LISTING OF EXTENDED ABSTRACT TITLES BY SESSION viii

ABSTRACTS

Monday Orals
- Spray Ionization 1a
- Fast Chromatography/Mass Spectrometry 13a
- Accelerator Mass Spectrometry 22a
- Distonic Ions 26a

Monday Posters
- Metabolism and Drugs 32a
- Carbohydrates 73a
- Environmental 112a
- Computer Applications 144a
- Ion Molecule Reactions 160a
- Petroleum, Process Monitoring & Misc. 201a
- FAB/SIMS/Plasma Desorption 213a
- Nucleotides 240a

Tuesday Orals
- Biopolymers & Their Ions 263a
- Neutralization-Reionization MS 277a
- LC/MS Determination of Small Molecules 286a
- Metal Ions/Ion Molecule Reactions 298a

Tuesday Posters
- Metabolism of Drugs 310a
- Proteins 347a
- Environmental 388a
- Laser Desorption/Ionization 407a
- Trapped Ions 438a
- Ion Fragmentation & Structure 476a
- Biological Miscellaneous 514a
- Polymers 524a

Wednesday Posters
- Metabolism & Drugs 540a
- Proteins 578a
- Environmental 622a
- Laser Desorption/Ionization 649a
- Trapped Ions 681a
- Elemental Analysis & Isotope Ratios 721a
- Electrospray, API, Supersonic Beams 740a

Thursday Orals
- Laser Desorption/Ionization 773a
- Trapped Ion MS 789a
- Environmental Analysis 803a
- Elemental & Isotope Ratio Analysis 815a

Thursday Posters
- Metabolism & Drugs 831a
- Proteins 867a
- MS/MS 910a
- TOF 940a
- Ion Molecule Reactions 958a
- Ion Fragmentation and Structure 1000a
- Electrospray, API, Supersonic Beams 1040a

Friday Orals
- Immunology 1076a
- Fullerenes & Metal Carbon Clusters 1082a
- Analysis of Surfaces 1087a
- Polymer Analysis 1092a

Plenary Lecture, The Mass-Changing Reaction Between MS and MS, Christie G. Enke and Richard A. Yost 1099a
- Recipients of 1993 Award for Distinguished Contribution in Mass Spectrometry

WORKSHOP AND INTEREST GROUP MEETING REPORTS
- Young Mass Spectrometrists, "Perspectives on Publication from the Inside" 1101a
- Field/Portable Mass Spectrometry 1102a
- Isotopic Applications Interest Group; "Signals and Noise" 1103a
- Laboratory Managers Interest Group; "Automation in the Mass Spectrometry Laboratory" 1104a
  - Matching LC with MS; Current and Future Options 1105a
- Summary of Discussion at the ASMS Meeting 1106a

INDEX OF AUTHORS 1107a

INDEX OF KEY WORDS 1119a

INTRODUCTION

This volume represents the official record of the annual meeting and is designated as the Proceedings of the 41st ASMS Conference on Mass Spectrometry and Allied Topics.

The extended abstracts contained in the Proceedings provide brief descriptions of the research presentations made at the meeting and include both oral and poster contributions. In addition, reports from workshops and interest groups and the ASMS business meeting are included.

Special thanks are given to Chris Enke for overseeing the arrangement of the technical program and Judith A. Sjoberg and her staff of Professional Association Management for coordinating the printing and distribution of the Proceedings.

Alan G. Marshall
Editor and Member-at-Large
ASMS Board of Directors

CITATION NOTICE

This volume contains the extended abstracts of papers presented at the 41st ASMS Conference on Mass Spectrometry and Allied Topics. The material is not copyrighted and appearance of material in this volume does not jeopardize the author's right to publish the information in scientific journals.

Reference to individual abstracts contained in this volume should be cited as follows:

> Author(s); title; Proceedings of the 41st ASMS Conference on Mass Spectrometry and Allied Topics, San Francisco, CA, May 30 - June 4, 1993

ASMS BOARD OF DIRECTORS

President	Henry M. Fales National Institutes of Health Building 10, Room 7N 318 Bethesda, MD 20892
Vice President for Programs	Christie Enke Department of Chemistry Michigan State University East Lansing, MI 48824
Vice President for Arrangements	Sanford P. Markey Nat'l Inst. of Mental Health Building 10, Room 3D40 Bethesda, MD 20892
Secretary	Brian Chait The Rockelfeller University 1230 York Avenue New York, NY 10021
Treasurer	Barbara Larsen E. I. duPont de Nemours E228-120A Post Office Box 80228 Wilmington, DE 19880
Member-at-Large (Proceedings)	Alan G. Marshall The Ohio State University 120 West 18th Avenue Columbus, OH 43210
Member-at-Large (Education)	Kenneth L. Busch Sch. of Chem. & Biochem. Georgia Inst. of Technology Atlanta, GA 30332
Member-at-Large (Measurements and Standards)	Jack D. Henion Coll. of Vet. Med. @ Cornell Diagnostic Laboratory 925 Warren Drive Ithaca, NY 14850
Past President	Robert C. Murphy The National Jewish Center 1400 Jackson Street Denver, CO 80206
Executive Director	Judith A. Sjoberg 815 Don Gaspar Santa Fe, NM 87501 (505) 989-4517

INTEREST GROUP COORDINATORS

Laboratory Managers	Andrew N. Tyler Harvard University (617) 496-3571
Biomedical Applications	Steven A. Carr Smith Kline & French (215) 270-6650
Computer Applications	David E. Smith P-E Sciex (416) 881-4646
Desorption Ionization	Richard Van Breemen North Carolina State Univ. (919) 747-2942
Elemental Analysis	Robert (Sam) Houk Iowa State University (515) 294-9462
Energy & Petrochemicals	Dean V. David Unocal Science & Technology (714) 577-1212
Environmental Applications	M. Judith Charles Univ. of North Carolina (919) 966-3857
Fundamentals	Robert R. Squires Purdue University (317) 494-7322
History of Mass Spectrometry	Lawrence R. Phillips National Cancer Institute (301) 496-5531
Isotopic Applications	James Stoffel(s) Batelle Northwest Laboratories (509) 376-2142
LC/MS & Related Topics	Ross C. Willoughby Extrel Corporation (412) 967-5708
Metal Ion Coordination Chemistry	Julie Leary Univ. of Calif. @ Berkeley (415) 642-0701
Polymeric Materials	George J. Kallos Dow Chemical Company (517) 636-5340
Surface Science	Allen Brown Kratos Analytical (201) 825-7500
Young Mass Spectrometrists	Jon Amster University of Georgia (706) 542-2001

ASMS COMMITTEES

Asilomar Conference	Laszlo Tokes (chair) Syntex Research (415) 855-5713
	Arnie Falick R. Graham Cooks Alan G. Marshall Robert C. Murphy
Audit	Kelsey D. Cook (Chair) University of Tennessee (615) 974-8019
	Frank H. Field Peter J. Todd
Education	Kenneth L. Busch (Chair) Georgia Inst. of Technology (404) 894-4030
	John Chakel James A. Kelley Elizabeth A. Stemmler Alfred Yergey
Measurements & Standards	Jack D. Henion (Chair) Cornell University (607) 255-3235
	John Bartmess Phillip C. Price Sharon Lias Anne Giordani
Nominating	Jean H. Futrell (Chair) University of Delaware (302) 831-1247
	Catherine Fenselau Sharon Lias Michael Story Richard Yost
Sanibel Conference	Jeannette Adams (Chair) Emory University (404) 727-6522
	Edward Chess Jack D. Henion Rebecca O'Malley Vernon Reinhold

MONDAY ORALS

Spray Ionization

On the Release of Ions from Charged Droplets in Electrospray Mass Spectrometry 1a

Ethylene Glycol as a Solvent for Electrospray Mass Spectrometry 2a

The Potential of Electrospray Ionization with Ultra-high Resolution Mass Spectrometry for Biopolymer Characterization 3a

A Reflecting Time-of-Flight Spectrometer with Orthogonally Injected Electrospray Ions 4a

Studies of a High Intensity Electrospray Ion Source Connected to a High Mass Post Accerleration Ion Detector 5a

Observation of Noncovalent Complexes by Electrospray Ionization on a Magnetic Sector Mass Spectrometer 6a

Conformation Dependent Copper Binding Ability of an Engineered Protein Assessed by Electrospray mass Spectrometry 7a

The Observation of Biomolecular Ions Beyond m/z 3,000 by Electrospray Ionization Mass Spectrometry 8a

Capillary Electrophoresis/Electrospray Ionization on a Magnetic Sector Mass Spectrometer 9a

Rapid Separation of Enzymatically Digested Proteins Using Packed Capillary Perfusion Column LC/ESI/MS 10a

Technique for the Removal of Buffers and Heart Cutting of Peaks in Gradient Capillary HPLC Prior to Electrospray Mass Spectrometry 11a

A New API Source for Magnetic Sector Instruments 12a

Fast Chromatography/Mass Spectrometry

High Speed GC/MS with Focal-Plane-Ion Detection 13a

Maximizing the Utility of Fast GC Analysis with TOF-MS and Time Array Detection 14a

Orthogonal Acceleration TOFMS for Micro-column Chromatography 15a

A Electrospray Time-of-Flight Mass Spectrometer for Chromatography Applications 16a

Time-of-Flight Technology for High Speed GC/MS 17a

Recent Developments in LC/TOF Mass Spectrometry 18a

Two Approaches to Fast GC/MS for Process Monitoring 19a

Fast GC-MS in Supersonic Molecular Beams 20a

Interfacing High Speed Transfer Line Gas Chromatography to Ion Trap Mass Spectrometry; Advantages and Limitations 21a

Accelerator Mass Spectrometry

Tracing Attomoles of 14C-Labeled Organic Compounds in Natural Systesm 22a

Calcium Kinetic Study in Human by 41Ca Tracing 23a

Advances in the Earth Sciences through Accelerator Mass Spectrometry 24a

The Anlysis of Heavy Elements by AMS; A New Mass Spectrometry 25a

Distonic Ions

Distonic Ions; their Status in Gas Phase Ion Chemistry 26a

Investigation of Distonic Radical Cations by Ion-Surface Collisions 27a

Synthesis and Structural Characterization of Novel Distonic Ions Using Ion-Molecule Reactions 28a

Neutralization-Reionization (NR) Studies on Distonic Radical Cations 29a

The RF-Only Mode Event in FTMS: A Means of Generating and Characterizing Distonic Ions 30a

Ion-Molecule Chemistry of The Methylene Dimethylsulfonium Ion: A Novel Alpha-Distonic Ion 31a

MONDAY POSTERS

Metabolism and Drugs

Electrospray LCMS Analysis of Ganefromycins 32a

Analysis of Flavins by Thermospray HPLC/MS and Electrospray MS 33a

Quantitation of Vecuronium Bromide by Electrospray/Tandem Mass Spectrometry 34a

The Application of Electrospray Ionization in the Analysis of Catecholamines by LC/MS 35a

Electrospray MS and MS/MS for Metabolite Identification in Various Animal and Human Biotransformation Studies 36a

Electrospray Ionization Mass Spectrometry of Glutathione and N-Acetylcysteine Conjugates of Electrophilic Metabolites of Acetaminophen 37a

Identification of Tamoxifen Metabolites in Breast Cancer Patients by Electrospray LC/MS 37c

Determination of Antibiotics by using Ultrasound Nebulization Electrospray Mass Spectrometry 38a

Determination of Cysteinyl Leukotrienes Using Electrospray/Tandem Mass Spectrometry. 39a

Structure Elucidation of Taxanes by ESI-MS and ESI-MS/MS 40a

The Metabolism of Substance P Studied by in vivo Microdialysis and On-Line LC/ESI/MS 41a

Monitoring In-Vitro Enzymatic Reactions Using An Integrated microdialysis/Ionspray Tandem Mass Spectrometry System 42a

Metabolism of Hexamethylene Diisocyanate (HDI) in the Rat Utilizing Ionspray LC-MS/MS Techniques 43a

Identification, and Quantitation of Metabolites of a Novel Non-benzodiazepine Anxiolytic Compound (CL 273,547) by Thermospray LC/MS in Tandem with 14C Detection and an Off-Line Stable Isotope 44a

Determination of Reserpine in Plasma by Ion Spray LC/MS/MS 45a

Determination of Vitamin B12 by Ionspray Liquid Chromatography Mass Spectrometry 46a

Nanoliter Flow, LC-ESI-MS for Analysis of Endogenous Neuropeptides 47a

Characterization of Brimonidine Metabolites by HPLC/Thermospray Mass Spectrometry 48a

Simultaneious HPLC Radioactivity and Mass Spectrometry Monitoring. A Drug Metabolism Application 49a

Investigation of Factors Influencing In Vivo Microdialysis/MS/MS Studies 50a

Analysis of Quaternary Isoquinoline Alkaloids by Ion Spray Ion Trap Mass Spectrometer (IS/ITMS) 51a

Assessment of in-vitro Liver Slice Metabolic Activity Using Microcolumn Separation Systems Coupled with ESI/MS 52a

Quantitative Analysis of the Immunosuppressant FK-506 in Rat Serum by high Performance Liquid Chromatography-Electrospray MS/MS Techniques 53a

Structural Analysis of Rapamycin and Related Compounds Using (M+Li) + Ions Generated by LSIMS 54a

Investigation of Photochemical Reactions via on-line Thermospray Tandem Mass Spectrometry 55a

Comparison of GC/MS and LC/MS Methods for Determining Nicotine Absorption in Tobacco Smokers 56a

Electrochromatography/Mass Spectrometry of Steroids: 57a

Mass Spectrometrically-Guided Development of a Fluorescent Label for Enhanced Detection in HPLC 58a

A Comparison of the Analysis of Gentamicin Sulfate by Thermospray and Electrospray HPLC/MS 59a

Recognition of Quaternary Amines and Ammonium Salts Using Tandem Mass Spectrometry 60a

Analysis of N-acetyl-cysteinyl-ursodeoxycholic Acid in Human Bile by Solid Phase Extraction and HPLC - cf-FAB Detection 61a

Mass Spectral Characteristics and Identification of Metabolites of Mesoridazine and Other Related Piperidine Type Phenothiazines 62a

Automated Interpretation of Biological Fluid Organic Samples by a Benchtop GC-MS 63a

Rapid GC/MS/MS Assay for 5-Methoxyflavone in Plasma 64a

Immunoaffinity Chromatography and GC/MS/MS for the Identification of Cross-reactants with an immunoassay for Benzoylecgonine 65a

Microscale Chemical Reactions to Probe the Structure and Reactivity of Isolated Natural Products 66a

Detection of Vitamin D Metabolites by On-Line Capillary Liquid Chromatography and Fast Atom Bombardment Mass Spectrometry 67a

Determination of Cortisol in Human Plasma by Gas Chromatography/Negative Ion Chemical Ionization/Mass Spectrometry 68a

The Rapid Structure Characterization of Synthetic and Natural Products by FAB-Mass Spectrometry using Na+ and K+ Salts 69a

Characterization of Human Cerebrospinal Fluid (CSF) Phospholipids by Fast Atom Bombardment Mass Spectrometry (FABMS) 70a

Quantitative Determination of Hydroxybutorphanol and Norbutorphanol in Human Plasma by GC/ECCI/MS 71a

The Characterization of Abscisic Acid Metabolites Using Packed Capillary LC/Continuous Flow Secondary Ion MS 72a

Carbohydrates

A Mass Spectrometric Study of Phenolic Glycolipids 73a

The Characterisation of Lipophilic Peroctylated Cyclodextrins by Electrospray Mass Spectrometry 74a

Characterization of Chemically-modified Cyclodextrins and their Host-Guest Complexation with Drugs by Ion Spray Mass Spectrometry 75a

Characterization of Avidin by Electrospray Ionization Mass Spectrometry 76a

Characterization of Oligosaccharides by LC-MS Technologies 77a

A General Approach to Carbohydrate Characterisation of Glycoproteins by Exo-glycosidase Digestion and Matrix Assisted Laser Desorption Mass Spectrometry 78a

Characterization of Permethylated Gangliosides by off-line HPLC, LSIMS, MS/MS and MALDI-TOFMS 79a

Mass Spectrometry of C-Glucosides Containing S-Atom at C-2 80a

Analysis of Heterogeneity of Native -Acid Glycoprotein 81a

Predictability of Fragmentations in Negative Ion FAB MS of Reducitng Oligosaccharides 82a

Does Conformation Play a Role in the Fragmentation Behavior of Oligosaccharides? A Study with Three -D-NeuAc-(2-6)-SS-D-Gal Sialosides and Six Related, Conformationally more Rigid -D- 83a

Comparative Study of Carbohydrate Structrues of Recombinant Human Platelet-Derived Growth Factor Expressed in Chinese Hamster Ovary and in Saccharomyces Cerevisiae 84a

Electrospray Mass Spectrometry of heparin Oligosaccharides 85a

Structure Determination of the Major Sialylated Oligosaccharide Chains of Recombinant-Derived Erythropoietin Expressed in Chinese Hamster Ovary Cells 86a

Structural Characterization of the Carbohydrate Chains of Saponins by FAB-MS/MS 87a

Structural Studies of the Glycosylation of the Gastric H+, K+-ATPase 88a

Structural Determination of the O-linked Oligosaccharides of Recombinant Human Granulocyte-Colony Stimulating Factor 89a

Structural Determination of a Sulphated Tetrasaccharide Ligand for the Cell Adhesion Molecule E-Selectin by LSIMS 90a

Structural Analysis of Glycosylation on the HIV Envelope Glycoprotein gp 120 91a

Structural Elucidation of Branched Oligosaccharides: Isotope Labeling Studies 92a

Detailed Structural Characterization of an Exopolysaccharide from Rhizobium Meliloti by ESI and Low Energy CID 93a

Sequencing of Glycopeptides Using Sequential Digestion Followed by Microbore HPLC/Electrospray Mass Spectrometry 94a

Microcolumn HPLC-CF-LSIMS of UV-absorbing Neoglycolipids Derived from Oligosaccharides 95a

Electrospray Ionization of Divalent Metal Chloride-coordinated Oligosaccharides 96a

An Analysis of Mono- and Oligosaccharides by Electrospray Mass Spectrometry 97a

Use of Matrix-Assisted Laser Desorption Mass Spectrometry for Examination of Oligosaccharide Mixtures 98a

Analysis of Glycoalkaloids in a Crude Mixture by Positive-Ion and Negative-Ion L-SIMS and Four-Sector Tandem Mass Spectrometry 99a

Oligosacharide Profiling by LC-ESI-MS: Focus on Mucins 100a

Glycoform Detection in CHO-derived Interleukin-4 by LC / CID / Electrospray Mass Spectrometry 101a

Enhanced Carbohydrate Detection by Multiple Ion Monitoring (MIM) of HPLC Effluents 102a

Quantitation of D-Glucose and 13C6-(U)-D-Glucose methylboronate Pentafluoropropionates in Human Plasma by Methane NCI GC-MS 103a

Quantization Studies of Polymethylated -cyclodextrins by ESMS 104a

Matrix Additives to Enhance Signal Intensity of Gangliosides in Negative FAB-MS Analysis 105a

The Self-Association of Sialyl Lewis X 106a

Optimisation of Identification of Oligosaccharides by Matrix-assisted Laser Desorption Mass Spectrometry 107a

Matrix-Assisted Laser Desorption of O-Glycopeptides Using Linear and Reflectron Time-of-flight Instruments 108a

The Role of Lipooligosaccharides in Pathogenesis of Haemophilus Species and Possible Strategies for Therapeutic Intervention 109a

Mass Spectrometry of Cyclodextrin Amino Acid Adducts: 110a

An Integrated Mass Spectrometric Approach (PD, FAB, ESI and Low Energy CID) to Characterize the Peptidoglycan of Various Microorganisms 111a

Environmental

Strategies for the Identification of Compounds Causing Odors in Water. A Study of a Creosote Spill 112a

Tandem Mass Spectrometry of Human Skin Emanations for the Determination of Mosquito Attractants 113a

Direct Analysis of Polycyclic Aromatic Hydrocarbons in Airborne Particulate Matter by Laser Time-of-Flight Mass spectrometry 114a

Laser Photoionization Time-of-Flight Mass Spectrometry Applied to Nitrated Polycyclic Aromatic Hydrocarbons and Nitrobenzocoumarin Derivatives 115a

Laser Photoionization Time-of-Flight Mass Spectrometry of Arsenic and Chromium Compounds in Airborne Particulate Matter 116a

Analysis of Sulfonated Azo Dyes by GC/MS of Their tert-Butyldimethylsilyl Derivatives 117a

GC/MS Detection of Thiodiglycol and Thiodiglycol Sulfone in Water and Concrete Using TMS Derivatization 118a

Mass Spectrometric Studies of Tetraphenylborate Hydrolysis Products from a Simulated Feedstock 119a

Real-time Measurement of Reactive and Toxic Hydrocarbons in Auto Exhaust 120a

Thermal Study of Rutin by Thermogravimetry/Gas Chromatography/Mass Spectrometry 121a

Interpretation of the Distribution of Environmental Contaminants in Gulf of Mexico Oysters using Log-Normal Distribution Functions 122a

Supercritical Fluid Extraction in the Analysis of Environmental Organic Pollutants 123a

Selectivity and Sensitivity Enhancements of Halogen Detection Utilizing MIP/CRIMS and Negative Chemical Ionization 124a

Determination of Benzene in Food by Direct Sampling Ion Trap Mass Spectrometry 125a

Development of a Method for the Direct Purge Analysis of Volatile Organics in Water 126a

Multispectral Identification of Chlorine Dioxide Disinfection By-Products in Drinking Water 127a

Identification of PCB Degradation Products in Gamma-Ray Irradiated Solution of PCB's in Isopropanol 128a

The Analysis of TCDD in Human Serum using Very High Resolution SIR 129a

Investigation into Interferences in Dioxin Analysis by HRGC-HRMS 130a

Mass Profile Monitoring in Trace Analysis: Polychlorinated Dibenzo-p-dioxins and Dibenzofurans in Crab Tissues from Raritan/Newark Bay System 131a

Comparison of Pre-operational and Post-operational PCDD/F in Milk Samples Taken from Farms Located Near a New Recovery Incinerator by HRGC/HRMS 132a

Pattern Analysis of Alkyl Aromatic Compounds from Biota Samples Taken After the Exxon Valdex Oil Spill 133a

GC Inlet Modifications Improving the Analysis of Aromatic Hydrocarbon Metabolites in Fish Bile 134a

Comprehensive Analysis of Mississippi River samples by GC/PCI/MS/MS and GC/NCI/MS 135a

Alkylbis(trifluoromethyl)phosphine Sulphide Homologs as Multidetection Retention Index Standard in GC/MS and in GC/MS/MS 136a

Identification and Quantification of 2,4,6-Tribromoaniline in the Color Additive D&C Red No. 22 (Eosin Y) by GC/MS 137a

The Photolytic Degradation of Pentachlorophenol in Organic Solvents 138a

A Sampling/Calibration "Pipeline" for the Analysis of Hazardous Gas Cylinders 139a

MicroVolume Gas Analysis: Design, Construction of Utilization of a Mass Spectrometer System for Analysis of Gases in Semiconductor Packages 140a

FAB MS and HPLC Analysis of Fumonisin B1 and Fumonisin B2 in Food Substrate Cultures 141a

The Use of Internal Standards to Improve Linearity and Reproducibility in the Thermospray LC/MS Analysis of Chlorinated Phenoxyacetic herbicides 142a

Liquid Chromatography/Thermospray Mass Spectrometry for Characterization of Commercial Chlorinated n-paraffin Mixtures 143a

Computer Applications

Chemometric Assessment of GC/MS and GC/MS/MS Data Naphthenic Biomarkers 144a

Computer Program for Interpreting Peptide Mass Spectra Utilizing Hydrogen-Deuterium Exchange Information 145a

Quantitative Aspects of Maximum Entropy Applied to Multiply Charged Electrospray Data 146a

Curve-fitting for Resolution of Overlapping Chromatographic Peaks in High Precision Gas Chromatography-Combustion Isotope Retio Mass Spectrometry (GCC-IRMS) 147a

Analysis of Natural and Adulterated Essential Oils by MDGC/FTIR/MS 148a

The Application of Self-modelling Mixture Analysis to Automated Mass spectrometry 149a

Evolving Factor Analysis and GC/MS - An Ideal Combination 150a

Resolution and Quantization of Geometric Isomers using Solids Probe/Factor Analysis 151a

Improving Performance of Mass Spectral Search Algorithms 152a

The Control of Quality in a Comprehensive Mass Spectral Library 153a

PC-based Modular Data System for Time-of-Flight Mass Spectrometry 154a

Software for Acquisition and Analysis of TPEPICO-TOF-MS 155a

Networking a Laboratory Information Management System (LIMS) with a Mass Spectrometer Data System 156a

An Instructional HyperCard Stack for Users of the Mass Spectrometry Laboratory at the University of Illinois 157a

Ion Optical Study of Low Acceleration Ion Source 158a

Identification of Proteins by their Peptide Masses in DNA Databases 159a

Ion Molecule Reactions

Complexation Selectivity of Metal Cations toward Organic Molecules by FAB Mass Spectrometry 160a

Mechanistic Investigations into the Anionic Oxy-Cope Rearrangement in the Gas-Phase 161a

Complexation of Alkaline Earth and Transition Metal Ions with Polyethers in a Quadrupole Ion Trap 162a

Examination of Hydrogen-Bonding Interactions in Host-Guest Chemistry and Selective Ion-Molecule Reactions in a Quadrupole Ion Trap 163a

Recognition of Chiral Ammonium Salts using Chiral Crown Ether Hosts in the Gas-Phase 164a

Fourier Transform Ion Cyclotron Resonance Mass Spectrometric Investigation of Gas Phase Cryptate Complexes 165a

Influence of Polarizability and Ligand Flexibility on Multidentate Attachment of Alkali Metal Cations: Kinetics and Thermochemistry of Cation Binding by Isomers of Dicyclohexano-18- 166a

Fourier Transform Ion Cyclotron Resonance Mass Spectrometric Investigation of Calixarenes and their Complexes with Alkali Metal and Organic Cations in the Gas Phase 167a

Chiral FAB Mass Spectrometry 168a

Gas Phase Reactions of the Group 11 Ions with Small Alkanes 169a

Transition Metal Ion Reactions with Laser Desorbed Amino Acid and Peptide Neutrals in a Fourier Transform Mass Spectrometer 170a

Chemistry of NO and CO Ligands on MCon+ Clusters (M = Sc, V; n =1, 2) 171a

Formation of Strongly Bound Trasition-Metal Molecular Silane Complexes. n2-Coordination of Si-H 172a

Fe-(L)+(L=c-C5H6, C4H6) Mediated Extrusion of CO from Furan. A Model Study Relevant to Catalytic Hydrodesulfurization 173a

Hydrogenolysis Rates of Group 4 Methyl Metallocenes 174a

The Change in Reactivity of the FeCp+ Ion After Collisional Thermalization Using Quadrupolar Excitation 175a

Gas Phase Ion - Molecule Chemistry of Cyclooctatetraene Iron Tricarbonyl { 4-C8H8Fe(CO)3} by FT-ICR Spectroscopy 176a

Activation of Metal Carbonyls by Charge Transfer Reaction 177a

Gas-Phase Study of RCCo3(CO)9 (R=H, CH3, Ph, Cl) with Selected Organic Neutrals 178a

Reactions of Metal Carbonyl Anions with Methyl Formate in the Gas Phase 179a

Gas-Phase Ion-Molecule Reactions of Cr2(CO)5 - with Ketones and Alkenes 180a

Electron Affinity Measurements of Halogenated Metalloporphyrins 181a

Photoactivated Gas Phase Ligand Switching 182a

Thermoneutral Proton and Ligand Exchange Reaction Rates for Protonated and proton Bound Dimer Dimethyltartrate ions 183a

A Redetermination of the Proton Affinity Scale from Nitrogen to t-Butylamine by Variable Temperature High Pressure Mass Spectrometry 184a

Isomers of CHNO+ and the proton affinity of NCO at N 185a

Role of Reactant Vibrational Excitation and Collision Energy in the Ion-molecule Reaction NH3+ + ND3 186a

Br+ Addition to Gaseous Aromatic Compounds: Mechanism and Linear Free Energy Effects on Reaction Rates 187a

A Study of the Temperature Dependence of the SN2 Reactions of Cl with Methyl Bromide, Ethyl Bromide, iso-Propyl Bromide and n-Butyl Bromide at Atmospheric Pressure Using an Ion Mobility-Mass 188a

Kinetic Isotope Effects for the SN2 Reactions of Solvated Anions with Methyl Halides 189a

Competitive SN2/SNi Reactions Occuring in the Collision Cell of Triple Quadrupole from Low Kinetic Energy MH+ and [M+NH4]+ Ions Prepared from the Disastereomeric 1,2-Indanediols 190a

Guided-Ion Beam Studies of Reactions of Ions with NO 191a

Effects of Kinetic Energy on Both Endothermic and Exothermic Ion-Molecule Reactions in a Quadrupole Ion Trap Mass Spectrometer 192a

H/D Exchange in low Energy Collisions Between Protonated Aromatics and D2) or DC3OD 193a

Target Capture and Ion/Molecule Reactions in High Energy CID of Peptides Ions 194a

Gas Phase Basicities of Guanidine and Urea 195a

Breakdown Curves for the Dissociation of Protonated Peptide Ions Obtained by Laser Desorption/Chemical Ionization 196a

Proton Transfer Rate Constrants Measurements of Amino Acids and Dipeptides in a fourier Transform Mass Spectrometer 197a

Gas-Phase Basicities of Small Carbohydrates 198a

Gas-Phase Basicity Studies of Glycine and Diglycine by Mass Spectrometry and Ab Initio Calculations 199a

The Experimental and Theoretical Gas-Phase Basicity of Linear Oligomeric Peptides - Trends and Sites of Protonation 200a

Petroleum, Process Monitoring & Misc.

Analysis of High Molecular Weight Hydrocarbons by Short Column Gas Chromatography Mass Spectrometry 201a

Characterization of Wax Fractions from Lube oil Basestocks by Thermal Extraction-Gas Chromatography/Mass Spectrometry 202a

The Analysis of a Complex Mixture of Acidic Materials Derived from Petroleum by Capillary Electrophoresis and ESI - MS.: a Preliminary Off-line Investigation 203a

Characterization of Asphalts and Estimation of Bond Strengths Between Organic Components and Aggregates by Probe Microdistillation/Mass Spectrometry 204a

Evaluation of Mass Spectrometric Methods for Determination of Sulfur Types in Petroleum Samples 205a

The Determination of 2-Napthylamine in Petroleum Products by High-Performance Liquid Chromatography and Mass Spectrometry 206a

Geoporphyrin Analysis using Electrospray Ionization-Mass Spectrometry 207a

Using in-situ Mass Spectrometry to Study the Chemistry of a Small Scale Benchtop Minireactor 208a

In-situ Mass Spectrometry for Process Monitoring in a Chemical Plant 209a

Two Improved Probe Designs and a Modified Source for Desorption Chemical Ionization on the HP5989A Mass Spectrometer 210a

The Analysis of Alkylated Diphenyl Amines by High-Performance Liquid Chromatography / Particle-Beam / Mass Spectrometry 211a

Comparison of Field Desorption and Thermospray Mass Spectrometry for the Analysis of Petroleum Residua 212a

FAB/SIMS/Plasma Desorption

Multi-Sample Probe for Fast Atom Bombardment Mass Spectrometry 213a

The Use of a Variable Focus Cesium Ion Source to Facilitate the On-line Generation of FAB Spectra with particle Beam LC/MS 214a

Selective Enhancement of Ions Intensity by Adding Surfactant in Static FAB 215a

FAB MS of Non-Volatile Compounds in the Transition Range between Liquid and Solid 216a

Investigation of [M-H]+ Formation in FAB/LSIMS for a Compound with High Proton Affinity 217a

Improved Dynamic LSIMS (FAB) Sensitivity Using a Cold Finger to Enhance Pumping 218a

The Effects of Analyte and Matrix Properties on the "True" Reduction-Oxidation Extents Observed in FAB/LSIMS Analysis of Peptides 219a

The Effect of Functional Groups on the Reduction Behavior of Phenothiazine-related Dyes in LSIMS/FAB Mass Spectrometry 220a

A Comprehensive Study of Beam-Induced Dehalogenation of Organic Compounds in LSIMS: Effect of Analyte Structure, Halogen Type and Matrix Chemistry 221a

Sample Charge Compensation on a Large Sample Ion Microprobe 222a

Determination of Flux from a Saddle Field Fast Atom Bombardment Gun 223a

Time-of Flight Secondary Ion Mass Spectrometric Analysis and Imaging of Avian Egg Membranes 224a

Liquid Secondary Ion Mass Spectrometry of Hypervalent Siliconates 225a

Massive Cluster Impact (MCI) Mass Spectrometry - Source Design and Performance 226a

A Kinetic Model for Sensitivity Enhancement by Surfactant-analyte Ion Pairing in Liquid Matrix Assisted SIMS 227a

TOF-SIMS Studies of Ion Formation and Fragmentation Mechanisms in Polyglycols 228a

Secondary Ion Mass Spectrometry Depth Profilling of Ti-Implanted AlInAs and InP at Room and at Elevated Temperatures 229a

Measurement of Secondary Emission from Low Work Function Materials: Potential Emission for High mass Analysis by Mass Spectrometry 230a

Characterization of Fingerprint Residues on Surfaces using Neutral-Beam SIMS 231a

Correlation Between Initial Radial kinetic Energies and Chemical Composition of Secondary Ions, Sputtered Electronically from Organic Solids 232a

Comparision of Plasma Desorption- and Thermospray-Mass Spectra of Mercapturic Acids 233a

Applications of PD-MS in the Analysis of the Genetics of Quaternary Ammonium Compound Accumulation in Plants 234a

The Characterization of Tri-Nickel Cluster Compounds using 252cf Plasma Desorption and FAB Mass Spectrometry 235a

LC-MS Analysis of some Photographic Colour-Coupling Compounds Using a Continuous-Flow FAB Interface 236a

Information on the Ionization Processes Involved in FAB/LSIMS through Electrospray Ionization 237a

Formation and Sputtering of Fullerenes by MeV Ion Beams 238a

Identification of Degradation Products of the Antibiotic Laidlomycin Propionate by Mass Spectrometry 239a

Nucleotides

Quantification of Malondialdehyde-deoxyguanosine (M1G-dR) Adduct by GC ECNCI MS 240a

Differentiation of Isomeric C8-Substituted Dinitrotoluene Adducts of Guanine by FAB MS/MS 241a

Distinguishing Isomeric Monomethyl Guanines by FAB Mass Spectrometry Combined with Permethylation 242a

Low Energy Tandem Mass Spectrometry of Diol-Epoxide-Deoxynucleoside Adducts 243a

Characterization of Modified Oligodeoxynucleotides by Electrospray Mass Spectrometry 244a

Computer-Assisted Interpretation of Electrospray-Tandem Mass Spectra of Oligonucleotides 245a

MALDI Mass Spectrometry of Oligonucleotides and Nucleic Acids 246a

Electrospray LC-MS of Modified Oligonucleotides 247a

The Use of On-Line Field Amplification Stacking for the Capillary Electrophoresis-Mass Spectrometric Analysis of DNA Adducts 248a

Experimental Conditions for the Matrix-Assisted Laser Desorption FTMS Analysis of Modified Oligonucleotides 249a

MALD-FTMS for the Characterization of Ultraviolet and X-ray Damage to Nucleic Acid Constituents 250a

7 Day Low Level Dose Response Study of MeIQx in Rats using Accelerator Mass Spectrometry 251a

Analysis of DNA-Carcinogen Adducts by Electrospray CZE-MS 252a

Spatial Distribution of Nucleic Bases Using SIMS 253a

Mass Spectrometric Identification of 2'-Deoxycytidine Adducts from Reactions with Acrolein and 2-Bromoacrolein 254a

Enhanced Sensitivity in the Negative Ion FAB-MS Analyses of Polyanionic Organic Compounds Through the Use of Cationic Additives to the FAB Matrix 255a

Quantitative Fast Atom Bombardment Mass Spectrometry: Estimation of Cyclic nucleotide-Dependent Protein Kinase Activity 256a

Ultra Trace Analysis of Oxidized Nucleosides in Biological Matrices 257a

Use of On-Line Thermal Denaturation to Study the Stability of Quadruple-Stranded Nucleic Acid Structures 258a

Collision-Induced Dissociation of Permethylated Derivatives of Site-Specifically 15N and 18O-Labeled Guanosines 259a

Evaluation of Variable Post-Translational Modification of Histones by Electrospray Ionization Mass Spectrometry and Tandem Mass Spectrometry 260a

Product Ion Scans of the BH2+ Ion: A Tool for Investigating the Structure of Deoxynucleosides Modified by Arylamine and Diol-Epoxide Carcinogens 261a

Studies on the Binding of Actinomycin D to Single-Stranded DNA by Negative Ion Spray Mass Spectrometry 262a

TUESDAY ORALS

Biopolymers & Their Ions

Posttranslational Modifications and Mass Spectrometry: What the Well Dress Protein is Wearing and How to Tell 263a

Mass Spectrometric Based Strategies for the Structural Characterization of Recombinant Human IL-12" 264a

Combination of Mass Spectrometric Methodologies for the Determination of Peptide and Protein Structure 265a

A Strategy for Mass Spectrometric Characterization of Nucleotide-Protein Complexes after UV-induced Cross-linking 266a

Application of Ion Spray Mass Spectrometry in Probing Protein-Protein/Protein-Ligand Intramolecular Interaction 267a

Identification of proteins in One-and Two-Dimensional Gels by Mass Spectrometric Peptide Mapping 268a

Surface Induced Dissociation of Peptides in a Four Sector Mass Spectrometer 269a

Determination of Posttranscriptional Modification in Ribosomal RNA by Mass Spectrometry 270a

The Hows and Whys of Multiply-charged Oligonucleotide Decompositions 271a

Electrospray Ionization of Plasmid DNA and Detection by Mass Spectrometry 272a

Quantification of Apolipoprotein A-1 by Isotope Dilution FAB MS 273a

Detailed Structural Characterization of Carbohydrate and Glycoconjugate oligomers Using Selective Chemical Modification, ES and CID Analysis 274a

MS/MS of Cobalt-coordinated Branched Pentasaccharide Isomers: Linkage Position Determination using Electrospray Ionization 275a

From the Outer Membrane to the GAS Phase: Making Ions of Bacterial Surface Antigens 276a

Neutralization-Reionization MS

Neutralization-Reionization Mass Spectrometry 277a

Neutralized Ion Beam Studies of O2: A New State for an Old Molecule 278a

Collisional Electron Transfer: Where Does the Electron Go? 279a

Investigation of Ion Structures by Neutralization-Reionization Mass Spectrometry Methods 280a

Neutralization-Reionization Mass Spectrometry; what next? 281a

The Quest for the Elusive Iminols with NRMS and Multiple Collision Experiments (MS/MS/MS) 282a

Investigation of Ionized Cyclopropanol. Does it Exist? 283a

Detection and Characterization of Novel [C2H3NO] + Isomers and their Neutral Counterparts 284a

The Characterization of Labile Metallocenes and Their Neutral Counterparts by Tandem Mass Spectrometry 285a

LC/MS Determination of Small Molecules

Current Status and New Leads in the Analysis of Small Molecules by LC-MS 286a

Electrospray Ionization at LC Compatible Flow Rates on a Magnetic Sector Mass Spectrometer 287a

LC/ESMS Characterization of Small Molecule Mixtures in Industry 288a

Liquid Chromatography (LC)/Particle Beam (PB) and Thermospray (TSP)/Mass Spectrometry (MS) in Environmental Analyses 289a

Electrospray LC/MS of Lower Molecular Weight Molecules 290a

New APCI Technology Enhances Pharmacokinetic Studies in Biological Samples 291a

Comparison of Thermospray and Ionspray for the Analysis of Drug Conjugates 292a

Characterization of Low Molecular Weight Thermally Labile Analytes Using Capillary Supercritical Fluid Chromatography/Mass Spectrometry (SFC/MS) 293a

Profilling of Bacterial Metabolites by On-line Capillary LC - Electrospray MS 294a

Plasma Source Atmospheric Pressure Ionization Detection of Liquid Injection Using An Ion Trap Storage/Reflection Time-of-Flight Mass Spectrometer 295a

Structure Elucidation Strategies Applied to Taxol and Taxanes 296a

Petroleum Polars Characterized by Compound Class Separation and On-Line LC/MS 297a

Metal Ions/Ion Molecule Reactions

Bond Energies and Electronic States of Unsaturated Organometallic Complexes 298a

Substituent Effects and Solvation Energetics from Electron-Transfer Equilibirum Studies of Gas-Phase Metal Complexes 299a

Reaction of State Selected V+ with C2H6 and C3H8 300a

Accurate Bond Dissociation Energies from Equilibrium Clustering Measurements: Co+.(H2)1-7, V+.(H2)1-6, Co+.(CH4)1-3 and Co+.(C2H6)1-3 301a

Gas-Phase Ion-Molecule Reactions of Fe+ with Model Peptides: Ground Versus Excited Electronic State Reactions 302a

Isotopic Fractionation in the Formation of He2 303a

Fundamentals of Tandem Mass Spectrometry 304a

Isotopomer Differentiation Using Metal Ion Chemical Ionization 305a

Transition Metal Cluster Anions: Periodic Trends in Oxidation and Chemisorption Reactions 306a

The Negative Chemical Ionization Reactions of the Atomic Oxygen Radical Anion with Selected Alkenes 307a

Antiaromatic Ions: The Formation, Reactivity, and Thermodynamic Properties of a Cyclopropenyl Anion 308a

Ion-Molecule Reactions of Dicoordinated Boron Cations 309a

TUESDAY POSTERS

Metabolism of Drugs

The Structure Elucidation of Taxol Analogs and Impurities Using LC/MS and LC/MS/MS Profiling Protocols 310a

Detection of Alkaloids by Positive Ion Thermospray LC/MS Using a Nonconventional Ion Pairing Agent 311a

Coupling of Capillary High-Performance Liquid Chromatography with Continuous-Flow Liquid Secondary Ion Mass Spectrometry for the Determination of Flavonoid Conjugates 312a

Mass Spectrometry of Three New Toxins Produced by Alternaria Alternata f.sp. lycopersici 313a

Supercritical Fluid Extraction and LC/MS of Thiosulfinates Found in Allium Species 314a

LC/MS Identification and Characterization of Components Isolated from Chaparral 315a

Separation and Identification of Didemnins and Ecteinascidins by On-line Microbore Liquid Chromatography/Continuous Flow Fast Atom Bombardment Mass Spectrometry 316a

Identification of S-linked Conjugates of 2-Chloroethyl Isocyanate as metabolites of N,N-bis(2-Chloroethyl)-N-nigrosourea(BCNU) in the Rat by Ionspray LC-MS/MS 317a

The Utilisation of Modern LC/MS Methods to Study the Phase I and Phase II of Metabolism of Trimetazidine in Human Subjects 318a

Development of a LC/MS/MS assay for FIAU 319a

Particle Beam LC-NCI MS Assay of Kynurenic Acid in the Media of Cultured Cells 320a

Identification of Rat Liver Microsomal Metabolites of Atevirdine Mesylate by Particle Beam LC/MS 321a

Quantitation of Hydroxybenzoates in Biological Fluids as Indices of Hydroxyl Radical Production 322a

Quantitative Determination of Retinoic Acid in Rat Serum and Rabbit Plasma by GC/NCI-MS 323a

Quantitative Determination of Lanosterol and Dihydrolanosterol in Plasma, Serum, and Tissues by GC-MS for Evaluation of Cholesterol Lowering 324a

Quantitative Determination of Butorphanol in Human Plasma by GC/ECCI/MS 325a

Quantitative Determination of the Antipsychotic Agent CP-88,059 in Human Serum by HPLC/MS/MS 326a

A NCI GC/MS Method for Olanzapine in Human Plasma 327a

Analysis of Bile Acids and Sterols in cecum and Colon Contents from the Sprague-Dawley Rat by GC/FID-MS 328a

Quantitative Determination of -Cyclodextrin in Human Urine by Electrospray LC/MS 329a

Quantitative Analysis of GR38032 by Isotope Dilution Partcile Beam-LC/MS using Normal Phase and Reverse Phase HPLC 330a

Quantification of Peptide Isotopomer Abundances and Determination of Protein Turnover Rates by Using Mass Isotopomer Distribution Analysis (MIDA) 331a

Determination of 15N Enrichment of Taurine in Cat Urine by GC/MS 332a

Enantioselective Glucuronidation of the Antipsychotic Agent 5-Fluorophenyl-hydroxbutyl-5-fluoro-phrimidinylplperazine (5F-FHPP) and Related Analogs by Rat Liver UDP-glucuronosyltransferases 333a

Derivatizations for Enhanced Detection of N-linked and O-linked Glucuronide Conjugates by LSIMS 334a

Analysis of Insulin-Acyl Glucuronide Adducts by Electrospray/Mass Spectrometry 335a

Assay of the 13C-enrichment and Concentration of Acetate in Biological Fluids 336a

Applications of GC-CRIMS to the Investigation of Metabolic Disease 337a

A Comparison of Substituted Phenylboronic Acids as Derivatization Reagents for NCI/MS 338a

Quantitative Analysis of Peptido-Leukotrienes in Nasal Secretions by Two-Dimensional Gas Chromatography/Mass Spectrometry 339a

On the Problem of Sensitivity for Detection of LTC4, LTD4, and LTE4 in LC CF-FAB 340a

Continuous Flow Liquid Secondary Ion Mass Spectrometry (CF-LSIMS) Characterization of in vitro and in vivo Metabolism of 5-Lipoxygenase Inhibitor L-702,618 341a

Characterization of Pineal Metabolites by Thermospray LC/MS/MS and GC/MS 342a

Characterization of Synthetic Immunostimulatory Lipoidal Peptides by FAB-, ESI- and MALDI-MS 343a

Enzymatic Conversion of NAAG to NAA in vivo using Microdialysis/Mass Spectrometry 344a

Hydrolysis of Peptide and Protein Drugs by Immobilized Hepatic Proteases Measured Using Continuous-Flow FAB LC-MS and MS-MS 345a

An Essay for Urinary Peptidal Leukotrienes using Immunoaffinity Extraction and Capillary HPLC / CF-LSIMS Detection 346a

Proteins

Association of Peptides with Bovine Serum Albumin (BSA) by Electrospray Ionization Mass Spectrometry 347a

Study of Molecular Association by Electrspray Mass Spectrometry 348a

Structural Characterization of the Lung Surfactant Protein SP-B by Mass Spectrometric Methods 349a

Use of Electrospray MS to Characterize Covalently Modified Proteins: Factors Affecting Resolution and Sensitivity 350a

Structural and Functional Characterization of the Lung Surfactant Protein SP-C -Electrospray Mass Spectrometric Identification of Noncovalent Dimers 351a

Reversibility of Heat Induced Conformational Changes of Proteins Studied by Electrospary Ionization Mass Spectrometry 352a

Determination of Primary Structure and Biological Activity of Different Recombinant Human Epidermal Growth Factor Proteins 353a

Structural Characterization of Cyclic RGD-Containing Peptides by Ionspray Tandem Mass Spectrometry 354a

Application of Electrospray Mass Spectrometry to Structure Studies of Bovine Adenosine Deaminase 355a

Electrospray Mass Spectrometry Characterization of Cathepsin B C-Terminal Processing 356a

Studies of The ras P21-GDP/GTP Noncovalent Complexes by Ion Spray Mass Spectrometry 357a

Comparison of Charged Peptide Derivatives for High Energy CID MS/MS 358a

High Resolution and MS/MS Matrix-assisted Laser Desorption on a fourier Transform Mass Spectrometer 359a

The Analysis of Biomolecules by Electrospray Ionization on a Magnetic Sector Tandem Mass Spectrometer 360a

Analysis of Pyridinoline and its Derivatives by Positive-Ion L-SIMS and four-sector Tandem Mass Spectrometry 361a

HPLC-PB-CI-MS and HPLC-TSP-MS of Linear Peptides (Efrapeptins) and Cyclodepsipeptides (Destruxins) of Fungal Origin 362a

Capillary HPLC/MS Analysis of Hydrophobic Peptides from the 2-Adrenergic Receptor 363a

Electrospray mass Spectrometry Analysis of Opioid Peptide Precursors 364a

Tandem Mass Spectrometric Identification of a Specific Cysteic Acid Residue in Oxidized Low Density Lipoprotein 365a

Structural Determination of a Modified Membrane Lipopeptide from Mycobacterium avium by Using Electrospray, FAB, and Precursor Ion Scanning 366a

Mass Spectral Analysis of Peptide Adducts of the Lipid Peroxidation Product 4-Hydroxy-2-nonenal 367a

Structure Determination of ESI-MS of Putative Locust Diuretic Peptides 368a

Characterization of the Dragline Protein Collected from the Spider Nephilia clavipes 369a

Charting of Pituitary Glycoproteins by Capiliary Liquid Chromatography - Electrospray Mass Spectrometry 370a

Analysis of Abnormal Glycoproteins of Patients with Carbohydrate Deficient Glycoprotein Syndrone 371a

Structure of the Disialylated Transferrin Specifically Found in Carbohydrate-Deficient Glycoprotein Syndrome 372a

HPLC/ESI/MS of Tryptic Digests on Modified Cytochromes 373a

Characterization of Cytochrome P450lin by Mass Spectrometry 374a

Chemical and Mass Spectrometric Characterization of the Heterogeneous N-terminal Lipid Modification of Photoreceptor G-Protein -Subunit 375a

Characterization of Peptides Extracted from the Human Class I MHC Molecule, HLA-B7 376a

Structural Analysis of Peptides Associated with the Class I MHC Molecule HLA-A24.1 377a

Application of Mass Spectrometry in the Determination of the Primary Structure of Interleukin-1 Converting Enzyme (ICE) 378a

Characterisation of Recombinant IL4 379a

Protein Ladder Sequencing in Solid Phase Peptide Synthesis 380a

Technical Improvements Needed to Fully Integrate MS into the Reference Hemoglobinopathy Laboratory 381a

Amino Acid Sequence Determination of Neuropeptides by Using Electrospray Ionization on a Magnetic Deflection Mass Spectrometer 382a

Use of High Resolution MSn Capabilities for Peptide Sequence Determination Using a Quadrupole Ion Trap Mass Spectrometer 383a

A Mass Spectrometric Assay for The Detection of Pyroglutamic Acid in Peptides 384a

Matrix Assisted Laser Desorption/Ionization of RNase Glycation 385a

Automated Peptide Mapping and Sequencing by LC-ESI-MS 386a

Probing Secondary Structures of Proteins by Mass Spectrometry 387a

Environmental

An Atmospheric Pressure Low-Power Microwave Plasma Ionization Source for Liquid Chromatography - Mass Spectrometry (LC-MS) 388a

A Comparison of Analytical Techniques (API/MS, GC/MS and FTiR), for the Measurement of Combustion Products from a Variable-Fuelled Automobile 389a

The Application of HPLC Flow-FAB anmd ESI-MS to the Analysis of Pesticide Transformation Products 390a

A Quantitative Study of Carbamate Pesticides Using Direct Injection/Electrospray Ionization Mass Spectrometry 391a

Sensitivity Enhancement in an Atmospheric Pressure Ionization (API) Source Mass Spectrometer via Gas-Phase Neutral Derivatization 392a

Application of Thermospray LC/MS to the Study of Small Organic Acids in Radioactive Mixed Hazardous Wastes 393a

Capillary Liquid Chromatographic Mass Spectrometric Identification of Arsenic Compounds used as Animal Feed Additives 394a

Short Path Thermal Desorption GC-MS for the Analysis of Sodium Carbonate and Sodium Bicarbonate 395a

Thermospray LC-MS Measurement of Brucine in Serum and Urine 396a

Formation of Dialkyl- and Diaryltin Buffer Adduct Ions Under Electrospray-LC/MS Positive Ionization Conditions 397a

Analysis of Ionic Textile Dyes and Degradation Products Using CE-MS and CE-MS-MS with Ionspray Ionization 398a

Characterization of Maillard Reaction Products by Capillary Electrophoresis-Mass Spectrometry 399a

Capillary Electrophoresis/Electrospray Mass Spectrometry of Some Hazardous Industrial and Agricultural Chemicals. 400a

Determination of Tin Alkylates in Environmental Samples using Thermospray and Electrospray LC/MS 401a

A Study of the Relative Particle Beam Transport Efficiency of Typical Commercial Additives in Common Reverse Phase Solvent Systems 402a

The Identification of Organosulfur Compounds in Produced Water by Mass Spectrometry 403a

Determination of Hydroxyatrazine in Water at Low-ppt Levels by using Carbon Black Cartridge Extraction and High Resolution FAB-MS 404a

