the case for the other β-agonists.

ROLE OF HYDROXYL RADICALS IN THE FORMATION OF NEUROTOXIC METABOLITES OF 3,4-(METHYLENEDIOXY)METHAMPHETAMINE (MDMA): A MASS SPECTROMETRIC STUDY

H.K. Lim and R.L. Foltz, Center for Human Toxicology, Department of Pharmacology, University of Utah, Salt Lake City, UT 84108

The ability of dopamine uptake blocker to attenuate the neurotoxic effects of MDMA suggests the involvement of dopamine in the neurotoxicity of MDMA; an oxidative stress mechanism has been postulated to be responsible for the neuronal injury (1). That oxidative stress may be involved in MDMA-induced neurotoxicity is illustrated by the ability of a spin-trapping agent (N-tert-butyl-alpha-phenyl nitrone [PBN]) to attenuate the neurotoxic effects of MDMA (Figure1); the serotonin concentration is measured by a capillary GC-NCI/MS assay which is a modification of that previously reported by Markey et al. (2). Precisely how oxidative stress is involved in MDMA-induced neurotoxicity is unclear but conceivably hydroxyl radicals generated during oxidative stress can react with MDMA to form reactive and neurotoxic metabolites.

To test this possibility, MDMA was incubated with classical Fenton's reagent for 20 min according to a previously reported procedure (3); the reaction was terminated by aqueous derivatization with pentafluorobenzoyl chloride under Schotten-Baumann conditions. A second derivatization by silylation was performed prior to capillary GC-NCI/MS analysis. The mass spectrometer was set to monitor fragment anions corresponding to loss of H_2O and $(CH_3)_3SiH$ from the molecule anions of the phenolic amine metabolites; however, the molecule anion was selected for MDMA. Figure 2 shows the identification of 2,4,5-trihydroxymethamphetamine (THM), 6-hydroxy-MDMA and 3,4-dihydroxymethamphetamine (DHM) from incubation of MDMA with Fenton's reagent; their conclusive indentification was achieved by coinjection with derivatized authentic standards. Also, THM was identified after incubation of either 6-hydroxy-MDMA or DHM with Fenton's reagent. Since THM is formed by reaction of MDMA with hydroxyl radicals, it was not surprising to detect THM when MDMA was present during autooxidation of dopamine (Figure 3). This may be one of the ways dopamine can participate in the neurotoxicity of MDMA. The formation of THM was greatly reduced when PBN was incubated together with MDMA and Fenton's reagent (Figure 4); the decreased formation of THM could be rationalized by removal of hydroxyl radicals by PBN. This may be the basis for the protection against MDMA-induced neurotoxicity by PBN. In addition, 2,4,5-trihydroxymethamphetamine, 6-hydroxy-3,4-(methylenedioxy)amphet-amine and 3,4-dihydroxyamphetamine were formed by incubation of the N-demethylated metabolite of MDMA [3,4-(methylenedioxy)amphetamine] with the Fenton's reagent.

ENANTIOSELECTIVE QUANTITATION OF 3,4-(METHYLENEDIOXY)METH-AMPHETAMINE (MDMA) AND THREE OF ITS PRIMARY METABOLITES BY GC-NCI/MS

H.K. Lim, S. Zeng, and R.L. Foltz, Center for Human Toxicology, Department of Pharmacology, University of Utah, Salt Lake City, UT 84108

MDMA has an optically active alpha carbon and therefore, consists of a pair of enantiomers with S-(+) and R-(-) configurations. The two enantiomers of MDMA display different pharmacodynamic properties following interaction with chiral biomacromolecules in the body; only the S-(+) enantiomer is neurotoxic. Whether this difference in the pharmacodynamic properties of the two enantiomers of MDMA is related to differences in disposition is unknown.

The procedures for synthesis of N-heptafluorobutyryl-S-prolyl chloride and aqueous derivatization of MDMA and three of its primary metabolites are similar to those previously reported by Lim et al. (1), except that the aqueous derivatization was carried out directly in the biological specimens after an acid cleanup step. The mass spectrometer was set to monitor molecule anions of 4-hydroxy-3-methoxymethamphetamine (HMM), 4-hydroxy-3-methoxyamphetamine (HMA) and 3-4-(methylenedioxy)amphetamine (MDA), but for MDMA and the internal standard [3,4-(methylenedioxy)propylamphetamine] the fragment anions corresponding to loss of HF from their molecule anions were monitored instead.

The chiral capillary GC-NCI/MS assay permitted simultaneous quantitation of each enantiomer of MDMA, MDA, HMM and HMA from 5 to 1000 ng/mL in urine, and each calibration curve gave a correlation coefficient of at least 0.995. A mean recovery of ≥ 60% was obtained for each enantiomer of MDMA and the three metabolites. Validation of the accuracy of the assay gave measured concentrations of each enantiomer of MDMA and the three metabolites within 20% of the target values at both the lower and upper ends of the calibration curve. In each case, the accuracy was achieved with a mean coefficient of variation of less than 15% for both intra- and inter-assay validation.

The chiral GC-NCI/MS assay was applied to comparative investigation of disposition profiles of the pair of enantiomers of MDMA in rats and mice. Figure 1 shows ion current profiles from analysis of 24-h urine from a rat injected subcutaneously with 10 mg/kg MDMA; enantiomeric distortion of each compound clearly indicates that there is stereoselectivity in disposition of MDMA. The 24-h urinary excretion of the enantiomeric pairs [S-(+) and R-(-)] of MDMA, MDA, HMM and HMA were [8.5 and 11.7], [5.5 and 3.3], [6.1 and 7.7], and [1.4 and 0.4] %, respectively. For mice, the 24-h urinary excretion of the enantiomeric pairs [S-(+) and R-(-)] of MDMA, MDA, HMM and HMA were [16.7 and 17.2], [6.2 and 4.8], [5.8 and 9.5], and [1.7 and 1.1] %, respectively, of the administered dose of 10 mg/kg MDMA. There are no significant species differences in 24-h urinary excretion of the three metabolites; however, significantly greater excretion of the parent compound by mice is accounted for entirely by the excretion of the neurotoxic S-(+) enantiomer.

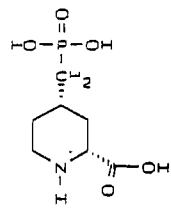
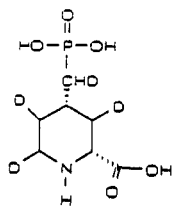
Determination of a New NMDA Antagonist (CGS 19755) in Human Plasma, Cerebral Spinal Fluid and Brain Tissue Using Negative CI GC/MS

*L. Khemani, M. J. Hayes and M. L. Powell, Clinical Pharmacokinetics and Disposition, Pharmaceutical Div., CIBA-GEIGY Corp., Ardsley NY,10502

INTRODUCTION

An analytical method has been developed for the determination of CGS 19755, a compound that has been shown to be an NMDA antagonist. It is a member of new class of compounds with potential to mediate a variety of brain injuries. The method is based on GC/MS and utilizes stable-isotope labeled CGS 19755 as the internal standard. The method can be used for analysis of drug in plasma, cerebral spinal fluid (CSF) and brain tissue. Samples (1 ml) were first acidified (pH 2), then extracted using a solid phase aminopropyl ion exchange column. Extracts were derivatized with a mixture of pentafluoropropionic anhydride and pentafluoropropanol, and analyzed by GC/MS. Separation was accomplished on a DB-225 capillary column (15 m x 0.32 mm) with a 0.25-μm film thickness. Mass spectrometry was carried out under negative ion ammonia CI conditions with selected ion monitoring at m/z 760 and 764 for derivatized CGS 19755 and the internal standard respectively. The limit of quantification (LOQ) is 2 ng/ml in plasma, 5 ng/ml in CSF and 5 ng/250 mg wet brain tissue.





Results And Discussion

GC analysis resulted in multiple chromatographic peaks for both drug and internal standard (Fig. 1), all with the same molecular weight. The largest well resolved peak was used for quantification. Sustitution of pentafluoropropionic anhydride with heptafluorobutyric anhydride resulted in an increase of 100 in the apparent molecular weight, indicating that the two substituents arise from the anhydride reagent and two from the pentafluoropropanol. High resolution MS indicates a formula of $C_{19}H_{12}NO_6F_{20}P$. Phosphorus, proton and carbon NMR of the mixed derivative were too complex for conformation of the structure, but indicates the presence of the double bond. Based on the information collected we have proposed structures shown in Fig. 2. The method was validated by analyzing quality control samples from three analysis days. The inter and intra-day accuracy and precision data is summarized in Table 1. Figure 3 shows an application of the method to a clinical study.

A SYSTEMATIC STUDY OF THE EFFECTS OF EXPERIMENTAL FACTORS ON THE BEAM-INDUCED DEHALOGENATION OF CHLORPROMAZINE

R. Theberge, G.J.C. Paul and Michel J. Bertrand
Regional Center for Mass Spectrometry, Department of chemistry
University of Montreal,Montreal, Canada, H3C 3J7

Several organic compounds have been reported to undergo dehalogenation under FAB/LSIMS conditions. However, despite the numerous reports on dehalogenation reactions that occur in desorption-ionization techniques, there has been little or no systematic study of the experimental factors that potentially affect the extent of these reactions. This well known phenomenon is, thus, poorly characterized. The importance of dehalogenation in FAB/LSIMS resides in the fact that their occurrence can lead one to falsely conclude that a dehalogenated species is present in a sample. This can have serious consequences in metabolic studies or compound identification. In order to systematically characterize the role of FAB/LSIMS parameters such as beam density, beam energy, analyte concentration, matrix, and matrix additive, a systematic study was undertaken where the individual parameters were varied. Chlorpromazine was chosen as a model compound because it readily undergoes dehalogenation, had been previously studied and is soluble in several matrices commonly used in FAB/LSIMS.

All mass spectral data were obtained using a VG AutoSpec-Q spectrometer equipped with a caesium ion gun. The beam energy was 16-28 KeV and the beam density was in the range of 0.012-0.065 $\mu A/mm^2$. Chlorpromazine and p-chloro-phenylalanine ethyl ester were used as hydrochlorides. Solutions were prepared by dissolving the compound directly in the matrix and the concentration range was 0.006M to 0.11M. The main peaks observed in the positive ion LSIMS spectrum of chlorpromazine in glycerol are the protonated molecular ion at m/z 319, characteristic fragments of the amino side chain at m/z 86 and 58, as well as an ion at m/z 285 that corresponds to dechlorinated chlorpromazine. This ion presumably arises as a consequence of beam-induced replacement of chlorine by hydrogen. The extent of dehalogenation is expressed as $(M_H+H)/(M_X+H)$ $+(M_H+H)$ For chlopromazine, (M_H+H) represents the relative intensity of m/z 285 with respect to the intensity of the protonated molecular ion $(M_X+H)^+$ at m/z 319. In the experiments conducted in this study the extent of dehalogenation was pronounced and found to be in the range 16%-60%. As previously reported the % dehalogenation of chlorpromazine was found to be significantly increased with time of beam irradiation.

Figure 1 shows the % dehalogenation for chlorpromazine at various concentrations with time. The apparent time and concentration dependences of the % dehalogenation can readily be seen. The plot for the 0.11M solution appears to indicate that the dechlorination maximizes at around 3 minutes This can be rationalized by increased fragmentation of the amino side chain at increasing concentrations since it can be seen in the spectrum that m/z 285 and 319 decrease with time while m/z 58 increases. A correction factor was, therefore, introduced in % dehalogenation in order to take into account the increased fragmentation of m/z 285 and 319 with time.

$$\%R = \frac{100\,(M_H+H)^+}{(M_H+H)^+\,(M_X+H)^+}\left[\frac{I_{58}}{I_R}\right]$$

The term %R represents the % dehalogenation corrected by the ratio of I_{58}, the actual intensity of m/z 58 ,to I_R, the average intensity of m/z 58 at the lowest concentration i.e. where the amino side chain fragmentation is lowest. The correction factor compensates for the increased fragmentation, which alters the calculated % of dehalogenation by distorting the mesured peak intensities of (M_H+H) and (M_X+H). Figure 2 shows the corrected data for %R which indicates that dehalogenation augments with increasing time and concentrations.

Although beam energy appears to have no significant effect on the rate of dechlorination of chlorpromazine, an increase in beam density results in a corresponding increase in the % dehalogenation as demonstrated by Figure 3. This phenomenon can be rationalized by the greater number of impacts per unit area, thus, creating an increase in the concentrations of ions and radical formed which are ultimately responsible for beam induced reactions. In order to validate the results obtained for chlorpromazine and allow perhaps more general

conclusions to be drawn on the dehalogenation process, a second compound known to undergo dehalogenation was investigated. With p-Cl-phenylalanine ethyl ester, the effect of concentration and beam density were significantly smaller than those observed with chlorpromazine under similar conditions If one assumes that similar dehalogenation processes are involved for the two analytes, a tentative explanation of the differences observed on % dehalogenation with time and concentrations can be suggested on the basis of their respective surface activity and/or solvation in glycerol. Since chlorpromazine is a more surface active compound, it is expected to be more affected by concentration changes relative to p-chloro-phenylalanine ethyl ester. Its propensity as compared to 4-chloro-phenylalanine ethyl ester will be to migrate to the surface of the droplet where the reactive species are locally being generated, thus, increasing the probability of the analyte undergoing reaction. For opposite reasons, p-chloro-phenylalanine ethyl ester does not exhibit marked time or concentration effect since it is less surface active and better solvated. This appears to be confirmed by the presence of glycerol adducts which are absent in chlorpromazine LSIMS spectra. This kinetic rationalization of differences observed between both compounds is also in line with the trends observed in the effect of beam flux on relative dehalogenation.

Given the wide variety of liquid matrices available for FAB/LSIMS and the importance of matrix chemistry in effecting or inhibiting beam induced reactions, the LSIMS spectrum of chlorpromazine was obtained in 8 different matrices. The resulting % dehalogenation values obtained are shown in Table 1. The values correlated well with the expected scavenging properties of the individual matrices. No dehalogenation was observed when the matrix was HEDS, HBSA, or NBA The results obtained with HEDS are coherent with the greater scavenging capacity of the -SS- group relative to the -S- group in TDG. Dehalogenation is present with DMBA and HPEA (electron donors) which should reduce the scavenging properties of the phenyl ring and absent with NBA and HBSA (electron withdrawers) which should increase it. These results suggest that dehalogenation can be drastically reduced if glycerol is avoided. In the event, however, that glycerol must be used, dehalogenation can be reduced using doping agents such as TFA and NBA.

QUANTITATIVE DETERMINATION OF CGS 18081A IN HUMAN PLASMA USING CAPILLARY GAS CHROMATOGRAPHY/MASS SPECTROMETRY

R. Iannucci, M. Hayes and M. L. Powell
Drug Development Department, Pharmaceutical Division
CIBA-GEIGY Corporation, Ardsley, New York

CGS 18081A {1-[(6-fluoro-3,4-dihyro-2H-1-benzothiopyran-3-yl)methyl]-4-piperidinyl}(4-fluorophenyl)-methanone hydrochloride (figure 1), is a serotonin (5HT-2) antagonist currently under development as a potential antipsychotic agent with weak to moderate dopamine antagonism.

An analytical method for the determination of CGS 18081A in human plasma has been developed and validated which is based on gas chromatography/mass spectrometry and utilizes CGS 17988A, a structural analog of CGS 18081A, as the internal standard. Samples (2 ml) were extracted with ethyl acetate/pentane (40:10) and then analyzed, underivatized, by GC/MS. Separation was accomplished on a 86% dimethyl-14%- cyanopropylphenyl polysiloxane capillary column (15 m x 0.25 mm) with a 0.25-μ film thickness. The chromatograms for blanks and spiked plasma are shown in Figure 2. Mass spectrometry was carried out under positive ion ammonia chemical ionization (CI) conditions with selected ion monitoring of the ions at $[M+H]^+$ = 388 and 404 for CGS 18081A and the internal standard, respectively. Specificity was demonstrated by the lack of interfering peaks at the retention times of the drug and internal standard. A summary of the results of the validation quality controls is shown in Table 1. Recovery (102.5%) and reproducibility (CV = 3.0 - 8.4%) assessments indicate good accuracy and precision over the validated concentration range of 0.25 to 25 ng/ml. The limit of quantification (LOQ) was 0.25 ng/ml. Calibration curves were generated using weighted ($1/y^2$) linear least squares regression of the amount of CGS 18081A added versus the measured peak area ratios of CGS 18081A/CGS 17988A (internal standard).

A new analytical method based on microdialysis, capillary column gas chromatography, and mass spectrometry, capable of simultaneously measuring N-acetyl aspartic acid (NAA) and N-acetyl aspartylglutamic acid (NAAG)[1] levels in brain extracellular fluid has been developed to study the interrelation between these two neurochemicals. Although both compounds have been shown to act as neurotransmitters, experimental data demonstrating their simultaneous release in the live animal brain upon depolarization is limited.[2] This information is important in establishing the neurotransmitter role of these compounds; therefore, we report the application of this methodology to this neurochemical system. The recently identified NAALADase is a membrane bound hydrolytic enzyme with high activity in the degradation of NAAG to NAA and glutamate.[3] This hydrolytic enzyme could be responsible for rapid breakdown of synaptic NAAG upon its release. The hypothesis has not yet been tested, but we addressed this issue by infusing known amounts of NAAG-d3 via the microdialysis probe and measuring isotopically labeled NAA-d3 in the collected microdialysate by the GC/MS method.

Adult male Sprague-Dawley anesthetized rats were used. A 3 mm microdialysis probe was stereotaxically inserted into the hypothalamus. The dialysate used in these experiments was an artificial CSF solution containing 5 mM KCl and set at a flow rate of 1.2 μl/min. A solution of artificial CSF containing 100 mM KCl was used as a depolarization stimulus. Samples were collected at 30 min intervals to ensure adequate accumulation of neurochemicals for quantitative measurements. The relative % recoveries by the microdialysis probe for NAA and NAAG were 10% and 6%, respectively. Both compounds were chemically modified to N-butyl esters by reaction with 3NHCl in n-butanol at 65° C for 15 min. After the reaction mixture was evaporated to dryness by nitrogen gas, phosphate buffer at pH 7 was added to the residue, then, extracted with ethylacetate. Stable-isotopically labeled NAAG-d3 and NAA-d6 were used as internal standards. Separation of the biological sample was carried out by a 15 m DB-5 capillary column. Chemical ionization was used with ammonia as a reagent gas. Selective ion chromatographic methods were used for the quantitative measurements.

Fig. 1

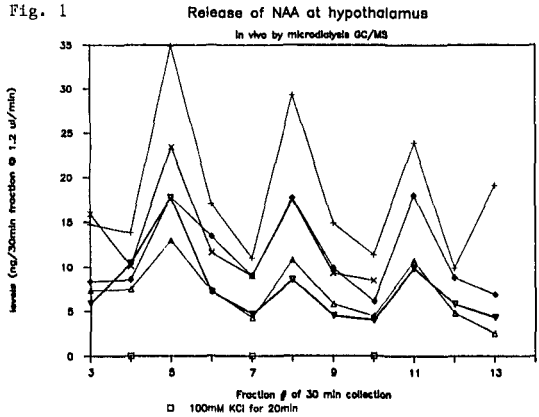

Figure 1 shows the release of NAA in vivo. Five rats were used in this experiment. Three depolarization stimuli were administered to each rat in series by infusion via a microdialysis probe for 20 min. The entire animal experiment lasted 8 hrs. Consistent stimulation-induced increase of NAA was obtained upon each infusion on every animal. On the other hand, over the group of animals tested, we did not measure similar significant elevation of NAAG upon depolarization.

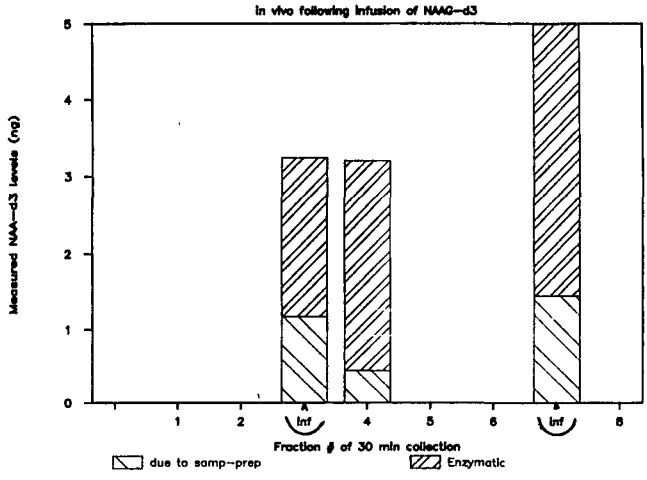
A known amount of NAA-d3 (4.2 μg in 500 μl artificial CSF) was infused via the microdialysis probe for 30 min at a flow rate of 1.2 μl/min. Isotopically labeled NAA-d3 and NAAG-d3 in the microdialysate were measured. The amounts of NAA-d3 found in these samples (see Figure 2) were used to confirm the *in vivo* hydrolytic enzyme activity. During methodology work up, approximately 1% of the NAAG-d3 added to the biological sample was chemically hydrolyzed to NAA-d3, as indicated in Figure 2.

Figure 2 **Metabolism of NAAG-d3 to NAA-d3**



In conclusion, we are able to simultaneously monitor the time course of NAA and NAAG release by the serial depolarization stimuli to enable us to study the interrelationship between the two compounds in brain. With a physiological depolarization stimuli, there is a consistent release of NAA, but not NAAG, from hypothalamus. We have also shown that NAAG is converted to NAA in vivo through infusion of NAAG-d3 and measuring NAA-d3 levels. The importance of these data is to establish the NAAG/NAA system as an important neurotransmitter system in brain.

Mapping the Adrenergic Lingand Binding Domain of the Porcine Brain α_2-adrenergic Receptor by Mass Spectrometry

*Jane J. Z. Huang[1], Amy L. Wilson[2], Lee E. Limbird[2] and Ian A. Blair[1,2]

Departments of Chemistry[1] and Parmacology[2], Vanderbilt University
Nashville, TN 37232-6602

α_2-adrenergic receptors are membrane proteins that bind endogenous epinephrine and norepinephrine and are involved in the regulaton of a variety of physiological processes. Through molecular cloning, the entire DNA sequence of the α_{2A}-subtype of receptor is known. However, the precise region of receptor which is involved in the ligand binding remains undefined. Nanomole quantities of α_{2A}-receptor protein were obtained by over-expressing the porcine brain α_2-receptor gene in *LLC.PK1* cells. Purification of the protein was carried out by yohimbine-agarose affinity chromatography. Receptor protein concentration was determined using a binding assay with the α_2-receptor antagonist ^{3}H-yohimbine.

A photoaffinity labelled probe ^{125}I-Rau-AzPEC (17α-hydroxy-20α-yohinbane-16β-[N-(4-azido-3-I-iodo)phenethyl] carboxamide) was bound specifically to the adrenergic binding pocket of the α_2-receptor. The labelled receptor moved as a single band at molecular weight around 66 kDa. on SDS polyacrylamide gel. Extensive trypsinization of the α_2-receptor yielded a hydrophobic tryptic core which retained the binding ability. This suggested that the binding domain was within the transmembrane region of this receptor. Enzyme proteolysis of the photolabelled α_2-receptor with immobilized trypsin resin was followed by SDS-Tricine gel electrophoresis which was capable of resolving low molecular weight fragments. The radiolabelled tryptic fragments were then transferred to nylon membranes and microsequencing was carried out. To date it has not been possible to specifically identify the binding site using this methodology.

Concurrent with our microsequencing studies, model peptides have been synthesized in order to to facilitate liquid secondary ionization (LSI) MS/MS identification of the residues involved in ligand binding to the receptor. Chymotryptic fragments of the 3rd membrane span (amino acid residues 101-141) were synthesized on a MilliGen/Biosearch peptide synthesizer. The following peptides were prepared: FGLAW, GLAWCGIY, LALDVLFCY, WSITQAIEY, SSIVHLCAISLDRYW. These model peptides were sequenced by positive LSI MS/MS on a tandem four-sector Kratos Concept mass spectrometer. The matrix played an important part in generating meaningful spectra of these hydrophobic peptides. It was found that a mixture of DMSO/glycerol (1 μl; 1:1) in the presence of 18-crown-6 (0.5 μl of 10 mg/ml in glycerol) was the best matrix . In general, B and Y series ions were dominant in the spectra. Sometimes D and W ions generated by side chain cleavages were useful in distiguishing between Ile and Leu. Figure 1 shows the MS/MS mass spectrum generated by collision induced dissociation of the molecular ion from FGLAW (amino acids 101 to 105). Further structural studies will now be possible on the chymotryptic fragments from the immobilized trypsin digest of the labelled α_2-receptor.

DETERMINATION OF β-AGONISTS IN CALF URINE AND SERUM BY IMMUNOAFFINITY EXTRACTION AND GC-MS

* R. Bagnati and R. Fanelli
Istituto di Ricerche Farmacologiche "Mario Negri", via Eritrea 62, 20157 Milano, Italy

INTRODUCTION

β-agonists are drugs normally employed in human and animal therapy, but in the last years they have been also employed as growth promoters in many species of meat producing animals. Their use is now widely spread in several countries, including those (as EEC countries) where anabolics are prohibited. To detect illegal use of these substances in Italy, we have developed a method for the determination of some β-agonists in bovine urines and sera, using immunoaffinity chromatography and GC-MS.

PREPARATION AND USE OF IMMUNOAFFINITY COLUMNS

The immunoaffinity columns (IACs) were purchased from Genego S.p.A. (Gorizia, Italy). They were prepared by coupling CNBr-Sepharose to immunoglobulins obtained from rabbits immunized with a protein conjugate of clenbuterol (Multi-Prep III ®).
The columns were able to recover also other cross reacting β-agonists, as salbutamol, terbutaline, mabuterol and a mabuterol analog here indicated as t-pentil-mabuterol.
The extraction procedure was a slight modification of that recommended by the manufacturer:
- Centrifugation of samples and drawing of a 1 or 2 ml aliquot;
- Addition of internal standard(2 ng of deuterated terbutaline);
- Addition of acetate buffer (0.05 M, pH 4.8) and of β-glucuronidase/arylsulphatase for hydrolysis of conjugates (16 h at 37 °C);
- Dilution of samples with phosphate buffer (0.05 M, pH 7.4) and application to IACs;
- Washing of IACs with phosphate buffer and with water;
- Elution of antibody-bound substances with 2 x 1.5 ml aliquots of 95% ethanol;
- Evaporation of the eluate and derivatization for GC-MS;
- Further washing of IACs with methanol/water 70/30 and with 10 mM acetic acid and regeneration with water and phosphate buffer.

PREPARATION OF INTERNAL STANDARD (TERBUTALINE-D_3)

Terbutaline (1 mg) was incubated with 100 µl of 0.5 M deuterium chloride in deuterated water (DCl in D_2O) and 500 µl of monodeutero methanol (CH_3OD) for 4 days at 60 °C.
The reaction mixture was evaporated under nitrogen, redissolved in ethanol and stored at -20 °C.
After this time three deuterium atoms were introduced in the aromatic ring, with a yield of about 80% (as measured by GC-MS).

DERIVATIZATION AND GC-MS

The dried extracts from IACs were derivatized with N,O-bis-trimethylsilyl-trifluoroacetamide (BSTFA) at 60 °C for 30 min, to give trimethylsilyl derivatives of β-agonists (fig 1).
The detection was performed on a Hewlett-Packard 5971 Mass Selective Detector (MSD) with 5890 gas chromatograph, in the SIM mode. The GC column was a CP Sil 8 CB, 25 m l. x 0.25 mm I.D., film thickness 0.25 µm; temperature program: 110 °C (1 min) to 160 °C at 25 °C/ min, then to 325 °C at 15 °C/min; injector: splitless at 240 °C.

RESULTS

The percent recoveries of the β-agonists were calculated extracting blank urines spiked with known amounts of every substance: clenbuterol 84%, mabuterol 76%, terbutaline 56%, salbutamol 52% and t-pentil-mabuterol 42%. The capacity of the columns was about 20 ng of total β-agonists.
The sensitivity of the method was of 0.5 ng/ml for every substance, when extracting 2 ml samples.
The method described was applied to the analysis of urine and serum samples coming from calves and steers of the northern Italy (fig. 2).
The substances which were found to be used more intensively were salbutamol and clenbuterol, with concentrations ranging from 0.5 to 200 ng/ml (ppb) in urine. Other substances, as mabuterol and t-pentil-mabuterol were found only occasionally and terbutaline was not found in the samples analized.

CONCLUSIONS

The combination of a simple and highly selective purification technique for the preparation of samples (immunoaffinity chromatography) and of a powerful detection technique (SIM-GC-MS, with the use of internal deuterated standard) seems to be optimal for the analysis of residues of illegally used substances in biological samples.
The method here presented is suitable of extension to other substances of biological interest.

Introduction

In the peripheral and central nervous system, dopamine is the precursor for the neurotransmitters norepinephrine and epinephrine. It has been suggested that aberrations in dopamine metabolism might be related to the degeneration of dopaminergic neurons as observed in Parkinson's disease.[1] Whether or not such aberrant metabolism of dopamine occurs in vivo remains an unanswered question. We decided to explore this possibility in vitro, using horseradish peroxidase (HRP)/hydrogen peroxide (H_2O_2) as the model system to mimic the peroxidatic component of the mammalian peroxidase, prostaglandin H synthase (PHS). Postmortem studies of human brain have shown both the cyclo-oxygenase and hydroperoxidase activity of PHS to be present in the caudate, putamen and substantia nigra.[2] The hydroperoxidase activity of PHS can metabolically activate catechols to form toxic metabolites and to form adducts with cellular nucleophiles in the presence of hydrogen peroxide. HRP has been used to study the in vitro metabolism of phenolic compounds.[3]

Results and Discussion

Using the HRP/H_2O_2 in vitro system4 we have isolated and characterized some of the products resulting from the oxidation of dopamine. Oxidation of dopamine in an aqueous medium gave 2,3-dihydro-1H-indole-5,6-dione (an aminochrome, Figure 1). Two additional compounds were isolated from the reaction mixture after reduction with sodium hydrosulfite. These were 2-(3,4-dihydroxyphenyl)-1-nitroethane and 2-(3,4,6-trihydroxyphenyl)-1-nitroethane (Figure 2). Reduction of the trihydroxyphenyl derivative by NADPH-cytochrome c reductase gave the known neurotoxin 6-hydroxydopamine. Two thioether conjugates isolated from the nucleophilic addition of N-acetylcysteine to quinone oxidation products were also identified. These were 5-S-(N-acetylcysteinyl)-3,4-dihydroxyphenethylamine and a compound tentatively identified as 7-S-(N-acetylcysteinyl)-5,6-dihydroxyindole. The one-to-one condensation products of malonaldehyde, an end product of lipid peroxidation, with dopamine, norepinephrine, and serotonin were prepared and characterized. The structural identities of these products were established by a variety of mass spectrometric techniques and in some cases by chemical synthesis. Using this information, it is now possible to determine whether these compounds are made in vivo in certain pathological conditions. For example we are currently assaying for these compounds in parkinsonian brain tissue.

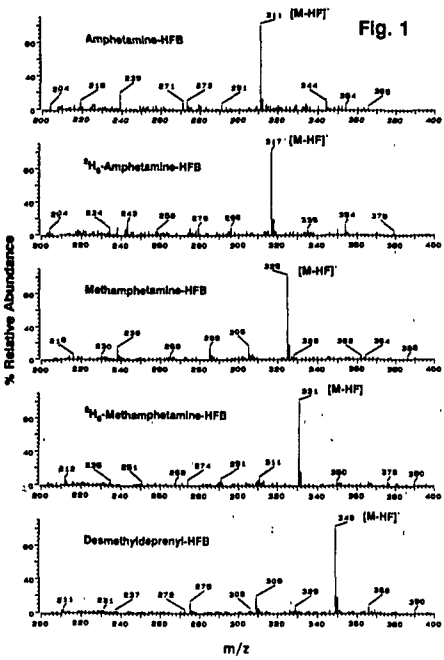
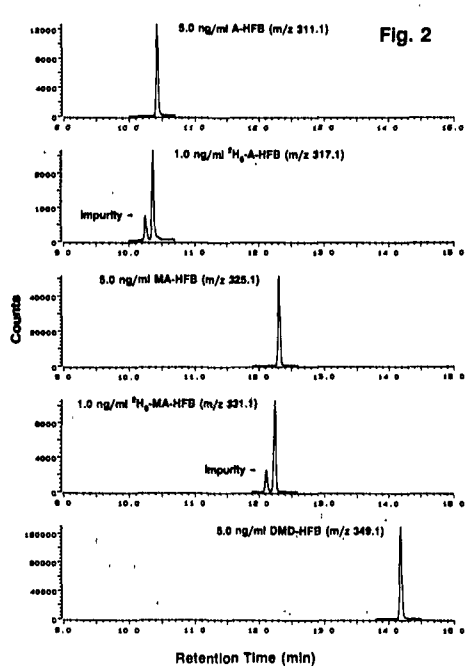
Introduction. Deprenyl (selegiline; N,α-dimethyl-N-2-propynylphenethylamine) is a selective monoamine oxidase type B inhibitor that has been proven effective in the treatment of Parkinson's disease. In this study, methane negative ion chemical ionization (NCI/CH_4) GC/MS is used to determine the plasma concentrations of the N-heptafluorobutyryl (HFB) derivatives of three deprenyl metabolites: desmethyldeprenyl (DMD), methamphetamine (MA) and amphetamine (A). Quantitation is performed by stable isotope dilution using $^2H_6$-A and $^2H_6$-MA as internal standards. Selected ion monitoring (SIM) of the $[M-HF]^-$ ions for A-HFB (m/z 311), $^2H_6$-A-HFB (m/z 317), MA-HFB (m/z 325), $^2H_6$-MA-HFB (m/z 331) and DMD-HFB (m/z 349) resulted in a limit of quantitation of 50 pg/ml.

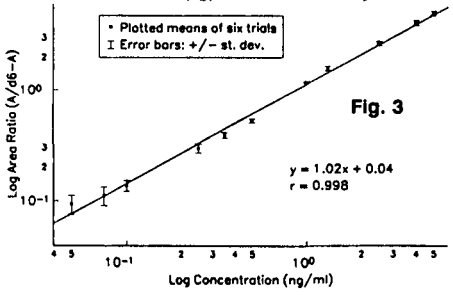
Sample Preparation. Blank plasma (1 ml) was spiked with 100 μl of a methanol solution containing 1.0 ng/ml of both $^2H_6$-A and $^2H_6$-MA, as well as A, MA and DMD in one of the following concentrations: 0.00, 0.05, 0.075, 0.10, 0.25, 0.35, 0.50, 1.00, 1.31, 2.50, 4.00 and 5.00 ng/ml. A 100 μl aliquot of 1% Triton X-100 was added and the solution was made basic (pH 10) before extracting into 6 ml of toluene. The organic layer was then back-extracted into 1.0 ml of 0.1N HCl. Finally, the aqueous layer was made basic and re-extracted into 100 μl of toluene. The HFB derivatives were prepared by adding 100 μl of 30% heptafluorobutyric anhydride in ethyl acetate and heating at 60°C for 10 min. The solution was cooled, washed with 1.0 ml of KH_2PO_4 buffer (pH 6), and the organic layer analyzed.

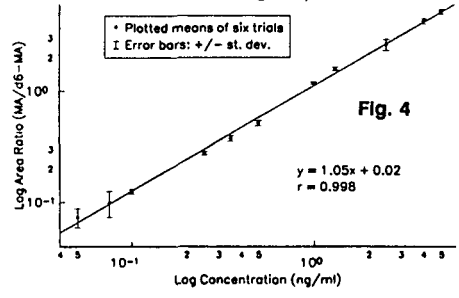


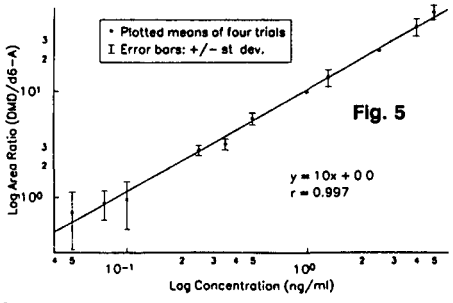


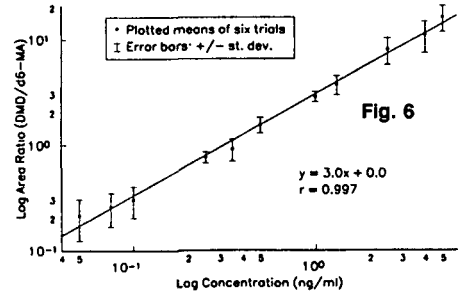
Instrumental. GC/MS analyses were performed using an HP 5890A gas chromatograph coupled directly to an HP 5988A quadrupole mass spectrometer. Samples were introduced by splitless injection (1.0 μl) on to a fused silica DB-1 capillary column (30 m x .25mm; 0.25 μm) heated initially from 70 to 120°C at 60°C/min, then from 120 to 170 at 5°C/min. Methane NCI spectra were obtained at a source temperature of 150°C and at a source pressure of 0.30 Torr.

Results and Discussion. The full scan spectra of the five HFB derivatives (Fig. 1, previous page) each exhibit $[M\text{-}HF]^-$ as their primary high-mass ion, with minor ions attributed to $[M\text{-}2HF]^-$ and $[M\text{-}3HF]^-$ visible in some instances. Typical SIM profiles of a 5.0 ng/ml plasma extract are shown in Fig. 2, demonstrating the excellent chromatographic behavior of the HFB derivatives. Absolute signal responses varied from A-HFB (and $^2H_6$-A-HFB) to MA-HFB (and $^2H_6$-MA-HFB) to DMD-HFB in approximately a 1 : 3.33 : 10 ratio, perhaps reflecting differences in column trapping or ionization efficiencies. For the quantitative work, a "3 by 2" format (three successive days with two curves/day) was followed. Standard curves for A/$^2H_6$-A, MA/$^2H_6$-MA, DMD/$^2H_6$-A and DMD/$^2H_6$-MA are given in Figures 3, 4, 5 and 6, respectively. Least-squares regression analyses indicate excellent linearity for all determinations, with somewhat poorer precision for the DMD regressions, possibly due in part to the absence of an isotopically-labelled DMD internal standard. The limit of quantitation (LOQ) was determined to be 50 pg/ml for each analyte, where the LOQ is defined as having a S/N ratio of 10.









Summary. A sensitive method for the determination of desmethyldeprenyl, methamphetamine and amphetamine in plasma using stable isotope dilution/negative chemical ionization GC/MS is demonstrated. Extraction procedures are straightforward and reaction with N-heptafluorobutyric anhydride (HFBA) yields derivatives which exhibit good chromatographic behavior and excellent electron capture characteristics. Selected ion monitoring of the $[M\text{-}HF]^-$ ions of both the analytes and internal standards results in an LOQ of 50 pg/ml and excellent linearity (r = 0.997 to 0.998) over a concentration range of 0.05 to 5.00 ng/ml.

Determination of Deprenyl and Three Metabolites in Human Plasma by Capillary Gas Chromatography Positive Chemical Ionization Mass Spectrometry

* K. Michaelis and H. Jaeger, LAB Inc., 700 Grand Avenue, Ridgefield, NJ 07657

Deprenyl (Selegiline) is used in the treatment of Parkinson's disease. It is a monoamine oxidase (MAO) inhibitor with selective action against the B form of the enzyme. It inhibits the intracerebral degradation of dopamine. Deprenyl allows the reduction of levodopa in therapeutic regime without reduced efficiency. It is primarily effective in the early stages of the disease.

Deprenyl is rapidly absorbed from the gastro-intestinal tract and is converted by first pass metabolism to three major metabolites: desmethyl deprenyl, methamphetamine and amphetamine.

Until now, no pharmacokinetic data were available for the parent drug, deprenyl, because the expected plasma levels should be very low. Therefore, we developed and validated highly selective and sensitive GC/MS methods for the determination of deprenyl and the simultaneous measurement of its three major metabolites. GC/MS analysis was performed on a VG Fisons instruments Trio 2000 mass spectrometer. A HP 5890 gas chromatograph was fitted with 25 m X 0.32 mm DB1 capillary column. Mass Spectrometry was carried out under positive ion methane chemical ionization conditions with selected ion monitoring. Response factors for all three were greater in positive ion than with a negative ion technique.

The metabolites were derivatized with pentafluorobenzoyl chloride. Deprenyl was determined un- derivatized (figure 1.). The removal of the drugs from plasma was accomplished by liquid/liquid extraction with pentane.

Calibration curves for deprenyl were prepared at concentrations ranging from 50 to 2000 pg/ml. The limit of quantification was 50 pg/ml (figure 2.). Calibration curves for the metabolites of deprenyl were prepared with concentrations range of 0.1 - 25 ng/ml. The limit of quantification for all three metabolites was 0.1 ng/ml.

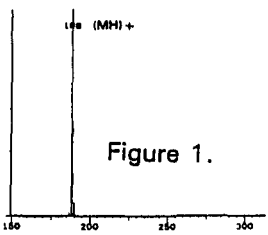

Figure 1.

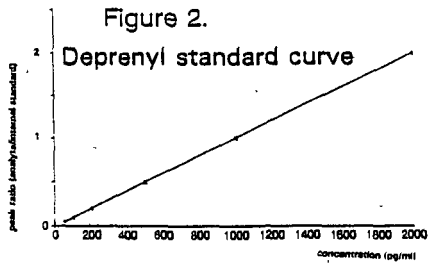

Figure 2.

The calibration curves were calculated (linear regression with 1/x weighting) from the peak area ratios analyte/internal standard and the nominal analyte concentrations. Accuracy and precision were better than 5% for all analytes.

The selected chromatograms for a subject sample of deprenyl and a control sample spiked with the three metabolites at 1 ng/ml are shown in figure 3.

The new analytical methods were applied to a pharmacokinetic pilot study with three subjects and proved to be suitable to measure the unchanged parent compound, deprenyl, and the metabolites in human subject samples after an oral dosage.

Blood samples were drawn at intervals over 72 hours. Plasma was rapidly separated and frozen at - 80 degrees centigrade.

The highest peak concentrations of deprenyl were reached at 0.4 hours (mean) post dose. C_{max} was 0.5 ng/ml. Half life measured was 0.4 hours (figure 4.).

Now for the first time, plasma levels of deprenyl could be measured and pharmacokinetic parameters determined.

COTININE-N-GLUCURONIDE, A MAJOR URINARY METABOLITE IN SMOKERS

G. D. Byrd, W. S. Caldwell, M. S. Uhrig, J. M. Greene, K.-M. Chang, and J. D. deBethizy, Pharmacology Division, R. J. Reynolds Tobacco Co., Winston-Salem, NC 27102. P. A. Crooks, A. Ravard, and R. M. Riggs, College of Pharmacy, University of Kentucky, Lexington, KY 40536-0082.

Recent work in our laboratory demonstrated that glucuronide conjugates of nicotine, cotinine, and 3'-hydroxycotinine in smokers' urine account for approximately 30% of total nicotine excretion [1]. Indirect quantification was done using a thermospray LC/MS method to monitor release of aglycons following enzymatic treatment of urine with beta-glucuronidase. In our study, cotinine glucuronide was the most abundant of these three accounting for an average of 17% total nicotine excreted in smokers (n=11). This study confirmed earlier observations that nicotine can be metabolized to glucuronide conjugates in humans [2-4]. Reports of urinary excretion of quaternary ammonium-linked glucuronide conjugates of xenobiotics [5-6] and consideration of the structure of (S)-(-)-cotinine led us to believe that some cotinine was excreted as an inner salt with N-conjugation on the pyridine ring. A candidate standard synthesized to establish the identity of this metabolite was the inner salt [N-(beta-D-glucuranopyranosyl)-(S)-(-)-cotinium] uronate (Figure 1). The details of this synthesis are described elsewhere [7]. Using thermospray LC/MS and a d_3-labeled analog of the compound as an internal standard, this material was determined in four smokers' urines and compared to indirect determination by monitoring cotinine release following enzyme treatment.

Thermospray LC/MS analyses of the standard and urine samples were done on a Hewlett-Packard 5988A quadrupole system with thermospray option. The instrument was operated in the filament-off mode. Cotinine-N-glucuronide proved thermally unstable under thermospray conditions and decomposed almost completely to give the aglycon cotinine which was protonated to yield $(\text{cotinine}+H)^+$ at m/z 177. A small amount of m/z 353 was produced but this is isobaric with the commonly occurring proton-bound cotinine dimer. The standard was analyzed by electrospray ionization using a source obtained from Analytica of Branford. Electrospray proved gentler than thermospray and considerably more of the protonated molecular ion was observed. Thermospray LC/MS was used for quantification. Separation was done using a 25 cm x 4.6 mm strong cation exchange column with 1 mL/min of the following solvent: 45% 50 mM ammonium formate adjusted to pH 3.4 and 55% isopropanol. Ammonium acetate (0.1 M) was added post column at 0.4 mL/min. Urine samples were spiked with d_3-cotinine-N-glucuronide, filtered, and injected directly onto the LC column. For quantification the mass spectrometer monitored m/z 177 and 180 (unlabeled and labeled cotinine aglycons) with a dwell time of 700 ms each. Figure 2 shows the m/z 177 response for a) a nonsmoker's urine, b) a nonsmoker's urine spiked with the cotinine-N-glucuronide standard, c) a smoker's urine, and d) a smoker's urine after treatment with beta-glucuronidase. The system was calibrated with a series of standards prepared by spiking the urine of a nonsmoker with d_3-cotinine-N-glucuronide at 15 nmol/mL and cotinine-N-glucuronide from 3 to 30 nmol/mL. The response was linear with an R-squared value of 0.9997 for this range. The limit of detection was 0.70 nmol/mL.

Four smokers' urines (24 hour samples) were analyzed with this direct method and the results compared with the indirect method of monitoring cotinine release from enzyme treatment. The results are summarized below and compared to those from the indirect method:

	Cotinine-N-glucuronide in nmol/mL		
SMOKER #	Direct Method	Indirect Method	% Diff.
1	< 0.70	0.76	-
2	18.85	17.77	6%
3	7.91	6.85	14%
4	20.74	18.52	11%

One of the smokers produced essentially none of the cotinine-N-glucuronide which reflects metabolic differences among individuals. For the other three smokers, the difference in measured values was 15% or less for the two methods.

The NMR and MS data in this study support the structure of the synthesized standard. Thermospray LC/MS and enzyme hydrolysis support the identity of this material in the urine of smokers. Direct determination of cotinine-N-glucuronide compares favorably with the previously reported indirect determination.

Improved Detection of Glutathione and Glucuronide Conjugates by Thermospray Mass Spectrometry Following Esterification.

P.Haroldsen,I.Massey, Syntex Research, Palo Alto CA 94304 and T.Pham, Dept. Chemistry, U.C.Berkeley, Berkeley, CA.

Analysis of glucuronide and glutathione(GSH) conjugates by thermospray mass spectrometry (TSP-MS) is problematic since diagnostic ions, MH+ or M+NH4+, are often not detected due to thermal instability or poor ionization. This is especially evident with GSH conjugates. Improvement in the detection of cysteinyl and mercapturate adducts by TSP-MS following methylester formation has been observed(1,2). Others have successfully used other derivatizations to improve analyte responses by TSP-MS(2-5). Here we report improvements in detection and yield of diagnostic ions, MH+ or M+NH4+, of both glucuronide and GSH conjugates, following conversion to methyl, propyl or Hexyl ester derivatives.

DERIVATIZATION: -methyl, n-propyl, n-hexyl esters were formed using the respective alcohols made acidic (0.28M in HCL) by addition of 40ul acetylchloride per ml of alcohol. 100ul of acidified alcohol was added to 10 - 20ug of conjugate in a screw cap tube and heated at 45°C for 45 minutes. The samples were dried under N2 and the residue reconstituted in methanol/water 1/1 for TSP-MS.

TSP-MS: A Finnigan TSQ-70 mass spectrometer was used interfaced with a TSP-2 thermospray unit to obtain mass spectral data. Tvap=90-110°C, Tsource=200-210°C, Repeller=10-50V. The mobile phase consisted of 35 or 70% acetonitrile with 0.15% (v/v) trifluoroacetic acid brought to pH3 with NH4OH. Derivatized conjugates were analyzed at 35% acetonitrile. Samples were introduced into the mass spectrometer via flow injection at 1-1.2 ml/min. Improvement in detection was calculated from ratios of maximal ion currents of the MH+ or M+NH4+ for esterified vs free acid on a per mole basis. The results are reported in Tables I and II.

All esterified glucuronide conjugates analyzed showed enhanced MH+ or M+NH4+ ion intensity as compared to the native free acid form(Table I) indicating an increased yield of diagnostic molecular ions and hence improved detectability. As summarized in Table I this improvement was modest for diethylstilbestrol(5X), estradiol(7-8X), testosterone(6-12X) and RS-27504(20X). The greatest improvement was observed for the glucuronides of phenothalein(51-55X) and particularly mycophenolic acid(122-454X; Figure 1A,B).Two possible mechanisms could account for these observations, improved stability of molecular ion esters and/or increased ionization yield of the esterified conjugates. Phenothalein and mycophenolic acid undergo a single fragmentation to form a base peak aglycone fragment ion. In these two simplest of cases a comparison of ratios of ion currents of molecular ion to aglycone for acids and esters indicates increased ratios for the esterified conjugates of 10 to 100 fold. This indicates an enhancement in molecular ion stability of the conjugate esters. For all GSH conjugates analyzed(Table II), the esterified derivatives gave a substantial improvement in the yield of diagnostic molecular ions (MH+). This improvement ranged from a 22 fold increase for S-butyl GSH hexylester to 195 fold increase for dinitrobenzene-GSH hexylester (FIG 2A,B). In the most extreme case a molecular ion for reduced GSH was not detectable up to 4.8 nmole of material analyzed. As the hexylester derivative 1nmole of material produced a MH+ (m/z=476) that was readily detectable and was 75% of the base peak (m/z = 214). The observed improvements in the yield of esterified-GSH MH+ ions are due to their increased stability and/or enhanced ionization yield. Regardless of the mechanism involved the end result is a much improved yield in diagnostic molecular ions.

A Comparison of Thermospray and Particle Beam LC/MS Analyses for Topiramate, a Novel Anticonvulsant and Related Fructopyranose Derivatives and their Quantitation in Biological Samples.

John A. Masucci, William J. Jones, Gary W. Caldwell and Wu-Nan Wu, The R.W. Johnson Pharmaceutical Research Institute, Spring House, Pennsylvania,19477

Topiramate, 2,3:4,5-bis-*O*-(1-methylethylidene)-ß-D-fructopyranose sulfamate(1), a potent anticonvulsant[1] and eighteen analogs were investigated by thermospray (TSP) and particle beam (PB) LC/MS and TSP LC/MS/MS. Electron ionization (EI) of several of these compounds has been previously reported.[2] The purpose of this study is to extend MS analyses for these compounds to lower levels typically found in biological samples. Since topiramate, its polar analogs and metabolites are subject to thermal decomposition during GC/MS analysis, and since most of these compounds have no UV chromophore, LC/MS is the analytical method of choice.

Studies have shown that topiramate is not significantly metabolized in rats, dogs, and humans[3]. We, therefore, concentrated our efforts specifically on its detection and quantitation.

TSP analyses were performed using a Finnigan MAT TSQ-70 mass spectrometer with a vaporizer temperature of 112 °C and source block at 218 °C. The instrument was scanned from 150-600 daltons in 1 sec., with a multiplier voltage range of 1.8 to 2.2KV and electrometer at 10^{-7} amp/volt. The mass range 356-372 daltons was scanned in 0.5 sec. for quantitation by TSP.

PB analyses were performed using a Hewlett Packard 5989A mass spectrometer with a separator temperature of 50 °C and source block 150 °C. The instrument was scanned from 70-600 daltons in 0.5 sec., with a multiplier voltage of 2457 V. The mass range 323-335 was scanned in 0.43 sec for quantitation by PB. The quantitation mass ranges for TSP and PB are explained below.

Qualitative analyses were performed by loop injection; bypassing the column. Quantitative analyses were performed chromatographically as described below.

Reversed-phase HPLC analyses were performed with TSP using a 70/30 methanol/0.05M aq. ammonium acetate buffer mobile phase at 1.5 ml/min through a 15cm x 4.6mm C_8 column. HPLC analyses with PB were performed using 100% methanol at 0.3 ml/min through a 10cm x 2.1mm C_{18} column. Elution times for topiramate were in the 1.5 min range on both systems.

Rat, dog and human urine samples were treated only by appropriate dilution with methanol. Human serum samples were appropriately diluted with methanol, followed by centrifugation. The diluted solutions were injected through a 0.45 µm nylon filter. No further biological sample treatment was required for analysis.

The detection limit of these compounds by TSP LC/MS analysis is typically in the nanogram range full scan and picogram range using multiple ion monitoring. The detection limit for PB LC/MS is typically in the 300ng range full scan, approaching 20 ng by multiple ion monitoring in EI mode. The ammonium adduct ion $[M+NH_4]^+$ in TSP LC/MS and the methyl loss fragment ion $[M-CH_3]^+$ in PB-EI LC/MS, which are base peaks respectively, were used for quantitation and detection. An internal standard of d_6-d_{14} labelled topiramate was added for quantitation by the isotope dilution analysis method. Peaks in the molecular ion region of topiramate and the deuterated internal standard were respectively summed to improve quantitation.

TSP exhibited a linear response within the 400 pg to 20 ng range investigated. PB-EI deviated from linearity at the lower levels (50-100 ng) of its investigated range (50-2000 ng). This non-linearity of response for PB has been previously reported, and is attributed to matrix effects[4].

Both TSP and PB LC/MS analyses were useful for qualitative studies of topiramate and its analogs. Quantitative analysis of biological samples yielded comparable results by both methods within experimental error. TSP, with its 100 fold lower detection limit and linear response, was better for quantitation. The typical analysis time for quantitation was 2 min/sample after calibration curves were determined and samples were prepared. TSP LC/MS/MS analysis resulted in very few diagnostic peaks due to the high stability of the ammonium adduct parent ions. Future studies to determine topiramate levels in cerebral fluid samples are currently being planned.

CHARACTERIZATION AND QUANTITATION OF THYMIDINE ADDUCTS FORMED IN REACTIONS OF 2-BROMOACROLEIN WITH DNA

Ahmed Chenna and Charles R. Iden

Department of Pharmacological Sciences, School of Medicine
Health Sciences Center, SUNY at Stony Brook, Stony Brook, NY 11794-8651

INTRODUCTION

Acrolein is a known mutagen that reacts with DNA, and several DNA adducts, including exocyclic adducts, have been characterized. 2-Bromoacrolein (2-BA) has a higher mutagenic potency than acrolein (as measured by the Ames *Salmonella typhimurium* strain TAS 100 test both in absence and presence of a metabolic system).[1] In addition, this substance is a metabolite of the flame retardant *tris*(2,3-dibromopropyl)phosphate (Tris-BP)[2] and the nematocide, 1,2-dibromo-3-chloropropane.[3] Gordon *et al.* have claimed that Tris-BP is activated by conversion to reactive electrophiles such as 2-BA by cytochrome P-450[4], and 2-BA has been suspected to be responsible for the genotoxic effects of Tris-BP. Halogen substitution at the C-2 position of acrolein should increase the rate of DNA adduct formation. In recent articles, Meerman *et al.* investigated the chemical structure of the products from the reaction of 2-BA with 2'-deoxyguanosine[5,6] and thymidine.[6] In addition, an unstable thymidine adduct has been identified in the reaction of 2-bromoacrolein with DNA.[7]

RESULTS AND DISCUSSION

2-Bromoacrolein (0.2 mmol) was added to thymidine (0.02 mmol) in a potassium phosphate buffer at pH 7.4. The solution was shaken and incubated at 37°C, and reaction products were separated by reverse phase HPLC. Three products of the reaction were found, and the relative concentration of each product was measured over a period of 100 h. The results are shown in Figure 1. Initially, an unstable substance (A) is formed, but it is quickly lost in less than four hours. A new product (B) is formed and is stable in the conditions of the reaction for approximately 100 h. A third substance, product C, was evident after two hours; however, it became the major product after 30 h. Note that the sum of the products, B + C, remained roughly constant from 4 h to 90 h, indicating that C was derived from product B.

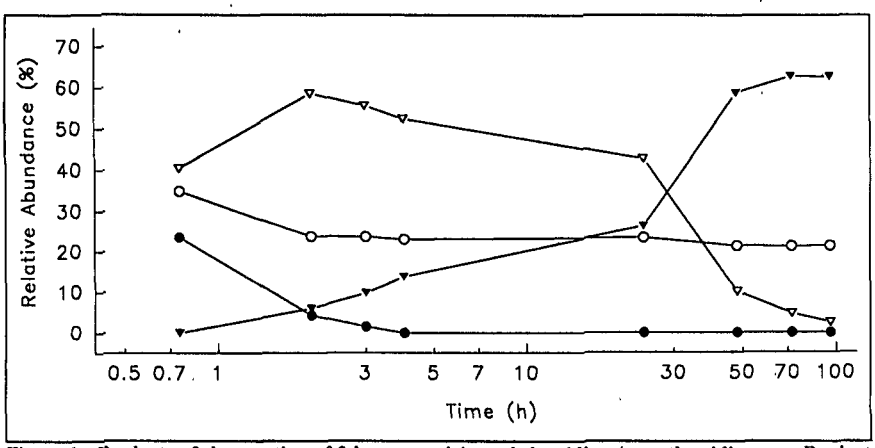

Figure 1. Products of the reaction of 2-bromoacrolein and thymidine (-o- , thymidine; -●- ,Product A; -▽- , Product B; -▼- , Product C.

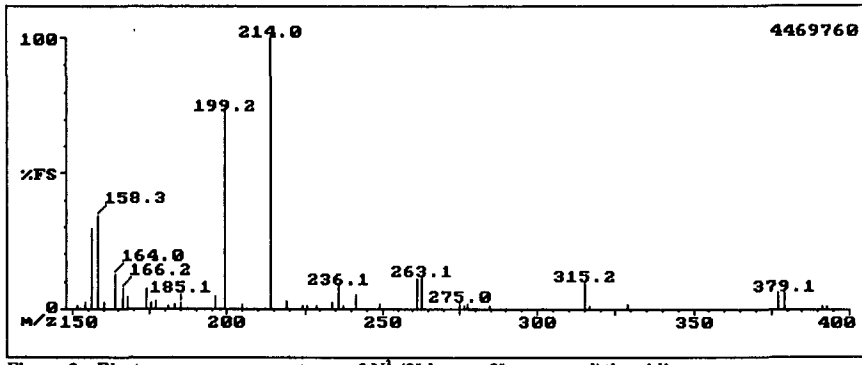

Figure 2. Electrospray mass spectrum of N^3-(2"-bromo-3"-oxopropyl)thymidine.

An HPLC fraction containing Product A was collected, and immediately a loop injection of this material was made into the electrospray source. The mass spectrum obtained is shown in Figure 2 and is an average of five scans. It clearly shows the bromine isotopes for the MH^+ at m/z 377 and 379. In addition, the same isotopic distribution is found for the BH_2^+ at m/z 261 and 263. Because of the instability of this compound in aqueous solution, the mass spectrum also contains some peaks from rearrangement products, i.e., m/z 315 and 199; however, this is the first spectral evidence for this thymidine adduct, N^3-(2"-bromo-3"-oxopropyl)thymidine. The structures of Products B and C were determined by FAB mass spectrometry and ^{1}HNMR. The structures are N^3-(2"-hydroxy-3"-oxopropyl)thymidine and N^3-(2"-oxo-3"-hydroxypropyl)thymidine, respectively. The MH^+ ion at m/z 315 and the BH_2^+ ion at m/z 199 are intense ions in the FAB mass spectrum of both compounds.

A selected ion monitoring GC/MS assay for the stable thymidine products of the reaction of 2-bromoacrolein with DNA has been developed to detect adduct formation in DNA. In this procedure both thymidine adducts, B and C, are obtained from enzymatic degradation of DNA and converted to the same *tetrakis*-trimethylsilyl derivative. In the EI mass spectrum, this compound displays a strong molecular ion (M^+) at m/z 602 and a BH_{2+} ion at m/z 342 [*bis*(trimethylsilyl)thymine], and the intensities of these ions are monitored in the SIM assay. In selected ion chromatograms of derivatized standards of B and C, two peaks appear at retention time 13.3 min and 14.4 min which are *cis* and *trans* isomers. Both peaks also appear in derivatives synthesized from enzymatic digests of DNA; this was verified by coinjection.

An On-Line Thermospray LC-MS/MS Method for the Simultaneous Quantitation of Felbamate and Three Metabolites in Dog Urine without Sample Clean-up

*Robert E. Sparadoski Jr., Joseph K. Wichmann, Norbert Kucharczyk and R. Duane Sofia
Wallace Laboratories Division of Carter-Wallace, Inc., Cranbury, NJ 08512

OBJECTIVE

To quantify Felbamate and four metabolites in dog urine using Thermospray LC-MS/MS techniques without any sample clean-up.

INTRODUCTION

Felbamate, 2-phenyl-1,3-propanediol dicarbamate, is a novel orally active antiepileptic compound exhibiting low toxicity and a unique profile of activity in laboratory animals. This profile of minimal toxicity and good efficacy has also been observed in extensive clinical trials. Pharmacokinetic analysis of felbamate in the dog required development of a quantitative assay for parent drug and metabolites in dog urine. Long sample preparations and endogenous interferences made it difficult to quantitate these compounds in urine samples using classical HPLC-UV techniques alone. The simultaneous combination of reverse phase HPLC and Thermospray LC-MS/MS allowed the separation and specific quantitation of felbamate and three metabolites in dog urine.

STANDARD AND SAMPLE PREPARATION

A stock solution of felbamate and metabolite standards was prepared in internal standard methanol solution containing equal quantities of both the structural analog and tetradeutero-labelled internal standards. The standard solution series was prepared from the stock solution and diluted 10-fold with water before injection. The final concentrations achieved were 0.00, 1.00, 2.00, 4.00, 8.00, 16.0, 32.0, 64.0, 128 and 160 μg/mL. Each solvent standard was vortexed before injection.

The pooled control urine sample was prepared from equal volumes of urine obtained from adult and pediatric male and female dogs. Pooled urine sample solutions (0.90 mL) were spiked with 0.10 mL of the appropriate standard stock solution to yield standard spiked urines of approximately 0.00, 1.00, 2.00, 4.00, 8.00, 16.0, 32.0, 64.0, 128 and 160 μg/mL. Urine samples was maintained on ice and vortexed before injection.

EXPERIMENTAL

The HPLC system consisted of a Waters U6K injector, 600MS Silk pump, oven, 484 UV detector at 210 nm. The HPLC column was a YMC AQ 303, S-5, 120 A, ODS maintained at 40°C. A Brownlee/Rainin RP-18 pre-column was used. The mobile phase was H_2O:CH_3CN:CH_3OH (70:24:6) in 0.1% formic acid at a flow rate of 1.2 mL/min. The analysis time was 10 min with a 10 min wash. Direct injections of 100 μL were made for all analyses. The UV detector was placed in line with the TSP vaporizor. The mass spectral analysis was performed using a Finnigan MAT TSQ-70A equipped with Thermospray I (TSP I) option. Neslab CC-100 immersion cooler with Savant instruments silicon based solvent. Conditions: vaporizer 75°C, block 230°C, repeller 50 V, discharge ionization 800 V, electron multiplier 1800 V, collision offset -10 V. Collision cell pressure 1.1 mTorr Argon. SRM conditions: Felbamate: daughters m/z 239 - m/z 178 and 117; W-2986: daughters m/z 255 - m/z 194, 133 and 105; W-2992: daughters m/z 255 - m/z 194, 133 and 105; W-873: daughters m/z 196 - m/z 135, 117 and 91; W-3049: daughters m/z 210 - m/z 149, 131 and 103; D_4IS: daughters m/z 243 -m/z 182, 121; analog IS: daughters m/z 269 - m/z 208 and 147.

RESULTS

Direct injection analyses were performed on solvent standards in water and standard spiked urine samples resulting in 90 analyses for each of the two sets of samples. Each set of 90 analyses was completed over three days, 30 analyses per day (triplicate determinations of 10 concentrations). SRM data was acquired for 18 individual parent/daughter ion transitions for each TSP-LC-MS/MS analysis using an ICL procedure. The specific daughter ions characteristic for each of the five analytes and two internal standards were clearly observed and measured during all SRM experiments.

Figures 1 and 2 show the SRM RIC's of representative 16 μg/mL solvent and spiked urine standards, respectively. The endogenous interferences in the UV chromatograms of spiked urine standards are not present in the SRM RIC's. Each target component observed by TSP-LC-MS/MS was separated and easily integrated. The relative standard deviation (RSD) and relative mean error (RME) were used to evaluate the precision and accuracy of the method, respectively. The total error (TE) was used to evaluate the overall quantitative performance of the method. The TE was calculated as (2 X SD + |ME|)/true value and is expressed as the percentage.

Figure 1 SRM RIC's of a 16 μg/mL Solvent Standard

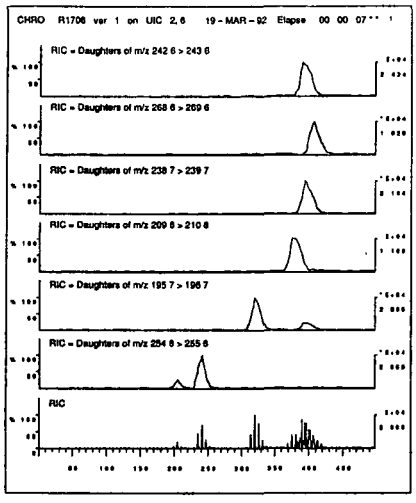

Figure 2 SRM RIC's of a 16 μg/mL Spiked Urine Standard

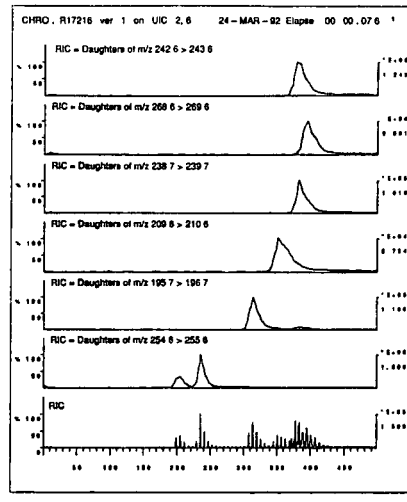

Good assay performance was obtained for all analytes except W-2986. Assay performance for solvent standards and spiked urine standards was equivalent, as was assay performance using either of the internal standards. The RSD's observed for each concentration of all analytes but W-2986 over the three day period were less then 30% with the majority less than 25%. The RME's for all but the lowest concentration point for these compounds in the spiked urine standards were better than 25%. Use of the tetradeutero-labelled IS for the quantitation of felbamate affords no better assay performance than the cheaper structural analog IS.

Acceptable quantitative ranges for the compounds in spiked urine, defined as TE < 50%, were: Felbamate 1.0 to 160.8 μg/mL; W-2992 2.0 to 161.2 μg/mL; W-873 2.0 to 160.8 μg/mL. If the acceptable TE is extended to 60%, W-3049 can be quantitated from 8.0 to 160.1 μg/mL. W-2986 could not be acceptably quantitated.

CONCLUSIONS

Direct injection of urine samples and quantitation by TSP-LC-MS/MS is applicable for the analysis of Felbamate and metabolites. The selectivity, specificity, and reproducibility of the method was adequate for the quantitation of felbamate and three of four metabolites. The sensitivity of the method is adequate, projected urinary concentrations of all compounds are above 6 μg/mL for 36 hours following a single 60 mg/kg oral dose of felbamate.

Although the performance of this method is encouraging, other soft ionization approaches will be investigated for improved quantitation of W-3049 and W-2986. Since Felbamate is somewhat thermally labile, techniques such as Continuous Flow FAB (CFF) LC-MS/MS will be considered. The use of deutero-labelled internal standard was found to offer no advantage over the less expensive structural analog internal standard.

CONFIRMATION AND IDENTIFICATION OF AZITHROMYCIN METABOLITES IN THE DOG BY HPLC/ATMOSPHERIC PRESSURE IONIZATION MS/MS

M. J. Avery, R. A. Ferraina, R. M. Shepard and H. G. Fouda
Central Research Division Pfizer INC, Groton, CT 06340

Azithromycin is a novel azalide antibiotic for the treatment of respiratory, skin, sexually transmitted and soft tissue infections. Previous work had identified several metabolites in rat urine and bile by HPLC/ atmospheric pressure ionization tandem mass spectrometry (HPLC/APIMS/MS). We have identified the structures of twelve metabolites in dog bile by HPLC/APIMS/MS. Three of the metabolites are novel and nine are identical to those previously observed in the rat.

Dog bile extracts (10μL) were analyzed by reversed phase HPLC using a 4.6x250mm Zorbax Rx C8 column (Dupont). The mobile phase was a 40/60 mixture of acetonitrile and 50 mM ammonium acetate. The effluent from the HPLC column at 1 ml/min was introduced into a SCIEX API III tandem mass spectrometer via a heated nebulizer interface.

Azithromycin was determined to be metabolized in the rat *via* deconjugation of desosamine and cladinose sugars, dealkylation of aglycone and desosamine, and N-oxidation. Selective multiple-reaction-monitoring (MRM) experiments were initiated to confirm the presence of 9 of the 11 previously identified metabolites.

The CID spectrum of azithromycin(Figure 1) suggests that neutral loss of 159 daltons would detect metabolic changes on the aglycone moiety of azithromycin molecule. Analysis of a dog urine sample produced the extracted parent chromatograms shown in Figure 2. The parent drug at m/z 750, the previously identified des methyl metabolite C at m/z 736 and the new metabolites O, P, and Q at m/z 764 were detected. The possible molecular weight of 763 daltons suggests a gain of 14 daltons. This gain could be due to N-acetylation or hydroxylation followed by dehydrogenation. CID daughter spectra indicate that the novel metabolites are due to N-acetylation of 9a-N-desmethyl azithromycin (metabolite O) (Figure 3), oxidation on the desosamine sugar followed by dehydrogenation (metabolite P) and acetylation of the 3' amino group of 3',3'-N,N-didesmethyl azithromycin (metabolite Q).

ANALYSIS OF ESTRADIOL PHASE II CONJUGATES USING COLUMN-SWITCHING LC/MS AND MS/MS

Kathy A. Halm, M. Arthur Moseley, and Steve E. Unger
Department of Drug Metabolism, Glaxo Research Institute
Research Triangle Park, NC 27709

Traditionally, phase II conjugates have been analyzed indirectly as the free metabolite following enzymatic hydrolysis. Due to the high polarity of the conjugates, their extraction, separation and detection from biological matrices is challenging. Thermospray LC/MS is capable of providing intact ions of these polar metabolites from complex mixtures but lacks the detection sensitivity of electrospray. While electrospray offers improved sensitivity it is more restricted in its ability to handle high ionic strengths or more complex mixtures.

To provide for both optimum separation and MS analysis, column-switching HPLC techniques have been used. (1-3). We evaluated the use of column-switching HPLC for sample preparation, coupled with thermospray or electrospray LC/MS and MS/MS to analyze estradiol conjugates in urine.

The filtered urine sample was injected onto the first column where an isocratic mobile phase buffer removed polar urine components and salts for the first five minutes. Then, the first column was switched in line a second column and a mobile phase gradient of 15 % to 30% acetonitrile (over 5 minutes) was used to elute the estradiol conjugates from the first column onto the analytical column. Finally, a mobile phase gradient from 30% to 50% acetonitrile (over 15 minutes) was used for the chromatographic analysis of the estradiol conjugates.

Using negative ion thermospray on the Finnigan TSQ-700 MS, the deprotonated molecule was observed for all of the estradiol conjugates. In the full scan mass spectra the doubly-charged $(M-2H)^{2-}$ ion at m/z 215 was observed for the bis-sulfate as well as the sulfate-glucuronides (m/z 263). Daughter ion mass spectra were obtained for the estradiol conjugates recovered from rat urine at the 2 nanomole on column level. All estradiol conjugates were successfully analyzed by single-ion monitoring (SIM) at the 200 pmol level recovered from rat urine. Only the glucuronides at 20 picomoles and the mono-sulfate at 30 picomoles could be reliably detected from rat urine using thermospray.

In a similar manner, the estradiol conjugates were analyzed using electrospray MS with a 500:1 split ratio to the interface. This provided a flow rate of ca. 2 uL/min of analyte with coaxial addition of 0.5 uL/min of i-prOH to the Analytica of Branford source. SF_6 was used to suppress discharging. Single-ion monitoring of rat urine produced results similar to those obtained by thermospray but on a lower absolute amount of material (fmol range) because of the flow splitting.

The column-switching procedure for sample clean-up ensured good recovery of the polar metabolites, their analysis below the 2 nanomole level in urine, and was less labor intensive than other recovery methods.

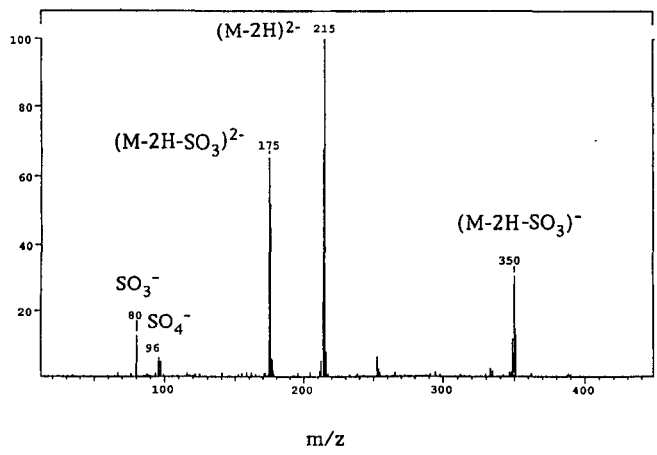
TSP Daughter Ion Mass Spectrum of m/z 215 Ion Arising From E-3,17S



Application of Electrospray Ionization for the Mass Spectrometric Determination of Veterinary Drugs

Rolf Straub and Robert D. Voyksner, Analytical and Chemical Sciences,
Research Triangle Institute, P. O. Box 12194, Research Triangle Park, NC

An important advance in the field of mass spectrometry (MS) in recent years has been the development of various spray techniques for forming ions. One of them, electrospray (ES) ionization, has recently proven the capability to produce intact ions with multiple charges from large complex and fragile parent species. The ES technique is very sensitive and can produce structurally significant fragment ions through collisional activated dissociation (CAD) in the transport region of the ES interface.

A number of veterinary drugs such as β-lactam antibiotics, aminoglycosides, tetracyclines, and sulfonamides are frequently used as growth promoters and to prevent infections. These drug residues can contaminate meat and milk products destined for human consumption. In order to ensure human food safety, new methods using ES-MS were evaluated to monitor these antibiotics. We have studied the influence of different HPLC mobile phases (methanol acetonitrile and water combinations) and various mobile phase additives or buffers such as trifluoroacetic acid, formic acid (FOA), acetic acid (HOAc), ammonium acetate, ammonium hydroxide (NH_4OH), heptafluorobutyric acid, and oxalic acid in the positive and negative ionization.

The initial determination of each antibiotic evaluated the (CAD) spectra that could be generated between the capillary and skimmer in the interface. The β-lactam antibiotics show various characteristic fragmentations, mostly within the β-lactam ring and the amide group. Aminoglycosides mainly form fragments across the glycolate bond. Tetracycline antibiotics present an intense molecular ion and losses of chlorine or hydroxy groups. Sulfonamides form characteristic molecular ions and $[NHR]^+$ fragment ions. The ions at m/z 92 ($[H_2NC_6H_4]^+$), m/z 108 ($[H_2NC_6H_4O]^+$) and 156 ($[H_2NC_6H_4SO_2]^+$) are common in all mass spectra. Response for a particular compound in a given solvent can vary drastically. Usually, the more organic in the solvent, the higher the ES response. Also, in many cases use of acetonitrile results in slightly better ion currents than methanol, when comparing equal percentages of either organic in water. The ES response of most of the tested antibiotics can be enhanced by the addition of FOA or HOAc to the mobile phase methanol/water (1:1). A moderately low pH (pH 3-4) promotes the formation of $[M+H]^+$ as well as characteristic fragment ions. Higher or lower pH of the medium decreases the signal intensity, sometimes drastically.

In general, the negative ion spectra are lower in intensity, exhibiting an $[M-H]^-$ ion and with less fragmentation at higher CAD voltages as compared to positive ion detection. The β-lactam antibiotics produce fragments from loss of COOH, HCO_2CH_3 and opening of the β-lactam ring, resulting in ions at m/z 289 and 192 for penicillin G, m/z 319 and 222 for amoxicillin, respectively. The negative ion mass spectra of aminoglycosides are low in intensity, showing extremely weak molecular ions. Fragmentation results from cleavage across the glycosylate bond as observed in positive ion detection. The tetracyclines exhibited $[M+H]^-$ ions and simple fragments from the loss of $N(CH_3)_2$ and CON or Cl groups from the $[M-H]^-$ ion. The sulfonamides gave an abundant $[M-H]^-$ ion and minimal fragmentations unlike positive ion detection. It was also found that in all cases better ion currents were obtained from selected classes of drugs at higher pHs (pH 10, achieved through the addition of NH_4OH in 2-propanol/water 8:2), but negative ion response ranged from 0.2 to 38.5% of the response obtained from positive ion detection. The β-lactam antibiotics and the sulfonamides produced the best negative ion sensitivity.

Mass Spectrometric Characteristics of the Immunosuppressive agent Rapamycin (AY-22,989).

J. Cantone and *K. Chan, Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543.

Rapamycin is an antitumor, antifungal, and immuno-suppressive agent isolated from the fungus *Streptomyces hygroscopious* (1). It is currently under development as an immuno-suppressant after transplantation (2). The structure of rapamycin was originally determined by X-ray crystallography (3), nuclear magnetic resonance spectroscopy (4,5), and chemical correlations (4). It is a neutral macrolide consisting of a 31-membered lactone ring, a highly unstable tri-ketone region, and a conjugated triene. Rapamycin presents an unique challenge for mass spectrometry because of its size (MW 913.5), its thermal lability, and its relatively non-polar nature. The original electron ionization mass spectrum (4) of rapamycin obtained via direct sample insertion showed only low mass fragment ions (< m/z 310). Since the discovery and characterization of rapamycin in 1975 and 1978-1980, respectively, numerous new mass spectrometric ionization and sample introduction techniques have been developed. We now report the mass spectrometric characteristics of rapamycin using soft ionization techniques such as desorptive chemical ionization (DCI), fast atom bombardment ionization (FAB), and ionspray (IS) ionization. These data are essential in the characterization of analogues or metabolites of rapamycin.

DCI data were obtained on a Finnigan-MAT 8230 mass spectrometer. Chemical ionization was achieved by 50 µA of 200 eV electron and methane or isobutane as the reagent gas. The DCI wire was heated at a rate of 8 mA per second. FAB experiments were carried out on a Kratos MS 50 spectrometer; the primary beam was 1 mA of 7 kV Xeon. Matrices employed have included glycerol, thioglycerol, triethanol amine (TEA) , nitrobenzyl alcohol (NBA), and NBA + NaCl. High resolution measurements were carried out at R=10,000 (10% valley) using ions from cesium iodide and polyethylene glycols as external reference. IS data were obtained on a Perkin-Elmer SCIEX API *III* spectrometer, through the courtesy of Dr. T. Sakuma of SCIEX. The ionspray needle was at + or - 3.5 kV, the mobile phase consisted of 1:1 methanol and 50 mM ammonium acetate at a flow rate of 10 µL per minute. MS/MS experiments were carried out with argon as collision gas at a thickness of approximately $5x10^{14}$ atoms/cm^2.