Identification of Volatiles and Semi-Volatiles in Honey 405a

Using GC/MS for the identification of Volatile and Semi-Volatile Components in Food 406a

Laser Desorption/Ionization

Photodissociation-Photoionization Mass Spectrometry 407a

Protein Phosphorylation Site Study 408a

Complex Formation Between Macromolecules in Matrix-Assisted Laser Desorption Ionization 409a

Structural Characterization of A Cytosolic Glutathione-s-transferase by Fast Atom Bombardment CAD and Matrix Assisted Laser Desorption Mass Spectrometry 410a

Gas-Phase Ion-Molecule Reactions of Peptide Ions with Small Neutral Molecules 411a

A Comparative Study of Matrices for Matrix-Assisted Laser Desorption/Ionization (MALDI) of Taxol and Various Taxanes 412a

Matrix-assisted Laser Desorption/Ionization by Fourier Transform Mass Spectrometry 413a

Applications of Mass Spectrometry to the Determination of Tertiary and Quaternary Protein Structure 414a

Mass Spectrometric Investigation of Proteins Separated by 2-dimensional Electrophoresis 415a

Matrix-Assisted Laser Desorption/ionization TOF Mass Spectrometry as a Probe of Protein Structure 416a

Evaluation of Phosphorylation-dependent Protein Bioactivity by Matrix-assisted Laser Desorption Time-of-flight Mass Spectrometry 417a

Evaluation of Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry for use in Clincial Assays 418a

Real Time Analysis of Single Aerosol Particles 419a

Examination of Native and Degraded IgG Antibodies by Micellar Electrokinetic Capillary Chromatography and Matrix Assisted Laser desorption/Ionization Mass Spectrometry 420a

Carbohydrate-Containing Matrices for MALDI: Applications to Recombinant Protein Digests and in situ Digests of Proteins from Two-Dimensional Gels 421a

An Investigation into the Advantages Offered by an Array Detector on Magnetic Sector Instrumentation for Different Ion Sources 422a

Comparison of Field Desorption and Matrix Assisted Laser Desorption Ionization of An Industrial Oligomeric Additive 423a

Direct MALD-MS Analysis of Protease Digests: Comparative Study of Analysis Parameters 424a

Cleavage of the Asp-Pro Bond of Peptides in MALD-TOF Mass Spectrometry 425a

MALD on a Magnetic-Sector Mass Spectometer equipped with an Integrating Array Detector 426a

An Improved Illumination System for Matrix-Assisted Laser Desorption 427a

Spatial Map of the Polycyclic Aromatic Hydrocarbons (PAHs) in the Allende (CV3) and Bjurbole (L4) Meteorites 428a

Analysis of Polycyclic Aromatic Hydrocarbons (PAHs) in Cosmic Dust 429a

Laser Desorption Studies of Oxidative Decomposition in K3C60 and related Fullerenes 430a

Analysis of Lipid-A from Gram Negative Bacteria Using Matrix-assisted Laser Desorption Time-of-Flight Mass Spectrometry 431a

Matrix-Assisted CO2 LD/FTMS of Peptides 432a

Direct LD/FTMS of Microbial Polyesters 433a

Detection of Large Molecular Ions by Secondary Ion and Electron Emission 434a

Photodissociation of Precursor Ions Produced by MALDI in a Four-Sector Tandem Mass Spectrometer 435a

Matrix-Assisted Laser-Desorption Mass Spectrometric Analysis of Proteins Adsorbed on Nylon Membranes 436a

Time-of-Flight Mass Spectrometry Studies of Laser Desorbed Neutral Gramicidin S Molecules 437a

Trapped Ions

Consideration for the Size and Power Reduction of a Field Transportable Ion Trap Mass Spectrometer 438a

The Next Horizon in Portable GC/MS for Air Monitoring Applications 439a

Larger Cells for ICR Spectrometers with Electromagnets 440a

Laser Desorption Ion Trap Mass Spectrometry of the Polymeric Component of Coal 441a

Isotopic Masses at ppb Precision (!) from FT/ICR Mass Difference Measurements 442a

Applicaton of a Mechanical Shutter for Pressure Control in External Source Electrospray FTICR 443a

A Novel Benchtop Ion Trap Mass Spectrometer for GC/MS/MS 444a

Infrared Multiphoton Dissociation Studies in the Quadrupole Ion Trap using a Multi-Pass Optical Arrangement 445a

Boundary-Activated Dissociation of Mass-Selected Ions in a Quadrupole Ion Trap 446a

Nature and Effect of Non-Linear Resonances in Ion Traps 447a

Quadrupolarized ICR Cubic Ion Trap 448a

Contaminant Analysis Using Novel Sampling Strategies and Laser Desorption Mass Spectrometry 449a

An Improved Calculation of Peak Shape in FTMS 450a

SWIFT Excitation/Ejection of Ion Axial Motion in Quadrupole Ion Trap Mass Spectrometry 451a

Minimization of Radial Electric Field Effects in Open Cell Geometries used for External Source FTICR 452a

New Methods of Operation for the Quadrupole Ion Trap 453a

Time-Dependent Behavior of Multiply Charged Electrosprayed Ions Trapped in a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer 454a

Enhanced Trapping of Laser Desorbed Ions in a Quadrupole Ion Trap by use of a Transient RF Trapping Field 455a

The Reduction of Matrix Effects in a Quadrupole Ion Trap Mass Spectrometer 456a

Protein Structural Elucidation by Electrospray Ionization Tandem Fourier-Transform Mass Spectrometry 457a

Ion Trap Mass Spectrometry Combined with Inductively Coupled Plasma/Mass Spectrometry 458a

Effects of Ion Trap Parameters on Mass Axis Stability: Influence of Manifold Temperature, Pressure, and Axial Modulation Voltage on Mass Spectra of Hydrocarbons 459a

Optimizing Ion Accumulation in External Source Fourier Transform Mass Spectrometry 460a

Electrospray on an Ion Trap Mass Spectrometer: Comparison of Axial vs. Diagonal Injection of Ions into The Trap 461a

Off-Center ICR Cubic Ion Trap: Reduction of Space Charge and Manipulations of Coherent magnetron Motion 462a

Non-Resonance Excitation and Ejection in Ion Trap 463a

A Simple Physical Model for the Origin of the 2 z Resonance in FT-ICR 464a

A Basic Theoretical Approach for the Description of Non-Linear Ion Traps 465a

A New Type of Structures of Linear Quadrupole Mass Filters and Ion Traps with and without FT Techniques 466a

Ion Trajectory Simulations for a Radio Frequency Glow Discharge Fourier Transform Ion Cyclotron Resonance Mass Spectrometer 467a

Selected Ion Storage Target Compound Analysis in Complex Matrices Using Ion Trap GC/MS 468a

Optimization of a New API Ion Trap System for On-Line HPLC and CE Applications 469a

Particle Beam Mass Spectrometry on Ion Trap and Sector Instrumentation for Pharmaceutical Analysis 470a

An Electrostatic Ion Guide Interface for SIMS with an FT/ICR Mass Spectrometer 471a

Determination of Ion Frequencies in an Quadrupole Ion Trap Using a Fast DC Pulse "Pump" and a Laser "Probe" 472a

Evidence for "Black Holes" during EI in a Quadrupole Ion Trap Mass Spectrometer 473a

Ion Isolation and Modulated Ion Excitation for GC-MS/MS In An Ion Trap Mass Spectrometer 474a

Ion Energy-Modulated Stored Waveform Ion Modulation (SWIM) Two-Dimensional FT/ICR MS/MS 475a

Ion Fragmentation & Structure

Activation of Aromatic Rings in Thermal Energy Gas Phase Metal Ion-Molecule Reactions 476a

Intermediacy of Ion-Neutral Complexes in the Dissociation of Protonated Alkyl Ether Ions 477a

On the Role of Ion-Neutral Complexes in the Alkene Loss from the Molecular Ions of Alkyl Phenyl Thioethers 478a

Competitive Fragmentation Pathways for Ion-Neutral Complexes in Metastable Ions from Electron Impact on SS-Fluorophenetole 479a

Structure and Vibrational Frequencies of ionized Ethane: A Fluctional Molecule? 480a

Theoretical Study of the Ring Closure of the 1,7-Octadiyne Cation 481a

Doubly Ionized States of Fluorinated Methanes 482a

Singlet State Energy Levels of C2H4 2+ 483a

Dynamics of the Unimolecular Dissociation of Dimethylformamide Radical Cation 489a

Fragmentation of Diethyl Dicarboxylates under EI and CI Conditions 490a

A Comparative Study of the Dynamics of Low and Medium Energy Collision-Induced Dissociation of Isomeric Ions 491a

Internal Energy Effects on the Fragmentation of Ions and Neutrals 492a

Decomposition of the Ethyliodonium Ions in the Gas Phase 493a

Dechlorination of PCB's in Electron Capture Negative Ion Chemical Ionization Mass Spectrometry 494a

EI-Linked Scan Studies of Dimethylaminomethylene-O-Trialkylsilyl Nucleosides 495a

The Neutral Products from the Remote Site Fragmentation of Fatty Acid Derivatives 496a

Collisional Dissociation Technique for Assignment of metalloporphyrin Cation Electronic Structure 497a

Ion Molecule Reactions and MS3 Studies on Taxol and Related Natural Products 498a

Investigation of Fluoroformic Acid, Its Radical Cation, and Its Protonated Form by Tandem Mass Spectrometry Techniques 499a

Negative Ion Chemical Ionization/Collisionally Activated Dissociation Studies of Aryl Pentafluorobenzoates 500a

HTeTeH is Stable in the Gas Phase 501a

Organic Sulfur Radicals by Neutralization-Reionization Mass Spectrometry 502a

Neutralization-Reinization Mass Spectrometry (NRMS) Studies of Ethylene Glycol Polymers 503a

Analysis of Triphenylmethane Dyes by Mass Spectrometry 504a

Do Reactivity Probes Reveal Ion Structure? The Case Against Dipole-Stabilized Ions 505a

The Structures of Gas-Phase C7F7+ Ions 506a

Structural Investigation of Impurities in Synthesis of LY225698 507a

Where do Fullerenes Come from, Anyway? 508a

The Resilience of C60 Towards Decomposition and Ionization 509a

Isotope Effects on the Mass Spectral Fragmentation of the Mixed Glycerol-d5-glycerol Clusters 510a

Comparison Between Tandem Mass Spectra of Cyclic Peptides Obtained with a Four-Sector Mass Spectrometer and an External Ion Source FTMS 511a

Mechanisms of Fragmentations of Cationic Peptide Ions: 512a

Elimination of Propene from Metastable n-Propyl- and isopropylammonium Ions 513a

Biological Miscellaneous

Measurement of Long-Chain Fatty Acyl CoA Species by GC/MS 514a

Low-energy Tandem Quadrupole Mass Spectrometry of unsaturated FAME: A Revealing Study of Unique Ion Chemistry 515a

Tandem Mass Spectrometry of Multiunsaturated Triacylglycerides: Problems and Solutions 516a

Characterization of Dairy Triglycerides Isolated Using Supercritical Fluid Fractionation by Field Desorption, Desorption Chemical Ionization, and Tandem Mass Spectrometry 517a

Analysis of Bull Sperm Plasma Membrane Phosphatidylcholines by Negative Ion FAB-CAD-MS/MS 518a

Characterization of Oxidized Phospholipids Using Fast Atom Bombardment Tandem Mass Spectrometry 519a

Thermospray LC/MS Analysis of Phospholipid Molecular Species in Rat Brain Mitochondria 520a

Positive-ion L-SIMS and Four-Sector Tandem Mass Spectrometry of Aminophospholipids Using Scanning-array Detection 521a

Characterisation of Glycolipids and Sphingolipids by Matrix-Assisted Laser Desorption 522a

Examination of Phospholipids by Matrix-Assisted Laser Desorption 523a

Polymers

Comparison of Several Contemporary Ionization/Mass Analyzer Techniques for Large Components of Complex Fossil-Derived Materials 524a

FAB-MS and SIMS Characterization of Polyamic Acid Precursor Formation from BPDA and ODA 525a

Secondary Ion Detection of Polymers in Matrix-Assisted Laser Desorption Mass Spectrometry 526a

Rapid Evaluation of Polymers using Particle Beam/Chemical Ionization Mass Spectrometry 527a

Desorption Chemical Ionization and Liquid Secondary Ion Mass Spectrometry of Dimer and Trimer Fatty Acids 528a

Application of MALDI Mass Spectrometry to Different Classes of Synthetic Polymers 529a

Direct Analysis of Polypropylene Compounds by Thermal Desorption and Pyrolysis Mass Spectrometry 530a

Thermal Decomposition-(Gas Chromatography)-Mass Spectrometry [TD-(GC)-MS] for Thermal Behavior Study of Polymers 531a

A Method for Distinguishing Chlorosulfonated Polyethylene from Chlorinated Polyethylene Using Pyrolysis/GC/MS 532a

GC/MS Determination of Aromatic Isocyanates and Amines as Degradation products in Polyurethane Foams Used in Breast Implants 533a

GPC/MS Using a Particle Beam Interface 534a

Polyamic Acid and Polyimide Characterization Using GC/MS and Particle Beam LC/MS 535a

Direct Chemical Analysis of UV Laser Ablation Products of Organic Polymers Using Reflection Time-of-Flight Mass Spectrometry (Re TOF-MS) and Gas Chromatography/Mass Spectrometry (GC/MS) 536a

Analysis and Quantification of Polymer Additives in Polyolefins by Particle Beam LC/MS 537a

Surface Additives on Bulk PET Studied with High Mass Accuracy ToF-sSIMS 538a

Nonpolar Polymer Analysis by Continuous Flow Fast Atom Bombardment Mass Spectrometry (CF-FAB/MS) 539a

WEDNESDAY POSTERS

Metabolism & Drugs

Analysis of Acycarnitines in Biological Fluids by Electrospray LC/MS: Application to Human Metabolism Studies 540a

Derivatives for Detection of Anabolic Ketosteroids by Positive Electrospray Mass Spectrometry 541a

Determination of 5-HT3 Antagonists in Biological Fluids Using Heated Nebulizer and Electrospray LC/MS and LC/MS/MS 542a

Identification of Xenobiotic Conjugates by Positive and Negative Ion Electrospray Mass Spectrometry 543a

Identification of Metabolites and RG-12915 in Human Urine Using API-LC/MS and LC/MS/MS Techniques 544a

Characterization of Biliary Rapamycin Metabolites by Ionspray Liquid Charomatography/Mass Spectrometry 545a

Saxitoxin Detection in Rat Urine by HPLC and CE-ESIMS 546a

Confirmation of Des-Methyl Danofloxacin Residues in Swine Liver by HPLC/ESI-Tandem Mass Spectrometry 547a

An HPLC/ESI-Tandem Mass Spectrometry Method for the Confirmation of Doramectin Residues in Cattle Liver and Fat 548a

Identification of the Anticonvulsants Felbamate and Phenytoin and their Metabolites by Thermospray Tandem Mass Spectrometry in Clinical Human Urine Samples 549a

Identification of the Felbamate Metabolite 3-Carbamoyloxy-2-Phenylpropionic Acid (W-3049) in Human and Dog Urine by Negative Ion Thermospray Tandem Mass Spectrometry 550a

Analysis of The Squalestatins By On-line Packed Capillary LC-DLSIMS 551a

DCI, TSP and ESI Investigations of SS-carbolines 552a

Identification of Fadrozole (CGS 16949a) Metabolites in Human Urine by Stable Isotope Pattern Recognition Gas Chromatography/Mass Spectrometry 553a

Drug Metabolism Studies Using "Intrinsic" and "Extrinsic" Labels: 15N vs CI In Midazolam 554a

Profiling of Tryptophan Metabolites in Cell Culture by HPLC-CRIMS 555a

The Application of Liquid Chromatography/Chemical Reaction Interface Mass Spectrometry (LC/CRIMS) to Quantitative Studies in Drug metabolism 556a

Analysis of Catecholamine Metabolites by Electron Capture Mass Spectrometry 557a

Studies of nitrogen Metabolism Using CRIMS: Labeled Glutamine in Cell Culture 558a

Hepatic First-Pass Metabolism of Diphenhydramine in Sheep 559a

Characterization of Metabolites of [14C] Cyoctol Excreted in the Urine of Rats by Gas Chromatography-Mass Spectrometry 560a

The Metaboism of Essential Fatty Acids in Humans: Studies on the Effects of Dietary Fats on the Conversion of 2H5-18:3n3 & 2H5-18:2n6 to Long Chain Polyunsaturates 561a

The Metabolism of Fluorinated VPA Analogues 562a

Identification of Glutathione Conjugates of Tris-(2,3-Dibromopropyl)phosphate by Tandem Mass Spectrometry: Applications of Stable Isotopes as Mechanistic Probes 563a

A GC-MS-MS Screening Strategy for the Identification of N-Acetylcysteine Conjugates Derived from Chemically-Reactive Drug Metabolites of Haloalkanes 564a

Applicaiton of Negative Ion Chemical Ionization Isotope Dilution Gas Chromatography/Mass Spectrometry to Pulse Dose Bioavailability Studies of mefloquine 565a

Intensive Hydrogenation: A New Concept for Biological Sample Preparation 566a

In Vitro Pancreatic Lipase hydrolysis of Emulsified Common Fats and Oils by high Temperature Gas Chromatography/Flame Ionization and Mass Spectrometry. 567a

Plasma Testosterone by Negative Chemical Ionization GC/MS 568a

Comparison of Electron Impact, Positive and Negative Chemical Ionization Mass Spectrometry of Benzodiazepines 569a

Characterization of LTD4 Antagonist Metabolic Profiles Using Capillary HPLC / Continuous-Flow Liquid-Secondary-Ion Mass Spectrometry 570a

FAB Accurate Mass Measurements Using a Rotating Probe on the VG ZAB-2SE Mass Spectrometer 571a

Structure Determination and Diagnostic Value of Abnormal Bile Acids in Urine from Patients with Generalized Peroxisomal Disease 572a

The Identification of Ketoconazole Metabolites in the Mouse Liver by liquid SIMS ms/ms 573a

Complete Mass Spectrometric Structure Elucidation of an Unknown Possible Metabolite 574a

Structure Elucidaton of Novel Leukotriene B4 metabolites from Cultured human Keratinocytes 575a

Multiresidue Analysis of Sulfonamide Antibiotics in Milk Using LC-Atmospheric Pressure Chemical Ionisation-MS 576a

Studies of New Secondary Metabolites of Streptomyces Spectabilis by FABMS, FABMS/MS, and LC/FABMS Moving Belt Interface 577a

Proteins

Analysis of Very Hydrophilic Proteins by Electrospray Mass Spectrometry 578a

Mass Spectrometric Characterization of a Family of Hydrophobic Peptides with Antibiotic Properties Containing Both L- and d-Amino Acids 579a

Comparative CID Study of Peptides Using Electrospray Ionization Versus LSIMS as the Primary Ionization Method 580a

Electrospray Ionization Mass Spectrometry of Peptides and Proteins in the Presence of Detergents 581a

Optimization of LCMS Flow Rate for Maximum Mass Spectrometer Detection and Minimum Run Time. 582a

Analysis of Peptides by the Desorption/Ionization Technique K+IDS, K+-Ionization of Desorbed Species 583a

Fast Atom Bombardment Mass Spectra of Peptides Derivatized with 2-Iminothiolane 584a

Chloroformate Derivatization of Peptides for Detection by FAB-MS 585a

Identification of Novel Chemical Modifications in Proteins: gem-Diamino formation and Guanidino N-displacement Product in -Lactamase and Carbonic Anhydrase 586a

The Characterization of Products of Reactions of Hydroxyl radical with Amino Acids and Peptides using GC/MS 587a

ESI/MS Detection and Characterization of Novel Thiohydantoin Amino Acid Derivatives 588a

Synthesis and Mass Spectrometric Characterization of Reference Phosphopeptides 589a

Tandem Mass Spectral Studies of N-Acylated Tetraglycines and Tetraalanines as Models for the Free Oligopeptides 590a

Hydrogen/Deuterium Exchange of Gaseous, Multiply-Charged Protein Ions 591a

Conformation of Proteins Studied by Deuterium Exchange Electrospray Ionization Mass Spectrometry 592a

Protein Backbone Amide Hydrogen Exchange Determined by HPLC FABmS: Applicaton to Rabbit muscle Aldolase 593a

Using AMASS to Determine a Criterion for the Verification of Peptide Structrue 594a

Interpretation of Peptide CID Spectra using Artificial Neural Networks 595a

Rapid Identification of Proteins by Database Matching of Proteolytic Peptide Masses 596a

Molecular Characterization of Surface Topology in Protein Tertiary Structures by Amino-Acylation and Mass Spectrometric Peptide Mapping 597a

Characterisation of the WHO International Reference Standard for Thyroxine Binding Globulin by ESMS 598a

Phosphorylation of Human and Bovine Prothymosin In Vivo 599a

Characterization of the Phosphorylated Ribosomal Protein S7 from Tetrahymena 600a

Mass Spectrometry of Phosphopeptides Isolated by Immobilized Metal-Ion Affinity Chromatography 601a

An Approach to Characterize Phosphorylation Sites in Phosphopeptides and Phosphoproteins by Combining Enzymatic and Chemical Reactions with MALDI-TOF Mass Spectrometry 602a

Analysis of Amylin and Related Peptides from Biological Fluids Using LC/MS/MS 603a

Characterization of SS-Amyloid1-42: A Major Component of Cerebrovascular Amyloid Deposits 604a

ESMS of Human Serum Amyloid P Component: Confirmation of the Structure and Analysis of the Role of the Glycan 605a

Identification of Water Insoluble Human Lens Crystallins by Mass Spectrometry 606a

Elucidation of High-order Structure in Lens -crystallin by Continuous-Flow HPLC FABMS 607a

Analysis of the Bacitracin Complex by LC-Ionspray mS 608a

Post Translational Modifications of Recombinant Barley -amylase 1 Expressed in Yeast, Characterized by Electrospray Mass Spectrometry 609a

Capillary LC - Electrospray - MS Reveals Expression of more than one Rat Proopiomelanocortin 610a

Characterization of Three Isoforms of Soybean Agglutinin by ESI MS 611a

Characterization of Protein Post-Translational Modification by ESI-MS 612a

Primary Structure Characterisation of Legume Lectins; Sequence Assignment and Identification of post-translational Modifications using LC-MS and 1C-MS-MS 613a

Investigations into the Post-Translational Modification and Mechanism of Isopenicillin N: Acyl-coenzyme A Acyltransferase using EIMS 614a

Recombinant Human Neurotrophin-4 (NT-4): Characterization of Protein Folding by Matrix-Assisted Laser Desorption TOF and Electrospray Ionization Mass Spectrometry 615a

Effects of Anions on Electrospray Ionization Mass Spectra of Peptides and Proteins 616a

Analysis of Biliproteins by Electrospray Ionization Mass Spectrometry 617a

Determination of the Disulfide Bonding Pattern of Peptide Toxins from the Spider Agelenopsis Aperta Using Electrospray Ionization Mass Spectrometry 618a

Mass Spectrometric Characterization of the Phosphorylated Proenkephalin A-neuropeptides 619a

Identification of Two Sites of Phosphorylation in Bleached Bovine Rhodopsin by Tandem Mass Spectrometry 620a

Mass Spectrometry of Protein Samples Containing Detergents 621a

Environmental

Predicting Degradation Products of Environmental Contaminants by On-line Electrochemistry/Mass Spectrometry 622a

A Mass Spectrometer Based Diagnostic to Analyze the Hostile, High Enthalpy Exhaust of a Hypersonic Engine 623a

Identification of Polychlorodibenzothiophenes in Crab Tissues from Raritan/Newark Bay 624a

Neutral Precursor Scans 625a

Residual Volatiles Analysis of Deacidification Treatment of Books Using On-Line SFE GC MS 626a

MS/MS Characterization of Phosphate Esters 627a

Extraction of Trace Elements in Coal Fly Ash and Subsequent Determination by Inductively Coupled Plasma Mass Spectrometry (ICP-MS) 628a

Determination of Methanol in Water Samples using a Modified EPA Method 8015, Direct Injection GC/MS, and Purge and Trap GC/MS 629a

Chemical Ionization of Pesticides Using Ion Trap Technology 630a

Low PPB Detection Limits for the Analysis of Atmospheric Contaminants in Ultrapure Inert Gases 631a

Enhancement of Molecular Ion Detection by Variation of Mass Analyzer Thermal Energy for C10-C28 Alkanes by ITD/MS 632a

Survey of Volatile Organic Chemical Emissions from Waste Compsoting Facilities Using Protable Samples and Thermal Desorption Gas Chromatography/Mass Spectrometry 633a

Direct Detection of Tributyl Phosphate Adsorbed on Surfaces of Environmental Interest by Static SIMS 634a

A New Analysis Technique for Environmental Levels of Mercury Using Inductively Coupled Plasma-Mass Spectrometry 635a

Evaluation of Electrospray and FAB for Study of Organometallic Parasiticides 636a

Determination of Acid and Base-Neutral Pesticides in Water by LC-MS with a New Micro Particle Beam Interface 637a

Analysis of Pesticide Residues in Food Using GC/MS/MS with an Ion Trap Mass Spectrometer 638a

Ion Trap GC/MS Analysis of Pesticides Using Chemical Ionization with Selective Ion Ejection 639a

Compositional Analysis of Submicron Particles in Air by Time-of-Flight Mass Spectrometry 640a

Matching Probability of Library Search in Screening Environmental Samples by GC/MS 641a

Identification of Surfactants in Formulated Detergents by using FAB on the AutoSpec-Q Mass Spectrometer 642a

Detection of Metal Complexing Agents on Mineral Surfaces by Static SIMS 643a

Infraret Pyrolysis of Polymers for GCMS Analysis 644a

Modular Inlet Systems and Sampling Devices for Mobile Environmental Mass Spectrometry 645a

Automated Analysis of Selected Organic Compound in Urban Air by a (low cost ?) Isotopic Dilution Criofocussing GC/MS Method. 646a

A Novel High Resolution Mass Spectrometer for Automated Target Compound Analysis 647a

LC/MS Analysis of Mutagenic/Carcinogenic heterocyclic Aromatic Amines in Food Products 648a

Laser Desorption/Ionization

Indirect Measurement of Spatial Spread and Initial Velocity Spread of Ions Produced in MALDI 649a

High Mass Resolving Power for High-Mass Ions in LD FT/ICR/MS: Quadrupolar Axialization and Ion Cooling 650a

MALDI Fourier Transform Mass Spectrometry 651a

Heavy Atom Effects on Matrices for Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry 652a

Direct UV Laser Desorption Ionization of Peptides containing Absorbing Chromophores 653a

Matrix Assisted Laser Desorption Ionization of Hydrophobic Peptides and Proteins 654a

Monitoring Biomolecular Reactions Using Matrix Assisted Laser Desorption Mass Spectrometry 655a

Geometric Signal Averaging Applied to Matrix-Assisted Laser Desorption/Ionization Time-of-Flight Mass Spectrometry 656a

Matrix-Assisted Laser Desorption/Ionization of Oligonucleotides 657a

Ladder Sequencing of Post-translationally Modified Proteins 658a

Matrix-assisted Laser Ablation of Proteins and Oligonucleotides Using Nanosecond pulses of Tunable Mid-ir Radiation 659a

Structural Characterizationof Oligonucleotides by Matrix-Assisted Laser Desorption/Ionization Mass Spectrometry 660a

Collector Studies of Angular Distributions and Fragmentation of Proteins and Oligonucleotides Ablated from Ice and Uv-absorbing Matrices 661a

Effects of Desorption Technique and Post-Ionizing Laser Pulse Width on Molecular Fragmentation 662a

Laser Desorption and High Temperature Methods for Vaporization and Ionization in Particle Beam LC/MS Interfacing 663a

Power-dependent Calibration Shifts in Pulsed Laser Ablation Time-of-flight Mass Spectrometry 664a

Hyperthermal Surface Ionization Mass Spectrometry in Supersonic Molecular Beams 665a

pH Effects and Insulin Cleavage in Matrix Assisted Laser Desorption Mass Spectrometry 666a

Investigating the Ionization Step in MALDI: Matrix-Dependent Formation of [M+H]+ vs. [M+Na]+ Ions of Small Peptides 667a

A Postacceleration Detector for Time-of-flight Mass Spectrometry Utilizing Ion To Photon Conversion 668a

High Mass Resolution and High Mass Accuracy MALD/I Spectra with a Triple Electrostatic Analyzer Time-of-Flight Mass Spectrometer (TOF-MS) 669a

Initial Kinetic Energies of Peptide Ions Formed by MALDI 670a

Design of a New Flow Probe for Continuous-Flow Matrix-Assisted Laser Desorption Ionization 671a

Optimization of Ion Extraction and Ion Detection for Continuous-Flow Matrix-Assisted Laser Desorption Ionization 672a

Basic Matrices for the Matrix Assisted Laser Desorption/Ionization Mass Spectrometry of Proteins and Nucleic Acids 673a

Influence of Amino Acid Gas Phase Proton Affinities on Ion Yield from Matrix Assisted Laser Desorption Ionization (MALDI) 674a

A New Matrix for MALDI Analysis of Water Insoluble Organic Molecules 675a

Studies of Oligonucleotides by matrix-assisted Laser Desorption Time-of-Flight Mass Spectrometry 676a

Cleavage of Interchain Disulfide Bonds Following Matrix-Assisted Laser Desorption 677a

Analysis of Mycotoxins from Amanita Phalloides by Matrix Assisted Laser Desorption Mass Spectrometry 678a

Antisense DNA Therapeutics: Use of Matrix-Assisted Laser Desorption Mass Spectrometry for Complete Sequence Verification of Methylphosphonate Oligonucleotides 679a

Angular- and Time-resolved Intensity Profiles of Ejected MALDI Ions 680a

Trapped Ions

An External Ion Source FTMS for the Analysis of High Molecular Weight Biomolecules 681a

Storage Tandem MS, Nucleophilic Substitutions in the Gas Phase 682a

The Effect of Z-Direction Stretched Geometry on Ion Injection into a Quadrupole Ion Trap Mass Spectrometer 683a

Deflection of Laser-Produced Ions in Laser-Desorption/FTMS 684a

Determination of Relative Dissociation Energies in an Ion Trap Mass Spectrometer 685a

Trajectory Modeling of Electrosprayed Protein Ions in an FT/ICR 686a

Equilibrium Distribution of Space Charge in a Quadrupole Ion Trap 687a

Chemical Ionization in Ion Trap GC-MS Using Selective Ion Ejection Techniques 688a

Numerical Computation of Trapping and Excitation Electric Fields and Ion Trajectory Simulations in an ICR Ion Trap 689a

Non-Linear Resonance Conditions and their Relationships to Higher Multipole Fields in Quadrupole Mass Filters and Non-linear Ion Traps 690a

Electric Trap Fields and High Mass Ions in FTMS: Peak Ratios 691a

Simulation of Excitation Profiles Generated by External Source FTICR Ion Distributions 692a

Experimental Investigation of Ion Secular Frequency During Isolation in a Quadrupole Ion Trap 693a

Optimization of the Simple Open Cylindrical Trapping Geometry for FT/ICR 694a

Determination of Phosphorylation Sites on the Sendai Virus P Protein by MALD-TOF and MALD-ITMS 695a

Mechanistic Study of Saccharide Fragmentations Using Fourier Transform Mass Spectrometry and Semi-empirical Calculations (AM1) 696a

Investigations Into The Factors Which Affect Mass Measurement Accuracies Obtained with the Quadrupole Ion Trap Mass Spectrometer 697a

Uni-Directional Ion Ejection in Ion Trap 698a

Internal Ion Impact Ionization in FT/ICR Mass Spectrometry 699a

Mass-Selective Ion Accumulation in the Ion Trap: Ion Injection Using Filtered-Noise Fields 700a

Self-CI in the Ion Trap 701a

Combined RF and Magnetic Trapping in a High Pressure Fourier Transform Mass Spectrometer 702a

Electron Beam Potential Depression as an Ion Trap in Fourier Transform Ion Cyclotron Resonance Mass Spectrometer 703a

Ion Molecule Reactions and Electron Detachment of O2 - in a Quadrupole Ion Trap Mass Spectrometer 704a

Negative-ion Fragmentation Pathways of Four Isomers of Dinitrotoluene (DNT) 705a

Extended Mass-to-Charge Range Operation of a Non-Linear Quadrupole Ion Trap 706a

Pulse Sequency for the Study of Simultaneously Trapped Positive and Negative ions with ICR 707a

Multiparticle Simulations of Operating Modes of the Quadrupole Ion Trap Mass Spectrometer 708a

New Applications of Ion Tomography 709a

Computer Simulations of Ions in an Electrostatic Ion Guide for FT/ICR Mass Spectrometry 710a

Investigations in Resonance Excitation in the Quadrupole Ion Trap Mass Spectrometer 711a

Characterization of High-Mass Analysis on the Quadrupole Ion Trap Mass Spectrometer 712a

Evaluation of a Low Cost, Low Homogeneity, Vertical Bore 7 T Magnet for FTICR 713a

Matrix-Assisted Laser Desorption/Ionization in the Quadrupole Ion Trap: A New Method for Trapping Energetic Ions Using Controlled Gating of the Trapping Field 714a

The Development of Mass-Selected Automatic Gain Control on a Quadrupole Ion Trap Mass Spectrometer 715a

Gas Chromatography/Ion Trap Mass Spectrometry Using an External Ion Source 716a

A New Model for the Estimation of Ion Kinetic Energy in a Quadrupole Ion Trap 717a

FTMS External Ion Source for Ion-Molecule Reactions 718a

Characteristics of a FT/ICR Mass Spectrometer based on a 0.4 T Permanent Magnet 719a

High-Resolution Fourier-Transform Mass Spectrometry of Large Biomolecules 720a

Elemental Analysis & Isotope Ratios

Experimental and Theoretical Relative Ion Yields for Glow Discharge Mass Spectrometry 721a

Development of a Pulsed-Gas Glow Discharge Ion Source for High mass Resolution on a Fourier Transform Ion Cyclotron Resonance Mass Spectrometer 722a

The Effect of Cryogenic Cooling on the Gaseous Impurity and Analyte Ion Signals in GDMS 723a

Characteristics of a Radio Frequency Powered Glow Discharge Cell for the Analysis of Flat Samples 724a

Analysis of Electrodeposited Metal Ions by Glow Discharge Mass Spectrometry 725a

An Improved Double Quadrupole Mass Spectrometer for Versatile Radio Frequency Glow Discharge Studies 726a

Glow Discharge - Isotope Dilution Mass Spectrometry 727a

Isotopic Analyses by Glow Discharge Mass Spectrometry 728a

Design of an Array - Detector Mattauch - Herzog Mass Spectrometer for Atomic Mass Spectrometry 729a

Optimization of an ICP/High Resolution Mass Spectrometer System for Elemental Analysis 730a

ICP TOFMS System for Use in Elemental Analysis 731a

Elemental IonSpray-Mass Spectrometry: Analysis of Solutions of Metal Salts 732a

Metal Isotope Ratio Determination with Laser Desorption Time-of-Flight Mass Spectrometry 733a

Determination of Subpicogram Quantities of Technetium-99 in Environmental Samples by Positive Thermal Ionization Mass Spectrometry 734a

Simultaneous Observation of UO+ and U+ Ion Ratios via Total Evaporation Thermal Ionization Msss Spectrometry 735a

Lead Analysis by Electron Capture Negative Chemical ionization GC/MS 736a

A Study of Meso-Substituted Zinc Tetrabenzporphyrins by Fast Atom Bombardment Mass Spectrometry (FAB/MS) 737a

Gas Chromatography-Combustion Isotope Ratio Mass Spectrometry (GCC-IRMS) at Femtomole Carbon Levels and High Enrichments (dPDB>100 0/00) 738a

Comparison of Polymer Additives Analysis by High Temperature GC/MS vs. Particle Beam LC/MS 739a

Electrospray, API, Supersonic Beams

The Roles of Solvation, Basicity, and Hydrophobicity in the Electrospray Mass Spectrometry of Amines and Amino Acids 740a

Sensitivity, Dynamic Range and Solvent Effects in Electrospray Ionization 741a

Investigation of Aqueous Solution Chemistry using Electrospray Mass Spectrometry 742a

Peptide Charge State Effects on Electrospray and Capillary Electrophoresis/Electrospray Mass Spectrometry 743a

The Use of Multiple Sprayer System in the Electrospray Mass Spectromety 744a

Characterization of a New Atmospheric Pressure Ionization Interface for Liquid Chromatography-Mass Spectrometry 745a

Fundamental Energy Studies of Electrospray Ions Entrained in a Free Jet Expansion 746a

Application of Orifice Potential Ramping for the Sequence Identification of Phosphorylated Proteins 747a

Capillary LC/MS and LC/MS/MS Analysis of Peptides Using a New Capillary LC/MS Interface and A Redesigned Collision Cell 748a

Combining Capillary Electrophoresis with Electrospray ionization/Ion Trap Mass Spectrometry for Biopolymer Analysis 749a

High Mass Accuracy Electrospray Fourier Transform Ion Cyclotron Resonance Mass Spectrometry 750a

FTICR Characterization of Beam Dynamics and Electrostatic Contributions to Electrospray Ion Kinetic Energy 751a

A Direct Injection Electrospray Source for Fourier Transform Ion Cyclotron Resonance Mass Spectrometry 752a

High Energy CID of Multiply Charged Polypeptides and Polynucleotides Produced by Electrospray 753a

High Flow Electrospray LCMS on a High Performance Magnetic Sector Mass Spectrometer 754a

On-Line Interface of Capillary Electrophoresis with Time-of-Flight Mass Spectrometry 755a

Electrospray Ionization-Collisionally Activiated Dissociation on a Bench-Top Mass Spectrometer 756a

Secondary Electron Resolved Mass and Charge State Spectrometry 757a

The Use of a Fast Scanning Focal Plane Detector in LC-ESI/MS 758a

Quantitative Analysis of Pharmaceutical Target using a CCD Array Detector and Electrospray Mass Spectrometry 759a

Direct Formation of Liquid Ions from Polar Liquid Solutions 760a

Creation of Molecular Beams for Inducing Surface Ionization of Organic Compounds in LC-MS using a Modified Particle-Beam Interface 761a

The Application of Low Flow Techniques to Particle Beam Liquid Chromatography / Mass Spectrometry 762a

Use of Ionspray MS/MS for Verification of Methylphosphonate Oligonucleotide Sequences 763a

The Effect of Physical Parameters on Electrospray Response 764a

Studies of the Physical Processes of Electrospray 765a

Optimization of the Ionspray Mass Spectrometer as an LC Detector 766a

Chemical Derivatization for Electrospray Ionization-Mass Spectrometry 767a

High Resolution Precision Mass Measurements of Noncovalently Bound Protein Aggregates Using Electrospray Ionization Fourier Transform Ion Cyclotron Resonance Mass Spectrometry 768a

Determination of a Hypolipidaemic Agent in Plasma by Liquid Chromatography Tandem Mass Spectrometry using Atmospheric Pressure Chemical Ionization 769a

THURSDAY ORALS

Laser Desorption/Ionization

Wavelength Specific Resonance Enhanced Multiphoton Ionization for Isomer Discrimination Via Fragmentation and Metastable Analysis 773a

Application of PSD-MALDI to the Localization of Modification Sites in Peptides 774a

Evaluation of Crystallization Methods for Matrix-Assisted Laser Desorption-Ionization of Proteins 775a

Suppression of Metastable Interference in MALDI Spectra Obtained with a Reflecting Time-of-Flight Mass Spectrometer 776a

Heat Load on Guest Molecules in Matrix Assisted Laser Desorption 777a

Anomalous Ionization in a Laser Time-of-Flight Mass Spectrometer 778a

LDMS of Proteins and Peptides Absorbed on Membranes 779a

Matrix Assisted Laser Desorption Ionization of Aerosols 780a

Solid-phase Reactions of Picomole Quantities of Proteins Monitored by Matrix-assisted Laser Desorption/ionization TOF Mass Spectrometry 781a

REMPI and Mass Spectra of Cold Perfluorinated Polyethers 782a

Hydrocarbon Polymer Analysis by Laser Desorption/Chemical Ionization Fourier Transform Mass Spectrometry (LDCI/FTMS) 783a

MALDI Mass Spectrometry of Gel-electrophoretically Separated Proteins 784a

Laser Desorption/Ionization of Small Biomolecules 785a

Laser Vaporization and REMPI TOF Detection for DNA Sequencing 786a

Matrix-Assisted Laser Desorption Mass Spectrometry of Oligonucleotides 787a

Fragmentation of Small Oligodeoxynucleotides by MALDI/TOF Mass Spectrometry Using 355 nm Radiation 788a

Trapped Ion MS

Ion Trap Mass Spectrometry 789a

Mass Resolution in a Quadrupole Ion Trap 790a

Parallels and Perpendiculars Between Magnetic and non-Magnetic Ion Traps 791a

Penning Traps in Physics Research 792a

Biological Ion Trap Mass Spectrometry 793a

Fundamentals and Recent Applications on an Atmospheric Pressure Ionization Differentially Pumped Benchtop Ion Trap 794a

Estimation of the Polarizability of Gaseous Ions by Ion Trap Mass Measurements 795a

Ion Remeasurement in Fourier Transform Ion Cyclotron Resonance Mass Spectrometry 796a

Characterization of Large Linear Molecules by Tandem Mass Spectrometry 797a

Remeasurement and Collisional Thermalization of Ions by Quadrupolar Excitation in a Fourier Transform mass Spectrometer 798a

Averaging Theory for Ion Motion in a Cubic FT-ICR Cell 799a

Precise Mass Determination of Trapped Microparticles and Macro-ions by Optical Techniques 800a

Non-Linear Resonance Effects During Ion Storage in a Quadrupole Ion Trap 801a

Development of Automated Selected Ion Storage for Quadrupole Ion Trap Mass Spectrometry 802a

Environmental Analysis

Environmental Analysis with Quadrupole Ion Traps: Past, Present, and Future 803a

On-Line Analysis of Single Microparticles by Laser Desorption 804a

High-Speed Two-Dimensional GC and GC/MS for Complex Environmental Samples 805a

Ultratrace Analysis of Organic Compounds in Water 806a

Application of ICP-MS to the Determination of Radioactive and Nonradioactive Trace Constituents in Water from Abandoned Urnium Mines 807a

Detection of Trace Drug and Explosive Evidence by Ion Mobility Spectrometry 808a

Application of Mass Spectrometry in the Studies of Degradation Mechanisms of p-Phenylenediamine in Aquatic Environments 809a

Tandem Mass Spectrometry Study of Cyano Containing Pyrethroid Insecticides: 810a

Discrete Energy Electron Capture Mass Spectrometry with Gas Chromatographic Inlet 811a

Congener Specific Quantitation of Polychlorinated Biphenyls by GC/MS/MS 812a

Reliable Compound Identification at Low Levels in Complex Environmental Samples 813a

Monitoring Life Support Environments via Ion Trap Mass Spectrometry 814a

Elemental & Isotope Ratio Analysis

Trace Element Determination by GC/MS 815a

Radiofrequency Plasma Ionization Time-of-Flight Mass Spectrometry 816a

Multi-Channel He ICP Mass Spectrometer for Elemental Analysis with Transient Signals 817a

Recent Advances in Isotope Ratio Measurement by Inductively Coupled Plasma-Multiple Collector-Mass Spectrometry 818a

Application of ICP-MS to Impurity Analysis of Semiconductors for Room Temperature Radiation Detectors 819a

Sputtered Atom Ionization in a Pulsed Radio Frequency Powered Glow Discharge 820a

Optimization of a Radio Frequency Powered Glow Discharge Mass Spectrometry (rf-GDmS) System 821a

RF Glow Discharge Ionization with FT/ICR/MS Detection 822a

Using Ion-Molecule Reactions to Enhance High Resolution GD/FTICR Mass Spectrometry 823a

Direct Analysis of Soils by Radio-Frequency Powered Glow Discharge Mass Spectrometry 824a

The Application of Glow Discharge-Fourier Transform Ion Cyclotron Resonance (GD-FTICR) Mass Spectrometry to Isotope Ratio Measurements 825a

Imaging Isotope Ratio and Trace Element Analysis of Gold Ore 826a

High Spatial Resolution Isotope Ratio Imaging Using Secondary Ion Mass Spectrometry 827a

High Precision Liquid Chromatography-Combustion Isotope Ratio Mass Spectrometry (LCC-IRMS) 828a

Isotope Chemistry in the Jar: Direct Isotopic Analysis from Head Space Gas Mixtures using a GC-IRMS System 829a

THURSDAY POSTERS

Metabolism & Drugs

Metabolism of 4-VPA to Glutathione Conjugates in the Rat: Identification of Novel Adducts Using Ionspray LC/MS/MS 831a

Quantification of Topiramate, A Novel Anticonvulsant, in Rat Brain Fluid by In-Vivo Microdialysis and Thermospray Liquid Chromatography / Mass Spectrometry 832a

On-Line Capillary Electrophoresis-Tandem Mass Spectrometry of Drug metabolite mixtures 833a

Estradiol and Estradiol Metabolites Analysis by Electrospray Mass Spectrometry 834a

Electrospray Mass Spectrometry Analysis of Isomeric C-Glycosidic Flavonoids 835a

Matrix-Assisted Laser Desorption Mass Spectrometry of Dynorphin A (1-17) Processing in Human Plasma and Rat Brain 836a

Rapid Analysis of Erythromycin A and its Metabolites in Fish Tissue using LC-MS and MS-MS 837a

High Performance Liquid Chromatography - Electrospray MS/MS and MS/MS/MS for Metabolite Identification of a Peptide-Based Renin Inhibitor 838a

Mass Spectrometric Determination of Indole Carbinol, its Glucosinolate, and Analogs in Cruciferous Vegetables 839a

Characterization of Flavonoids by LC/MS/MS 840a

Analysis of Carotenoids in Human Serum by Using Capillary Column Continuous-Flow Fast Atom Bombardment Liquid Chromatography-Mass Spectrometry 841a

Further Developments in Neonatal Screening by Automated Dynamic LSI Tandem Mass Spectrometry 842a

Structure Determination of Metabolites from the Neuroleptic Drug Haloperidol Using Ion Trap MS 843a

Regioselective Analysis of Hydroxyeicosatetraenoate in Phophatidycolines in LSI/MS/MS 844a

EI, CI, and FAB Mass Spectral Characterization and Identification of Noberastine Metabolites 845a

Negative Ion Fast Atom Bombardment / Collision-Induced Dissociation Mass Spectrometry in the Study of Ursodeoxycholic Acid Metabolism in Man. 846a

Charge-Remote Fragmentation of Doubly Conjugated Bile Acids 847a

Mass Spectrometry of Sertraline and Related Compounds 848a

Fast Atom Bombardment Mass Spectrometry Using a Glycerol Matrix Saturated with a 3:1 Mixture of Non-Labelled and Trideuterated Tetramethylammonium Hydroxide to Count the Number of Anionic 849a

GC-MS Analysis of Phenylacetic Acid Conjugates in the Rat Brain 850a

Quantitative Analysis of 11-Hydroxy, 8,9-epoxy-eicosatrienoic Acid from human Umbilical Venous Endothelial Cells (HUVEC) by GC/EC NCI MS 851a

Mass Spectrometry-based Strategy for Checking Originality of Metabolites in Biologically Active Fermentation Broths 852a

Characterization of 20-hydroxyeicosatetraenoic Acid Glucuronide by LSI/MS/MS 853a

A Single Assay for the Determination of Oxalic, Glycolic, Glyceric, Glyoxylic and Hydroxypyruvic Acids in Urine by Positive Ion Chemical Ionization GC/MS 854a

Thermally Induced Fragmentation in the NCI Mass Spectra of Amino Acid n-Propyl Ester, N(O,S)-Heptafluorobutyramide Derivatives (AA-PrHFB) 855a

Interfering Substances in the Gas Chromatographic Analysis of Diamines in Seafood 856a

Trace Analysis of a Lewisite Decomposition Product in Urine and Serum 857a

Collision Induced Intramolecular Claisen Condensation in Triglyceride Negative Ions and Assignment of Positional Isomers 858a

Isolation and Detection of Drugs from Spent Fly Puparia (Phoridae): "Drugs in Bugs" 859a

Characterization of 4-Quinolone Antiobiotics by Chemical Ionization Ion Trap Mass Spectrometry 860a

The Analysis of 1,4-Benzodiazephines by Selective Ion-Molecule Reactions with Dimethyl Ether Ions in a Quadrupole Ion Trap 861a

Partial Identification of Metabolites of a Novel Platelet Activating Factor Antagonist by Mass Spectroscopy 862a

Mechanistic Studies on the Metabolic Oxidation of Terminal Olefins to Carboxylic Acids 863a

Automated Statis Headspace Sampling with Gas Chromatography - Mass Spectrometry for the Identification and Quantitative Analysis of Volatile Organic Impurities in Drugs and 864a

A Comparison of Gas Chromatography-Mass Spectrometry Assays for In Vivo Lipid Peroxidation 865a

Analysis of Polyethylene Glycol with TSP LC-MS 866a

Proteins

Selective Detection of Phosphopeptides by Electrospray LC/MS 867a

Application of Electrospray Mass Spectrometry to the Identification and Quantitation of a Novel Variant in a Dimeric Recombinant Protein 868a

Mass Spectrometry of Non Covalent Complexes 869a

Electrospray Ionization Mass Spectrometry of Hemoglobin Adduct Formation in Rats 870a

An Ion Spray Mass Spectrometric Study of Molecular Recognition between the Vancomycin Family of Antibiotics and a Model Bacterial Cell Wall Mucopeptide Precursor 871a

Mass Spectrometry of Bi-Substrate Inhibitors and Their Targeted Protein Kinases 872a

The Use of Packed Capillary LC/MS to Monitor Phosphokinase Activity in Rat Cardiomyocytes 873a

Probing the Catalytic Domains of Protein Kinases with the Aid of Mass Spectrometry 874a

Analysis of Iron-Sulfur Proteins by Electrospray Mass Spectrometry 875a

Effect of Proline Residue in Transition Metal in Binding in Peptides Studies by 252Cf-PDMS 876a

Studies of Anticancer Drugs Binding with the Metal-Detoxification Protein, Metallothionein II, by Ion Spray Mass Spectrometry 877a

Formation Study of Metal Complexes self-assembly by ESMS 878a

Studies of Metallothionein and Anticancer Alkylating Agent Interactions 879a

ON THE RELEASE OF IONS FROM CHARGED DROPLETS IN ELECTROSPRAY MASS SPECTROMETRY

F.W. Röllgen, U. Lüttgens, Th. Dülcks and U. Giessmann[1]
Institute of Physical and Theoretical Chemistry, University of Bonn,
Wegelerstr. 12, D-53115 Bonn, FRG
[1]Finnigan MAT, D-28197 Bremen, FRG

In electrospray mass spectrometry (ES MS) charged droplets are formed by electrohydrodynamic disintegration of liquids at atmospheric pressure. Induced by solvent evaporation, ions are released from these droplets and mass analyzed. The mechanism of release of ions from charged droplets is not clear yet. Two basically different mechanisms are currently discussed. In the so-called "ion evaporation model" solvent evaporation leads to a decrease of the radius of charged droplets and an increase of the surface field strength by successive decompositions at the Rayleigh limit, until the critical field strength of ion evaporation is reached for sufficiently small droplets below the Rayleigh limit. In the second model, the electrohydrodynamic decomposition of droplets above the Rayleigh limit is considered to produce small droplets, from which one or several ions are desolvated by solvent evaporation, charge condensation and coulomb repulsion. Both mechanisms require significant solvent evaporation to achieve the required surface field strength for the release of ions by electrohydrodynamic or ion evaporation processes. By raising the electrolyte concentration the solvent evaporation also decreases the Debye length, which provides a measure of the interaction between cations and anions in the desolvation process.

We have measured the intensity ratio Ba^{2+}(solv)/$BaBr^{+}$(solv), obtained from $BaBr_2$ dissolved in a water/methanol solution (vol. ratio 1:1), as a function of concentration (Fig. 1) to investigate the effect of electrolyte concentration on the release of ions from droplets. For a concentration of the initial solution of $c_o=10^{-3}$ M an intensity ratio $Ba^{2+}/BaBr^{+} > 10$ was obtained. The mean size and charge state of the droplets could be estimated from the observed colored sprays (Higher Order Tyndall Spectra), the applied flow rate of 2 µl/min and the measured spray current of ~100 nA. Accordingly, the electrolyte concentration (c_{Ra}) of the droplet reaching the Rayleigh limit was by a factor of about 10^2 higher than the initial concentration. Considering the Debye lengths for the water/methanol solvent of $\lambda(c_o) = 5$ nm and $\lambda(c_{Ra}) < 0.5$ nm for the solution at the Rayleigh limit, the above ion intensity ratio of 10 is hardly compatible with the release of ions from droplets with concentrations of $c > 10^2 c_o$.