Negative ion FAB spectra of rapamycin are best obtained with a TEA matrix. Both molecular ion species (M^-, m/z 913) and structurally diagnostic fragment ions (m/z 167, 321, 590) are observed (Figure 1). High resolution measurements on the ions of m/z 590 and 321 confirmed that they are the complementary fragments formed by cleavages of the ester bond and the C28-C29 bond via a retro-aldo mechanism (Scheme **A**). The measured mass of the ion at m/z 167 was 167.0670, suggesting an elemental composition of $C_9H_{11}O_3$ (Δ=3.8 mmu) which is likely to contain the tri-ketone region of rapamycin. Similar results can be obtained with thioglycerol and NBA matrices; the advantage of TEA is that the ion signal is more intense and longer lived. No rapamycin related ion was detected when glycerol was used. Positive ion FAB mass spectrum of rapamycin obtained in a NBA + NaCl matrix or thioglycerol matrix are similar and shows a $[M+Na]^+$ ion at m/z 936. Minor fragment ions, such as $[M-OCH_3]^+$ and $[M-OCH_3-H_2O]^+$, are observed at m/z 882 and 864, respectively (Figure 2). When only NBA was used, no molecular ion was detected; only fragment ions were observed. No rapamycin related ion was detected when glycerol was the matrix. Interestingly, the +FAB mass spectrum of rapamycin in TEA shows a very weak $[M+TEA+H]^+$ quasimolecular ion.

Negative ion DCI mass spectrum of rapamycin is almost identical to -FAB spectrum, except for relative intensities and less the ions from the FAB matrix. Positive ion DCI mass spectrum shows no molecular ion species; only fragment ions which correspond to elimination of H_2O and OCH_3 from the molecule and the retro-aldo fragments are detected.

Negative ion IS spectrum shows only the M^-, $[M-H]^-$, and $[M+CH_3COO]^-$ ions. MS/MS spectrum of the M^- (Figure 3) shows fragmentation similar to those observed in the -FAB spectrum (i.e. m/z 167, 321, 590). Other ions detected can be assigned as further decomposition products from M/Z 590 (see Scheme **A**). Positive ion mass spectrum obtained from IS shows only the

molecular ion species $[M+NH_4]^+$ and $[M+Na]^+$ at m/z 931 and 936, respectively. Upon CAD by argon, fragment ions similar to those observed in the +FAB spectrum were detected.

In conclusion, rapamycin can be characterized by DCI, FAB, and IS ionization techniques. In fact, the data obtained from these techniques are quite similar, suggesting similar ionization mechanism. In general, characterization of rapamycin in the negative ion mode is more useful because both the molecular ion species and structurally diagnostic fragment ions are observed. This observation is in agreement with other mass spectrometric studies on some oligomycins (6). Presumably, the triene in rapamycin can capture an electron to form the radical anion or the lactone ring can open to generate a carboxylate anion. Our future work will evaluate the relative detection limit of these ionization techniques when coupled directly to a liquid chromatograph in the analysis of rapamycin analogues or metabolites.

Anagrelide, 6,7-dichloro-1,5-dihydroimidazo-[2,1-b]-quinazolin-2(3H)-one monohydrochloride (BL-4162A, Figure 1), a phosphodiesterase inhibitor, is a potent inhibitor of platelet aggregation.[1] It will inhibit aggregation of platelet rich plasma in response to ADP, arachidonic acid, collagen, thrombin, antigen/antibody complexes, and platelet activating factor.

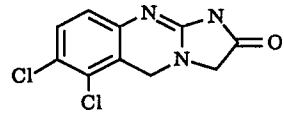

Figure 1.

Anagrelide has been found to cause thrombocytopenia when administered to human patients, which may suggest that it is having an effect on megakaryocytes.[2] Metabolic studies have been carried out using carbon-14 labeled anagrelide in fasted rats (80 μg/kg), rhesus monkey (50 mg/kg), dogs (30 μg/kg) and humans (1 mg), from which it was found that in humans about 70 % of the radioactivity was excreted in the urine within 72 hr, compared with 60 % by the monkey. The major metabolite in humans represented 30 % of the excreted radioactivity. This metabolite was also excreted by dogs (11 %), monkeys (3 %) and rats (1 %). In this study, several *in vitro* incubations were investigated in order to determine the route of metabolism of anagrelide. All of the *in vitro* systems tested; rat and human liver homogenates and microsomes, rat liver slices, whole blood, bone marrow cell culture and rat intestinal mucousa microsomes failed to result in the formation of any metabolite of the parent drug.

The major human urinary metabolite of anagrelide was isolated by using Chem-Elute extraction and HPLC with the metabolite peak appearing at approximately 18 minutes. The fractions corresponding to the metabolite peak were collected and combined. The solvent was removed *in vacuo* to afford the purified urinary metabolite. The resulting solid was dissolved in 250 μL of methanol. The metabolite was obtained relatively pure from the HPLC and was subjected to structural identification through the use of mass spectrometry and ^{1}H NMR. The positive exact mass FAB spectra gave a m/z of 216.0080 and a calculated chemical composition of $C_8H_8N_3Cl_2$ for the $[M+H]^+$ ion. The ^{1}H NMR of the metabolite showed a set of signals at 7.46 δ (2H, d) and 6.93 δ (2H, d) resulting from the ortho coupled protons in the aromatic ring. A signal at 4.62 δ (2H, s) resulted from the protons located on the benzylic carbon of the quinazolin ring.

Capillary LC/electrospray afforded a single peak with a retention time of 5 minutes (Figure 1). There was a difference of approximately 3 minutes between the UV detection and the response in the TIC of the mass spectrometer was due to the low flow rate and the distance between the UV monitor and the electrospray source. The spectrum which was obtained from this sample (Figure 2) gave an intense molecular ion at m/z 216 with a chlorine isotope peak at m/z 218. Structural information was obtained from the fragmentation with loss of the primary amino group resulting in the fragment at m/z 199 and cleavage of the quinazolin ring to afford the m/z 174 fragment.

Discussion

The antiplatelet drug, anagrelide has been found to have a large difference in the inter-species metabolism. There is a major urinary metabolite in man which is present in only small amounts in animals. This metabolite was isolated and purified in sufficient quantities to obtain ^{1}H NMR, exact mass FAB and capillary/LC electrospray mass spectra data. The use of capillary/LC electrospray proved to be an extremely sensitivity method for the characterization of this metabolite. The final purification which was afforded by the capillary LC system, removed impurities which greatly affected the sensitivity and quality of the spectra when the sample was

infused directly. Electrospray was very useful, in that, the amount of fragmentation could be controlled and a large amount of structural information obtained without loss of sensitivity.

In this study several *in vitro* incubation systems were investigated in order to determine the possible route of *in vivo* metabolism of the drug Anagrelide. We were unable to obtain the observed urinary metabolite as well as any possible precursors to this product. We have proposed a possible route by which the urinary metabolite may be formed (Figure 3). The first step involves hydroxylation of the carbon α the carbonyl, a hydrolase enzyme could then cleave the amide linkage and the resulting intermediate could loose glyoxylic acid to afford the observed urinary metabolite.

AN ION SPRAY HPLC/MS/MS METHOD FOR THE DETERMINATION OF AMINOGLYCOSIDE DRUG RESIDUES IN BOVINE KIDNEY

Lee McLaughlin, Thomas Huggins and Jack Henion, Drug Testing and Toxicology, Cornell University, 925 Warren Dr., Ithaca, NY 14850

As part of a regulatory effort for determining aminoglycoside residues in tissues and milk of livestock, the U.S. Food and Drug Administration (FDA) requires confirmatory methods based on mass spectrometry. We have developed a multi-residue method for the confirmation of six priority aminoglycoside antibiotics in bovine kidney. For this class of compounds we have found the use of the Ion Spray interface for the coupling of a reversed-phase ion-pairing HPLC separation with tandem mass spectrometric detection to be a feasible approach. The combination of retention time data and collision-induced dissociation (CID) mass spectra provides residue identifications in samples screened positive by less specific methods. The purpose of this work is to optimize multi-residue conditions in order to detect all analytes at their FDA action levels, which range from 0.02 ppm for hygromycin B to 0.5 ppm for streptomycin and dihydrostreptomycin. Application of the method to confirmation of incurred samples is demonstrated and some quantitative aspects of our method discussed. Data are presented for spectinomycin, hygromycin B, streptomycin, dihydrostreptomycin, gentamicin C, and neomycin B in the selected reaction monitoring (SRM) LC/MS mode of operation. Tobramycin is used as an internal standard.

EXPERIMENTAL

HPLC/MS work was done with a YMCbasic, 2 mm i.d. x 100 mm column and 2 mm i.d. x 10 mm pre-column at a flow of 200 µL/min using an Applied Biosystems Inc. Model 140A pump. Mobile phases consisted of 5% MeCN in 20 mM PFPA (pentafluoropropionic acid) (B) and 50% MeCN in 20 mM PFPA (A). A step gradient from 100% B to 65% B after 5 minutes was used. Column effluent was split with a PEEK tee such that 20 µL/min reached the Ion Spray interface that was maintained at 3 kV. The mass spectrometer, a Sciex TAGA 6000E upgraded to an API III, was used in the positive ion detection mode. Collision-induced dissociation (CID) experiments were accomplished with argon at 200 x 10^{12} atom/cm^2 and collision energies ranged from 50-100 eV (laboratory frame). Bovine kidney was extracted using the matrix solid-phase dispersion (MSPD) technique (1) with modifications for this class of compounds (2). Analytes were eluted from the MSPD column with 1 mL water and 8 mL 0.1 M formic acid. A 5-mL aliquot of the eluate was concentrated to 100 µL, adjusted to 100 mM PFPA, filtered, and 20 µL injected onto the HPLC column.

RESULTS AND DISCUSSION

The gentamicin C components, neomycin B, and tobramycin are more highly retained than the other four analytes and require use of a gradient program. Using a simple step gradient all analytes can be separated in approximately 16 minutes (see Figure 1). The YMC-basic column was found to provide much improved peak symmetry for the gentamicin C components and neomycin B compared with several ODS columns used previously. The reversed-phase ion-pairing method using PFPA was found to be very sensitive to sample composition. It was necessary to use formic acid as the MSPD eluate instead of sulfuric acid, which distorted HPLC peak shape and affected retention times. Sample matrix also shortened retention time by approximately one minute relative to that of a standard solution. Addition of PFPA to the sample reduced this effect, although not completely. Cleaning of the column with 50% MeCN between injections was found to be necessary to help preserve peak shape and retention times. Further sample clean-up would make the method more rugged, but is not necessary from a detection standpoint as interferences do not present a problem in the SRM mode.

Confirmation is accomplished by LC/MS/MS in the SRM mode. Two different sets of CID conditions were used during the two sections of the gradient. There is not enough time between elution of components to make switching of CID conditions for each analyte practical. Conditions used were optimized for doubly-charged precursors, except for spectinomycin for which the singly-charged species predominates over a broad range of declustering potentials. This constitutes the more sensitive scheme for all analytes except hygromycin B for which use of the singly-charged precursor gives much better sensitivity as well as an additional product ion. (There is only one significant product ion formed from the doubly-charged precursor.) For all other analytes there are at least three ions in the CID

spectra that may be used for confirmation. Under these conditions all analytes except spectinomycin and hygromycin B can be determined at their action levels (i.e. proposed tolerance levels). See Figure 2. The recovery of spectinomycin using the MSPD procedure is approximately 25%. Much better recovery can be obtained by using MeCN instead of MeOH because spectinomycin elutes during the MeOH wash. However, this approach requires further clean-up beyond the MSPD procedure.

We have detected hygromycin B, neomycin B, gentamicin C and spectinomycin in incurred kidney tissue from dosed animals. The MSPD procedure thus appears to be effective for extraction of aminoglycosides from incurred samples. However, we have not yet determined if there is a discrepancy between recovery from fortified and incurred tissue. We have also used the method to distinguish closely related members of this class, i.e. streptomycin and dihydrostreptomycin, in a field sample that the microbial test used for screening could not. Preliminary quantitative assays were performed using fortified tissue samples as calibration standards due to the matrix effects on chromatography described above and observed ionization suppression for some analytes. An internal standard was found to be necessary as absolute response may change during the course of a day. Acceptable linearity and repeatability (9% intraday RSD) were observed.

ACKNOWLEDGEMENTS

The authors thank the U.S. FDA for funding this work under agreement # FD-U-000577-02, Dr. Philip J. Kijak for helpful discussions, and the Animal Research Division for supplying incurred tissues. We also thank the FSIS-USDA for providing screened field samples. DIONEX Corp. is acknowledged for the generous loan of a pulsed amperometry system as is SCIEX for hardware and research support.

Detection of Azaperone Metabolites in Equine Urine by GC/MS and LC/MS/MS

*Y.C. Chui, B. Esaw, R. Zarate, L.M. Young and B. Laviolette

CanTest Ltd., 1523 West 3rd Ave., Vancouver, B.C., V6J 1J8, Canada

Introduction

Azaperone, a short-acting neuroleptic butyrophenone tranquilizer, has reportedly been used by horsemen to calm horses before racing. In cattle, azaperone was mainly excreted in urine as metabolites (1, 2). In man, after a suicide attempt by an ingestion of approximately 2 g of azaperone, azaperone, azaperol and *N*-despyridyl-azaperone were identified in the patient's urine (3). Using GC/MS for the analysis of hydrolyzed urine extracts, we had previously reported the detection of hydrogenation of the keto group and hydroxylation of the pyridyl ring of azaperone in horses (4). Recently, Woods *et al.* (5) synthesized and identified 5'-hydroxy-azaperone and 5'-hydroxy-azaperol in equine urine. In the present study, the phase I and phase II metabolism of azaperone in horses was investigated using LC/MS/MS and the results were compared with the findings of the GC/MS studies.

Experimental

Drug administration and sample collection: Stresnil^R (40 mg) was administered intramuscularly to standardbred mares. Urine samples were collected at various time intervals for a 5 day period.

Urine Extraction: Urine samples (75 mL) were adjusted to pH10 with borate buffer and ammonium hydroxide and extracted with 4% isopropanol in dichloromethane. The organic layers were backwashed with 0.1N HCl and re-extracted at pH 10 with 4% isopropanol in dichloromethane. The extracts were dried at 50°C with a stream of nitrogen, reconstituted in 0.5 mL of methanol and analyzed by LC/MS/MS. The aqueous layers were acidified to pH 1 and autoclaved at 120°C for 10 minutes. The autoclaved samples were extracted at pH 10 with 4% isopropanol in dichloromethane, backwashed and analyzed as the organic layers.

For the extraction of conjugated metabolites, urine samples (50 mL) were adjusted to pH 9.5 with ammonia buffer. The samples were adsorbed on approximately 2 grams of XAD-2 resin. The XAD-2 resin was washed with 20 mL of 50% ethyl acetate in dichloromethane, 10 mL of 10% acetic acid in water and 10 mL of dichloromethane. The resin was then eluted with 10 mL of 10% methanol in ethanol. The eluates were dried, reconstituted in methanol and analyzed by LC/MS/MS.

LC/MS: The chromatographic system consisted of an ABI (Foster City, CA) 140A dual syringe pump equipped with a 250X2.1 mm Suplex pKb-100 (Supelco) column. The mobile phase was gradient programmed from 20% acetonitrile and 80% pH 10 ammonium acetate buffer (50 mM) to 100% acetonitrile in 20 minutes and the flow rate was 0.2 mL/min. The mass spectral analyses were performed using a Sciex (Thornhill, Ontario) API III triple quadrupole LC/MS system with a heated nebulizer interface.

Results

After I.M. administration of 40 mg of azaperone, N-despyridyl azaperol, N-despyridyl azaperone and a low concentration of azaperone were detected in the unhydrolyzed equine urine extracts using LC/MS/MS analysis. Six metabolites, hydroxy-azaperol, two hydroxy-azaperones, azaperol, N-despyridyl azaperol and N-despyridyl azaperone were detected in the acid hydrolyzed urine. All the azaperone metabolites show identical characteristic daughter ions compared with the azaperone or azaperol analytical standards. When the urine was extracted by XAD-2 resin, three glucuronide conjugated metabolites (hydroxy-azaperol glucuronide, hydroxy-azaperone glucuronide and azaperol glucuronide) were detected in the urine extract. All these metabolites show characteristic daughter ions as the unconjugated metabolites. The glucuronide conjugated azaperone metabolites were partially hydrolyzed in the heated nebulizer interface to unconjugated metabolites which showed identical daughter ions as the metabolites detected in the hydrolyzed urine.

Conclusion

Our study shows that hydrogenation, hydroxylation and N-dealkylation are the major metabolic pathways of azaperone in the horse. Azaperone metabolites were conjugated with glucuronide before excretion into equine urine. All the azaperone metabolites (hydroxy-azaperol, hydroxy-azaperone, azaperol and N-despyridyl azaperone), which have been reported in animals using GC/MS, have been detected by our developed LC/MS/MS method in horse urine. N-Despyridyl azaperol is a newly discovered metabolite in animals. Moreover, the glucuronide conjugated azaperone metabolites have also been successfully isolated and confirmed by LC/MS/MS in our study.

Daughter ion mass spectra of azaperone metabolites isolated from the urine of the horse I.M. administered with 40 mg of azaperone. Metabolites 1-6 were obtained from the hydrolyzed urine extract and metabolites 7-8 were obtained from the XAD-2 resin purified urine extract.

Detection of Androgens and their Conjugated Metabolites using an Atmospheric Pressure Ionization LC/MS/MS

*Y.C. Chui[1], G.K. Poon[2], B. Esaw[1], and B. Laviolette[1]
CanTest Ltd[1]., 1523 West 3rd Ave., Vancouver, B.C., V6J 1J8, Canada and Drug Development Section[2], Cancer Research Campaign Lab., Institute of Cancer Research, Sutton, Surrey, UK.

Introduction

Androgens (androgenic and anabolic steroids) are used as therapeutic and veterinary medications but they are also used to enhance the performance in athletes and race horses. Androgens are mainly excreted as conjugated metabolites in humans and animals.

Since the early 1970's, detection of androgens in biological fluids by GC/MS has been extensively examined (1, 2). However, all the GC/MS methods require hydrolysis of the conjugated androgens and derivatization into less polar forms before the analysis. Using a tandem mass spectrometer equipped with an ion spray interface, Weidolf et al. (3) developed a sensitive method to detect the presence of sulfate conjugated steroids in equine urine. Nevertheless, the daughter ion mass spectra from their method lacked characteristic fragments for chemical identification and structure elucidation.

In this study, heated nebulizer and ion spray interfaces coupled with an atmospheric pressure ionization tandem mass spectrometer were used to investigate the detectability of androgens and their conjugated metabolites in biological fluids.

Experimental

Urine Extraction: For the extraction of sulfate conjugated boldenone, urine samples (50 mL) were adjusted to pH 9.5 with ammonia buffer. The samples were adsorbed on approximately 2 grams of XAD-2 resin. The XAD-2 resin was washed with 20 mL of 50% ethyl acetate in dichloromethane, 10 mL of 10% acetic acid in water and 10 mL of dichloromethane. The resin was then eluted with 10 mL of 10% methanol in ethanol. The eluates were dried, reconstituted in methanol and analyzed by LC/MS/MS.

The method for extraction of conjugated 4-hydroxy-4-ene-3,17-dione in human urine was according to that described by Weidolf *et al.* (2). Urine samples (5 mL) were diluted with 5 mL of 20% methanol in pH 5.4 ammonium acetate (0.65M). The samples were applied onto a C18 sep pak cartridge (1 mL) and then washed with 5mL of pH 5.5 ammonium acetate (25 mM), 5 mL of 40% methanol in pH 5.5 ammonium acetate (25 mM) and 5 mL of water. The samples were eluted with 2 mL of 40% methanol in water. The eluates were dried under nitrogen at 30°C, reconstituted and analyzed by LC/MS.

LC/MS: The chromatographic system consisted of an ABI (Foster City, CA) 140A dual syringe pump equipped with a 250X2.1 mm Supelcosil LC-18 (Supelco) column. The mobile phase was gradient programmed from 20% acetonitrile and 80% pH 7 ammonium acetate buffer (10 mM) to 100% acetonitrile in 20 minutes and the flow rate was 0.2 mL/min. The mass spectral analyses were performed using a Sciex (Thornhill, Ontario) API III triple quadrupole LC/MS system with a heated nebulizer interface or an ion spray interface.

Results

Negative ion mode LC/MS with ion spray ionization was a sensitive technique to detect the sulfate and glucuronide conjugated androgens. However, the negative ion mode daughter ion mass spectra did not provide intensive characteristic fragments for chemical identification or structure elucidation. Androgens were best detected by positive ion mode LC/MS with a heated nebulizer interface. Androgens were partially decomposed in the heated nebulizer interface into the dehydrated products. Positive ion mode daughter ion mass spectra of androgens and their dehydrated products showed characteristic fragments which can be used for the chemical identification and structure elucidation. Sulfate or glucuronide conjugated androgens were decomposed in the heated nebulizer interface into the unconjugated androgens and their dehydrated products which showed identical characteristic fragments in their daughter ion mass spectra as unconjugated androgens. The presence of sulfate conjugated boldenone in equine urine and glucuronide conjugated 4-hydroxyandrost-4-ene-3,17-dione in cancer patient's urine was detected by both ionization methods.

Conclusion

Using the ion spray ionization technique, negative ion mode LC/MS had high sensitivity for the detection of sulfate and glucuronide conjugated androgens, but the daughter ion mass spectra lacked

characteristic fragmentation. Conjugated androgens degraded in the heated nebulizer interface into the unconjugated androgens which showed characteristic daughter ions in their positive ion mode mass spectra. The combination of these two ionization techniques was successfully used to detect and identify the presence of sulfate conjugated boldenone in equine urine and glucuronide conjugated 4-hydroxyandrost-4-ene-3,17-dione in cancer patient's urine. However, inconsistency of dehydration and hydrolysis of some androgens in the heated nebulized interface was observed when the samples were analyzed on different days. Further studies are in progress to elucidate the dehydration and hydrolysis mechanism of conjugated androgens in the heated nebulizer interface.

IDENTIFICATION OF POLAR METABOLITES OF CP-70,490 BY HPLC/IONSPRAY TANDEM MASS SPECTROMETRY

M. J. Avery, A. V. Kuperman, T. E. Liston and H. G. Fouda,
Central Research Division, Pfizer INC, Groton, CT 06340

The novel 5-lipoxygenase inhibitor CP-70,490 is metabolized in rats to several polar metabolites. Ionspray HPLC/tandem mass spectrometry was used to determine the structures of one major and five minor metabolites.

Metabolites of CP-70,490 were separated on a 3.9x150mm NovaPak C18 column. The HPLC mobile phase, a binary mixture of methanol and 100 mM ammonium acetate, was varied from 20% methanol to 80% methanol over 40 min. and was delivered at 1 mL/min. Only 50 µL/min of the HPLC column effluent was introduced into the ionspray interface of a SCIEX API III tandem mass spectrometer. Negative ions formed in the ion source were detected by scanning the first quadrupole over the mass range of 135 to 600 daltons. Collision induced dissociation (CID) studies were performed at 27 eV collision energy using argon collision gas at an indicated thickness of 6.0×10^{14} atoms/cm^2.

CP-70,490 produces a deprotonated molecule ion at m/z 298 daltons and an acetate adduct ion at m/z 358 daltons under the above ionization conditions. The sole daughter ion formed by CID has a m/z value of 137 (Figure 1). This ion was most likely formed by the neutral loss of the phenyl-n-hexyl side chain. The most abundant metabolite in rat bile was due to glucuronidation of the aromatic hydroxyl. This identification was confirmed by comparison of CID daughter spectra and HPLC retention times of the biliary metabolite (H) and of a synthetic standard. Fragment ions at m/z 298 and 137 are indicative of consecutive neutral losses of glucuronic acid and the phenyl-n-hexyl side chain. Additional low mass ions at m/z 59, 85 99 and 113 were apparently due to internal fragmentation of the glucuronic acid.

Five additional minor metabolites were also evident in rat bile (Figure 2). Metabolites C and D were found to be glucuronides exhibiting aglycone daughter ions at m/z 314 and 316 respectively. This suggests gains of 14 and 16 daltons over the parent drug, presumably due to hydroxylation and dehydrogenation. The site of oxidation could not be unambiguously determined from the CID data. Metabolites F and G produced CID spectra consistent with sulfate conjugate analogues of glucuronide metabolites C and D (Figure 3 for metabolite F). Metabolite I was identified as the sulfate conjugate of the parent drug.

A Biotransformation Study Utilizing Electrospray Ionization Mass Spectrometry (ESI/MS)

Todd A. Gillespie, Bradley L. Ackermann, Brian T. Regg,
Kimberly F. Austin and John E. Coutant
Marion Merrell Dow, Inc. Cincinnati, OH 45215

Dolasetron is a potent and selective 5-HT_3 receptor antagonist presently undergoing clinical investigation as an antiemetic adjunct to cancer chemotherapy. The drug undergoes rapid and extensive first pass metabolism in all species evaluated after intravenous administration. Evaluation of dolasetron metabolism in vivo in rat, rabbit, dog, and monkey has shown that a major metabolite of dolasetron is formed via a reduction of the 3-oxo (ketone) function to the corresponding alcohol. The biotransformation of dolasetron has been studied through the use of ^{14}C-labeled dolasetron mesylate administered intravenously to normal human volunteers.

The application of electrospray ionization mass spectrometry (ES/MS) in the study of proteins and peptides appears throughout the literature. However, utilization of ES/MS as a "universal" liquid chromatography (LC) interface for smaller molecules has not been wide spread. Two different LC interfaces, thermospray (TSP) and continuous-flow FAB (CF-FAB), have been extensively used to solve various biotransformation problems in our laboratory. The purpose of this study was to compare these two techniques with ES for a conventional biotransformation study.

Urine samples (1 mL) were centrifuged and the supernatant then filtered thru a 0.45 µm filter, . Pooled urine collected between 2 and 6 hours was used for metabolic profiling. A 100µL aliquot was injected onto the HPLC, fractions collected at 1.5 in intervals, and then subjected to scintillation counting. The radio profile obtained indicated all significant radioactivity eluted between 26 and 60 minutes. The eluent from this collection interval was collected from approximately eleven 100 µL injections. These collections were pooled into a large flask, lyophilized, reconstituted, and separated evenly into four tubes for identification by LC/MS.

LC/MS analysis using TSP was performed on a Finnigan MAT TSQ-700 mass spectrometer equipped with a Vestec Thermospray ion source. The mobile phase consisted of: (A) 0.1% TFA (B) ACN/0.1% TFA, 95:5 with a gradient of 15-60% B over 45 min. at a flow rate of 0.8 mL/min. Ammonium acetate (0.5M) was added post column at 0.4 mL/min to promote ionization. UV data was obtained on line at 280 nm.

CF-FAB was performed using a packed capillary interface described previously (1). The mobile phase was identical to the TSP analysis with a flow rate of 2 µL/min. However, the gradient consisted of 0-50% B over 50 min. Matrix (25% glycerol) was added post column at 1µL/min. The mass spectrometer was a V.G. ZAB2-SE using a cesium ion gun.

Figure 1

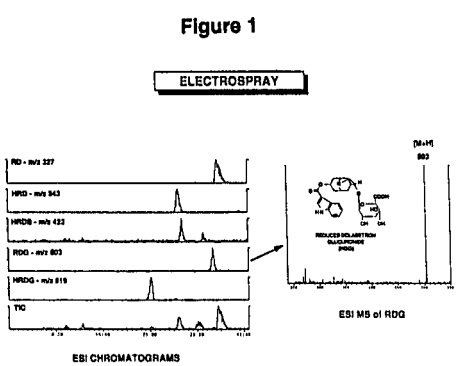

Figure 2

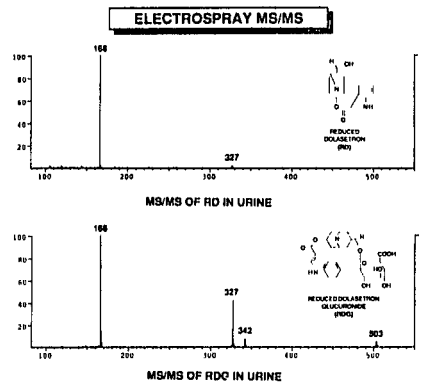

ES data were acquired on a TSQ-700 using an ES interface supplied by Analytica. For all LC/MS experiments, a voltage of -4.8 kV was applied to the cylindrical counter electrode and the nitrogen drying gas, introduced at a flow of 20 cc/min, was heated to an apparent temperature of 230°C. All LC/MS/MS experiments utilized a collision pressure of 2 mTorr (argon) and a collision offset of -30 eV. The transfer line from the end of the LC column to a point 1 mm inside the SS sheath tube was 200µm o.d. x 50 µm i.d. fused silica. The LC/MS used a mobile phase of: (A) ACN/0.1% HOAc, 5:95 (B) ACN/0.1% HOAc, 95:5 with a gradient of 0-50% B over 50 min. at a flow of 2 µL/min and a sheath flow of 3 µL/min.

TSP was the least sensitive and detected no conjugates. Four out five of the metabolites found were detected by CF-FAB. Chemical background was high and only molecular weight information (no fragmentation) was available. Sensitivity was low and, as a result, no MS/MS could be obtained. All five major biotransformation products of dolasetron were detected by ES (figure 1). The sensitivity obtained by ES allowed detection of the sulfate of hydroxy reduced dolasetron (HRDS), a trace metabolite not observed by the other techniques. MS/MS spectra of all metabolites were obtained providing structural information.

The CID spectra of reduced dolasetron (RD) and hydroxy reduced dolasetron (HRD) exhibit a base peak at m/z 166 representing the loss of indole-3-carboxylic acid from the protonated molecular ion (figure 2). The structural assignment for the CID spectrum of the glucuronide of RD (RDG) is based on the characteristic loss of 176 daltons from the protonated molecular ion and the characteristic ion at m/z 166. The small ion at m/z 342 is due to the loss of indole-3-carboxylic acid and indicates that the glucuronide is not attached to the indole portion of the molecule (figure 2). The structural assignment for the CID spectrum of the sulfate of HRD (HRDS) is based on the characteristic loss of 80 daltons from the protonated molecular ion to give the ion at m/z 343 and the characteristic ion at m/z 166 due to the dolasetron substructure (figure 3). In addition, to search for other possible biotransformation products, parent scans of m/z 166 were acquired in a separate LC/MS/MS run. Although no new metabolites were identified in this search, each product appearing in the metabolic scheme of dolasetron was confirmed (figure 4).

ES outperformed the other interfaces investigated with regards to sensitivity and selectivity for the detection and identification (by MS/MS) of small, singly charged molecules. The combination of ES and micro LC along with tandem MS is a powerful combination for obtaining assignments regarding metabolic pathways at trace levels.

Identification of Mitomycin C DNA Adducts by LC/MS: A Comparison of Techniques.

*Steven M. Musser[1] , Maria Tomasz[2] and James A. Kelley[3].

[1] Division of Contaminants Chemistry, USFDA , Washington, DC 20204. [2]Dept. of Chemistry, Hunter College, New York, NY 10021. [3]Laboratory of Medicinal Chemistry, NCI, NIH, Bethesda, MD 20892.

Introduction

Mitomycin C is one of several anticancer drugs whose proposed mechanism of action involves site-specific alkylation of DNA. Characterization of the type of DNA adduct formed and the position of covalent modification on the individual bases is essential to understanding how these drugs work and provides important information for designing new drugs. Use of mass spectrometry in this area is often complicated by the inherent chemical and thermal instability of the adducts that are formed and the small amounts of sample isolated from complex biological matrices. Accordingly, LC/MS methods appear the most promising for the rapid analysis of DNA adducts. Because there are now several ionization methods compatible with on-line LC/MS analysis of these types of compounds, we evaluated three: thermospray, continuous flow/FAB and electrospray for their usefulness in determining adduct structure. The monofunctional mitomycin C adduct, deoxyguanosine-mitomycin C (*cis*- MdG2, 1), was used as a model compound for this evaluation.

Preparation of DNA Adduct

Mitomycin C adducts were prepared by reduction of mitomycin C in the presence of synthetic polynucleotides or calf thymus DNA. A solution containing 0.7 mM oligonucleotide, and 35 mM mitomycin C in 15 mM Tris buffer (pH 7.4) was deaerated with argon and treated with 22.5 mM sodium hydrosulfite. The resulting mitomycin C-DNA adducts were removed from the starting materials using a Sephadex G-25 column. The adducts were converted to nucleosides enzymatically, by first digesting the purified DNA with Nuclease P_1 followed by treatment with phosphodiesterase and finally incubation with alkaline phosphatase. Nucleoside adducts were then separated using semipreparative HPLC and fractions containing adduct were frozen and lyophilized.

Mass Spectrometry

For continuous flow/FAB experiments a VG 7070E magnetic sector instrument equipped with a xenon FAB gun and using a 6 kV accelerating voltage was used. An aqueous mobile phase consisting of 25 mM ammonium formate, 1% thioglycerol and 5 % methanol was used at a flow rate of 5 µl/min. For thermospray experiments a Finnigan 4500 quadrupole mass spectrometer equipped with a Vestec thermospray ion source was used. The mobile phase consisted of 50 mM ammonium formate, and a linear gradient of 0-50 % methanol and a flow rate of 1.2 ml/min. For electrospray experiments a Vestec Model 201 quadrupole mass spectrometer equipped with an electrospray ion source that had been modified for ionspray was used. The mobile phase consisted of a 5 mM formic acid with an acetonitrile gradient and a flow rate into the ion source of 20 µl/min. All separations were performed on C-18 reverse phase HPLC columns. In all cases the conditions used were optimized for the largest molecular ion peak of mitomycin C and the least amount of fragmentation.

Discussion

Of the LC/MS methods investigated, only thermospray and electrospray yielded useful structural information about the adduct. Continuous flow/ FAB failed to yield any useful information about this adduct, even at high concentrations and even though it has been used successfully to identify various DNA constituents. Thermospray provided useful structural information about *cis*-MdG2; however, it was often difficult to obtain molecular weight information on a consistent basis. Electrospray proved to be the method of choice for this type of analysis. Electrospray consistently yielded protonated molecules ($[M+H]^+$, m/z 570) and provided structural information about the adduct without using MS/MS. In addition, electrospray was approximately an order of magnitude more sensitive than thermospray, allowing detection of 45 picomoles *cis*-MdG2 injected on column.

AN ELECTROSPRAY MASS SPECTROMETRIC METHOD FOR THE RAPID DETERMINATION OF HISTAMINE AND ITS METABOLITES IN URINE.

A.I. Mallet and M. Thomas[§], Institute of Dermatology, U.M.D.S., University of London, St Thomas' Hospital, London SE1 7EH, England, and [§]Department of Chemistry, University of Maryland, Baltimore County, MD 21228, USA.

INTRODUCTION.

Dermatoses which are believed to involve excessive or abnormal release of mast cell products are frequently treated by systemic administration of H_1-antihistamine drugs. At best these are only partially effective particularly in the treatment of the physical urticarias which are transient itchy skin swellings provoked by a number of physical stimuli including pressure, heat and cold.

Histamine (H) is one of several pharmacologically active substances released from mast cells and it serves as a convenient marker for the activation and degranulation of these cells. Measurement of histamine in man is complicated by the variety of exogenous sources for this molecule, by difficulties in otaining accurate results from immuno-based assays, especially in urinary samples, and with the complex nature of the current GC-MS based methods for the principal metabolites of histamine, *viz* methyl histamine (MH) and N^t-Methylimidazole acetic acid (MIAA).

This investigation seeks to develop a method whereby minimal sample extraction, derivatisation and purification can be employed prior to mass spectrometric analysis by a stable isotope dilution assay, based on sample introduction in a liquid stream into an electrospray source.

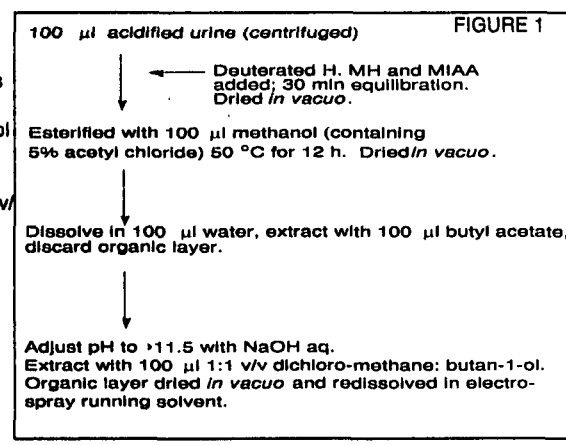
METHODS.

Standard histamine, methyl histamine and N^{τ}-methylimidazole acetic acid were obtained from Sigma UK, Poole, Dorset and the deuterated analogues were provided by Merck Isotopes, Montreal, Canada, in the case of $\alpha,\alpha,\beta,\beta,$-$[^2H]_4$-histamine, while $[^2H]_3$-methyl histamine and $[^2H]$-N^{τ}methylimidazole acetic acid were synthesised as previously described (1). All solvents were provided by Fisons Ltd., Loughborough, UK. The mass spectrometry was performed on a VG Masslab Trio-2000 fitted with a VG Biotech Electrospray source (Fisons Instruments, Manchester, England.). Solvent flows of 5 to 10 µl/min were maintained using an Isco Syringe pump (Jones Chromatography Ltd, Cardiff, Wales).

Samples of urine were provided by normal human volunteers and were immediately acidified with 0.5% v/v of 0.1M HCl. The sample processing steps are shown in Figure 1.

Electrospray conditions were standard for the apparatus used; solvent systems investigated included 1:1:0.01 Methanol or Acetonitrile:Water:acetic acid or HCl or formic acid usually in the proportions 1:1:0.01 - 0.001 v/v/v. The electrospray needle voltage was 4 kV and the cone voltage was optimised using standards each day but was usually in the range 33 to 37 volts.

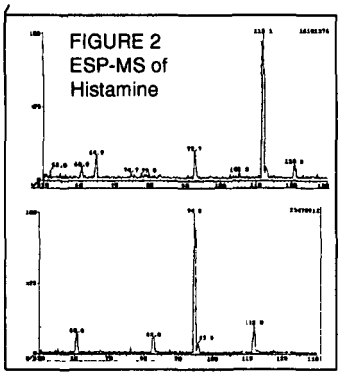
FIGURE 1



RESULTS

The extraction procedure

described here has been designed to obtain optimum recoveries of the three target analyte molecules from human urine. We have found that esterification of the MIAA provides a relatively simple method for increasing the efficiecy of extraction of this amphoteric molecule which is difficult to recover from biological matrices. Studies with radio-labelled molecules indicated that the overall recoveries were better than 25% for each of the substrates.



The electrospray spectrum of histamine is shown in Figure 2 at two different cone voltage settings. All three analyte molecules showed strong $[M+H]^+$ ions in both methanol and acetonitrile containing solvents, but the latter organic modifier led to much less noisy baselines when selected ion recording traces were obtained with low concentrations of analytes.

Stable isotope dilution techniques in which electrospray has been employed as the ionisation method, have not been widely reported in the literature. We have investigated the linearity and reproducibility of the relevant calibration curves for these three analytes and have found them to be at least as good as those obtained by GC-MS methods.