This result and results of other ES MS investigations, such as the observed correlations between the kind and abundance of ions in ES spectra and ion concentrations in the applied solution point to the release of ions from solutions with solute concentration not significantly enhanced by solvent evaporation.

Consideration of possible decomposition pathways of charged droplets and the particular conditions of ESI regarding the movement of charged droplets in a dry, frequently heated gas led us to propose a new mechanism of release of ions from charged droplets. In this mechanism the "slow" decomposition of ellipsoidally shaped,

charged droplets, moving in a dry gas, i.e. under conditions of a high rate of solvent evaporation, leads to the repeated release of ions from the tip shaped apex of the droplets.

Ellipsoidal droplets with a sufficiently long main axis decompose below the Rayleigh limit and do not relax into a spherical shape for a charge state of $\beta = N/N_{Ra}$ with $1 > \beta \geq 0.5$, where N is the number of charges of the droplet and N_{Ra} the number of charges at the Rayleigh limit. Such ellipsoidal droplets may be formed by electrohydrodynamic disintegration of the solution at the end of the capillary and by disintegration of droplets at the Rayleigh limit ($\beta = 1$). The change of a spherical to an ellipsoidal shape of moving droplets may be induced by the imposed difference of the external pressure in the direction of the field and/or by a different evaporation rate of the solvent in and perpendicular to the moving direction of the droplets.

The formation of a protrusion at the apex of the ellipsoid and the repeated release of ions from the protrusion is driven by the coulomb repulsion between the excess charges, a decrease of the flow resistance, a high rate of solvent evaporation and a fast charge relaxation in the protrusion compared to the "slow" electrohydrodynamic disintegration of the protrusion.

The release of ions from charged droplets, as proposed by this mechanism, is favored by a low heat of vaporization, a low surface tension of the solvent and a low concentration of the electrolyte. It is compatible with the observed critical dependence of ES ionization on a high rate of solvent evaporation from the droplets, the high ionization efficiency of ES ionization and the rather uncritical dependence of ES mass spectra on the electrospray conditions (axial and rim emission modes, IonSpray conditions etc.).

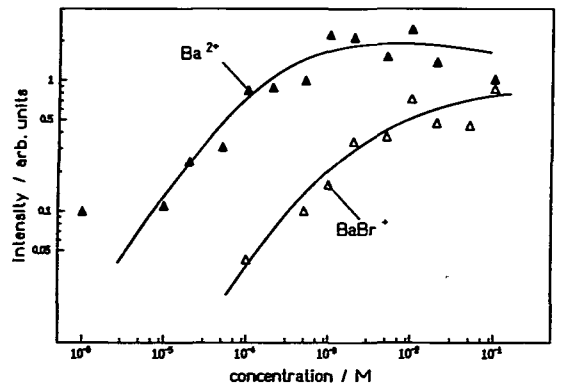

Fig. 1: Intensity of Ba^{2+} and $BaBr^{+}$ signals of ES spectra vs. different concentrations of a solution of $BaBr_2$ in H_2O/MeOH (vol. ratio 1:1); flow rate: 2 µl/min.

ETHYLENE GLYCOL AS A SOLVENT FOR ELECTROSPRAY MASS SPECTROMETRY

K.W.M. Siu, R. Guevremont and J.C.Y. Le Blanc, Institute for Environmental Chemistry, National Research Council of Canada, Montreal Road, Ottawa, Ontario, Canada K1A 0R6

Ethylene glycol solutions of gramicidin s, myoglobin and tetrabutylammonium bromide have been analyzed by means of electrospray mass spectrometry and their spectra compared with those of aqueous solutions. The evaporation of water and ethylene glycol droplets, initially at room or elevated temperatures, in air at room temperature has been modelled. It was found that under conditions where a water droplet's radius would shrink approximately 30%, an ethylene glycol droplet shrinks negligibly. Further, droplets that are initially hot (such as those that are ejected from a heated electrospray needle) cool very rapidly due to evaporation and heat loss to ambient air, and subsequently evaporate much like droplets that are initially at room temperature. Figure 1 shows the evaporation of a water and an ethylene glycol droplet, both initially at 70°C, in air at 25°C. For gramicidin s, the ion abundances in ethylene glycol as solvent (Figure 2b) were approximately 200 times lower than those in water (Figure 2a) under room temperature operating conditions. In experiments where the spray probe was heated to approximately 100°C to reduce the viscosity of ethylene glycol (Figure 2c), the gramicidin response difference between the solvents decreased to about a factor of 40. Similar trends were observed for myoglobin and the tetrabutylammonium ion. The experimental gramicidin responses in ethylene glycol are orders of magnitude larger than the responses expected from the degree of ethylene glycol evaporation. This observation calls the conventional solvent evaporation electrospray mechanism in question. The temperature dependence of the $(M+2H)^{2+}$ ion abundance appears to correlate well with that of ethylene glycol viscosity (Figure 3). It is speculated that reducing solvent viscosity by means of heating the spray probe increases the velocity of ions drifting in ethylene glycol towards the solution/air interface and increases the total number of analyte ions desorbed at the Taylor cone during electrospray.

The Potential of Electrospray Ionization with Ultra-High Resolution Mass Spectrometry for Biopolymer Characterization

Richard D. Smith, Steven A. Hofstadler, James E. Bruce, Brian E. Winger and Alan L. Rockwood

Chemical Sciences Department
Pacific Northwest Laboratory
Richland, WA 99352

Electrospray ionization (ESI) allows a broad range of large biopolymers to be analyzed using mass spectrometry. Given a sufficiently pure sample of a biopolymer, molecular weight measurements of approximately 0.01% accuracy, or better, can generally be made using ESI with quadrupole mass spectrometers operating with a resolving power of approximately 10^3. However, such pure samples are the exception due to the difficulties, costs and losses associated with purification; most biopolymer samples are actually mixtures. In addition to the common heterogeneity of biopolymers, which can arise from an assortment of chemical and biochemical processes, ESI mass spectra can be complicated by adduction of small solution species, residual solvation, dehydration, and (depending upon interface conditions) dissociation products. In these situations, higher resolution mass spectrometric analysis can provide additional information that can greatly assist characterization. Higher precision mass measurements, which generally accompany higher resolution measurements, can aid in the identification of adducting species, biopolymer variants, or components of noncovalent complexes. The use of ESI with high resolution MS for characterization of biopolymers also has a number of other advantages. Resolution of the 1-Da isotopic spacing allows the charge state to be determined, a capability which is particularly useful for interpretation of complex CAD mass spectra.

To realize the benefits of higher resolution measurements for molecular ions of larger biopolymers, a significant gain in resolution is necessary over that generally provided by low resolution mass spectrometers. One typically desires sufficient resolution to resolve the 1 Da differences of the isotopic envelope. Figure 1 shows calculated mass spectra for an equimolar mixture off two adducts of a model ß-chain Hemoglobin in three different resolution regimes. At a resolution of 3000, typically the best obtainable by "low resolution" instrumentation, the isotopic envelope is unresolved and the protein molecular weight is determined from the peak apex or centroid. At high resolution (40,000), as shown in the middle of Figure 1, the isotopic envelope is resolved to nearly baseline. However, at this resolution the small 0.03 Da mass difference between the two adducts is insufficient for their resolution. At extremely high resolution (>5 x 10^5 for the case illustrated), these two species can be resolved. The inset on the right side of Figure 1 shows the isotopic "fine structure" associated with one peak in the isotopic envelope. Two points are noteworthy regarding ultra-high resolution of large biopolymers. First, resolution of the isotopic "fine structure" requires a huge additional increase in resolution (generally to >10^7 for molecules of this size) and would be extremely challenging due to statistical constraints upon abundance measurements. Second, the isotopic "fine structure," if unresolved, ultimately places a limitation upon the application of very high resolution methods as molecular weight increase. However, within these mild constraints, high resolution can in principle provide an effective approach for separating such mixture components and assisting in their identification.

The prospects are excellent for such ultra-high resolution ESI-MS based upon Fourier transform ion cyclotron resonance (FTICR). As shown in Figure 2, high resolution spectra of proteins can be obtained using ESI-FTICR instrumentation being developed at our laboratory. At present, resolving powers of better than 2.5 million and mass measurement accuracies to better than 1 ppm have been obtained.

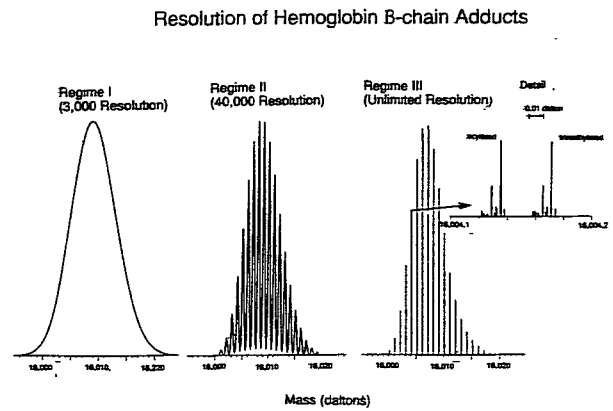

Figure 1 Calculated masses for a equimolar two component mixture of model hemoglobin ß-chain adducts at three resolving powers.

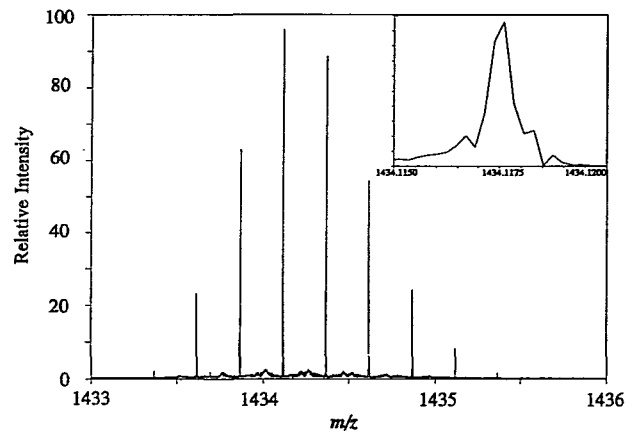

Figure 2 Ultra-high ESI-FTICR mass spectrum for the $(M+4H)^{4+}$ molecular ion of bovine insulin demonstrating a resolving power of 2.5 x 10^6.

This research was supported by internal PNL exploratory research through the U.S. Department of Energy. Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy, through contract DE-AC06-76RLO 1830.

A Reflecting Time-of-Flight Mass Spectrometer with Orthogonally Injected Electrospray Ions.

A. Verentchikov*, W. Ens and K.G. Standing,
Physics Department, University of Manitoba, Winnipeg, Canada R3T 2N2

An electrospray (ESI) source, similar to the one designed by Aleksandrov et.al. [1], has been coupled to a reflecting time-of-flight mass spectrometer (TOF) [2]. Ions are injected into the instrument perpendicular to the flight path and extracted by pulses applied to a deflection plate using the method introduced by Dodonov *et al* [3]. Signals, observed in either the linear or reflecting mode, were recorded by a time-to-digital converter at a repetition rate of ~5kHz.

The resolution was considerably improved by operation in the reflecting mode giving a value $(M/\Delta M)_{FWHM}$ ~5000 (Fig.1) for melittin (2846u) and the B-chain of Insulin (3496u) comparable to the value observed in SIMS measurements [2]. This resolution enabled assignment of the charge states (1+ to 4+) of the peaks in the spectrum obtained from a tryptic digest of a recombinant protein (28,932u) [4], which was found to have suffered a post-translational modification (loss of ~700u). For peptides heavier than insulin the analytical resolution is defined by the overall width of the isotopic distribution (from 1000 to 1500).

Precision. Though the resolution for peptides of ~30,000u is higher than in MALD, the accuracy of mass determination appears to be similar (~100 ppm).

The sensitivity of the instrument is demonstrated by the spectra in Fig.2, which consumed 50 and 10 fmoles of Cytochrome C (12,361u, 1 pmole/µL solution at flow rate 0.01µL/sec, recorded in 5 and 1 sec). The absence of unimolecular decay and a single ion counting mode for data acquisition produce spectra with a very low background. The sixth isotope of angiotensin (883u) (10^3 times smaller than the first one) is clearly seen after a minute of recording time.

The mass/charge (m/z) range is practically unrestricted on the TOF instrument. This was used to show that the ion formation mechanism in the ESI ion source sometimes provides ions with a high m/z (i.e. with a low charge). Fig.3 shows the upper part of the spectrum of β-Galactosidase (113,600u), containing the second (less charged) part of the envelope in the range 3000<m/z<6000. Spectra of some other peptides- porcine pepsin (in a positive mode) and proteinase-K in a unfolded form- showed peaks beyond the normal m/z range for quadrupole instruments (m/z<2400). A murine anti-(human α1- acid glycoprotein) monoclonal antibody with an average molecular weight of 149,600 u, recorded previously on a quadrupole instrument [5], was observed in ESI/TOF to be mainly concentrated in the region 2500<m/z<3500 (Fig.4). A higher m/z range is often necessary when intact complexes are analyzed under mild conditions (water solution with neutral pH). Figure 5 illustrates two spectra of the enzyme Carbonic Anhydrase, with acidic solution and in pure water. The latter spectrum shows the intact complex of the enzyme with its cofactor Zn, but it appears at much higher m/z.

STUDIES OF A HIGH INTENSITY ELECTROSPRAY ION SOURCE CONNECTED TO A HIGH MASS POST ACCELERATION ION DETECTOR

Y. Xu*, Y. Bae, R.J. Beuhler, and L. Friedman

Chemistry Department
Brookhaven National Laboratory
Upton, N.Y. 11973

Electrospray ionization (ESI) has been shown to generate multi-charged ions which can be identified by determination of mass to charge ratios.(1) Mass or charge determination in electrospray mass spectra requires sufficient resolution to separate ions carrying different charges. With sufficient resolution of very high molecular weight ions, the identification of masses of unknown samples may be difficult or impossible. If ions are subjected to post-acceleration followed by determination of secondary electron pulse spectra,(2) ion masses and charges can be established. Secondary electron pulse spectra are obtained by accelerating electrons generated from a detector dynode and determining the energy deposited by the electron pulse into a solid state detector. Electron pulses measure the electronic excitation deposited in the detector dynode. This excitation is related to the sum of the atomic masses in a molecular ion and its velocity.(3) Ion velocities can be calculated directly from ion mass to charge ratios and ion kinetic energies. Thus secondary electron yields can provide the information necessary for computation of ion masses.

The application of this technique of mass determination to ESI spectra of polyethylene glycols(4) provides evidence of decomposition for polymers with

molecular weights greater than 20,000 amu. The conclusion that PEG polymers with mass 5,000,000 amu can be generated with 4000 charges must be seriously questioned. The possibility that decomposition occurs in the acceleration column after mass analysis was tested by using energy selector plates to filter lower energy ions before impact on the detector dynode. The results of this test indicated decomposition prior to mass analysis.

Secondary electron spectra can reveal the presence of ions with radically different mass or charge in spectra which show unresolved ions with similar or identical mass to charge ratios. The use of secondary electron pulse spectra for mass determination of multi-charged ions will be demonstrated in studies of the monomer and dimer of apoferritin (molecular weights of 480,000 and 960,000 and with m/e values of approximately 13,500 and 19,000 respectively). Multi-charged high molecular weight solvent clusters containing methanol and water were also detected and the charge determined to be 21 on a mass of 294,000 amu. The larger linear PEG polymers were the only cases in a variety of studies where evidence was found for ion decomposition.

This research was carried out at Brookhaven National Laboratory under contract DE-AC02-76CH00016 with the U.S. Department of Energy and supported by its Division of Chemical Sciences, Office of Basic Energy Sciences.

Observation of Noncovalent Complexes by Electrospray Ionization on a Magnetic Sector Mass Spectrometer

Joseph A. Loo
Parke-Davis Pharmaceutical Research
Division of Warner-Lambert Company
2800 Plymouth Road, Ann Arbor, MI 48105

Noncovalent interactions play many significant roles in biochemistry. Many types of superstrate/substrate binding are examples of intermolecular noncovalent interactions, including antibody-antigen, protein-cofactor, receptor-ligand, and enzyme-substrate pairings. Intermolecular noncovalent interactions are also responsible for aggregation of proteins into multimers (quaternary structure). These weak interactions can be disrupted by a varying solution conditions, such as pH, temperature, and solvent composition.

Electrospray ionization (ESI) has become an almost indispensable method in determination of peptide and protein primary structure. In electrospray, highly charged liquid droplets containing the analyte are formed at atmospheric pressure. By virtue of its ability to form stable gas phase ions with a paucity of fragmentation, ESI has been classified as an "ultrasoft" ionization method. Recently, several groups have shown that ESI-MS has the capability to examine noncovalently-bound systems. Because noncovalent bond energies are about an order of magnitude lower than typical covalent bond strengths, such weakly-bound molecular entities are very susceptible to collisionally activated dissociation. Previous ESI work on noncovalently-bound systems have been performed on quadrupole mass spectrometers. ESI analysis on a double focusing mass spectrometer requires ion acceleration to keV energies. Several noncovalent systems were investigated to test the feasibility of studying such weakly-bound biochemical systems with ESI-magnetic sector MS.

Instrumentation. ESI-MS analyses was performed on a Finnigan MAT 900 mass spectrometer (E-B geometry) equipped with a 20 kV conversion dynode/electron multiplier point detector and an array-type focal plane detector. Analyses were performed at full accelerating voltage (5 kV).

An electrospray ionization interface based a heated glass capillary inlet was used. Droplet desolvation was accomplished by a countercurrent stream of warm nitrogen and by collisional processes in the electrospray interface by adjustment of the voltage difference between the tube lens at the exit of the metalized-end of the glass capillary and the first skimmer element. A stream of SF_6 coaxial to the spray aided in suppression of possible corona discharges, especially important for electrospray of aqueous solutions.

Results and Discussion. Several noncovalent biochemical systems are amenable to ESI with magnetic sector instruments. In general, for studying such weakly-bound systems, the type of mass spectrometer is less important than the type of electrospray interface employed. Energy must be applied to strip away solvent molecules as the analyte travels through the ESI interface. However, applying too much energy to the system may disrupt the weak noncovalent forces holding two/several macromolecules together.

Peptide Heterodimer Interaction. ESI-MS was used to test for noncovalent interactions between human angiotensin II (M_r 1046) and 8 synthetic octapeptides that are considered complementary peptides (encoded by DNA sequences complementary to the DNA sequence that codes for human angiotensin II) or analogues of these antisense peptides. The relative abundance of the doubly-charged heterodimer complex broadly correlates to the trend observed with solution phase studies such as ^1H NMR. Dissociation constants for the reaction in solution is in the high micromolar range.

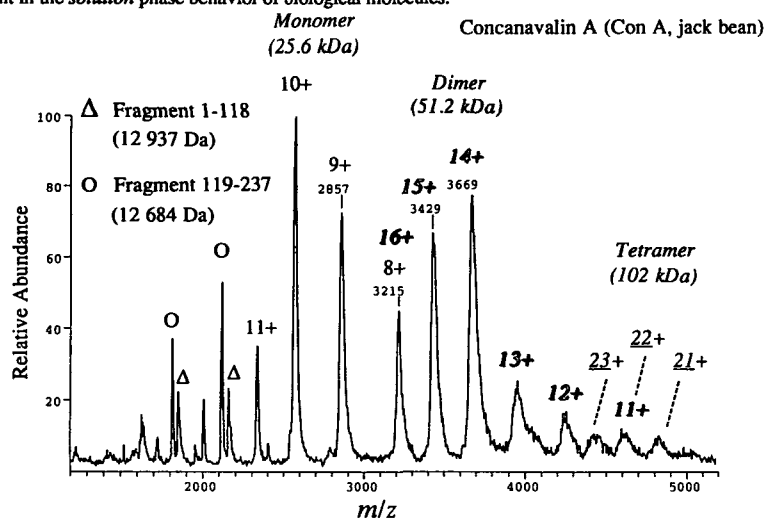
Heme-Globin Protein Interactions. Myoglobin is composed of a polypeptide chain (16.9 kDa for horse myoglobin) and a heme prosthetic group (Fe-protoporphyrin IX) noncovalently bonded in a hydrophobic crevice. Organic solvents and low pH conditions are known to denature myoglobin, expelling the heme

from the pocket. The mass spectrum of myoglobin taken from solutions of acidic pH reflects a molecular mass for the apo-protein only (and a peak representative of a singly charged ion for the heme). ESI mass spectra taken from pH 6 aqueous solutions shows only ions for the myoglobin protein-heme complex. Increasing the voltage difference between the tube lens and skimmer of the electrospray interface promotes collisional dissociation of the complex. Similarly, hemoglobin (Hb) is a tetrameric complex composed of two α-chains and two ß-chains, each bound to one heme molecule. At physiological pH, the tetramer is in equilibrium with the dimer species (α-heme/ß-heme, not α-heme/α-heme or ß-heme/ß-heme). From an aqueous solution, the α-heme and ß-heme complexes were observed in the mass spectrum, along with the 32.2 kDa α-heme/ß-heme complex.

Protein aggregation. Many protein systems exist as multimeric species or aggregates in solution. Alzheimer's disease is a neurodegenerative disorder characterized by abnormal deposition of protein in the brain. These amyloid deposits are composed of a polypeptide 39-43 residues in length. Amyloid peptides are known to form higher order aggregates in solution. ESI-MS of the ß-amyloid peptide (1-40) in water shows evidence for dimer, trimer, and tetramer formation. The 1-28 peptide did not show this tendency for self-association, consistent with previous literature studies.

Concanavalin A (Con A, 25.6 kDa) is a lectin metalloprotein isolated from jack bean that selectively binds polysaccharides. Con A has been reported to be a dimer at pH 5.5 and a tetramer at pH greater than 7. Abundant multiply-charged dimer species and a weaker set of multiply-charged ions for the tetrameric form was detected by ESI-MS for Con A at pH 6 (Figure below).

Conclusion. Several noncovalent biochemical systems are amenable for study with electrospray ionization and magnetic sector mass spectrometry. The larger *m/z* range of a magnetic sector instrument is an important advantage for studying such systems. Understanding how instrumental parameters affect the observed relative abundance of weakly-bound species is critical for characterizing such systems. Mass spectrometry is a powerful technique for analyzing *gas* phase molecules, but it also may eventually provide insight in the *solution* phase behavior of biological molecules.



Conformation Dependent Copper Binding Ability of an Engineered Protein Assessed by Electrospray Mass Spectrometry

Gert Talbo, Kenneth Morand, Mark Kelly, Matti Saraste and *Matthias Mann

Protein and Peptide Group,
European Molecular Biology Laboratory,
Heidelberg, Germany

An engineered protein was constructed by introducing a copper binding site (Cu_A-like site) into the previously copper less CyoA subunit of the *E.coli* cytochrome *o* quinol oxidase complex [1]. Cu_A is a unique metal center; it is not known whether it has one or two copper atoms. Work by Allen and Hutchens [2] suggested the possibility of assessing the copper binding ability of the genetically engineered protein by electrospray mass spectrometry (ESMS).

ESMS was first employed in assessing the correctness of a series of mutants used in determining the number of necessary ligands to the copper or coppers in the CuA like site. Subsequent measurements of the wild type protein resulted in the expected molecular weight and also showed two different conformations of the protein when sprayed in 1% aqueous formic acid. The presence of different conformations was indicated two envelopes with different charge states.

Mutants with no ability to bind copper where then analyzed in the presence of 10 and 100 μM $CuCl_2$. At the 100 μmolar level they showed a significant adduction of one and two copper atoms per molecule.

The engineered protein was produced with copper present in the growth medium and ESMS analyzed. The resulting spectra show almost exclusively peaks corresponding to the compact conformation of the protein with two bound copper atoms (Fig 1). These findings - together with spectroscopic and chemical assay data not shown here - strongly support the bi nuclear model of the Cu_A site. Unspecific association of copper - as in the case of non copper binding protein in large access of copper containing solution - would have lead to a distribution of the number of copper atom per molecule.

Engineered protein was also grown in the presence of trace amounts of copper in the growth medium and analyzed while taking care to avoid copper containing solvents as much as possible. It then showed the expected molecular weight and the compact and extended conformation. Additionally, the compact conformation of the engineered protein showed an extra set of peaks corresponding to two bound copper atoms (Fig. 2).

In addition to lending strong support to the bi nuclear Cu_A model, the above findings indicate that ESMS can be used to verify the number of metal ions in redox centers of proteins. Interpretation of the copper adducts as specific protein metal interaction rests on comparisons of wild type and engineered protein, the fact that a discreet +2 Cu state was observed and that the Cu binding occurred only on the "native" conformation under conditions of trace amount of copper during cell growth.

THE OBSERVATION OF BIOMOLECULAR IONS BEYOND *m/z* 3,000 BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY

Karen J. Light-Wahl, Brian E. Winger and Richard D. Smith, Chemical Sciences Department, Pacific Northwest Laboratory, P.O. Box 999, Richland, WA 99352

The production and detection of multiply-charged molecular ions by electrospray ionization (ESI) of relatively low *m/z* values (< 3,000) with quadrupole mass spectrometers is well established for proteins extending to at least M_r > 200,000. The mechanisms most commonly proposed for ion formation suggest that highly functionalized molecules such as peptides and proteins will generally form molecular ions with sufficiently high charge such that they will be observed below *m/z* 3,000.

An extended *m/z* range low resolution quadrupole mass spectrometer has been developed to investigate the low charge state, high *m/z* ions, that may be produced by ESI. Initial results have shown that ions can be produced and observed by ESI-MS to well beyond *m/z* 3,000 under appropriate solution and interface conditions.[1] For example in the negative ion ESI mass spectrum of bovine cytochrome *c* in 10 mM NH_4OAc, ions are observed with charge states extending to the $(M-H)^-$ ion at *m/z* ~12,400. The negative ESI-MS of porcine pepsin (M_r 34,584) in 1% acetic acid solution has produced the highest *m/z* ion observed to date as a broad peak near the $(M-H)^-$ ion at *m/z* ~ 34,000 (Figure 1).

Perhaps the most important aspect of using an extended *m/z* range quadrupole instrument is the ability to observe ions from solutions that are at near physiological pH. Most ESI-MS experiments of proteins have been carried out in acidic solutions (or alkaline solutions for negative ion formation) to increase the protonation of the molecule. These conditions allow species with lower *m/z* values to be detected within the *m/z* range of most commercial quadrupole mass spectrometers. However, the recent application of ESI-MS to the study of biologically important noncovalent associations[2] and higher order protein structure has brought about the need to use solution conditions more amenable to preserving weak structural associations which often require near neutral pH solutions. Conformational constraints under these solution conditions (i.e. hydrogen bonding, secondary structure) can reduce the number of potential charging sites. In addition, the more compact structures generally existing under these conditions might also be expected to increase Coulombic contributions and tend to decrease charging in the gas phase. Thus, ESI-MS with neutral pH solutions generally benefits from the use of an extended *m/z* range quadrupole instrument.

Concanavalin A (Con A), a lectin composed of four nearly identical 237 amino acid protomers, provides a good example of the importance of an extended *m/z* range instrument when studying noncovalent associations with ESI-MS.[3] At pH >7 this protein is known to exist primarily as a tetramer in solution; whereas, at pH ~ 5 it should be primarily a dimer. No trimer species are known to be present at either solution pH. Figure 2a shows the ESI mass spectrum obtained from Con A in a pH 5.7 solution (10 mM NH_4OAc), where it should exist in solution primarily as a dimer. Ions indicative of the tetramer are observed near *m/z* 5,000 in the positive ion ESI mass spectrum of Con A in aqueous 10 mM NH_4OAc (pH 8.4) and are labeled Q^{20+} to Q^{22+} in Figure 2b. Under appropriate interface conditions, this solution behavior is qualitatively observed by ESI-MS utilizing the extended *m/z* range quadrupole mass spectrometer. These and other results confirm that high *m/z* ions can be formed by ESI and that weak noncovalent associations are most likely to be retained for low charge state species.

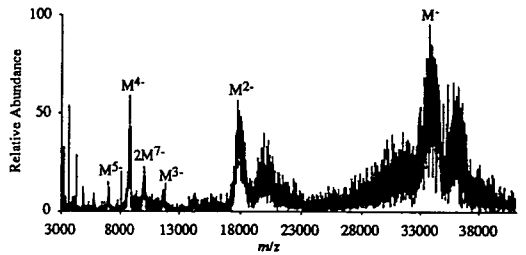

Figure 1. Negative ion ESI mass spectrum of porcine pepsin in 1% HOAc solution.

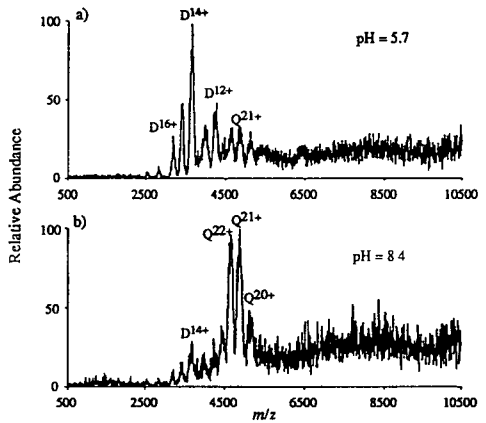

Figure 2. Positive ion ESI mass spectrum of concanavalin A in aqueous 10 mM NH_4OAc with a) pH = 5.7 and b) pH = 8.4. The peaks labeled Q represent the intact tetramer of Con A whereas the peaks labeled D represent the dimer species.

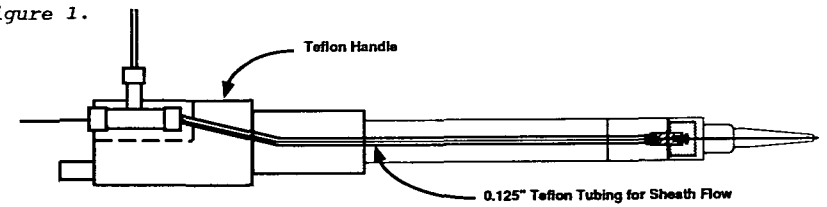
CAPILLARY ELECTROPHORESIS/ELECTROSPRAY IONIZATION ON A MAGNETIC SECTOR MASS SPECTROMETER

Kenneth B. Tomer[1] and John R. Perkins[2], [1]National Institute of Environmental Health Sciences, PO Box 12233 Research Triangle Park, NC 27709, USA [2]Kratos Analytical, Barton Dock Road Urmston, Manchester M31 2LD UK

Capillary electrophoresis (CE) provides a rapid, highly efficient means of separating complex mixtures with high sensitivity. As part of our interest in coupling nanoscale separation techniques with mass spectrometry, we have interfaced CE with both continuous flow FAB on a magnetic sector instrument (1) and electrospray ionization (ESI) on quadrupole instruments (2,3,4). We have now also interfaced CE with ESI on a magnetic sector mass spectrometer (a Kratos Concept ISQ). In this interface, the standard Kratos probe has been modified to accommodate a sheath flow (Fig. 1). A plexiglass handle has been incorporated to isolate the union between the sheath flow and the CE column.

Figure 1.



In addition to simple peptide mixtures, we have challenged the combination of techniques using a naturally occurring complex mixture of polypeptides and proteins, namely snake venoms. Although the raw snake venoms have been reported to contain 20 to 30 components, analysis by capillary electrophoresis in combination with mass spectrometry has shown the presence of over 100 components in the venom from *Dendroaspis polylepis* (4). One example which illustrates the necessity of both the separating power of capillary electrophoresis and the mass-resolving capabilities of the MS is in the CE/ESI/MS analysis of the venom of the black and white cobra (*Naja melanoleuca*). Two of the phospholipases, DE-III (M_r = 13346) and DE-IIIA (M_r = 13350.9), which differ in only two out of 120 amino acids, have identical pI's indicating that they would exhibit similar electrophoretic mobilities, and, thus, not be readily separated by CE. One of the major components in the CE/ESI/MS analysis showed $(M + 8H)^+$ and $(M + 7H)^+$ ions at mass 1669.6 and 1908.2, respectively (Fig. 2). Detailed analysis of the data showed that, in fact, each ion was a composite of two components (Fig. 3). M_r values of 13348.9 and 13345.7 were determined for the two components which were within 0.015% of the theoretical values.

INTRODUCTION

Perfusion particle chromatography was introduced recently as a novel development in the field of HPLC for the rapid separation of biomolecules. The principal advantage this method affords over conventional reverse phase HPLC is the ability to operate at very high flow rates while maintaining both high sample loading capacity and chromatographic resolution. The principal advantage this technique brings, therefore, is speed, a critical operating parameter for industries in which the major focus is either process development or high throughput applications. Unlike conventional RP-HPLC, in which liquid flows around the particles surface (convection) and diffuses into the particle pores (via molecular diffusion), perfusion column chromatography enables analyte to be transported not only around the particle surface but within the particle as well. This was made possible by the ability to manufacture particles consisting of a complex network of through pores (6000-8000Å) and smaller diffusive pores (300 Å). The potential for exploiting the features of perfusion column chromatography for liquid *chromatography-mass spectrometric applications was achieved recently by members of our laboratory (1). The* optimal flow rates of perfusion columns are, in general, 5-10 times the flow required for reverse phase porous packing materials (*i.e.,* C18, C4). We demonstrated that by packing perfusion material into 320 µm i.d. capillary fused silica, the columns could be operated at flow rates compatible with electrospray ionization while maintaining linear velocities that fell within the perfusive flow regime. Three principal advantages that packed capillary perfusion columns offered for mass spectrometric analysis were; the ability to i) rapidly desalt protein samples, ii) rapidly separate protein and large peptides in 1/10 the time required using capillary C4 columns and iii) recycle rapidly, thereby allowing higher sample throughput.

RESULTS AND DISCUSSION

Packed capillary perfusion columns have now been evaluated for their ability to rapidly separate and sequence enzyme digests by HPLC/MS/MS using electrospray ionization (ESI) and compared directly against packed capillary reverse-phase materials (*e.g.,* Vydac C18, 5 µm, 300 Å particles). The sensitivity of the technique when coupled directly to electrospray ionization was examined against conventional capillary HPLC. Columns were operated under perfusing conditions, using a flow rate of 45 µl/min. In general, chromatographic retention times were reduced by a factor of 4-6 while maintaining comparable resolution to that of capillary C18 180 µm i.d. and 320 µm i.d. columns The feasibility of performing in-line LC/MS/MS for the sequence determination of enzymatic digests using capillary perfusion columns was determined. Tryptic digested src homology (SH2) domain of $pp60^{c\text{-}src}$ was used for this in-line LC/MS/MS study. Using a modified PE-Sciex API III collision cell it was possible to fully sequence several of the tryptic peptides of SH2 from a total sample concentration of 25-50 picomoles The results are shown below.

For these studies, enzyme digests were compared directly using packed capillary C18 (180 µm i.d.) and packed capillary perfusion columns coupled to electrospray ionization mass spectrometry. Total ion current chromatograms generated for 10 picomole and 50 picomole of c-src SH2 tryptic digest injected onto a packed capillary C18 and packed capillary perfusion column were compared, The total analysis time was reduced by a factor of 5 in the case of the perfusion column experiment (data not shown). However, the sensitivity of detection (both UV and mass spectrometric) was approximately 25-fold higher for the capillary C18 analysis The enhanced sensitivity for the capillary C18 analysis could be attributed to the flow rate used in the analysis (*i.e.,* 2 µl/min) relative to the flow rate used in the perfusion analysis.

Even so, the signal-to-noise achieved for the perfusion analysis (at the 50 picomole level) was more than sufficient to generate very interpretable LC/MS/MS spectra at high signal-to-noise. A modified API-III collision cell was evaluated in these studies. The collision cell was modified to provide a multiple collision regime as described elsewhere (PE-Sciex, Thornhill, Ontario, Canada). Shown in Figure 1a and 1b are the LC/MS/MS spectra for m/z 847, the $[M+2H]^{2+}$ ion of one of the SH2 tryptic peptides. The quality of the CID spectra generated by both the capillary C18 and perfusion column LC/MS/MS analyses were excellent. A 21-fold signal enhancement was observed using the Vydac C18 column relative to the perfusion column. Importantly, the signal-to-noise of the perfusion LC/MS/MS CID spectrum at the 50 pmol level for this 13 amino acid peptide compared quite favorably with the Vydac C18 LC/MS/MS CID spectrum. The entire sequence of this peptide was deduced readily from the observed prominent y_n ion series (13). CID spectra of the same quality and signal-to-noise were achieved for all 6 of the peptides characterized by perfusion chromatography/MS/MS in real time.

Capillary perfusion column flow rates used are generally 10-25 times greater than those corresponding to conventional 320 µm i.d. and 180 µm i.d. capillary C18 columns. Consequently, the elution volume of the peptides will be greater and hence the concentration of analyte in the elution volume will be decreased. Peak widths are found to be reduced, typically by a factor of 2-3, when comparing 320 µm i.d. packed capillary perfusion columns with 180 µm i.d. packed capillary C18 columns. This difference, though, is not sufficient enough to overcome entirely the dilution effect to the analyte. One method to overcome this limitation is to pack perfusion material into smaller i.d. capillaries (*e.g.,* 180 µm i.d. or 100 µm i.d. columns). We have now had the opportunity to evaluate chromatographically such column packings. Optimal flow rates for 100 µm i.d. and 180 µm i.d. perfusion columns have been determined to be 4-7 µl/min and 25-30 µl/min, respectively. Figure 2 shows the sensitivity enhancement achieved (using UV detection) for the separation of SH2 tryptic peptides (40 pmol injections) upon going from 320µm to 180 µm to 100µm i.d packed capillary perfusion columns The UV generated data demonstrate that an order of magnitude increase in sensitivity is possible with column packings of 100 µm i.d.and therefore should enhance the sensitivity of detection by MS analysis.

TECHNIQUE FOR THE REMOVAL OF BUFFERS AND HEART CUTTING OF PEAKS IN GRADIENT CAPILLARY HPLC PRIOR TO ELECTROSPRAY MASS SPECTROMETRY.

*John Roboz, Ankuo Meng, and Qitao Yu, Department of Neoplastic Diseases, Mount Sinai School of Medicine, New York, NY, 10029, and Remco van Soest, LC Packings, 1057 HM Amsterdam, The Netherlands.

Objectives: (1) Remove buffers which interfere with electrospray (ESP) analysis of proteins and peptides by source clogging or by suppressing ionization; (2) Facilitate introduction of selected HPLC peaks or peak portions from multicomponent samples to prevent source contamination with unimportant constituents, or remove overwhelming components when trace analytes are poorly resolved.

Principle of Technique: (1) Use mobile phase composition to retain important constituents on top of capillary column; (2) Wash out buffer isocratically, directing effluent to waste; (3) Separate constituents with appropriate HPLC gradient; (4) Introduce selected HPLC peak or parts thereof into ESP source by switching dump valve.

Experimental. Samples: Protein and peptide mixtures were prepared in water, and in two buffers: (1) Phosphate, 0.05 M, pH 7.0; (2) "Tris-Mix": 20 mM tris-acetate, pH 7.5, 20 mM NaCl, 0.1 mM EDTA, and 15 mM 2-mercoptoethanol. HPLC. Capillary columns: 15 cm X 320 um, packing 5 um, 300 A pore; C-18 type for peptides, C-4 for proteins. Mobile phase: A= Acetonitrile-water, 1:9 v/v plus 0.1% TFA, B= same as A but 9:1 v/v. Buffers were washed out with 10% B for 10 min. Separation gradient: 10% B to 90% B in 15 min, isocratic for 10 min. Starting flow rate from conventional HPLC pumps 0.4 mL/min, reduced to 5 µL/min by mixer-splitter before entering the column and subsequently the ESP source. UV detector: µ-flow cell (8 mm path), detection at 220 nm. ESP-MS. Cone voltage (VG Quattro ESP): 70 V; source temp.: 65 C; scan speed: 10 sec/500-1400 mass range.

Results. Features of the system (Fig. 1) include flow reduction from conventional HPLC pumps from mL/min to µL/min with a mixer-splitter, a convenience valve to switch from protein to peptide column, µ-flow cell to increase UV sensitivity, and a proprietary electronic micro-dumping valve to direct flow into the ESP source or to waste.

Fig. 2 shows that the transformed ESP spectra of β-lactoglobulin A and B (from a 10 pmole protein mixture) are identical from samples dissolved in water and in the phosphate and tris-mix buffers after washing; without washing, ESP spectra could not be obtained at all. Similarly, ESP spectra of 6 peptides (oxytocin, met-enkephalin, leu-enkephalin, α-melanocyte stimulating hormone, insulin B, and neurotensin, 10 ng ea) dissolved in phosphate and tris-mix buffer were the same as controls after buffer removal.

Fig. 3a shows HPLC heart cutting with the dumping valve in a mixture containing 50,000 fmole luteinizing hormone releasing hormone, LHRH, and 500 fmole of angiotensin B; as shown in Fig. 3b, intense ion current of the doubly charged ion could be obtained using mass chromatography, while most of the excess LHRH was removed as shown by total ion current (TIC). Significantly lower detection is possible with selected ion monitoring.

Experiments aimed to determine the effects of rapidly switching the dumping valve on the ability to recover and maintain ESP beam stability revealed that switching for as little as 3 sec and scanning for as little as 10 sec would still maintain ion current equilibrium in a gramicidin model for tuning and performance checking.

It is concluded that this simple technique may be widely employed to eliminate problems caused by buffers, and to facilitate easy introduction of individual HPLC peaks or parts of peaks.

A New API Source for Magnetic Sector Instruments

P. Dobberstein, R. Pesch, and E. Schroeder, Finnigan MAT, Bremen, Germany

The API source from the TSQ 700 quadrupole instrument [1] was adapted to the magnetic sector instruments MAT 95 and MAT 900. The principal components stayed in principle unchanged, as there are the heated metal capillary after B. Chait and coworkers [2], the tube lens, the skimmer, and the rf-only octapole (see **Fig. 1**).

The major modifications are:

1) An additional pumping stage for the octapole compartment, providing a pressure of about 2×10^{-5} Torr in the ion acceleration region.

2) The + /- 5 kV high voltage insulation for the region between the capillary and the lens system.

3) Modification of the supply electronics for operation at +/- 5 kV.

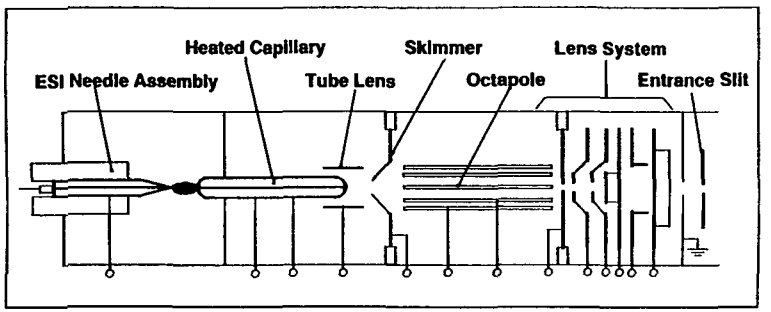

Fig. 1

Both components, the metal capillary and the octapole, which have proven their good performance with respect to reliability and ion transmission already on the TSQ 700, show excellent performance on the sector instruments as well, resulting in high sensitivity and extremely high resolving power.

On a MAT 95 a resolution of **R = 20 000** is obtained easily in ESI operation, allowing baseline resolution of the isotope pattern of multiply charged **Myoglobin** ions.

An **Exact Mass Determination** was performed using the **11+** isotope pattern of **Lysozyme** as the reference and the **13+** isotope pattern of **Myoglobin** as the "unknown".

The raw spectrum obtained by summation of narrow electrical high resolution scans shows

baseline resolution on both isotope patterns (**Fig.2**).

For data evaluation the measured spectrum was smoothed and with CMASS recalibrated, using the highest isotope peak in the measured 11+ pattern of Lysozyme as the lock mass and the corresponding peak in the calculated isotope pattern of Lysozyme [613c 915h 185o 193n 10s +11h]/11 as the reference.

The comparison of the calculated isotope pattern of the 13+ peak of Myoglobin with the recalibrated experiment is given on **Table 1.** The average mass deviation of the 12 most intense isotope peaks is:

1.5 mmu at m/z = 1 305 or 1 ppm

HIGH-SPEED GC/MS WITH FOCAL-PLANE ION DETECTION

Piet A. Leclercq and C.A. Cramers
Laboratory of Instrumental Analysis, Department of Chemical Engineering
Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands

Scanning mass spectrometers, such as quadrupoles or magnetic sector instruments, waste all but a small fraction of the ions leaving the ion source. Due to this inefficiency, detection limits in conventional GC/MS are of the order of 1 ng/s of solute, which is about the maximum sample capacity of narrow-bore (50 μm I.D.) columns.

Each type of mass spectrometer has a maximum scan rate which is determined by fundamental laws that govern the scanning process and the minimum time required to measure the intensity at each mass [1]. A modern quadrupole mass spectrometer may be scanned at a rate of up to 10 - 20 spectra/s [2], whereas magnetic instruments are substantially slower. There are, however, two reasons which demand that at least 5 - 10 spectra per GC-peak width should be acquired. The first is to minimize changes in sample concentration in the ion source during one scan, in order to minimize distortion of relative peak intensities for a given spectrum. The second reason for high scan-repetition rates is to enable the accurate reconstruction of the chromatogram from consecutively recorded mass spectra, and the deconvolution of overlapping GC peaks.

The limitations in sensitivity and spectrum repetition rate of scanning instruments are incompatible with the working range and separation speed of narrow-bore gas chromatography. These limitations can be overcome by applying non-scanning mass spectrometers. By measuring all masses at the same time, the speed for obtaining mass spectra is virtually only limited by state-of-the-art detectors and electronics. Moreover, detection limits are in the sub-picogram range, because this kind of measurement is equivalent to selected ion monitoring at all masses simultaneously.

Three techniques can be used for the detection of an array of masses without scanning [1]. These are *spatial array* detection, applicable with magnetic mass dispersion, *time array* detection in time-of-flight (TOF) mass spectrometry, and *frequency array* detection in FT ion cyclotron resonance mass spectrometry. (The quistor, or ion trap detector (ITD) can detect about half of the ions present by scanning, and might be seen as a time array detector as well). While capillary GC/FTMS is feasible, and GC/ITD has become very popular nowadays, both methods do not fully utilize the sample because ionization is performed in a pulsed mode.

GC/TOFMS with time array detection is being pursued at the Michigan State University, in cooperation with Wollnik *et al.* from the Giessen University in Germany [3]. At the Eindhoven University we opted for the spatial array detection of all ions along the focal plane of a Mattauch-Herzog type double focussing sector analyzer (AMD MMH1). The detector is a microchannel electron multiplier array, also called a microchannel plate (MCP) multiplier. Basically, the MCP can be seen as an "electronic photoplate", which converts the ions into secondary electrons. Our first approach [4], the use of 1000 discrete collector electrodes with 1000 electron counters covering 100 mm of the focal plane (0.6 of a mass decade), turned out to be not practical. The need to still switch electric or magnetic fields in order to acquire a complete spectrum, as well as the very high costs, were prohibiting. Since then we are developing an electro-optical ion detector (EOID) covering 300 mm of the focal plane [5], applying modern optical readout systems used in image processing for office automation (copiers, fax machines). The construction of a MCP with an active length of 300 mm (spanning 1.2 mass decades), by stacking 6 pieces in a row without junction discontinuities, is one of the technological barriers yet to overcome. In this array detector, the electron image from the MCP is converted into photons by a phosphor screen. The light image is transferred via fiber optics ("rod lens array") and detected by a linear CCD array with 4800 photodiodes. The photodiode array can be read out in a few microseconds once every millisecond.

While still developing the detector, Sinha and Gutnikov published the results of a similar approach recently [6]. They used a small Mattauch-Herzog type mass spectrometer with an EOID of 127 mm, covering the mass range of 25 - 500 amu. Applying a 3 m x 50 μm i.d. GC kolom, they could obtain complete mass spectra every 20 ms. The detection limit was found to be 75 fg for benzene, and the linear dynamic range was 10^3.

Maximizing the Utility of Fast GC Analysis with TOF-MS

J.F. Holland, J. Allison, J.T. Watson, R.D. McLane and C.G. Enke
Department of Biochemistry and Chemistry, Michigan State University, East Lansing, MI 48824

The proliferation of chromographic techniques, detection and injection procedures has encouraged the authors to postulate an analytical power factor for chromatography. As shown in Equation 1 this factor is defined empirically as the number of components eluted per second. As shown in Equation 2, a

$$\text{Emperical } P = \frac{\text{Compouds Successfully Analyzed}}{\text{Total Chromatographic Elution Time}} \qquad \text{Equation (1)}$$

$$\text{Theoretical } P = \text{Maximum that can be analyzed per second} \qquad P = f_c \times f_o \times f_d \times f_g \qquad \text{Equation (2)}$$

theoretical factor may be determined by taking into account a chromagraphic separation factor (f_c), that is enhanced by an overlapped peak deconvolution ability factor (f_o), and by a multi-channel detection factor (f_d), all of which are attenuated by Poisson distribution factor (f_g). This theoretical power factor gives the maximum number of compounds that can be resolved chromatographically and detected with a single channel detection and a Poisson factor of one. In fast chromatography, the peak widths at baseline (FWB) are typically from 50 to 200 milliseconds. The minimum number of data points needed for reasonable levels of quantitative accuracy for isolated peaks is approximately 10. The number of points needed for the deconvolution methods would be from 20 to 40 per peak. This implies that for the peak widths commonly experienced in fast chromatography, data collection rates ranging from 50 to 400 per second would be required. These rates are within the realm of a single channel detector system, however, there are problems with fast chromatography, such as the onerous requirements of speed and reproducibility on the injection process; the need for internal standards; the need for reproducible elution profiles on the intensity axis and reproducible behavior on the time axis; the limited effectiveness of deconvolution routines; and the magnitude of problems presented by unknowns. The attempted solution of these problems places stringent requirements on the mechanical and instrumental aspects of this methodology. Clearly, many of these requirements would be ameliorated if more than one channel of detection were employed as in mass spectrometry. Converting the band-pass requirements for the simple case of isolated peaks necessitates spectral generation rates from 50 to 200 per second. Peaks needing deconvolution would require still higher rates.

These spectral generation rates simply cannot be accommodated by modern commercial mass spectrometry. Only an array-detection type mass spectrometer is appropriate to meet these data collection demands with acceptable ion counting statistics. Of the array types, frequency, spatial and temporal, only the spatial array of ion detection or the time-array subsequent to time-of-flight (TOF) extraction appear to be adequate.

Historically, the application of TOF to chromatography has not been successful. The reasons for this have been overcome. The first reason is the data collection methodology. The development

of time-array detection (TAD) using an integrating transient detector wherein all the information within each and every transient wave form is collected and used, increases the efficiency of the information utilization by 10^4 over conventional approaches. The second drawback of the poor resolution with a 3-D ionization volume has been solved by using an ion mirror to reconstruct the space focal plane on the detector surface. The third historical drawback has been the deleterious effect of pressure on the ion source. Smaller columns and flow have abated this problem. The last major drawback was the loss of information suffered by duty cycles. Sources are being designed to store ions between source extractions to recover signal otherwise lost in the duty cycle. All of these advances in TOF have led to the development of an M-TOFMS-TAD with good sensitivity and resolution, and with spectral generation rates up to 300 s^{-1}. This has led to the development time-compressed chromatography (TCC) whereby the chromatographic resolution is intentionally degraded by increased carrier flow to reduce the analysis time. The high-speed M-TOF-TAD spectral files are processed by deconvolution routines to recover the information in 1/10 to 1/100 the time required by convetional analyses. Figure 1 shows a portion of a TCC run in which 22 compounds are analyzed in 14 seconds. Positions of individual detected compounds are revealed by clusters of peak coincidence lines along the abscissa. The empirical power factor for this chromatography would be 1.57 s^{-1}. The theoretical power factor, even when considering the attenuation of the multi-dimensional detector factor due to fragmentation of the various components, still yields a theoretical power factor 100 s^{-1}. Clearly, this potential will carry TCC well into the realm of fast chromatography.

Milton L. Lee
Department of Chemistry, Brigham Young University, Provo, UT 84602-4672, USA

Desty demonstrated in the early sixties that speed could be significantly increased in capillary column gas chromatography by using short, narrow-bore, capillary columns [1]. Limitations in speed are primarily defined by instrumental factors, one of the most important being detection.

High speed detection has been emphasized by several recent studies involving comprehensive multidimensional separations. A comprehensive two-dimensional GC-GC separation has been demonstrated by Liu and Phillips [2]. In that system, a conventional capillary column (250 μm i.d.) was used in the first dimension and a short, narrow bore column (50 μm i.d.) was used in the second dimension, with a thermal desorption modulator as an interface. The separations on the second column could be generated every 2 s. The peak widths in the high speed chromatograms ranged from 30 to 100 ms. A scan rate of 1.5 to 20 ms was required in order to define such narrow bands. Bushey and Jorgenson recently demonstrated a high speed, comprehensive 2D system using a combination of LC-CE [3] with a switching valve as an interface. A solute eluting in the high speed CE separation in their LC-CE system had a migration time of 55 s, with an eluting band width of less than 1 s. A comprehensive, on-line SFE-GC system has recently been reported [4] in which high speed GC separations were used to monitor the extraction process. The extracted material from an SFE cell was sampled continuously with 10-s time intervals; therefore, a high speed GC chromatogram was generated every 10 s.