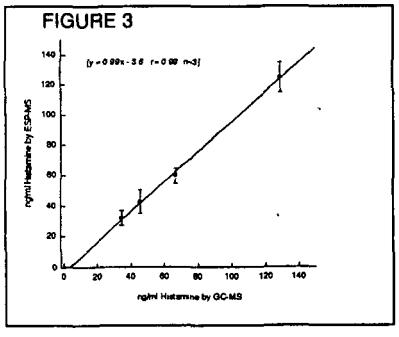


Figure 3 shows the results of analyses of MIAA extracted from spiked urine samples by both GC-MS and by the present method. There is a small systematic error but the agreement between the two methods is excellent.

The limits of detection of the three analytes, defined by a signal-to-noise ratio of greater than 3 were: 25 pg/ml for H and 200 pg/ml for MH and MIAA.

CONCLUSIONS

We have developed a rapid and sensitive method for the analysis of Histamine, Methyl Histmaine and Methyl imidazole acetic acid in human urine using electrospray mass spectrometry and are in the process of appplying this to study the metabolism of Histamine in relation to the degranulation of mast cells in urticarial patients . The agreement with earlier results obtained by a more laborious GC-MS method is good.

Immunoaffinity Chromatography/LC/MS Using Protein G for On-Line Extraction and Confirmation of Basic Drugs

Geoffrey Rule* and Jack Henion, Equine Drug Testing, Cornell University, 925 Warren Drive, Ithaca, NY 14850

INTRODUCTION

The use of antibodies for enrichment and purification of small molecules coupled with HPLC instrumentation was first done by Nilsson in 1983 (1). Since that time a number of research groups have been utilizing antibodies in immunoaffinity chromatographic (IAC) columns for both high and low pressure applications (2,3). Another research group has described a system in which immunoaffinity columns are directly coupled to UV detectors via HPLC for purification and analysis of steroids from urine, tissue, and bile (4). Additional research is reported in which immunoaffinity columns are used for off-line sample pretreatment followed by GC/MS analysis for confirmatory purposes (5). The technique described here couples immunoaffinity chromatography directly to an ion spray-quadrupole mass spectrometer through a conventional coupled-column HPLC system. This approach allows extraction and mass spectral analysis of drugs at trace levels directly from a diluted urine sample.

EXPERIMENTAL

The method employs non-covalently bound drug-specific IgG in a protein G immunoaffinity column to capture drugs from 20 % urine solutions in phosphate buffered saline (PBS, pH 7.4). Protein G, originally derived from Streptococcal bacteria, is genetically engineered and bound to 30 µm macroporous silica to produce a commercially available IAC column that can tolerate flows of 10 ml/min. (Chromatochem Inc., Missoula, MT). Protein G has the unique property of binding specifically to the IgG class of antibody in antiserum. When drug-specific antiserum is loaded onto the column only IgG is retained. The antibody is then used to capture drug molecules from the solution of urine as it is pumped through the column. Using column switching techniques the IgG and drug are desorbed onto a trapping column by using a pH 2.6 solution of acetic acid. Use of a special semi-permeable surface type trapping column (Regis Chemical Company, Morton Grove, IL) allows trapping of the small drug molecules while the large IgG protein passes through to waste. The trapping column is next back-flushed to an analytical column for final separation and detection (Fig. 1).

All work was done using a Hewlett-Packard 5985B mass spectrometer modified in our laboratory to sample ions from an ion spray source at atmospheric pressure. A high energy dynode detector and a recently developed liquid shield "lens" (see Poster by Hopfgartner) are additional alterations to this instrument. Analyses were performed using a 4.6 mm diameter analytical column at a flow of 1 mL/min to the ion spray source.

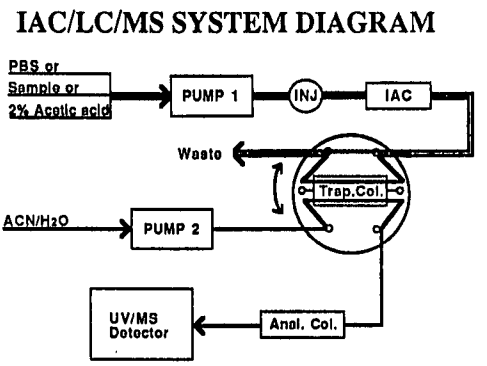

Figure 1

RESULTS

Analyses of urine containing propranolol or LSD can be done within 20 minutes. Only a small amount of neat antiserum is required for each analysis (5-10 µL containing approximately 5 µg of drug-specific IgG) in order to capture drugs at trace levels (nanograms). For commercially available polyclonal antisera this is equivalent to approximately $0.5-1.00 of expended antibody per analysis.

For propranolol we have obtained a detection limit of less than 2 ng/mL using SIM for the protonated parent ion. A detection limit of less than 500 pg/mL has been obtained for this drug using UV detection with a 2 mm. i.d. column. With LSD we have a detection limit of 500 pg/mL in spiked urine using SIM for the protonated parent ion and at the 1 ng/mL level for three-ion SIM (Fig. 2 and 3).

Experiments conducted to characterize the capture of drug by the IAC column indicated that there is approximately a 34% decrease in recovery of drug going from a flow rate of 1 mL/min to 10 mL/min while loading the sample. Other experiments with differing concentrations of urine in PBS indicate a decline in recovery with increasing urine concentration. Solutions of urea (0.28 M) in PBS, made to simulate the concentration of urea in urine, indicate that the decrease in recovery with increasing urine concentration is due only in part to this compound.

Experiments also confirmed that the amount of drug recovered , using a given amount of antibody, reaches a plateau at higher drug concentrations as the antibody becomes saturated. The total amount of drug recovered from urine at higher drug levels can be increased by using a greater amount of antibody.

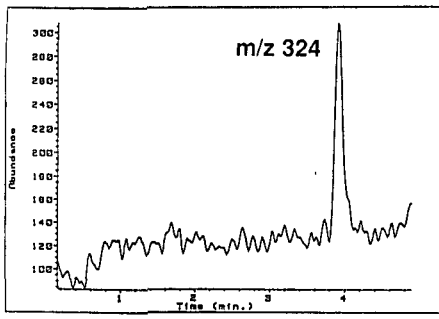

Figure 2 - Three-ion SIM analysis for LSD in urine at 1 ng/ml level using IAC/LC/MS.

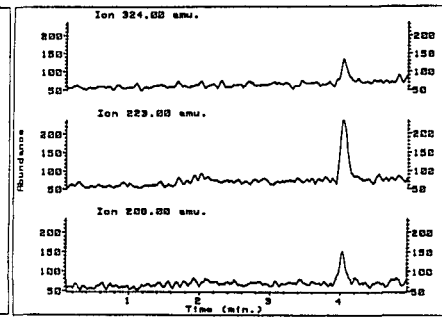

Figure 3 - One-ion SIM analysis for LSD in urine at 500 pg/mL level using IAC/LC/MS.

CONCLUSIONS

This method of analysis gives excellent purification of drugs from urine solutions so that direct coupling to reverse phase HPLC columns and ion spray mass spectrometry is possible.

The use of immunoaffinity chromatography coupled to mass spectrometry in this fashion may be of use for automated MS confirmations directly from urine samples especially for compounds that are difficult by GC/MS analysis. Sample preparation is simple, requiring only dilution and filtration prior to introduction onto the IAC column. This method also has potential for reduction of solvent use. The only solvent required is for the final HPLC/MS analysis.

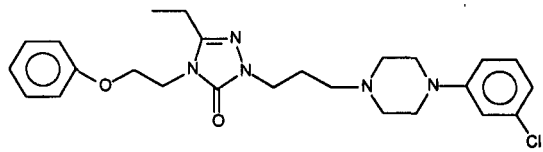
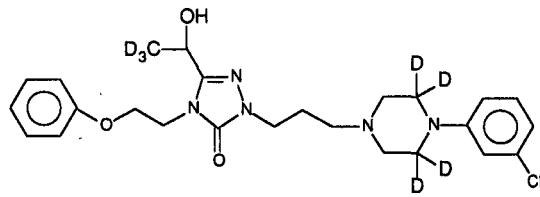
Quantification of Nefazodone, Hydroxynefazodone and Their Heptadeutero Analogs in Human Plasma by LC/API-MS.

David Wang-Iverson, Mohammed Jemal and Allen I. Cohen
Bristol-Myers Squibb Pharmaceutical Research Institute
New Brunswick, New Jersey 08903-0191

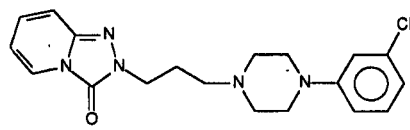
Nefazodone is an anti-depressant currently in clinical trials at Bristol-Myers Squibb. As a part of these trials, a stable isotope label (SIL) study was designed to test the bioequivalence of two formulations. SIL studies, which require mass spectrometric analysis, are an extremely powerful tool for this type of work as they provide high statistical power with relatively few subjects. Heptadeutero nefazodone was adminstered as an oral aqueous solution to act as an *in vivo* internal standard. Measurement of d_0 and d_7-nefazodone (NFZ) as well as the d_0 and d_7 hydroxy metabolite, hydroxynefazodone (HO-NFZ) was required. Such an assay, based on the combination of high performance liquid chromatography and atmospheric pressure ionization mass spectrometry (LC/API-MS), was developed for the quantitative determination of these compounds in human plasma. The internal standard was trazodone (TRZ).



nefazodone



d_7-hydroxynefazodone



trazodone

Liquid-liquid extracts (n-butyl chloride) of buffered plasma were analyzed on a 1 mm ID Hypersil-ODS column using an isocratic mobile phase that contained 85% methanol, 15% water and 10 mM ammonium acetate at a flow rate of 40 µL/minute. The analysis time was six minutes per sample. The LC/MS interface was pneumatically assisted electrospray (ionspray). Positive ionspray mass spectra for all these compounds yielded very strong protonated molecular ions; thus, the $(M+H)^+$ ion for each compound was used in single ion monitoring mode for quantitative purposes. Standard curves over the range 5 ng/mL to 1000 ng/mL were found to be non-linear but were well modeled with a quadratic function. The curves were weighted by reciprocal concentration. More recent work in our laboratory suggests that the non-linearity of the assay is due

to the fact that the detector on our instrument operates in the pulse counting mode and is therefore prone to saturation at high count rates. Accuracy of the assay was within 10% of nominal for three concentrations in the range of the standard curve and for one concentration that required dilution. Total variability of the assay was less than 11% for all analytes. The assay proved to be extremely rugged and allowed processing rates in excess of 300 samples per week.

QUANTITATIVE ANALYSIS OF A REACTIVE GLUTATHIONE CONJUGATE BY IONSPRAY TANDEM MASS SPECTROMETRY

M.R. Davis[1], L.H. Ericsson[2], R.S. Johnson[2] and *T.A. Baillie[1]

[1]Department of Medicinal Chemistry and [2]Department of Biochemistry
University of Washington, Seattle, WA 98195

N-Methylformamide (NMF) is an experimental antitumor drug which is believed to undergo cytochrome P-450-mediated oxidative metabolism to yield a highly reactive and potentially toxic intermediate, methyl isocyanate (MIC). MIC can be trapped by glutathione to form *S*-(*N*-methylcarbamoyl)glutathione (SMG), which has been identified in bile of mice dosed with NMF[1]. SMG can serve as a carbamoylating agent and has been found to be cytotoxic *in vitro*, probably due to its ability to release MIC under physiological conditions[2].

Recent *in vitro* evidence supports a role for the specific isozyme, cytochrome P-450 2E1, in the metabolism of NMF to MIC[3]. The objective of the present study was to develop a method for the quantitative analysis of SMG in bile in order to determine the effects of inducers of cytochrome P-450 2E1, such as acetone, and inhibitors, such as disulfiram, on the metabolism of NMF to SMG *in vivo*.

$H_3C-NH-CHO$	$H_3C-N=C=O$	$H_3C-NH-CO-SG$	$^2H_3C-NH-CO-SG$
NMF	MIC	SMG	$^2H_3$-SMG

Figure 1. Structures referred to in the text (G = Glutathione).

Experimental:

Bile from rats given an i.p. dose of NMF (400 mg kg^{-1}) was collected over ascorbic acid for 4 hours after dosing. Acetone was administered as a 1% (v/v) mixture in drinking water for 7 days prior to dosing with NMF. Disulfiram was administered in a single dose (1g kg^{-1} i.p. or p.o.) 18 hours prior to dosing with NMF.

Samples were introduced into a Sciex API III triple quadrupole mass spectrometer equipped with an IonSpray™ (ISP) interface, by means of sample infusion or on-line HPLC. For sample infusion, internal standard ($^2H_3$-SMG; 2 µg in 10 µl methanol) was added to filtered 10 µl aliquots of bile and the mixtures were diluted to a final volume of 1 ml with methanol / 1% aqueous formic acid (1:1). Samples were infused at a rate of 5 µl / min. For on-line HPLC, internal standard (1 µg in 10 µl acetonitrile) was added to aliquots (5 µl) of filtered bile and the resulting mixtures were diluted to a final injection volume of 200 µl with acetonitrile. Mobile phase consisting of aqueous acetonitrile (10:90) containing 0.06% trifluoroacetic acid was pumped at a constant flow rate of 200 µl / min. HPLC separations were achieved on a narrow-bore (150 mm x 2.0 mm ID) normal phase column. A post-column tee was used to split the flow (3:1) such that 150 µl / min was delivered to a UV detector set to monitor absorbance at 214 nm and 50 µl / min was delivered to the ionspray source.

Following collisional activation of the MH^+ ions of SMG and the internal standard, loss of the elements of glutamic acid (129 Da) proved to be a major route of fragmentation and was employed to develop a selected reaction monitoring assay for the conjugate of interest. Thus, the transitions *m/z* 365 → *m/z* 236 for SMG, and *m/z* 368 → *m/z* 239 for the internal standard were monitored and the resulting ion currents were integrated over multiple data acquisition cycles.

Results and Discussion:

Since metabolites of NMF are present only in very low concentrations in the highly complex biological matrix of bile, a highly sensitive and selective technique for quantitative analysis of biliary SMG was required. Moreover, due to the chemical instability of SMG, there was a need for rapid analysis of this conjugate, preferably avoiding laborious sample preparation steps. Quantitative analysis of SMG by ionspray tandem mass spectrometry was found to satisfy these requirements, in that it provided for rapid and reproducible analyses for samples in the 30 to 300 picomole range, requiring no sample preparation other than filtration. While satisfactory results were obtained by direct infusion of samples into the ionspray source, added selectivity can be achieved by the on-line LC/MS/MS approach (Figure 2).

Following administration of a hepatotoxic dose of NMF to rats (400 mg kg^{-1}, i.p.), 0.066 ± 0.028% of the dose was found to be excreted as SMG in bile collected over 4 hours. Animals which were pre-treated with acetone, an inducer of cytochrome P-450 2E1, exhibited a four-fold increase in SMG excretion in bile when compared to control animals. On the other hand, animals which were pre-treated with disulfiram, an inhibitor of cytochrome P-450 2E1, exhibited a three-fold decrease in SMG excretion in bile when compared to control animals. From these data, it can be concluded that cytochrome P-450 2E1 is the principal isozyme involved in the metabolic activation of NMF to an electrophilic species which is excreted in bile as the labile conjugate SMG.

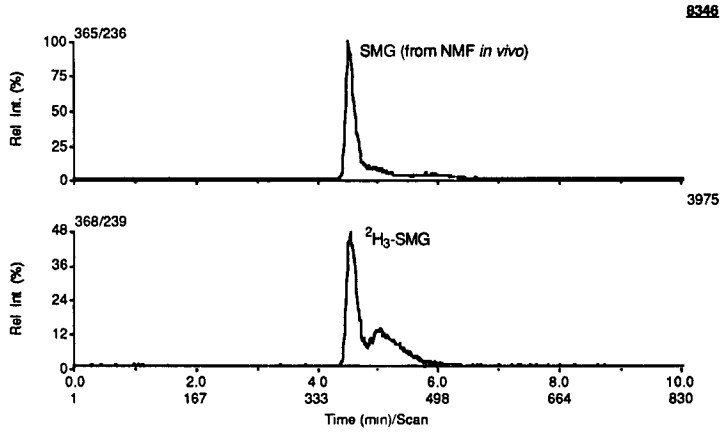

Figure 2. Ion current chromatograms obtained from LC/MS/MS analysis of a 5 µl aliquot of the 0-4 hour pooled bile specimen collected from a rat dosed with NMF (400 mg kg^{-1} i.p.). The upper chromatogram corresponds to unlabeled SMG (*m/z* 365 → 236) and the lower chromatogram corresponds to the internal standard ($^2H_3$-SMG; *m/z* 368 → 239).

Quantitation of the Renal Selective Antihypertensive Prodrug SC-47792 by Electrospray Mass Spectrometry

Carol A. Lisek, Heidrun Engler and Larry D.Tyler
Monsanto Corporate Research and G. D. Searle, St. Louis, MO 63198

Tissue specific drug delivery and action is a highly desirable goal in the development of new drug delivery systems. One of the approaches is to design prodrugs which are selectively cleaved in the target organ. SC-47792 (MW 364) is an N-acetyl-gamma-glutamyl derivative of fusaric acid (MW 179), a known antihypertensive. SC-47792 has antihypertensive activity. It has been hypothesized that SC-47792 is selectively hydrolyzed to fusaric acid in the kidney by gamma-glutamyl transferase, a kidney-specific enzyme, as shown in Figure 1. A method which could simultaneously monitor and quantitate both the prodrug SC-47792 and fusaric acid in plasma extracts and in urine from kinetic studies was desired to evaluate this hypothesis.

The prodrug was initially analyzed by continuous-flow (CF) fast atom bombardment and thermospray mass spectrometry. Both the CFFAB and TSP spectra contained a fragment ion with a mass identical to the mass of the protonated molecular ion (m/z 180) of fusaric acid. Quantitating the relative amounts of SC-47792 and fusaric acid present in a biological extract by CFFABMS or TSPMS was not practical because of this fragmentation process. SC-47792 was then analyzed by electrospray (ES) mass spectrometry. No fragment ion at m/z 180 was observed. Electrospray mass spectrometry therefore was the method of choice for further analyses.

Rat plasma was spiked with 0 to 320 ug/mL each of fusaric acid and SC-47792. Sep-Pak eluates from plasma spiked with fusaric acid and SC-47792 were analyzed by ESMS. Aspartame (Asp-Phe-OMe, MW 294, 1.5 ug/mL) was added as an internal standard to the eluates prior to ESMS analysis. The conditions for the ESMS analyses were as follows: Sciex API-III mass spectrometer fitted with an ionspray interface, orifice potential 50 V, nebulizing gas (air) pressure 65 psi, curtain gas (nitrogen) pressure 1.2 L/min, solvent 0.1% TFA in 60:40 acetonitrile:water, flow rate 50 uL/min, sample introduction by flow injection using an HP-1090 HPLC with an autosampler, injection volume 5 uL, 3 min per injection, 3 injections per sample. The protonated molecular ions of fusaric acid (m/z 180), SC-47792 (m/z 365), and aspartame (m/z 295) were selectively monitored. The m/z 180:m/z 295 and m/z 365:m/z 295 peak area ratios were calculated for each injection. The ratios obtained for a particular concentration of fusaric acid and SC-47792 were averaged then plotted versus the concentration to generate plasma calibration curves. The curves were linear with correlation coefficients of 0.999.

Rats were administered either fusaric acid (10 mg/kg i.v.) or SC-47792 (20 mg/kg i.v. or intraportally i.e. into the portal vein which leads to the liver). The concentrations of fusaric acid and SC-47792 in Sep-Pak eluates from the plasma obtained at different timepoints (0, 1, 5, 30, 60, and 120 min) were quantitated by ESMS using the above plasma calibration curves. Shown in Figures 2 (fusaric acid i.v.), 3 (SC-47792 i.v.), and 4 (SC-47792 intraportal) are the results of these kinetic studies. The shorter half-life (15.5 min i.v., 18.6 min intraportally) of SC-47792 relative to fusaric acid (30.7 min) indicates that SC-47792 was cleared more rapidly from the plasma than fusaric acid. Note also that only a very small amount (< 4 ug/mL) of fusaric acid was observed in plasma samples following either i.v. or intraportal administration of SC-47792. The above observations suggest that first pass metabolism (i.e. liver metabolism) of SC-47792 to fusaric acid does not occur. The data also suggests that SC-47792 might be transported to the kidney.

Shown in Figures 5 and 6 are the results of ESMS analyses of Sep-Pak eluates of urine samples 60 minutes after i.v. administration of either fusaric acid or SC-47792 (a: fusaric acid, b: oxygenated fusaric acid, c: glycine conjugate of fusaric acid, d: glycine conjugate of oxygenated fusaric acid, e: acyl glucuronide conjugate of fusaric acid, ?: unknown metabolite; all other peaks observed in urine blank). Whereas fusaric acid was extensively metabolized, minimal metabolism of SC-47792 occurred. These observations suggest that only a small fraction of SC-47792 is hydrolyzed selectively to fusaric acid in the kidney. SC-47792 is mainly cleared from the kidney intact and excreted. Thus, the mechanism for the observed antihypertensive activity of SC-47792 is unknown.

Use of Matrix-Assisted Laser Desorption Mass Spectrometry to Identify Protein Expression Errors, T. Keough, M.P. Lacey, C.L. Oppenheimer and D.A. Thaman, The Procter and Gamble Co., Miami Valley Laboratories, PO Box 398707, Cincinnati, OH 45239-8707.

Matrix-assisted laser desorption mass spectrometry has been used to examine more than twenty-five structurally related proteins expressed in Bacillus Subtilisis. The expressed proteins include either single or multiple point mutations of subtilisin BPN', a protein containing 275 amino acid residues, five methionines and no disulfide bonds. Its amino acid sequence has been previously published[1]. The protein expression products have molecular masses ranging from about 27,500 to 28,200 u. They are expressed extracellularly at a concentration of 75 to 100 μg/ml (3 to 4 nmols/ml).

All LD mass spectra were obtained on a Vestec 2000 linear time-of-flight mass spectrometer. The expression products were desalted and then purified on a S-Sepharose column prior to analysis. For each analysis, a 2-5 pmol/μl solution of the purified protein, in 0.1% aqueous TFA, was mixed with an equal volume of a bovine trypsinogen solution having a concentration in the range of 1-5 pmol/ul. Bovine trypsinogen served as the internal standard for mass calibration. The resulting protein solution was then mixed with an equal volume of a saturated solution of sinapinic acid, prepared by the procedure of Beavis and Chait[2]. Two μl of the final mixture were loaded onto the solids probe, dried at ambient temperature and inserted into the mass spectrometer. The sample was irradiated with the frequency-tripled output of a Q-switched Nd:YAG laser (355 nm, pulse width 10 nsec, repetition rate 10 Hz). Typically, mass spectra produced from 50 laser shots were accumulated (LeCroy transient recorder, TR8828D). All spectral processing and display were accomplished with modified Lab Calc software (Galactic Industries, Salem, NH), which forms the basis of the time-of-flight data system we have developed[3].

The majority of proteins studied had measured molecular masses that agreed with the values calculated based upon their expected primary structures. The root-mean-square of the differences between the measured and calculated masses was ±3.3 u (0.012%). This level of mass measurement accuracy agrees well with previous LDMS results obtained using linear time-of-flight mass analyzers[4].

One mutant enzyme, shown to be 99% pure by enzyme activity and UV absorption measurements, was formed by inserting three alanines between residues 272 and 273 in native subtilisin BPN'. The resulting product had the correct molecular mass. Surprisingly, the spectrum also showed a major (approximately 20% relative abundance) impurity having a measured mass about 197 u lower than the value calculated for the desired product. The relative abundance of this lower mass component increased dramatically upon storing the sample at -15C in a freezer for two months. This unexpected component was likely formed by autolysis or hydrolysis of the desired product. Loss of either the two N-terminal or C-terminal residues, AQ in both cases, would lower the protein molecular mass by 199 u. Differentiation between these two possibilities was accomplished by CNBr digestion of the lower mass component. Analysis of the resulting mixture of peptides revealed the N-terminal fragment was intact, corresponding to subtilisin BPN' (1-50), while the C-terminal fragment weighed about 199 u less than the value calculated for the intact C-terminal fragment. Clearly, hydrolysis occurred exclusively at the C-terminus of the mutant enzyme.

One mutant enzyme was produced by replacing the lysine at residue 27 with a phenylalanine. Initial DNA sequencing indicated the desired product had been correctly produced. However, the measured molecular mass was 16.4 u greater than the calculated value. Again, CNBr digestion was carried out, and the resulting fragments were separated by HPLC. The isolated fragments were analyzed by PD and LDMS. Five of the six expected fragments were observed, and four of them had measured molecular masses in agreement with the calculated values. However, the measured molecular mass of the N-terminal fragment, (1-50), was 16.3 u greater than the calculated value.

This result confirmed there was an error somewhere in the N-terminal fragment, and suggested the previous DNA sequencing results were misinterpreted.

Reanalysis of the DNA sequencing data, spanning the mutagenesis site at residue 27, confirmed the desired mutation had been correctly made. However, a possible remote-site error was discovered. It was suggested that residue 40 might correspond to Leu rather than Pro. Interestingly, the mass difference between Leu and Pro is +16 u. This remote-site error was subsequently confirmed. The N-terminal fragment (1-50) was isolated by HPLC. It was then digested with trypsin to produce a lower mass fragment corresponding to residues (13-43). C-terminal microsequencing of that fragment, using carboxypeptidase Y, was carried out. The resulting products, which were monitored directly with LDMS, showed conclusively that the fourth residue lost from the C-terminus was Leu (or Ile) and not Pro. As it turned out, the codon corresponding to residue 40, in the expressed protein, was the final codon in the oligonucleotide primer used for the expression of this enzyme. And, a change of only a single nucleotide in that codon would alter residue 40 from Pro to Leu.

In the final example we'll discuss, we attempted to change the Arg at residue 247 in subtilisin BPN' to Tyr. Unfortunately, the measured molecular mass of the product was 8.9 u lower than the calculated value. This suggested the desired mutation had not been made since Arg weighs 7 u less than Tyr and, within experimental error, this would explain the molecular mass measurement. Again, the DNA sequencing results were re-examined. It was concluded the desired modification had been properly made.

The suspect mutant enzyme was digested with CNBr and the lower mass fragments were analyzed by LDMS. The C-terminal fragment, residues (223-275), had a measured molecular mass 7.2 u lower than the calculated value for the desired product. This fragment was isolated by HPLC and further digested with trypsin. We wanted to localize the error and then, if necessary, submit the erroneous peptide to Edman sequencing for final identification. Three of the four expected tryptic fragments were observed by PDMS of the unseparated mixture. The fourth fragment, residues (238-256), was not detected. However, an unexpected peptide having a measured molecular mass of 1252.2 u was observed. This latter result clearly demonstrates that the fragment (238-256) must itself contain a trypsin labile site (Arg or Lys). In fact, the measured molecular of this unexpected component corresponds to the value calculated for (238-247), assuming residue 247 corresponds to Arg. In contrast to DNA sequencing, mass spectrometry confirmed that the desired mutation had not occurred.

In summary, LDMS has proven to be quite useful for the rapid screening of protein expression products. The high sensitivity and minimal purity requirements enable LDMS to be used at an early stage to evaluate protein expression. LDMS clearly complements DNA sequencing. We've presented two examples where LDMS caught errors that should have been detected by DNA sequencing, but were missed. LDMS can also detect errors that simply cannot be detected by DNA sequencing. We've shown one example where the protein was probably expressed properly, but subsequently hydrolyzed losing two C-terminal amino acids. Errors of this nature can only be detected by protein analysis, and can't be detected by analysis of the gene used to express the protein. Finally, we've shown that LDMS can also detect impurities not detected by classical procedures like enzyme activity assays or UV absorption measurements.

UTILIZATION OF A MATRIX-ASSISTED LASER DESORPTION TOF MS MODIFIED FOR BIOLOGICAL STUDIES AT MULTIPLE WAVELENGTHS

C. E. Costello, P. Juhasz, H. J. Köchling
I. A. Papayannopoulos, C.-H. Zeng and K. Biemann
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

In order to extend the variety of matrices and wavelengths that may be used with the VESTEC VT2000 time-of-flight mass spectrometer at MIT, we have installed an Er:YAG laser (2.94 µm, 100 ns, electro-optically Q-switched laser, Schwartz Electro-Optics, Orlando, FL) and a N_2 laser (337 nm, 3 ns, Laser Science Inc., Newton, MA), in addition to the original frequency quadrupuled Nd:YAG laser (266 nm, 10 ns, Q-switched laser, Lumonics, Inc., Ottawa, ONT). Simultaneous availability of the three lasers provides the opportunity for comparison, with the same instrumental configuration, of the results at different wavelengths for a single sample/matrix preparation (Fig. 1) or the identical sample combined with multiple matrices. The opportunity for immediate comparisons is particularly important during the analyses of biological samples that are available only in very small quantities and/or are unstable. Two video cameras (Pulnix, Sunnyvale, CA) are used with this instrument: the first permits observation of the sample/matrix deposition on the target before its introduction into the ion source; the second allows continuous observation of the target and its surroundings during irradiation.

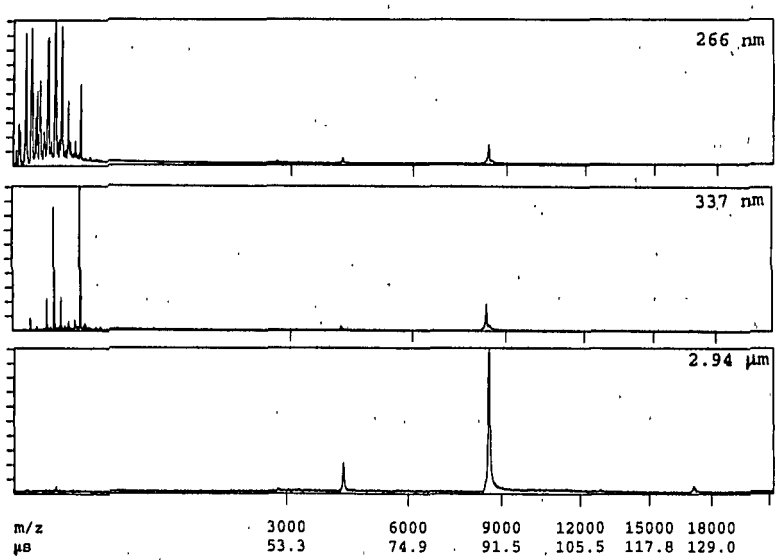

Fig. 1. MALD ionization mass spectra of the same loading of the protein ubiquitin in 6-aza-2-thiothymine matrix, recorded at three wavelengths: 266 nm, 337 nm, and 2.94 µm. Typically, the matrix contribution to the total signal observed is minimized during infrared irradiation.

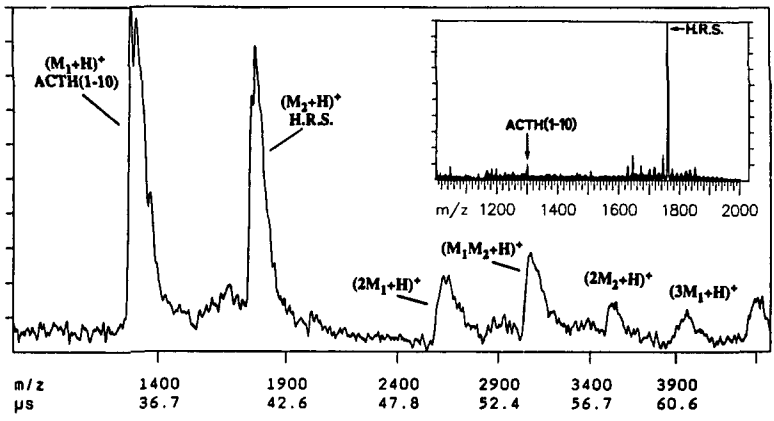

Fig. 2. IR MALD ionization mass spectrum of a 1:1 mixture of ACTH(1-10), $(M+H)^+$ *m/z* 1299.6 and human renin substrate, $(M+H)^+$ *m/z* 1759.9, with glycerol as matrix. Inset shows the Cs^+ LSIMS spectrum of the same sample, also with a glycerol matrix.

The compatibility of FAB matrices (glycerol, *O*-benzylglycerol, 3-nitrobenzyl alcohol) with MALD ionization allows a direct comparison of these two very different ionization techniques. Suppression effects observed in FABMS in NBA and other matrices have not been observed in MALD ionization spectra taken at 266 nm. For pairs of peptides known to exhibit suppression effects in FABMS, laser irradiation at 2.94 μm produced spectra free of these effects, when the samples were applied to a thin film of glycerol (Fig. 2). IR MALD ionization mass spectra could also be obtained for samples dried directly on the target without any added matrix.

The advantages of this flexible instrument for analyses of biological compounds have been evaluated with standards and with examples from ongoing investigations. Included among the current results are spectra obtained for ACTH(1-10) *vs.* human renin substrate; ubiquitin; and structural studies of enzymes, *e.g.*, the external invertase from yeast (*Saccharomyces cerevisiae*), a glycoprotein that contains 513 amino acids and up to 50% carbohydrate; the membrane protein bacteriorhodopsin and analogs prepared by site-directed mutagenesis; specifically cross-linked hemoglobins; phospholipids that serve as cell-surface anchors on parasites; and gangliosides. Both sample preparation (isolation procedures, derivatization) and measurement conditions (choice of wavelength, matrix, sample concentration, instrument polarity) affect the outcome, and attention to the specific properties of various sample types is conducive to optimizing results.

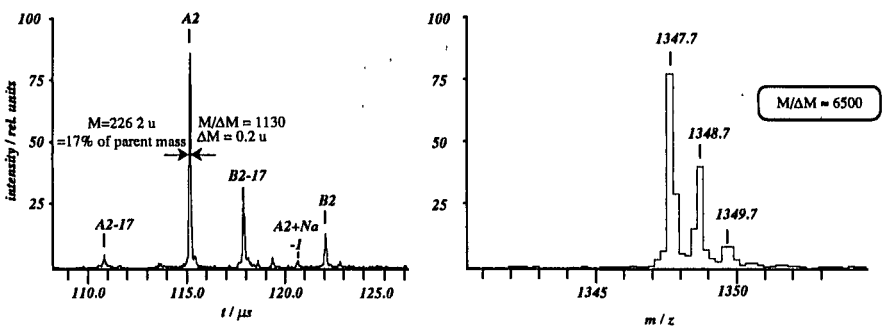
Peptide Sequencing by Post-Source Decay in Matrix-assisted Laser-desorption Mass Spectrometry

*Bernhard Spengler, Dieter Kirsch, Raimund Kaufmann,

Institute of Laser Medicine, University of Düsseldorf, Moorenstr. 5, D-4000 Düsseldorf, Germany

Large peptide and protein ions formed by matrix-assisted laser desorption are known to be rather unstable with respect to decay reactions following ion acceleration[1]. Although prompt fragmentation prior to desorption usually is lacking when using this technique, both unimolecular and bimolecular fragmentation reactions have been found to take place to a great extent in the field-free drift region of a time-of-flight mass spectrometer. The dependencies of these decay reactions on the different instrumental parameters have been the topic of detailed investigations[2]. As a result, fragments from this so-called post-source decay (PSD) have been found to carry valuable structural informations, that can be used for peptide sequencing. The amount of fragmentation can be varied by tuning the instrumental parameters, such as laser irradiance and residual gas pressure. Mass analysis of the fragment ions has been performed using a two-stage reflectron time-of-flight instrument. Mass determination was done by calculating total flight times of the metastable fragment ions. Calculation of metastable ion masses is more complicated for a two-stage reflectron compared to a single-stage reflectron. Mass resolution, however, is much better for the two-stage reflectron, due to the large energy spreads of the PSD ions.

The performance of the new method has been tested using different smaller and larger peptides. The efficiency of dissociation appears to be rather high, even for peptides in the mass range of 3000 dalton. This behavior can be attributed to the observed strong influence of the ion's internal energy prior to collision.



Section of the PSD spectrum and molecular ion region of substance p, matrix 2,5-dihydroxybenzoic acid, λ=266 nm

[1] B. Spengler, D. Kirsch, R. Kaufmann, *Rapid Comm. in Mass Spec.* 5, (1991) 198-202
[2] B. Spengler, D. Kirsch, R. Kaufmann, submitted to *J. Phys. Chem.*, 1992

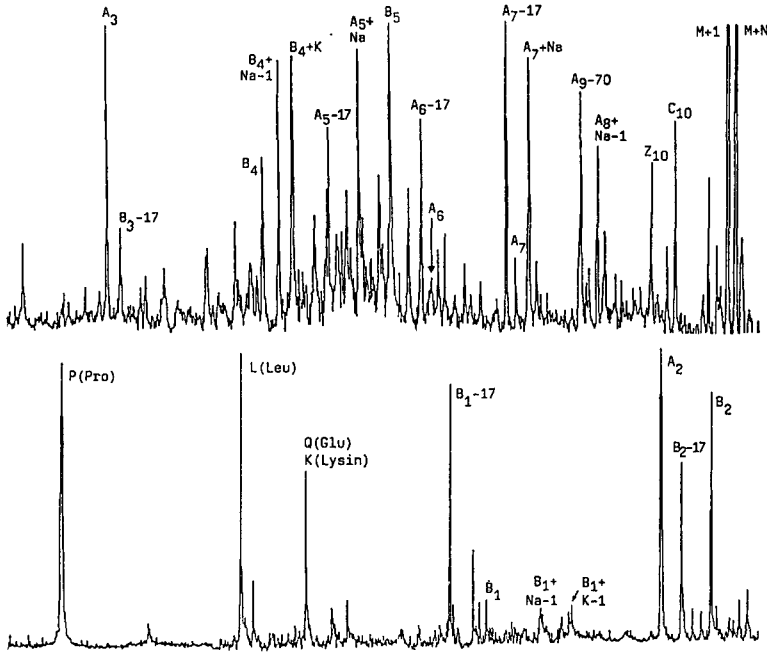
PSD spectra obtained so far, are of remarkebly good quality. For the parent molecular ions a mass resolving power between 4500 and 6500 (FWHM) has been obtained. Daughter spectra of these ions usually still show a mass resolving power of $M/\Delta M \approx 1100$ (FWHM) even for small fragment ions.

The precision of mass determination is currently in the order of $\pm 10^{-3}$ of the fragment mass. The sensitivity can be expected to finally be of the same order as that for molecular weight determination (i.e. in the femtomolar range).

PSD ions can be obtained down to very small fragment masses, such as Na^+ as a decay product of an alkali attached peptide. Immonium ions of all used amino acids have been observed in the PSD spectra of several peptides. These ions can give valuable hints about the presence and abundance of various amino acids.

Peptide sequencing using PSD in matrix-assisted laser desorption appears to be a valuable alternative to other methods of ion excitation, such as collision induced dissociation, surface induced dissociation or photoinduced dissociation. Besides its comparebly low equipment price, the predicted short analysis time of only several minutes can be seen as a big advantage of PSD-MALDI time-of-flight analysis over established techniques for peptide sequencing.

SUBSTANCE P/DHB, sequencing by PSD



THE UTILITY OF MATRIX-ASSISTED LASER DESORPTION FOR THE DIRECT ANALYS OF ENZYMATIC DIGESTS OF PROTEINS

P. Juhasz, I. A. Papayannopoulos, Ch. Zeng,
V. Papov, and K. Biemann
Dept. of Chemistry, Mass. Inst. of Technology, Cambridge, MA 02139

The efficiency of matrix-assisted laser desorption (MALD) ionization for the analyses of complex mixtures have been demonstrated previously on the examples of enzymatic digests of proteins [1]. However, the potential of this ionization technique is not exploited yet routinely on the direct analyses of enzymatic digests, that is without previous HPLC fractionation of the reaction mixture. The main impediment of this application of MALD has been the intense background due to the matrix ions in the mass region below 1 kDa. Sinapinic acid, maybe the most widely used matrix at 337 nm, is particularly problematic in this respect because of its liability to form charged oligomers sometimes up to 1.5 kDa. The introduction of new matrices, notably that of the 2,5-dihydroxybenzoic acid (DHB) by Strupat et al. [2], and that of the α-cyano-4-hydroxycinnamic acid by Beavis and Chait [3], has resulted in significant improvement in the quality of mass spectra of complex peptide mixtures. It has been observed in our laboratory that employing more than one matrix for the analysis of a given digest usually increases the amino acid coverage which attains 100% frequently. In order to find the optimal experimental conditions we performed analyses on a variety of enzymatic digests with several matrices. A summary of these results is presented in Table 1.