The main limitation in coupling mass spectrometry to microcolumn separations is the inherently slow speeds of scanning mass spectrometers. Typically, scan times are greater than 100 milliseconds for quadrupole and sector instruments. Assuming that a minimum of 10 points is required to define a chromatographic peak, these instruments are limited to peaks that are 1 s or greater in width.

Because of its high spectral acquisition rate, time-of-flight mass spectrometry (TOFMS) is the ideal mass spectral detection system for high speed separations. A full spectrum is obtained in less than a millisecond. Recently, a new TOFMS system based on atmospheric pressure ionization (API) was constructed, and preliminary data were reported [5]. This system utilizes a supersonic jet expansion into the vacuum chamber to improve resolution, and off-axis pulsing into the flight tube to increase sensitivity. In this study, preliminary testing of this new API TOFMS system was made, particularly with reference to its possible coupling with the various microcolumn separation techniques. Our initial studies have centered on the coupling of capillary supercritical fluid chromatography to the MS. Figure 1 shows a schematic diagram of the coupled system, and Figure 2 shows averaged full-scan spectra of N-nitrosodiphenylamine obtained by SFC analyses of this thermally labile compound with different interface/ion source temperatures.

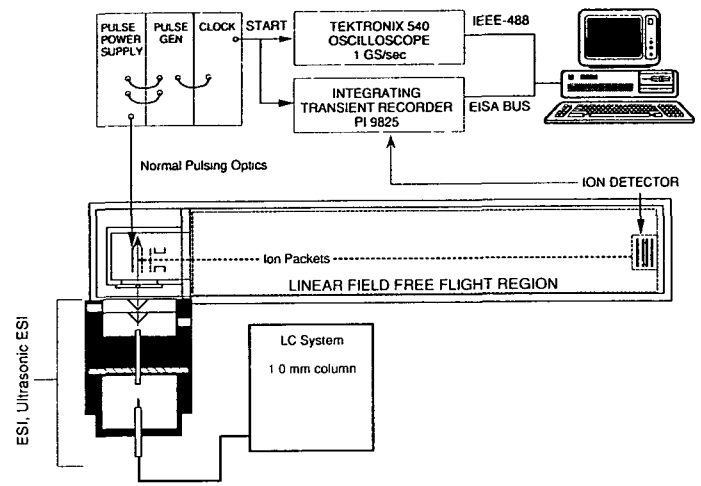
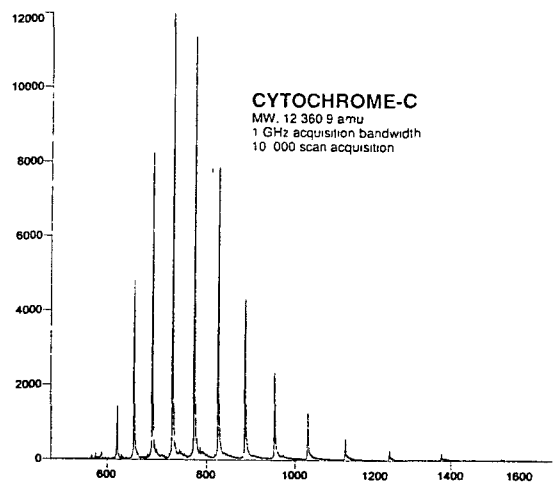
Continuous ionization sources have been coupled to time-of-flight mass spectrometers for many years. Interest has renewed in this practice as researchers seek the benefits of direct MS coupling to separations systems, 'soft' ionization sources which provide sub-picomole sensitivities, unlimited m/z range capability and systems with characteristic scanning speeds capable of analyzing rapidly eluting compounds. A particular configuration of an Electrospray-TOF-MS has been fabricated which meets each of these criteria.

Using a modified Electrospray ion source with excellent parallel focussing optics and well characterized ion energy profiles, TOF mass spectra have been generated in the linear mode using an orthogonal extraction technique for enhanced mass resolving power. A compact, linear geometry instrument has been shown to yield mass resolving powers in excess of 500. Sensitivities for various biomolecules allow full mass spectra to be recorded on the second and sub-second time frames. The instrument is completely free of mass dependent aberrations, allowing detection efficiency to be optimized for all m/z constituents simultaneously. Mass accuracies have been found to quite good (less than 50 ppm) by virtue of the TOF timebase stability. Despite synchronization losses, TOF duty cycle factors associated with the ion source geometry are still greater than dispersive instruments in the scanning mode.

Both pure electrospray and ultrasonically assisted electrospray (Ultraspray) have been interfaced to this system, allowing the use of both low (1-10 $\mu l\ min^{-1}$) and moderate (50 $\mu l/min^{-1}$) flowrates. An LC system (1.0 mm I.D.) with flowrates of ca. 50 $\mu l\ min^{-1}$ has been coupled to the ESI-TOF instrument to generate time resolved mass spectra of compound mixtures. We have found that the optimal acquisition of these data necessitate the use of high speed acquisition hardware with integrating capabilities for enhanced signal to noise ratios.





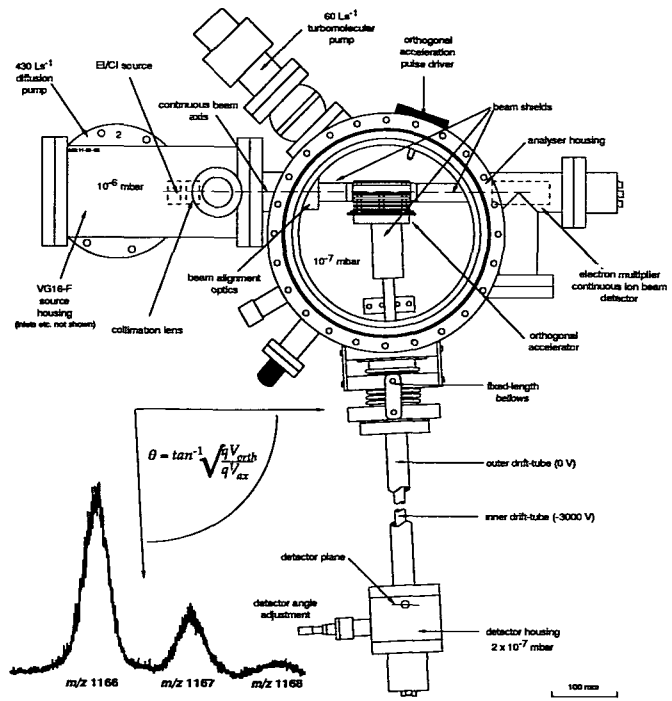
Time-of-Flight Technology for For High Speed GC/MS

J. Coles and M. Guilhaus, Department of Analytical Chemistry,
The University of New South Wales, PO Box 1 Kensington, NSW 2033, AUSTRALIA

Introduction

Most ion sources used in chromatography/mass spectrometry are continuous and involve the ionization of gaseous molecules. The distribution of molecular speeds of ions, time of ionization and their starting positions prior to TOF analysis preclude the attainment of analytically useful mass resolving powers unless steps are taken to correct for these initial dispersions.

A key advantage of TOFMS for chromatography/mass spectrometry is its speed which is limited by the arrival time of the heaviest ion (typically 100μs) and the requirement to obtain adequate statistics (several hundred ions in a spectrum). Adequate statistics can now be achieved with 100 to 1000 duty cycles from an EI source if the TOF duty-cycle efficiency is high. This results in data acquisition rates of 10 to 100 spectra per second which is a significant advance on scan rates on quadrupole and sector mass spectrometers.



Extraction of ion packets from a low-energy continuous ion beam by application of a pulsed orthogonal field can be an effective way to achieve relatively high duty-cycle efficiencies [1]. Once a section of the beam has been orthogonally extracted and leaves the first mesh delimited accelerating field, the extraction pulse can be relaxed to allow the continuous ion beam to refill the extraction region. With the correct choice of instrumental geometry and ion energies, the time for the heaviest ion to drift to the detector can be made to be about the same as the time for that component of the ion beam to refill the extraction region. Thus the analyzer efficiency increases towards the high mass end of the spectrum where it is usually most needed (opposite to the transmission characteristics of quadrupole mass filters).

If the ions in the continuous ion beam are traveling with minimally divergent trajectories, ion velocity vector components orthogonal to the beam are very small and if the orthogonal direction is chosen for the TOF analysis, conventional spatial focusing methods are able to correct for the spread of ion initial distances from the detector without the complication of a significant initial velocity dispersion. The acceleration pulse can be applied very quickly and reproducibly thus practically eliminating the temporal dispersion.

Our device does not require a reflectron and is designed to conserve the ion velocity components in the direction of the ion beam giving rise to an oblique ion trajectory in contrast to other "orthogonal" instruments which retard the ion-beam velocity with deflection optics [2]. Our investigations show that this steering step perturbs the space-time focusing advantage of the minimized initial orthogonal velocity spread and significantly decreases the resolving power attainable.

Results

Our prototype achieves a resolving power of m/Δm (fwhm) = 4000 at m/z c.1000. At higher mass the resolution approaches 5,000. The duty cycle efficiency leads to a sensitivity advantage over scanning analyzers of in the range of 100-1000 in terms of the number of ions detected or 10-30 in S/N. With suitable detection electronics, data acquisition rates of 50-100 spectra per second will be readily available.

Conclusion

The orthogonal acceleration / beam-velocity-conserved TOFMS geometry offers optimum duty-cycle efficiencies (high sensitivity) high resolving powers without the need for steering plates or ion reflectors. The approach is modular with respect to other continuous ion sources for broader use in chromatography/mass spectrometry. A GC/MS TOF instrument could be compactly designed to provide adequate resolving power (say m/Δm = 1000) with a 0.5m flight tube.

RECENT DEVELOPMENTS IN LC/TOF MASS SPECTROMETRY

Liang Li
Department of Chemistry, University of Alberta
Edmonton, Alberta T6G 2G2, Canada

We are in the process of developing interfacing techniques for combining solution-based separation methods with time-of-flight MS. Specifically, a pulsed sample introduction (PSI) interface [1] is being developed for combining conventional LC with TOF using laser-induced multiphoton ionization (MPI). In addition, continuous-flow matrix-assisted laser desorption (CF-MALD) [2] is being developed for micro-LC and capillary electrophoresis detection. In this presentation, new results on the performance of these interfaces were highlighted. However, much of the development and improvement in these areas is dependent on the use of a sophisticated data system for recording and storing transient signals and performing postdata analysis. In this report, we briefly describe the data system and illustrate its applications for PSI LC/TOFMS and CF-MALD. To our knowledge, no commercial data system dedicated for chromatography/TOF is currently available. We note that several groups have developed quite sophisticated data acquisition systems for high speed TOF [3-5].

Our data acquisition system is developed for laser ionization TOFMS. It involves the use of a digital oscilloscope (LeCroy 9400A) for mass spectral recording, followed by the transfer and storage of the data to a PC (486DX) via a GPIB. A software based on LabWindows is written to maximize the speed of data transfer and storage. To achieve rapid data storage, software double buffering is used so that the GPIB board can transfer the data from the LeCroy digitizer by direct memory access (DMA) to one buffer, while concurrently the contents of the second buffer is transferred to the disc. Table 1 lists the data recording speed of our system with different record lengths. This table shows that mass spectra can be recorded and stored at a speed ranging from 14 spectra/sec to 50 spectra/sec. This simple and readily adaptable system is found to be adequate and useful for operations in laser work where the use of very high repetition rates possesses no advantages or in the situations where only limited repetition rates can be used. It should be noted that the disk consumption rate is very high with laser ionization LC/TOF. For example, when the laser is operated at 10 Hz and the record length of one mass spectrum is set at 10 k, a 30-min chromatographic run would generate more than 180 Mbytes of data. In our system, the stored data can be transferred to other computers via ethernet. For offline data storage, a Hewlett Packard 35470A SCSI DAT drive is currently used to download the data from the hard disk to a tape. A 90 m tape can store 2 gigabytes of data. The data transfer rate is 10 MBytes/min.

In the past we relied on a boxcar integrator to monitor the ion intensity changes during the elution of samples in PSI LC/TOFMS. With the new data system, both total ion and selective ion chromatograms can be constructed from the mass spectra recorded. Figure 1 shows a comparison between the UV chromatogram of seven PAHs and the total ion chromatogram obtained from LC/TOF with the PSI interface. Figure 1 illustrates that the PSI interface does not degrade the performance of LC separation significantly. The data system also allows us to perform flow injection experiments with CF-MALD. Figure 2 shows the ion profile of five repeat injections of myoglobin obtained by flow injection CF-MALD with a parallel ion extraction configuration which has been described elsewhere [6]. The total amount of sample for each injection is 400 femtomoles. To construct the ion profile (i.e., peak area vs time) shown in Figure 2, the area of the myoglobin peak is calculated by the data system. Then ten peak areas are averaged to generate one time point in Figure 2. Since the mass spectra are recorded at a repetition rate of 10 Hz, one time point represents one second. In addition, 5-point data smoothing was performed to generate Figure 2.

In summary, much of the progress in LC/TOF is dependent on the use of a dedicated data system. We have developed a mass spectral recording and storing system based on GPIB data transfer for laser ionization LC/TOFMS. We have demonstrated that the system is essential and extremely versatile for performing PSI LC/TOF and CF-MALD.

TWO APPROACHES TO FAST GC/MS FOR PROCESS MONITORING

Steve Doherty, Bill Winniford
Dow North America, Western R&D Labs, Pittsburg,CA 94565.

We have investigated two approaches to the coupling of fast GC with a mass spectrometer for rapid analysis of vapor-phase reactors. Fast GC uses narrow I.D. or short capillary columns to reduce the analysis times compared to conventional GC by a factor of 10-100. This work has been directed towards providing an analytical system for unattended operations on processes that may have high variability over time, such as catalyst screening reactors or for fenceline monitoring. Both applications used a Hewlett Packard 5971A mass selective detector (MSD) to perform the mass spectrometry.

The first approach involved modifications to a commercially available fast gas chromatograph, the Microsensor Technologies Inc. (MTI) Model 200D GC. The MTI GC has been used extensively in-house for monitoring reactor eluents and process streams, due to its analytical flexibility and portability. Typical separations take less than two minutes, but the integral thermal conductivity detector (TCD) can not provide any structural information on unknowns. Since the TCD is a non-destructive detector, the GC eluent can be directed through the TCD and into a mass spectrometer for analysis by EI. The modifications required for interfacing the mass spec did not impair the integrity of the chromatographic separation, and provided an additional dimension of information for identifying unknowns.

The second approach employed short lengths (2.5 to 15 feet) of narrow-bore (10-100 micron I.D.) capillary chromatographic column held within a temperature controlled isothermal transfer line. The same length of capillary is used to both provide pressure drop into the mass spec ion source, and effect a separation of the individual components. Injection was made via a Valco 6 port valve with an external sample loop. In these experiments the MSD was the only detector used. **Figures 1** and **2** show typical separations, with baseline resolution in less than 30 seconds in both cases.

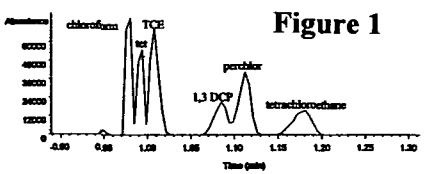

Figure 1

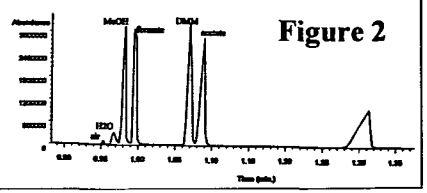

Figure 2

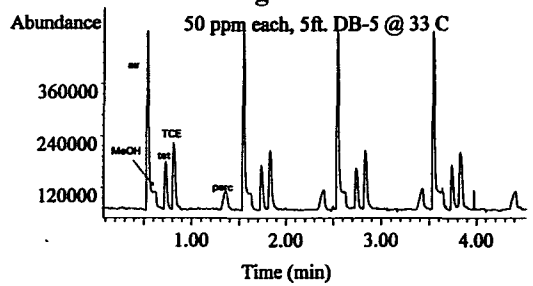
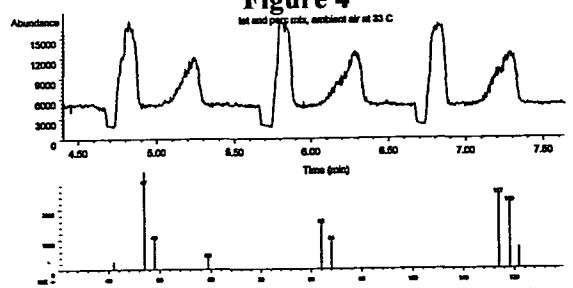
In addition to providing very rapid separations, this method offers a high degree of flexibility. We have used membrane inlets for monitoring organics in water, and with what were far from optimized conditions, we obtained reproducible analyses (RSD's < 5%) on the 30-45 second time scale, as seen in **Figure 3**.

Figure 3



Another interesting application is demonstrated in **Figure 4**. In this analysis, 200 ppm carbon tetrachloride and perchloroethylene were separated in 30 seconds at ambient temperature, using ambient air as the carrier gas. Combined with the fact that the mass spectrometer and valve actuation are easily automated, this provides a flexible GC/MS system that could be used for unattended process monitoring with a lmost no maintenance.

Figure 4



This combination of fast GC and mass spec provides rapid, highly efficient separations and sensitive detection . The molecular specificity of the mass spectrometer has another advantage; by using selected ion monitoring plots, the analyst can even resolve partially overlapping spectra (provided that each analyte has at least one characteristic ion), effectively increasing the resolving power of the combination. The hardware is inexpensive and mechanically simple, and is well-suited to automation. As such, it is ideally suited to process monitoring and environmental assessment applications.

FAST GC-MS IN SUPERSONIC MOLECULAR BEAMS

Aviv Amirav and Shai Dagan

School of Chemistry, Tel Aviv University, Tel Aviv 69978, Israel, Fax 972-3-6409293

A supersonic molecular beam is based on the expansion of the sample molecule seeded in a light carrier gas into the mass spectrometer vacuum system. A short 50 cm long megabore capillary column connects the heated injector-atmospheric pressure inlet and the supersonic nozzle. This column serves as an ultra-fast GC with total analysis time down to one second.

Fast GC-MS in supersonic molecular beams (SMB) is characterized by a very high carrier gas flow rate up to 240 ml/min and a carrier gas linear velocity controlled in the range 40-2000 cm/sec. This high flow rate and the septum free manual injection facilitate a very fast injection response time.

Both fly through electron impact and hyperthermal surface ionization serve as ion sources for the mass spectrometric analysis. The hyperthermal directional molecular kinetic energy serves to discriminate against the vacuum background ionization. Thus only molecules from the fast GC are ionized and mass analyzed (quadrupole) with the resulting ultra-fast ion source response time. In Fig. 1 the one or two seconds single ion monitoring GC-MS of four aromatic molecules is shown. In addition, the vacuum background elimination also result in a tail free fast GC-MS even with relatively non-volatile molecules as shown in Fig. 2.

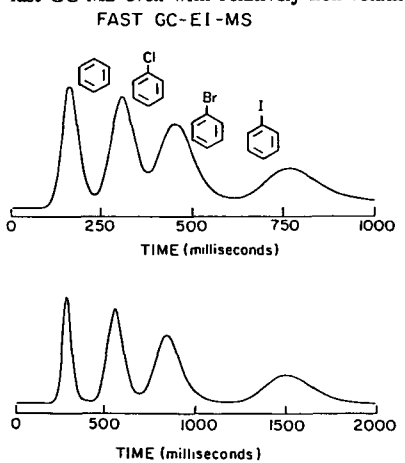


Fig.1 - Fast GC-MS

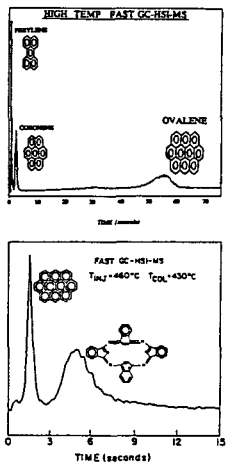

Fig.2 - High Temperature Fast GC-MS

The combination of fast elution time and hyperthermal surface ionization enables minimum detection level of 400 attogram as extrapolated from figure 3 which demonstrate the detection of 100 femtogram perdeuterated anthracene featuring noise free baseline with single ion monitoring quadrupole mass analysis. Fast GC-MS with final elution time constraint will be discussed in terms of optimal column length and carrier gas velocity. The fast analysis of thermolabile molecules and target compounds in complex mixtures such as tetraethyllead in gasoline will be demonstrated and discussed. In figure 4 two seconds GC-MS detection of coffeine in coffee is shown both in regular and decaffeinated brands. The fast GC inlet can also be coupled to a conventional GC with practically unlimited carrier gas flow rate and injected sample size. Over 100 mL splitless injection can be tolerated repeatedly.

Interfacing High Speed Transfer Line Gas Chromatography to Ion Trap Mass Spectrometry; Advantages and Limitations

Neil S. Arnold, William H. McClennen and Henk L.C. Meuzelaar
Center for Micro Analysis & Reaction Chemistry
University of Utah, Salt Lake City, UT 84112

The Ion Trap Detector (ITD, Finnigan-MAT) was originally introduced as a gas chromatography (GC) detector for laboratory benchtop GC/MS analyses. Its introduction coincided with a rising interest in vacuum outlet short column GC/MS [1] for high speed chromatographic separations. Advantages for such short column applications, including high operating pressures (10^{-3} torr) sensitivities (.1 fg/s) and scan speeds (5500 amu/s) relative to conventional quadrupole instruments, have fueled interest in ion trap based instruments for high speed, high resolution GC/MS analyses. Subsequent interest has been fueled by new developments in mobile instruments, high sensitivity MS^n capability, AGC-based dynamic range enhancement, and axial modulation based resolution enhancement.

High performance GC separations, produced in capillary flow restrictors (so-called "transfer line (TL)GC") and utilizing a simple vapor sampling interface [2] have been shown to provide rapid and sensitive atmospheric vapor analyses in GC separations requiring less than 10 s. This interface enables introduction of vapor samples via only deactivated quartz and fused silica surfaces into the transfer line GC column. The use of such sampling systems allows high speed GC/Ion Trap MS to be a near real time technique with low ppb level sensitivities. Figure 1 illustrates a repeated (x 2) selected ion chromatogram of a 4 ppb alkyl benzene mixture demonstrating a 10 to 1 S/N ratio. In Figure 2, the concentration of various substituted benzenes are traced as evolved from a 2 minute rotary kiln combustion experiment. Vapor samples are taken at 10 s intervals allowing the concentrations to effectively be traced in real time.

In Figure 2 GC resolution between peaks is effectively governed by the duration of the sampling pulse. With sufficiently high detector scan rates high GC resolutions may be utilized. Figure 3 illustrates the relationship between various GC parameters in the fixed pressure drop TLGC system (see reference 3). Obtaining theoretical plate values of 1000 to 10,000 plates at few second retention times implies that 10-100 ms wide GC peaks must be resolved to utilize the full potential of the GC separation. Figure 4 illustrates the potential of such separations in SIM traces of m/z 57, obtained from headspace of unleaded gasoline. This sampling rate of 15.6 scans/sec was obtained on a quadrupole instrument (HP 5971A) rather than an ITD instrument, but illustrates the need for higher ion trap scan rates.

Hardware considerations have limited ITD instruments and their successors (e.g., Magnum, Saturn) to an actual scan rate of 5500 amu/s and an effective rate which is over 4 times lower. The demands of interfacing ITD instruments to high speed transfer line GC require extending the limits of the ion trap based system. It should be pointed out that actual scan function durations are approximately 60 ms long (150 amu scan range) in an ITD based system so that internal data processing overhead reduction should allow scan rates up to 16 scans/sec in redesigned hardware systems. More importantly, the combined use of buffer gas and axial modulation have already allowed 2nd generation Ion Trap instruments to obtain peak widths between .1 and .2 amu wide for a 3 to 6 times improvement over unit mass resolution.

Figure 5 illustrates a PFTBA spectrum obtained at 4 x 10^{-4} torr in He at 22000 amu/s on a modified ITMS system. Inset are the actual data system peak profiles for m/z 69 and 502. While the A/D conversion rate is only 1.5 conversions/amu, unit mass resolution was verified by an analog oscilloscope. Actual peak width for m/z 502 is ~.6 amu FWHM and the C_{13} peak is readily resolved in the analog signal. This is 4 times the "normal" scan speed for the Ion Trap system. Theoretical evaluations [4,5] indicate that resolution in a high scan speed limit should decrease inversely with the square root at the scan speed.

If this is the case the prospects of obtaining total scan rate improvements of 10 to 50 times at unit mass resolution seems practical on both theoretical and hardware grounds.

TRACING ATTOMOLES OF ^{14}C-LABELED ORGANIC COMPOUNDS IN NATURAL SYSTEMS

J.S. Vogel[1], K.W. Turteltaub[2], C.E. Frantz[2], M.R. Creek[2], E.D. Fultz[2], K.T. Bogen[3] and G. Keating[3]
[1]Center for Accelerator Mass Spectrometry, [2]Biomedical and Biotechnology Research Program, and [3]Environmental Research Division
University of California, Lawrence Livermore National Laboratory
Livermore, CA 94550

Soon after the discovery of radiocarbon, two distinct applications of the isotope were developed that still predominate present uses: radiocarbon dating for chronometry, and radiocarbon tracing of labeled chemicals, especially in biological research. A primary goal in the development of accelerator mass spectrometry was the enhancement of ^{14}C dating through mass spectrometic detection. Although it was recognized that AMS could also be used for tracing ^{14}C in biomedical applications, no effort was made to develop practical methods for handling enhanced ^{14}C levels with AMS until biomedical researchers joined in forming the Center for AMS at LLNL in 1988.

AMS measures ^{14}C as an isotope ratio from graphite that is compared to that of a standard. Combustion and conversion to graphite of the samples destroy all chemical information. Careful separation and definition of all carbon in the sample before combustion are essential. Small amounts of natural or unlabeled organic materials will not change the isotope ratio appreciably, but attomole amounts of compounds labeled at many mCi/mmol easily contaminate samples. Contamination in laboratories previously used for ^{14}C labeled compounds can only be avoided by the most scrupulous use of disposable containers and processes that protect the sample from contamination through active design.

Living components of the biosphere contain 115 amol of ^{14}C per mg of carbon, or 1.4 parts per trillion. AMS is sensitive to 1 ppq for ^{14}C dating purposes, equivalent to 57,000 years of decay from biosphere levels, or 80 zmol per mg. Precisions of 0.5-2% are readily obtained in AMS measurements, sufficient to measure enhancements of a few amol in contemporary biological tissues. Sample preparation processes developed for biomedical use are not as sensitive as those for dating, but we detect 800 zmol/mg in samples as small as 100 µg. Samples are ideally 1 mg in size for efficient conversion to graphite for use in an AMS cesium sputter source, but the sample may contain a large fraction of ^{14}C-free carbon carrier as a dilutant. Separated samples of DNA or defined proteins may only weigh nanograms or micrograms but ^{14}C is quantified in them to 10 amol precision after dilution to 100-1000 µg. A 100 amol/mg sample produces a count rate of 200-400 cps in AMS, in contrast to it's decay rate of 0.0015 dpm. The upper limit to AMS quantification is set at 10-50 fmol ^{14}C per mg carbon (specific activity ≈20 pCi/mmol) to avoid contaminating the ion source which is also used for ^{14}C chronometry.

The most direct use of ^{14}C-AMS in biomolecular tracing measures the ^{14}C content of tissues or fluids at specific time points after dosing, or after a series of different doses at a

single time in an array of hosts. If the dissection or collection is contamination free, the isotope ratio converts directly to a specific dose per tissue weight for pharmacokinetic studies. For example, maximum levels of 1000 amol/mg-tissue of 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) are found in organs to a sensitivity of 2 amol/mg less than an hour after a single dose of 41 ng/kg. A chronic daily dosing with 47 ng/kg of 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx) resulted in liver and kidney saturation levels of 470 amol/mg-tissue. Benzene in whole liver tissue was quantified at 6 amol/mg after an acute dose of only 1 ng/kg. Dermal absorption of 5 ppb aquatic solutions of trichloroethylene and chloroform was qauntified at pmol/mg levels after exposures as short as 1 minute from compounds labeled only at the 5-10 µCi/mmol level (0.01% labeled). Such low radioactive and chemical doses could permit realistic human exposures to be tested directly on human subjects.

Pharmacodynamic study of detailed chemical binding with specific biomolecules requires selection and purification of components from bulk tissues. Since contamination is likely from equipment used in previous studies, we use individual and disposable separatory tools for each sample. DNA samples are purified on ion exchange columns designed for PCR analysis. Silica and cellulose TLC plates can be scraped to remove the spot or area containing the desired component. Affinity media, dialysis, precipitation/solubility, and molecular weight separations are performed in disposable plasticware. More complex molecular analysis requires the use of HPLC or electrophoresis. We created the world's largest HPLC by collecting 1 minute elution solutions, diluting a portion of each into carrier carbon, converting these to graphite, and measuring ^{14}C content by AMS. The sensitivity, determined by the baseline of hydrolyzed hepatic DNA from an undosed mouse, is 20 amol/min. Similarly digested DNA from an acutely ^{14}C-MeIQx dosed mouse (30mCi/mmol, 50mg/kg) indicates 65 fmol of MeIQx bound per µg of DNA throughout the rigorous DNA purification. The absolute quantity of the deoxynucleotides injected is determined from the UV trace before eluent collection. Our initial tests of plate gel electrophoresis show that molecular weight markers, even supposedly "unlabeled" ones, may migrate sufficiently across lanes to cause ^{14}C contamination, but that the procedure can detect differential binding of a labeled compound among proteins. The acrylamide gel itself provides the carrier carbon in small plugs excised at developed spots. Capillary zone electrophoresis is also being explored and may prove a more effective method than gel electrophoresis for studying binding of labeled compounds to macromolecules using AMS.

Presently, CAMS/LLNL is the only AMS facility of the 25-30 worldwide that devotes a significant effort to ^{14}C detection for biomedicine. We plan to increase throughput to 500-1000 samples per week by obtaining a dedicated spectrometer. Small spectrometers are being developed for more widespread application of this sensitive technique.

Calcium Kinetic Study In Human By ^{41}Ca Tracing.

E. Venczel[b], E. Boaretto[a], Z. Gelbart[b], G. Hollos[c], R. R. Johnson[b], M. Paul[a], J. Prior[d], V. Sossi[b], : (a) Racah Institute of Physics, Hebrew University, Jerusalem, Israel; (b) TRIUMF and University of British Columbia, Vancouver; (c) Accelerator Laboratory, Weizmann, Rehovot, Israel; (d) Vancouver General Hospital, Vancouver, Canada.

^{41}Ca ($T_{\frac{1}{2}} = 1 \times 10^5$ years) is an ideal tracer [1] for long-term studies of calcium kinetics in biological systems for several reasons: (i) due to its long half life it behaves as a stable nuclide for a human time scale causing no collateral radiation effects; (ii) its natural abundance is extremely low (^{41}Ca/^{41}Ca $= 10^{-15}$); (iii) using Accelerator Mass Spectrometry (AMS) ^{41}Ca isotopic concentrations can now be measured to very high sensitivity (typical sensitivity of our system ^{41}Ca/^{41}Ca $< 10^{-13}$).

An experiment was initiated in a human subject by intravenous injection of a 126ng dose of ^{41}Ca on July 18, 1990. The ^{41}Ca concentration and the ^{41}Ca/^{40}Ca isotopic ratios in serum and urine were measured at time points over a 900 day period. The isotopic ratio decreases exponentially with a slope change in the later time period corresponding to the slow release of calcium from the stable bone pool. A three compartmental model analysis indicates that the data are in relative agreement with known (D. Elmore et al, Nucl. Instr. and Meth. B52 (1990) p531) time constants of the different calcium pools (Fig 1).

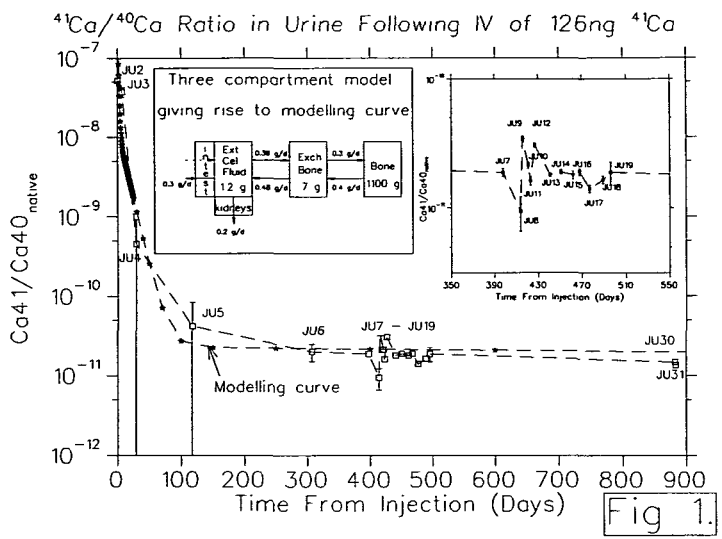

Fig 1.

This information established the steady-state concentration of ^{41}Ca in the subject's skeletal bone pool.

Preparation of samples for analysis by AMS required simple chemistry. With an injected dose of 100ng, required volumes of urine from day1 - day200 fall in the range of 0.1-3.0mL plus an appropriate quantity of carrier ^{40}Ca to attain a ^{41}Ca/^{40}Ca ratio $\sim 10^{-11}$ were needed. From day 201 onward the required sample size typically 1000mL, was large enough to recover 30mg of native calcium so that no additional carrier was necessary. Calcium recovered from the biological samples was prepared as calcium hydride (Fig. 2), the required molecular form of calcium for AMS analysis. The prepared CaH_2 samples were analyzed by AMS on the Pelletron Tandem Accelerator at Weizmann, Rehovot, Israel.

At time points after the establishment of a relative steady-state, fluctuations in the native ^{41}Ca/^{40}Ca ratio were observed (Fig 1). we are developing a more sophisticated compartmental model to take into account these ^{41}Ca/^{40}Ca ratio variations. a relationship between these changes and hormone balance is being explored.

Further studies in women during pre-menopause and after may help to understand the effects of hormonal influences on bone resorption Such studies may also show which subjects may be suffering from the early onset of osteoporosis, indicated by significantly higher native ^{41}Ca/^{40}Ca ratios, due to elevated resorption of bone calcium.

In conclusion we have demonstrated: The ability of monitoring ^{41}Ca levels in biological samples from a human subject over a long time period; life-long observations of bone resorption are feasible with a nominal dose of 100ng of ^{41}Ca (equivalent to 0.01% of background radiation) with no significant radiation effects.

Advances in the Earth Sciences through Accelerator

Mass Spectrometry

Fred M. Phillips, Geoscience Department, New Mexico Tech, Socorro

Measurement of many naturally-occurring long-lived radionuclides by decay counting is difficult or impossible due to the long counting times or large sample sizes that are required. This impediment has been removed by the application of accelerator mass spectrometry (AMS), which can routinely measure many rare radionuclides on milligram-sized samples at atomic abundance ratios as low as one in 10^{15}. This analytical development has for the first time allowed the application of many cosmogenic and anthopogenic nuclides to problems in the earth sciences. This talk will focus on three applications:

Demonstration of rapid sediment recycling through volcanoes over subduction zones. Berylium-10 produced is by cosmic rays in the atmosphere, but only negligibly in the subsurface. The atmospheric ^{10}Be is deposited in relatively high concentrations in oceanic sediments, since deposition of sediment is low in the open ocean. ^{10}Be has now been measured by AMS in the lava of volcanoes that overlie subduction zones. This proves that subducted ocean crust is indeed recycled through volcanoes. It also shows that the time for recycling is short, since ^{10}Be has only a 1.4 million year half-life.

Dating the formation age of landforms. Most landforms cannot be dated by conventional methods, rendering difficult the development of chronologies for earth-surface processes. This difficulty can now be overcome by using AMS to measure the amounts of cosmogenic radionuclides that have accumulated in surface rocks, and hence inferring the exposure time. Nuclides that are produced by cosmic radiation in rocks include ^{10}Be, ^{26}A1, ^{36}C1, and ^{40}Ca. They can be used to date the exposure time (or to determine the erosion rate) of rocks on time scales from 10^3 to 10^6 years. Applications include dating young lava flows, determining chronologies of glacial advances, dating meteorite impact craters, estimating erosion rates of mountain ranges, and revealing the history of sand dunes.

Reconstruction of variations in cosmic radiation. The intensity of cosmic radiation is thought to have varied in the past due to changes in the terrestrial and solar magnetic fields. It is now possible to test these magnetic field histories by using AMS to measure cosmogeic nuclides in suitable geological repositories. ^{10}Be has been measured in ice cores and shows marked changes in concentration with time. More recently, ^{36}C1 has been measured in fossil urine from pack rat midden collected in the western United States. The ^{36}C1/C1 ratio in this fossil urine has varied by a factor of approximately two over the past 20,000 years.

Presented at the 41st ASMS Conference on Mass Spectrometry

The Analysis of Heavy Elements by AMS; A New Mass Spectrometry?

L.R.Kilius. IsoTrace Lab, University of Toronto, Toronto, Canada, M5S 1A7

Whereas the light isotopes such as ^{10}Be, ^{14}C, ^{26}Al and ^{36}Cl are measured routinely on dedicated Accelerator Mass Spectrometry (AMS) facilities, the measurement of heavy nuclides on similar equipment has not been as widespread. This has been in part due to the more stringent requirements of resolution and bending power for magnetic and electrostatic analyzers in order to separate molecular hydrides and the more abundant atomic beams near the masses of interest.

A successful measurement of heavy elements cannot be performed by a simple scaling of existing AMS systems to accomodate the heavier masses. Backgrounds generated by an extended ion energy distribution from sputter ion sources, small angle scattering within the residual gas, the decay of metastable molecules and other atomic process dominate in the high mass region ($M \gg 40$). The traditional AMS solutions for atomic and molecular isobar separation using nuclear physics detector technology to identify uniquely the atomic number is not possible in this mass region. At best, molecular fragments can be separated on the basis of energy differences, provided they were not originally hydrides. Atomic isobars must be eliminated at the ion source using negative ions or must not be present, as for example, in the measurement of platinum group element abundances.

Generally the lessons learned from conventional mass spectrometry need be applied. Multiple arrays of electric and magnetic analyzers prior to injection into the accelerator and for post acceleration analysis are required. In all cases the resolving power of these devices should exceed the resolution attainable by detector technologies. This includes energy and time of flight detectors. Therefor the accelerator is no longer bound by the requirement to generate ions in an energy range suitable for ion detectors. Instead it serves to decouple the low energy spectrometer system from the high energy spectrometer system by virtue of charge exchange and an energy shift. This has the effect of removing most backgrounds generated by the sputtering process. The higher energy also benefits the reduction of backgrounds created by scattering in the residual gas as ions will tend to lose charge rather than maintain the same charge state at these energies.

At the IsoTrace laboratory, we have successfully extended AMS for the routine measurement of ^{129}I. Figure 1 illustrates the distribution of ^{129}I measured along coastal sites within the northern hydrosphere (Rai). The $^{129}I/^{127}I$ ratios ($x10^{-10}$) range over 4 orders of magnitude and are associated with the massive releases near nuclear fuel reprocessing facilities such as those at Sellafield, UK and Cap la Hague, France. Within the English channel, sample sizes smaller that 3 ml of water were used while ^{129}I in samples as small as 100 ml from the Arctic were measured (Rai). A higher dynamic

range is attainable as the machine background for AMS measurements is consistenly below $2x10^{-14}$.

We have also utilized the heavy element system for the study of negative ions for which little or no previous data were available. Positive identification of the group IIb negative ions(Ca-Ra) have been made in addition to the negative ions of Ce, Pr, Nd, Sm, Eu, Gd, Tb, Dy, Tm, Yb, Lu, Hf, and Pu (Gar). In some cases binding energies have been determined using electric field dissociation and AMS (Nad).

The heavy element program continues to evolve with the addition of high resolution injection systems for the analysis of actinides (Zha) and the development of ion sources with microprobe capabilities for in-situ platinum group element analysis.

DISTONIC IONS; THEIR STATUS IN GAS PHASE ION CHEMISTRY.

John L. Holmes, Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N

Distonic ions have been a feature of gas phase ion chemistry for about 25 years, but it is only in the past 10 years that methods, both experimental and theoretical, have been developed sufficiently to establish distonic ion structures and energies.

At the same time, parallel and overlapping studies of distonic and ylid ions in matrix-isolated radiolyses and similar experiments, using electron spin resonance spectroscopy, have been conducted with remarkably little contact or even cross-referencing between the two disciplines.

At the present stage of development of the detailed understanding of ion fragmentation mechanism, distonic ions can be introduced with confidence as stable reaction intermediates and/or as alternative configurations for molecular ions. This confidence springs from the relative ease with which the (proposed) distonic ion can often unequivocally be generated via fragmentation reactions of larger ionized molecules. This approach is particularly fruitful when the distonic ion has the structure of a protonated free radical, e.g. is generated by the intramolecular transfer of a proton to a hetero atom within a larger molecular ion, followed by the loss of a small molecule.

In marked contrast the intermediacy of ion-radical complexes in ion fragmentations is much harder to establish by experiment and so rests heavily on ab initio molecular orbital theory calculations.

One of the earliest distonic ions was the intermediate species in the McLafferty rearrangement, e g the ion $HC^+(OH)CH_2CH_2C^{\bullet}H_2$, formed from butanal as the intermediate leading to $HC(OH)CH_2^{+\bullet}$ + C_2H_4. The existence of such an ion as a stable intermediate was long a subject for sharp controversy as "stepwise" or "concerted" was debated for the nature of the γ-hydrogen transfer in the molecular ion, leading to the above products [1]. It is now generally accepted that such ions are stable species in the gas phase, capable of being independently generated and studied.

Perhaps the most thoroughly studied simple distonic ion (experiment and theory) is the ethene-water complex ion $C_2H_4OH_2^{+\bullet}$, discovered by Terlouw et al. in 1981 [2]. The ion cannot rearrange to any isomeric $C_2H_6O^{+\bullet}$ structure and has only one dissociation channel, producing the formal ion-dipole component species, ionized ethene and water [3]. It is also the $C_2H_6O^{+\bullet}$ ion of lowest enthalpy.

Identification of distonic ions is pursued by all the presently available mass spectrometric techniques, $\Delta_fH°$ determinations, measurement of metastable ion (MI) and collision induced dissociation (CID) mass spectra, isotopic labelling and, as has been emphasized recently [4], by reactivity studies. Such work is often greatly aided by high level molecular orbital theory calculations.

Unfortunately, the unequivocal identification of a distonic ion, or even the proof of its participation in a fragmentation mechanism is often no easy task. The presence of a distonic ion will be obscured if it can undergo extensive interconversion with other isomeric forms below the lowest dissociation energy of the ensemble. Thus the existence of the ethene-methanol ion $C^{\bullet}H_2CH_2O^+(H)CH_3$ is very difficult to substantiate because it certainly rearranges, before fragmenting to ionized

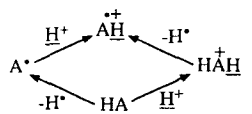
cyclopropane and a water molecule. Indeed, the three $C_3H_8O^{+\bullet}$ isomers $^{\bullet}CH_2CH_2O^+(H)\ CH_3$, $^{\bullet}CH_2O^+(H)CH_2CH_3$ and $CH_3CH_2CH_2O^{+\bullet}H$ all fragment via the same distonic species, $^{\bullet}CH_2CH_2CH_2O^+H_2$ [5].

Note that for labelled saturated molecular ions, information on structure and/or fragmentation mechanism assignment may be lost, due to H/D scrambling prior to dissociation. However, H/D mixing in such species must involve the participation of distonic ions.

Finally, the preparation of structurally "pure" distonic ions (e.g. for reactivity studies) may be frustrated if facile rearrangements are possible at energies close to the ground state of the ion.

Many distonic ions, e.g. $^+CH_2OC^{\bullet}H_2$, $^{\bullet}CH_2CH_2OC^+H_2$, $^{\bullet}CH_2CH_2C^+H_2$, correspond to ring opened molecular ions. It is easy to show that the relative $\Delta_fH°$ values only rarely correlate with the potential release of ring strain energy if the distonic ion were produced from the cyclic form.

It has been customary to estimate $\Delta_fH°$ values for distonic ions using the thermochemical cycle:



In general the [C-H] bond dissociation energy (BDE) in the neutral HA and its proton affinity (PA) are known or can be estimated. It is then assumed that the BDE in the protonated species $HA^+\underline{H}$ is the same as in HA and that the PA value for $A^{\bullet}$ if the same as that of HA There is no doubt that this approach works well for a wide range of keto/enol type distonic ions [6], but for the simple ions $^{\bullet}CH_2O^+H_2$, $^{\bullet}CH_2CH_2O^+H_2$, $^{\bullet}CH_2Cl^+H$, $^{\bullet}CH_2CH_2CH_2O^+H_2$ the estimated $\Delta_fH°$ values are more than 10 kcal mol^{-1} lower than the best experimental and theoretically derived values from high level ab initio molecular orbital theory calculations. Thus the [C-H] bond energies in e.g. $D[H\text{-}CH_2CH_2O^+H_2]$ are much higher than in their neutral counterparts (e.g. $D[H\text{-}CH_2CH_2OH]$). State-of-the-art theoretical calculations have failed to show any geometrical change in the molecule upon protonation which can readily account for the strong C-H bond [7] and so the explanation lies elsewhere.

Investigation of Distonic Radical Cations by Ion-Surface Collisions J. L. Jones, Á. Somogyi, R.L. Franklin, A. Dongré, M. B. Smith, V.H. Wysocki; Department of Chemistry, Virginia Commonwealth University, Richmond, VA 23284-2006

Experimental. All experiments are performed in an instrument designed for ion-surface collisions.[1] The instrument consists of two quadrupoles arranged at 90°, with a surface placed to intersect the ion optical path of the quadrupoles. The mass-selected incident ion beam collides with the surface at 45° with respect to the surface normal. Surfaces used for this work consist of self-assembled monolayer films of alkanethiols chemisorbed onto vapor-deposited gold ($CF_3(CF_2)_7CH_2CH_2SAu$, $CH_3(CH_2)_{17}SAu$, and $CD_3(CD_2)_{19}SAu$).[2]

Calculations. MNDO and *ab initio* (HF/6-31G**) calculations have also been carried out on several ion structures. MNDO bond orders are also used for the description of ion structures and fragmentation processes.[3]

Results and Discussion. Our investigations of distonic radical ions are based on application of ion-surface collision mass spectrometry and quantum chemical calculations. The ions currently being investigated are listed below along with the reason for investigation:

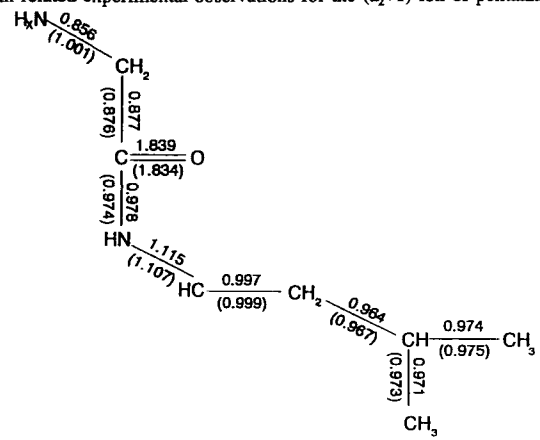
Ion	Purpose	Ion	Purpose
$CH_2(CH_2)_nOH_2^+$	standards; well-characterized by other techniques, allows evaluation of ion-surface collision behavior (surface-induced dissociation or ion-surface reaction)	$CH_2{=}YH^+ + Z$ ↓ ZCH_2YH^+ or CH_2YHZ^+ Y=heteroatom, Z=surface species	determine whether distonic or conventional ion is produced by reaction of even-electron ions with radicals from surface; compare with theory
$CH_2(CH_2)_nOHX^+$ X=Li, Na	these and related ions are proposed distonic ion products of CAD experiments; attempt to confirm whether distonic	peptide (a+1) and (z+1) ions (precursors to d and w ions, respectively)	determine whether actually distonic, support with model based on MNDO bond order calculations
$RCHS^+(CH_3)_2$ ↓-e $RCHS^+(CH_3)_2$ R=C_6H_5CO	determine whether these solution-stable sulfonium ylidions can be produced by oxidation of the ylide in the ESI source		

For $CH_2(CH_2)_nOH_2^+$ ions (n=0, 1), collisions with the fluorinated organic monolayer surface lead to characteristic dissociation products. Collisions at monolayer surfaces with available H from alkanethiolate surfaces lead to H-addition with subsequent fragmentation of the adduct. A deuterium labeled surface is used to confirm reactions (e.g., $CH_2OH_2^+ + CD_3(CD_2)_{19}SAu \rightarrow CH_2D^+$). Ionized ethanol

$CH_3CH_2OH^+$ appears to be more reactive toward H-addition than does its distonic isomer, $CH_2(CH_2)_nOH_2^+$. This is in line with enthalpy calculations, which show that H addition is more exothermic for the conventional isomer (using C_7H_{16} as a model for the surface chains). Allow H addition is predicted to be exothermic for both isomers and fragmentation of either is endothermic, fragmentation competes favorably with reaction which suggests a fairly high barrier to the entropically less favorable H addition.

Ab initio calculations show that replacement of H^+ with Li^+ or Na^+ leads to structures that are best described as ion-radical complexes with formally separate charge and radical sites. The ion-radical complexes differ from the distonic isomers of small alcohols in that the O-X bond is more ionic in character.

MNDO bond order calculations suggest that the (a+1) and (z+1) distonic peptide ion fragments are reasonable intermediates for formation of side-chain cleavage ions (as proposed by Biemann based on experimental results[4]). Bond order values for the a_2+1 ion shown below (Scheme I) predict easy loss of NH_3, consistent with related experimental observations for the (a_2+1) ion of pentaalanine.[5]



Scheme I. MNDO bond orders for the neutral (x=2) are shown in parentheses. (For (a_2+1) model, x=3.)

Synthesis and Structural Characterization of Novel Distonic Ions By Using Ion-Molecule Reactions

Rebecca L. Smith, Krista M. Stirk, Hilkka I. Kenttämaa
Department of Chemistry, Purdue University, West Lafayette, IN 47907.

In recent years, it has become that distonic ions are common and stable gas phase species. The long-lived molecular ions of many common organic compounds spontaneously rearrange to a distonic form. Distonic ions are also formed as intermediates in unimolecular dissociation reactions of gaseous radical cations, including the McLafferty rearrangement. In order to examine the properties of distonic ions, it is necessary to be able to generate a variety of stable distonic ions. Distonic ions are typically made by isomerization or dissociation of conventional radical cations. For example, the α-distonic ion $^{+}CH_2OCH_2^{\cdot}$ is generated by loss of formaldehyde from ionized 1,3-dioxolane. This approach, however, limits the type and size (number of heavy atoms between the charge site and radical site) of distonic ions which can be formed.

Ion-molecule reactions performed in an FT-ICR can be used to synthesize a variety of novel distonic ions. For example, $^{+}CH_2OCH_2^{\cdot}$ can be used to transfer $CH_2^{+\cdot}$ to neutral acetone to produce the α-distonic ion, $(CH_3)_2C^{+}OCH_2^{\cdot}$. Neutral ketene transfers CH_2-groups in consecutive reactions to various radical cations, yielding stable distonic product ions. For example, transfer of a CH_2-group to the distonic ion $^{\cdot}CH_2CH_2CH_2CO^{+}$ generates the first known stable δ-distonic ion: $^{\cdot}CH_2CH_2CH_2CH_2CO^{+}$.

Compared to other types of radical cations, distonic ions demonstrate unique reactivity toward many neutral reagents, such as dimethyl disulfide and cyclohexanone. Distonic ions typically undergo radical type reactions with these reagents while most conventional radical cations react by charge exchange. For example, the ion $^{\cdot}CH_2CH_2CH_2CH_2CO^{+}$ abstracts a thiomethyl group from dimethyl disulfide whereas its conventional isomer, ionized cyclopentanone, as well as numerous other isomeric structures studied, undergo facile charge exchange (Figure 1). Cyclohexanone is another neutral reagent which can be used to distinguish between various radical cations: conventional radical cations typically undergo charge exchange with cyclohexanone, while many distonic ions transfer a radical chain as a radical cation to this molecule.

It appears likely that many distonic ions, such as $^{\cdot}CH_2CH_2CH_2CO^{+}$, react with neutral reagents such as dimethyl disulfide via a charge initiated mechanism. In this mechanism, a covalent bond is initially formed between the charge site of the ion and a sulfur lone pair of electrons. Radical substitution then occurs at one of the sulfur atoms, resulting in a sulfur-sulfur bond cleavage followed by loss of a thiomethyl radical from the collision complex. Support for this mechanism is obtained for example from the fact that thiomethyl abstraction by $^{\cdot}CH_2CH_2CH_2CO^{+}$ involves a six-membered transition state and occurs with 26% efficiency, while the reaction with $^{\cdot}CH_2CH_2CH_2CH_2CO^{+}$ occurs with only 2% efficiency. The latter reaction would involve a seven-membered transition state (Figure 2).

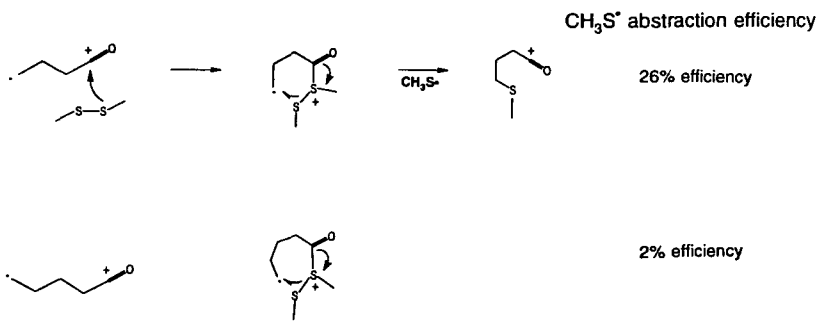
Proposed Mechanism for Reaction of Several Distonic Ions with CH_3SSCH_3



NEUTRALIZATION-REIONIZATION (NR) STUDIES ON DISTONIC RADICAL CATIONS

Chrys Wesdemiotis, Michael J. Polce, Sarka Beranova, and Fred. A. Wiedmann
Department of Chemistry, The University of Akron, Akron OH 44325-3601

Distonic radical cations represent the molecular ions of diradicals, *i.e.* species with two unpaired electrons at non-adjacent atoms. Being extremely reactive, diradicals do not exist freely. In sharp contrast, the corresponding distonic radical ions are usually stable and readily accessible in the mass spectrometer. The tailored preparation of specific distonic ions is possible through known rearrangement fragmentations or ion-molecule reactions. Once formed, these ions can serve as the starting material for the synthesis of gaseous, elusive diradicals in neutralization-reionization mass spectrometry (NRMS) experiments. The incipient diradical formed upon neutralization may survive intact, rearrange, or dissociate. The mass spectrum obtained after reionization of the neutral product(s) can reveal information on the stability and reactivity of the intermediate diradical as well as on the structure of the original distonic ion.

The distonic ion $\cdot CH_2CH_2OCH_2^+$ ($\mathbf{1}^{\cdot+}$), which represents the C-C ring-opened isomer of oxetane ($\mathbf{2}^{\cdot+}$), is formed from the 1,4-dioxane molecular ion by $CH_2{=}O$ loss. In the metastable time window, $\mathbf{1}^{\cdot+}$ and $\mathbf{2}^{\cdot+}$ decompose via complicated rearrangements. Both cations mainly lose $\cdot H$ to yield $CH_3CH_2C{\equiv}O^+$, as established by MS/MS/MS. Cation $\mathbf{1}^{\cdot+}$ also produces $C_2H_6^{\cdot+}$ (CO loss) and $C_2H_3O^+$ ($\cdot CH_3$ loss), whereas for $\mathbf{2}^{\cdot+}$, the elimination of $\cdot CH_3$ is not observed and the loss of CO proceeds to a lesser extent and with a ~5 times smaller kinetic energy release (2.3 vs. 19 meV). Upon CAD, $C_2H_4^{\cdot+}$ which can be formed by direct bond cleavage(s) from both ions becomes the base peak but several rearrangement processes, such as the CO loss, still remain dominant. The CAD spectra of $\mathbf{1}^{\cdot+}$ and $\mathbf{2}^{\cdot+}$ contain diagnostic differences: the abundances of $C_3H_{0\text{-}3}^+$ are substantially higher for $\mathbf{2}^{\cdot+}$ and the CH_2 loss more dominant for $\mathbf{1}^{\cdot+}$, in agreement with the original ion structures. This result is in line with the unique ion-molecule reactions of these two isomers [1].

Neutralization of $\mathbf{1}^{\cdot+}$ gives the diradical **1**, a proposed intermediate in the pyrolysis of oxetane to ethylene (28 Da) and formaldehyde (30 Da). The NR spectra of $\mathbf{1}^{\cdot+}$ (Figure 1a) and d_6-$\mathbf{1}^{\cdot+}$ (Figure 1b) attest that **1** indeed dissociates extensively into $CH_2{=}CH_2 + O{=}CH_2$. In contrast, the NR spectrum of $\mathbf{2}^{\cdot+}$ contains an abundant survival ion (Figure 1c) and is fairly similar to the corresponding CAD spectrum, consistent with the expected stability of **2**. Thus, large differences are observed between the NR spectra of $\mathbf{1}^{\cdot+}$ and $\mathbf{2}^{\cdot+}$ due to the distinct reactivities of the intermediate neutrals. The dissociation products of **1** are also characteristic for the connectivity of the precursor distonic ion.

It is evident from the presence of ions above *m/z* 30 in Figure 1a (above *m/z* 32 in Figure 1b) that **1** does not decay entirely. The small fraction remaining undissociated neither ring-closes to **2** (Figures 1a vs. 1c) nor undergoes 1,4-H migration to the carbene **3** (Figures 1a vs. 1d; $\mathbf{3}^{\cdot+}$ is produced by electron impact of ethyl glyoxylate). This means that the critical energies needed for C-C bond formation (**1** → **2**) and H-atom migration through a five-membered ring (**1** → **3**) must be higher than the energy required to cause C-O bond cleavage in the diradical.

Characterization of a diradical is only possible if the spectra of isomerically pure ions are known. In the above case, the chemistry of **1** could be assessed because isomers $\mathbf{2}^{\cdot+}$ and $\mathbf{3}^{\cdot+}$ yield unique fragments (see Figures 1c and 1d), based on which any isomerization of **1** can be probed. This is not true for other isomers. For example,

the CAD spectrum of the distonic ion $^+CH(CH_3)OCH_2\cdot$ ($\mathbf{4}^{\cdot+}$, from 2-methyl-1,3-dioxolane) is identical within experimental error to the spectra of ionized propylene oxide ($\mathbf{5}^{\cdot+}$) and ionized vinyl methyl ether ($\mathbf{6}^{\cdot+}$). The NR spectra of the first two isomers also are practically indistinguishable, corroborating that ring-opening of $\mathbf{5}^{\cdot+}$ to yield the more stable distonic ion $\mathbf{4}^{\cdot+}$ is facile. However, differences are observed between the NR spectra of $\mathbf{4}^{\cdot+}$ and $\mathbf{6}^{\cdot+}$, suggesting that the resemblance between the CAD spectra of these two isomers is due to collision induced isomerization prior to dissociation. Isomeric ions decomposing via common pathways can still show distinct NR spectra because of different neutralization cross-sections of the precursor ions and/or distinctive reactivities and reionization cross-sections of the intermediate neutrals. Based on absolute abundances (*i.e.*, NR yields), the NR spectrum of the distonic ion $\mathbf{4}^{\cdot+}$ contains ≤30% $\mathbf{6}^{\cdot+}$. Whether the ~30% $\mathbf{6}^{\cdot+}$ result from isomerization (in µsecs) of the original precursor ion $\mathbf{4}^{\cdot+}$ before neutralization and/or from rearrangement of the intermediate diradical **4** to **6**, remains unclear. Ion-molecule reactions have shown that the former does take place in the msec time domain [2].

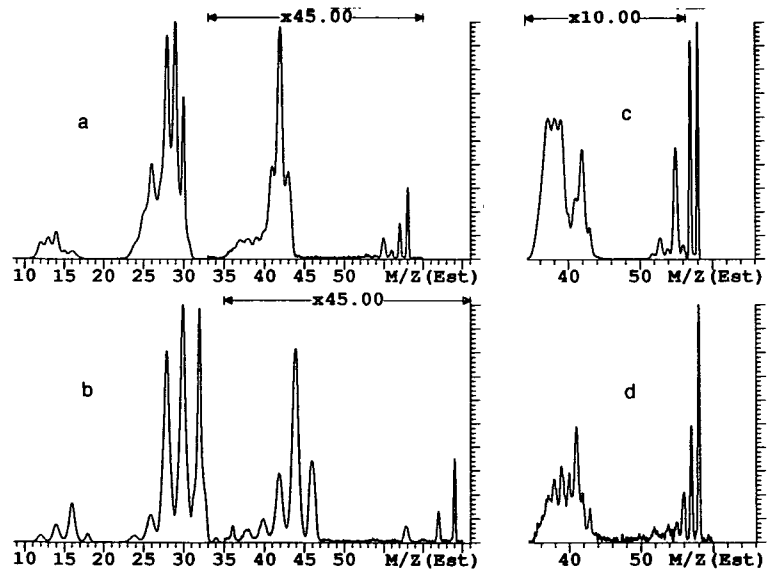


Figure 1. NR Xe/O_2 mass spectra of (a) $\cdot CH_2CH_2OCH_2^+$, $\mathbf{1}^{\cdot+}$ and (b) $\cdot CD_2CD_2OCD_2^+$, d_6-$\mathbf{1}^{\cdot+}$. Partial NR Xe/O_2 spectra of (c) ionized oxetane, $\mathbf{2}^{\cdot+}$ and ethoxy carbene, $\mathbf{3}^{\cdot+}$.

The RF-Only Mode Event in FTMS: A Means of Generatilon and Characterizing Distonic Ions

M.L. Gross, D.L. Rempel, C.L. Holliman, Dept. of Chem., Univ. of Nebraska, Lincoln, NE 68588

For over twenty years, we have been interested in the reactions of radical cations and nucleophiles. One of the earliest reactions we discovered was that of the cyclopropane radical cation and ammonia to give the distonic ion $\bullet CH_2NH_3^+$ [1,2]. Although this bimolecular reaction appeared to provide an interesting route to distonic ions, characterization by using sequential ion-molecule reactions was difficult because the distonic $\bullet CH_2NH_3^+$ is a good gas-phase acid and disappears in rather uninteresting proton-transfer reactions.

Nevertheless, the opportunity of studying bimolecular reactivity of distonic ions remained intriguing. Success would require the design of distonic ions with no acidic protons on the heteroatom. Other workers have shown that suitably configured distonic ions can be used as reagents in bimolecular reactions [3,4].

A potential solution to the problem is to use, in lieu of ammonia, a base with no hydrogens bonded to nitrogen. Pyridine is an obvious choice, and we recently found that the cyclopropane radical cation reacts with pyridine to give $C_5H_5\overset{+}{N}\text{-}CH_2\bullet$ [5].

An interesting question is whether distonic ions, such as $\bullet CH_2NH_3^+$ and $C_5H_5\overset{+}{N}\text{-}CH_2\bullet$, can be used to explore the intrinsic reactivity of gas-phase free radicals. To address this question, we decided to generate the β-distonic ion $C_5H_5\overset{+}{N}CH_2CH_2\bullet$ in which the unpaired electron site is "insulated" from the aromatic ring by a methylene group. We hoped that a distonic ion of this type would react as a primary free radical.

This β-distonic ion can be easily generated in an ionized mixture of pyridine and ethene in a high-pressure (chemical ionization) source. Interfacing the high-pressure source to a tandem mass spectrometer, we were able to study the product ion by obtaining CAD spectrum.

The principal reactions of the putative $C_5H_5\overset{+}{N}CH_2CH_2$ are reversion to the pyridine radical cation, formation of protonated pyridine, and some charge stripping to give the doubly charged version of the distonic ion. Replacing pyridine with C_5D_5N gave a new ion which, when activated, gave return to not only $C_5D_5N^+\cdot$ but also $C_5D_5HN^+\cdot$, $C_5D_3H_2N^+\cdot$, etc. This isotopic "scrambling" is strong evidence that a covalently bonded species had formed.

Although a tandem mass spectrometer outfitted with a high-pressure source is appropriate for demonstrating that the alleged distonic ion can be prepared in the gas phase, it suffers two major drawbacks in a program to characterize the ion in question. The first is that the origin of the ion cannot be easily determined. Is it the C_2H_4 or the C_5H_5N radical cation? The second is that sequential reactions of the adduct ion are difficult to conduct because the residence time of the ions in a CI source is short. Thus, a trapping technique is motivated.

Fourier transform mass spectrometry is one possibility, but the low pressure of FTMS will not support formation of the pyridine/ethene adduct. The energy released as bonding occurs between the two reactants sometimes causes the adduct to revert to starting materials or to produce fragments of the adduct. Although no adduct is seen under normal conditions (i.e., 10^{-6} torr) of FTMS, evidence could be obtained that a short-lived adduct is forming because isotopic exchange occurs, and $C_5D_5N^+\cdot$ becomes $C_5D_4HN^+\cdot$.

To solve problems of this type, an FT mass spectrometer must be modified to operate momentarily as a high-pressure trap. In that way, not only can the advantages of high pressure sources or traps be imported to FTMS but also the usual feature of FTMS (e.g., ion trapping, high resolving power, exact mass measurement, nondestructive detection, and multichannel detection) can be utilized in ion chemistry studies.

D. Rempel [6] recently solved this problem by designing and implementing a high pressure ("ion trap") event for the FTMS event sequence. This strategy allows one to switch rapidly from the usual Penning trap mode of FTMS to the Paul (quistor or quadrupole ion trap) mode so that collisional stabilization of product ions can occur. Following that, the Penning mode can be reestablished for double resonance, collisional activation, or mass analysis. A series of Penning-Paul-Penning sequences can be stitched together so that collisionally stabilized adducts formed in the first Paul mode can be subsequently reacted in a second Paul mode.

When the pyridine radical cation is allowed to react in the presence of ethene during the high-pressure Paul mode, the adduct $C_5H_5\overset{+}{N}CH_2CH_2\bullet$ can be prepared in high yield. The only other product of any significance is protonated pyridine. No adduct is seen if all conditions remain the same except the ethene radical cation replaces the pyridine radical cation, confirming that the latter reacts with neutral ethene to give the pyridine/ethene adduct.

We are now in a position to examine the reactivity of the $C_5H_5\overset{+}{N}CH_2CH_2\bullet$ species. The putative distonic ion can be prepared in high yield and stored in the presence of neutral pyridine and ethene for periods of tens of seconds. The first neutral reagent that was tested was molecular oxygen, a stable diradical. The choice was motivated by the strong prospect that the adduct has an unpaired electron and should react readily with molecular oxygen.

The preferred means of conducting the reaction with oxygen is to add a second rf-only-mode event to follow the isolation of the pyridine/ethene adduct, a process that is readily conducted in the Penning (usual FTMS) mode. High yield of a species, possibly existing as $C_5H_5\overset{+}{N}CH_2CH_2OO\bullet$, was achieved. The reaction is consistent with the proposed β-distonic ion structure.

Semiempirical molecular orbital calculations (AM1) also support the β-distonic ion structure assignment. The ion's calculated heat of formation is 216 kcal whereas those of the conventional ethyl pyridine isomers are in the range of 230-235 kcal, demonstrating the inherent stability of the adduct ion. The calculations were carried out by Professor K. Fountain of N.E. Missouri State University.

Conditions were then worked out so that a survey of bimolecular reactivity could be rapidly conducted. The adduct ion was prepared in the Paul mode at a pressure of He of greater than 0.001 torr. After a return to the Penning mode, unwanted ions such as protonated pyridine were ejected. A return to the Paul mode was then implemented during which a pulse of a neutral reagent accompanies the helium pulse. Mass analysis in the Penning mode completed the event sequence.

Reactive neutrals include a set of molecules containing electron-deficient double bonds: methyl vinyl ether, methyl acrylate, and 1,3-butadiene. Adducts are formed for each neutral, and in some cases, the ethene moiety was replaced by the new olefin. Unreactive neutrals include ethene, propene, 1-butene, acetonitrile, and vinyl chloride. It also was not possible to abstract H from isobutane or a halogen from methylene chloride or methyl bromide. It appears that the distonic ion radical prefers to react with electron-deficient olefins, a preference that points to a nucleophilic nature for the radical ion.

In summary, the new capabilities for FTMS are well-suited for ion chemistry. Specifically, the high pressure mode can be used to prepare and the to react the β-distonic $C_5H_5\overset{+}{N}CH_2CH_2\bullet$. It now appears possible to establish the intrinsic reactivity of free radicals by using mass spectrometric methods to follow the chemistry of distonic ions.

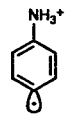
The Use of Distonic Ions to Study Free-Radical Reactions by Mass Spectrometry

Leonard J. Chyall, Rebecca L. Smith, Krista M. Stirk, and Hilkka I. Kenttämaa

Department of Chemistry, Purdue University, West Lafayette, IN 47907-1393

Distonic radical ions have spatially separated radical and charge sites which result in both ionic and radical-type reactions with neutral reagents. Recently, we have been interested in the ion-molecule chemistry of distonic ions which react preferentially at the radical center. The study of these ions offers the possibility of using mass spectrometry to model free-radical processes in the gas phase. In this study, a dual cell Fourier-transform ion cyclotron resonance mass spectrometer was used to examine the radical-type chemistry of two novel distonic ions: the methylene dimethylsulfonium ion (**1**); and the 4-dehydroanilinium ion (**2**).

1



2

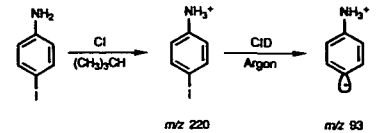
Ion **1** (*m/z* 76) was prepared in the source side of the dual cell instrument by a variety of ion-molecule reactions. The reaction between ionized ethylene oxide and dimethyl sulfide provides the most practical synthetic route to **1**.[1] The distonic structure of **1** was established by its reaction with added dimethyl disulfide; transfer of a thiomethyl group took place to give a product ion of *m/z* 123. Thiomethyl abstraction is typically observed when distonic ions react with dimethyl disulfide, while there are no examples of conventional radical cations which react in this manner.[2]

The reactivity of **1** with several types of neutral reagents which are known to be good radical traps was examined. It was found that alkyl iodides cleanly transfer an iodine atom to **1**. The efficiency of this reaction increases with increasing methyl substitution at the carbon of the C-I bond in the neutral reagent. For example, methyl iodide did not react with **1** while *tert*-butyl iodide underwent iodine atom transfer at 24% of the predicted collision rate. The efficiencies for abstraction of an iodine atom from ethyl iodide and isopropyl iodide fell between these two limits. These results are consistent with radical-type behavior for **1**.

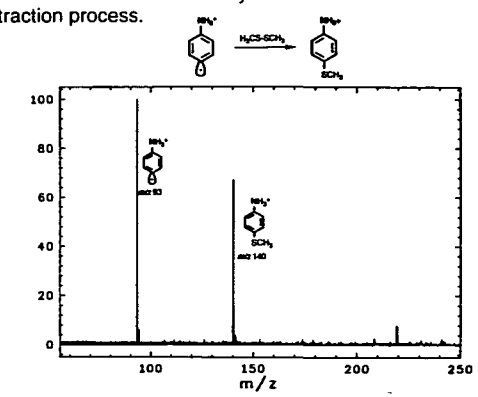
The ion-molecule reactions of **1** with hydrogen atom donors was also examined. Hydrogen atom transfer occurs when **1** is allowed to react with thiophenol and benzeneselenol, giving rise to the trimethylsulfonium ion. Reaction of **1** with 1,4-cyclohexadiene provided the trimethylsulfonium ion along with two other product ions which correspond to transfer of ionized methylene, and adduct formation with loss of a methyl radical. Similar products were also observed when **1** was allowed to react with 1,3-cyclohexadiene and cyclohexene. The products which correspond to adduct formation with loss of a methyl radical indicate that the charge site is participating in the reaction.

The proximity of the charge site to the radical site in **1** makes it difficult to determine the role the charge site plays in these reactions. This issue can be addressed by studying the

radical-type reactivity of distonic ions in which a neutral reagent can interact with either the charge site or the radical site, but not with both centers simultaneously. We have synthesized the 4-dehydroanilinium (**2**) which uses the inflexibility of the aromatic ring to inhibit the interaction between the two reactive sites of the molecule. The synthesis of **2** was accomplished by performing collision-induced dissociation (CID) on protonated 4-iodoaniline.



Ion **2** (*m/z* 93) abstracts a thiomethyl group from dimethyl disulfide and an iodine atom from isopropyl iodide. These two reactions clearly demonstrate that the charge site need not participate in the abstraction process.



In summary, we have shown that reagents which contain relatively weak bonds will undergo abstraction reactions with **1** and **2**. Ion **2** represents a novel class of distonic ions where the charge and radical sites are separated by a rigid carbon skeleton. The ion-molecule chemistry of these ions is a promising method to examine free-radical chemistry in the gas phase using mass spectrometry.

Electrospray LCMS Analysis of Ganefromycins

Mahender R.Alluri*, Guy T. Carter and Donald B. Borders,
American Cyanamid Company, Natural Products Discovery,
Lederle Laboratories, Pearl River, NY 10965.

INTRODUCTION: Ganefromycins (formerly designated LL-E19020 antibiotics) isolated from *Streptomyces lydicus* ssp. *tanzanius*, are a new family of elfamycin antibiotics. Ganefromycin α (1) shows very promising activity as a performance enhancement agent in livestock, while displaying an extremely narrow spectrum of antibacterial activity versus human pathogens including mainly *Streptococci* and several anaerobes. Owing to the thermal lability of ganefromycin, TSP-MS failed to give molecular ions as did EI and CI, and only FAB had been successful in the production of molecular ion species. Our preliminary experiments with electrospray ionization (ESI), however, have shown abundant $[M+Na]^+$ ions can be generated. ESIMS analysis of ganefromycins is fairly sensitive yielding useful spectra with 10 picomoles of sample. In addition to molecular ion species, fragment ions can be produced by varying the repeller voltage in the ESI (Vestec) source. In this report we will discuss the advantages of ESIMS analysis of the ganefromycins in comparison with TSP-MS and present an analysis of the ESI fragmentation.

EXPERIMENTAL: Mass spectra were recorded using a TSP-46 single quadrupole instrument (Finnigan-MAT, San Jose, CA) interfaced with a Vestec ESI source or Finnigan TSP source. ESI spectra were obtained in the positive ion mode whereas TSP spectra were obtained in both positive and negative ion mode. ESI-MS conditions were : electrospray needle voltage 2kV; flow rate 2 µl/min; mass range 200-1700 amu; 5 sec/scan; repeller voltage 20-60 V TSP-MS conditions jet 230 °C; vaporizer temperature 70-85 °C; repeller voltage 1KV; discharge ionization electrode voltage 1 kV; flow rate 1.2 ml/min; mass range 200-1300 amu; 2 sec/scan. The HPLC system consisted of a Waters 600-MS solvent delivery system and WISP 710B autosampler with 990-MS photodiode array detector. The ganefromycins were separated on a C-18 column (5µ, 150 mm x 3.9 mm). The mobile phase was a gradient of CH_3CN in 0.1M NH_4OAc (pH=6.5) buffer at a flow rate of 1.2 ml/min. The detection was by UV absorbance at 230 and 300 nm. Ganefromycins were isolated from culture broths in our laboratory. Samples (1 mg/ml) were dissolved in $CH_3CN/H_2O/HOAc$/0.1 % aq. NaCl (50/50/3/1) for ESI-MS analyses. An artificial mixture (2mg/ml each) of the 3 compounds was separated on the above HPLC system and the corresponding peaks were collected for ESI-MS analysis. The mixture (10 µl) was also subjected to TSP-LC/MS analysis.

RESULTS AND DISCUSSION: Ganefromycins showed abundant $[M+Na]^+$ ions by ESI-MS when the repeller voltage was held between 30-40 V. To achieve maximum sensitivity of 10 pmole as the minimum detectable amount, it was necessary to add Na^+. At higher repeller voltages, eg. 60 V, structure-specific fragment ions were also observed (Figs. 1 & 2). HPLC separation of ganefromycins α, γ and β-methyl ester is shown in Fig. 3. Collection and concentration of these peak fractions provided ample material for ESI-MS analysis. Although TSP-MS was unable to generate molecular ion species for the ganefromycins, the whole molecule was represented by fragment ions. Thus in the positive TSP spectrum, abundant ions derived from the trisaccharide moiety were observed, whereas the negative TSP spectrum contained abundant ions derived from the aglycone.

INTRODUCTION

Flavins are redox cofactors in many biological redox systems. Some of these compounds such as flavin-adenine dinucleotide (FAD) or flavin 5´-monophosphate (FMN) can not be submitted to GC/MS analysis due to their lability, high polarity and ionized phosphate moieties.
In this work we report on the analytical conditions for Riboflavine, FAD and FMN characterization by Thermospray (TSP) HPLC/MS and by Electrospray (ESP) MS. These techniques were applied to the characterization of a flavine-like compound detected by HPLC-Vis in extracts from Fe-depleted plants (*Beta vulgaris*). The HPLC fraction containing the unknown was shown to be a mixture of two compounds (X1 and X2) that were isolated and submitted to ESP and TSP analysis (1).

EXPERIMENTAL

Spectrometer: Finnigan TSQ 700 triple quadrupole mass spectrometer
Column: 5 µm (15x0.46 cm) Spherisorb ODS-2 (Phase Separations)
Eluents: A) a 0.05 M ammonium acetate in water (1% formic acid).
B) a 0.05 M ammonium acetate in water/methanol (1:1 v/v, 1% formic acid).
Gradient: From 5% to 40%B in 4 min. Then up to 60% B in 9 min.
Thermospray: Finnigan interface and source
Interface, source and manifold temps.: 105 °C, 250 °C and 70 °C respectively.
Acquisition rate: 0.5 scan/s.
Electrospray: Analytica of Branford interface
Sample flow rate: 1 ul/min. Drying nitrogen flow: 5 ml/min
Electrospray voltage: 3500 V (positive ions) and 2800 V (negative ions)
Scan range: 200-1000 amu; Scan rate: 2 sec.

RESULTS

ESP spectra of flavins afforded mainly molecular weight information with signals due to proton or sodium adducts. In the negative ion mode, FMN and FAD showed intense $[M-2H]^{-2}$ ions, due to the acidic phosphate moieties, that are an indication of the number of acidic places in these molecules. The best responses were obtained for FAD and FMN in the negative ion mode and Rfv in the positive ion mode. Only for FAD in the positive ion mode a molecular ion could not be observed (conc. 10 pmols/µl in MeOH).
TSP HPLC/MS analysis allows the characterization of flavins by means of common and intense fragment ions that contain the flavin ring (Figure 1). Signals corresponding to the $[AH_2]^+$ and $[BH_2]^+$ ions in the positive ion mode and to the A^- and B^- ions in the negative ion mode are observed in all cases. Other intense ions formed by loss of HPO_3 (FMN, fragment R) or to the adenine and

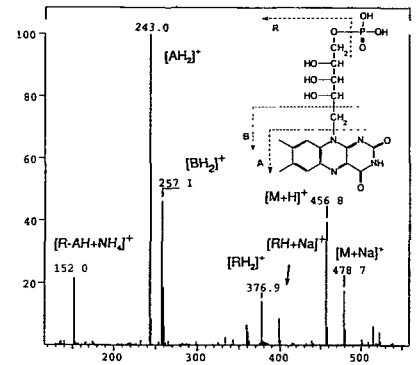

Fig. 1 Thermospray MS of FMN.

adenosine moieties (FAD) affords additional estructural information. Taking into consideration the $[M+H]^+$ and $[M-H]^-$ signals for Rfv and FMN and the $[AdenineH_2]^+$ and $[M-H]^-$ signal of FAD, response follows the order: FAD(+) > Rfv(+) > FMN(+) > Rfv (-) > FMN(-) > FAD(-).

When compounds X1 and X2 isolated from plant extracts were submitted to ESP analysis, both showed identical ESP mass spectra indicating the same molecular weight than FMN (456 u), but differing from the spectrum of the later by the absence of the $[M-2H]^-$ signal. In addition, ^{35}P-NMR indicated the absence of phosphor. These results suggested the presence of sulphur which was confirmed by ICP spectroscopy and tandem MS. Unequivocal characterization of the compounds was completed by H-NMR and shown to be two riboflavin derivatives not previously described in plants: riboflavin 3´-sulphate and riboflavin 5´-sulphate.

Tandem MS of the isobaric $[M-H]^-$ ions of FMN and the sulphate ester isomers (Figure 2) allows a) differenciation of phosphates and sulphates: ion at m/z 79 (PO_3^-), absent in sulphates; weak signal at m/z 80 (SO_3^-) in sulphates; b) differentiation of the position of esterification: Characteristic ions at m/z 139 (**g**) (5'- and 3'-esters) and at m/z 153 (**h**) (only 3'-esters) and intense signal at m/z 241 (**a**) (3'-esters).

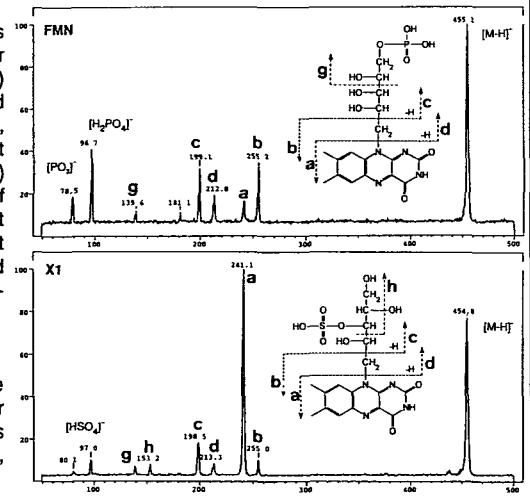

Fig. 2 Daughter ion spectra of the $[M-H]^-$ signal of FMN and riboflavine 3'-sulphate (X1).

Analysis of Vecuronium Bromide by Electrospray/Tandem Mass Spectrometry of Doubly-Charged Ions

Diane Rindgen[1], Jeevendra A. J. Martyn[2] and Paul Vouros[1], [1]Department of Chemistry and the Barnett Institute, Northeastern University, Boston, MA 02115, [2]Massachusetts General Hospital and Shriners Burns Institute, Boston, MA 02114

Vecuronium bromide is a monoquaternary ammonium steroid in clinical use as a muscle relaxant. The normal scan ESI spectrum of this compound shows a characteristic doubly-charged ion at *m/z* 279.4 as the base peak. This ion forms by loss of the bromide counter-ion and attachment of a proton. We have previously investigated the collision-induced dissociation behavior of this ion and have identified both doubly- and singly-charged fragment ions (1). Critical evaluation of these data indicates ion processes with potential analytical utility. For example, a singly-charged product ion at *m/z* 430.6 results from the combined loss of piperidine and an acetyl group. An analogous transition is observed for hexadeuteriated vecuronium bromide (*m/z* 282.4 ---> *m/z* 433.6). A transition involving formation of a singly-charged product ion from a doubly-charged precursor ion is highly selective in that the fragment ion being detected appears at a higher *m/z* value than the precursor ion. The selective nature of this type of transition can be advantageous when analyzing drugs in complex biological matrices. Toward that end, we have evaluated the suitability of the *m/z* 279.4 ---> *m/z* 430.6 transition for the quantitative determination of vecuronium bromide in plasma.

The MRM and normal scan ESI data were acquired on a VG Quattro triple quadrupole mass spectrometer equipped with a VG electrospray ionization source. The infusion solution consisted of a 50/50, by volume, mixture of HPLC grade acetonitrile/water with 1% glacial acetic acid and was continuously infused using an Isco uLC-500 Micropump operated at a flow rate of 2.5 - 3.0 uL/min. NF grade nitrogen was used as both the nebulizing and bath gas and the flow rates of each were optimized on the day of the analysis. Samples were analyzed in a flow injection mode using a Rheodyne injector equipped with either a 0.5 uL internal sampling loop or a 5 uL external loop. Vecuronium bromide was provided by Organon Laboratories, Ltd. and a standard stock solution was prepared in acetonitrile. Working solutions were made by dilution in the infusion solution. Bis-trideuterioacetyl (d_6) labeled vecuronium was prepared by acetylation of 3,17-deacetylvecuronium using d_6-acetic anhydride. Solid phase extractions were performed using Bond Elut C_1 cartridges from Varian Sample Preparation Products (Harbor City, CA).

Systematic studies were performed to evaluate the effect of different source and instrument parameters on the signal intensity of the *m/z* 279.4 ---> *m/z* 430.6 transition. The results of these studies indicate that the signal response for this transition optimizes at the following settings: source temperature = 60 °C; sampling cone voltage = 60 V; collision energy = 10 V; IE2 = 10 V. Examination of standard samples of vecuronium and the hexadeuteriated internal standard indicates that detection at physiologically significant levels can be realized (Figure 1).

The solid phase extraction procedure used for the isolation of vecuronium bromide and the internal standard, d_6-vecuronium, from plasma was similar to that described in reference 2 with changes made in the compositions of the eluting and reconstitution solutions. The analytes were eluted from Bond Elut C_1 columns as ion pairs using ammonium acetate in methanol. The optimal

concentration of the eluting solution was determined to be 50 mM. Extracts were reconstituted in a 0.01% trifluoroacetic acid/acetonitrile (by volume) solution prior to mass spectrometric analysis.

Preliminary studies of plasma samples show that the signal intensities from this transition are not consistent with those obtained from the pure samples. The recovery data suggest that signal loss may be due to co-extracted plasma constituents causing suppression of ion formation by charge competition or adsorption of the drug on residual matrix components. In either case, further sample cleanup is indicated.

The Application of Electrospray Ionization in the Analysis of Catecholamines by LC/MS

*Alexander B Schilling, The Hewlett Packard Company, Naperville, IL 60566

Introduction:

Catecholamines are a group of neurotransmitters of interest to workers in biology and medicine. Normally their analysis using liquid chromatography is accomplished with the use of electrochemical or fluorescence detectors because of the high sensitivity achievable (femtomole level) with these detectors Earlier work employing thermospray (TS) LC/MS has demonstrated detection limits on the order of a picomole for this class of compounds. The electrospray ionization (ESI) technique is believed to produce ions via the same ion evaporation mechanism postulated for TS, but with a higher efficiency. As a result, lower detection limits have been reported for a number of biologically active compounds than were possible by employing TS LC/MS. The chromatographic analysis of these compounds requires the use of ion-pairing agents such as octane sulfonic acid to improve the retention and separation of these polar compounds on reverse phase columns. In thermospray LC/MS the concern is that the usual ion pairing agents may lead to clogging of the vaporizer probe. In ESI the concern lies with the effect of buffer modifiers on the ability to form a spray and therefore the ionization process as well as whether any physical obstruction may occur. An earlier evaluation[1] of the compound pentadecafluorooctanoic acid (PDFOA) on thermospray found that it was a good substitute for the sulfonic acids in the analysis of catecholamines It would be of interest therefore, to investigate the effects of using PDFOA in the ESI analysis of these compounds.

Experimental

A mixture of catecholamines including dopamine, epinephrine, norepinephrine, and several metabolites were run on a HP 5989A LC/MS/DS with an Analytica electrospray interface. The source was equipped with a chromatography spray needle and operated under positive ion mode with the CapEx voltage at 90V and either in scan mode (80-220 amu) or SIM mode. A Supelco LC-18-DB column (2.1 x 250 mm 5 u particle) was used on a HP 1090L HPLC equipped with a diode array detector (280 nm) with an isocratic solvent system consisting of 77·23 (0.01 M NH_4Ac pH 4.0 with 0.01 M PDFOA 0.01M NH_4Ac in methanol with 0.05% formic acid and 0 01 M PDFOA) A flow rate of 0.4 mL/min was used and a column temperature of 40 C was maintained The injection volume was 3 uL. The column effluent was combined with a co-organic solvent flow of 0.4 mL consisting of either n-butanol:ACN, isopropanol, or methanol using a valco tee prior to entering an Accurate solvent splitter The splitter has the capability of providing either a 50·1 or 125:1 split ratio resulting in final flow rates of 16 or 6 4 uL/min respectively to the electrospray source

Results and Discussion·

The results indicate that ESI produces the same type of ions observed in the thermospray MS of these compounds In the absence of the ion-pair agent, ESI can exceed the detection limits of thermospray (1 pmole) by an order of magnitude or more (20-100 fmole). Under

[1] Schilling, A.B., The 40th ASMS Conference, Wsahington D.C. 1992

chromatographic conditions using the ion-pair reagent (PDFOA), the detection limit for these compounds is actually less than that of thermospray by almost an order of magnitude. This decrease may be due to a decrease in the efficiency of the spray or ionization process or by physical occlusion of the inlet capillary. The decrease occurs even if the co-organic solvent flow is varied from mixtures less likely to mix readily with the mobile phase (nBu·Acn) to those more likely to mix well (MeOH). Co-organic solvent addition generally facilitates spraying at higher flows in ESI by lowering the surface tension of the effluent and increasing droplet formation. It is unlikely that physical occlusion is occurring as it was possible to restore full sensitivity after discontinuing use of the ion-pair even after large lengths of time spent spraying the reagent into the source This suggests that PDFOA may yet have other applications in ESI as a discharge suppresser in negative ion mode or when trying to chromatograph these or other compounds requiring an ion pair in APCI work, where gas phase ionization predominates. PDFOA does produce an intense ion at 413 amu in the negative ion mode, so SIM mode may be necessary depending on the mass range required. Since only amine containing catecholamines are readily detected in positive ion mode, many deaminated metabolites possessing catechol functional groups that can be detected electrochemically are not amenable to this mode of ESI. It should be mentioned that others have demonstrated that the catecholamines can successfully be chromatographed without ion-pair reagents on the newer polymeric columns and this bypasses the problem of dealing with the ion-pairing agent altogether

Summary of Base Ions Detected for The Catecholamines in ESI vs TS LC/MS (Positive Ion Mode)

Compound	MW	Base Ion (TS)	Base Ion (ESI)
DOPA	197	198	198

Electrospray MS and MS/MS for Metabolite Identification in Various Animal and Human Biotransformation Studies

T.A. Gillespie, P.L. Bonate, J.D. Cornpropst, A.F. DeLong and L.A. Shipley
Eli Lilly and Company, Lilly Corporate Center, Indianapolis, IN 46285

LY246708/NNC 11-0232 (3 - [4- (hexyloxy) - 1,2,5 - thiadiazol - 3 - yl] - 1,2,5,6 - terahydro - 1- methylpyridine) is a potent and selective muscarinic M_1-agonist. It is currently undergoing clinical investigation for the symptomatic treatment of Alzheimer's disease. Early pharmacokinetic/balance studies conducted in rats and monkeys suggested extensive metabolism of parent compound. A biotransformation study was conducted in human volunteers using ^{14}C-labeled LY246708 at an oral dose of 75 mg (50µCi). The purpose of this work was to identify urinary and plasma metabolites of LY246708 (figure 1) in man.

Sample Preparation

Human urine was pooled (500 mL) from 0 - 24 hr, freeze-dried and reconstituted with 25 mL of MeOH/H_2O (50/50). The samples were then applied to a C18 SPE cartridge , washed and then eluted with MeOH. The urine samples were dried and reconstituted in 250 µL of MeOH/H_2O (50/50). Samples were then injected onto a YMC Basic column (25 cm x 0.46 m) and separated by using a gradient consisting of 20% MeOH/80% 50 mM NH_4OAc for 30 min, then to 100% MeOH over 75 min. Fractions were collected and dried. Human plasma samples were pooled (30 mL) from 1, 1.5, 2 and 4 hr time points. These samples were obtained from a nonradiolabled study conducted in man at an oral dose of 150 mg of LY246708. The plasma samples were applied to a CN/C18 combination SPE ("piggy-backed"), washed and eluted with methanol. The samples were then injected onto a Zorbax RX-C8 column (25 cm x 0.46 mm) and separated using 100% 50 mM NH_4OAC (pH5) for 15 min, followed by a gradient up to 100% MeOH over 60 min. The fractions were then collected and dried for analysis.

Experimental

All experiments were performed on a Finnigan MAT TSQ700 coupled with an Analytica of Branford ES source. The urine samples were injected (100 - 150 µL) onto a short YMC Basic column (5 cm x 0.46 mm) coupled to the ES interface. The isocratic system was ACN/0.2M acetic acid (50/50) at a flow of 1 mL/min. This was then split with a low dead volume tee for infusion into the ES source at 2.5 µL/min. The drying gas (N_2) was 30 mL/min @ 250°C. A voltage of approximately -4200 V was used for ionization. Mass spectral analysis was performed in centroid mode at 1 sec/scan. Plasma samples were direct infused (DI) at a rate of 2 µL/min after reconstitution with 200 µL of MeOH/1% acetic acid (50/50). The drying gas (N_2) for this analysis was 20 mL/min @ 250°C. A voltage of between -3500 to -3800 V was used. Analysis was performed in the profile mode at 1 sec/scan and averaged for 1 min. Daughter (product) ion spectra were obtained using a collision offset voltage of -20 eV and a collision pressure of 2.0 mTorr (argon).

Results and Discussion

Identification of the urinary metabolites of LY246708 in man was accomplished almost immediately after the completion of the ^{14}C-labeled study. The use of a short (5 cm) HPLC column provided sufficient separation, coupled with ES and MS/MS to give positive identification of 8 tentative metabolites of LY246708 in urine. This information confirmed that extensive first pass metabolism was occurring in humans. In addition, utilizing DI/ES, 8 tentative metabolites were identified in human plasma by MS/MS. The hexyl side chain appeared to be the major site of metabolism in that 7 of the 8 metabolites identified in the urine and plasma exhibited some form of oxidation to this side chain. Furthermore, the tetrahydropyridine ring also demonstrated biotransformation in 5 of the metabolites identified in urine and 4 identified in plasma. N-oxidation appeared to be the major metabolism route in the

case of this ring. The CID spectra of the N-oxide metabolites found in both urine and plasma exhibit a base peak at m/z 197 representing the loss of H_2O and subsequent loss of the side chain from the protonated molecular ion (figure 2). In addition, the peak at m/z 60 (addition of oxygen onto the peak a peak at m/z 44 observed for the parent CID spectrum representing the ion $[CH_3NHCH_2]^+$) was used to confirm the site of metabolism as occurring on the tetrahydropyridine ring. The N-oxide was further confirmed through the use of deuterium labeled exchange experiments performed with the ES interface. In addition, a glucuronide has been identified in human urine following oxidation of the side chain. The CID spectrum of the glucuronide metabolite shows a base peak at m/z 298 representing the characteristic loss of 176 daltons from the protonated molecular ion (figure 3). The site of hydroxylation on the side chain is unknown at this time. The thiadiazole nng appears to be metabolically inert in humans. The summary of identified metabolites for LY246708 is shown in figure 4.

Conclusions

ES can be successfully utilized for identification of a variety of metabolites in animal and human biological fluids. Coupled with MS/MS, ES can provide positive, rapid identification of metabolites when biological samples are sufficiently "clean". ES/MS/MS is an extremely valuable tool for the identification of conjugated metabolites found in a variety of biological fluids. Short column (5 cm) LC can be utilized to provide additional clean-up for identification of metabolites in "dirty" biological samples.

ELECTROSPRAY IONIZATION MASS SPECTROMETRY OF GLUTATHIONE AND N-ACETYLCYSTEINE CONJUGATES OF ELECTROPHILIC METABOLITES OF ACETAMINOPHEN

S. Oishi[1], G. E. Bronson[2], L. Baczynskyj[2], and W. J. Adams[2]
[1]Department of Medicinal Chemistry, University of Washington, Seattle WA 98195;
[2]Upjohn Laboratories, The Upjohn Company, Kalamazoo, MI 49001.

Acetaminophen (APAP) has previously been shown to be metabolically activated to form the reactive, electrophilic metabolites N-acetyl-p-benzoquinoneimine (NAPQI) and p-benzoquinone (BZQ) when administered *in vivo* [1]. Both NAPQI and BZQ readily undergo conjugation reactions with glutathione (GSH, γ-glutamylcysteinylglycine) to form glutathion-S-yl conjugates which can then be biotransformed to N-acetylcystein-S-yl (NAC) conjugates and excreted in the urine. The toxicity of APAP, which is observed when high doses of APAP are ingested, has been attributed to NAPQI. However, latent forms of NAPQI that are less powerful oxidizing agents have been proposed to account for the fact that high doses of APAP do not cause oxidant stress *in vivo*[2,3] (e.g., *ipso* GSH conjugate[3]). It has also been reported that the glutathion-S-yl conjugates of p-hydroquinone (HQ) are more nephrotoxic that BZQ itself[4]. These observations suggest that the glutathion-S-yl conjugates and perhaps the N-acetylcystein-S-yl conjugates of APAP may play a role in the toxicity of APAP. We report here an investigation of the *in vitro* reaction of BZQ and NAPQI with GSH or NAC under physiologically relevant conditions; and the utility of electrospray ionization mass spectrometry (ESIMS) for the detection of the GSH and NAC conjugates formed.

EXPERIMENTAL: Synthetic BZQ and NAPQI were added dropwise to a molar excess of GSH or NAC in phosphate buffered saline (pH 7.4) at 37°C under both argon and air at two different concentrations of GSH and NAC (2 mM and 100 mM). Samples were periodically withdrawn from the reaction mixtures and quenched by lowering their pH to ≤ 3.5 by addition of 0.25 M HCl before storage at -20°C. The quenched reaction mixtures were chromatographed on a reversed-phase HPLC column (Vydac C_{18}, 330 A, 4.6 mm i.d. x 25 cm) using water/methanol/acetic acid mobile phases and either isocratic or linear gradient conditions. Column eluate was monitored with a UV detector (254 nm). Chromatographic fractions were collected for direct introduction into the mass spectrometer; or were lyophilized and redissolved in water/methanol/acetic acid solutions before introduction into the mass spectrometer. ESI mass spectra were recorded using a Vestec 201A mass spectrometer equipped with a Vestec ESI source and a Teknivent Vector II data system.

RESULTS AND DISCUSSION: Chromatographic analysis of quenched reaction mixtures indicated that the reaction of BZQ and NAPQI with GSH or NAC under anaerobic or aerobic conditions resulted in the formation of multiple products (e.g., see Figure 1). ESIMS characterization of these products demonstrated that the mono- and di-glutathion-S-yl-hydroquinone conjugates and the mono-, di- and tri-N-acetylcystein-S-yl-hydroquinone conjugates (e.g., see Figure 2) were formed following reaction of GSH or NAC with BZQ; and that the mono- and di-N-acetylcystein-S-yl-acetaminophen conjugates were formed following reaction of NAC with NAPQI. Although we were not able to confirm by ESIMS that the di-glutathion-S-yl-acetaminophen conjugate was formed because of the limited availability of NAPQI (only limited experiments at GSH concentrations of 2 mM were done), it seems probable that the di-glutathion-S-yl-acetaminophen conjugate was formed based on evaluation of the chromatographic data. Differences clearly exist in the reactivity of BZQ and NAPQI under

physiologically relevant conditions. BZQ reacts almost exclusively with GSH and NAC *via* a Michael addition reaction, whereas NAPQI is extensively reduced to APAP in addition to reacting *via* a Michael addition reaction. Since the more highly substituted conjugates were formed under anaerobic conditions in the presence of BZQ or NAPQI and excess nucleophile, it follows that the oxidation potentials of the mono- and di-substituted hydroquinone conjugates and the mono-substituted acetaminophen conjugate are lower than those of p-hydroquinone and acetaminophen, respectively. Comparison of chromatograms of mixtures incubated under anaerobic and aerobic conditions (e.g., compare Figures 1A and 1B) indicated that the glutathion-S-yl- and N-acetylcystein-S-yl-hydroquinone conjugates are susceptible to oxidation by molecular oxygen to reactive quinones, but that the corresponding acetaminophen conjugates are not susceptible to oxidation by molecular oxygen to reactive quinone imines. The results of this study suggest that protein cysteinyl thiols adducted *in vivo* by reaction with BZQ or NAPQI are susceptible to chemical oxidation to the corresponding quinone and quinone imines, respectively, and subsequent protein crosslinking reactions, which may be of toxicologic significance. The utility of ESIMS for the detection of the GSH and NAC conjugates of p-hydroquinone and acetaminophen was demonstrated by this research.

Introduction

The major clinical application of tamoxifen [*trans*-1-(4-[2-dimethylamino)ethoxy]phenyl)-1,2-diphenylbut-1-ene] [1] is in the treatment of breast carcinoma. It is an antiestrogen and inhibits tumor growth by competitively antagonizing the binding of estradiol to estrogen receptors. When the drug is given orally to the patient, it is extensively metabolized. The metabolic profile of tamoxifen in female patients is well documented [see review 2]. In plasma, *N*-desmethyltamoxifen (metabolite X) is the major metabolite; 4-hydroxytamoxifen (metabolite B) is a minor metabolite; *N*-didesmethyl-tamoxifen (metabolite Z) is present in serum when the patients are receiving long term tamoxifen treatment; 4-hydroxy-N-desmethyltamoxifen (metabolite BX) and metabolite B are excreted as conjugates in bile and urine; and finally, metabolite D [3,4-dihydroxytamoxifen] has been tentatively reported in human bile and faeces of animals. In the previous studies, determination of these metabolites relies on off-line liquid chromatographic (LC) separation with mass spectrometric (MS) detection, or LC separation with fluorescence detection, or GC/MS with sample derivatization before the analysis. This study has demonstrated that tamoxifen and its analogues can be easily analyzed in the biological fluid by on-line LC/MS using a pneumatically assisted electrospray interface.

Experimental

Plasma and urine samples were collected from patients who had been given a single dose of tamoxifen. Phase I metabolites were extracted with hexane (containing 2% butanol) and Phase II metabolites were purified using solid phase cartridge. The extracts were applied to a microbore HPLC system using a Suplex pKb-100 column (250 x 1mm) and a linear gradient elution from 20% acetonitrile : 80% buffer to 100% acetonitrile in 20 min at 0.2 ml/min. Identification of the metabolites are achieved by LC/ESI/MS on a Sciex API III triple quadrupole mass spectrometer. Tandem mass spectrometry was performed to provide structural information.

Results

In the plasma sample, the parent drug was detected ($[M+H]^+$ at m/z 372), *N*-desmethyltamoxifen ($[M+H]^+$ at m/z 358) is the major metabolite and tamoxifen *N*-oxide [$(M+H]^+$ at m/z 388) is present in trace amount [Fig. 1 a-c].

In the urine extracts, four glucuronide conjugates of tamoxifen analogues were obtained. These include the glucuronide conjugates of 4-hydroxy-tamoxifen [Fig. 1d], two *N*-desmethyl-hydroxylated tamoxifen and a dihydroxy-tamoxifen.

Conclusion

Glucuronide conjugation is a principle metabolic pathway of tamoxifen. This report describes for the first time direct analysis of tamoxifen metabolites in human urine and plasma samples, the isolation of tamoxifen *N*-oxide in human and the identification of conjugated metabolites as their intact molecules. Some of these metabolites (as aglycone) could make important contributions to the biological actions of tamoxifen in patients.

DETERMINATION OF ANTIBIOTICS USING ULTRASONIC NEBULIZATION ELECTROSPRAY MASS SPECTROMETRY

Robert D. Voyksner, Markus Linder and Rolf Straub,
Analytical and Chemical Sciences, Research Triangle Institute,
P. O. Box 12194, Research Triangle Park, NC 27709

INTRODUCTION

A number of veterinary drugs (β-lactams) are frequently used to prevent infections. These drug residues can contaminate meat and milk products destined for human consumption. In order to insure human food safety, new methods using HPLC/ES-MS were evaluated to monitor these antibiotics. These methods must handle large numbers of samples (fast) and provide the sensitivity and specificity to identify the antibiotics at ppb levels.

Typically the speed of the HPLC/MS analysis has been limited by HPLC retention times. However, the development of perfusion HPLC provides a tremendous speed advantage over conventional packed columns. Unlike conventional packing material, perfusion packing enables transport of molecules through the pores of the packing material. Now flow rates can be increased without large back pressure and diffusional flow can be minimized resulting in high chromatographic resolutions together with short retention times. These higher flow rates (50 μL/min) can be handled by the electrospray interface using a capillary shield to assist in desolvation and ultrasonic nebulization to assist in the initial droplet formation.

This paper presents the development of a perfusion LC/electrospray MS method for β-lactams. Emphasis will be placed on parameters that affect LC resolution and ES sensitivity.

EXPERIMENTAL

Separations were performed on Poros II LC Packing Perfusion column 0.32 x 150 mm, 7-8 μm particles, 4000Å porous. The mobile phase was a gradient from 100% water to 40-60% acetonitrile in water in 4 or 5 minutes. Buffers including formic acid (FOA), heptafluorobutyric acid (HFBA) and trifluoracetic acid (TFA) were added to the mobile phase at 0.1-1% levels up to 25 mM for HFBA). The flow rates for the separation were 40-50 μL/min and injection volume was 0.5 μL.