Protein	$(M+H)^+$	Digest	Matrix				
			SA	CA	DHB	αCCA	aTT
HbA β	15,127	tryptic		97%	97%	97%	86%
HbA β	15,127	Endo Asp-N		100%	100%	100%	49%
HbA β	15,127	Endo Glu-C		100%	100%	100%	100%
Horse myoglobin	16,952	Endo Asp-N			95%		95%
RNase B	15,000	tryptic	100%				
bovine rod transducin α-chain	44,000	tryptic	82%				

SA - sinapinic acid, CA - caffeic acid, DHB - 2,5-dihydroxybenzoic acid
αCCA - α-cyano-4-hydroxycinnamic acid, aTT - 6-aza-2-thiothymine

Table 1 Amino acid coverage in various digests

Investigation of mixtures of well-characterized peptides with the same matrices revealed that, in case of multicomponent mixures, DHB had increased sensitivity in the region between 500 and 1,000 Da, with respect to the other matrices, whereas sinapinic acid or caffeic acid was slightly more sensitive in the region above 3,000 Da. However, there seemed to be an intrinsic discrimination against peptides below 500 Da. These low molecular weight peptides were not seen in most digests even if the matrix backgroung was low.

A representative example of the studies is the analysis of various digests of singly cross-linked human hemoglobin β-chains in order to prove the site of the cross-link. X-ray crystallography data have shown that the cross-linking with 2-nor-2-formylpyridoxal-5'-phosphate linked the N-terminal of one of the β-chains with the Lys-82 residue of the other [4]. The same type of cross-link has been assumed for the bispyridoxal-tetraphosphate, (bisPL)P_4. Fig. 1 shows the MALD spectrum of the enzymatic digest with endoprotease Glu-C at pH 8 (when the C-termial sides of the Glu and Asp residues are cleaved). The cross-linked peptide is shown in the expanded insert. The experimentally found mass differs by 0.1 Da from the calculated value, thus the assumed type of cross-link has proved to be correct.

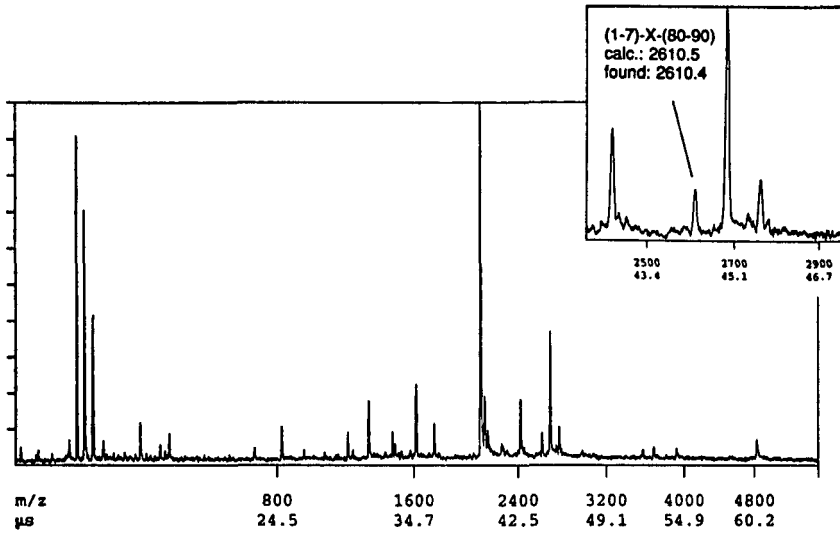


Fig. 1 Endo Glu-C digest (pH 8) of (bisPL)P_4 cross-linked human hemoblobin β-chains. Matrix: DHB, wavelength: 337 nm

Detailed comparisons with FAB data on various digests suggested that MALD, in general, offers better coverage with superior sensitivity. Further improvement can be achieved by previous fractionation of the mixture by HPLC. In case of the tryptic digest of the glycoprotein ribonuclease B three times more peptides were detected by MALD than by FAB. Interesting results can be expected from the application of IR-lasers (Er:YAG at 2.94 µm was used) to digest analyses. Preliminary experimets demonstrated increased sensitivity in the low mass range below 500 Da when a mixture of urea and tris served as matrix.

Protein Surface Metal Binding Domains Identified in Unfractionated Proteolytic Digests of Metal Transport and Storage Proteins by Matrix-assisted UV Laser Desorption Time-of-flight Mass Spectrometry

Tai-Tung Yip and T. William Hutchens

Protein Structure Laboratory, USDA/ARS Children's Nutrition Research Center, Department of Pediatrics, Baylor College of Medicine, 1100 Bates St., Houston, Texas 77030

SUMMARY

We have used matrix-assisted UV laser desorption/ionization (MALDI) time-of-flight (TOF) mass spectrometry to identify specific metal-binding domains on peptides present in unfractionated proteolytic digest mixtures. Sequence-specific metal ion interactions involving either His, Glu, Asp, or phosphoserine residues were identified within peptides derived from metal ion transport and storage proteins. Unfractionated proteolytic digests were analyzed by MALDI-TOF before and after addition of specific metal ions. Peptides with bound metal ions were identified based on specific alterations in mass that were characteristic for a given type of metal ion. In each case, the amino acid sequence of the metal-binding peptide was identified based on definitive mass values associated with known trypsin digest fragments. In several cases, the primary structure of metal-binding peptides identified in this manner was confirmed experimentally (by automated Edman degradation) after purification by reverse-phase HPLC. Finally, to characterize further the metal binding properties of the peptides identified by mass spectrometry, the same peptides were prepared by chemical synthesis and analyzed in more detail by MALDI-TOF and by conventional methods (e.g., by spectrophotometric titration, atomic absorption, thermal ionization mass spectrometry, and immobilized metal ion affinity chromatography).

INTRODUCTION

Several different types of protein structural motifs are responsible for binding specific metal ions. Identifying such metal-binding domains on the surface of a protein is important to understand metal ion-dependent protein-protein recognition events, protein-nucleic acid interactions, and metal-ion transfer between biomolecules.

We have reported the use of MALDI-TOF mass spectrometry to characterize individual peptide-metal ion interactions (1-5) and to identify specific Cu(II)-binding peptides in unfractionated proteolytic digests of a human plasma protein referred to as histidine-rich glycoprotein (6). These first studies, and similar investigations by electrospray ionization (ESI) mass spectrometry (4), illustrated one class of interaction, namely, histidine (imidazole nitrogen)-dependent peptide-Cu(II) complexes. We now report that the MALDI-TOF experimental approach has been extended to include several other examples of Cu(II) and Zn(II) interactions with N-dependent electron donors as well as Fe(II) and Ca(II) interactions with O-linked electron donors.

EXPERIMENTAL

The proteins evaluated (e.g., β-casein, histidine-rich glycoprotein, hemopexin, albumin, and ceruloplasmin) were digested with trypsin at a substrate:enzyme ratio of 100:1. MALDI-TOF was performed on a Vestec Model 200 linear time-of-flight mass spectrometer as described previously (2,6) using 2,5-dihydroxybenzoic acid as the matrix. Metal ion binding and enzymatic dephosphorylation (with alkaline phosphatase) reactions were initiated directly on sample probe tips (i.e., in situ) as described previously (2).

RESULTS

The results presented in the table on the next page summarize the specific metal-binding peptides identified during these investigations.

CONCLUSIONS

MALDI-TOF mass spectrometry is an important new approach to the sequence-specific identification of metal-binding ligands and specific transition metal ions are amenable to characterization by these methods. However, due to difficulties caused by the reaction of reduced Cys residues with the type of matrix used in these investigations (2,5-dihydroxybenzoic acid), ESI has been used to characterize metal ion interactions involving S-ligands (7,8, see FOB 12:15). In the case of metal ion interaction with N- and O-ligands, the ability to obtain useful information about metal-binding capacity, affinity and specificity within minutes and with less than 1 pmol of sample makes MALDI-TOF the procedure of choice in the case of unfractionated mixtures.

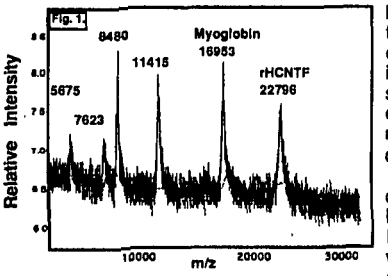
Analysis of Recombinant Human Ciliary Neurotrophic Factor (rHCNTF) by Laser Desorption TOF Mass Spectrometry.

Tanuja Chaudhary, Roger Steinmetz and *James E. Labdon.

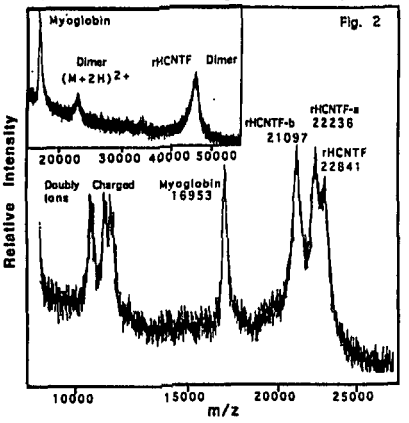
Regeneron Pharmaceuticals Inc., 777 Old Saw Mill River Road, Tarrytown, NY 10561

Ciliary neurotrophic factor[1-2] is a 200-residue protein (see sequence below) which promotes the survival of some cultured neurons and might be of therapeutic use in certain degenerative or traumatic neurological diseases. Phase I clinical trials of rHCNTF have recently started in patients afflicted with amyotrophic lateral sclerosis (ALS or Lou Gehrig's disease). The cloning, expression and purification of recombinant human rHCNTF has been described.[3]



We have examined purified rHCNTF by laser desorption (m/z 22796, Fig. 1) and electrospray MS (mass 22,800, not shown). A Finnigan MAT Lasermat was used for all LDMS analyses, while electrospray spectra were obtained with a TSQ-700. The highest quality LDMS spectra were obtained using a-cyano-4-hydroxy cinnamic acid (4-HCCA) as a sample matrix.[4] The ions at 11415 and 8480 in Figure 1 represent the doubly charged ions $(M+2H)^{2+}$ of rHCNTF and the myoglobin calibrant respectively. Both MS techniques produced ions which agreed closely with the theoretical average mass of 22,798.4, for rHCNTF lacking an N-terminal methionine residue. This observation was supported by automated Edman sequence analysis, which confirmed the presence of alanine as the first residue (see sequence below). Tryptic maps of clinical grade rHCNTF were obtained by direct LDMS of the peptide mixture in 4HCCA matrix and by LDMS analysis of the individual peptides isolated by RP-HPLC. The results were consistent with the predicted sequence of rHCNTF (data not shown).

Some preparations of rHCNTF appear heterogeneous by reversed-phase HPLC (RP-HPLC) and gel electrophoresis. The latter shows two lower molecular weight bands in addition to the full-length molecule (not shown). Matrix-assisted LDMS revealed at least three variants which accounted for the observed heterogeneity. A dimer, consisting of two molecules of rHCNTF linked by a disulfide bond involving the lone cysteine residue at position 16, was isolated by RP-HPLC. LDMS of HPLC-purified dimer showed an ion $(M+H)^+$ at approximately twice the predicted m/z of the monomer (Fig. 2, inset). This ion was significantly more intense than the $(2M+H)^+$ ion normally observed for monomeric rHCNTF.



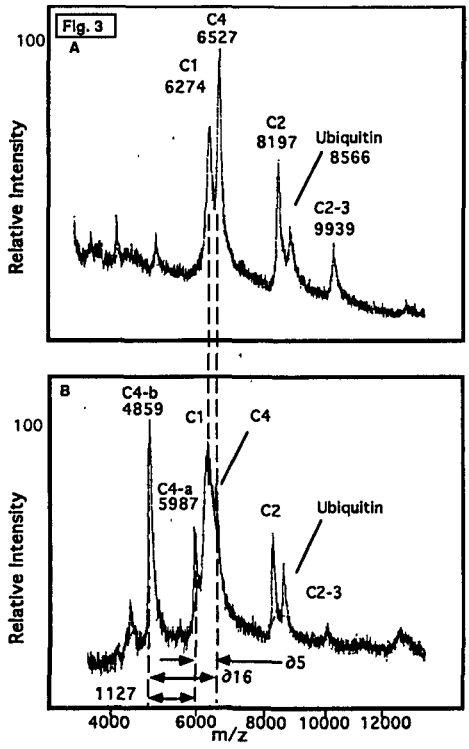
In addition to the dimer, two truncated forms, designated rHCNTF-*a* and rHCNTF-*b* on the basis of their electrophoretic migration, were observed in some preparations of rHCNTF. The N-terminal sequence of these variants was determined by automated Edman sequence analysis of material isolated from Western blots to a polyvinylidine difluoride (PVDF) membrane. Both bands showed the expected N-terminal sequence for full-length rHCNTF.

This suggested that both the *a* and *b* forms were C-terminal truncates. Full-length rHCNTF and the variants were isolated as a mixture of three peaks by RP-HPLC. LDMS analysis of the purified mixture was consistent with a mixture of the intact molecule with the two truncates. (Fig. 2). The mass differences suggested cleavages of 5 and 16 amino acids from the C-terminus for forms a and b respectively.

In order to confirm this interpretation, the mixture was treated with cyanogen bromide (CNBr) which cleaves the C-terminal peptide bond of methionine residues. Cleavage of rHCNTF would be expected to produce 4 peptides, designated C-1 through C-4, in sequence order as shown below. Methionine residues are converted to homoserines by this process.

rHCNTF Cyanogen Bromide Fragments	Average Mass
C1-AFTEHSPLTPHRRDLCSRSIWLARKIRSDLTALTESYVKHQGLNKNINLDSADGhS	6217
C2-PVASTDQWSELTEAERLQENLQAYRTFHVLLARLLEDQQVHFTPTEGDFHQAIHTLLLQ-VAAFAYQIEELhS	8206
C3-ILLEYKIPRNEADGhS	1714
C4-PINVGDGGLFEKKLWGLKVLQELSQWTVRSIHDLRFISSHQTGIPARGSHYIANNKKhS	6526

*hS = Met residue converted to homoserine lactone.



LDMS analysis of the CNBr digest of rHCNTF, purified to homogeneity by RP-HPLC, is shown in Fig 3 A. Internal calibration with ubiquitin allowed assignments of peptides C-4, C2 and C3 to the ions at m/z 6527, 8197 and 1715 respectively (the ion at m/z 1715 was omitted from Fig 3 for clarity). The ion at m/z 6274 was assigned to C1, but appears heterogeneous, possibly as a result of modification of the peptide during the cleavage reaction. The ion at m/z 9939 most likely results from incomplete cleavage of the methionine residue between C2 and C3.

LDMS analysis of the CNBr digest of the rHCNTF preparation containing the truncates (Fig. 3 B) showed a considerably weaker ion corresponding to the intact C-terminal peptide, and the presence of two new ions representing the truncated forms of C-4. The mass differences observed between C-4 and the ions at m/z 5987 and 4859 suggested that they arose from CNBr-cleaved peptides representing deletions of 5 (∂5) and 16 (∂16) residues respectively from the C-terminus of rHCNTF. Furthermore, the mass difference between the ions representing C4-a and C4-b (1127) was close to the theoretical value of 1123 (Fig. 3 B).

LDMS of a cyanogen bromide digest of the dimer revealed, in addition to the ions observed in Fig. 3 A, an ion resulting from the cross-linked N-terminal peptides (m/z approx. 12,500, not shown) which was not observed in digests of monomeric rHCNTF.

Quantitative Analysis of Proteins Using Matrix-Assisted Laser Desorption Time-of-Flight Mass Spectrometry.

Randall W. Nelson, Mathew A. McLean, Marvin L. Vestal
Vestec Corporation
9299 Kirby Drive
Houston, TX 77054

Since Karas and Hillenkamp first introduced the use of nicotinic acid to assist in generating vapor-phase biomolecular ions during 266 nm laser desorption /1/, matrix-assisted laser desorption time-of-flight mass spectrometry (LDTOF) has found widespread use in the field of protein chemistry. Constant development of the technique has allowed the rapid molecular weight determination of proteins with an absolute accuracy of 0.01%, while requiring, in most cases, less than a picomole of analyte /2/. Use of the proper matrix-laser wavelength combination has yielded molecular ion signal from samples possessing high concentrations; of buffer salts /3/, SDS /4/ and multiple protein components /3,5,6/. While in these cases, and many others, matrix-assisted LDTOF has proven itself to be an invaluable qualitative, or molecular weight determining, tool, quantitative analysis has yet to be attempted using the technique.

The two main experimental parameters which effect the absolute quantity of ion signal obtained from a protein analyte are the laser power density at the sample surface and sample preparation. As these factors are not constant from sample to sample, there is no fixed instrumental constant which determines the absolute quantity of ion signal. For this reason, a quantitative method has been developed which uses the ratio of the analyte protein ion signal normalized to that of an internal reference protein.

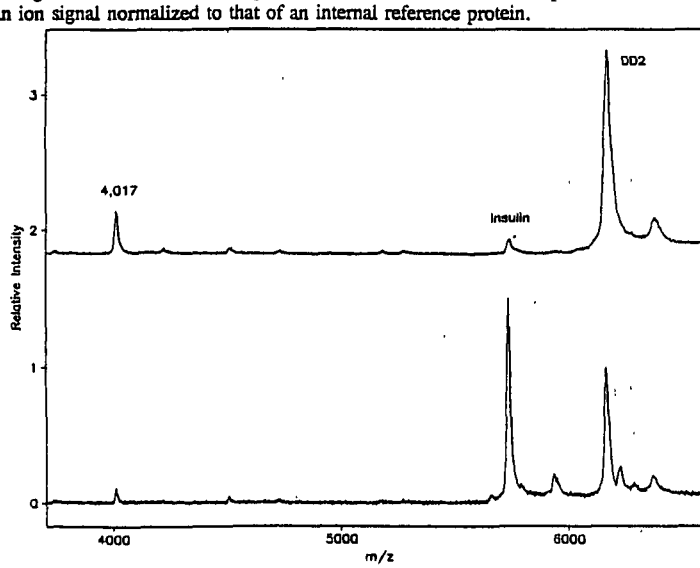

Fig.1 Mass spectra of insulin/4017/DD2 system: Top, insulin concentration = 1 pmol/ul. Bottom, insulin concentration = 11 pmol/ul, 4017 and DD2 concentrations the same as the top spectrum.

To demonstrate principle, experiments were performed using common proteins as analytes. The experimental procedure used in these studies was as follows: To a 500 ul volume of solution containing reference proteins at fixed concentrations, multiple aliquots (5 or 10 ul) of concentrated analyte protein (100

pmol/ul) was added. After the addition of each aliquot, and mixing, the same aliquot volume was removed and 1 ul used for matrix-assisted LDTOF (1:1 V:V mix with sinapinic acid matrix in 30% ACN, air dried on probe tip). In this way the analytical volume remained constant, and the experiment proceeded in the fashion of standard addition. Analyte ion signal (intensity and integral) was then normalized to the reference protein signal and plotted vs. analyte concentration.

Results of the preliminary experiments indicate the ability to obtain linear signal response over at least one order of magnitude concentration difference. Fig.1 shows the mass spectra obtained from an experimental system containing three proteins. In this case, bovine insulin ($[M+H]^+$ = 5,734.5 Da) was used as an analyte protein. Reference proteins are observed at $[M+H]^+$ = 6,170.7 Da (labeled DD2) and $[M+H]^+$ = 4,017.0 Da. The two spectra represent the reference proteins in solution at constant concentration (~5 pmol/ul) and the bovine insulin at two concentrations 1 pmol/ul (top) and 11 pmol/ul (bottom). Fig.2 shows normalized signal vs. insulin concentration plots for these, and four other, insulin concentrations (each point the average of 5 - 100 laser shot mass spectra). In the case of both the normalized signal intensity and integral, a linear response is observed over the order of magnitude concentration range. Of equal interest is apparent lack of signal augmentation of the 4,170 Da peak due to the addition of the insulin. Results similar to these have been obtained during additional experiments involving higher molecular weight man-made and natural protein systems.

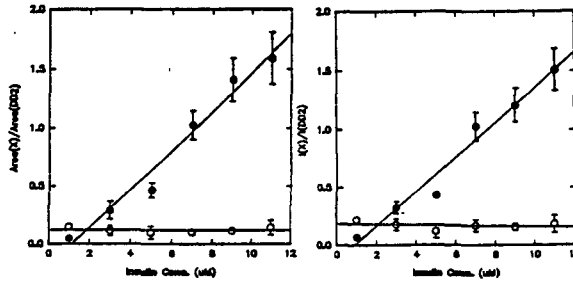

Fig.2 Normalized integral (left) and intensity (right) vs. insulin concentration plots for the insulin/4017/DD2 system. *Solid dots* = Response(ins)/Response(DD2); *Hollow dots* = Response(4017)/Response(DD2), error bars are 1 s.d. from 5-100 laser shot mass spectra. Both cases exhibit approximately the same degree of linearity and error (~20%).

Conclusions that can be drawn from these studies include:

1) Both the intensity and integral data yielded similar response and accuracy (~20 % error).
2) Linear Response was obtained over one order of magnitude. This is considered adequate for in most cases the analyte can be concentrated or diluted in solution to yield sufficient initial signals.
3) In multiple component systems addition of the analyte had minimal effect on ion signal obtained from proteins other than the analyte.
4) The ability to achieve similar results from natural systems eludes to the possibility of using matrix-assisted LDTOF as a rapid form of quantitation in biomedical assays.

SAMPLE IMMOBILISATION PROTOCOLS FOR MATRIX ASSISTED LASER DESORPTION MASS SPECTROMETRY

K. K. Mock, C. W. Sutton, and J. S. Cottrell,
Finnigan MAT Ltd., Hemel Hempstead HP2 4TG, UK.

One of the particular strengths of Matrix Assisted Laser Desorption (LD) is its extraordinary tolerance to contaminants such as buffer salts and surfactants. This makes LD an excellent choice for preliminary screening experiments on biological extracts, enzymatic digest mixtures, fermentation broths, and similar complex mixtures. Nevertheless, the presence of significant amounts of buffer salts or surfactants causes degradation in the quality of the spectra. This degradation may take the form of a combination of reduced signal intensity, poor persistance, and peak broadening. Certain contaminants, such as SDS, sodium azide, and glycerol can cause complete loss of signal if present above a certain concentration.

In these cases, it would be highly desirable to have a method of quickly and efficiently cleaning up a few picomoles of sample. Such a method was developed for use in ^{252}Californium Plasma Desorption by Jonsson et al., (Anal. Chem. **58** 1084-7 (1986)). The sample was immobilised on a layer of nitrocellulose and then unbound contaminants, such as salts and surfactants, rinsed away.

We have modified this protocol to enable surfaces to be used for *in situ* sample clean-up in LD. Using this method, spectra can be obtained from low picomole quantities of protein samples in the presence of any contaminant which does not inhibit the binding of the protein to the surface.

A layer of electrosprayed nitrocellulose works well, especially for larger proteins. We have also found that the rough gold surface of a standard sample slide works almost as well for peptides and smaller proteins.

Adsorption Protocol

Adsorption Approx 1 μl sample solution is applied to the centre of the target and allowed to dry. For the nitrocellulose surface, a wetting agent may be required (e.g. 15% methanol).

Rinsing For an unknown sample, gentle rinsing with a jet of water for a few seconds. For a known sample, alternative solvents, solutes and pH may be chosen. Dry thoroughly, ideally under rough vacuum.

Matrix Addition Add 0.5 μl matrix solution, e.g. sinapinic acid in 60% acetonitrile, 40% water, 0.1% TFA. Cover target to retard drying for 3 minutes.

The rinsing stage offers considerable scope for optimisation. The object is to maximise the removal of the contaminants, while minimising the loss of protein. Some correlation is seen between the pH of the rinse solution and the isoelectric point of the protein, but it is difficult to investigate these effects systematically because non-volatile buffers leave a residue which can itself interfere with the ionisation process. Another side effect of certain residues is that they can encourage the matrix solution to spread across the surface of the slide in an uncontrolled manner.

	1% Sod. Azide		1% SDS		5% Glycerol	
	Gold surface	NC surface	Gold surface	NC surface	Gold surface	NC surface

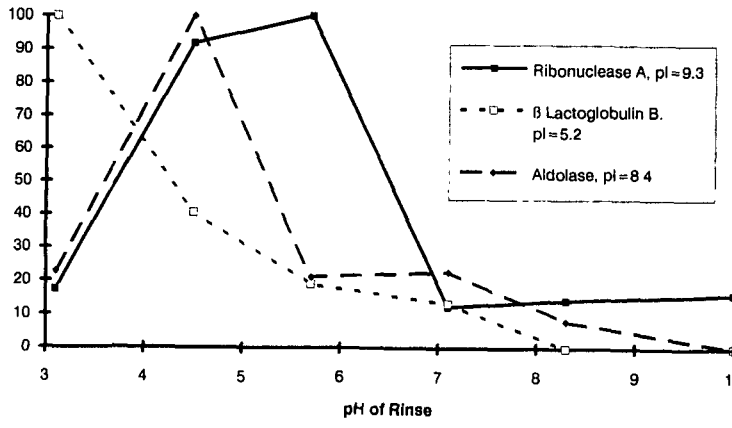
The effectiveness of the immobilisation protocol on gold and nitrocellulose substrates for a range of proteins and contaminants. Values correspond to the heights of the protonated molecular ion peaks after immobilisation and rinsing. For each sample, values are normalised to 100 for the non-contaminated protein, conventionally loaded by mixing with matrix solution on the target.



Effect of varying the pH of the rinse solution for three proteins dried onto a gold surface. The Y axis is relative intensity of the molecular ion peak.

Matrix Assisted Laser Desorption by Fourier Transform Mass Spectrometry

Charles L. Wilkins, John A. Castoro, and Claus Köster

Department of Chemistry
University of California, Riverside
Riverside, CA 92521

Since the introduction of matrix-assisted laser desorption/ionization (MALDI) mass spectrometry, it has proven to be a method capable of desorption/ionization and detection of species with masses in excess of several hundred thousand daltons. The literature reports of TOF-MALDI include impressive results demonstrating the ability to desorb and detect high mass molecules. Unfortunately, mass resolution, even with reflectron time-of-flight mass analyzers, has been less impressive, with typical resolution being less than 500. Accordingly, the idea of linking the proven high mass resolution capabilities of Fourier transform mass spectrometry (FTMS) with the mass range available by the MALDI technique is attractive. This paper addresses that prospect.

We recently demonstrated low resolution MALDI-FTMS results for a variety of proteins, including bovine insulin, equine cytochrome c, myoglobin, trypsinogen and others[1]. In that study and subsequent unpublished investigations, dimer ions, in addition to molecular ion species, were commonly observed, with the highest mass ion detected in our experiments corresponding to the m/z 58,000 dimer of carbonic anhydrase. In those first experiments, high resolution was obtained for synthetic polymers and some of the lower mass proteins (masses less than 6,000 daltons) but only low resolution (averaging 50-100) was obtained for the higher mass biomolecules. Thus, we devoted efforts to improving the mass resolution.

From a number of literature reports, it appeared that higher mass desorbed ionic species might well have energies incompatible with standard FTMS conditions. Unpublished evidence from our first studies showed that even relatively small proteins, such as insulin and melittin, could not be trapped for periods much above 50-60 msec when sinapinic acid was used as matrix. Furthermore, time-resolved studies, varying the delay between laser desorption and observation, revealed that the reason for low trapping times was decomposition of the original molecular ions into fragments. These results suggested that excess energy of the desorbed molecular ions were limiting mass resolution. As a consequence, attention turned to finding a means of cooling the high mass ions resulting from MALDI. Borrowing from the concept which led to the original MALDI breakthrough, it seemed reasonable to investigate whether other MALDI matrices or modified matrices might moderate energy deposition and, simultaneously, cool the desorbing species. It was discovered that addition of sucrose to a 2,5-dihydroxybenzoic acid matrix containing the high mass analyte resulted in the desired resolution improvement[2]. Furthermore, a variety of other sugars worked equally well, or better than sucrose. Thus, mass resolution in excess of 11,000, resolving the isotopic multiple of bovine insulin, Figure 1, was obtained and resolution approaching unit mass resolution for cytochrome c, partially resolving its isotopic multiplet, was obtained, Figure 2. Interestingly, only low resolution spectra are recorded in the absence of sugar. Required trapping potentials, following application of a suitable retarding potential during the desorption process, as described in Ref. 1, are well under 500 mV for the proteins with masses less than 13,000 daltons and decrease with increasing mass. Thus, this new method is a promising approach to high resolution MALDI-FTMS of both polymers and biomolecules.

Matrix-assisted Laser Desorption/Ionisation: Ion energies and the effect of electric field strength using the liquid matrix 3-nitrobenzyl alcohol.

A. W. Colburn, A. E. Giannakopulos, T.-W. D. Chan, E. N. Raptakis, P. G. Cullis*, P. Y. Yau and P. J. Derrick.
Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry CV4 7AL, United Kingdom.

The use of liquid matrices in matrix-assisted laser desorption/ionisation (MALDI) offers considerable advantages when this technique is combined with sector mass spectrometry. These include: good shot to shot reproducibility, extended sample lifetimes, simple sample preparation and possible use of liquid chromatography in continuous flow techniques. The liquid 3-nitrobenzyl alcohol (3-NBA) performs well as a matrix for MALDI, producing strong molecular-ion signals and enhancing cluster ion formation.

A strong relationship between the electric field strength close to the surface of the sample and the characteristics of time-of-flight mass spectra has been observed. Generally at lower field strengths the peaks due to analyte ions are enhanced to a greater extent. Figure 1 shows a new experimental set-up which has been used to investigate this effect.

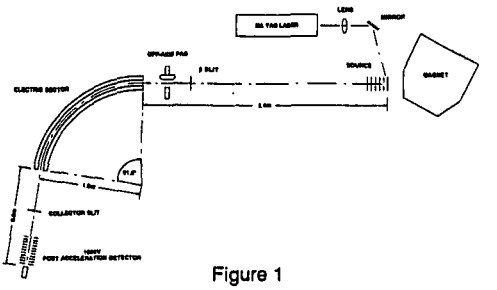

Figure 1

The experimental set-up combines sector and time of flight mass spectrometry in a parallel configuration. A laser desorption source is located at the beginning of the second field free region of a large reverse geometry sector instrument. Ions formed in the source are focused and steered through the β-slit by a double einzel lens, after which an off axis detector is used for tuning purposes. A 1m radius electric sector following the field free region acts as an energy filter. Ions are then detected after a total flight of 4.6m by a 100kV post acceleration detector which is coupled via a fibre-optic link to ion counting electronics.

Total ion kinetic energy spectra, obtained by scanning the electric sector, have shown that ions produced from 3-NBA/protein samples have keV energy spreads, if there is appreciable field strength at the target. It has also been demonstrated that the energy spreads may be reduced to a few eV by placing a grid 2mm above and at the same potential as the target. This would indicate that the energy spreads are predominantly energy deficits arising from the combination of high field and the desorption mechanism.

Total ion kinetic energy spectra are dominated by the matrix peak, which masks the majority of the contributions from the analyte. By stepping the electric sector through the required energy range and recording time-of-flight spectra at each point we produce energy resolved time-of-flight spectra. Figure 2 shows a 3-D plot of energy resolved TOF spectra. They provide a pictorial representation of the energy spectra for the entire suite of ions produced from the sample. By slicing the plot parallel to y-axis through a particular ion peak a time selected ion kinetic energy spectrum may be plotted.

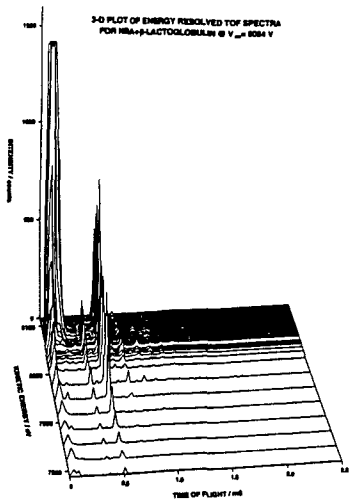

Figure 2

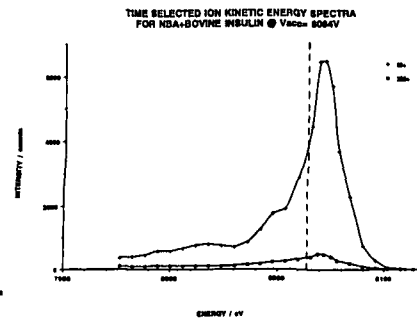

Figure 3

Figure 3 shows a time selected ion kinetic energy spectrum of NBA+Bovine Insulin for the molecular ion and dimer. The degree of metastable decay is illustrated along with the energy surplus associated with the initial velocity of the ion. Initial velocities have been measured for both matrix and analyte ions and found to be in good agreement with those by other groups.

Conclusions:

A short field free region above the sample surface is highly beneficial in the control of the energy spreads of ions produced in liquid matrix MALDI.

The investigation of ion energies using this technique should prove to be a powerful tool in understanding the fundamental desorption process.

Investigations of Matrix-Assisted Laser Desorption with a Reflecting Time-of-Flight Mass Spectrometer

W Ens, J Zhou, N Poppe-Schriemer, K G Standing and A Verentchikov
Physics Department, University of Manitoba, Winnipeg, Canada R3T 2N2

The ejection dynamics of the ion production process in matrix-assisted laser desorption (MALD) have an important influence on the spectrum in time-of-flight measurements. Previous experiments at Rockefeller [1] and in our laboratory [2] have examined the axial velocity distribution of molecular ions of insulin produced by MALD, by measuring the peak width as a function of flight path length. In these measurements, the ions were accelerated between the target at high voltage and a grounded grid. The Manitoba measurements indicate that the width of the energy distribution for insulin *after acceleration* to ~15 keV, is ~50 eV for laser irradiance approximately twice threshold and a sinapinic acid matrix. More recent measurements [3, 4] determined the axial velocity distribution for several proteins when the molecular ions are ejected into a field-free region. The average velocity of the ejected protein was found to be the same for all proteins independent of mass. The measurements give a velocity of about 500 - 700 m/s which corresponds to an energy of ~ 12 eV for the insulin molecular ion; considerably smaller than for the previous measurements described above.

Here we report measurements of the energy distributions of several molecular ions produced by MALD and ejected directly into an extraction field. Measurements were made in the Manitoba reflecting time-of-flight mass spectrometer [5] illustrated in Fig. 1. Ions produced by laser pulses from a nitrogen laser are accelerated by an electric field between the target at high voltage (15 kV) and a grounded grid, placed 1 cm from the target. An ideal electrostatic mirror has a sharp energy energy cutoff defined by the potential, V_m, applied to the final electrode. That is, ions of charge q entering the mirror parallel to the axis, with energy less than qV_m, are reflected, but ions with higher energy are not. Because of the small incident angle of ions entering the mirror in the present experiments, ions with an energy slightly higher than qV_m, are still reflected giving rise to an apparent shift of about 10 eV.

Fig 1 (right) shows the molecular ion region of the time-of-flight spectrum of insulin desorbed from a sinapinic acid matrix, for 3 values of the voltage difference V_m-V_a. The data show that some molecular ions of insulin are reflected even when the mirror voltage is 60 V *below* the acceleration voltage, indicating they have energy less than would be obtained from the extraction field alone; i.e. they have an energy deficit. In these measurements, the metastable daughter at [M-17] has sufficiently low energy so that it is completely reflected in each case, and serves as normalization.

A direct method of obtaining the integral energy distribution is to measure the intensity of the reflected signal as a function of the mirror voltage; the derivative of the resulting curve represents the energy distribution. To test the method, the energy distribution was measured for molecular ions of substance P produced by particle bombardment, since the initial energy distribution in this case is known to be small. As shown in Fig. 2a, when the effect of the incident angle is accounted for, a narrow distribution is observed within a few eV of the predicted position indicated by the dashed line.

The measured energy distribution for laser desorbed molecular ions from insulin is shown in Fig. 2b. The distribution was obtained under conditions typical for measuring insulin mass spectra and indicates an average energy deficit of about 25 eV.The energy deficit for insulin increases (up to ~ 100 eV) with the intensity of the molecular ion signal, and the energy deficit for different proteins increases with molecular weight [6]. The measurements indicate that in the presence of an extraction field, the ejection process in laser desorption *impedes* acceleration, in contrast to the situation with zero extraction, where the ejection process *contributes* energy. The results are qualitatively consistent with the loss of energy by collisions of the molecular ions in a rapidly exanding gas jet [3].

Investigations of the Kinetic Energy and Temporal Profiles of Ion Generation during Matrix Assisted Laser Desorption using an Electric Sector / Reflectron Time-Of-Flight Mass Spectrometer

Gary R. Kinsel and David H. Russell

Texas A & M University, Department of Chemistry, College Station, TX 77843.

The mechanism of molecule desorption and ion formation during Matrix Assisted Laser Desorption Ionization (MALDI) is of fundamental interest. A better understanding of the MALDI mechanism may allow more efficient introduction of large molecules into the gas phase or better approaches for improving ion signal resolution. Thus, a goal of a variety of researchers in the field has been the measurement of the physical parameters describing the ions produced during MALDI. These physical parameters include, but are not limited to, the kinetic energies of the ejected ions, the spatial distribution over which the ions are produced and the temporal duration of ion formation. We have recently developed a hybrid Electric sector \ linear REflectron Time-Of-Flight Mass Spectrometer (E-RETOF MS) which allows several unique experimental approaches for the measurement of these physical parameters to be pursued.

A simple block diagram of the E-RETOF MS instrument is shown in Figure 1. The instrument consists of the ion source region (8 kV max.), a 15" radius 90° electrostatic analyzer (ESA) and a 25 cm linear reflectron mass analyzer. Dual Microchannel plate detectors (MCP 1 and MCP 2) are mounted both behind the ion mirror and at the reflectron exit. Using this instrument design, ion kinetic energies may be measured either through retarding field experiments with the ion mirror or by scanning the source potential with a defined ESA ion kinetic energy bandpass. In addition, high resolution ion signals may be obtained at the reflectron detector by narrowing the ion kinetic energies analyzed using the ESA and operating the RETOF in the 2-stage ion mirror mode.

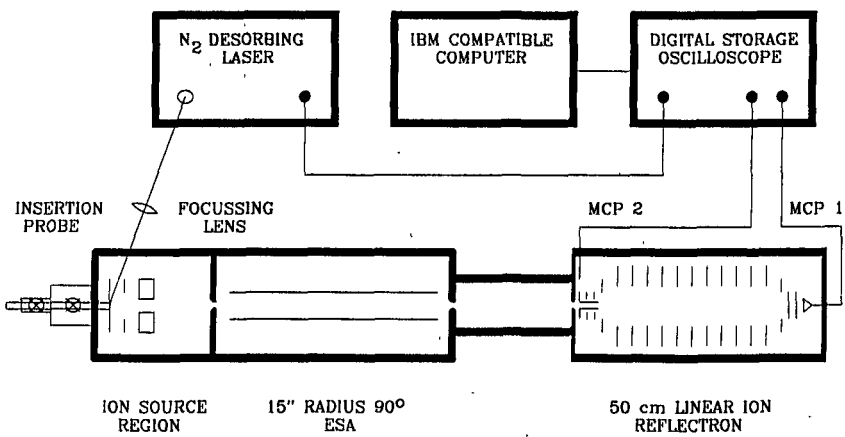

Figure 1: Block diagram of E-RETOF MS instrumentation.