The electrospray MS system was a HP5989 equipped with a HP electrospray interface with an ultrasound nebulizer (Analytica of Branford). The MS was scanned from 180-550 daltons in 1 s or SIM was used to improve scan speed (necessary for perfusion chromatography due to the 2-4 s peak widths) and sensitivity. For SIM operation the $[M+H]^+$ ion for each β-lactam was monitored for 50 or 100 ms to improve the cycle time to 0.3-0.6 s.

RESULTS AND DISCUSSION

The separation of the β-lactams by perfusion LC was evaluated in six different buffer systems. The ion chromatograms for the $[M+H]^+$ ions for the β-lactams in each mobile phase are presented to evaluate perfusion column resolution and electrospray sensitivity. The optimal solvent for electrospray sensitivity (FOA) was the least desirable for the LC separation of the individual β-lactams. The use of TFA (0.1%) provided slight improvement

in the separation but electrospray responses were from a factor of 4 (cetiofur) to 10 (penicillin G) lower than with formic acid. The addition of HFBA to the formic acid solution as an ion pair reagent improved the separation as the molarity of this reagent was increased from 0.5 mM to 25 mM. On the other hand, the electrospray signal decreased as the molarity of HFBA increased. The mobile phase employing 0.5% FOA and 5 mM HFBA resulted in the best compromise between sensitivity and chromatographic separation.

The electrospray mass spectra recorded for each β-lactam exhibited intense $[M+H]^+$ ions and several key fragment ions necessary for confirmation, at a capillary voltage of 120 V. The on-line LC/MS detection limits for the β-lactams studied ranged form about 30 ng to 200 pg. Cetiofur exhibited the best detection limits (200 pg) followed by cephapirin (600 pg), ampicillin (2 ng), penicillin G (10 ng) and cloxacillin (35 ng). The response of cetiofur and cephapilin was linear over the concentration range of 1-300 ng.

Ultrasonic nebulization aided in handling the higher flow rates, high aqueous mobile phase and buffers such as TFA and HFBA used in the separation of β-lactams. The ultrasonic nebulizer permitted perfusion LC separation at optimal flow rates of 50-60 μL/min. This flow rate resulted in less than 20% loss in signal intensity relative to the electrospray flow rates of 3-5 μL/min. Also, β-lactams eluting at greater than 80% water containing buffers such as 0.1% TFA or 25 mM HFBA could be effectively ionized without significant signal suppression or spike noise. For example, the relative response for cetiofur using ultrasonic vs conventional electrospray needle nebulization is presented in Table 1. The relative response for cetiofur is nearly constant using ultrasonic nebulization while the response using the conventional electrospray needle assembly ranged from 16% to 73% of the ultrasonic generated signal.

CONCLUSIONS

Perfusion LC/electrospray-MS offers the potential to separate and confirm target β-lactams in less than five minutes. The development of the perfusion LC/electrospray-MS conditions resulted in compromises in chromatography and electrospray-MS operation. Some of these compromises such as higher flow rates, high aqueous content and the presence of higher molarity of buffer were minimized by the use of ultrasonic nebulization.

DETERMINATION OF CYSTEINYL LEUKOTRIENES USING ELECTROSPRAY/TANDEM MASS SPECTROMETRY

Ralph Orkiszewski, Ulla Justesen, Hartmut Jaeschke* and Simon J. Gaskell
Center for Experimental Therapeutics, Baylor College of Medicine, Houston, TX 77030, and * Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001

We have previously reported[1] the use of [^{13}C]-isotope dilution and a GC/MS-based procedure (based on the method reported by Balazy and Murphy[2]) for the determination of cysteinyl-leukotrienes (LTC_4 and N-acetyl LTE_4) in rat bile. The procedure involves addition of [$^{13}C_4$]-internal standards (prepared in this laboratory[3]), fractionation of bile by reverse-phase HPLC, and hydrogenation to yield 5-hydroxyeicosanoic acid from each of the cysteinyl leukotrienes. (This approach accordingly requires efficient separation of individual leukotrienes prior to hydrogenation.) The product is converted to the pentafluorobenzyl ester, trimethylsilyl ether for GC-negative ion MS analysis with selected ion monitoring. This method has been applied to the study of endotoxin-induced cysteinyl-leukotriene production in vivo.[1,4] The biliary excretion of LTC_4 and N-acetyl LTE_4 was increased by 190 and 1000%, respectively, following administration of *Salmonella enteritidis* endotoxin. Studies involving the depletion or augmentation of serum complement indicated that complement mediates endotoxin-induced cysteinyl leukotriene formation.[4] In the present work, we have made further use of the GC/MS procedure to compare biliary leukotriene excretion in the rat following administration of endotoxin from two different sources, *S. enteritidis* and *E. coli*. Figure 1 shows the biliary concentrations of N-acetyl LTE_4 as a function of time. In agreement with previous studies,[1,4] administration of *S. enteritidis* endotoxin resulted in a marked elevation of biliary N-acetyl LTE_4. Endotoxin derived from *E. coli*, however, was without effect.

The complexity of the GC/MS-based procedure and the reliance on chromatographic separation for the differentiation of individual cysteinyl leukotrienes has encouraged further effort on the mass spectrometric detection of the intact analytes. In earlier studies,[1] FAB/tandem MS was used to confirm the presence of LTC_4 in rat bile. Additional HPLC fractionation was required before MS analysis, however, and the sensitivity of detection achieved was modest. We have therefore investigated the analysis of cysteinyl-leukotrienes using electrospray MS. Electrospray ionization yielded predominantly singly charged ions; both $[M+H]^+$ and $[M+Na]^+$ ions were observed, with N-acetyl LTE_4 showing a substantially greater propensity than LTC_4 for formation of the sodiated ion. Selected ion monitoring (SIM) analyses (with loop injection of authentic analyte) gave a detection limit for LTC_4 of approximately 100 pg, by monitoring of $[M+H]^+$ ions. This detectability is comparable to that observed in our previous work[1] using continuous-flow FAB; in our hands, however, electrospray MS is a substantially more robust method. Electrospray MS/SIM of N-acetyl LTE_4 $[M+Na]^+$ ions gave a detection limit of approximately 300 pg. Low energy CAD of LTC_4 $[M+H]^+$ yielded m/z 308 (protonated glutathione) as the most prominent product ion; selected reaction monitoring analyses for this fragmentation gave a detection limit of ca. 5 ng. Figure 2 shows a packed capillary LC-electrospray MS analysis of authentic N-acetyl LTE_4, with SIM of both $[M+H]^+$ and $[M+Na]^+$ ions. Satisfactory chromatography is observed and the sensitivity is sufficient to detect the leukotriene in amounts corresponding to those expected in extracts of bile following *S. enteritidis* endotoxin administration. Analyses of bile extracts (obtained by reverse-phase HPLC fractionation) by LC-electrospray MS/SIM, however, were disappointing, the response to the leukotriene components being masked or suppressed by other extract constituents. It is clear that further development of the procedure requires improved complementarity between the initial bile fractionation procedure and the chromatographic separation achieved during LC-MS.

Structure Elucidation of Taxanes by ESI-MS and ESI-MS/MS

Francis Bitsch, John Kim, and C.H.L. Shackleton
Children's Hospital Oakland Research Institute, Oakland, CA 94609, USA
Wenwen Ma and Matthew Nieder
ESCAgenetics Corps, San Carlos, CA 94070, USA

Introduction

Taxol, a natural component extracted from the bark of the yew tree (*Taxus* species) has been shown to be an efficient antitumor agent especially in the treatment of ovarian, breast and skin cancer. Until recently, most taxol was obtained by extraction of the bark of the pacific yew tree, *Taxus brevifolia* but the supply is limited because this species is neither abundant nor fast growing. Only about 100mg is obtained from 1kg of dry yew tree bark so it takes approximately three trees to provide enough taxol to treat one patient.

Different sources of taxol were therefore explored. Our studies (ESCAgenetics) have demonstrated the biosynthesis of taxol and taxanes by *Taxus* species cell cultures.

Mass spectrometry of taxol using EI, CI, FAB, electrospray ionization and thermospray ionization has previously been reported. We were interested in the structural characterization of taxanes using microbore HPLC and electrospray ionization mass spectrometry. Collision activated decomposition in the atmosphere-vacuum interface and CID MS/MS were used for the structure elucidation of taxanes with various C-13 side chains.

Results

We were able to detect protonated molecule ions of taxanes at the level of 10 ng in full scan MS and 200 pg using Selective Ion Recording.

Collision Activated Decompositions (CAD) in the atmosphere vacuum interface yielded specific fragments. The fragments observed under low collision energy conditions are similar to those observed in CID MS/MS (**Figure 1**). The main fragmentation occurs at the bond between the taxane ring and the side chain (C-13) and the fragmentation yield at this position is particularly great in the case of 10-deacetyl taxanes.

The fragments observed by CAD in the electrospray interface were used as markers for the location of taxanes in cell culture extracts.

Structure modifications in the side chain are frequently observed among cell culture produced taxanes. We were able to partially elucidate the structure of the side chain of various known and new taxanes by CID tandem mass spectrometry of the side chain fragment obtained by collisional activation in the ES source.

Effectiveness of this technique is demonstated using the well-known taxane compounds cephalomannine and taxol (**Figure 2**).

METABOLISM OF SUBSTANCE P BY *IN VIVO* MICRODIALYSIS AND LC/ESI/MS

P.E. Andrén, M.R. Emmett, B.B. DaGue and R.M Caprioli
The Analytical Chemistry Center and Department of Biochemistry
The University of Texas Medical School, Houston, Texas 77030

INTRODUCTION

Neuropeptides constitute a large and still growing group of putative neurotransmitters or neuromodulators in the nervous system. Little is known about their metabolism and inactivation *in vivo*, although many investigations have been done by *in vitro* techniques. The present studies focus on intracerebral metabolism of exogenous substance P (SP), an eleven amino acid peptide, using microdialysis and nanoscale liquid chromatography electrospray ionization mass spectrometry (LC/ESI/MS).

METHODS AND MATERIAL

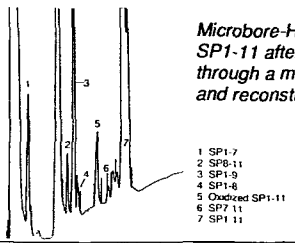
Rats (Sprague-Dawley, 250-400 g) were anesthetized with an intraperitoneal injection of pentobarbital 45 mg/kg and a microdialysis probe (CMA/10, 4 mm membrane length) was stereotaxically implanted into the striatum. The probe was perfused at a flow rate of 0.3 μL/min with artificial cerebrospinal fluid (5 mM KCl, 120 mM NaCl, 1.2 mM $MgCl_2$, 1.8 mM $CaCl_2$, 0.15% phosphate buffered saline, pH 7.4). Two hours after probe implantation, a 1, 10, 25 or 50 μM solution of SP in artificial CSF was introduced into the microdialysis probe and infused for several hours. The microdialysis probe was used to both introduce SP1-11 into the brain, as well as collect proteolytic fragments produced by enzymic hydrolysis.

Nanoscale-LC/ESI/MS The recovered dialysis samples were loaded into a 10 μL loop on a 10-port injection valve and injected onto a fused silica capillary column (50 μm i.d. x 10 cm packed with 10 μm spherical C-18 particles) using a syringe pump at 5 μL/min. After washing with 5% methanol/0.25% acetic acid, the peptides were eluted with 50% methanol/0.25% acetic acid at about 800 nl/min in a one-step elution program. The spray nozzle of the ESI source (Vestec Corp) was a fused silica capillary (50 μm i.d. x 280 μm o.d.) which had the tip modified by HF treatment to form a cone about 75 μm o.d. in order to increase the sensitivity (for further technical details, see Emmett and Caprioli). The mass spectrometer (Finnigan TSQ70) was scanned from 200-1000 Da in 4 sec. All data were acquired in the profile mode.

Microbore-HPLC. In addition to nanoscale-LC/ESI/MS, the dialysate of two hours infusion of SP1-11 (1 μM) into the striatum were collected and analyzed and fractionated using microbore-HPLC. Fractions were lyophilized and then analyzed by direct infusion using ESI/MS.

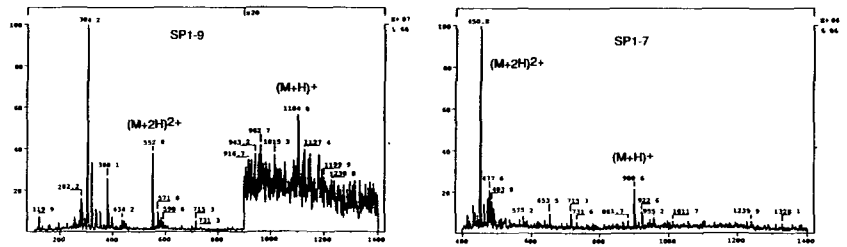
RESULTS

A: IDENTIFICATION OF SP-FRAGMENTS PRODUCED IN VIVO

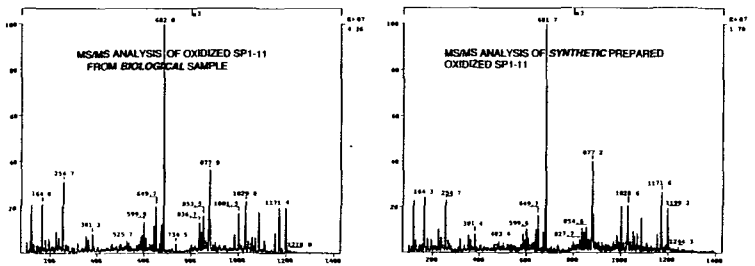


Microbore-HPLC of degradation products (SP fragments), derived from SP1-11 after a two hours infusion of 1 uM SP1-11 into the striatum through a microdialysis probe. Fractions were collected and lyophilized and reconstituted in 4 uL H_2O and analyzed by ESI/MS.

Electrospray mass spectra of SP fragments produced in vivo.



B. FORMATION OF OXIDIZED SP1-11 IN VIVO



CONCLUSIONS

1. The coupling of high performance fused-silica LC nano-columns with micro-ESI/MS in this study takes advantage of the similar liquid flow requirements of each system, to provide a sensitive and highly specific analytical system.
2. The present data show that *in vivo* microdialysis can be used to study protease activity, and that several SP fragments were identified after exogenous infusion of SP at low *concentrations*.
3. Both N- and C-terminal fragments with partly overlapping sequences were found in the present study, showing the complexity of SP-degradation. The SP-metabolites formed were N-terminal fragments SP1-9, SP1-8, SP1-7 and C-terminal fragments SP5-11, SP6-11, SP7-11, SP8-11 and oxidized SP (SP-O). When deuterated SP, [D_8-phe^8]SP, was infused into the striatum, the corresponding metabolites were formed.
4. The combination of microdialysis and LC/ESI/MS can be used to provide direct monitoring of aqueous biological samples, including *in vivo* intracerebral analysis. Our future plans to further characterize the proteases involved in SP-degradation include the use of several specific enzyme inhibitors.

MONITORING IN-VITRO ENZYMATIC REACTIONS USING AN INTEGRATED MICRODIALYSIS/IONSPRAY TANDEM MASS SPECTROMETRY SYSTEM

Edward H. Kerns, Steven E. Klohr, Kevin J. Volk, and Mike S. Lee
Bristol-Myers Squibb Pharmaceutical Research Institute
Wallingford, Connecticut 06492

Microdialysis is an effective sampling method for obtaining nanogram quantities of analyte from biological systems with a minimum of disruption of the system (1-5). Applications of microdialysis include the intra-cerebral sampling of neurotransmitters, the on-line analysis of drugs in the blood of living systems and the sampling of reaction mixtures. Previous reports have discussed fundamental studies of on-line systems combining microdialysis sampling with mass spectrometers via a continuous flow FAB ion source (3-5), a thermospray ion source (6) and an ionspray ion source (7). Methods of coupling microdialysis sampling probes with ionspray tandem mass spectrometers and applications of this system for monitoring dynamic *in-vitro* biochemical systems have been further investigated using model compounds (buspirone, angiotensin I, and biotin methyl ester). This approach utilizes the mass spectrometer to provide structural and quantitative information for dynamic *in-vitro* biochemical systems in real time.

Microdialysis was performed using model CMA/12 microdialysis probes (20 kD cutoff) and a CMA/100 syringe pump (Bioanalytical Systems). A Sciex API III triple quadrupole mass spectrometer was used with an ionspray interface operated in the positive ion mode. Dialysis fluid was acetic acid (0.05%) for peptide cleavage and buspirone metabolism studies, and 2 mM ammonium acetate (pH 6 9) for avidin binding studies Peptidase reactions were carried out with Carboxypeptidase Y and Angiotensin I (40 ng/µL) with a final volume of 200 µL. Liver metabolism studies utilized approximately 0.1 g of minced rat liver (Hilltop) incubated with 5 µg of buspirone in a 300 µL volume of 2 mM ammonium acetate for approximately 6 hr prior to direct analysis by microdialysis Protein binding studies utilized Avidin, biotin methyl ester (BME), and biocytin (BC). Reactions were caried out at 37 C in a 0.5 mL conical Reactivial (modified to 200 µL) equipped with a stirring bar. Constant stirring provides sample mixing and eliminates dialysis gradient formation in the solution. The vial was placed in a block heater/stirrer for temperature control and mixing The microdialysis probe was coupled directly to the ionspray interface vial a zero dead volume coupling.

Results using these model systems were as follows: Rapid Carboxypeptidase Y cleavage of angiotensin I was monitored using microdialysis/MS. The reaction proceeded rapidly up to residue 4 (proline). The appearance and degradation of each peptide was independently observed, indicating the use of this system for monitoring biochemical reaction products and kinetics. Metabolites of buspirone with a mass 16 Daltons greater than buspirone were observed after incubation of buspirone with liver preparation. One metabolite was determined to be hydroxylated on the pyrimidine ring and the other was determined to be hydroxylated on the azaspirone ring using MS/MS substructural analysis on line with microdialysis sampling. These metabolic products are consistent with previously characterized metabolites of buspirone, indicating the use of this system for monitoring *in-vitro* tissue activity. The binding of biotin methyl ester to avidin was very rapid, as indicated by an immediate quantitative decrease in free BME ligand concentration in the supernatant monitored by microdialysis. The bound avidin-BME complex was excluded from the dialysate by the dialysis membrane, thus providing a differentiation between free and bound components. Competitive binding studies, in which biocytin was added to avidin-BME complex indicated that BME was not competitively released by BC at concentrations twice the BME concentration. Thus, protein-ligand binding may be monitored using microdialysis on-line with mass spectrometry.

The microdialysis membrane permits higher molecular weight components to be excluded from the sample going to the mass spectrometer Thus, only free reactants, products and ligands are monitored and the concentration of protein in the dynamic reacting system is undisturbed. Using this approach biochemical reactions can be monitored and structural information can be obtained in real time without the need for sample storage, time consuming HPLC separations and sample degradation. Thus, the combined MD/MS/MS system may be used for studying in-vitro tissue reactions, enzymatic reactions and protein binding.

Metabolism of Hexamethylene Diisocyanate (HDI) in the Rat Utilizing Ionspray LC-MS/MS Techniques.

*K.M. Brandt, M.R. Davis and T.A. Baillie

Department of Medicinal Chemistry, School of Pharmacy,
University of Washington, Seattle, WA 98195

1,6-Hexamethylene diisocyanate (HDI) is used as an electrophilic crosslinking agent in the plastics industry. Normally, glutathione (GSH) captures electrophilic xenobiotics to form *S*-linked conjugates which are excreted into bile. However, it has been shown recently with methyl isocyanate (MIC) that conjugation with GSH is reversible under physiological conditions and it has been proposed, therefore, that GSH may serve as a "carrier" of this toxic isocyanate *in vivo*. The focus of the present study was to determine if conjugation with GSH is involved in the metabolism of HDI in the rat.

Ionspray LC-MS/MS techniques were developed using a Perkin-Elmer Sciex API III triple quadrupole mass spectrometer to detect and quantify both the GSH conjugates and the subsequently formed *N*-acetylcysteine (NAC) conjugates of HDI in bile and urine, respectively, of rats dosed with HDI. GSH conjugates were analyzed by constant neutral loss scanning (loss of 129 Da, derived from cleavage of the γ-glutamyl moiety) while NAC conjugates were analyzed by parent ion scanning of *m/z* 143 (protonated 6-aminohexylisocyanate).

Experimental:

Bile from rats given an i.p. dose of HDI (60 μmol) was collected over ascorbic acid for 4 h after dosing and was filtered before analysis. Urine from rats dosed with HDI (60 μmol for the qualitative study and 20 μmol for the quantitative study) was collected over ascorbic acid for 4 h and 24 h after dosing for the qualitative and quantitative experiments, respectively. Urine samples were filtered prior to analysis. Biological samples were analyzed by ionspray LC-MS/MS with Ar as the collision gas.

Results and Discussion:

Figure 1 shows the reconstructed LC-MS/MS chromatograms of the synthetic NAC-HDI conjugates, while Figure 2 shows the reconstructed LC-MS/MS chromatograms obtained from urine of HDI-dosed rats. The quantitative analysis revealed the presence of the NAC conjugates of HDI in urine (1.3 ± 0.9% of dose), but not of the corresponding GSH conjugates in bile. Control experiments indicated that the GSH-HDI adducts are unstable in bile, and decompose to the corresponding diamine, 1,6-hexamethylenediamine. Although the results of this study suggest that conjugation with GSH is not a quantitatively important metabolic pathway of HDI in the rat, this study nevertheless demonstrates the operation of such a process *in vivo*, and raises the possibility that reactive, carbamoylating GSH conjugates of HDI may mediate the toxic effects of this important industrial chemical.

Identification and Quantitation of Metabolites of a Novel Nonbenzodiazepine Anxiolytic Compound (CL 273,547) by Thermospray LC/MS in Tandem with ^{14}C Detection and an Off-Line Stable Isotope Recognition Computer Program.

Elizabeth Graham*, D. Cosulich, W. DeMaio, J. Ashraf, G. Morton, I. Zagloul;
American Cyanamid, Metabolism Reseach and Radioisotope Synthesis Dept.
Medical Research Division, Pearl River , NY 10965

Anxiolytic, CL 273,547, a nonsedative, nonbenzodiazepine, is being developed as an anxiolytic agent. This work was performed to elucidate the structures of CL 273,547 metabolites (Figure 1), and to compare human and dog *in vivo* metabolism. CL 273,547 metabolites were isolated from the urine of dogs dosed orally 50 mg/kg (specific activity 0.31 µCi/mg). These metabolites were compared to urine metabolites from humans dosed orally 90 mg (45 mg tetradeuterated CL 273,547 and 45 mg CL 273,547, specific activity of 0.182 µCi/mg).

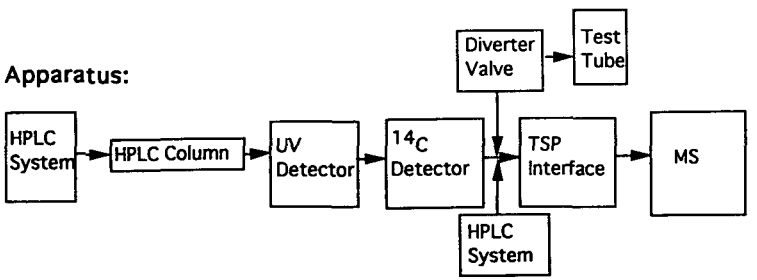
Experimental

Sample Preparation: Urine samples were lyophilized and extracted into methanol. The methanol was evaporated and the extracts were redissolved into HPLC mobile phase before injection to the HPLC system.

Instrumental: Thermospray (TSP)/MS analysis was performed on a Finnigan MAT TSQ-70 mass spectrometer with a Vestec Model 704A TSP interface. The HPLC system consisted of two LKB 2152 pumps with a gradient controller. UV detection was performed using a Spectroflow 783 Kratos at 230 nm with a 100 µL high pressure cell. ^{14}C detection was performed using a Raytest Ramona LS-4 system with a 100 µL lithium glass scintillator flow cell.

A Waters Model 510 HPLC solvent pump was used for post column addition of mobile phase.

Apparatus:



The dog produced M1, M2, M2', M4 and M8. The human produced all of the metabolites shown in Figure 1. In addition, there was significant intrasubject differences both in the metabolite and amount they produced. A typical HPLC ^{14}C profile in man is shown in Figure 2a. The corresponding TSP/MS chromatogram is shown in Figure 2b.

Confirmation of drug related metabolites in humans was achieved by recognition of the D_0-D_4 pattern of the drug, dosed 50% D_4-CL 273,547 and 50% D_0-CL 273,547. A stable isotope recognition program in "C" was written for the Apple Computer to identify this pattern.

Determination of Reserpine in Plasma by Ion Spray LC/MS/MS, Timothy Wachs and Jack D. Henion, NYS College of Veterinary Medicine, Cornell University, 925 Warren Drive, Ithaca, NY 14850.

Determination of basic drugs such as reserpine and LSD present many analytical challenges by conventional GC/MS techniques. However, the basicity of these drugs makes them ideal candidates for ionization techniques such as ion spray that do not require volatility. Additionally, HPLC, the method of choice for separation of basic drugs, is an ideal way to introduce the analyte into an ion spray or electrospray interface.

Reserpine, which is used as an antihypertensive agent in humans and as a tranquilizer in the horse is administered at dose levels of 1-3 µg/kg of body weight. In order to monitor plasma levels in clinical studies or for forensic determination, detection limits in the low picogram/mL of plasma are required. For clinical analyses where a large number of samples need to be analyzed, rapid methods for sample preparation and analysis are also desirable.

Sample extraction, liquid chromatography, and the mass spectrometer interface and mass spectrometry were investigated separately and together in order to optimize sensitivity and the speed of the analysis. For quantitation, MS/MS selected reaction monitoring was chosen, which also adds a final "clean-up" step in the general separation scheme. Since reserpine (see figure) is a basic drug with low volatility, atmospheric pressure ionization (via ion spray) is a method of choice. Internal standards, which are necessary for quantitative analysis, were compared for suitability. Labeled reserpine was not readily available thus two analogous compounds were chosen, triethoxyreserpine and rescinnamine (see figure).

Ideally, the internal standard should co-elute for API applications since interactions and ion suppression may occur with other co-eluting impurities in the sample. The mass spectral behavior of the internal standard and the analyte should also be similar. Of the two potential internal standards, rescinnamine does co-elute under the HPLC conditions used and was chosen as the internal standard in spite of dissimilar fragmentation behavior. Under the optimal reserpine MS/MS conditions used in this study, rescinnamine fragments to a much greater degree, requiring careful control of MS/MS conditions.

Use of 2 mm id LC columns vs 4.6 mm is advantageous because of the increase in sensitivity of ion spray while still maintaining reasonable (10-20µL) injection volumes. The full 200 µL/min HPLC flow rate was directed to the ion spray interface on a Sciex API instrument. This is possible since the eluent has a high organic content (80% acetonitrile) and the sprayer was carefully positioned with respect to the heated interface plate such that any condensation did not interfere with ion sampling. A 30-40% loss in sensitivity is the price paid for the elimination of a post-column split and its inherent shortcomings.

The goal of very rapid analysis times can be met by combining good sample extraction and clean up with fast liquid chromatography and MS/MS as the final separation step. Isocratic conditions are a must if rapid analysis time is to be achieved without resorting to precise timing of injection sequences. A Keystone Scientific Inertsil ODS2 100 x 2 mm column with 80:20 acetonitrile:water, 5 mM ammonium acetate, provides a retention time of approximately three minutes for reserpine with good separation of residual components from serum extractions. The resultant analyses can be done in five minutes or less.

Two different extraction schemes were investigated in order to provide "clean" extracts. A three step liquid/liquid extraction (1) provides clean extracts and good (~50%) recovery at the low picogram levels. However, the method is tedious and very time consuming but could probably be automated. The recent introduction of several solid phase extraction systems based on a thin disk of fiber glass or Teflon and adsorbent provides promise for the rapid and easy separation of drugs like reserpine from plasma. In order to

develop a method using this technology, a Hewlett-Packard 5985B mass spectrometer equipped with an API heated capillary interface was used to monitor the extraction of rescinnamine from equine and human plasma. Spiked plasma that was diluted 1:1 with n-saline and carbonate buffer was extracted with ToxiLab Spec C8 cartridges. A 20% acetonitrile wash was used for clean up Recovery of the analyte was done with 300µL of methanol. Recovery levels were one half or less than that for the liquid/liquid system but ease of use and the short work-up time of this method warrants further development of the method.

Using liquid/liquid extraction, the limit of determination of reserpine in human plasma was at the 25 pg/mL level with a linear response up to at least 500 pg/mL. Human administrations are usually at the 100 to 500 µg dose level, with plasma levels rarely exceeding the 500pg/mL level. The level of reserpine in human plasma from a 100 µg administration study could be quantified out to 36 hours after administration.

Determination of Vitamin B_{12} by Ionspray Liquid Chromatography Mass Spectrometry

Isamu Matsumoto, Yoshihisa Umeda*, Yasuko Ogawa*, Ikunoshin Kato* and Tomiko Kuhara.

Division of Human Genetics, Medical Research Institute, Kanazawa Medical University, Uchinada, Ishikawa, Japan and *Biotechnology Research Laboratories, Takara Shuzo Co., Ltd., Kusatsu, Japan

Introduction

The vitamin B_{12} dependent reactions can be classified in two groups, on the basis of the cofactor used: methylcobalamin; CH_3Cbl or deoxyadenosylcobalamin; AdoCbl. Only three reactions have so far been discovered in mammals. These reactions are catalysed by methionine synthetase (EC2.1.1.13. CH_3Cbl cofactor), methylmalonyl CoA mutase (EC5.4.99.2. AdoCbl cofactor) and leucine mutase (AdoCbl cofactor). Thus the reduced biosynthetic activity of either CH_3Cbl in the cytosol or AdoCbl in the mitochondoria results in a metabolic disorder of homocystinuria or methylmalonic acidemia. The frequency of the latter diseases is relatively high in all over the world. About half of them are the deficiency of apoenzyme, thus are not responsive to vitamin B_{12} therapy. However, the remaining half are due to the reduced activity of an enzyme of AdoCbl synthesis.

We have attempted to determine CH_3Cbl, AdoCbl and cyanocobalamin in order to understand the above mentioned 2 metabolic disorders more precisely. The principal difficulty of the determination of vitamin B_{12} is that the serum concentration is only in minute (10^{-10}g/ml) amounts and is labile to the heat and light. Thus we have applied ionspray mass spectrometry (ISMS) for the analysis of vitamin B_{12}.

Experimentals

Authentic cyanocobalamin was dissolved in purified water to the final concentrations of 50, 100, 250, 500, and 1000 pg/µl. A 20 µl portion of the solution was applied to the column (Develosil ODS-5, 1.5 x 150 mm, Nomura Chemical Co., Ltd., Nagoya, Japan), and eluted by a linear gradient at a flow rate of 80 µl starting with 100% H_2O followed by increase in the acetonitrile concentration to 40% in 5 minutes; the concentration of TFA was kept at 0.1% (v/v). The Perkin-Elmer Sciex API III triple quadrupole mass spectrometer was used for the quantitation.

We have also determined cyanocobalamin by ^{252}Cf-plasma desorption mass spectrometry, using Biolon TM_{20} Mass Analyzer.

Results and Discussion

In ionspray mass spectrum of cyanocobalamin, singly charged molecular ion was observed at m/z 1356 and doubly charged ion at m/z 679 (Fig. 1). The plot of peak areas of the selected ion monitoring chromatogram (SIM) versus amount of cyanocobalamin in the five injected solutions showed good linearity over the range from 50 pg/µl to 1 ng/µl.

Our LC/SIM method was confirmed to be useful to determine cyanocobalamin in serum by a recovery test; a serum containing 0.4 ng/µl of cyanocobalamin was pretreated with microfilter, and subjected to LC/MS assy resulting in the concentration of 0.34 ng/µl (85% recovery). ^{252}Cf-plasma desorption MS gives almost the same sensitivity as LC/MS assay (Fig. 2). However, the above results obtained with ionspray LC/MS and ^{252}Cf-plasma desorption MS are not satisfactory for the quantitaion of blood level of vitamin B_{12}. Further studies are undertaken.

Department of Biochemistry and Molecular Biology
University of Texas Medical School, Houston, Texas 77225

INTRODUCTION

Electrospray ionization mass spectrometry (ES/MS) has the capabililty to accurately determine mass over a large range. As with other soft-ionization techniques, ES is sensitive to high salt concentrations which severely inhibits sensitivity. By coupling LC to an ES interface, the problem of salt interference can be greatly reduced. High salt concentrations are present in all biological fluids and this along with very dilute analyte concentrations (atto and femtomolar concentrations for many neuroactive substances) have limited the application of MS techniques to the biological sciences. The specificity of MS technology is needed in these areas due to the incontinance of antibodies that are used in radioimmunoassay and radioreceptorassay (1).

In vivo microdialysis is a technique that allows sampling of extracellular fluids from a living animal. Microdialysis eliminates the need to extract substances from post mortem tissue and can be used to monitor the accumulation/release of neuroactive substances in specific brain regions over time in one animal, thus eliminating the sacrifice of several animals to provide a single pharmacological time course. Microdialysis does have the limitation in that samples gathered are very dilute and in high salt biological fluids.

In this report, we discuss the modification of a Vestec ES source to deliver a "microspray" at nanoliter flow rates. These modifications increased the sensitivity by 100 fold along with increased signal stability. By coupling this modified source with nanoflow-LC chromatography (2, 3), we have developed a system that is capable of detecting endogenous release of neuropeptides in the brain collected by in vivo microdialysis.

MATERIALS AND METHODS

ES/MS: ES spectra were generated using a modified Vestec Electrospray Ion Source (4) with a 5 kV dynode.

Microspray: In order to detect the endogenous release of neuropeptides via microdialysis, the sensitivity and stability of the ES/MS had to be greatly increased along with a decrease in the solvent flow rate. These three parameters were achieved with the introduction of the "microspray" needle.

To reduce the flow in our system, a smaller i.d. needle was constructed. Van Berkel (5) described a system in which the HV connection was made through the liquid flow and the sample sprayed from a 100 micron fused silica capillary. We varied the i.d. of the capillary and constructed a cone shape tip for the spray "needle". Microspray "needles" were constructed from fused silica capillary with i.d. ranging from 5 to 250 microns. The polyamide was burned away (approximately 0.5 cm) with a microtorch and the exposed silica tip lowered into a 49% solution of hydrofluoric acid (HF) while distilled H_2O was pumped through the capillary at 500 nl/min. The progress of the etching was monitored with a microscope every 10 min. If the tip was rough after digestion, either digestion was repeated or the tip was carefully ground to a flat end under a stereomicroscope. The breech of the "needle" was attached to a stainless-steel zero dead volume fitting with a 0.02" thru-hole, the high voltage connection was here. Needle voltage varied from 2.0-3.5 kV. Nozzle voltages averaged 200 to 280 V. The repeller voltage was set to 10.

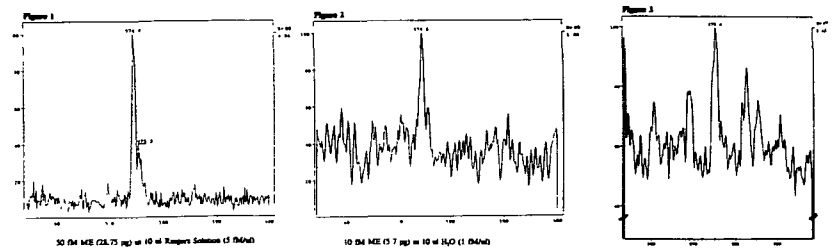
N_2 Carrier Gas: The standard Vestec ES system uses no counterflowing gas, but does allows the entry of ambient air. When maximum sensitivity was needed, the background from ambient air

would sometimes mask the signal of interest. The problem was eliminated by using ultra-pure, dry N_2 at approximately 1 ATM.

Nanoliter Flow Liquid Chromatography: Columns were packed using procedures as described by Mosely et. al. and Kennedy, R.T and Jorgenson, J.W. (2, 3) with modification. Mobile phase varied from 5-50% MEOH with 0.25% HOAC.**Microdialysis:** CMA/10 microdialysis probes (BAS inc.) were used in the in vivo experiments. Probes were stereotaxically implanted into the striatum of male Sprague/Dawley rats under pentobarbital anesthesia. In all experiments, Ringers solution (artificial CSF, 5 mM KCl, 120 mM NaCl, 1.2 mM $MgCl_2$, 1.8 mM $CaCl_2$, 0.15% phosphate buffered saline, pH 7.4) was perfused thru the probe at a rate of 436 nL/min.

RESULTS

Figs. 1 and 2 illustrate the sensitivity of nanoscale LC/Micro-ES/MS, ME at 50 and 10 fm total. Fig. 3 shows the endogenously released ME from rat striatum.



CONCLUSIONS

The development of a Microelectrospray source has provided greatly increased stability and sensitivity for low flow rate applications. This LC/ES/MS interface is now capable of detecting endogenously released neurocompounds from biological microdialysates in physiological salt solutions.

In Summary:

I. The combination of a narrow spray, the close proximity of the "needle" and nozzle and nanoliter flow rates are major contributing factors yielding the enhanced performance shown here.

II. Addition of dry, ultrapure N_2 increases our signal to noise up to 5 fold.

III. The combination microelectrospray with nanoscale LC allows analysis of samples down to 10 fM ME (5.7 pg of ME) in a total volume of 10 ul of biological salt solution obtained from a 50 AMU mass scan.

Characterization of Brimonidine Metabolites by HPLC/Thermospray Mass Spectrometry. *Andrew Acheampong, Hai Nguyen, Dale Harcourt, Diane Tang-Liu and Michael Garst. Allergan, Inc. Irvine, CA 92713-9534.

Brimonidine [also known as AGN 190342 and UK-14,304-18) is a potent ocular hypotensive currently being evaluated for the treatment of glaucoma. It is a more selective α2-adrenergic agonist than clonidine which also contains the 2-amino-imidazoline moiety. Following intravenous or oral administration of ^{14}C-brimonidine tartrate to animals and humans, the degree of brimonidine metabolism was investigated by generating plasma and urinary metabolite profiles. Using reverse phase ion-pair HPLC, the in vivo metabolite profiles revealed 9 metabolites (I, IIa, IIb, IIIa, IIIb, IV, V, VI, VII). In this report, we describe the application of HPLC/thermospray (TSP) mass spectrometry to identify metabolites produced in vitro by rat liver 10,000*g* preparations. The identification of metabolites was supported by comparison with synthesized compounds.

Brimonidine and ^{14}C-brimonidine were incubated in rat liver homogenate 10,000*g* fractions prepared using standard procedures. Following incubations and extraction, metabolites were partially separated by HPLC fractionation methods. LC/MS analyses were performed using a Vestec TSP interface with vaporizer at 160-170°C and source block at 260-300°C. A Beckman C18 column (25 cm x 4.6 mm id, 5 µm) was used in ion-pair LC and LC/MS analyses. The mobile phase was either MeOH/NH_4Ac (20:80 v/v) or MeOH/H2O//TEA/AcOH (14:86:0.075:0.1 v/v) pumped at a flow rate of 1ml/min. Reverse phase ion-pair HPLC was employed to compare retention times of metabolites and authentic standards. The ion-pairing reagent was heptanesulfonate.

Analysis of rat liver extracts by ion-pair HPLC with radioisotope detection (Figure 1) showed at least 7 metabolites (I, IIc, IIIa, IV, V, VI, VI and VII). Under positive ion TSP/MS conditions, brimonidine and metabolites produced debrominated-protonated ions, protonated molecular ions, or other diagnostic ions for structural identity of new metabolites of brimonidine (Table I). Like FAB/MS, TSP/MS also showed ions formed by debromination with addition of H. Metabolite VI is the known guanidine derivative formed probably by the N,N dealkylation pathway. Figures 2 and 3 show the TSP mass spectra of metabolites IIIa and MV, respectively. Metabolite IIIa was confirmed as the quinoxalin-2,3-dione derivative (Figure 4). Metabolites IV and V which exhibited characteristic ions at m/z 280, 282 $(MH-CO)^+$ were proposed to be either 2 or 3-quinoxalinone derivative. Preliminary studies suggest that IIIa, IV and V are formed with mammalian liver aldehyde oxidase. MVII was 4',5'-dehydrobrimonidine.

Table I. Thermospray Mass Spectral Data of Metabolites and Reference Compounds

Compound	Characteristic Ions (m/z)
Brimonidine	292, 294 $(MH)^+$; 214 $(MH - Br + H)^+$
Imidazolin-4'-one derivative	228 (MH-Br+H); 306,308 $(MH)^+$; 407,409 $(MH+TEA)^+$
Metabolite IIIa	245 $(MH - Br)^+$; 246 $(MH - Br + H)^+$
Quinoxalin-2,3-dione derivative	324, 326 $((MH)^+$; 245 $(MH-Br)^+$; 296, 298 $(MH-CO)^+$
Metabolite IV	280, 282 $(MH - CO)^+$; 202 $(MH - CO - Br + H)^+$
Metabolite V	308, 310 $(MH)^+$; 280, 282; $(MH - CO)^+$; 202
Metabolite VI	266, 268 $(MH)^+$
Guanidine derivative	266, 268 $(MH)^+$; 188 $(MH - Br + H)^+$
Metabolite VII	290,292 $(MH)^+$; 212 $(MH-Br+H)^+$; 391,393 (MH+TEA)
4',5'-dehydro brimonidine	290, 292 $(MH)^+$; 212 $(MH - Br + H)^+$

The results of this study indicate that LC/MS with TSP ionization was useful for the identification of brimonidine metabolites. The debromination fragmentation ions facilitated the identification of metabolites. Under the TSP conditions used, most of the protonated molecular ions underwent extensive fragmentation and were prominent only at high concentrations of metabolites or reference standards.

Simultaneous HPLC radioactivity and mass spectrometry monitoring. A drug metabolism application

Hassan G. Fouda, Michael Avery and Kimberly Navetta
Central Research Division, Pfizer INC, Groton, CT 06340

The usefulness of electrospray and atmospheric pressure chemical ionization mass spectrometry for drug metabolism studies is now widely appreciated. Electrospray is particularly indispensable due to its high ionization efficiency and its applicability to labile conjugates and polar metabolites. Indeed, the powerful combination of HPLC - electrospray and collision induced dissociation (CID) was shown in our laboratory to generate substantial information on the metabolism of xenobiotics in various *in vivo* and *in vitro* matrices. However, since the ionization efficiencies of unknown metabolites vary and since their CID daughter spectra are not always predictable, definitive quantitative metabolism information can only be obtained by radiolabeled studies.

We have put together an HPLC system incorporating electrospray ionization, CID mass spectrometry and radioactivity monitoring. Both the radioactivity and the mass spectrometry data are acquired in the same time domain by a single data system, hence facilitating matching the two types of information.

The utility of the system was demonstrated by application to investigatinG the metabolic pathways of tenidap, a new anti-inflammatory agent. The relative abundance and structural information of four metabolites were determined from direct HPLC injection of a crude bile sample from a monkey administered ^{14}C labeled tenidap.

INVESTIGATION OF FACTORS INFLUENCING *IN VIVO* MICRODIALYSIS/MS/MS STUDIES

L.J. Deterding[1], K. Dix[2], L.T. Burka[2], and K.B. Tomer[1]

[1]Laboratory of Molecular Biophysics

National Institute of Environmental Health Sciences
Research Triangle Park, NC 27709

Microdialysis (MD) has become an important technique for the *in vivo* sampling of extracellular fluid in discrete compartments of living systems. This technique is being widely used in physiological, pharmacological, toxicological, and behavioral studies for the recovery of endogenous or exogenous substances. MD offers several advantages over conventional (CONV) sampling techniques-such as, minimal damage to sampling site, little alteration of fluid balance, ability to simultaneously introduce and collect substances, and ability to continuously sample over a desired length of time. We have recently shown that *in vivo* microdialysis coupled with tandem mass spectrometry (MD/MS/MS) is an effective technique for the real-time analysis of tris(2-chloroethyl) phosphate (TRCP), an organophosphate flame retardant and suspected carcinogen, in biological systems (1). Free TRCP concentration vs time profiles were generated following MD sampling in the blood via the jugular vein of anesthetized animals. CONV studies were also performed in awake animals which involved blood withdrawal followed by sample workup and chromatographic analysis. Free TRCP concentration vs time profiles were generated and compared to those obtained from the MD/MS/MS studies. The most noticeable difference observed was that the initial free TRCP concentrations in plasma in MD/MS/MS studies were much higher (by an order of magnitude) than those observed in the awake animals in the CONV studies. Beyond 10-min post-dosing, similar free TRCP concentrations were observed between MD/MS/MS studies and CONV studies. Several factors may contribute to the observed differences in initial free TRCP concentration, including effect of anesthesia, presence of the indwelling jugular cannula in CONV studies, blood sampling regimen in CONV studies, and the *in vitro* standard calibration curve in plasma for the MD/MS/MS studies.

The above mentioned factors and the possible contribution they may have on the observed differences in the initial TRCP concentrations between MD/MS/MS studies and CONV studies have been investigated. In the CONV studies, the animals were awake, heparinized and dosed via the indwelling jugular cannula whereas in the MD/MS/MS studies, the animals were anesthetized, not heparinized and dosed via the femoral vein. The presence of heparin, anesthesia, and/or the cannula may alter TRCP plasma protein binding, distribution and pharmacokinetics. In addition, the site of i.v. administration may be a contributing factor. CONV studies, therefore, were performed in anesthetized animals to determine what effect the anesthesia had on the initial TRCP concentration. The animals were dosed via the femoral vein and sacrificed 2-4 min post-dosing and blood was removed and analyzed for TRCP concentration. In addition, animals were anesthetized and dosed without the presence of the indwelling jugular cannula to determine if the cannula may alter the TRCP pharmacokinetics in any manner. In CONV studies, blood is removed from the animal at each timepoint, thereby, altering the fluid balance of the animal. Conversely, MD maintains fluid balance as there is not net loss or gain of blood volume. The effect of the withdrawal of blood samples in CONV studies was investigated by anesthetizing animals and implanting them with MD probes which were not connected on-line to the mass spectrometer. The results of these studies are shown in Table 1. These parameters seem to alter the observed initial TRCP concentrations, but

none of these factors are solely responsible for the observed difference in initial TRCP concentration in plasma from animals studied by CONV methods vs the MD/MS/MS method.

Another factor investigated is the validity of the *in vitro* calibration of the microdialysis probes for use in studies *in vivo*. The effects of both biological fluid and temperature were investigated to determine if these parameters effected the *in vitro* calibration of the microdialysis probes. Blood, plasma, and water were used at both 24 °C and 37 °C. The relative recovery of free TRCP concentration varied with the biological fluid used and increased as temperature increased (Figure 1). It, therefore, appears that the method of *in vitro* calibration of the microdialysis probes has a major effect on the MD/MS/MS studies. The reason for this is possibly due to the fact that it is difficult to measure and/or mimic such a dynamic system as the living animal.

Determination of Quaternary Isoquinoline Alkaloids by Ion Spray Ion Trap Mass Spectrometer (IS/ITMS).

H. K. Lim[1,3], W-N. Wu [2], A. Mordehai[3] and J.D. Henion[3], [1]Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543, [2]The R.W. Johnson Pharmaceutical Research Institute, Spring House, PA 19477, and [3]Drug Testing and Toxicology, Cornell University, Ithaca, NY 14850.

Natural products are an important source of novel therapeutic agents in a drug discovery program. For example, the isoquinoline alkaloids isolated from *Berberidaceae*, *Menispermaceae*, *Papaveraceae*, *Rutaceae*, and *Ranunculaceae* families have hypotensive, analgesic, antimicrobial, muscle relaxant and antitumor activities. Previously, structural elucidation of a total of 8 quaternary isoquinoline alkaloids in the bark (280 g) from *Phellodendron wilsonii* involved exhaustive extraction with hot ethanol, liquid-liquid partitioning, column chromatography and finally repeated crystallization prior to mass spectrometric characterization (1). Furthermore, all these quaternary isoquinoline alkaloids have been analyzed by FAB/MS which is an insensitive technique for characterizing these compounds as indicated by typical sample requirements of ≥10 µg (2).

The aim of this study is to investigate the suitability of IS/ITMS for the determination of these quaternary isoquinoline alkaloids. Good quality mass spectra were successfully acquired for 12 protoberberines, 4 aporphines, 2 protopines and 2 bisbenzylisoquinolines isolated from *Rutaceae* and *Ranunculaceae* families by flow injection analysis of 5 ng of each compound in 50% acetonitrile/5 mM NH_4COOH pH 3.5 at a flow of 50 µL/min. Low "up-front" CID (30 V) mass spectra show predominantly molecular (quaternary), doubly charged molecular (bisquaternary) and protonated molecule (tertiary) ions. Increasing the "up-front" CID voltage to 68V resulted in mass spectra with structurally informative fragment ions in addition to molecular weight. The results show that IS/ITMS is a thousand fold more sensitive than FAB/MS for detecting these compounds. Further appreciation of the potential sensitivity of the IS/ITMS is from Figure 1 which shows the limit of detection for berberine corresponding to on-column injection of 6.25 pg under full-scan mode (m/z 150-400) and gave a reasonably good quality background-subtracted mass spectrum (Figure 2).

On-line LC-IS/ITMS was developed for separation and confirmation of a total of 7 and 5 isoquinoline alkaloids in methanolic extracts from bark (*Phellodendron wilsonii* , 5g) and an herbal medicinal tablet (0.3g), respectively. Conclusive identification of each compound was by a combination of co-injection with authentic standard and/or comparison of retention time and mass spectra generated under low and high "up-front" CID conditions. Figure 3 shows the total ion chromatogram from LC-IS/ITMS analysis of a mixture of standards and bark extract. Also, a reasonably good quality high "up-front CID mass spectrum is obtained for a minor component in the extract identified as jatrorrhizine (Figure 4). Other alkaloids that have also been identified include berberine (major component), palmatine, phellodendrine, tetrahydropalmatine, magnoflorine and thalifendine. Also, tentatively identified are some isomeric alkaloids. Therefore, the data obtained clearly indicate that on-line LC-IS/ITMS is a very powerful analytical tool for rapid structural elucidation of constituents in a natural product for drug discovery.

ASSESSMENT OF *IN-VITRO* LIVER SLICE METABOLIC ACTIVITY USING MICROCOLUMN LC/ESI/MS AND LC/ESI/MS/MS,

*M.A. MOSELEY, J.S. WALSH, J.E. PATANELLA, K.A. HALM, AND S.E. UNGER, DEPARTMENT OF DRUG METABOLISM, GLAXO RESEARCH INSTITUTE, RESEARCH TRIANGLE PARK, NC 27709

The combined tools of chromatography and mass spectrometry have proven to be very useful in the profiling of drug metabolites derived from animal toxicology studies and in the identification of metabolites from human clinical trials. The discovery of biologically active human drug metabolites not previously observed in the animal toxicology studies can adversely affect the clinical study, therefore, the ability to identify human metabolites prior to clinical trials is advantageous. Precision cut liver slices have been used as an *in-vitro* model of coupled Phase I and Phase II drug biotransformations (1), and the use of slices of "transplant quality" human livers allows the generation of human drug metabolites prior to clinical trials. This *in-vitro* liver slice approach offers the ability to rapidly and inexpensively generate metabolites from animal and human systems in a relatively clean matrix, and characterization of the resultant samples by LC/MS and LC/MS/MS provides a similarly rapid means of identifying the metabolites. The goal of this work was to demonstrate the utility of the combined techniques of *in-vitro* liver slice metabolism and LC/ESI/MS and LC/ESI/MS/MS identification of human drug metabolites.

This approach requires a method for assessing the viability of the liver slicse, and 7-ethoxycoumarin (7-EC) has proven to be a particularly useful probe of coupled Phase I and Phase II biotransformations (2-3). The metabolic viability of the liver slices was quantitatively determined using a LC/UV assay with authentic standards of 7-EC and its principle metabolites (7-hydroxycoumarin, 7-hydroxycoumarin sulfate, and 7-hydroxycoumarin glucuronide) (4), and LC/ESI/MS was used to confirm the structures of the 7-EC metabolites.

Omeprazole, an inhibitor of gastric acid secretion, was chosen as a test compound to demonstrate the utility of the combined techniques of *in-vitro* liver slice metabolism and LC/ESI/MS/MS identification of the resultant metabolites. Previous MS analysis of *in-vivo* omeprazole metabolites from rat urine (5) had shown this compound generates a number of both Phase I and Phase II metabolites which have proven to be difficult to analyze by either direct probe insertion electron ionization (even with derivatization) or by on-line thermospray LC/MS. While LC/ESI/MS has been applied to characterize omeprazole metabolites in rat urine (5), no LC/MS/MS data on omeprazole metabolites (animal or human) has been reported.

To assist in the data interpretation, constant infusion of a $5x10^{-5}$M solution of omeprazole was used to generate a MS/MS reference spectrum comprised of 12 daughter ions. Use of a high orifice bias voltage (100V) generated the same fragments in the ion source, permitting the acquisition of MS/MS spectra of the eight most abundant ions observed in the MS/MS spectrum of omeprazole, in effect yielding MS/MS/MS spectra of omeprazole.

Human liver slices were incubated with 156 µM omeprazole for 4 hours. Solid phase extraction was used to remove salts and concentrate the drug and its metabolites. Five microliter aliquots of the 10x concentrated samples were injected onto a Hypersil BDS C18 LC column (1 mm i.d., 250 mm long), corresponding to an injection of 12 nmoles or 4 µgrams of omeprazole. The drug and its metabolites were eluted with a gradient elution program of 5% to 80% (over 75 minutes) acetonitrile in 2mM ammonium acetate (pH 6.8), with a mobile phase flow rate of 40 µL/minute. Unmetabolized omeprazole was the major component of the sample, however, numerous metabolites were also observed, including both Phase I and Phase II metabolites. LC/ESI/MS/MS spectra permitted the identification of most metabolites, including the differentiation of isobaric metabolites. For example, the alcohol metabolite (Figure 1) and the sulfone metabolite (Figure 2) are clearly distinguished on the basis of their LC/ESI/MS/MS spectra. While the majority of the previously reported metabolites in rat urine (5) were found in this study to also be *in-vitro* human metabolites, several of the rat urine metabolites were not found, and several of the *in-vitro* human metabolites were not found in the rat urine study. Moreover, this current work identified all of the human metabolites which have been found to be reported in the literature, as well as several additional human metabolites not yet reported.

The microbore LC/ESI/MS and LC/ESI/MS/MS analyses were performed on a Sciex API-3 equipped with an IonSpray™ interface, and the capillary LC/ESI/MS analyses were performed on a Finnigan TSQ-700 with an Analytica of Branford ESI interface.

The high throughput of the combined techniques of *in-vitro* human liver slice metabolism and LC/ESI/MS and LC/ESI/MS/MS identification of human drug metabolites permits the rapid screening of a number of structurally different drug candidates. This approach should prove to be of significant utility to the drug discovery and drug development process.

Quantitative Analysis of the Immunosuppressant FK-506 in Rat Serum by High Performance Liquid Chromatography-Electrospray MS/MS Techniques.

R. P. Schneider *, M. J. Cole, and H. G. Fouda. Central Research Division, Pfizer Inc, Groton, CT 06340

FK-506 is a macrolide immunosuppressant agent that is currently used in organ transplant patients.[1] Although structurally different from cyclosporin A, FK-506 shares many of the pharmacological effects of cylclosporin A.[2] Published methods of FK-506 quantitation have included enzyme immunoassays [3] and fluorescence derivatization procedures,[4] with minimum detection limits of *ca.* 2 ng/mL.

A specific HPLC/MS/MS assay has been developed for FK-506. The assay utilizes reverse phase microbore HPLC coupled to a pneumatically assisted electrospray (Ionspray) interface of a Sciex API III mass spectrometer. During the assay development, it became apparent that extracted components of the serum matrix were binding to the uncoated fused silica tubing normally used in the electrospray interface. This phenomenum caused poor reproducibility and accuracy for FK-506 quantitation, especially at concentrations less than 0.5 ng/mL. Replacement of the uncoated fused silica tubing with a crosslinked capillary column (DB-5) provided accurate and reproducible results.

Control rat serum was fortified with FK-506 and cyclosporin (the internal standard), followed by extraction at serum pH with methyl t-butyl ether. The organic solvent was recovered and evaporated to dryness. Serum residues were reconstituted in 25 µl of HPLC mobile phase and 5 µl were injected onto the HPLC/MS/MS system. Monitoring the collision induced dissociation product ions of the FK-506 and cyclosporin ammonium adducts provided good sensitivity and specificity. Quantitation of the analyte was accomplished over a linear dynamic range of 100 pg/mL to 20 ng/mL. The intra-assay precision was < 11% (for n=5), and the accuracy of the assay was less than or equal to 8.6% of the fortified concentrations. Instrumental reproducibility for replicate injections of standard solutions was 2.2% when monitoring ratios of drug/internal standard.

Structural Analysis of Rapamycin and Related Compounds Using $(M+Li)^+$ Ions Generated by LSIMS. *J P. Kiplinger, M A. Guadliana; Pfizer, Inc., Groton, CT 06340

Rapamycin (**1**) is an antitumor, antifungal, and immuno-suppressive agent isolated from cultures of *Streptomyces hygroscopicus*[1]. The compound presents a difficult mass spectrometric problem, producing little structural information by positive CI, EI, FAB and Ionspray[2].

Because of its structural homology with FK-506, rapamycin is of interest to a number of pharmaceutical companies as an immunosuppressant[3]. The ability to structurally characterize rapamycin analogues in small amounts by mass spectrometry is of potential value in a search for new drug candidates. It is therefore desirable to develop a mass spectrometric method for rapid screening of novel rapamycin-like molecules which gives useful structural information.

Alkali metal salts are often added to LSIMS matrices in order to cationize samples with alkali metal ions. Rapamycin cationizes poorly with proton, but very well when sodium ions are present in the matrix. Similarly, we have found that lithium ions cationize rapamycin and related molecules, producing strong $(M+Li)^+$ ions and abundant fragment ions, particularly when they are activated collisionally. These fragments have been attributed to their precursors using B/E linked scanning and identified using high-resolution LSIMS. Some of the fragment ions were shown by labeling with $^6Li^+$ ions[5] to be derived from an $(M+2Li-H)^+$ ion, but all other significant fragments were monolithiated.

Structures of the fragment ions of the $(M+Li)^+$ ion of rapamycin were assigned based on reasonable assumptions about fragmentation mechanisms, and by examining spectra of rapamycin analogues. These structures were then confirmed, wherever possible, by peak matching at high resolution to poly(ethylene glycol) standards.

Fragment m/z	Measured mass	Formula	Δ (ppm)
818	818.5047	$C_{46}H_{69}NO_{11}Li$	+1.99
626	626.3480	$C_{33}H_{49}NO_{10}Li$	- 5.83
593	593.4017	$C_{35}H_{54}O_7Li$	- 2.12
591	591.4249	$C_{36}H_{56}O_6Li$	+2.04
443	443.3011	$C_{25}H_{40}O_6Li$	+5.88
329	329.2297	$C_{19}H_{30}O_4Li$	- 2.17

The fragmentation scheme shown is particularly useful in characterizing rapamycin-like molecules that have been modified at one or two sites. Virtually every part of the molecule is present in at least one charged fragment, and is also lost as an uncharged fragment. This means that a modification at one location that produces a change in mass may be localized to a region of the molecule by noting which fragments change in mass relative to rapamycin and which do not. We have examined other analogues of rapamycin, and the changes in masses of the fragment ions make identification of modified structures straightforward.

Since biosynthetic pathways producing rapamycin-like molecules cannot produce random, infinite variations in the compound, it is likely that most analogues will be simply modified in one or two places. Furthermore, these modifications should be consistently found at certain locations within the molecule. In such cases, it should be easy to identify many new structures based entirely on the fragment ion spectra generated from their $(M+Li)^+$ ions.

Investigation of Photochemical Reactions via on-line Thermospray Tandem Mass Spectrometry

J. D. Laycock* and R. A. Yost; Dept. of Chemistry, University of Florida, Gainesville, FL 32611
J. Martin E. Quirke; Dept. of Chemistry, Florida International University, Miami, FL 33199

Introduction

Initial results show the feasibility of using photochemistry/TSP/MS/MS to monitor reactions occurring at biologically relevant wavelengths. A high intensity illuminator afforded a high yield of photoproducts and MS/MS data provided information to elucidate possible structures of the products. We will use our instrumentation to investigate the photosensitization reactions of classes of biomolecules such as amino acids, nucleic acids, and short chain peptides. In the preliminary studies reported here, the monitoring of the photosentization of tryptophan (trp) by hematoporphyrin (Hp) has been demonstrated.

Experimental

A schematic of the on-line photolysis system is shown in **Fig. 1**. The setup consists of an Isco LC-2600 syringe pump, a loop injector, a photochemical reactor, a Vestec thermospray probe and ion source, a Finnigan TSQ 45 mass spectrometer, a liquid nitrogen cold trap, and a 300 L/min mechanical pump.

The photochemical reactor was designed in our laboratory and consists of a 300 W xenon arc lamp and a flow cell with an aluminum housing, both of which are contained in a vented, black box. The arc lamp and the cell housing are fan cooled. The box is vented to a hood to remove ozone that is generated by the lamp. Previous photolysis TSP/MS work utilized a PTFE KOTR (knitted open tubular reactor) as the flow cell. Our interest in the investigation of photochemical reactions at visible wavelengths using a high intensity arc source necessitated the development of a new cell. The cell was made from Pyrex 7740 1/4" tubing. In order to withstand the thermospray backpressures, a brace was constructed to hold the swagelock fittings in place.

All data were collected using a Finnigan TSQ 45 with a Vestec thermospray ion source installed. The buffer solution consisted of 0.1 M ammonium acetate solution with the pH adjusted to 10.4 by the addition of ammonia. The flow rate for all experiments was 1.0 mL/min, which corresponds to a residence time of 1.0 min for the cell. The 300 W lamp was operated at 17 A.

All mass spectra were obtained in the filament-off mode with a source temperature of 260 °C and a probe tip temperature of 205 °C. The collision energy was 30 eV with an argon pressure of 1.4 mTorr in Q2.

Results

Fig. 2a shows the normal thermospray mass spectrum of trp (MW 204). The spectrum exhibits almost exclusively the $[M+H]^+$ ion at m/z 205. Low intensity ions at m/z 222 (indicating the $[M+NH_4]^+$ adduct) and m/z 161 (loss of CO_2) were detected. When the same solution of trp was injected with the lamp on (**Fig. 2b**), additional low intensity ions were observed at m/z 145, 177, 201, and 218. The ion at m/z 161 was significantly increased in intensity.

Fig. 3a shows the spectrum for the trp/Hp mixture with the lamp off. The ions at m/z 145, 161, 201, and 218 were detected but were much lower in intensity than in **Fig. 2b**. In **Fig. 3b**, is shown the spectrum for the trp/Hp mixture with lamp on. The ions at m/z 145, 201, and 218 were dramatically increased in intensity with numerous other ions also detected.

In **Fig. 4**, the proposed structure is 4-(2-amino-2 carboxyethyl) quinazoline. The dominant

ion in the daughter spectrum appears at m/z 145 and can be accounted for as the [M+H]+ ion of 4-methyl quinazoline. The ions at m/z 155 and 183 can be attributed to neutral loss NH_3+HCOOH and NH_3+H_2O respectively.

Conclusions

Visible-wavelength photochemistry on-line with TSP/MS/MS for the detection and structure elucidation of tryptophan (trp) photoproducts has been demonstrated. A 300 W arc lamp provided sufficient light intensity to convert approximately 80% of trp to photoproducts in the presence of hematoporphyrin (Hp). Hp was found to increase dramatically the abundance of photoproducts observed. MS/MS data led to the proposal of quinazoline derivatives as the main photoproducts. This is in accordance with previous observations that trp reacts to give quinazolines when photosensitized in the presence of ammonia.

COMPARISON OF GC/MS AND LC/MS METHODS FOR DETERMINING NICOTINE ABSORPTION IN TOBACCO SMOKERS

*G. D. Byrd, Biological Chemistry Laboratory, R. J. Reynolds Tobacco Co.
Winston-Salem, NC 27102.

Studies have shown that more than 80% of nicotine absorbed by humans is excreted in some form in the urine [1,2]. Thus, quantification of nicotine and its metabolites in 24 h urine samples is a viable means for estimating nicotine absorption in smokers. Most absorbed nicotine is excreted as free and conjugated forms of nicotine, cotinine, and 3'-hydroxycotinine. Various analytical methods have been used to determine these analytes in biological matrices. In this study, two methods for the determination of nicotine and its metabolites in smokers' urine were compared. The first method was a thermospray-LC/MS method developed in our laboratory [3] and the other was a modification of a published GC/MS method [4].

As part of our comparison, we prepared a standard smokers' urine by pooling urine from nine smokers and freezing 5 mL aliquots. This standard urine is routinely used for quality control and methods development in our laboratory and for comparative studies with other laboratories. Ten samples of the standard urine were analyzed by each method following beta-glucuronidase treatment to hydrolyze glucuronide conjugates. An immunological assay was also performed on the standard urine using a polyclonal RIA method for both nicotine and cotinine.

According to the GC/MS method of Voncken et al. [4], a saturated potassium carbonate solution was added to urine followed by extraction with n-butylacetate. The organic layer was sampled by injection in the splitless mode onto a DB5 column directly interfaced to a quadrupole mass spectrometer. The method was modified to include labeled analogs of each analyte (methyl-d_3 for nicotine, cotinine, and 3'-hydroxycotinine) as internal standards and by treating the urine with beta-glucuronidase prior to addition of potassium carbonate and extraction. Isotope dilution provided a more accurate and precise quantification and enzyme treatment freed glucuronide conjugates of these analytes to improve total accounting of absorbed nicotine. Although this method does not directly account for nicotine-N'-oxide, this compound decomposes thermally in the GC to nicotine, which adds to the total account of nicotine absorption.

The thermospray LC/MS method [3] used the same internal standards and glucuronidase treatment as the GC/MS method. The treated urine was filtered and injected directly onto the reversed-phase HPLC column for analysis. Samples were also analyzed without enzyme treatment to assess the amount of glucuronide conjugates by differences in the free forms of nicotine, cotinine, and 3'-hydroxycotinine. The LC/MS method provided data on the minor metabolites nicotine-N'-oxide, cotinine-N-oxide, and demethylcotinine.

Analytical results on the standard urine are summarized in Table I below. There was good agreement for major analytes (nicotine, cotinine, and 3'-hydroxycotinine) between the LC/MS and GC/MS methods with differences less than 20%. Total nicotine excretion determined by the two methods showed a difference of less than 5%. For the same set of standards ranging from 0.1 to 23 ug/mL, the GC/MS method had better sensitivity for nicotine (3 times) and 3'-hydroxycotinine (1.5 times) than the LC/MS method. Both methods had similar sensitivity for cotinine. Though limited in number of analytes, the RIA supported data from the chromatographic methods. The polyclonal RIA results agreed well for total cotinine and nicotine.

These results show that both methods are suitable for the determination of total nicotine absorption in smokers. The GC/MS method is more sensitive, easier to operate, and available to more laboratories. However, the LC/MS method provides a better quantitative metabolic profile. Both methods could be expanded to include certain minor metabolites.

ELECTROCHROMATOGRAPHY / MASS SPECTROMETRY OF STEROIDS

D. B. Gordon, G. A. Lord, Dept. Biological Sciences, Manchester Metropolitan University.
D. S. Jones, Kratos Analytical, Manchester.
L. W. Tetler, Centre for Mass Spectrometry, UMIST, Manchester, M60 1QD, UK.

INTRODUCTION.

Coupling of HPLC to mass spectrometers has resulted in a synergistic relationship extending the power of both techniques. The direct introduction of HPLC effluent into a FAB source via a fused-silica capillary as reported by Ito et al. [1], offered compatibility with the low flow rates used with packed capillary columns. These columns enable the analysis of extremely small amounts of sample, of particular importance for biological material, and show increased chromatographic performance.

Traditionally, solvent flow through HPLC columns is achieved by hydrodynamic pressure produced by suitable pumps, but as early as 1974, Pretorius [2] demonstrated the phenomenon of electroosmosis, effecting solvent flow through packed fused-silica capillaries, hence the term "Electrochromatography". The method was forgotten until 1981, when it was revived by Jorgenson and Lukacs [3], as an aside to their paper on capillary zone electrophoresis (CZE). However, it was Knox and Grant in 1987 [4] who developed the technique, and led to current interest.

The advantage of electroosmosis is that a flat flow profile is produced, in contrast to the parabolic Poisseuille flow of pressure driven systems, resulting in enhanced chromatographic performance, which can be particularly useful in coupling to mass spectrometry, when narrower chromatographic peaks produce higher mass flux.

EXPERIMENTAL.

Fig. 1 shows a schematic diagram of the system, utilizing a conventional CZE instrument (Isco Model 3140 Electropherograph).

The column consisted of a fused silica capillary 70 cm. x 50 μ i.d., slurry packed to a depth of 35 cm. with 3 μ ODS Hypersil (Shandon, U.K.). The eluent used was 80% acetonitrile 20% sodium tetraborate 4 mM, and a voltage of 30 kV was applied. Electromigration was used to apply samples onto the column, and detection was by UV (200 nm.) through the capillary wall, 50 cm. from the inlet.

Mass spectrometry was carried out on the first two sectors of a Kratos Concept IIHH, in positive mode. Acceleration voltage was 8 kV with 8 keV Xe FAB ionisation, and mass range 230-500 was scanned at 3 s. per decade.

The column was connected to a frit-FAB probe via a tee-piece, at which glycerol was incorporated as a 1% solution in 50% methanol / 50% water, to act as matrix and to make up the flow to approx 5 μl/min.

RESULTS & DISCUSSION.

Fig. 2 shows an off-line separation of aromatic compounds, and demonstrates the high number of theoretical plates achievable, (N~400,000/M. for benzyl alcohol).

Fig. 3 is a mass chromatogram of an on-line separation of three steroids, approximately 10 pmol. of each on-column. Mass spectra are shown in Fig. 4.

The main drawback with the technique, besides the intricacy involved, is disruption of flow due to air bubble formation in the column, presumably resulting from Joule heating and de-gassing of the eluent. When this occurred, it was necessary to use pressure pumping to push solvent through the column and drive out the bubbles in order that electroosmotic flow could be restored.

We are continuing work on this technique, particularly in regard to overcoming some of the problems encountered, such as air bubble formation in the column and extending applicability to a wider range of compounds. We believe the technique offers particular advantages in coupling to MS, especially with the possibility of using sub-micron packings and longer columns, than feasible with conventional HPLC. This may enable separation and determination of previously intractable mixtures, especially in the biological field, and often where amounts only in the femtomole region are available.

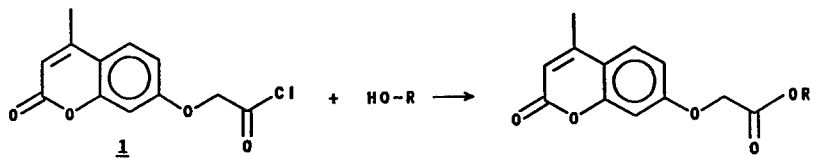
Division of Cancer Research
National Cancer Institute
Frederick, Maryland 21702-1201

Summary: *The alkylacylation reagent 7-[(chlorocarbonyl)methoxy]-4-methylcoumarin was synthesized, spectroscopically characterized, and investigated for its potential to give stable, highly fluorescent compounds of primary and secondary alcohols, for enhanced detection in high-performance liquid chromatography (HPLC).*



Introduction

7-[(Chlorocarbonyl)methoxy]-4-methylcoumarin 1 (CMMC) has been proposed for fluorescent labeling of primary and secondary hydroxyl groups[1]. We have developed synthetic procedures which allow the gram-scale production of 1 in high purity and we have thoroughly characterized this acid chloride by mass spectrometry and multinuclear and multi-dimensional nuclear magnetic resonance spectroscopy. Reagent 1 reacts smoothly with a variety of primary and secondary hydroxyl compounds to give the corresponding esters.

Methods

Synthesis. CMMC was synthesized from 7-(carboxymethoxy)-4-methylcoumarin by modification of the method proposed by Karlsson, et. al.[1] To 7-(carboxymethoxy)-4-methylcoumarin (100 mg, 0.43 mmol) was added freshly distilled thionyl chloride (1.5 ml, 20.6 mmol). The resulting mixture was stirred and heated to reflux for 1 h. Heating was discontinued and the reaction mixture, a clear, yellow-green solution, was stirred at ambient temperature for an additional 18 h. Hexane (8 ml) was then added to the reaction mixture, and the resulting precipitate was collected on a fritted disc filter. The collected solid was washed with an additional 10 ml of hexane. The slightly bluish-white solid was then freed of solvent *in vacuo*, yielding 96 mg of crystals (0.38 mmol, 88%) mp 126-127°C (uncorrected). ^{1}H-NMR ($CDCl_3$): δ 7.54 (d ($^3J_{HH}$=8.8 Hz),1H), 6.87 (dd,1H), 6.78 (d ($^4J_{HH}$=2.2 Hz),1H), 6.19 (s,1H), 5.00 (s,2H), 2.39 (s,3H). ^{13}C-NMR (^{1}H decoupled; $CDCl_3$): δ 18.67, 72.17, 102.19, 112.07, 113.14, 115.22, 126.08, 152.09, 155.01, 159.38, 160.68, 169.40. Mass spectrum (70 eV): *m/z* 252 ($M^{+\cdot}$, 100), 224 (34), 189 (64), 159 (34), 147 (68). HRMS, *m/z* 252.0180 (calculated for

$C_{12}H_9ClO_4$: 252.0189). For storage, 93 mg of the CMMC was transferred to a 25 ml volumetric flask, dissolved in methylene chloride (final concentration was approximately 14.8 mM), sealed under nitrogen, and stored in the dark at 5°C.

Derivatization Procedure. To a solution of CMMC (0.93 mg, 3.7 µmoles) in 0.25 ml of methylene chloride was added methyl alcohol (10 µl, 7.9 mg, 247 µmoles) and pyridine (5 µl, 4.9 mg, 62 µmoles). The resulting solution was vigorously mixed, allowed to stand for 10 minutes, and then concentrated to dryness under a stream of nitrogen gas at room temperature. The residue was analyzed without further purification.

Results and Discussion

Although ester derivatives of 1 readily elute from reversed-phase HPLC columns, analyses of these compounds by capillary GC/MS were unsuccessful for all but the lowest molecular weight materials due to limited volatility. Although there are reports of the use of CI and FAB MS in the examination of compounds of similar structure, we find that EI (70 eV) MS provides the most extensive indication of chemical structure.

Table. Selected ions from the electron-ionization (70 eV) mass spectra of various esters of 7-(carboxymethoxy)-4-methylcoumarin.

	R-OH	m/z 189 (% rel. abund.)	base peak (m/z)	M^+ m/z(%)
1	Methanol	(16)	147	248(93)
2	Ethanol	(30)	262	262(100)
3	Decanol	(58)	374	374(100)
4	Benzyl alcohol	(20)	91	324(42)
5	2-Propanol	(65)	43	276(73)
6	2-Butanol	(63)	290	290(100)
7	Cyclododecanol	(60)	234	400(59)
8	Cholesterol	(5)	368	602(12)
9	2-Adamantanol	(5)	135	368(20)
10a	1,4-Butanediol	(58)	306	306(100)
10b	1,4-Butanediol	(41)	234	522(20)
11	tert-Butanol	[presence of ester not detected]		

All molecular ions yielded exact mass data consistent with proposed molecular formulae. Derivatization conditions were manipulated to yield either 10a, the monoester, or 10b, the diester.

All derivatives give a distinctive molecular ion (relative abundance (100%-12%), and ions at m/z 189 which are indicative of the 7-carbonylmethoxy-4-methylcoumarin moiety. Loss of CO from the coumarin group occurs unpredictably. For those compounds possessing a suitable structure in the alcohol portion of the ester, the McLafferty rearrangement is seen, leading to a characteristic ion at m/z 234.

A Comparison of the Analysis of Gentamicin Sulfate by Thermospray and Electrospray HPLC/MS

T.A. Getek[1] and T.M. Heinze[2]
[1]Forest Laboratories, 300 Prospect Street, Inwood, NY 11696
[2]National Center for Toxicological Research, Jefferson, AR 72079

Overview: Previous work has reported the successful separation of the gentamicin sulfate (GS) complex by HPLC/MS using Thermospray (TS) ionization with a trifluoroacetic acid (TFA) ion pair mobile phase [1] The three major fractions of GS, C_{1a}, C_2, and C_1, were detected via TS ionization, as well as a minor fraction considered to be the C_{2a} component. A comparison was undertaken to determine the advantages of TS ionization versus electrospray (ES) ionization for GS and, in general, for aminoglycoside antibiotics.

Thermospray Ionization: The experimental and chromatographic conditions for the HPLC/MS have been reported [1], and a typical trace can be observed in Figure 1. The mass spectrum for the C_{1a} component of GS is seen in Figure 2. Because of the glycosidic bonds, the components in GS are thermally labile and the predominating mass spectral peaks are the individual sugars that have resulted from the breaking of these bonds. The $[M+H]^+$ peak as noted in Figure 1 is only a few percent relative abundance (%RA). Although not observed in the C_{1a} mass spectrum, a m/z 322 ion is sometimes observed for a disaccharide fragment. For quantitation purposes, the ions in the region of m/z 125 to 165 were utilized for GS.

Electrospray Ionization: ES ionization used a Vestec ES probe and controller interfaced to a Finnigan 4500 quadrupole. The mass spectra displayed were acquired using the infusion techniques at flow rates of 1 to 6 μL/min. Nominal concentrations of GS and other aminoglycosides were 100 μg/ml, and 95/5 water/methanol was the liquid carrier unless noted otherwise. Typical ES settings were 2.5 kV generating approximately 0.15 μA. The repeller was approximately 8 V and the nozzle (flat plate design) ranged from 50 to 200 V. The ES mass spectrum for the GS complex barely produced discernible $[M+H]^+$ ions at high concentrations infused, but did generate the $[M+2H]^{2+}$ ions as the base peaks. In addition, because the sulfate salt was infused, the sulfuric acid adducts of GS were detected as the $[M+2H\ H_2SO_4]^{2+}$ ions. Previously unreported work [2] for the ES ionization of GS gave the $[M+H\ H_2SO_4]^+$ ions as well, which was also noted in earlier FAB studies of GS [3]. In order to verify the ES effects of sulfate salts of gentamicin, a sample of tobramicin (TB) which was the free base was analyzed by ES ionization. The mass spectrum for TB (non-sulfate) can be seen in Figure 3. In this case, a significant singly charged species is observed at m/z 468, as well as the doubly charged molecular ion at m/z 235. On addition of sulfuric acid to TB, followed by infusion and ES ionization, the mass spectrum changed as indicated in Figure 4. With sulfuric acid, the TB singly charged molecular ion has completely vanished and the doubly charged species remained the base peak. An ion at m/z 283 which is representative of the $[M+2H\ H_2SO_4]^{2+}$ ion is now observed with addition of sulfuric acid. This confirmed the effect of sulfate on the appearance of the ES mass spectrum for GS.

Summary: The type of information obtained via TS and ES are unique for the two ionization modes. Although ES ionization via infusion is reported here, it was estimated that the detection limits for GS by HPLC/MS with ES ionization would be approximately 40 ng on-column for the conditions and instrumentation utilized. This is a factor of ten better than reported for TS ionization. The type of ions used for quantitation in the two ionization modes, however, would be different: fragment ions for TS and doubly charged molecular ions for ES. One disconcerting point about ES ionization for GS is that the appearance of the mass spectrum using similar equipment and conditions from several laboratories is quite diverse. This could be a point to consider for potential interlaboratory quantitations for analytes of interest via ES ionization with HPLC/MS.

THERMOSPRAY HPLC/MS OF GENTAMICIN

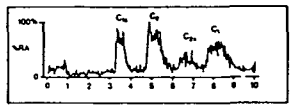

Figure 1 HPLC/MS of gentamicin sulfate by thermospray ionization using TFA containing mobile phase. Percent relative abundance (%RA) was plotted against chromatographic run time.

THERMOSPRAY MASS SPECTRUM OF C1a FRACTION

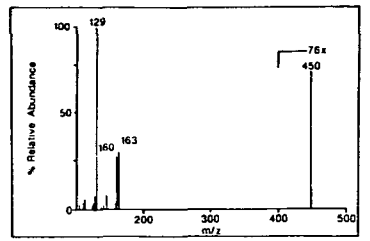

Figure 2. The TS ionization of gentamicin sulfate at the conditions selected produces substantial fragmentation of the compound as exhibited for the C1a fraction. The ions at m/z 129, 160 and 163 represent the individual sugar fragments that constitute the C1a component The $[M+H]^+$ ion is observed at m/z 450. Although not seen in Figure 3, an ion at m/z 322 is sometimes observed and is indicative of a disaccharide fragment

ELECTROSPRAY IONIZATION OF TOBRAMICIN (NON-SULFATE)

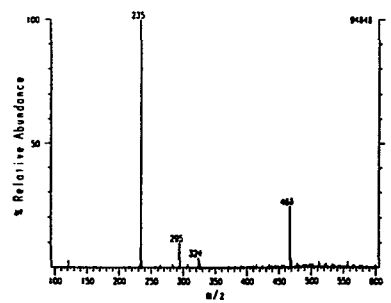

Figure 3. The infusion of tobramicin (non-sulfate) was performed at 5 4 μL/min with 95/5 water/methanol and 1.25% acetic acid added. The doubly charged ion at m/z 235 is observed; however, a significant $[M+H]^+$ ion is detected at m/z 468. When acetic acid was not present in the infusion, a weak but detectable ion was observed at m/z 468 with no ion discernible at m/z 235. The ion at m/z 295 may represent some acetic acid adduct of the doubly charged species.

ELECTROSPRAY IONIZATION OF TOBRAMICIN WITH H_2SO_4 ADDED

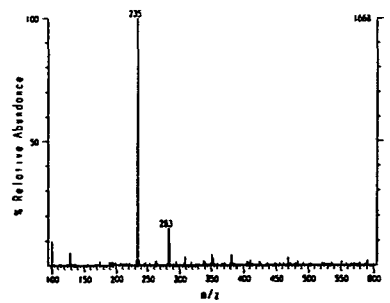

Figure 4. The mass spectrum shows tobramicin with sulfuric acid added. The infusion was 95/5 water/methanol with 0.25% H_2SO_4. It is seen that the singly charged ion at m/z 468 has disappeared and the base peak is the $[M+2H]^{2+}$ ion at m/z 234 The ion at m/z 283 represents the $[M+2H{\cdot}H_2SO_4]^{2+}$ ion.

Recognition of Quaternary Amines and Ammonium Salts Using Tandem Mass Spectrometry;

Daniel L. Norwood, Dixie L. Fisher, James O. Mullis, and M. Arthur Moseley; Glaxo Research Institute, Five Moore Drive, Research Triangle Park, NC 27709.

Introduction:

A problem often encountered in pharmaceutical development projects is the recognition of quaternary amine/ammonium salt drug substance degradation products and impurities. Thermospray (TSP), liquid secondary ion mass spectrometry (LSIMS), and electrospray ionization (ESI), the most commonly used techniques in such studies, do not distinguish $[M+H]^+$ ions of neutral species from the M^+ ions of quaternary amines. In the process of developing enhanced methods for molecular weight confirmation of drug substance related structures, an interesting behavior of quaternary ammonium salts was observed. Precursor scans of quaternary ammonium M^+ ions observed in $LSIMS^+$ exhibited prominent cluster ions of the structure $[xM+(x-1)anion]^+$. This differs from the cluster ions $[xM+H]^+$ commonly observed from neutral species in LSIMS and TSP.

Three classes of quaternary ammonium chlorides (sigma-bonded, conjugated, and sigma-bonded with a single carboxylic acid group) and a series of hydrochloride salts of neutral amines, representative of a range of drug products, were studied with LSIMS, TSP HPLC/MS, and ESI HPLC/MS to investigate cluster ion behavior. Precursor scans of M^+ and $[M+H]^+$ ions ("molecular weight confirmation scans") and full scan spectra (positive and negative ion) were examined to identify ions unique to quaternary ammonium compounds. The utility of a wide range of LSIMS matrix modifiers (positive and negative ionization modes) was investigated, as was TSP mobile phase modification with trifluoroacetic acid.

Experimental:

LSIMS spectra were obtained using VG 70VSEQ (hybrid) and VG Quattro (triple quadrupole) mass spectrometers. All compounds (0.1M, 1 µL) were analyzed in glycerol (neat or 5% aq.), with additives in a 1:1 molar ratio. Matrix additives investigated were: *p*-toluene sulfonic acid, potassium ferricyanide, potassium ferrocyanide, tetrabutylammonium dihydrogen phosphate, trifluoroacetic acid (TFA), sodium chloride, lithium iodide, trichloroacetic acid, and cobalt dichloride.

TSP spectra (positive and negative ion) were obtained using the VG Quattro; full scan and precursor ion spectra were generated from 0.5 mg/mL solutions (40:60 methanol:water, 0.1% TFA), introduced continuously into the ion source at 1 mL/min. Further studies were done, injecting 5 µg aliquots onto a guard column (AdSorbosphere C18, 5 µ particles), eluting with 100% methanol (0.2 mL/min.), makeup flow 0.4 mL/min. 3% TFA (aq.).

ESI^+ spectra (full scan and precursors of M^+ ions) were acquired using a Sciex API III triple quadrupole instrument, orifice voltage 35V and 150V. Samples were introduced via fused capillary, 10 µL/min., $1X10^{-4}$M in methanol.

Results/Discussion:

Full scan mass spectra of quaternary ammonium chlorides consistently exhibited abundant dimeric cluster ions at either $[2M^+$+anion$]^+$ (unique to quaternary ammonium compounds) or $[2M^+-H]^+$ (equivalent in mass to $[2M+H]^+$). These ions can serve as a "tripwire", or indication, that a compound has a quaternary ammonium structure. Precursor ion spectra of M^+ and $[M+H]^+$ ions were generated as "molecular weight confirmation scans", clearly establishing the ion relationships despite, in many cases, a considerable amount of chemical background. Addition of LiI and NaCl

yielded equivalent results, with $[2M+anion]^+$ ions formed only from quaternary amines not containing a carboxylic acid group (see Figure 1) and $[M^+-H+cation]^+$ or $[M+cation]^+$ ions formed from carboxylic acid-containing quaternary ammonium salts or neutral compounds. None of the matrix modifiers examined in $LSIMS^+$ experiments was useful in distinguishing between the carboxylic acid-containing quaternary ammonium compounds and neutral species.

$LSIMS^-$ experiments were needed for definitive distinction between neutral compounds and carboxylic acid-containing quaternary ammonium compounds. The most obvious feature is that none of the quaternary ammonium compounds studied form an ion at equivalent mass to the neutral species' $[M-H]^-$ (not formed by all neutrals). Two acidic protons would need to be present in a quaternary ammonium compound to form an ion at an equivalent mass to $[M-H]^-$. Matrix addition using trifluoroacetic acid gave consistently abundant cluster ions, but spectra were no more definitive than the positive ion experiments. However, addition of LiI showed consistent formation of an abundant $[M^+-H+I+LiI]^-$ for acid-containing quaternaries in approximately a 1:1 ratio with $[M^++2I]^-$, forming a doublet 6 amu apart. Other species showed only the $[M^++2I]^-/[M+I+HI]^-$ ions, and sometimes extremely weak ions at $[M^+-H+I+LiI]^-/[M+I+LiI]^-$.

Thermospray experiments were not promising for quaternary recognition. Precursor cluster ions ($[2M^++Cl]^+$ and $[2M^+-H]^+$) were observed only when extremely high concentrations of sample solution were infused directly into the mass spectrometer. Attempts to generate TFA adduct ions (5 µg/injection, 2% TFA) were not successful

Initial electrospray ionization experiments, which included a single example from each compound class, show promise for quaternary recognition. The two quaternary ammonium compounds studied (no carboxylic acid group) exhibited ions at $[2M^++Cl]^+$. Conversely, spectra of octanoyl carnitine chloride (a carboxylic acid-containing quaternary ammonium salt) exhibited $[2M^+-H]^+$ ions. No dimeric species was observed in ESI spectra of Ranitidine HCl, a neutral amine.

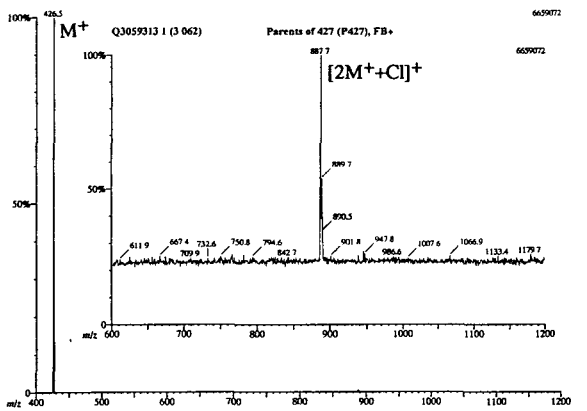

Figure 1. LSIMS+ molecular weight confirmation scan (precursors of M+, m/z 426) of methylbenzethonium chloride in the presence of a 1:1 molar ratio of NaCl.

Analysis of N-acetyl-cysteinyl-ursodeoxycholic acid in human bile by solid phase extraction and HPLC - cf-FAB detection.

R. Bagnati [1], E. Davoli [1], E. Zuccato [1], G. Galliani [2] and R. Fanelli [1].

SUMMARY

The new drug N-acetyl-cysteinyl-ursodeoxycholic acid (URSCYS), a bile acid analog, is under investigation for its effectiveness in dissolving gallstones. We present here a preliminary study on the metabolism of this drug in man. For the identification of URSCYS and its metabolites we developed a method involving purification of bile samples by solid phase extraction, and subsequent analysis by HPLC - cf-FAB, with a capillary split interface between the liquid chromatograph and the mass spectrometer. The method was able to identify and quantitate URSCYS, its metabolites glyco-ursodeoxycholic acid and tauro-ursodeoxycholic acid and all the major natural bile acids in their free and conjugated forms.

EXPERIMENTAL

Bile samples were extracted with silica-C_{18} cartridges and with columns packed with 0.5 g of piperidinohydroxy-propyl Sephadex LH-20, according to Goto et al. (Clin. Chim. Acta, **87**:141-7, 1978). This procedure allowed separation of different bile fractions, containing free, glyco and tauro conjugated bile acids. The purified extracts were dried and dissolved in the initial mobile phase for HPLC analysis (solvent A: ammonium acetate 0.01 M + ammonia 0.01 M + glycerol 0.8% / solvent B: methanol + glycerol 0.8%; 50:50, v/v) and separated with a C_{18}-analytical column, using a gradient elution from 50% B to 74% B in 12 minutes (0.4 ml/min flow rate). An UV detector (206 nm) was first connected at the end of the column and then a "capillary split" was used to interface the HPLC with the cf-FAB probe. The "capillary split" was made by using a zero-dead volume T-connector and deactivated fused silica capillaries as tubings. A 150 µm ID capillary (30 cm lenght) was used from the UV detector to the T-connector and a 50 µm ID capillary (240 cm length) was used from the T-connector to the cf-FAB probe. The third capillary connected to the T-interface was a 150 µm ID capillary (50 cm length) and was directed to waste. The split ratio of the T-interface was ca. 1:100, producing a 4 µl/min flow rate in the cf-FAB probe and an excellent stability of the signal. The mass spectrometer was a double focusing (EB optics) instrument, controlled by a Teknivent Vector 2 data system and equipped with a saddle field FAB gun which was operated with xenon at 7 kV and 1.5 mA discharge current. Detection of URSCYS and identification of its metabolites was made using full scan aquisition from m/z=200 to m/z=600.

RESULTS

Standard solutions of URSCYS and other bile acids were injected into the HPLC-cf-FAB system to acquire the relative retention times and FAB mass spectra. The cf-FAB mass spectra of URSCYS and of glyco and tauro conjugated bile acids showed the presence of protonated molecular ions and of other ions corresponding to the addition of NH_4^+, Na^+ or K^+ ions and to the loss of water molecules and of the conjugated aminoacid molecules. The retention times of the substances obtained with cf-FAB detection were about 3 min higher than those obtained with the UV detector. The delay was due to the time necessary for the samples to flow through the capillaries of the cf-FAB interface.

Human bile samples were collected from 1 h to 12 h after administration of a single oral dose of 1.5 g of URSCYS. In all samples the presence of URSCYS and of unconjugated ursodeoxycholic acid was not evidenced. Four natural bile acids (glyco-cholic acid, glyco-chenodeoxycholic acid, tauro-cholic acid and tauro-chenodeoxycholic acid, in their respective SPE fractions) were instead present at constant concentrations in all samples. The presence of two metabolites, identified as glyco-ursodeoxycholic acid and tauro-ursodeoxycholic acid, with increasing concentrations, was evidenced in the bile samples collected starting after 2 h and 30 min from administration (fig. 1). The identification was made by comparison with retention times and cf-FAB mass spectra of authentic standards of the substances (fig. 2).

The quantitation of the substances was made by comparison of the peak areas of the UV traces of samples and standards. Quantitation by cf-FAB mass spectrometry was not accurate because of the lack of a suitable internal standard.

CONCLUSIONS

The method here developed allowed the analysis of several bile acids by HPLC-cf-FAB detection. The operations of the cf-FAB interface and sources were relatively simple, reproducible and reliable. During a working day, after an initial conditioning time (about 1 h), the system did not require cleaning of the FAB probe or substantial re-optimization of the operating conditions.

The use of HPLC-cf-FAB detection with the capillary split connection described may be of great interest for the analysis of several substances difficult to analyze with other methods.

Mass Spectral Characteristics and Identification of Metabolites of Mesoridazine and Other Related Piperidine Type Phenothiazines

Ge Lin, G.McKay, E.M.Hawes and K.K.Midha, College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N 0W0.

Mesoridazine (I Fig. 1) is a piperidine-type phenothiazine antipsychotic agent. This drug (2-$SOCH_3$) and two related drugs of this class, namely thioridazine (2-SCH_3) and sulforidazine (2-SO_2CH_3, II Fig. 1) are extensively metabolized and the established metabolic routes include S-oxidation of the ring 2-substituent, aromatic hydroxylation and S-oxidation of the phenothiazine ring. Although metabolic oxidation of the piperidine ring to lactams and N-oxides might be predicted, the literature information concerning such metabolism is lacking.

In view of our recent interest in the lactam formation of piperidine-type phenothiazine antipsychotic agents, the metabolism of mesoridazine in rat after oral administration was investigated by mass spectrometry with various modes of ionization and plasmaspray HPLC-mass spectrometry.

Mesoridazine besylate was a gift from Sandoz Inc. All synthetic reference standards were synthesized in these laboratories. β-glucuronidase enzyme (also containing sulphatase activity) was from Sigma Chemical Company and the silylating reagent, N-methyl-N-(tert.-butyldimethylsilyl)-N-trifluoroacetamide (MTBSTFA) was from Pierce. HPLC grade solvents were from BDH Chemicals Canada Ltd. The metabolic study was carried out in Lewis rat (n=5), dosed orally with mesoridazine 20 mg/kg and the 0-24h urine collected. Organic extracts of urine samples were first chromatographed by HPLC. Fractions corresponding to the observed chromatographic peaks were collected, dried and analyzed by direct probe mass spectrometry using different modes of ionization. The identity of each metabolite was confirmed by comparison of its HPLC and mass spectral behaviour with that of authentic reference standards. Except sulfoxides the positive EI mass spectra of all other metabolites exhibited molecular ions (M^+) with high intensity, while sulfoxides gave very weak molecular ion signals. Other diagnostic fragment ions, such as the ion at m/z 112 corresponding to the piperidinone moiety for lactam metabolites, were also observed in this mode (Table 1). For negative EI mode an appropriate molecular ion (M^-) for each sulfoxide was observed as the base peak (Table 1). Pseudomolecular ions were observed for all compounds including sulfoxides in FAB. The FAB mass spectral profile of each metabolite was similar to that obtained from EI positive mode. PSI mass spectra of all metabolites gave the protonated molecular ions (MH^+) with high intensity but almost no fragment ion information. In the case of lactam metabolites, an adduct ion formed with diethylamine present in the HPLC solvent system formed the base peak (MH^++73) (Table 1).

The urinary extracts were also analyzed by in-line HPLC-MS using a plasmaspray interface. In all cases the identity of metabolites were confirmed by direct comparison of their retention times and mass spectral data with those obtained for synthetic standards (Table 2). The availability of authentic samples of putative metabolites of mesoridazine synthesized in these laboratories (Lin et al. J.Hetero.Chem.,28,215,1991) enabled definitive characterization of the isolated metabolites. The identification of phenolic metabolites were also examined by use of HPLC-MS after derivatization with MTBSTFA. The metabolites identified were sulforidazine (II), mesoridazine ring sulfoxide (III), sulforidazine ring sulfoxide (IV), N-desmethylmesoridazine ring sulfoxide (V), lactam of mesoridazine (VI), lactam of mesoridazine ring sulfoxide (VII), lactam of sulforidazine ring sulfoxide (VIII), hydroxylated sulforidazine (IX), con-jugated hydroxylated sulfo-ridazine (X) and conjugated hydroxylated

mesoridazine (XI). Figure 1 summarizes the metabolic profile proposed for mesoridazine in rat.

AUTOMATED INTERPRETATION OF BIOLOGICAL FLUID ORGANIC SAMPLES BY A BENCHTOP GC-MS.

James D. Shoemaker MD PhD, E.A. Doisy
Department of Biochemistry and Molecular Biology, St. Louis University School of Medicine, St. Louis, MO 63104

Most initial screening of urine samples for inborn errors of metabolism is performed on the isolated acidic fraction of urine by gas chromatography, with or without analysis of amino acids and carbohydrates by other means. We now report our experience with over 1000 samples screened by automated GC-MS. The method of sample preparation [J. Chromatogr., 1991, 562:125-138] allowed quantitation of untargeted and 159 targeted carbohydrates, amino and organic acids in each sample. Software to automate the interpretation of these samples was adapted to a low-cost, benchtop GC-MS.

A DOS-based program was written in the EPAL language supplied with the instrument, a FISONS MD 800. The program elicited entry of patient data and non-targeted library search parameters, and controlled the automatic sampler. During acquisition of data, the program identified TIC peak tops, matched the respective mass spectra against a library of over 1900 spectra of TMS derivatives of biological interest, and entered the name of the best match, the TIC peak area, height and other parameters in a dBASE-compatible data base. Adjacent peaks matching the same library entry were automatically combined. At the end of each run, the program printed a normalized TIC chromatogram, a list of "best matches" (with their fit parameter, area percent and area as a percent of creatinine area), a page for the analyst's interpretation headed by the patient data, and performed a targeted search of 159 peaks from 127 compounds. Concentrations were printed as millimoles analyte per mole creatinine. Creatinine itself was a major constituent of most samples and was itself quantitated in each run by isotope dilution of d_3-creatinine added as an internal standard. Finally, the program automated the transfer of the patient information and concentrations of 127 metabolites to a dBASE database. A menu-driven search program was created to retrieve the excretion rates of compounds according to diet, medications, diagnoses and other patient parameters.

Results from the benchtop instrument were comparable to results from the VG Trio 2 which was used for the initial screening of over 1000 clinical samples for inborn errors of metabolism. The benchtop instrument identified metabolites consistant with diagnoses including: medium chain acyl-CoA dehydrogenase (MCAD) deficiency, lysinuric protein intolerance, glycerol kinase deficiency, ornithine transcarbamylase deficiency (hetero- and homozygotes), homocystinuria, transferase galactosemia, methylmalonic acidemia, renal glycosuria, maple syrup urine disease, sialic acid storage disease, Canavan's disease, aspartylglucosaminuria and others.

The quantitation of amino acids and carbohydrates resulted in useful diagnostic information in about 20% of cases, and essential diagnostic information in about 1%. For example, 306 of 903 samples reviewed contained significant amounts of di- or monosaccharides. In 5% of the 903 samples, disaccharide was accompanied by intermediates such as 3,4-dihydroxybutyric acid (DHB) which may arise from bacterial fermentation of carbohydrate, suggesting inefficient assimilation.

One or more amino acids was abnormally elevated in 251 of 903 samples reviewed. In 58 cases the pattern of amino aciduria supported or suggested the diagnosis of renal or hepatic dysfunction. In 23 cases, kynurenine, formiminoglutamic acid or 3-methylhistidine were increased suggesting pyridoxine deficiency, folate deficiency or negative protein balance, respectively. Very high glutamate and/or glutamine excretion was found to accompany some cases of metabolic acidosis.

Metabolites of medications were found in 282 of 903 samples. The most common in descending order of frequency were: acetaminophen glucuronide, an unknown beta-lactam antibiotic metabolite, valproic acid glucuronide, isomaltose (a contaminant in i.v. dextrose solutions), chloral hydrate glucuronide, vitamins (including ascorbate, pantothenate, niacin, and 4-pyridoxic acid) and carbamazepine diol. Drug metabolites were of diagnostic significance in only one case when aspirin poisoning was the unsuspected cause of metabolic acidosis in a 2-week-old infant.

Very high levels of hexitols, including mannitol, inositol, galactitol and sorbitol were noted in 197 of 903 samples reviewed. Therapeutic use of mannitol or its presence in radiographic materials accounted for a minority of cases of mannitol hyperexcretion. A prospective study in adults has led to the hypothesis that these hexitols are produced as "compatible osmolites" in renal cells during periods of dehydration and hyperosmolarity, then excreted upon rehydration. However, hyperexcretion of hexitols was documented in only 14 of 38 cases where dehydration was part of the presenting complaint. Most samples were collected after fluid resuscitation.

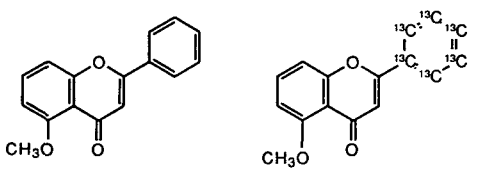
Laboratories which perform organic acid screening for the detection of inborn errors of metabolism may use gas chromatography alone as the initial screening tool. The cost-effectiveness of initial screening by GC-MS rather than GC alone was illustrated by comparing the cost of the automated GC-MS with the cost of a single ICU admission for a hypothetical "near-miss" Sudden Infant Death case due to MCAD deficiency. This diagnosis sometimes depends on detection of low concentration acyl-glycines which may be missed on gas chromatograms.

A Rapid GC/MS/MS Assay for 5-Methoxyflavone in Plasma

Timothy R. Baker*, Linda J. Tulich, Kenneth R. Wehmeyer, and Gary R. Kelm,
The Procter & Gamble Company, Miami Valley Laboratories, Cincinnati, OH, 45239-8707

In the course of drug discovery and development, analytical assays for various pharmaceutical candidates in biological fluids are required. These assays provide input for pharmacokinetic, toxicokinetic, and pharmacodynamic studies. Compounds must be quantitated in a variety of complex matrices such as plasma, urine, and feces. Matrix differences in the biological fluids of different species studied (e.g. rat, dog, human) are also a factor in developing an analytical assay. Often, a limit of quantitation in the low ng/mL range is required for these assays. During the course of the development of a successful drug, analysis of over 10,000 samples could be required.

The drug candidate 5-methoxyflavone (5MFL), currently under investigation, is shown below with its $^{13}C_6$-labeled internal standard (IS). Other analytical techniques like GC/MS or HPLC could be utilized for the analysis of a compound like 5MFL, however, there are a number of compelling reasons for using Gas Chromatography/Tandem Mass Spectrometry (GC/MS/MS). Firstly, the high degree of specificity and sensitivity afforded by MS/MS requires considerably less method modification (retention changes or cleanup) for different matrices. Additionally, distinct compounds of similar volatility can be determined with similar assays by simply modifying the MS/MS transition monitored.The 5MFL assay was quickly developed from GC/MS/MS procedures initially designed for quantitation of another flavone analog. In general, MS/MS detection reduces method development time. Also, a very high sample throughput is possible since significant chromatographic separation is not required. For this assay the GC is primarily an inlet system that separates the analyte from the solvent. Finally, the high degree of specificity reduces interferences and increases the level of confidence in the data.



Plasma samples (1.0 mL or 0.1 mL) were prepared using solid phase extraction techniques. GC/MS/MS experiments were conducted on a Finnigan/MAT TSQ700 tandem mass spectrometer, using an Rtx-5 capillary column. Analytes were ionized using standard electron ionization (EI) conditions. Product ions were created via collisionally activated dissociation (-20 eV) with 1.0 torr of argon in the second quadrupole.