Preliminary retarding field experiments with the ion mirror have been performed to measure the MALDI ion kinetic energies for several matrix / analyte combinations. In these experiments the ESA slits are opened completely in order to pass a broad distribution of ion energies. The voltage applied to the reflectron is then varied from ca. 50 V less than to 50 V greater than the source accelerating potential (5.97 kV) while monitoring the ion current detected at MCP 1. An example of the results obtained for 2,5-dihydroxybenzoic acid (DHB) matrix mixed with Bradykinin is shown in Figure 2. One striking feature of this plot is the broad distribution of high ion kinetic energies with an average of ca. +15 to +20 V. These values are significantly higher than previously measured values and may be due to the particular matrix employed, the somewhat high desorbing laser power (30 MW/cm^2), or the short desorbing laser pulse employed (600 ps N_2 laser pulse @ 337 nm). A second surprising feature of the plot in figure 2 is the abundance of ions having less than the full acceleration energy. These ions may be indicative of source region metastable decompositions of some larger ionic precursor species, source region gas phase ion formation reactions, or of metastable decompositions occuring in the RETOF mass analyzer. We have also noted in other experiments that, under identical conditions, the matrix ion kinetic energies are much higher and broader in distribution for the pure matrix than for a given matrix / analyte combination. When combined the matrix and analyte ions give very similar kinetic energy distributions indicating a strong expansion interaction between the two materials. Future experiments will focus on further examination of these preliminary observations and exploitation of the unique features of the E-RETOF MS for determining the physical parameters describing ion formation in MALDI.

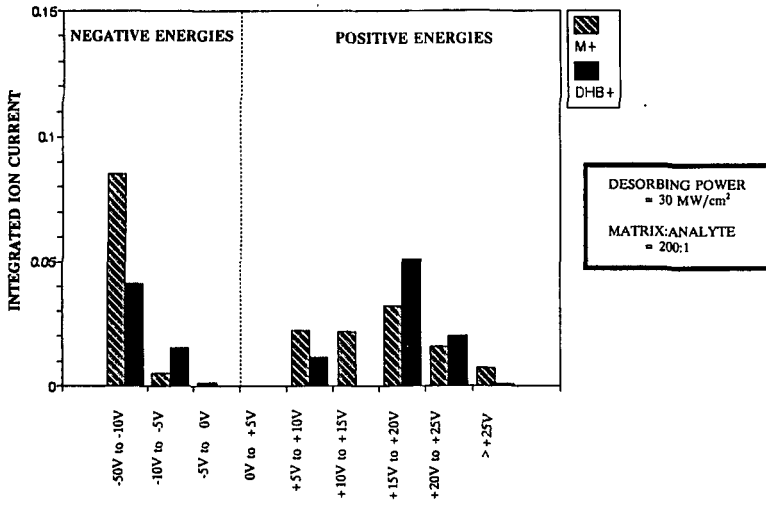

Figure 2: Measured ion kinetic energy distribution for DHB\BRADYKININ. Negative energies indicates ions having less than the full source region accelerating potential while positive energies indicates ions having kinetic energies greater than the full source region accelerating potential. M+ includes the $[M+H]^+$ and $[M+Na]^+$ ions for Bradykinin. DHB+ includes the M^+, $[M+H]^+$ and $[M+H-H_2O]^+$ ions of 2,5-dihydroxybenzoic acid.

Studies of Peptide Negative Ions by Using Matrix-Assisted Laser Desorption Ionization:Comparison with Positive Ion Data

*L. M. Preston and D. H. Russell
Dept. of Chemistry
Texas A&M University
College Station, Texas 77843

Matrix-Assisted-UV-Laser Desorption Ionization (MALDI) has helped to expand the range of biomolecule mass spectrometry to samples having molecular weights in excess of 100 kilodaltons (1). Efforts have concentrated on using this technique to ionize large biomolecules for molecular weight determination, and to ascertain the mechanism of the desorption/ ionization process. These experiments have been done largely in positive ion mode, with much less emphasis on exploring the usefulness of the negative ions formed by MALDI.

Preliminary results from our studies indicate that the use of negative ions in studying peptides can provide data which gives structural information in addition to that provided by positive ions. An example of this is shown in figures 1 and 2. These tables show the positive and negative ions of the pentapeptide Arg-Lys-Glu-Val-Tyr using 4-nitroaniline as a matrix. The fragment ions shown are generally 10% to 20% relative abundance to the $(M+H)^+$ seen in the positive ion spectrum. Fragmentation is seen from both the C-terminus and N-terminus of the peptide, and does not seem to be isolated to one series.

These studies have been carried out with a variety of peptides that show a degree of fragmentation similar to that seen for Arg-Lys-Glu-Val-Tyr. Additionally, other matrices were used to

determine if varied fragmentation patterns would be seen using different matrices. Using Arg-Lys-Glu-Val-Tyr as an example, the matrix compound α-cyano-4-hydroxy cinnamic acid yields some fragmentation that is different from that seen using 4-nitroaniline (see figures 3 and 4). This indicates that by using a variety of matrices with a particular peptide, the amount of structural information obtained can be increased.

The extent of analyte fragmentation seen using various matrices can be very different as is *illustrated by the data contained in* figures 1-4. We interpret this data as evidence that differences exist in the way that the peptide and various matrices interact or in the manner by which energy is transferred from the matrix to the analyte molecule. These differences suggest that differences in the physical/ chemical structure of a molecule directly affects its effectiveness as a MALDI matrix. Looking at these structural differences will be the focus of future studies. A particular feature that will be examined is how changing the type and location of electron withdrawing and releasing groups on a molecule will affect their relative excited state gas phase acidity.

A New Control System for a Four-Sector Tandem MS for Acquisition of MS/MS Spectra from Multi-Precursor Ions & Its Application for Facile Assignment of Daughter Ions to Peptide Sequence

Toshifumi Takao, Javier Gonzalez, Hideaki Hori, Kozo Yoshidome[†], Kimio Sato[†], Tôru Asada[†], Yoshihiro Kammei[†], and Yasutsugu Shimonishi

Institute for Protein Research, Osaka University, Yamadaoka 3-2, Suita, Osaka 565; [†]JEOL, Ltd., Musashino 3-1-2, Akishima, Tokyo 196, Japan

MS/MS using a four-sector tandem mass spectrometer has a great advantage of the complete separation of a precursor ion in MS1, allowing reliable analysis of daughter ions in MS2. It has been successfully applied to determination of amino acid sequences of peptides and proteins. However, manipulation of the four-sector tandem mass spectrometer is rather tedious, especially, in analysis of a mixture since MS1 needs to be manually switched mass to mass to the center of each precursor ion. It may often result in sample loss. To overcome such difficulty in operation of the present four-sector tandem mass spectrometer, we developed a new acquisition processor unit simultaneously to control MS1 and MS2 that makes it possible to acquire the MS/MS spectra from multi-precursor ions in a single measurement.

In the present system, the electric and magnetic fields of both MS1 and MS2 are simultaneously controlled by the instrument control part (Fig. 1). In order to switch the magnetic field (B1) on MS1 precisely to the center of each precursor ion, B1 is re-calibrated by using appropriate internal standard before sample measurement. The DAC lookup tables for B2/E2-linked scanning on MS2 corresponding to each precursor ion are created in the engineering workstation and stored in the memory of the instrument control part in advance. The daughter ion spectra from each precursor ion are consecutively acquired by B2/E2-linked scanning on MS2 synchronized with automatic B1-switching to each mass of the precursor ions on MS1.

Previously, we reported the methods for facile assignment of daughter ions to amino acid sequence [1] and identification of the specific sites for N-glycosylation in a glycoprotein [2] in CID and B/E linked-scan analysis of a ^{18}O-labeled peptide by a two-sector mass spectrometer. Here, we extended the method to a four-sector tandem mass spectrometer equipped with the above MS/MS control system for more precise and reliable assignment of the daughter ions. Figure 2 shows a comparison of the CID-MS/MS spectra from 832.5 (MH^+) and 834.5 ($M+3^+$) observed for an ^{18}O-labeled peptide produced by enzymatic hydrolysis of the light-chain of mouse immunoglobulin in buffer containing 40 atom % $H_2^{18}O$. The C-terminal sequence ions (*v, w, x, y, z*-series) could be differentiated from the N-terminal ones (*a, b, d*-series) by their shifts in mass by 2 u (lower spectrum in Fig. 2) due to incorporation of ^{18}O into the α-carboxyl group. Thus the amino acid sequence of the peptide was readily determined to be Thr-Ser-Thr-Ser-Pro-Ile-Val-Lys. It clearly demonstrates that comparison of the MS/MS spectrum of MH^+ to that of $(M+3)^+$ derived from the ion of a molecule labeled with ^{18}O at α-carboxyl group allows more easy and reliable assignment of daughter ions to peptide sequence. Furthermore, the CPU-controlled MS/MS from multi-precursor ions makes it easy and rapid to sequence a peptide and protein.

Sequential Analysis of Peptides at the Femtomole Level by Tandem Mass Spectrometry

Ron Orlando
Suntory Institute for Bioorganic Research
Wakayamadai, Shimamoto-cho, Mishima-gun, Osaka 618 Japan

In the conventional FABMS analysis of peptides at the low *p*mol level, the analyte signal observed is only slightly larger than the chemical background. As the sample quantity is further reduced, the signal-to-background ratio decreases and eventually the protonated molecule becomes indistinguishable from the matrix ions. In these extreme cases, no information is obtained from the analyte, consequently prior knowledge of the sample (molecular weight) is essential to select the precursor ion in MS 1 for MS/MS analysis. However, when the ion having the appropriate *m/z* value is subjected to CID, peaks produced by fragmentation of the matrix ion dominate the spectrum, as demonstrated by the analysis of 740 *f*mol of substance P (Figure 1). Although the identity of the background ion at this *m/z* value is unknown, the fragment ions observed in this spectrum consist of two series: 1) protonated thioglycerol clusters and 2) losses of neutral thioglycerol molecules from the precursor. Both of these series contain satellite peaks corresponding to the loss (es) of water molecules. As matrix interferences account for virtually all of the ions observed in Figure 1, all structural information pertinent to the analyte is lost. Consequently, the ultimate sensitivity of FABMS/MS analysis appears to be limited by the chemical background produced by the desorption/ionization process.

By reducing the amount of matrix, continuous flow (CF) FAB provides significantly better signal-to-background ratios than conventional FAB.[3] Although the protonated molecule produced by CF-FAB allows easy identification and selection in MS 1, MS/MS analysis at the sub-*p*mol/μL level requires the increased sensitivity provided by array detection. To demonstrate the enhanced sensitivity provided by this combination, analysis was performed on a 370 *f*mol/μL solution of substance P (Figure 2). This spectrum contains numerous immonium ions and two prominent series of N-terminal ions that confirm the amino acid sequence. In addition, this figure is very similar to the numerous high energy CID spectra of substance P present in the literature.[1,2]

The decreased interference provided by CF-FAB combined with the increased sensitivity of array detection yields dramatic reductions in sample requirements for MS/MS sequencing. In the analysis of substance P, this strategy provided a 25 to 75 percent decrease in sample quantity compared to the previous limits of analysis with FAB MS/MS.[1,2,4] Similar reductions in sample size have been reported in MS/MS sequencing of renin substrate tetradecapeptide and several other peptides using this strategy.[4]

Although the advantages of CF-FAB have been highlighted, this report also suggests a general strategy for reducing sample quantities for MS/MS analysis. As demonstrated, the current barrier to decreasing the amount of sample required for MS/MS sequencing is imposed by the intensity of the sample ion relative to the chemical background. Therefore, any technique that increases this ratio is expected to provide a similar gain in overall sensitivity, and permit more extensive use of the benefits associated with array detection.

LOW-ENERGY VERSUS HIGH-ENERGY COLLISION-ACTIVATED DISSOCIATIONS OF NEUROPEPTIDES

Chhabil Dass and D.M. Desiderio

University of Tennessee, Memphis, 956 Court Avenue, Memphis, TN 38163

Tandem mass spectrometry (MS/MS) using four-sector magnetic instruments has been applied frequently for sequence analysis of peptides. On the other hand, applications of magnetic sector/quadrupole hybrid tandem MS are very few and are not fully understood. These two types of instruments differ with respect to the fact that sector instruments deal with high-energy (keV) ions, whereas low-energy (eV) ions are accessible in the quadrupole section of a hybrid instrument. Consequently, the residence time of ions and the number of collisions they undergo in a quadrupole are increased. Thus, the CAD data obtained using a magnetic sector and a quadrupole may differ qualitatively.

In this study, we have compared low-energy and high-energy collision-activated dissociation (CAD) spectra of several neuropeptides of biological significance. These peptides include methionine enkephalin-Lys (YGGFMK, MW=701 Da), dynorphin A (1-7) (YGGFLRR, MW=867 Da), dynorphin A (1-8) (YGGFLRRI, MW=980 Da), β-neoendorphin (YGGFLRKYP, MW=1099 Da), and substance P (RPKPQQFFGLM-NH_2, MW=1346 Da). All data were acquired using a VG AutoSpec Q mass spectrometer. The advantage of this hybrid tandem mass spectrometer is that a single instrument can be used to perform high- (using the EBE section) and low-energy CAD, (using the quadrupole section). All peptides were ionized with the impact of a high-energy (35 keV) beam of Cs^+ ions, and accelerated out of the ion source at 8000 V potential. For high-energy CAD, the first two sectors were adjusted to mass-select the MH^+ ions into the third FFR, and their spectra acquired by scanning the second ESA (i.e., by using MIKE technique). For low-energy CAD, the mass selection of the precursor was by the EBE section and acquisition of the CAD spectra by scanning the second quadrupole. Helium was used as a collision gas for both experiments.

As a typical example, the low-energy and high-energy (MIKE) CAD spectra of methionine enkephalin-Lys are shown in Figure 1. From the data, it is obvious that both these techniques are able to provide sequence ion information. A complete set of a, b, y and z ion-series is present in those spectra. For the remainder of the peptides, at least one N- and C- terminus sequence ion-series is present in the low- and high-energy CAD spectra. The product ion resolution in the MIKE spectra, however, is very poor because of partitioning of the internal energy of the precursor into the translational energy of the fragments. For this reason, the low-energy CAD spectra of the peptides investigated here are superior to the MIKE spectra.

The yield of product ions for the low mass peptides (<1,000 Da) is higher in the low-energy CAD. For example, the most dominant ion in the low-energy CAD spectra of methionine enkephalin-Lys, dynorphin A (1-7), and dynorphin A (1-8) is 4, 2.5 and 3% respectively, relative to the precursor ion. The corresponding values in the high-energy CAD are 0.1, 0.3, and 0.15%. However, the facility with which reactions proceed through different fragmentation channels is higher in the high-energy CAD (Table 1).

It was also observed for methionine enkephalin-Lys that with an increase in the collision energy (E_{lab}), the yield of low mass fragments increases and that of the high mass fragments decreases in the low-energy CAD experiments (Table 2).

A NEW APPROACH FOR SEQUENCING PEPTIDES AND PROTEINS

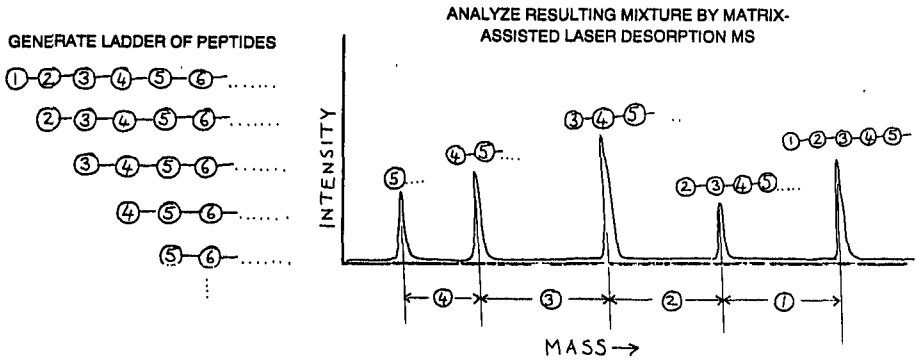
Brian T. Chait[1], Rong Wang[1], Ronald C. Beavis[2], and Stephen B. H. Kent[3], [1]The Rockefeller University, New York, N.Y. 10021. [2]Memorial University of Newfoundland, St. Johns A1B 3X7 Canada. [3]Scripps Research Institute, LaJolla, CA.

The approach to peptide and protein sequence determination described here consists of two steps:

Step 1. The generation by chemical means of a complete ladder of polypeptides, (see figure below) by repeated cycles of stepwise degradation in the presence of a terminating agent, which chemically blocks a small fraction of the peptide chain in each cycle.

Step 2. One-step readout of the resulting protein sequencing ladder by matrix-assisted laser desorption time-of-flight mass spectrometry (see figure below).

NEW APPROACH



The second step ("readout") of the procedure was thoroughly evaluated on peptide mixtures generated during the stepwise solid-phase synthesis of the 99-residue protein HIV-1 protease. After each consecutive amino acid coupling step, a fraction of the peptide resin was removed and pooled. Three important observations were made during the analysis of these peptide mixtures: (a) complex mixtures of more than 30 peptide components could be analyzed by matrix-assisted laser desorption mass spectrometry using alpha-cyano-4-hydroxycinnamic acid (1) as a matrix (see e.g., Fig. 1), (b) the masses of the components of such peptide mixtures were determined with an accuracy of 0.01% for peptide components with molecular masses up to 7000 u, and (c) aliquots of a peptide mixture produced intense molecule ion signals for components present in amounts of less than 1 pmol/μl.

In one variation of the new sequencing approach, peptides were subjected to repeated cycles of the Edman degradation (in the presence of a small proportion of the terminating reagent phenyl isocyanate) without separation of the reaction products (Fig 2). The crude mixture is subjected to mass spectrometric analysis, and the sequence is inferred from the mass differences between adjacent peaks. Figure 3 shows an analysis after 7 cycles of the above-described procedure on the 14-residue peptide [Glu-1] fibrinopeptide. Features of the new technique: (i) the readout is simple and fast, (ii) a high stepwise yield is not required, (iii) modified amino acids can be analyzed , (iv) leu cannot be distinguished from ile, and (v) mixtures can be analyzed. Present efforts are directed at refinement of the chemical degradation procedures and reduction in the amounts of polypeptide analyzed.

Fragmentation of Proteins in the 13-29 kDa Mass Range Observed by ^{252}Cf-PDMS

David M. Bunk and Ronald D. Macfarlane
Department of Chemistry, Texas A&M University
College Station, TX 77843-3255

We report here results from our continued studies of the fragmentation of peptides and proteins by ^{252}Cf-plasma desorption mass spectrometry (PDMS). For the five proteins examined for this study, proteins with masses ranging from 13 to 29 kDa, sequence-specific fragmentation was found to be a substantial component of their positive ion PD mass spectrum. These results demonstrate that the molecular excitation afforded by the plasma desorption/ionization process is sufficient to produce prompt, sequence-specific fragmentation from large, native proteins.

The fragmentation pattern in the spectrum of recombinant human granulocyte-macrophage colony-stimulating factor (GM-CSF), a protein with 127 residues and an average mass of 14451 Da, is shown in Figure 1.

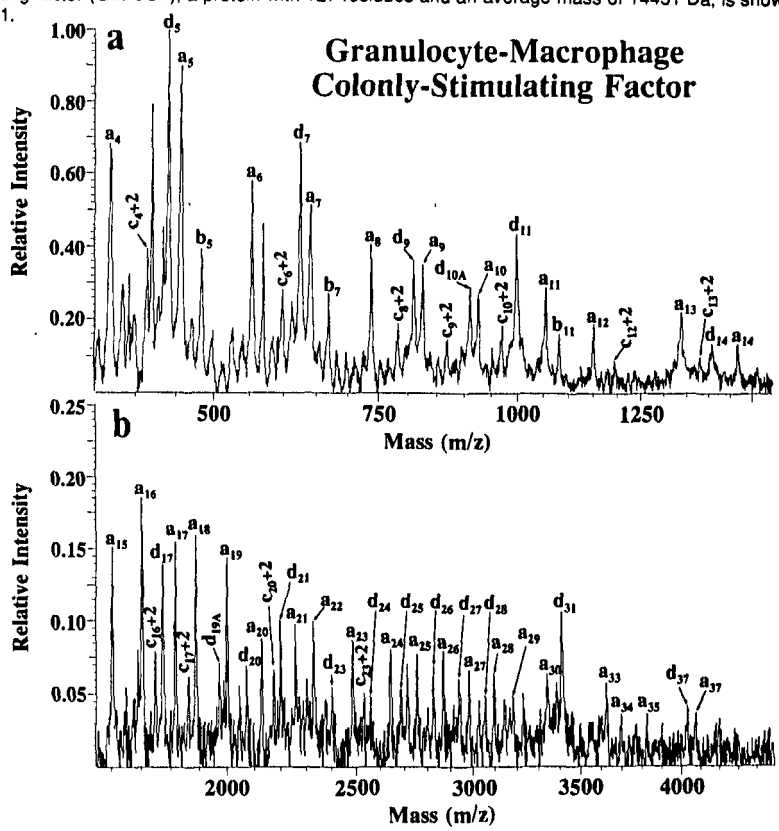

Figure 1. Positive ion PD mass spectrum of GM-CSF (a) in the range m/z 350-1550, and (b) in the range m/z 1550-4500. The spectrum was acquired for 720 min using approximately 200 pmol protein.

An extensive collection of sharp, N-terminal fragment ions is observed for this protein. The presence of several arginine residues near the N-terminus of the protein provide several strong protonation sites for the formation of charge-remote fragment ions. The relationship between the observed fragmentation and the structure of GM-CSF is shown in the fragmentation diagram in Figure 2. The lack of basic residues and a disulfide cross-link near the C-terminus hinder the formation of C-terminal fragment ions.

Substantial, coherent sequence-specific fragmentation similar to that of GM-CSF was also observed in the PD mass spectrum of ribonuclease A (M_r, 13682), papain (M_r, 23422), proteinase K (M_r, 28665). The N-terminal fragmentation of these proteins correlates well with their primary structures (1), particularly with the positions of basic arginine residues. The PD mass spectrum of recombinant human α_2-interferon (M_r, 19269) contains only C-terminal fragment ions, consistent with the presence of arginine residues near the C-terminus and a disulfide cross-linking the N-terminus.

For the intense a_n and d_n fragment ions of GM-CSF, the relative mass errors were approximately 100-150 ppm. As the mass of the protein increased, the overall signal-to-noise level of the fragmentation pattern in the PD mass spectra decreased. For the larger proteins, such as proteinase K, the prominent fragment ions were observed with relative mass errors of approximately 300-350 ppm.

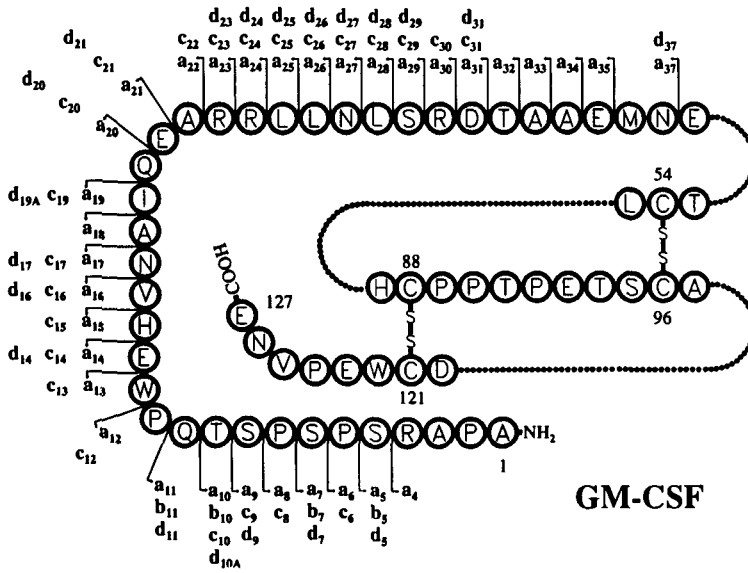

Figure 2. Fragmentation diagram of GM-CSF. The c_n+2 fragment ions have been labelled c_n.

Direct Molecular Weight Determination of Resin-Bound Oligopeptides using ^{252}Cf Plasma Desorption Mass Spectrometry.

P.A. van Veelen, E.M.A. Lambert, J.W. Drijfhout, U.R. Tjaden, J. van der Greef

Division of Analytical Chemistry, Center for Bio-Pharmaceutical Sciences, P.O. Box 9502, 2300 RA Leiden.

Some time ago we reported on fragmentation of oligopeptides up to 10 kDa, using PDMS.[1,2] This fragmentation can be used very well to obtain sequence information, especially important in the case of C-terminal fragments, one of the weak points in conventional Edman degradation. Directing the pattern and/or intensity of the fragmentation would be an important step forward in peptide sequence analysis.
Our idea was to bind oligopeptides covalently to the target surface, thereby hoping to influence the pattern and/or intensity of fragmentation. Resin-bound oligopeptides were selected as model system to study this, because these can be prepared relatively easily. Besides, this method, if succesful, can be used in the analysis of peptide synthesis.[3]
A resin-bound oligopeptide is the last but one product of peptide synthesis. After that the oligopeptide is cleaved off and deprotected in the final step. A resin-bound oligopeptide is schematically depicted in figure 1. The most important part for our studies is the linker, which serves to connect the growing oligopeptide to the resin and also provides a selective cleavage point at the end of the peptide synthesis. The linker is, together with the oligopeptide, the variable part in this study. Some linkers are shown in figure 2.

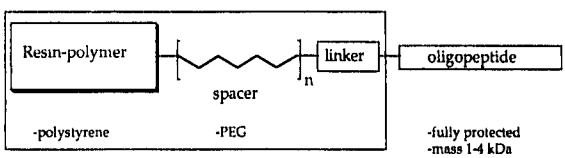

Figure 1

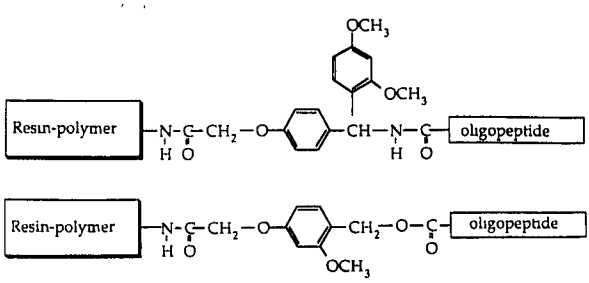

Figure 2

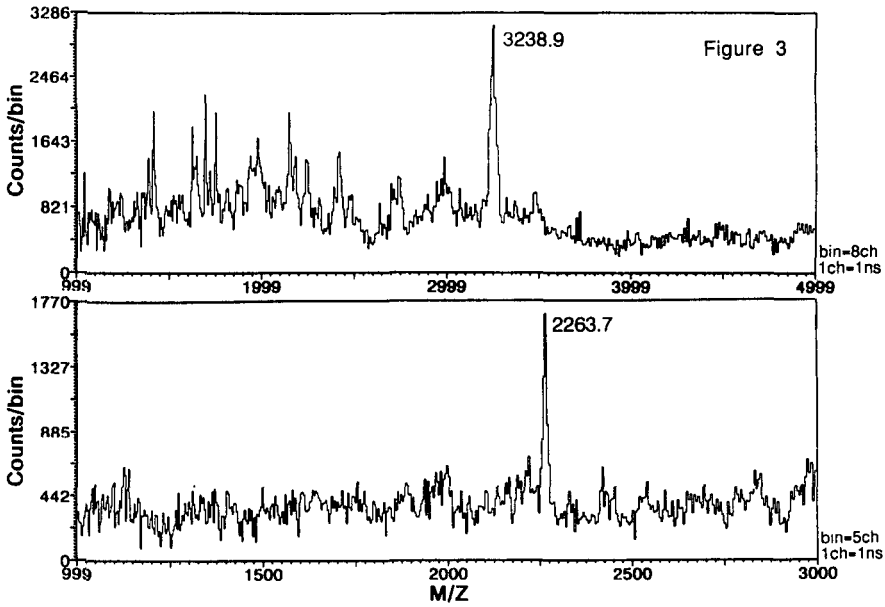
The polystyrene spheres to which the oligopeptides are attached are ground to a very fine powder. This powder is applied to the target foil and inserted in the mass spectrometer.
Some typical results of the first and second linker are shown in figure 3.



As can be seen, no fragmentation is observed. Whether this is a result of insufficient S/N ratio or of a more fundamental nature can not be concluded. However, quite surprisingly, we observed ions corresponding to the mass of the fully protected oligopeptide, one time even including the mass of the linker.[3] Apparently, cleavage often takes place at a well-defined place, which is very surprising. In case of some other linkers, no signal at all could be observed. The reason for this is not clear to us, since the linkers do not seem to differ that much.
Finally it can be stated that those linkers which are used most frequently in peptide synthesis yield useful information.

Determination of Gylcosylation Patterns, Disulfide Linkages and Protein Heterogeneities of Baculovirus Expressed Mouse Interleukin-3 by Mass Spectrometry.

Knepper, T., *Hogeland, K., Arbogast, B. and Deinzer, M.;
Oregon State University, Corvallis OR

Interleukin-3 (IL-3) is a protein with 140 amino acid residues, four of which are cysteines that could be involved in disulfide linkages[1]. There are also four possible sites for N-glycosylation (Figure 1). Initial mass spectral studies on baculovirus expressed mouse IL-3 produced in silkworm (*Bombyx mori*) indicated that two of the N-glycosylation sites might be glycosylated; Asn-16 and Asn-86[2]. The purpose of this study was to determine the nature of glycosylation and the disulfide linkages of silkworm produced mouse IL-3.

The crude silkworm hemolymph was purified by anion exchange chromatography and reverse phase high pressure liquid chromatography (RP-HPLC) with C4 and C18 columns. After separation on C4 two fractions were identified with IL-3 activity. The two, IL-3a and IL-3b, were collected with a ratio of 10:1 .

Positive ion liquid secondary ion (l.s.i.) mass spectrometric analysis of the chloroform-soluble material from the acetolysis of IL-3 afforded a spectrum which contained several peaks that could be assigned to acetylated carbohydrates. Various hexose and lactosamine type species were observed. Release of the monosaccharides by hydrolysis of the glycoprotein with 2M trifluoroacetic acid, then analysis by high pH anion exchange chromatography (HPAEC) with pulsed amperometric detection (PAD) showed the presence of fucose, glucosamine and mannose in a ratio of 1:3:4. These monosaccharides are indicative of the presence of N-linked glycans.

PNGase F (N-Glycanase) release of the N-linked oligosaccharides followed by reductive amination with n-hexylamine and permethylation gave derivatized oligosaccharides bearing a positive charge at the newly formed amino group[3]. Positive ion l.s.i. mass spectrometry of this mixture gave a spectrum with a major peak with m/z 1233 that corresponds to $Man_2[Fuc]GlcNAc_2$ (O II). Two minor peaks with m/z 1438 and m/z 1059 corresponding to $Man_3[Fuc]GlcNAc_2$ (O III) and $Man_2GlcNAc_2$ (0 I) also were present (Figure 2). A fourth peak with less than 1% relative abundance was observed for an oligosaccharide with four mannose residues (O IV) (Data not shown).

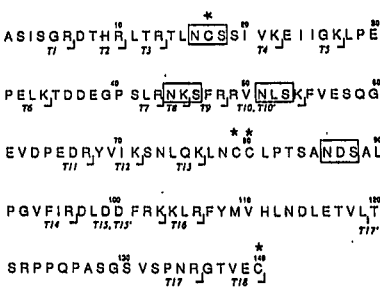

Figure 1. Interleukin-3 protein sequence. Observed tryptic peptides are shown. Cysteines are indicated by asterisk and N-glycosylation sites are indicated by boxes.

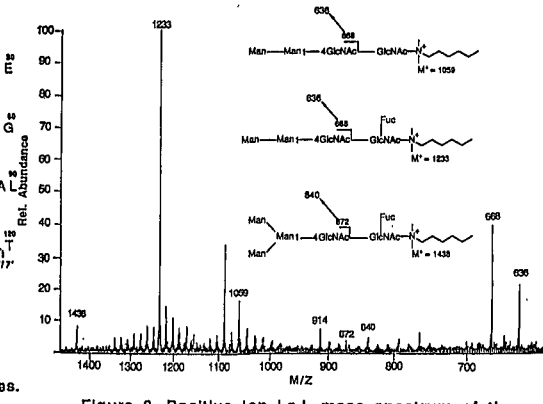

Figure 2. Positive ion l.s.i. mass spectrum of the reductivaly aminated, permethylated N-linked oligosaccharides released from IL-3. Matrix: Thioglycerol/glycerol (2/1).

Electrospray mass spectrometric analysis of the intact glycoprotein (IL-3a) gave an intense peak with m/z 17,423 . This could be assigned to the protein, with a calculated molecular weight of 15,669 Da, glycosylated with two O IIs at two sites. Less intense peaks could be assigned to protein glycosylated with O II, m/z 16,552, O I and O II, m/z 17,275 and O II and O III, m/z 17,591. Positive ion l.s.i. mass spectrometric analysis was carried out on the reduced mixture of the tryptic peptides derived from glycosylated and deglycosylated IL-3a. These studies showed that Asn-16 is heterogeneously glycosylated with all four oligosaccharides (Figure 3). Peaks were observed for the glycosylated tryptic peptide T4 with m/z 1695, 1841, 2004 and 2164. The tryptic peptide T14, which contains Asn-86, is either glycosylated with O II, m/z 2969 or non-glycosylated, m/z 2092.

Positive ion l.s.i. mass spectrometric analysis of the unreduced tryptic peptide mixture from both glycosylated and deglycosylated IL-3a indicates that Cys-79 and Cys-80 form disulfide linkages with Cys-17 and Cys-140. Peaks observed were for the glycosylated and deglycosylated tripeptide T4-SS-T14-SS-T18 with m/z 5312 and 5166 (glycoslylated) and m/z 3561 (deglycosylated).

The analysis of IL-3b showed that there is no difference in glycosylation pattern or disulfide linkages between IL-3b and IL-3a. Peptide mapping along with automatic Edman degradation indicate that IL-3b was proteolyticly cleaved at the C-terminal end between Ala-127 and Ser-128 (Figure 4). This presumably occurs in the first stages of purification when many proteolytic enzymes may be present.

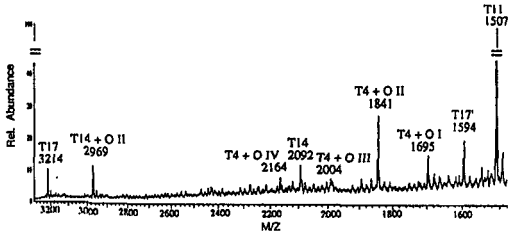

Figure 3. Positive ion l.s.i. mass spectrum of the tryptic glycopeptides of reduced IL-3. Matrix: DTT/DTE/0.1% TFA (1/1/1).

Mass spectrometric determination of the location of phosphorylation in two tick anticoagulant peptides

I.A. Papayannopoulos and K. Biemann, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139

Two very potent blood anticoagulant peptides (TAP-1 and TAP-2, both 60 amino acids long and differing only at four positions, as shown in Figure 1) were isolated from two related species of ticks and their sequences were deduced from cDNA data. Both were synthesized, but the synthetic products were found to have different HPLC retention times when compared with the native peptides, indicating post-translational modification(s) in the latter [1].

The molecular weights of TAP-1 and TAP-2 were determined by matrix-assisted laser desorption time-of-flight (maLD-TOF) mass spectrometry and were 80 u higher than the synthetic peptides (Figure 2); this indicated phosphorylation. After digestion with endoproteinase Lys-C (which cleaves reduced and alkylated TAP-1 and TAP-2 at two sites, resulting in three peptides), it was determined by mass spectrometry that the middle Lys-C peptide contained the modification. The serine residue at position 17 was the only possible phosphorylation site, and this was confirmed by further digestion of the middle Lys-C peptide with endoproteinase Asp-N.

During disulfide reduction and cysteine alkylation and the subsequent Lys-C digestion of the tick peptide, some of the phosphate was lost, as observed in the maLD-TOF mass spectrum shown in Figure 3. However, when the phosphorylated peptide is separated from the dephosphorylated one by HPLC, it no longer exhibits loss of 80 u, as is the case for the intact native peptide, as well (Figure 2). This is in agreement with the fact that no appreciable loss of 80 u (or 96 u) from the $(M+H)^+$ ion of the modified peptide, obtained after Asp-N digestion, was observed in the FAB mass spectrum (Figure 4), indicating that the modifying group is phosphate rather than sulfate, because, in the latter case, loss of SO_3 (-80 u) and SO_4 (-96 u) from the $(M+H)^+$ ion is pronounced [2].

Zinc-finger Peptide Interactions with Zn(II) and Cu(II) ions:

An investigation by Electrospray Ionization and Matrix-assisted UV Laser Desorption Time-of-flight Mass Spectrometry

SUMMARY

We have developed mass spectrometric techniques to evaluate the interaction of transition metal ions with specific peptides and protein surface metal-binding domains. A 71-residue "zinc-finger" metal-binding sequence from the DNA-binding domain of the human estrogen receptor protein (ERDBD) was evaluated by matrix-assisted UV laser desorption/ionization (MALDI) time-of-flight (TOF) and electrospray ionization (ESI) mass spectrometry (MS) in the absence and presence of Zn(II) and Cu(II) ions. Stable peptide-metal ion complexes with both Zn(II) and Cu(II) were observed.

INTRODUCTION

The direct observation of specific peptide- and protein-metal ion complexes is essential to characterize a wide variety of important regulatory biomolecular recognition events.

We have demonstrated that peptide-metal ion complexes involving one or more N-ligands (His residues) are stable to the volatilization/ionization processes associated with both MALDI and ESI (1-6). More recently, we have shown that peptide-metal ion complexes involving multiple S-ligands (Cys residues) are also stable to the ESI process (7-9). Furthermore, we have shown that both MALDI-TOF and ESI mass spectrometry can provide detailed information on peptide-metal ion interaction stoichiometry (molar distributions), affinity, capacity, selectivity, and interaction mechanism(s) (1-9); information not readily available by other techniques.

The DNA-binding domain of the human estrogen receptor protein contains two C_2-C_2 type "zinc-finger" sequences that are thought to require bound Zn(II) for DNA binding. We have now used MALDI-TOF and ESI to determine that the fully reduced ERDBD peptide (9 cys residues) can bind Zn(II), but it also binds Cu(II); the capacity and affinity of the ERDBD for Zn(II) and Cu(II) are quite different.

EXPERIMENTAL

The 71-residue estrogen receptor DNA-binding domain (K180-M250) was prepared by solid phase chemical synthesis, purified, and characterized as described previously (7,8). MALDI was performed on a Vestec Model 2000 linear TOF mass spectrometer as described previously (1-6). ESI was performed on a Vestec Model 201 single quadrupole mass spectrometer as described previously (7,8).

RESULTS

The calculated molecular mass of the ERDBD apopeptide (metal-free) in its fully reduced state (8248.5 Da) was observed by both MALDI-TOF and ESI. As reported previously for metal ion interactions with N-ligands (5), the use of sinapinic acid (3,5-dimethoxy-4-hydroxycinnamic acid) as a matrix for MALDI-TOF precluded the observation of ERDBD with bound metal ions. Furthermore, the use of 2,5-dihydroxybenzoic acid as a marix resulted in the formation of multiple covalent adducts due to reactivity with reduced Cys residues. Thus, the interaction of the ERDBD with Zn(II) and Cu(II) was investigated by ESI [e.g., Figure 1 shows the fully reduced ERDBD (left panel) and the ERDBD with 4 bound Cu (right panel)]; peptide-metal ion complexes were observed by electrospray from water alone or with up to 10 mM ammonium acetate. A Cu-induced conformational change is indicated by a frame-shift in the ESI charge envelope from 10^+ (fully reduced ERDBD) to 8^+ (ERDBD-Cu complex). Observed mass values for the ERDBD with up to two bound Zn(II) ions $[M+xH+yZn-4yH]^{x+}$ or four bound Cu(II) ions $[M+xH+yCu-2yH]^{x+}$ was consistent with a *tetra*coordinate covalent and *bi*coordinate covalent interaction geometry for bound Zn(II) and Cu(II) ions, respectively. Under all conditions tested (electrospray solvent composition and pH), added Cu(II) ions were bound with a greater capacity and affinity than were added Zn(II) ions. Metal binding stoichiometry at saturation was verified by spectrophotometric UV titration, atomic absorption, and by isotope dilution and thermal ionization mass spectrometry.

CONCLUSIONS

We conclude that 1) sulfur-dependent peptide-metal ion interactions are stable to the electrospray ionization process, 2) additional matrices are needed to optimize the investigation of sulfur-dependent peptide-metal ion complexes by MALDI-TOF, 3) by ESI, the anticipated Zn-binding stoichiometry was confirmed, 4) only peptides in the fully reduced state (8248.5 Da) were capable of binding two Zn(II) ions in the correct (i.e., tetracoordinate) geometry, 5) the ERDBD has a 2-fold higher capacity and a minimum 100-fold higher affinity for added Cu(II)

ions. Furthermore, relative to the ESI charge envelope observed for the fully reduced ERDBD apopeptide (10^+ optimum charge state) and the ERDBD-Zn complex (also 10^+ charge state optimum), the charge state optimum observed for the ERDBD-Cu complexes (8^+) demonstrated that bound Cu ions induce and/or stabilize a different conformational state (8).

Mass Spectrometric Investigations of Proteins Separated by 2-dimensional Electrophoresis

*Wenzhu Zhang [1], Ruedi Aebersold [2], Daniel Hess [2] and Brian T. Chait [1],
[1]The Rockefeller University, 1230 York Ave., New York, NY 10021

2-dimensional electrophoresis is a high resolution technique for spatially separating proteins in a complex protein mixture on the basis of mass and charge. The separation is performed in an anti-convective matrix, typically polyacrylamide gel and the separated proteins can be transferred to a membrane to facilitate structural analysis.

We have begun a program to investigate how proteins are processed and modified in biological systems by measuring molecular masses of proteins separated by 2-dimensional electrophoresis and also by obtaining peptide maps of these separated proteins.

To establish the method, we experimented with three isoforms of bovine casein and employed pepsin, trypsin and cyanogen bromide digestions to generate peptide fragments. The digestion reactions were performed directly on the separated protein spots on the membrane. With no further purification step, a fraction of the resulting peptide fragments was extracted from the membrane and subjected to matrix-assisted laser desorption mass spectrometry, using α-cyano-4-hydroxycinnamic acid as matrix. From the resulting mass spectra, we are able to construct maps of the peptides generated from the three isoforms of casein (e.g. see figure 1) and to identify sites of modification. As seen from figure 1, for the isoform shown, the entire bovine casein sequence is covered by peptide fragments identified in the mass spectra. Figure 2 shows the mass spectrum of the trypsin digest of this isoform. Twelve out of twenty one expected peptide fragments are identified and labeled with corresponding peptide numbers. The other nine expected peptide fragments were not identified. Eight of them have masses less than 400 u., which is difficult to detect. However, the mass of the remaining missing fragment is over 2300 u. and the reason for the absence of this peptide has not yet been elucidated. There are also many other peaks in the spectrum that were not identified.

Sensitivity has been tested on bovine serum albumin using cyanogen bromide digestion to generate peptide fragments. Intense peptide spectra were obtained for a total of 300 picomole loaded onto the 2-dimensional gel. An equally strong mass spectral response was observed when 75 picomole was loaded onto the gel. At 15 picomole loaded onto the gel, the peptide peaks, though clearly present, were much diminished in intensity.

Present efforts are directed towards further improvement in sensitivity and application of the technique to the solution of biological problems.

Capillary electrophoresis (CE) has gained rapid acceptance as a high resolution separatory technique complementing high-performance liquid chromatography (HPLC), and its application has been extended to a wide variety of compounds including proteins and peptides. This technique is characterized by small sample loadings (injection volumes are typically a few nL down to the pL range) and high separation efficiencies (in excess of 10^6 theoretical plates in less than 20 min [1]). Separation of proteins by CE presents unique challenges to the analysts as these biomolecules strongly adsorb to the inner walls of the fused silica surface. Minimisation of the electrostatic interactions of proteins with the negatively-charged walls can be achieved using buffers of high pH or altering the capillary surface with derivatisation agents or coating the capillary walls with polymers. The separation of closely related myoglobins by CE combined with electrospray mass spectrometry (CE-ES-MS) was demonstrated recently by Smith et al [2] using tris buffer pH 8.3 where the analytes were separated as anions and detected as cations. However better sensitivity is usually obtained when the proteins are both separated and detected in their cationic forms as demonstrated by Mosely *et al* with aminopropylsilane (APS) derivatised capillaries [3] or by coating the capillary using a cationic polymer [4]. Using this latter approach sub-picomole detection of proteins is usually achievable for acquisition performed in full-mass scan mode.

As an extension to our early study [4], we compared the performance of different types of modified capillaries in terms of their separation efficiencies and detection limits for the analysis of proteins by CE-ES-MS using polarity reversal and acidic buffers. A comparison of separation performed by CE-UV and CE-ES-MS is shown in Figure 1 for a mixture of 9 peptides and proteins ranging from 1,638 to 78,030 Da using a 0.1N formic acid buffer. The capillary was conditioned with 5% Polybrene and 2% ethylene glycol prior to the separation. With the exception of carbonic anhydrase I (human erythrocytes) and bovine serum transferrin, separation efficiencies were in excess of 150,000 theoretical plates in all cases. Figures 1B and 1C show the CE-ES-MS analysis conducted in selected ion recording (SIR) mode for sample loadings of ≈ 0.1 ng and 0.6 ng per component respectively. Comparison of Figures 1B and 1C indicated an improvement of a factor of 1.1-2 in separation efficiencies between the two sample loadings. Analyses conducted by CE-UV and CE-ES-MS on similar sample sizes (Figure 1A and 1C), yield comparable separations except that the peak widths observed by CE-UV were on average narrower by a factor of 2. The broadening of the CE peak observed in the CE-ES-MS analysis is thought to arise from the nebulisation of the analyte emerging from the CE column and from the transport of ionic species through the interface of the mass spectrometer. Table I presents the separation efficiencies obtained by CE-UV and CE-ES-MS (SIR) for a mixture of peptides and proteins corresponding to the injection of ≈ 0.6 ng per component.

Using a Polybrene-treated capillary, full mass-scan acquisition (m/z 800-1600) was obtained for the injection of 20-100 fmoles of the same mixture used for Figure 1. The mass spectra obtained provided abundant multiply charged ions from which the molecular weights of individual proteins could be deduced. The observed molecular weights were in good agreement with the predicted masses deduced from sequence information, and accuracies of 0.03% were generally obtained. Different types of modified capillary surfaces were also investigated for the analysis of proteins using acidic buffers. Separation efficiencies obtained with capillaries derivatised with APS, [(3-methacryloyloxy) propyl] trimethyl ammonium chloride (MAPTAC) were compared with those obtained with capillaries coated with Polybrene. Plate counts obtained with APS derivatised capillaries were generally lower by a factor of 1.5 compared with those obtained on either Polybrene or MAPTAC capillaries. However recoveries of proteins with MAPTAC derivatised capillaries were much lower than those observed with either APS or Polybrene, and injection of 10 times more concentrated solutions was necessary to obtain similar signal/noise ratios. The lower recoveries observed with MAPTAC capillaries are possibly due to stronger adsorption of the proteins on the modified polyacrylamide surface.

For practical considerations, Polybrene-coated capillaries were preferred for the separation of proteins and peptides. The Polybrene treated capillaries yield efficient separation of closely related proteins such as algal cytochromes C and glycoforms from ribonuclease B. Furthermore, the capillary can be

stripped of its coating by a simple washing with NaOH to regenerate the original silica surface, and can be used for separations requiring basic buffers. An application of this was demonstrated for the monitoring of an enzymatic digest of an octadecapeptide by a prolyl endopeptidase. A small fraction of the 30 µL digest was injected each 25 minutes. Identification of the site of cleavages could be unambiguously identified by the combined CE-ES-MS analysis.

SPATIALLY RESOLVED ORGANIC SURFACE ANALYSIS

J. T. Brenna

Division of Nutritional Sciences
Cornell University
Ithaca, New York

Spatially resolved organic analysis is a topic of great importance for surface science and industrial applications. In spite of its relevance the field is in its infancy. Until recently, instruments specifically tailored to the unique demands of organic microanalysis were nearly non-existent. Approaches to organic microanalysis combine the older distinct fields of organic mass spectrometry with elemental microanalysis.

Non-spatially resolved organic surface analysis by mass spectrometry has been a topic of great interest over the past 15 years and is now a powerful means to detect chemical changes on surfaces. A wide variety of phenomena have been described and are employed for surface sampling. For instance, matrix-assisted laser desorption (MALD), is the subject of numerous reports in this volume.

Elemental microanalysis is now a mature field in which several approaches are employed based on the demands of the particular analysis. The most prominent techniques, Electron Microprobe X-ray Microanalysis, Auger Electron Spectroscopy (AES), X-ray Photoelectron Spectroscopy (XPS), and Secondary Ion Mass Spectrometry (SIMS), account for 90% + of the surface analytical equipment in use. Of these, X-ray microanalysis and AES are employed to derive exclusively elemental information, princlply because they involve transitions of core electrons which do not carry unambiguous information about valence electrons. XPS, also involves core transitions but is commonly used to deduce bonding information as well as elemental information, since the transitions are related to the energy states of valence electrons in a straightforward way. However, SIMS is the only technique which has the *capacity* to provide true molecular information.

Traditional SIMS instruments are tailored to the requirements of elemental and isotopic analysis. Generally, monatomic ions are employed for analysis and steps are taken to eliminate interference from molecular species such as hydrides and oxides. The mass range can therefore be often limited for sector instruments to m/e 250 at full accelerating potential. Further, the requirement for high mass resolution can be tailored to fit all interferences up to a specific case, which are usually in the M/DM = 10,000 range since mass defects in small molecules tend to be substantial. Clean vacuums are required to minimize adsorption of residual gases onto the analysis surface. Transmission is optimized, often at the expense of mass resolution, to provide a wide dynamic range typically 7 orders of magnitude for a single analyte in a single analysis. Although there are numerous reports of organic surface analysis using instruments intended for elemental analysis, most applications are limited to special cases.

Spatially-resolved organic surface analysis presents a set of very challenging issues apart from elemental microanalysis. Firstly, the range of possible analytes consists of all possible organic molecules, which is clearly orders of magnitude greater than the number of stable and long-lived isotopes of the elements. The practical consequence of this inherent complexity is the requirement for high selectivity. Approaches such as high mass res-

olution, MS^n, resonant multiphoton ionization, which have been successful in non-surface applications might be employed.

Secondly, lability of molecular analytes is much greater than for elemental analytes. The energy transferred to the analyte in the volatilization process inherently must be of the order of magnitude of chemical bond energies, since intermolecular forces hold molecules on surfaces. This issue has prompted a great deal of activity in non-spatially-resolved organic surface analysis in areas such as MALD and electro-deposition. However, surfaces manufactured specifically for analytical requirements are of *very* limited use for microanalysis simply because such pretreatments destroy the spatial information. For this reason, all pre-treatment schemes for improvement of microanalysis must meet the basic requirement that the spatial analyte distribution is not disturbed at the resolution level of the analysis technique.

Finally, quantitative analysis of many orders of magnitude is likely to emerge as a critical issue in organic microanalysis as it did with elementals. Once the requisite sensitivity and specificity for particular analysis is achieved, quantitative issues will become important. There is a large body of empirical information on secondary ion formation in SIMS, but theorical treatments are ineffective for most practical purposes. Any approach to calibration for organics is expected to face the same problems are elementals, with the added issue of analyte loss due to damage by the excitation source.

While the field of organic microanalysis is in its infancy, approaches are now appearing to address many of these issues. This symposium covers many of the major ideas which hold promise. Early efforts using a time-of-flight (TOF)-based Nd:YAG-*laser* microprobe system have revealed much of the potential and limitations of commericially-available instrumentation of older designs. High transmission/high mass range/high mass resolution imaging time-of-flight (TOF) instrumentation is employed to address some of the limitations of earlier designs. Laser or ion beam volatilization are known to produce superior results depending on sample characteristics.

Additional dimensions of selectivity can be obtained by use of MS^n, as has been achieved by triple quadrupole SIMS and ultrahigh mass resolution available to Fourier transform mass spectrometry (FTMS). The spatially-resolved FTMS experiment has been executed exclusively using a single laser and has provided unique results. Finally, the volatilization and ionization can be separated in a two laser experiment using low power laser for desorption and second laser for ionization. This latter approach is expected to be very gentle and potentially highly selective and sensitive.

Future advances in organic microanalysis will include combinations of the approaches represented in this symposium.

Molecular Imaging SIMS: Limitations and Future Prospects

Greg Gillen,
Surface and Microanalysis Science Division,
National Institute of Standards and Technology, Gaithersburg, MD 20899

One of the most intriguing aspects of secondary ion mass spectrometry (SIMS) is its ability to characterize fragile organic molecules with very high sensitivity. Coupled with the imaging capability of state of the art SIMS instrumentation it should be possible to produce high spatial resolution ion images of organic molecules on surfaces. While this has proven practical in some systems, the general use of molecular imaging SIMS in real samples (biological tissue, for example) at physiological concentration levels has remained an elusive goal. A simple calculation illustrates the difficulty inherent in micrometer spatial resolution molecular ion imaging. Acetylcholine in rat brain is found at a bulk concentration on the order of $2x10^{-5}$ M, giving ~ 10^4 molecules/μm^3 of tissue that are available to be sampled. Factoring in a secondary ion yield of 10% and an instrument transmission of 10%, 100 molecules should be detected per cubic micrometer of the sample. Unfortunately, each primary ion, while desorbing one or more molecules from the surface layer, penetrates below the surface undergoing numerous collisions that can rupture bonds in many more molecules. After the outer layer has been removed by sputtering, few intact molecules would be expected to remain below the sputtered surface for a depth on the order of the primary ion range (~10-20 nm for normally incident 10 keV Ar^+.) Molecules lying below the damaged layers would, in turn, be expected to be fragmented by the penetrating primary ions before they are exposed by the continuing erosion of the sputtered surface. This process limits the number of molecules that will contribute to the analytical signal to those located in the outermost layers of the sample. In the example above, less than one ion per pixel would be detected. Because of the extremely sample-limited nature of molecular SIMS, much of the recent work in the field has focused on the development and application of time-of-flight (TOF) SIMS instrumentation to molecular ion imaging. The high secondary ion transmission and parallel mass detection capability of these instruments makes the most efficient use of the available signal. Another approach, the focus of our work at NIST, has been to study the fundamental parameters which influence the yield of intact, identifiable molecules. We have found several areas where optimization of experimental parameters can increase the likelihood of generating enough signal to produce meaningful molecular ion images. Several of these are listed below:

1. Primary Beam Damage

There is increasing evidence that many compounds may be more resistant to primary beam damage than previously expected. For example, dilution of various organic compounds in solid ammonium chloride is stated to result in enhanced molecular secondary ion signals, less fragmentation and increased sample longevity, compared with the undiluted compounds (1,2). Similar advantages were obtained by sputtering compounds from frozen aqueous solutions, a matrix chosen as a model for frozen hydrated biological tissue (3,4). Gillen, et al. found that frozen solutions ($1x10^{-3}$ M) of quaternary ammonium salts exhibited high and stable molecular ion signals, suitable for imaging, after primary ion doses exceeding $1x10^{15}$ ions/cm^2, and that ionization efficiencies from this system were several orders of magnitude higher than for neat compounds (3,4). Extrapolation of the parent ion signal-primary ion dose curve indicates that intact parent molecular ion signals would have been observed at doses greater than $1x10^{17}$ ions/cm^2, corresponding to an erosion depth of ~ 1 μm. Molecular ion emission at high primary ion doses has also been observed in polymer systems. In particular, characteristic fragment molecular ion signals have been observed after prolonged ion bombardment in high sputter yield (5) fluorinated polymers such as Polytetrafluoroethylene (PTFE) (6,7). More recent studies have indicated that for many bulk organic compounds, bombardment-induced fragmentation of parent molecules saturates at primary ion doses of $1\text{-}8x10^{14}$ ions/cm^2. Subsequent ion impacts cause little further accumulation of damage in the sample, and intact parent molecular ions are sputtered even after prolonged ion bombardment (i.e., primary ion doses $>1x10^{16}$ ions/cm^2). The results of this work indicated that conditions that minimize the influence of damage and maximize the parent ion signal include the use of lower primary ion impact energies, oblique primary beam incidence angles and more massive primary ions (8).

2. Sputter Yield

The number of molecules sputtered per incident primary impact is typically 30-60 molecules/ion (9). In order to maximize the signal intensity and also to minimize primary beam damage, conditions should be used that maximize the sputter yield. Preliminary studies of amino acid films have suggested that a peak in the sputter yield curve occurs for Argon bombardment at a primary impact energy of 10 keV (10). Further studies are being completed to measure independently the influence of both the primary impact energy and impact angle on the sputter yield and to determine the influence of primary ion dose on the measurement.

3. Secondary Ion Yield

Another important parameter which governs the potential success of a molecular imaging experiment is the secondary ion yield of the analyte molecule. Based on ion yield considerations, the highest signals will be obtained from preformed ions such as quaternary ammonium salts, followed by protonated and adduct molecular ions, and finally by radical ions. Experiments aimed at increasing the secondary ion yield would appear to be a fruitful avenue of research. In our laboratory we are experimenting with in-situ cationization using lithium to enhance ion yields from species which typically form protonated molecular ions. In addition to ion yield enhancements, there is evidence that lithium adduct species have smaller damage cross sections than protonated molecular ions (11). We have also observed the presence of molecular secondary ion yield matrix effects. In an experiment in which gelatin films were doped with various concentrations of tetrapentyl ammonium bromide, a saturation in signal for the higher concentrations was observed (12). This fall-off in signal in not observed for cocaine (preformed molecular ion vs. protonated molecular ion). For tetrapentyl ammonium bromide, the fall off may be due to a higher probability for reneutralization with increasing counter ion concentration (a similar saturation in signal has been observed for other tetraalkyl ammonium salts and methylene blue). The observation of molecular matrix effects suggests that care will have to be taken in the interpretation of quantitative data from real samples in which localized analyte molecular concentrations (or localized counter ion concentrations) may result in smaller secondary ion signals than from adjacent regions where the *true* concentration is actually lower.

4. Detection Limits/Background/Quantitation

Recently, experiments have been conducted using doped, spin-cast gelatin films to mimic the behavior of compounds in tissue (12). One of the most severe drawbacks in analyzing compounds in gelatin (and tissue) matrices is the presence of a discrete background arising from polyatomic cluster ions. This background can severally degrade detection limits for lower mass analyte compounds. Even for a compound such as acetylcholine, which is considered to have a high ion yield, the detection limit range for the parent cation (m/z 146) was between 0.001 gm/gm (0.1 wt%) and 0.01 gm/gm (1 wt%). Similar poor detection limits were obtained for other lower mass compounds such as epinephrine and tetraethyl ammonium bromide. In general, we have found that compounds with higher molecular weights give better detection limits even in cases where their ion yields may be lower. Protonated molecular ions such as cocaine and several of the barbiturates gave detection limits of ~ 100 ppm by weight. High secondary ion yield compounds, such as tetrabutyl and tetrapentyl ammonium bromide, gave detection limits of less than 10 ppm and linear response curves over several decades of concentration. In addition to bulk analysis, the homogeneity of the doped, spin-cast films makes them ideal as standards for quantitative molecular imaging. Linear working curves for compounds such as tetrapentyl ammonium bromide (generated using a slow-scan CCD camera) have been obtained over a concentration range of 2×10^{-5} gm/gm to .02 gm/gm.

Conclusion

In order to maximize the possibility of generating useful molecular images, one must be aware of the factors which influence the yield of intact molecular ions. Experimental conditions should be chosen to minimize primary beam damage. In general this involves lower impact energies, oblique incidence angles and more massive primary ions. Compounds which have high ion yields, such as organic salts, will almost always be much easier to image. If the ion yield of the compound to be analyzed is low, it may be possible to increase the ion yield in-situ by using cationization. Valuable information about the feasibility of a particular analysis may be obtained by examining the compound in a model tissue matrix before the actual analysis. This is particularly useful for determining the detection limit for the analyte compound.

Evaluation of the laser microprobe with time-of-flight mass spectrometer for organic surface and micro-analysis.

W. Van Roy, L. Van Vaeck and R. Gijbels
Department of Chemistry, University of Antwerp (UIA), B-2610
Wilrijk, Belgium

During the last decade, the rate of growing of methods for micro- and surface analysis of solids has been breathtaking. Laser microprobe mass spectrometry (LMMS) in particular with a time-of-flight (TOF) analyzer, has been shown to represent a suitable tool for the qualitative investigation of organic and inorganic consituents at the surface of solid samples in a variety of applications. The potential of the technique arises from the use of a focused laser beam to produce ions and the application of TOF MS for characterization of the generated species.

First of all, laser irradiation of solids provides a unique degree of experimental flexibility as to sample characteristics and ionization process. On the one hand, photon-solid interaction does not induce charging of dielectrical specimens as opposed to the primary ions beam in e.g. secondary ion MS (SIMS). An uncharged excitation beam does not affect the other fields e.g. applied for ion focusing and extraction. Laser characteristics i.e. directionality, monochromaticity and intensity, allow the design of an ion source for analysis in transmission or in reflection of thin or thick samples respectively with a very high spatial resolution, down to the diffraction limit of 0.5 μm at a laser wavelength of 266 nm. Specifically for organics, the extremely fast heating of the solid ensures the intact release of thermolabiles. On the other hand, the easy laser beam attenuation permits to largely vary the energy regime during ion formation. High power density conditions favour the production of elemental ions while the threshold mode suits organic analysis. Moreover, given processes can be favoured or discriminated, against e.g. the production of radical molecular ions, gas phase cationization, ion-molecule interactions, etc.

Secondly, the MS detection implies the capability to deal with a large variety of organic compounds even in complicated mixtures, as opposed to e.g. IR based spectroscopic techniques. Furthermore, MS yields "complete" information, i.e. molecular weight (MW) and functionalities. A TOF type analyzer offers high transmission, panoramic detection without scanning and a m/z range only limited by the desired mass resolution. Commercial instruments are completely optimized as a function of the ultimate sensitivity. Hence, continuous ion extraction is applied, making the TOF system depending on the kinetics of the ion formation process. As a result, severe limitations are imposed to the application area, in particular for organic analysis.

In practice, we experienced that the accuracy of the m/z determination and the resolution depend on the desorption characteristics of the compound. Ionic compounds are less suitable to TOF LMMS than the corresponding neutral analogs. The problems in TOF LMMS probably relate to the insufficient time-definition of these ions, which then only give rise to a continuous background. As a result, the useful MW range remains limited to about 500-1,000 Da. The m/z determination in TOF LMMS is less precise than e.g. in plasma desorption or static TOF SIMS.

Ion formation during laser microbeam irradiation of organic solids has not been fully understood yet. Theoretical studies stress the complicated nature of the energy deposition processes. In practice, the local regime depends on numerous microscopical parameters, which

cannot be controlled. Hence, quantitation is not yet feasible in general. The same applies to automated analysis because the mass spectra depend on the focus position as a function of the surface irregularities. Also fingerprinting approaches suffer from the same effects.

Consequently the real strengths of the TOF LMMS technique resides in the detailed structural information obtainable from organic compounds, the extensive speciation capabilities of inorganic substances, the surface sensitivity and the versatility for problem solving tasks. As to the first aspect, TOF LMMS has been shown to produce very informative mass spectra, which are frequently superior to fast atom bombardment (FAB) and SIMS data. In contrast to FAB MS, TOF LMMS produces spectra without matrix contribution. Furthermore, the fragmentation generally reflects a lower energy distribution of the parent ions and hence, the structure specificity of the daughters is better. Apart from the field of polymers, TOF LMMS yields a significantly larger number of structurally specific fragments compared to static TOF SIMS. Concerning inorganic speciation, the molecules are detected as adducts with the counter-ion, positive or negative, in the same way as organics. Hence, the relation of the resulting mass spectra with the original sample composition becomes straightforward in contrast to e.g. static SIMS. In respect to surface sensitivity, model system studies have evidenced that the organic structurally relevant ions issue from the upper 50 nm surface layer, even when a 1 µm deep crater is evaporated. In conclusion, TOF LMMS offers the possibility to detect organic and inorganic information from a large variety of materials with minimal sample preparation. Hence, the technique typically suits to industrial problem solving tasks as a first screening method, yielding valuable indications about the organic or inorganic nature of the cause in a short time.

At this moment, it has become clear that the actual TOF LMMS requires further developments to fulfil the high expectations. Several laboratories focuse their research on the laser ionization. It is tried to improve the time definition of the initial ion bunch by shorter pulses and different wavelengths. However, it turns out that shorter pulses imply an increased power density. This leads to the destruction of organics. The same applies to the use of excimers with shorter wavelengths. A tunable dye laser increases the selectivity of ion formation. However, tuning of the laser to the absorption of the target in the analysed solid is in practice not possible for heterogeneous samples.

An alternative approach aims at a laser microprobe on the basis of Fourier transform (FT) MS, offering a promising combination of high mass resolution capabilities and sensitivity. Panoramic detection is performed without scanning. The mass accuracy permits determination of the exact elemental composition of the detected ions. FTMS is virtually not affected by the precise kinetics of the ion formation process. As a result, laser FTMS has been shown to produce structural ions from polymers as opposed to TOF LMMS.

Oak Ridge, TN 37831-6365

We have developed an organic secondary ion microprobe that employs a large field of view (ca. 1.5 cm) and MS/MS. Associated with this large field of view is a spatial resolution of 100 μm. This instrument can be used to produce organic ion micrographs based on intensity of secondary and descendent ions obtained from an array of 40,000 of these 100μm X 100μm resolution elements. This large resolution element allows sampling of analytes low in concentration with sufficient sensitivity that the images produced show good contrast. The intended application of the instrument is determination of the spatial distribution of targeted analytes in biological tissue samples.

Figure 1a shows a photographic image of a sample of dog adrenal tissue mounted on the target stage. The central dark region of the sample corresponds to the medulla, with the surrounding light gray area corresponding to the cortex region. Epinephrin (adrenalin) and norepinephrine are found mainly in the medulla region of the sample, mainly bound in chromaffin granules. These granules have diameters <0.1 μm, and cannot be distinguished using this instrument. Corticosteroids are found mainly in the cortex.

Figure 1b shows the total positive secondary ion image of the sample. The most notable feature of the image is that emission from the medulla region is substantially different from emission from the cortex. The reason for this is unclear, but it marks the first reported observation of a <u>matrix effect</u> on molecular secondary ion emission from a biological tissue.

Figure 1c shows the distribution of the secondary <u>m/z</u> 184 (epinephrine cation) intensity from the same tissue. Note that its emission is enhanced from the medulla region of the sample. This is the expected result. There is also some evidence that epinephrine is distributed around the periphery of the sample. This may be a result of the sample preparation method, i.e., epinephrine eluted to the periphery of the sample during drying.

In principle, these images could also be produced using tandem mass spectrometry. However, when MS/MS was attempted, the intensity of the main descendent ion $(M-H_2O)^+$ from the <u>m/z</u> 184 was insufficient to produce a satisfactory image. While MS/MS with a triple quadrupole system may have a CAD efficiency of 100%, sensitivity is lost because (a) two stages of mass analysis are required, (b), not all the precursor ions can be dissociated, (c), the precursor ions dissociate to different descendent ions, and the intensity of only one daughter ion can be measured at a given time; the rest are lost. It is clear that improved sample preparation methods will be required before SIMS/MS images can be obtained from adrenal tissue. Furthermore, it must be demonstrated that images can actually be obtained using MS/MS, using a sample in which the distribution of targeted analyte can be verified using other methods.

The imaging capabilities of the SIMS/MS probe are demonstrated in Figure 2, which shows various images obtained from a KCl solution of glycerol into which has been placed a crystal of asparagine. Secondary glycerol-$^{41}K^+$ adduct, protonated asparagine and sputtered Cs^+ are all isobaric at <u>m/z</u> 133. Figure 2a shows the image based on the intensity of all <u>m/z</u> 133 secondary ions. Figure 2b shows the image based on the intensity of the secondary glycerol-$^{39}K^+$ adduct; this secondary ion image provides the reference necessary to show the distribution of potassium ion. Figure 2c shows the distribution based on the distribution of the $^{41}K^+$ descendent ion from the MS/MS of $^{41}K^+$-glycerol adduct at <u>m/z</u> 133. Note that figures 2b and 2c are nearly identical. Figure 2d shows the image of the descendent <u>m/z</u> 74 from protonated asparagine. The bright spot corresponds to location of the asparagine crystal, but this bright spot is completely invisible in Figure 2a.

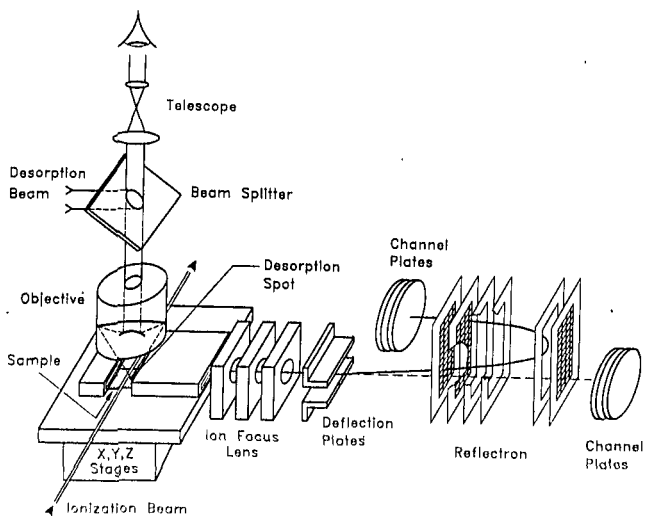
Laser Desorption Microscope Mass Spectrometry.

Mattanjah S. de Vries, Don Elloway, Heinrich E. Hunziker, and H.R. Wendt IBM, Almaden Research Center 650 Harry Road, San Jose, CA 95120-6099

Organic molecules on a surface constitute an analytical challenge. On the one hand there is an increasing need to detect and characterize small quantities of organic contaminants, on the other hand most surface analytical techniques are more suited for elemental, than for chemical identification. One increasingly successful approach uses laser desorption, combined with laser postionization and mass spectrometry, to detect large and fragile molecules on surfaces. This technique should be distinguished from laser ablation, in which secondary ions are detected and in which usually extensive fragmentation occurs. We have modified the laser desorption technique to allow for organic surface analysis with a high spatial resolution.

The desorption laser beam is combined with microscope optics and focussed to about one micron. Molecules are desorbed intact from this small area, postionized, and analyzed in a reflectron time of flight mass spectrometer. The small desorption spotsize is achieved with a reflective lens combined with a UV waveguide laser. The lens does double duty as a microscope objective for visual inspection. The sample is manipulated in vacuum by XYZ translation stages, driven by piezo inchworm motors. Feedback from linear encoders and computer control allow 2.5 cm travel while maintaining position accuracy of better than a micron. Desorbed molecules are ionized above the surface by a second laser. The ions are extracted by special ion optics into a reflectron time of flight mass spectrometer.

The performance of this, instrument is demonstrated with some recent applications, such as the study of microscopic organic particles.



BY JET ON A JOYOUS JAG

John B. Fenn

In my youth February was a memorable month because it meant escaping from school on the birthdays of Washington and Lincoln. Now in my seniority, it has lost some of its luster in a two-for-the-price-of-one scam by which we honor both both of those great men on a single "Presidents' Day". This year, however, February regained my affection because of two telephone calls on the day after the President's Day break. The first was from NIH with the welcome news that my program would be released from suspended animation. After eight consecutive strike-outs, our ninth proposal had driven in enough funds to get the lab back in the game. That in itself was reason enough for celebration but the next call brought gladder tidings of even greater joy. It was President Bob Murphy with the unbelievable news that I would be the lucky winner of the third ASMS annual award for Distinguished Contributions to Mass Spectrometry! Whether the award was for winning the grant, or the grant was for winning the award, or neither, 2/18/92 became a day to remember, a high point in my life.

Here and now, with mixed feelings of humility and pride, along with heartfelt gratitude to the giants of the past on whose shoulders we all stand, I accept this award on behalf of the many zealous colleagues with whose cooperation and support I have been blessed. They, along with many others of the ASMS fellowship, are largely responsible for having transformed Electrospray Ionization in a few short years from a bit player to a star in the theatre of mass spectrometry. Of course there is a price to be paid for this happy occasion. I am charged with the task of telling the story of ES development and you are obliged to hear it. That development, like others, has its roots in the efforts of many gifted investigators in many fields. Simply to enumerate their contributions, let alone to acknowledge them adequately, would take even more words than I sqandered in my too-long talk at the Conference, certainly more than I can fit in the four pages allowed for this written version. Therefore, I will construe my charge as an invitation to rush down memory lane, identifying a few milestones that may help trace the path that led me to this pinnacle.

Mass spectrometry may be viewed as simply the latest stage in the development of gravimetric analysis--that methodology by which Lavoisier buried the phlogiston theory, a notable milestone on the long road from the black art of alchemy to the science of chemistry. In that perspective my first step on the road to here and now might have been the essay I wrote for my freshman class in English Composition at Berea College in Kentucky. It was about Lavoisier's experiments on the oxidation of mercury. Neither I, the writer, nor Professor Weekes, the reader, really appreciated the significance of those experiments but he thought enough of my rhetoric to excuse me from class if I would turn in an essay each week for the rest of the term. My real initiation to the actualities of gravimetric analysis came in a sophomore chemistry course and was much less auspicious. I had to repeat the phosphate determination 32 times to obtain three results with acceptable reproducibility! Only Fate's whimsy can explain why my first job as a chemist, five years later, was in the Phosphate Division of Monsanto Chemical Company! Meanwhile, I had graduated from Berea in June of 1937, with a major in chemistry, my gravimetry problems not withstanding. Jobs were scarce but I did get accepted for graduate study at two universities, Northwestern and Yale. The former offered a larger stipend and reputedly had a better chemistry department but a number of bizarre reasons made me choose Yale. I thus postponed for half a century my chance to meet Malcolm Dole, then a young faculty member at Northwestern who became the founding father of Electrospray Ionization.

The highlights of my three years in New Haven included learning to play bridge, to drink beer, and to smoke a pipe, none of which had been permitted at Berea, or have much to do with mass spectrometry. My most important achieve-

ment was to persuade my bride of now 53 years to marry and support me during my last year in school. She, along with the vagaries of vacuum systems and the solvent properties of methanol-water, are the main vestiges of my graduate school days that survive in my affair with ESMS. However, I must mention another near encounter with a giant of its history. Just as I had come close to meeting Malcolm Dole by almost going to Northwestern, by actually going to Yale I came close to knowing another key figure in ES history, Professor John Zeleny. In the year I was born he had published the first definitive experiments on electrostatic dispersion of liquids and was still on Yale's Physics faculty, just across a lane from the Chemistry Department! Unfortunately, my only memory of him is a horizontal pipe that emerged from the highest gable of the Physics building. A small stream of water from that pipe played some sort of role in his measurement of electric fields in the atmosphere. To this day, the ghosts of both Dole and Zeleny still lurk in every ESMS experiment.

For 12 years after leaving Yale I worked in industry, starting, as noted, with Monsanto at Anniston, Alabama in 1940, thence to Sharples Chemicals at Wyandotte MI in 1942 and finally to Experiment, Inc. at Richmond, VA in 1945. Experiment was a small contract R&D company in Richmond, VA. that had been organized by Jim Mullen, a former colleague at Monsanto who had left there the same day I did. At Monsanto I had worked on development of processes to produce the then-unsuspected PAH's and PCB's. At Sharples it was still process development but the products became amines and mercaptans, famous for their pervasive fragrance. On many occasions I have walked into a bar or restaurant after the evening shift, only to have all the other customers walk out within a few minutes! My seven years at Experiment were an exciting adventure in research on combustion and propulsion problems related to rockets and ramjets or "flying stovepipes!" They gave me a conversational acquaintence with aerodynamics and its lingo of dimensionless numbers whose names honored such greats as Mach, Reynolds, Lewis, Prandtl and Rayleigh. Moreover, those years gave me enough of a reputation in combustion and propulsion to attract an offer from Princeton University to become director of Project SQUID, a program of "pure and applied research relating to jet propulsion" administered by Princeton University for the Office of Naval Research. Having spent the best part of my youth in the groves of academe I had long hoped for a chance to return. The invitation from Princeton thus seemed like an answer to a prayer, so I went to "Old Nassau", that "best old place" to which its alumni yearn to return.

Project SQUID comprised a prime contract between Princeton and the Navy. The research was carried out by a set of subcontractors including at any one time from 15 to 20 academic and industrial groups. The position of the director carried "the rank of professor" but his function turned out to be largely administrative. Not associated with any department he was not really a member of the academic family. Even so the job was not only stimulating, challenging and instructive, it provided lots of opportunities to meet with many scientists in government, industry and universities. A rewarding "spin-off" was the chance to spend the year of 1955 as a Scientific Liaison Officer for ONR London with an "obligation" to visit combustion and propulsion activities in laboratories all over western Europe. To this day, 36 years later, our three children identify that year as the all time high point in the Fenn family fortunes. It was also where my long love affair with free jets and "seeded beams" began.

By that time (1955) I had spent ten years, (over a quarter of my life!) in research on the phenomena and reactions of combustion. That experience had convinced me that flames, the most studied embodiment of combustion reactions, were much too complex in structure, composition and behaviour to be suitable for controlled experiments on reaction kinetics. In casting about for new approaches I began to think in terms of scattering experiments with intersecting molecular beams of the kind that had already earned Nobel Prizes in physics for Otto Stern and a number of his disciples including Isidor Rabi, Polykarp Kusch, Willis Lamb. Charles Townes and Norman Ramsey later joined that group. There had been a few attempts to carry out reactive scattering with intersecting beams but it was not until 1957 that Datz and Taylor reported their landmark

studies with intersecting beams of K atoms and HBr molecules. Their results stimulated a surge of activity that has already produced three Nobel laureates in chemistry, one of whom, Yuan Lee, gave the ASMS plenary lecture on 4 June.

To study combustion reactions would require beams with much higher intensities and energies than could be obtained from the effusion sources everyone was using. A paper by Kantrowitz and Grey in 1951 had proposed that low density supersonic free jets could produce beams with much higher intensities and narrower velocity distributions than effusive sources could provide. Marginal confirmation of this idea came that same year in experiments of Kistiakowsky and Schlicter. Convincing evidence came in 1954 from Becker and Bier at Marburg who used free jets to produce intense beams of hydrogen. Somewhat tired of pure administration and eager to spend some time in the laboratory I obtained permission from ONR and support from NSF in 1959 to pursue the wild idea I had had in London that heavy molecules seeded into free jets of hydrogen or helium could be accelerated to produce beams of molecules with energies of several eV, high enough to overcome the activation barriers in many reactions including those of combustion. That same year I became professor of Mechanical Engineerin at Princeton, having been labelled a chemist for 20 years! To make another long story short, we built a beam machine with lots of pumping speed and in the next few years learned a lot about free jets including how to make beams with the energies we wanted. Unfortunately, when Jim Anderson collided jet accelerated molecules of HI with DI, his quadrupole MS could detect no trace of HD product even from collisions with 4 times the required energy. That exercise dubbed the "Michelson-Morley" experiment of chemical kinetics by my friend Mich Boudart, was disappointing. We had achieved unprecedented control of translatic al energy only to find it an unimportant component of activation energy. Years later, after the laser revolution, we learned what we should have known all along, that vibrational energy was the key. Even so, the amazing versatilit of free jets has provided so many other opportunities for exciting research tha we continue to uncover more possibilities than we can pursue.

In 1967 after 15 years at Princeton I accepted an invitation to join the faculty of Chemical Engineering at Yale. Returning to New Haven was probably the reason I am writing this story because it was there that the late Professor "Sandy" Lipsky of the Medical School showed me Dole's paper on ESMS of macromolecules. I was intrigued enough to interest a graduate student, Mike Labowsky who repeated Dole's experiments in our big vacuum system and obtained similar results. Both groups soon abandoned further efforts because the ion currents were so small and Dole's retarding potential method for weighing macroions was troublesome. Then in 1981 Masamichi Yamashita, a young chemist I had met in Japan, came to Yale. He had been working on clusters in free jets and was ready to try something new. I suggested that he take another look at ESMS, this time with analyte species small enough to be "weighed" with the quadupole analyzer we had used in the "Michelson-Morley" experiment. Gado was a delightfu colleague and a marvelous experimentalist. He was largely responsible for the reincarnation of ESMS after Dole and we had let it die. Out of the precious jun I hoard, Gado put together a system that except for the analyzer was similar to Dole's. Another important difference was that the bath gas flowed countercurrent to the drift of charged droplets and ions toward the orifice into the vacuum system. Not only did this change achieve better drying of ions, it insured the absence of solvent vapor in the gas entering the orifice, thus avoiding resolvation during the cooling of the free jet expansion. Malcolm Dole was in the audience when I discussed this resolvation at the 1985 ASMS conference in San Diego. After the session he told me he was most grateful to learn about resolvation, that he not realized it could occur and thought it explained some anomalies in his mobility measurements that he had not been able to understand. That was the only time I met Dole, but we later exchanged severa letters. He was a most gracious gentleman and I was proud to be mentioned in his autobiography. I often wonder what would have happened had I ignored Charlie Pauck's advice in 1937 and gone to Northwestern instead of Yale.

With his new system built of old parts Gado began to obtain a variety of fascinating results. The most provocative spectra were obtained with various non-volatile analytes including quarternary ammonium compounds and amino acids. Excitement was in the air when he dissolved a vitamin B tablet and obtained peaks for intact ions of all its components having masses below the 400 Da limit of our analyzer. These ES spectra showed good sensitivity, no sign of any fragmentation of the most fragile parent species and no evidence of any interference between components of a mixture. About that time Brian Green of VG Instruments came to visit Sandy Lipsky who brought him over to see our laboratory. He seemed very much interested in our results and immediately asked if the technique would work with larger species. When he learned that the upper limit of our analyzer was 400 Da, he arranged for VG to lend us a quadrupole with an upper limit of 1500 Da. By that time Gado had returned to Japan and Craig Whitehouse had joined my group. With the VG quad as its centerpiece, Craig designed and assembled a new system further modified by the substitution of a glass capillary for the orifice between the ES chamber and the vacuum system. This device made it possible for all external parts of the system, including the sample source, to remain at ground, thus minimizing an operator's exposure to high voltage.

The new quad was tempermental and required much humoring but when the moon was in the right phase it performed very well. We began to obtain beautiful spectra of peptides with molecular weights as high as 1500, the upper limit of our analyzer. We were intrigued by peaks for doubly charged ions in spectra for the larger peptides so Shek Fu Wong undertook a series of experiments with poly (ethylene glycols) or PEGs. We chose these materials because their structure and composition were essentially the same for all values of Mr, and because Union Carbide gave us free samples! We found that the number of charges (Na+) per ion increased regularly with Mr, reaching a most probable value around 22 at Mr's of 20,000 (and 4000 at 5,000,000 as Takashi Nohmi recently found.) To us these results were remarkable but when we presented them at the 1987 ASMS meeting in Denver, the only people impressed enough to comment were Chuck McEwen and Jack Henion! Chuck had been one of the first to recognize electrospray's promise and Jack's group had recently found it useful. Meanwhile VG had lost interest, having decided that Marvin Vestal's Thermospray was the wave of the future.

It was a year later at the San Francisco meeting that ES really made its mark when we presented the work of Chin Kai Meng and Matthias Mann showing that ES could make protein "elephants" fly even when they had Mr's as high as 40,000. Moreover, the multiplicity and coherence of the peaks in their mass spectra made a modest quadrupole able to determine their Mr's to within 0.1 per cent or less. That disclosure launched ES into orbit. Within months the groups at Cornell and Battelle had confirmed and extended our results. The rest, as they say, is history. Investigators everywhere became seduced and began turning out exciting results in such abundance that at this meeting, I am told, ES plays a major role in over 150 communications. In the skilled hands of their authors the technique has proved capable of more things than were dreamt of in my philosophy. There can be no greater reward for any scientist than to see his or her ideas and efforts stimulate so much interest and activity by both colleagues and competitors. When he also receives the tangible and audible recognition embodied in this occasion, he must and surely does feel much blest. Let him therefore close his chronicle as he did his talk with cherished lines from Walt Whitman:

A noiseless, patient spider,
I mark'd where on a little promontory it stood isolated,
Mark'd how to explore the vacant vast surroundings,
It launched forth filament, filament, filament, out of itself,
Ever unreeling them, ever tireless speeding them.

And you, O my soul, where you stand,
Surrounded, detached, in measureless oceans of space,
Ceaselessly musing, venturing, throwing, seeking the spheres to connect them,
Till the bridge you will need be form'd, till the ductile anchor hold,
Till the gossamer thread you fling catch somewhere, O my soul.

AMERICAN SOCIETY FOR MASS SPECTROMETRY

BUSINESS MEETING

Washington Hilton Hotel
Washington, D.C.
Wednesday, June 3, 1992

President Robert Murphy welcomed the attendees and called the Business Meeting to order at 9:40 am. He reported the ASMS to be a healthy and vital organization with a growing membership. The number of attendees at the present conference will reach 2200, which represents the largest meeting yet held.

The 1992 ASMS Research Award, sponsored by Fisons/VG Instruments was presented to Dr. Vicki Wysocki of Virginia Commonwealth University.

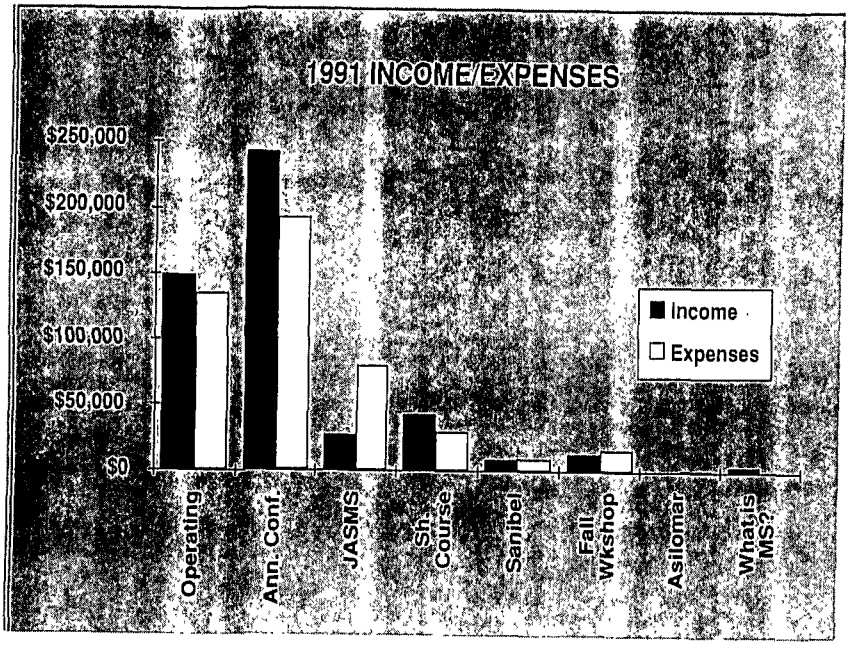
The 1992 ASMS Research Award sponsored by Finnigan MAT Corporation was presented to Dr. Kevin Schey of the Medical University of South Carolina.

Secretary Brian Chait reported the newly elected members of the ASMS Board of Directors: Vice-President for Programs, Chris Enke; Treasurer, Barbara Larsen; Members-at-large, Kenneth Busch and Jack Henion. Chait congratulated the recipients of the 1992 Student Travel Stipends to the ASMS Conference: Joseph Anacleto, Dalhousie University; Ann Qinghong, Emory University; John Caeser, Harvard University; Sesi McCullough Catalano, University of California, Davis; Brian T. Cooper, University of Arizona; Bedford Dwain Cox, Texas A&M University; Stephen Fuerstenau, Yale University; John Michael Gregson, University of Utah; Steven A. Hofstadler, University of Texas, Austin; Randall K. Julian, Jr., Purdue University; Brent L. Kleintop, University of Florida; Patrick Alan Limbach, Ohio State University; Baiwei Lin, Montana State University; Paul Michael Mayer, University of Ottawa; Philip H. Ratliff, University of Florida; Marin S. Robinson, University of Colorado; Anatoli N. Verentchikov, University of Manitoba; Paul G. Wenthold, Purdue University; Ten-Yang Yen, Oregon State University; Loreen C. Zeller, Purdue University; Xiaokui Zhang, Trent University, Peterborough.

Treasurer Jane Gale presented graphs that summarized the growth in ASMS membership and the growth in attendance of the Annual Conference between 1982-1992. During this time period, attendance of the Annual Conference has more than doubled to its present number of 2200 attendees. She also presented a summary of the total income and expenses of the ASMS for the years 1982-1991, which showed that the anomalous net loss incurred in 1990 has been reversed in 1991 (total income $525,000, total expenses $463,000). Gale itemized the income and expenses for 1991 (see Figure) and the projected income and expenses for 1992. Gale announced that six travel awards have been made to young scientists to attend the 1992 Kyoto Conference on Biological Mass Spectrometry; Francis Bitsch, Children's Hospital Research Institute, Oakland; David Dearden, The University of Texas at Arlington; Gary J.C. Paul, University of Montreal; Damon Papac, Medical University of South Carolina; Gary von Berkel, Oak Ridge National Laboratory; Vicki Wysocki, Virginia Commonwealth University.

Vice-President for Arrangements, Sanford Markey announced the locations and date for the next five ASMS meetings:

1993	San Francisco	Marriot	May 30 - June 4
1994	Chicago	Hyatt Regency	May 29 - June 3
1995	Atlanta	Marriot Marquis	May 21 - May 26
1996	Anaheim	Disneyland Hotel/ Pan Pacific	May 19 - May 24
1997	Kansas City	Hyatt Regency Westin (Crown Center)	June 1 - June 6



Markey reported that negotiations were under way for the 1998 site selection, where the most favored sites are Toronto, Boston, Philadelphia and Orlando.

Murphy thanked the outgoing members of the Board of Directors, P. Jane Gale, Robert J. Cotter, Michael T. Bowers and Ronald A. Hites for their considerable service to ASMS and presented each with a plaque. He also expressed appreciation for the outstanding efforts of Judith Watson, Executive Director of the ASMS.

Murphy announced that JASMS will expand to twelve issues in 1993. He encouraged the membership to press their organizations to take out library subscriptions to JASMS. He thanked Editor, Michael Gross for the high quality and success of the journal.

The meeting was adjourned at 9:58 am.

Respectfully submitted,

Brian Chait

Brian T. Chait
Secretary

YOUNG MASS SPECTROMETRISTS INTEREST GROUP

Workshop: Introduction to Management

The topic for this year's workshop was suggested by several graduate students at last year's conference. They were concerned that, although students are given extensive training in science, there is little if any training in the management of people, a skill that almost every scientist needs during his or her career.

John Stults opened the session by describing sources of further information. It was stressed that a one-hour workshop can only begin to give an idea of the wide range of concepts that are involved in management. Furthermore, the basics of management are equally valid for scientific and technical work, so specialized courses in "technical management" are not necessarily better than others. Formal courses in management are given by many colleges and universities. Many universities also offer shorter training courses, many of which are described in "Bricker's International Directory" (Peterson's Guides, Princeton NJ). Other courses are given by various organizations; among the best are the Center for Creative Leadership (5000 Laurinda Dr., P.O. Box 26300, Greensboro, NC 27438, ph. 919-288-7210) and The Forum Corporation (11400 Rockville Pike, Rockville, MD 20852, ph. 301-881-0866). A variety of short courses are offered by other groups, including ACS short courses. Finally, there are books, video tapes, and audio tapes available from many sources.

David Pinkston of Procter & Gamble gave a view of management based on the answers that he received by posing several questions to his colleagues. (a) As a new manager, how do you start working with an experienced technician? ...respect the knowledge and experience of a coworker; earn respect; make expectations clear; use strengths; develop weaknesses; don't oversupervise; give credit and praise fairly. (b) What surprises can you expect when beginning to manage? ...not everyone is highly self-motivated; others are not interested in your past accomplishments; you are in a powerful position; don't be afraid of failure. (c) How do you deal with negative behavior? ...seek the advise of others with experience -- peers and managers; confront fairly but firmly; do exactly what you said you would do. (d) What books would you suggest for people skills? ... "Getting to Yes," by R. Fisher and W. Ury [Penguin Books, 1991]; "Novations: Strategies for Career Management," by G.W. Dalton and P.H. Thompson [Scott, Foresman & Co., 1986] (e) What single piece of wisdom do you have related to people management? ...take it seriously; be flexible; be human; its never too soon to take on some management responsibilities in order to begin to develop these skills.

Rob Anderegg of Glaxo, who also spent a number of years as Assistant Professor at the University of Maine, offered three "pearls" that he gleaned/distilled from his years of management. (a) Management techniques are a means, not an end. Management skills are learnable. (b) Manage others as you would like to be managed. (c) As a manager, you are responsible for the development, motivation, and the environment of everyone in your group (and they should know that you understand this).

Rick Yost from the University of Florida examined some of the differences between academic and industrial management: Professors have immediate, extraordinary independence. The department has a non-hierarchical structure; other professors are your colleagues. You control your group size. You have a group of very young, very self-motivated workers who are "employed" for a fixed time period. There is a different set of priorities in academia: #1 -- personal growth of the worker, teaching "how-to"; #2 -- getting the work done. Rick gave two warnings to new professors: First, remember that students have a balancing act for their pressures (coursework, teaching, research). Second, different students require different styles of management. Rick also gave a series of recommendations: The role of a professor is advisor, friend, role-model, and father-figure. One should nurture creativity and independence, and instill enthusiasm. Be challenging, but not the source of frustration. Give students the resources to

succeed. On the ethics front, remember to test, not prove, hypotheses; most important advances arise from data that did not fit the hypothesis. Finally, make use of your resources -- your mentors, and your fellow faculty members. Rick particularly recommended the reading of "The Joy of Science" by Carl J. Sindermann [Plenum, 1985].

A lively question period followed these presentations. One person in particular asked why management is not part of a scientist's training. From the attempts by several to answer the question, it was apparent that, regardless of the reasons/excuses for not including management in a scientific curriculum, management skills are extremely important and need to be learned, and the sooner the better. Many at the workshop expressed a desire for further exposure to management techniques at future ASMS meetings.

Suggestions for future workshops: 1. More management concepts. 2. An introduction to vacuum systems.

Submitted by,

John T. Stults
Organizer, Young Mass Spectrometrists

REPORT ON PANEL DISCUSSION
The Status of Federal Grants

Five representatives of federal agencies which administer grants and have programs through which funding for mass spectrometry research can be obtained, participated in a panel discussion for ASMS, moderated by Dr. Robert C. Murphy. Present were:

Kenneth G. Hancock, Director, Division of Chemistry, National Science Foundation; James C. Cassat, Program Director, National Institute of General Medical Sciences; Harold Guard, Program Manager, Chemistry Division, Office of Naval Research; Clem D. Yonker, Office of Basic Energy Sciences, Department of Energy, Chemistry Division; and Charles Coulter, Acting Director, Biomedical Research Technology Program, National Center for Research Resources, National Institutes of Health.

Each of these administrators outlined the participation of the individual agency in funding mass spectrometry research. A summary of their remarks follows:

K.G. Hancock, NSF: Spoke about "balance points" of pairs of funding tissues which impact the health of science, as for example: 1) new education and training *vs* maintenance of current resources; 2) elitism *vs* populism; 3) federal funds *vs* non-federal funds; and 4) community pressures *vs* national priorities. Each of these areas affects funding decision and the individual scientist can affect each of these areas by a commitment of effort to influencing attitudes about these issues. With respect to individual grants, NSF tries to balance: 1) platforms *vs* the individual investigator; 2) staff review of proposals *vs* peer review; 3) investigator stability *vs* scientific flexibility; and 4) accountability *vs* free inquiry.

To strike this balance, Hancock said NSF is guided by policies and procedures which have set the following priorities for 1993:

With respect to research topic, NSF has the following five main priorities: 1) environmental chemistry; 2) advanced materials; 3) biotechnology; 4) high performance computing; and 5) non-linear sciences. With respect to programmatic function, NSF has established individual grants as a top priority, followed by instrumentation; centers and groups; and education and human resources.

Dr. Clem Yonker reported that all five divisions of DOE have interests in funding mass spectrometry, but that the chemistry division sections on separation and analysis and on processes and techniques offer the best possibilities for funding. More specifically, he reported that the section on separation and analysis was interested in developments in instrumentation related to spectroscopic methods (primarily laser programs) and mass spectroscopy. The main aims of this section was to seek understanding of the chemical and physical principles of analytical techniques with the goal to improve sensitivity and accuracy of chemical analysis.

Harold Guard, ONR, said that mass spectrometry funding opportunities are primarily in their chemistry division and that primary interests are in Naval and Naval related research, especially towards development of improved materials as well as study of ocean sciences. Solid state chemistry and fundamental processes are also of interest as they involve chemistry at surfaces. ONR is not interested in technique development, but does seek to fund instrument development as a means toward solving a specific problem of interest to the Navy. Dr. John Pazik is the solid state program manager (703-696-4410). Other agencies within the DOD with available funds include the Offices of Naval Applied Research and the Defense Advance Research Projects Administration (DARPA). DARPA is especially interested in environmental chemistry of higher molecular weight substances and in improved specification. Grants from ONR are not peer-reviewed and personal contact with a program administrator is exceedingly important for success in obtaining funding. Grants tend to range from $50-200K. On-line program information can be obtained via modem to FEDIX, 301-258-0953. Information can also be obtained at 1-800-232-4879.

James C. Cassat, NIGMS, urged investigators to call him at 301-496-7253 or Dr. Edward Zapolski at 301-493-7733 or Americo Rivera (Spectroscopic Techniques) at 301-496-7001 for detailed information about

specific programs at NIGMS. If a proposal targets a specific disease, NIGMS will refer it to the appropriate other institute as this agency funds primarily basic science and not disease related topics. Last year NIGMS funded 28 mass spectrometry grants averaging $170K for a total of $4.8M. The agency has three review rounds per year and several award mechanisms including regular research grants, first awards, small research grants, biotech research grants, and shared instrumentation programs. It was emphasized that investigator dialogue with program administrators is critical to improvement of the funding situation, a view which was forcefully re-enforced by each of the other panelists. Dr. Cassat also suggested that researchers contact their Congressional Representatives to inform them of the good work their lab is doing and the benefits to the community from their research efforts.

Charles Coulter, NCRR, said, in essence, that support for acquisition of expensive instrumentation is now nonexistent. NCRR is interested in funding problem-driven activity and the best source of funds for mass spectrometer acquisition is within the context of a problem important to a wide range of groups in this country. In 1990, 400 requests for funding in the shared instrumentation program were received, 41 of which were for mass spectrometry, 17 of the 400 requests received funding. NCRR currently funds five mass spectrometry centers with state-of-the-art instrumentation dedicated to solving biologically-oriented problems. Dr. Coulter also mentioned the young investigator program for recent Ph.D. graduates. In 1992, $3.7M of the $24M NCRR budget went to mass spectrometry.

A consensus position taken by the panelists was that the fundamental problem with funding generally is the shrinking budget. Specific to mass spectrometry, however, was a lack of communication through which mass spectrometry can establish a role in setting funding priorities at the federal level. Each of the panelists stated, directly or indirectly, that the responsibility for more funding falls squarely on the shoulders of the scientific community. There are no easy short-term solutions to inadequate funding and the only real hope for the future lies in our making the case for more funding in terms of the national interest. The panelists uniformly agreed that funding for mass spectrometry research depends very heavily on personal communication from PI to program directors about funding and research. It is incorrect to assume that federal funding program administrators know the value of your research. A panelist uniformly agreed that funding of mass spectrometry research depends very heavily on personal communication from P.I. to program directors about funding and research not only when you are asking for additional support.

This society was urged to take the lead in selling mass spectrometry to Congress. Public education about the value of mass spectrometry is the only certain method to ensure that future funding will be better. This society must expend continuous effort to communicate past successes and to convince the public and Congress that money invested in mass spectrometry yields a good return. The panelists concluded their remarks by pointing out that in the era of tight and fixed federal budgets, those groups who most effectively demonstrate the value of their enterprise will fare well; those who are unable to make that case face even more difficult federal funding in the future.

Dr. Chris Enke suggested that anyone interested in volunteering to help in a continuing effort of communication with federal agencies should contact him at 517-355-9715, x234.

WORKSHOP REPORT

ISOTOPIC APPLICATIONS INTEREST GROUP

A workshop on "The Practical Aspects of Negative Thermal Ionization Mass Spectrometry" was held on Wednesday, June 3, from 4-5:30. About 40 people attended, which is quite good considering the modest size of our group. Interest in negative ions is high at the moment due the ability to analyze many elements using this technique that have been difficult or impractical using conventional positive ion techniques. Elements discussed that are amenable to this technique include Tc, B, Os, Re, I and Cl.

The speakers were Don Rokop (LANL), Art Spivack (Scripts), and Jim Delmore (Idaho National Engineering Laboratory). The speakers all gave their "best guess" as to the theory behind negative ion formation and discussed the optimum "enhancer" ($Ba(NO_3)_2$, LaB_6, seawater, or nothing at all) for producing large, stable ion beams. Means of overcoming instrumental difficulties particular to negative ion work such as arcing due to the large electron currents (up to 1 ma), and focusing problems caused by these currents were discussed.

The workshop was generally quite informative and hopefully will encourage those considering this technique to pursue it.

Submitted by E. Larry Callis

Isotopic Applications Group Coordinator

Fuels & Geoscience Workshop

This workshop, the first held in some time dealing with modern mass spectrometry's role in the fuels and geoscience field, touched upon a variety of topics without going into great detail in any one area. The organizer of the workshop Sam Hsu began with an outline of the major areas to be covered. These included pyrolysis mass spectrometry, high resolution mass spectrometry of species in petroleum and related materials, hydrocarbon types analysis on a benchtop instrument, and possible formation of a new interest group within ASMS. Sam announced that he would be trying to have the papers from this years Tomas Aczel memorial symposium, 12 oral and 12 posters, printed as a special publication as a more permanent tribute to Tomas. Sam then turned the floor over to Dean Davis.

Dean began a discussion on formation of an interest group dealing with petroleum related topics within ASMS by polling the audience as to their interest in such a group. Those present indicated a strong interest for such a group, so a list was circulated to collect names and addresses of those people for forwarding to ASMS when seeking approval to form the group. A lively discussion of possible names for the new group ensued, with the final choice being Energy & Petrochemicals. It was felt that this name included all of the varied people who might benefit from participation in the new group. Dean then stated that he would serve as a chairman for the group if needed. A nomination from the floor was made and voted upon that Dean be recommended to ASMS as the chairman when this group was formed. During discussions of the relationship of this new group to the ASTM D2 Sec. 04M committee two view points were expressed. Emilio Gallegos of Chevron felt that we have already essentially abandoned standard methods in mass spectrometry and this ASTM committee may have outlived it's usefulness. Stu Schepple of Amoco on the other hand felt that some ties with the committee should be maintained in case in the future we find a need for new standard methods. The discussion was tabled until a later time.

Dean then turned the floor over to John Maddock from Horizon Instruments. John gave a overview of the Curie Point Pyrolysis instruments his company is marketing and it's possible petroleum applications. They have a dedicated Pyrolysis mass spectrometer, as well as automated add on inlets for other instrumentation, and a device which screws on to an already existing GC.

Stu Schepple then led a brief discussion of High Resolution Mass Spectrometry. Stu first provided some definitions defining that by high resolution he meant >7500 and only on materials which boil below 1050 deg. F and can

therefore be introduced to the MS via an all glass batch inlet system, a GC, an LC, or a direct probe. Stu also defined the types of ionization techniques which are currently being applied in this area; low voltage EI, field ionization, chemical ionization, and fast atom bombardment. Stu continued his discussion by outlining some current limitations of the most useful petroleum high voltage systems. The most widely used is sector instrumentation employing low voltage EI which has an upper resolution limit of 60000. A second popular configuration is sector instruments with field ionization, these are a bit less sensitive and have a resolution limit of about 20000. A promising but just mow being explored area is FTMS with low voltage EI where preliminary experiments show an upper bound of about 100000 resolution.

After this overview Stu then dealt with the application of these methods and some of their problems. He pointed out that these methods have their greatest utility as qualitative analysis tools where there main shortcoming is mass overlaps. There is currently a considerable research in removing these overlaps by application of GC and LC to these methods. This is an area Stu felt that the new interest group might address. Assignment of formulas and editing of results also takes up a lot of effort. Stu showed a calibration mixture that provides intense peaks at intervals of 10 to 14 amu between 80 and 600 amu. Unfortunately some of these compounds are not commercialized and therefore are not at the present time available to other labs.

Stu also touched on the greater desire for quantitative analyses using these techniques and felt this was an area where cooperation between many laboratories could be very fruitful. Currently a number of different laboratories provide quantitative information but cross checking of this information for accuracy is a common problem that should be addressed.

Emilio Gallegos of Chevron concluded the workshop with a short discussion of hydrocarbon type analysis on an Hewlitt Packard MSD instrument. He stated that in his lab compounds run on the MSD have mass spectra that have larger relative intensities at higher mass and smaller intensities at lower masses than mass spectra that were taken using the old CEC instruments. In order to switch the analysis from the old CEC to new MSD equipment without extensive recalibration he is employing mathematical techniques which make the data appear to be equivalent.

A WORKSHOP
Sponsored by the Academic (Analytical) Lab Managers' Interest Group

Purchasing an Instrument: Perils and Pitfalls

You have funds ranging from $100,000 to $1,000,000 burning a hole in your pocket. You finally have the opportunity to purchase a mass spectrometer system to do the work you have been wanting to do for years. You don't want to blow it, because a mistake will haunt you for a long time. How do you go about making the right decision?

Andrew Tyler (Harvard University) organized a workshop on this topic, asking three individuals -- David Bowen (Pfizer, Sandwich, U.K.), Gerald Didonato (Bristol-Meyers Squibb, New Jersey) and Vernon Reinhold (Harvard School of Public Health) -- who have recently purchased an instrument, to share some of their wisdom. We also asked two manufacturers' demonstration chemists -- Lance Nicolaysen (FISONS Instruments) and Robert Cody (JEOL, U.S.A.) -- to share their experiences on the subject from the point of view of performing instrument demonstrations. Each speaker covered remarkably similar points, and thus made his successor's job progressively easier. The following is a composite of their comments, and some of the points made in the following discussion from the audience.

I. Before trying to select an instrument, select your allies and your information sources. They are your customers, your colleagues and your instrument sales people.
II. Decide what you NEED the instrument to do, and differentiate this from what you would WANT the instrument to do. Decide how you will score the results of your investigations. The NEED items on your list should be scored pass/fail. The WANT items should be ranked in order of importance, and given some type of numerical rating of how well that WANT is satisfied.
III. Prepare yourself and the instrument demonstration lab for your visit as much as possible. You have a large number of different things to see in a short time. Schedule enough time to conduct the demonstration, and allow time for something to go wrong.
   A. Choose a reasonable number of test samples, which are representative of the things you NEED and WANT the instrument to do. These samples should provide for some discrimination among instruments. If all the instruments either succeed or fail with all of your samples, then you have only learned that you didn't use the right samples.
   B. Tell the demonstration lab in advance what you NEED to see, as well as what you WANT to see. If meeting a tough sensitivity specification is one of your NEEDS, tell them.
   C. Use the same test samples for all vendors. Consider sending them ahead of time, and if so, give each vendor the same amount of time.
   D. Communicate directly with the demonstration lab and the demonstration chemist. Don't rely on a chain of communication through several intermediaries.
IV. Conduct your demonstrations and make your decisions in a timely manner. Capabilities change very rapidly. The first instrument you examined six months ago may now have more capabilities than the one you just finished examining, including the capability that you used to eliminate it.
   A. Test the NEEDED capabilities first, then the WANTED capabilities. If you include a research sample, send it in advance and/or save it for last. Don't base your instrument choice on its ability to solve (or not solve) your hardest current research problem. If you are doing cutting-edge investigations that you don't know much about yourself, don't include such an experiment in a demonstration.
   B. Test the instrument, not the demonstration chemist (as stated by Q. Grindstaff in a Young Mass Spectroscopists workshop a few years ago).
   C. Test the chromatograph-mass spectrometer interface, not the chromatograph or the demonstration chemist's ability to do chromatography. You are not buying either a chromatograph or the demo chemist. Have your chromatographic conditions worked out ahead of time, and inform the demonstration lab of these conditions prior to arriving. Make the chromatographic runs as short as possible while still testing what you need to test.
   D. Don't send the boss to the demonstration. Send the people who will be responsible for making the instrument work in your laboratory. Also send the same people to all of the demonstrations.
V. Score the results of your demonstration visits, and select the instrument your tests tell you to buy. Consider:
   A. Ease of use of the instrument.
   B. Quality of the data collected on the instrument.
   C. Your overall impression of the vendor.

D. The data system: its current utility, its ability to integrate into your current computing environment, and its longevity (if possible in this modern very rapidly changing computer marketplace).
E. After-sale service by the vendor. Contact colleagues who have bought similar instrumentation about their level of satisfaction with their choice. Ask the vendors for users' lists.

VI. Strike a deal with the "winning" manufacturer. Get everything that is important to you in writing. Involve your purchasing and/or legal departments in considering some of these items. Discuss:
A. Price. Does the price include installation, on-site training, a factory training course, importation duties (if you are an academic institution)?
B. Warranty. How long is the warranty period, and what does it cover? Can it be for a longer time in return for a higher price?
C. Delivery schedule.
D. Payment schedule.
E. Availability of after-warranty service, service contracts, and spare parts.
F. Performance acceptance criteria. Are the "off the shelf" performance criteria assigned by the manufacturer sufficient to meet your needs, or do you need to include a requirement specific to your needs? Is it sufficient that the instrument perform for the installation engineer, or do you require that it meet performance criteria in the hands of your own personnel? Is it sufficient that the instrument meet performance specifications upon acceptance, or should it also meet specifications after a period of time in your lab? If so, how long afterwards?
G. What happens if the instrument will not meet one or more of your acceptance criteria?

VII. Tell the "losing" vendors why you did not choose their products. This latter information is what helps the manufacturers to improve.

Discussion from the floor followed the presentations, during which a number of points were made. It was stated that the instrument selection process is often really not a totally scientific process, and includes a number of subjective criteria. Be conscious of these, and be ready to accept your decision if they become important. It has also been statistically shown that the last successful demonstration is most likely to get the order.

Be aware of your employer's rules for purchasing such large price items as mass spectrometers, especially if your employer is a U.S. government agency. Be aware of the requirements of a "sole source" justification which would limit consideration to a single vendor. The government's rules must be adhered to. Try to write "performance specifications," not "hardware specifications." If you work for a university or other non -profit educational institution, be aware of and follow procedures regarding purchase of foreign instrumentation. It is very important in order not to jeopardize your ability to successfully petition for duty-free entry. It can make as much as 10% difference in the amount of money you will have to pay out.

Interest Group Business: This year's workshop was attended by upwards of 500 people. We hoped that the topic would have a wider appeal than to just those affiliated with this Interest Group, and it apparently did!

Suggestions were solicited for future group activities, and for future ASMS meetings. Suggestions for the group were: successes and failures in "automating" data collection and analysis; a group survey to collect data to compare with that collected when this group was formed in 1986, and to compare with our new industrial wing; a discussion on the uses and abuses of accurate mass measurements; an examination of the possible change in focus to more involved sample processing techniques; aspects of quality control, quality assurance, and good laboratory practices. Clearly there are a number of potential ideas to be explored.

This year's workshop has included participants from industrial mass spectrometry laboratories to reflect the Interest Group's expansion to include non-academic laboratories. Expansion was at the request of the ASMS board. All the responses I have received to date about this expansion have been very favorable. Speaking from the experience of having lived on both sides of this fence, the problems faced by academic and industrial labs are generally the same, and I think this cross-fertilization of experiences and ideas will be beneficial to all.

Andrew Tyler (Harvard University) has agreed, with the consensus of those remaining for the Interest Group business meeting, to assume the leadership of this group for the next two years. Two other individuals had indicated their willingness to lead the group. I would like to express my gratitude to Andy, and to these other two individuals, for their interest in this group and what it does, and to everyone who has participated these last four years in making this a rewarding experience for me, and, I hope, a rewarding experience for all of you. Please give Andy as much support as you have given me.

Interest Group Coordinator

Workshop on the Reaction and Dissociation of Large Molecules Ions

The purpose of this Workshop was to discuss recent experimental results pertaining to the reactions of large (and generally highly charged) molecular ions. The discussions centered about ions produced by electrospray ionization (ESI) largely due to the rapidly expanding availability of such instrumentation, the great success in generating molecular ions of biopolymers, and the capability for studying reactions under a wide variety of conditions. The scope of the Workshop discussions was also broadly influenced by early results presented from several laboratories suggesting that (at some level) molecular ions of different structures exist in the gas-phase, and are able to be related to, from "specific" liquid-phase structures.

The Workshop was initiated by spirited discussion following data presented by Fred McLafferty, Cornell University, showing the H/D exchange data (from D_2O/protein reactions in an FT-ICR) suggesting that two different gas-phase conformers of cytochrome *c* molecular ions can exist and that they arise due to different comformations present in solution. Then Brian Winger presented H/D exchange results obtained at near-atmospheric pressure. He studied proteins whose gas-phase structures were varied by the presence or absence of disulfide bridging bonds and showed that different structures produce different levels of H/D exchange. He also showed, using an extended *m/z* range quadrupole instrument, the existence of high *m/z* ion from electrospray (greater than *m/z* 10,000) and the importance of large "bioclusters" in this regime. Robert Anderegg, Glaxo, followed this by showing data in which H/D exchange reactions could be used in solution to probe protein structure. He noted preliminary results suggested that the ability to probe the site of exchange by CAD was apparently precluded by H/D scrambling.

Next a pair of presentations by Rong Feng (National Research Council, Canada) and Rachel Ogorzalek Loo (Pacific Northwest Laboratory) presented results from studies employing proton transfer reactions in the interface region of the electrospray source to probe gas-phase structural differences. The varying results obtained for similar systems suggested the need for fine control of experimental parameters in such studies.

Following these discussions, Vicki Wysocki, Commonwealth University, presented initial results on the surface induced dissociation of large ions. Initial results for the $(M+3H)^{3+}$ molecular ions of melittin produced dissociation spectra very similar to that observed earlier by Barinaga et al (Rapid Commun. Mass Spectrom. 3, 160 (1989)) using a triple quadrupole mass spectrometer. Scott McLucky, Oak Ridge National Laboratory, noted that strong similarities were also observed in their ITMS studies where collisional activation is restricted to the parent ion.

Bruce Reinhold, Harvard University, presented results showing the effect of charge state upon dissociation for various glycoprotein "anchors" and speculated on the possible origin of these effects.

Finally, Alan Rockwood, Pacific Northwest Laboratory, discussed the general role of coulombic repulsion in determining the reactivity and structure of highly charged gas-phase ions. His specific results of ab initio calculations for model proton transfer reactions in the presence of an electric field of different strengths (so as to emulate varying degrees of molecular ion charging) led to a spirited exchange between Alan

Rockwood and Bruce Reinhold, regarding the merits of assumptions underlying such methods. This exchange of viewpoints on important theoretical issues was of more limited interest to many Workshop participants, and allowed the Workshop to conclude on schedule.

It is the opinion of the organizer that the Workshop allowed a vital discussion of issues that could not have been addressed in the context of the formal presentations. It also emphasized the preliminary nature of many of the experimental observations, as well as the tentative basis of the initial interpretation and speculation upon these results. Most of all, however, it suggested the dawn of a broad new arena for ion chemistry related to large molecules. An arena in which some of the simplistic distinctions between the liquid and the gas phase may not apply, and where mass spectrometry may come to play an important role in probing large molecule structure in solution via gas phase processes. The possibility that mass spectrometry could provide insight into subtle aspects of weakly associated noncovalent structure for biopolymers would have been dismissed as insane only a few years ago. This possibility, though still very controversial, now appears to exist, and must be seriously investigated.

Respectfully submitted,

Richard D. Smith

WORKSHOP REPORT
PRESENT ISSUES IN ELEMENTAL ANALYSIS BY MASS SPECTROMETRY
ELEMENTAL ANALYSIS INTEREST GROUP

Approximately 40 people attended this interest group meeting, which followed the oral session on elemental analysis and isotope ratio measurements held Wednesday morning. The discussion focussed on three areas of elemental mass spectrometry that have evinced substantial growth recently. R. S. Houk from the Ames Laboratory and Iowa State University discussed recent developments in the mass spectrometric aspects of ICP-MS. One such issue is ion lens performance. Two new offset ion lenses from Turner Scientific and Yokogawa yield very high sensitivity (~ 10^8 counts/s per ppm) with reasonably low background, while a somewhat different lens from Houk's group yields moderate sensitivity with very low background and interferences. Another issue in ICP-MS is the use of mass analyzers other than the common quadrupole. VG Elemental and JEOL have spearheaded the use of double focusing mass analyzers with the ICP, and VG has constructed a prototype multicollector instrument for isotope ratio measurements with high precision. Efforts to interface the ICP to quadrupole ion traps and time-of-flight mass spectrometers are also getting underway.

Ken Marcus from Clemson University led a discussion of issues in glow discharge mass spectrometry. Apparently, the bulk of the audience, or at least the more vocal individuals, were glow discharge practitioners. Some important issues raised in this discussion were: availability and preparation of standards, possibilities for depth-resolved analysis by glow discharge MS, instruments with interchangeable sources (i.e., a glow discharge or an ICP on the same mass spectrometer), application of RF glow discharges to analysis of insulators, and the use of FT-ICR with the glow discharge for high spectral resolution, including resolution of different atomic ions at the same nominal m/z value.

Finally, K. W. M. Siu of the National Research Council of Canada presented an overview of the new kid on the block, namely electrospray of metal ions. This ionization method shows substantial promise of fulfilling a long-term analytical need for the measurement of elemental speciation. Examples of cases in which metal ions can be electrosprayed and mass analyzed with the original charge state and coordination sphere intact were presented. The effects of declustering conditions during ion extraction were surveyed. Some recent results from Gary Horlick's group at the University of Alberta show that relatively severe declustering conditions can be used to largely remove water clusters to yield relatively simple spectra that may prove useful for direct elemental analysis. This entire area is one that bears close scrutiny by mass spectrometrists interested in elemental analysis.