The EI mass spectra of 5MFL and its stable isotope labeled analog had base peaks at m/z 252 and m/z 258, respectively. These peaks corresponded to the M+· of each compound. The MS/MS spectra of these precursors (also not shown) were dominated by peaks at m/z 223 and 206 (m/z 212 and 239 for IS). Of particular interest here was the abundant dissociation of the M+· ion to form an ion of m/z 206 (m/z 212 for labeled 5MFL). This

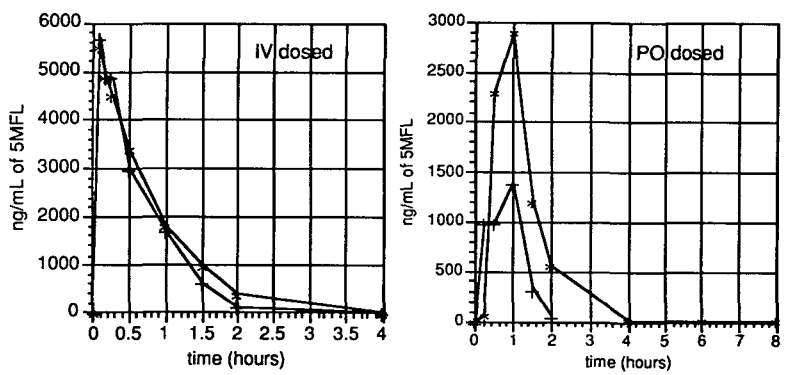
dissociation, or transition, was monitored for the selective detection of the two compounds (i.e., m/z 252 ---> m/z 206 and m/z 258 ---> m/z 212).

The determination of 5MFL (and $^{13}C_6$-5MFL) proceeds as follows. The plasma extract was injected (1 uL) into the gas chromatograph. The analytes eluted in about 4.5 minutes, directly into the ion source of the mass spectrometer and were subjected to electron ionization. Only molecular ions were allowed to pass through Q1. Fragmentation of these ions in Q2 created product ions, but only the product ions of m/z 206 (m/z 212 for IS) were allowed to pass through Q3 and strike the detector (electron multiplier).

The absolute recovery of the solid phase extraction process was validated with ^{14}C-5MFL. These recoveries ranged from 89-102%. The calibration curve used for the samples described here had a percent deviation of 5.05 and a correlation of 1.000 . To validate the method, blank dog plasma was spiked with varying amounts (50 to 1000 ng/mL) of 5MFL. The determined values ranged from 94-99% of the spiked amounts.

The assay has been utilized for several pharmacokinetic studies. Results of one of these is shown below. Previously generated total radiolabel plasma concentration data suggest that 5MFL is well absorbed in the dog and that the terminal elimination half-life of the radiolabeled species is over 200 hours. In contrast, the parent 5MFL plasma concentration data generated by these analyses indicated that the compound was rapidly cleared (extraction ratio greater than 0.9) with a terminal half-life of about 15 minutes. Bioavailability was variable, with values of 72 and 33% for the two dogs. Both of these values were in excess of the amount predicted by the clearance of the drug. One possible explanation is that first-pass metabolism was saturable. This could account for the variability observed in bioavailability.

The short plasma half-life of the compound and its rapid clearance suggests that additional work is needed to ascertain the duration of its pharmacological effects. If the duration of the pharmacological effects are similar to the plasma half-life, synthetic modifications to reduce the clearance of the compound to improve bioavailability and increase its plasma half-life and duration of action may be considered



Immunoaffinity Chromatography and GC/MS/MS for the Identification of Cross-reactants with an Immunoassay for Benzoylecgonine

Chad C. Nelson,[1] Jill Visor,[2] and Karen Fogerson[2]
[1] Northwest Toxicology, Salt Lake City, Utah 84124, [2] Syva Co., San Jose, CA 95161

Cocaine is readily metabolized in the human body to an array of products for which metabolic pathways have been extensively studied and reviewed.[1] In addition to cocaine metabolites, however, several cocaine structure-related natural products are commonly found in coca leaf extracts, and synthetic preparations are often characterized by numerous structural and optical isomers of cocaine. Although highly specific, immunoassays for benzoylecgonine, which is the major metabolic product of cocaine, are subject to minor levels of cross-reactivity with compounds structurally similar to benzoylecgonine. Following immunoaffinity chromatography, GC/MS has been previously used to confirm the presence of drugs.[2,3] The present study describes the combination of immunoaffinity chromatography and tandem mass spectrometry to provide a highly specific and selective means to identify and characterize components that exhibit interaction with the antibody of the immunoassay.

Mass spectra were acquired on a Finnigan TSQ-70 mass spectrometer using positive-ion CI with methane reagent gas. CID spectra were obtained using argon collision gas at 30-40% transmission of the incident protonated molecule at a collision energy of 25-40 eV. Immunoaffinity separations were performed using Syva polyclonal antibodies coupled to a CNBr-sepharose column. A urine sample was applied, then the column was washed with 55 mM Tris buffer (pH 8) with 50 mM NaCl. Analytes were eluted with 0.2M acetic acid (pH 2.6).

The Strategy used in the present study for characterizing possible cross-reactants with an immunoassay for benzoylecgonine involved the following: a) determine MS/MS scan functions which target possible structural modifications of benzoylecgonine and identify families of cocaine-related compounds, b) analyze benzoylecgonine-positive urine samples by GC/MS/MS for the presence of cocaine-related components, metabolites, and other natural products, and c) collect immunoaffinity-purified urine samples and analyze by GC/MS/MS to identify those components which specifically interact with the immunoassay antibodies. Initially, dissociation products resulting from collisional activation of protonated molecules of model compounds of benzoylecgonine (Figure 1), cocaine, and ecgonine methylester were studied. Several product ions and neutral eliminations common to the model structures were targeted and used to "screen" urine extracts by GC/MS/MS by utilizing specific parent and neutral-loss scan functions. For example, parent-ion analysis of *m/z* 82 and neutral-loss analysis of 122 u were used to identify components that have structural moieties of N-methylecgonine and benzoate, respectively. Parent-ion analyses of *m/z* 82 and 240 were the most informative experiements. GC/MS/MS analysis of several urine extracts revealed 11 different benzoylecgonine-related compounds and natural products. For example, The CID spectrum of meta-hydroxybenzoylecgonine is shown in Figure 2.

A previously unreported metabolite of cocaine, para-hydroxybenzoylecgonine (Figure 3), was identified in all of the urine samples analyzed and was confirmed by comparison with authentic standard. Meta-hydroxybenzoylecgonine was also present in all of the urine samples examined (Figure 3). Following immunoaffinity separation, parent-ion analysis of *m/z* 82 of the resulting eluent showed the presence of meta and para-hydroxybenzoylecgonines and *cis*-cinnamoylecgonine (a natural product) in all of the urine samples studied, demonstrating some level of cross-reactivity with the immunoassay for these compounds.

Microscale Chemical Reactions to Probe the Structure and Reactivity of Isolated Natural Products

Steven E. Klohr, Kevin J. Volk, Mike S. Lee, and Edward H. Kerns, Bristol-Myers Squibb
Pharmaceutical Research Institute, 5 Research Parkway, Wallingford, CT 06492

The structural diversity of biologically active natural products produced by plants and microorganisms provide challenging structure elucidation targets. This diversity often yields novel classes of compounds which posses a unique mechanism of action, providing important leads in the drug discovery effort. Our initial structure elucidation strategy involves the coordinated use of tandem mass spectrometry (MS/MS) and high resolution mass spectrometry (HRMS) to obtain detailed substructural information.[1,2]

In order to provide additional substructural information, we employ solution phase chemistry prior to mass spectrometric analysis. The insights obtained via MS analysis of various solution phase reactions complement those obtained in the gas phase. The specificity of this method allows for the evaluation of chemical reactivity, functional group identification, and provides detailed structural information that cannot be obtained from the isolated natural product. The sensitivity of mass spectrometric analysis enables these reactions to be performed with a few micrograms of material and characterized with little or no reaction workup. Furthermore, the small quantity of material required enables multiple reaction conditions and reagents to be evaluated early in the elucidation process when only limited quantities of material are available. The coupling of our existing structure elucidation protocols with this novel methodology provides further insights into the molecular structure of unknown natural products.

Here we demonstrate the role of microscale chemical reactions in the structure elucidation of natural products. This methodology is illustrated with the depsipeptides sandramycin and luzopeptin, the antitumor antibiotic kedarcidin and substance P. Our approach utilizes a systematic strategy with MS/MS and HRMS techniques for the substructure analysis of the isolated natural product. Reaction conditions are then selected to probe the structure or reactivity of the natural product with a few micrograms of material Full scan and MS/MS experiments are used to identify modified substructures of the reaction product and compare to the original compound.

Treatment of 5 ug of the depsipeptides luzopeptin and sandramycin with 10 ul of 0.1 M Na_2CO_3 and 10 ul of methanol for 3 hours hydrolyzed the esters linking the two substructures. MS/MS analysis of the protonated molecular ion provided sequence information that was not obtained from the MS/MS analysis of the cyclic parent species (Figure 1). The additional loss of 42 Daltons from the expected molecular weight of the luzopeptin product indicated the type of ester on the nitrogen heterocycle. The oxidation of 5 ug of the model thiol containing compound substance P with m-chloroperbenzoic acid, followed by MS analysis identified the site of oxidation (+16) as the methionine residue.

The reduction of the enediyne antibiotic kedarcidin [3] was performed with 5 ug of the kedarcidin chromophore in 20 ul of methanol for 30 minutes. The solution was evaporated to dryness and extracted with dichloromethane. Full scan Ionspray MS analysis indicated the addition of four hydrogens and MS/MS experiments localized this to the core (Figure 2). The reduction of two additional compounds in the extract indicated that these were also enediynes. Furthermore, the neutral loss of 144 (mycarose) was not apparent in the MS/MS spectrum of the unreduced material.

INTRODUCTION

The derivatization of vitamin D_3 metabolites with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) and their subsequent characterization by MS and MS/MS have previously been demonstrated[1]. A sensitive and unique ion transition has been identified and used for detection by multiple reaction monitoring (MRM). The transitions monitored are $MH^+ \rightarrow$ m/z 298 and $MH^+ \rightarrow$ m/z 314 (for A-ring hydroxylated metabolites). In the current work, an on-line capillary LC has been incorporated for sample introduction to the MS. The same ion transitions have been utilized for a variety of vitamin D_3 metabolites, and their detection limits and linearity by this method have been examined. Also, in a separate study, the increase in UV detectability due to the derivatization with PTAD has been investigated quantitatively.

EXPERIMENTAL

Chemicals: Vitamin D_2, D_3 and PTAD were purchased from Aldrich (Milwaukee, WI). All other metabolites were obtained from Hoffmann-LaRoche (Nutley, NJ). [26,27-^{3}H]25(OH)D_3 was purchased from Amersham (Arlington Heights, IL).

MS Conditions: All data were obtained on a VG Quattro triple quadrupole mass spectrometer (VG Biotech, UK). MS/MS was performed with a collision energy of 50eV and attenuation by Ar.

Capillary LC: A Carlo Erba Phoenix 30 capillary LC system (Fisons Instruments, MA) was operated on-line with the MS at 5μL/min in isocratic mode. A C_{18} (320μm I.D.) Fusica column (LC Packings, Switzerland) was used.

Analytical HPLC: A Waters 600E system with a 990 photodiode array detector (Waters Associate, Milford, MA) was employed. A C_8 (4.6mmx15cm) column (Rainin Instruments, Woburn, MA) was used. Wavelengths monitored were 226nm for the PTAD derivatives and 265nm for the metabolites.

RESULTS

(1) Figure 1 shows the MRM detection of 2 of the 4 vitamin D_3-PTAD derivatives examined at amounts near their detection limits (triplicate injections).

(2) Figure 2 demonstrates the specificity of MRM detection for metabolites that normally coelute (Fig. 2a, top: vitamin D_3-PTAD, 94pg; bottom: vitamin D_2-PTAD, 278pg) and/or isobaric (Fig. 2b, top: 24,25$(OH)_2D_3$-PTAD, 6.5ng; bottom: 1,25$(OH)_2D_3$-PTAD, 7.3ng). Triplicate injections were done in both situations.

(3) Figure 3 illustrates the increase in UV sensitivity of 25(OH)D_3 by PTAD derivatization. UV responses of labelled 25(OH)D_3 are compared before and after the reaction with PTAD. For the same amounts of sample, the UV sensitivity has been found to have increased by 5-fold after the derivatization.

CONCLUSIONS

The following has been achieved in our current work with vitamin D:

- The use of PTAD derivatization and capillary LC-MS/MS allows sensitive detection of the metabolites readily in the low to mid pg (mid to high fmol) levels;
- Specificity of MRM permits the distinction of isobaric and/or coeluting metabolites;
- The derivatization increases the UV response of the metabolites by 5-fold;
- The described method is applicable to synthetic metabolites such as Δ^{16}-1,25$(OH)_2D_3$-PTAD for which specific radioreceptor and protein binding assays are not yet available;
- Detection at physiologically relevant level has been achieved for all the test compounds except for 1,25$(OH)_2D_3$.

Determination of Cortisol in Human Plasma by Gas Chromatography/Negative Ion Chemical Ionization/Mass Spectrometry

*Fong-Fu Hsu, Liezhen Wang and Dennis M. Bier
Department of Medicine, Washington University School of Medicine
St. Louis, MO 63110

The reported GC/MS methods for the determination of cortisol in humans required complicated derivatization procedures. Moreover, only a limited sensitivity of 2 pmol (s/n = 3) can be achieved [1-2]. Quantification of daily cortisol production rate using thermospray liquid chromatography/mass spectrometry (LC/MS) has also been reported. Nevertheless, the method inherited the instability of a LC/MS, and the detection was limited to 5 pmol (s/n = 5) [3-4].

We developed a simple and sensitive method using negative ion chemical ionization capillary GC/MS detection by selected-ion-monitoring (SIM) of the molecular ion of cortisol-pentafluoropropionic acid ester. This method utilized readily available d_4-cortisol as an internal standard, a simple procedure for sample clean-up, and a single step for sample derivatization. A cortisol amount as low as 0.02 pmol (s/n > 10) can be easily detected. This detection method also allows precise determination at isotope ratio of 1 to 5 %, and therefore it can be potentially used in the quantification of cortisol production in humans, including infants and children where plasma sample volume is limited.

The derivatization of cortisol with HFB/acetonitrile or PFP/acetonitrile (50:50 v/v) at room temperature yields three compounds which can be separated easily and identified by GC/MS The mass spectra of the major component (93 %) and its d_4-labelling counterpart are shown in figure 1 (panel A and B).

Selected-ion-monitoring performed by simultaneous recording of m/z 782 for cortisol-PFP and m/z 786 for d_4-cortisol-PFP (M^- ion for both compounds) prepared from a 0.1 ml plasma (with 10 pmol addition of d_4-cortisol) is shown in figure 2. The linearity of the method can be shown from the area-response ratio of cortisol-d_0/cortisol-d_4 ranged from 0.1-10 pmol of cortisol (figure 3A). The correlation coefficient for the data exceeded 0.98 for five measurements.

Results obtained from different measurements are summarized in table 1. Table 1 also shows the amounts of cortisol added are in agreement with the amounts of cortisol measured. The standard curve plotted for 1 % to 10 % mole ratios of d_4/d_0 cortisol-PFP (n=5) after correction of the M + 4 ion current area contributed by natural isotopic abundance of unlabelled cortisol (0.138 %), is shown in figure 3B. The linearity of the detection method demonstrates that it could be used to quantify cortisol production in humans if d_4-cortisol were used as a tracer and infused intravenously at a constant rate to achieve a circulating isotopic enrichment between 1 and 5 mole % excess d_4-cortisol. Furthermore, the ability to precisely quantify isotope enrichment in plasma samples of 0.1 ml makes the method applicable to infants and children.

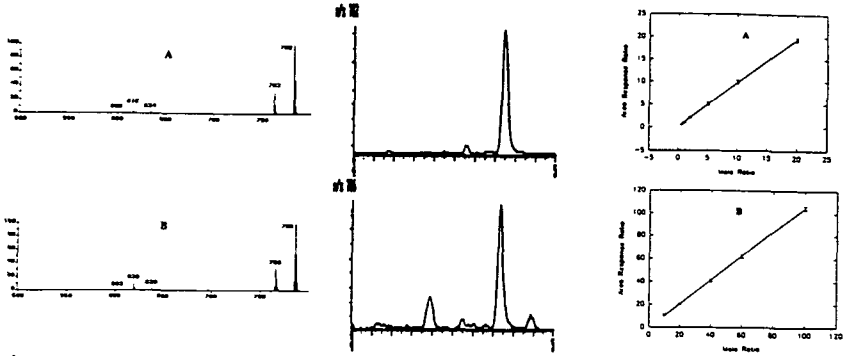

Figure 1. The NCI mass spectra of d_0- (panel A) and 9,11,12,12-d_4- (panel B) 3,11,21-tris(pentafluorobutyryl)-2,4,16-pregnatrien-20-one.

Figure 2. The SIM chromatogram of the PFP derivative prepared from a 0.1 ml plasma sample (with 10 pmol addition of internal standard).

Figure 3. Standard curve obtained by plotting relative area between unllabelled and labelled cortisol-PFP ion vs. the expected ratio. Curve A: plotted from 0.1-10 pmol injection of cortisol with 0.2 pmol of d_4-cortisol; Curve B: plotted from isotope ratio ranged between 1 and 10 mole % excess of d_4-cortisol.

TABLE 1. Accuracy of cortisol measurement in human plasma

Amount added (pmol)	Average amount measured (pmol)		
0.0	*35.6 ± 0.8;	27.1 ± 0.3;	31.6 ± 1.7
10	46.7 ± 0.5;	36.7 ± 1.6;	42.8 ± 0.9
20	55.4 ± 1.4;	45.7 ± 1.5;	54.4 ± 0.3
50	84.6 ± 0.6;	77.9 ± 1.9;	83.9 ± 1.5
100	132.8 ± 1.6;	**	134.7 ± 1.3

Each amount added was extracted in triplicate. The average amounts listed above were expressed in pmol/0.1ml plasma.
* Average amount of four measurements from the plasma pool of three different male subjects. ** not measured.

The Rapid Structure Characterization of Synthetic and Natural Products by FAB-Mass Spectrometry using Na^+ and K^+ Salts

*J.L. Whitney, S.E. Klohr, K.J. Volk, E.H. Kerns, M.S. Lee, Bristol-Myers Squibb Pharmaceutical Research Institute, 5 Research Parkway, Wallingford, CT 06492

The structure characterization of synthetic and natural products by mass spectrometry at Bristol-Myers Squibb typically involves the use of fast atom bombardment (FAB) ionization. Paramount to this characterization effort are the quick and efficient production of abundant molecular ions for molecular weight determination and diagnostic fragment ions for substructural information.

Traditionally, the molecular weight determination of an unknown natural product or unexpected synthetic product involves multiple analyses. Initial analyses often include sample and matrix only to look for potential $[M+H]^+$ ions. Subsequent analyses involve the addition of solid NaI or KI to the sample/matrix solution. Several separate analyses can be time consuming and not reproducible. Furthermore, the addition of salt in this manner does not guarantee an optimal amount present in the solution. Although salts have frequently been used for molecular ion confirmation and enhancement[1,2], their role in substructural characterization has not been commonplace.

We have developed a rapid characterization protocol utilizing a standard methanolic NaI/KI solution which is added to the probe prior to sample and matrix addition. This results in the consistent addition of a reproducible and optimal amount of salt. The optimal amount of salt present enhances molecular adduct ions, avoiding the problem of a "false negative" which can result from compounds which do not form $[M+H]^+$ ions. In addition to ion enhancement, radical ions are distinguished easily from protonated molecular ions when adduct ions are produced.

Structural information can also be obtained by unique functional group identification. Figure 1 illustrates the salt adduct pattern of etopiside phosphate. Notice the observation of all combinations of mono-and di-salt association, indicative of the phosphate group. These ion species and ratios are consistent and quite reproducible for many different classes of compounds containing a phosphate or carboxylic acid moiety.

Substructural characterization is possible since certain, often class specific, diagnostic fragment ions exhibit salt adduct ions. A class specific salt adduct substructural "template" for use in structure elucidation and confirmation can be generated. Figure 2 shows the salt adduct "fingerprint" of taxol. This pattern serves as a "template" by which other related taxane spectra can be compared to elucidate unique substructural fragments. This substructural "template" approach was used to characterize a mixture of two taxanes, 10-desacetyl taxol and taxol (figure 3). Molecular ion and sidechain and core substructural regions were "tracked" by identifying their respective Na^+ and K^+ adduct ions, differing by 16 daltons. The molecular ion region indicates a molecular weight difference of 42 daltons. By examining the core and sidechain fragment regions, the 42 dalton difference is localized to the core region. This is consistent with the expected structures of the two compounds.

The utility of this protocol for the rapid characterization of synthetic and natural products was illustrated with the antitumor compounds 10-desacetyl taxol, taxol and etopiside phosphate. The capability of identifying $[M]^+$ and $[M+H]^+$ formation, unique functional groups and fragmentation patterns was illustrated. A salt adduct substructural "template" approach was introduced and shown to be useful for elucidating unknowns, identifying components in mixtures, and characterizing expected reaction products.

INTRODUCTION

Elevated total phospholipid levels in CSF have been found in various diseases of the central nervous system (CNS)[1]. The commonly used method for analysis of CSF phospholipids is normal phase HPLC[2]. Although HPLC provides separation and quantitation of the components, no information is available concerning the number, type or structure of the individual molecular species within the phospholipid classes. Fast atom bombardment mass spectrometry (FABMS) combined with tandem mass spectrometry (FABMS/MS) has proven to be a valuable technique for analysis of phospholipid mixtures[3-5]. In this work, FABMS and FABMS/MS were used for analysis of CSF phospholipids to identify markers of neurotoxicity associated with cancer treatment in children.

METHODS

Sample preparation: The lipids are extracted from 1 ml of CSF and separated by normal phase HPLC[2]. The crude extracts were dried under N_2.

FABMS and FABMS/MS analysis was performed on a four sector instrument of BEBE geometry (AMD Intectra, Harpstedt, Germany) operating at an accelerating voltage of 6 kV in both the positive and negative ion detection modes. Data acquisition and instrument control were accomplished using two SAM 68k computers (KWS Computersysteme, GmbH, Ettlingen, Germany). The mass range was scanned from m/z 90-2000 at 60 sec/decade at resolution 2000. The dried HPLC fractions or crude extracts were dissolved in 5 μl $CHCl_3$ and 1 μl of the solution was mixed with 1 μl of m-nitrobenzylalcohol and placed on the target at 8°C. FABMS/MS spectra were obtained in the following manner: (1) precursor ions were mass selected with MS1 and linked B/E=const scans were performed using MS2. Collision-induced dissociations (CID) occurred in the third FFR with argon at a pressure sufficient to attenuate the precursor ion beam by 50%; (2) precursor ions were selected with B1 and Mass Analyzed Ion Kinetic Energy Spectra (MIKES) were acquired using MS1.

RESULTS

Treatment of childhood leukemia with methotrexate (MTX) may be associated with CNS cell membrane damage which is expected to induce changes in CSF phospholipid composition[6]. To investigate the effect of the MTX treatment on the CNS and to find markers of the cell membrane damage a series of patient CSF samples have been analyzed by normal phase HPLC and FABMS. Positive FABMS and MIKES was used for identification of diacylglycerol (DAG), phosphatidylcholine (PC) (Fig. 1) and lysophosphatidylcholine (LPC) fractions. MIKES of $[M-Me]^-$ for the most abundant PC molecular species (m/z 761, Fig. 1) in negative FAB ion mode was used for characterization of the type and the position of the fatty acid residues (Fig. 2). The presence of DAG and LPC is in agreement with the expected MTX treatment-related increased CNS cell membrane lipolysis, probably a result of activation of the phospholipases A_2 and C.

We analyzed a crude lipid extract of patient CSF using FABMS (Fig. 3). PC and sphingomyelin (SM) are the predominant molecular species possibly a result of the suppression effect under static FAB conditions. Four sector B/E=const linked scans were performed for characterization of the main PC (m/z 761, Fig. 4) and SM molecular species.

CONCLUSIONS

The application of FABMS and FABMS/MS analysis, in combination with normal phase HPLC, of human CSF phospholipids enables: **(1)** identification of the phospholipid classes; **(2)** identification of the various molecular species in the class of phospholipids; **(3)** structural characterization of the individual molecular species; **(4)** investigation of the mechanism of the cancer treatment related neurotoxicity in children.

FABMS and FABMS/MS analysis of total CSF lipid extracts provide characterization of only the major phospoholipid classes.

Quantitative Determination of Hydroxybutorphanol and Norbutorphanol in Human Plasma by GC/ECCI/MS

Daniel E. Mulvana
Bristol Myers Squibb, Pharmaceutical Research Institute
Syracuse, NY 13221

Butorphanol (**III**, Figure 1) is a synthetic opioid[1] indicated for the relief of moderate to severe pain. At the low transnasal doses administered (1 mg), the expected plasma Cmax is 1-2 ng/ml. Plasma levels of the metabolites hydroxybutorphanol (**I**, Figure 1)and norbutorphanol (**II**, Figure 1) are expected to be considerably less than this. Thus, a very sensitive assay was needed for the determination of complete plasma pharmacokinetic profiles of the metabolites. An assay method was developed which fulfilled this requirement by incorporating solid phase extraction, derivatization, and separation and detection by capillary gas chromatography-electron capture chemical ionization-mass spectrometry (GC/ECCI/MS). The assay will be used in conjunction with a separate assay for the parent drug.

Plasma samples (0.5 ml) containing butorphanol and the metabolites were diluted with 0.5 ml 10 mM ammonium acetate, pH 6.0. The internal standard (**IV**,Figure 1) was added and the samples were transferred to Bond Elut® CN-N extraction columns. Following two washes with buffer and one wash with 70% acetonitrile in water, the compounds were eluted with 1% triethylamine in acetonitrile with extraction recoveries of 73% for **I** and 64% for **II**. After removal of the elution solvent under nitrogen, the compounds were derivatized in a glove bag under a dry nitrogen atmosphere by adding 100 µl of 5% trifluoroacetic anhydride in ethyl acetate, capping and vortexing the tubes, and allowing them to remain at ambient temperature for 1 hour. The solvent was removed under nitrogen and the sample was reconstituted in 20 µl of toluene.

Separation and detection were accomplished using a Hewlett-Packard 5988A mass spectrometer interfaced to an HP 5890 Series II gas chromatograph. The processed samples (3 µl) were injected in the splitless mode onto a 15m DB-1 (0.25 mm ID, 0.25 µm film thickness) GC column at an injection port temperature of 285 °C. The initial oven temperature was 150 °C and was ramped at 25 °C/min to a final temperature of 310 °C for 2.1 min. The base peak was the trifluoroacetate anion (m/z 113) for all compounds (Figure 2). However, the signals from the molecular anions of both metabolites were sufficient to enable good sensitivity in the selected ion monitoring (SIM) mode. The derivatized compounds were detected by SIM of ions 451.0 for **II**, 631.0 for **I** and 505.0 for the internal standard. The ion source temperature was 120°C and methane was used as the buffer gas at a pressure of 0.75-0.85 Torr.

The assay was linear over the desired concentration range of 20 -1000 pg/ml for **I** and 50-1000 pg/ml for **II**. All standard curves from the validation (n=5) had r^2 values of ≥ 0.991 for **I** and ≥ 0.985 for **II**. The derivatives were stable in the cooled (~10°C) autosampler tray for at least 24 hours. Analysis of replicates (n=5) of plasma quality control (QC) samples at concentrations of 192, 580, and 868 pg/ml over three separate days showed the assay to be precise and accurate. For the hydroxybutorphanol assay, intra- and inter-assay precisions (%RSD) were within 9% and the grand mean predicted concentrations for all QC samples deviated from the nominal by less then 5%. Intra-assay QC deviations were all within 11%. For the norbutorphanol assay, intra- and inter-assay precisions (%RSD) were within 8% and the grand mean predicted concentrations for all QC samples deviated from the nominal by ≤ 6%. Intra-assay QC deviations were all within 13%.

The results show that the assay is sensitive, specific, precise, accurate, and reproducible and is expected to be sufficient for accurate determination of **I** and **II** in human plasma.

The Characterization of Abscisic Acid Metabolites Using Packed Fused Silica Capillary Liquid Chromatography/Continuous Flow Secondary Ion Mass spectrometry

L.R. Hogge, D.J.H. Olson, G.D. Abrams, and D.L. Barton, National Research Council of Canada, Plant Biotechnology Institute, Saskatoon, Sask. Canada S7N 0W9

INTRODUCTION:

Oxidation of the plant hormone abscisic acid (ABA) by plants is known to give rise to two isomeric alcohols, 7'-hydroxyabscisic acid (7' OH ABA) and 8'-hydroxyabscisic acid (8' OH ABA), the latter of which readily isomerizes to a third isomeric substance, phaseic acid (PA). A method has recently been developed in our laboratories which generates 8' OH ABA in solution from PA (unpublished), and we have sought an analytical technique for the separation and characterization of mixtures of the three isomeric metabolites that could be applicable to extracts of plant material.

. This report describes methodology developed in this laboratory utilizing packed fused silica capillary LC in conjunction with continuous flow secondary ion mass spectrometry for the separation and characterization of these isomers. The report includes the observed differences in the individual isomers SIMS and CID product ion spectra.

EXPERIMENTAL:

All LC analyses were done using an Applied Biosystems Model 140A solvent delivery syringe pump. Samples (1 microliter made up in 25% acetonitrile in water) were injected through a Rheodyne Model 7520 injector onto a reversed phase spherisorb 3 micron C18 ODS2 packed fused silica capillary column prepared in this laboratory .

The mobile phase used for the LC analyses consisted of the following:

Solvent A 0.1% TFA; 2% glycerol in 80% acetonitrile.

Solvent B 0.1% TFA in 2% glycerol

Elution was achieved by using gradient conditions (described below) at a flow rate of 3 microliters/min. The gradient elution program as follows: 85% B for 3 min, then decreased to 72% B in 15 min, held for 5 min and decreased to 30%B after 40 min

The LC system was interfaced to a VG Analytical 70-250 SEQ hybrid mass spectrometer equipped for continuous flow SIMS analysis. The continuous flow SIMS stainless steel frit probe tip was designed in this laboratory . The probe tip was maintained at 50 degrees C. Spectra were obtained by scanning from m/z 500 to 80 (resolution of 1000 10% valley) at a rate of 3 sec/decade with a 0.5 sec. delay.

Product ion spectra were acquired by scanning from 50 to 500 every 3 sec. Xenon was the collision gas used at a pressure of 8 $X10^{-5}$ Torr. The collision energy was 16 volts (laboratory frame).

RESULTS AND DISCUSSION:

Phaseic acid, 7' OH and 8' OH ABA could not be separated (with this LC hardware) using isocratic LC conditions. However, employing the above gradient elution completely resolved the isomers. Figure 1 shows the chromatogram obtained from the analysis of a synthetic mixture containing the three isomers.

The CF/LC/SIMS spectrum obtained for each isomer is presented in Figure 2. The three spectra are similar, all having intense ions at m/z 373 indicating the glycerol adduct ion, m/z 281, the protonated molecular ion and m/z 263, the protonated molecular ion - H_2O. However, the spectrum of PA contains a fragment ion at m/z 165 that is not observed in the spectra of either 7' OH or the 8' OH ABA. This ion could be formed as a result of the loss of water from the 1' position and a subsequent loss of a rearranged portion of the side chain, resulting from cleavage between carbons 4 and 5. The spectra of 7' OH and 8' OH ABA both contain an ion at m/z 233 which is not observed in the spectrum of PA. This ion is postulated

to be formed as a result of the loss of methanal and water from the protonated molecular ion. In the spectrum of 8' OH ABA, the protonated molecular ion is the base ion while in the 7' OH ABA spectrum the molecular ion - H_2O is the most intense ion.

The collision induced dissociation (CID) product ion spectrum of the protonated molecular ion was also recorded for each isomer. Although the CID spectra, shown in Figure 3, contain many of the same intense ions as the LC/SIMS spectra, such as m/z 263, the protonated molecular ion - H_2O, m/z 165 in the PA spectrum and m/z 233 in the 7' OH and 8' OH ABA spectra, they are distinct from each other.

These mass spectral data along with the retention data allow the analyst to distinquish the isomers from each other. It should be noted that although the CID product ion spectra are somewhat different for each of these isomers, chromatographic separation of isomeric mixtures in conjunction with MS/MS provides much more reliable data.

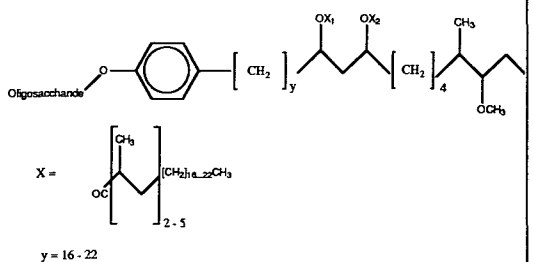
A MASS SPECTROMETRIC STUDY OF PHENOLIC GLYCOLIPIDS

A.I. Mallet[¶], D.E. Minnikin*, S. Hartmann* & M. Riddel[‡]l. St John's Institute of Dermatology[¶], UMDS, University of London, London SE1 7EH, UK, Dept pf Chemistry*, University of Newcastle upon Tyne, NE1 7RY, UK and Dept. of Medical Microbiology[‡], University of Gothenburg, S-41346, Sweden.

INTRODUCTION

Certain mycobacteria synthesise the dimycocerosic acid esters of 1,3 diols, the glycosylphenolphthiocerols, leading to the so-called phenolic glycolipids (PGL). Figure 1 shows the structures of these compounds and, apart from the stereochemical isomerism possible, there are a number of possible components according to the values of chain lengths present (x and y in the structures) and of the number of branched methyl groups on the mycocerosic acid side chains.

FIGURE 1. Phenolic glycolipid.



We report here the results of a study using FAB (LSIMS) MS in which we have surveyed families of PGL from a number of species and where we have determined the size of the mycocerosic acid chains. Confirmation of the substitution patterns has been obtained by tandem hybrid MS-MS. We have also investigated the use of MALDI-TOF mass spectrometry for analysis of the molecular species present.

METHODS.

Lipids were extracted by aqueous methanol:petroleum (1) from the dried organisms. Purification was carried out by silica gel chromatography.

Mass Spectrometry was performed on a VG Analytical (Fisons Instruments, UK) VSEQ hybrid tandem mass spectrometer. All spectra were obtained with a Cs gun operated at 30 kV and the sample (approx. 1 µg) was applied to a matrix of m-nitrobenzoic acid/methanol containing 0.1% NaI. MS -MS was carried out using a collision gas pressure of 2×10^{-6} torr (indicated) of Xenon in the Rf-only cell and a 20 ev collision energy (laboratory frame of reference). All spectra were collected in the continuum mode.

RESULTS

The PGL do not give protonated molecular ions by FAB ionisation and it is only by the formation of the sodiated (2) (or other alkali metal ion) species that a quasi-molecular ion can be detected. Clear spectra for mixtures of the molecular species present are obtained and these spectra also contain weak fragment ions corresponding to the successive loss of saccharide and of one mycocerosic acid side chain.

Table 1 summarises the species we have identified in a number of Mycobacteria and the tentative identification of the side chain lengths from the fragment ions present in the spectra.

In the case of *M. tuberculosis* (Canetti) we have been able to correlate the above identifications with the presence in the MS-MS spectra of two or three signals according to the presence of

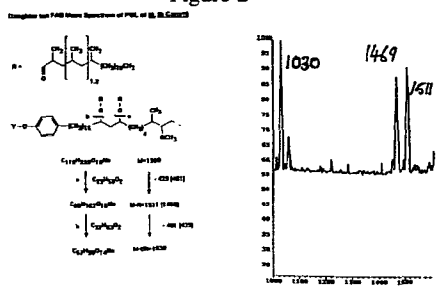
TABLE 1

Species	M+ + Na	M- - olig	M- - olig - f.a.	C atoms in phenol unit	C atoms in mycocerosate
M. tuberculosis	1905, 1922 1850	1411 1454	952	Y=16	29
M. bovis	1488, 1530 1572	1828 1418	910 952	Y=16	26 29
M. marinum	1572 1586 1602	1418 1440	980	Y=18	29
M. kansasii	2134 2149 2178	1553 1524 1567	-	—	—
M. ulcerans	2105 2049 2079	1524	994 1022 1050	Y=16	30 32 34

a symmetrically or unsymmetrically substituted pattern of the mycocerosic acid side chains -X in Fig. 1- (Figure 2). These results extend the discovery of symmetric patterns of substitution found by PDMS in this organism earlier (3).

Off-line collection of HPLC fractions serves to show the nature of the isomers present with separation of species with differing number of branched chain methyl groups being specially difficult.

Figure 2



We have also carried out a preliminary study of these PGL mixtures using MALDI-TOF mass spectrometry. In an esculetin matrix clear signals, again from M. tuberculosis (Canetti) are obtained for the molecular ion region (M + Na)+.

DISCUSSION

While we have made advances towards the molecular speciation of this family of compounds three important questions still remain to be answered.

1. What is the precise configuration of attachment of the mycoserosate side chains?
2. Can a distinction be made between the isomeric esters of the trimethyl-branched C_{29} and the tetramethyl-branched C_{30} mycocerosates?
3. Can the stereochemistry be determined?

We are attempting to develop an on-line continuous flow FAB system, using non-aqueous solvent systems, so as to be able to carry out HPLC separation directly linked to the mass spectrometer and in the hope that this will provide a long lasting stable ion beam from which MS-MS measurements can more easily be performed in both positive and negative ion modes.

ACKNOWLEDGEMENTS.

We thank Dr David Harvey for the MALDI-MS spectra.

The Characterisation of Lipophilic Peroctylated Cyclodextrins by Electrospray Mass Spectrometry (ESMS).

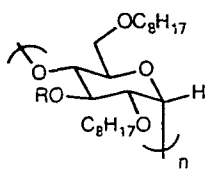
D. Parker and P.S. Bates, Dept. of Chemistry, University of Durham, South Road, Durham, DH1 3LE, UK. and B.N. Green, Fisons Instruments, VG Biotech, Tudor Road, Altrincham, Cheshire, WA14 5RZ, UK.

Lipophilic per-octyl cyclodextrins (CDs), when incorporated into an electro-active membrane, have been used as ionophores in enantioselective sensors for β-arylamino-alcohols. They contain a cavity which is size-selective for the binding and detection of tetrahedral ammonium ions. Hitherto, these compounds have been characterised by FDMS, but gave variable relative intensities for the various alkylated species. Methods involving NMR and DCI following reductive depolymerisation were reproducible but indirect.

Here we show that per-octyl α-, β- and γ-CDs may be characterised directly by ESMS, and the formation of complexes with various cations demonstrated. Furthermore, the selective binding behaviour of these CDs towards a variety of cations may be observed directly in competitive experiments by analysing them with mixtures of the cations in solution.

The water insoluble CD derivatives were analysed on a VG Quattro-BQ, a quadrupole instrument with a mass range of 4000 for singly charged ions. Of various solvents tested, 2-propanol containing 10 mM NH_4OAc gave intense, stable and reproducible spectra of the NH_4^+ adducts, suitable for characterisation, at concentrations of 20-50 pM/μl. Similar solutions containing various cation mixtures were used to study the competitive complexation phenomena. Mass scale calibration employed the NH_4^+ adducts from PPG3000 (1 μg/μl CH_3CN/H_2O plus 1 mM NH_4OAc). Masses were measured as average values based on the atomic weights of the elements .- C=12 011, H=1.00794, N=14.00674 and O=15.9994.

The α-, β- and γ-CDs contain 6, 7 and 8 glucose units resp. in a ring structure Incomplete octylation of the hydroxyls (3 per glucose), leaves a variable number of residual hydroxyls in the 3-position of the glucose units Methylation of the per-octyl CDs occurs on these residual hydroxyls to give the methyl-capped per-octyl CDs.



n=6 for α-CD
n=7 for β-CD
n=8 for γ-CD

R=H or C_8H_{17} for per-octyl CDs
R=CH_3 or C_8H_{17} for methyl-capped CDs

In Fig. 1 are spectra which illustrate the characterisation of per-octyl β-CD and methyl-capped per-octyl β-CD. They clearly show the distribution of species due to incomplete octylation of the CD. Good agreement for the mean number of octyls incorporated into all three CDs was obtained between ESMS and the less direct methods involving reductive depolymerisation Finally, Fig. 2 shows the response of per-octyl α-CD in a competitive experiment between a mixture of 0.2 mM ephedrinium trifluoroacetate and 10 mM NH_4OAc in 2-propanol. It shows that the selectivity for binding the ephedrinium ion is about 150 times higher than for the NH_4 ion.

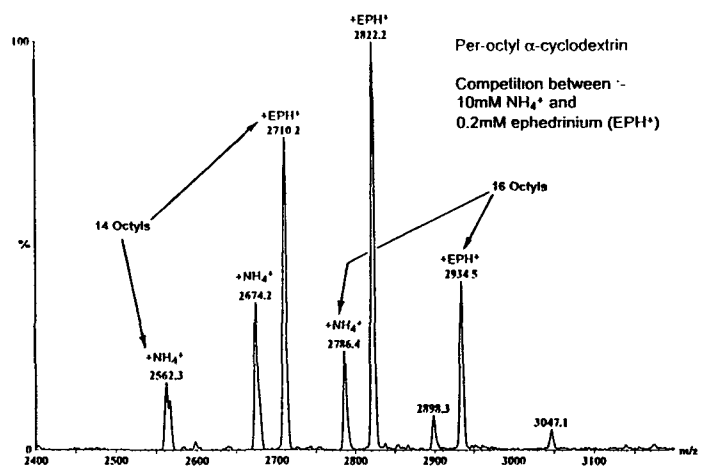

Fig. 2. Competitive binding of ephedrinium$^+$ and NH_4^+ with per-octyl α-CD.

Characterization of chemically-modified Cyclodextrins and their Host-Guest Complexation with Drugs by Ion Spray Mass Spectrometry.

H. K. Lim[1,2], K. Chan[1], M.Y. Zhang[1] and J.D. Henion[2], [1]Wyeth-Ayerst Research, CN 8000, Princeton, NJ 08543 and [2]Drug Testing and Toxicology, Cornell University, Ithaca, NY 14850.

Chemically modified cyclodextrins are cyclic oligosaccharides consisting of 6,7, or 8 α 1,4-linked glucose units which have undergone nonselective hydroxy chemical modifications. As a result, multiple species with various substituents are present which pose tremendous challenge to separation and characterization. These chemically modified cyclodextrins have a wide range of pharmaceutical use including enhancing solubility and separation of chiral drugs. The basis for these properties is related to the ability of these chemically modified cyclodextrins to form host-guest inclusion complexes with drug molecules. Substituents such as 2-hydroxypropyl or sulfate groups in varying numbers have been attached to the cyclodextrin molecules. Although 2-hydroxypropyl-β-cyclodextrin (HP-β-CD) has been characterized by electrospray MS, the number of substituents was not established (1).

We are interested in the full characterization of these modified cyclodextrins and their host-guest inclusion complexes by ion spray MS. The positive ion mass spectra of 2-HP-β-CD and 2-HP-γ-CD obtained at a mild declustering potential of 30V contained predominantly doubly charged ions corresponding to protonation of the cyclodextrins. In each case, the doubly charged ion cluster indicates the presence of 2-11 and 2-12 of 2-hydroxypropyl groups on the 2-HP-β-CD and 2-HP-γ-CD, respectively. Figure 1 is the positive ion mass spectrum of the 2-HP-β-CD containing species with 2-11 of 2-hydroxypropyl groups. The negative ion mass spectra of sulfated α-, β- and γ-cyclodextrins are characterized by three ion clusters with 3-5, 4-6 and 5-7 negative charges, respectively. These ion clusters indicate the presence of 5-11, 6-13 and 10-18 sulfate groups on α-, β- and γ-cyclodextrins, respectively. Figure 2 shows various species (6-13) and charge states (4-6) of sulfated β-CD.

Host-guest inclusion complexes have been observed with either 2-HP-β-CD or 2-HP-γ-CD and amine drugs like isoproterenol and atenolol. The mass spectra of host-guest complexation of either 2-HP-β-CD or 2-HP-γ-CD with isoproterenol or atenolol show the protonated drug molecule and the doubly charged ion clusters from protonation of the cyclodextrins and their respective complexes such as (drug)-cyclodextrin and (drug)$_2$-cyclodextrin. That host-guest inclusion complexes were not artifacts of the ion spray process is suggested by the presence of complexes even after centrifugal filtration with molecular weight cut-off of 1000 (figures 3). Futhermore, that the particular ions are indeed complexes is supported by MS/MS experiments which show the dissociation of the complexes into their respective protonated guest and host (Figure 4).

The application of electrospray ionization mass spectrometric techniques (ESI-MS) for the determination of the primary sequence of proteins has found widespread utility. However, only recently have these techniques been extended to the characterization of the oligosaccharide moiety of glycoproteins. Avidin a commercially available and relatively inexpensive glycoprotein was chosen as a test compound to evaluate the application of ESI-MS techniques to the characterization of glycoproteins.

The active form of Avidin a 60,000 Da. glycoprotein is a tetramer of 4 identical subunits[1]. The 128 residue primary sequence proposed by DeLange and Huang was confirmed by mass mapping and tandem mass spectrometric sequence analysis of proteolytic digests after enzymatic cleavage with endoproteinase Lys-C and removal of the carbohydrate moiety with N-glycosidase F. Comparison of results before and after N-glycosidase F incubation confirmed that the carbohydrate moiety was attached at Asn-17. A minor variant with Thr rather than Ile at position 34 was identified by tandem mass spectrometry as illustrated in Figure 1.

ESI-MS analysis of avidin revealed extensive sample heterogeneity, as illustrated in Figure 2. At least 16 different glycoforms were detected for the avidin subunit ranging in mass from 15,400 to 16,200 Da. Using the incremental masses for hexose and N-acetylhexose, it was possible to characterize the carbohydrate composition for each of the 16 glycoforms. Different distributions of the glycoforms were observed for different avidin preparations, suggesting the utility of ESI-MS for the determination of oligosaccharide heterogeneity in recombinant proteins.

Introduction

In the past few years, considerable progress has been made in the development of methods for characterization of oligosaccharides in complex mixtures, especially with respect to the on-line coupling of high-performance anion-exchange chromatography (HPAEC, the separation method of choice for oligosaccharides) to thermospray and ionspray mass spectrometry. In this presentation, attention is paid to three aspects related to these developments:

- On-line HPAEC thermospray MS analysis of sugar oligomers in complex mixtures.
- Negative-ion thermospray MS of oligosaccharides.
- Structure elucidation by tandem mass spectrometry.

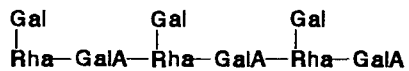
Experimental

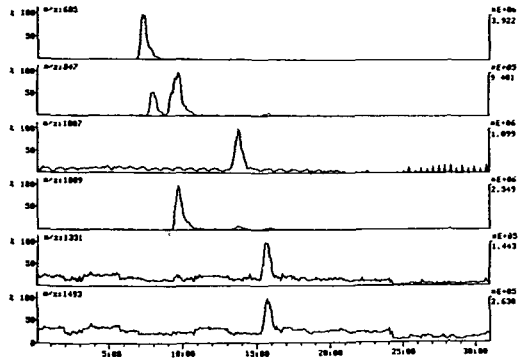
A Finnigan MAT TSQ 70 tandem mass spectrometer, equipped with a 20 kV conversion dynode detection system, is used. A thermospray interface, operated at a block temperature of 400°C, a vaporizer temperature of 100°C with discharge and filament off, is applied in combination with HPAEC (performed on a Dionex HPAEC system equipped with a CarboPac PA100 column and a PAD electrochemical detector). An electrospray interface, operated with 3-3.5 kV nebulization potential and optimized tube-lens and nozzle-skimmer potentials is used with constant infusion (1-2 µl/min) via a Harvard Apparatus Model 22 syringe pump.

Rhamnogalacturonan digests

Pectin molecules from apple cell-wall material are considered to contain a galacturonan backbone and so-called "hairy" (ramified) region with a galacturonan backbone rich in rhamnose. Modified hairy regions have been isolated from pectins in apple juice and digested with a new rhamnogalacturonase[5]. HPAEC-MS of these digests confirm previous observations with NMR[6]. The following peaks were detected:

#	m/z	identity
1	685	$(Rha)_2$-$(GalA)_2$
2	847, 435	$(Rha)_2$-$(Gal)_1$-$(GalA)_2$
3	847, 435	$(Rha)_2$-$(Gal)_1$-$(GalA)_2$
4	1009, 516	$(Rha)_2$-$(Gal)_2$-$(GalA)_2$
5	1007, 515	$(Rha)_3$-$(GalA)_3$
6	1331, 677	$(Rha)_3$-$(Gal)_2$-$(GalA)_3$
6'	1331, 677	$(Rha)_3$-$(Gal)_2$-$(GalA)_3$
7	1493, 758	$(Rha)_3$-$(Gal)_3$-$(GalA)_3$





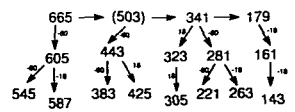
Negative-ion detection in HPAEC-thermospray-MS

Significant improvements in response are achieved in negative-ion mode relative to positive-ion mode. The mass spectra in negative-ion mode are more complex due to the formation of a series of adduct ions, e.g., $[M-H]^-$, $[M+OAc]^-$, $[M+HSO_4]^-$, and $[M+SO_4]^{2-}$. Further studies are needed to investigate negative-ion mode for other sugar types, e.g., glucuronic acid containing oligomers.

Tandem Mass Spectrometry of Oligosaccharides

Under the present ionization conditions, no fragmentation is observed. Fragmentation is required for further characterization of unknown oligosaccharides with respect to type of sugar and linkage and linkage position. Therefore, the use of tandem mass spectrometry was investigated, initially in combination with constant sample infusion in electrospray MS. Preliminary results indicate that differentiation between isomeric oligomers based on type of fragments and/or relative peak intensity is possible. As an example, the typical fragment ions observed in the negative ion MS-MS of two tetraose are given below:

Glc-(α-1,4)-Glc -(α-1,4)-Glc-(α-1,4)-Glc



Gal-(α-1,6)-Gal-(α-1,6)-Glc-(α1-β1)-Fruct

Rapid and Sensitive Sequencing of N-Linked Oligosaccharides Using Matrix Assisted Laser Desorption Mass Spectrometry (MALD) and Mixtures of Specific Glycosidases.

*C.W. Sutton, J.A. O'Neill and J.S. Cottrell, Finnigan MAT Ltd., Hemel Hempstead, Herts. HP2 4TG, UK.

As more and more proteins are isolated it becomes apparent that an increasing number are glycosylated. In addition, many of the proteins that are being developed for therapeutic applications are also glycosylated. In the latter case quality control of the product is important for meeting FDA approval. Whereas rapid and sensitive techniques are available for characterisation of the protein component, developments in the analysis of the carbohydrate moiety have been much slower.

Edge et al (1) recently demonstrated the potential of using glycosidases to determine the carbohydrate sequence of free oligosaccharides. Subsequent analysis of the digest products was by the relatively slow and low resolution technique of Bio-Gel P4 gel permeation chromatography. This limited the approach to isolated oligosaccharides cleaved from the protein. MALD, on the other hand, is a high resolution technique with good accuracy (<0.1% error), sensitivity (0.1 to 10 pmol) and rapid analysis time (5 minutes). It has already been well established in the analysis of a wide range of biomolecules including peptides and oligosaccharides. As MALD has a high tolerance to buffers and is economical in sample use it is ideal for monitoring glycosidase digests.

A strategy for the general preparation and preliminary identification of glycopeptides is briefly described. The combination of glycosidase digests and MALD analysis is then used to demonstrate the effective elucidation of oligosaccharide structures. This approach is illustrated with special attention to the detailed characterisation of the two glycosylation sites of Tissue Inhibitor of Metalloproteinases (TIMP 1), Asn_{30} and Asn_{78} using specific glycosidases. Both sites have common features - (i) extensive heterogeneity due not only to varying levels of terminal sialic acid residues, but also in levels of terminal galactose residues, (ii) predominantly fucosylated antennary complex oligosaccharides are present, though Asn_{30} has a higher proportion of tri- and tetra-antennary structures than Asn_{78}. Digests using two different proteases enabled identification of non-glycosylated Asn_{78}-containing peptides indicating that there was only partial site occupancy.

The published specificity of the exoglycosidases had been primarily determined using free oligosaccharides as substrates. Bovine fetuin glycopeptides of known structure are used to demonstrated that the enzymes retained the same cleavage specificity in the presence of the peptide moiety.

In addition, a number of glycopeptides of well characterised glycoproteins - bovine fetuin, human α_1-acid glycoprotein and recombinant human tissue plasminogen activator - have been analysed in analogous digests to assess the potential accuracy of MALD for quantification. Comparison of results from MALD with previously published data, suggest that MALD can be used to determine the proportions of asialo-oligosaccharides on a particular glycosylation site with excellent reproducibility (Table 1).

Characterization of derivatized gangliosides by off-line HPLC, LSIMS, MS/MS and MALDI-TOFMS

*H. Perreault and C.E. Costello
Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139

INTRODUCTION Gangliosides are essential membrane-bound glycosphingolipids of all vertebrates occurring in highest concentration in the central nervous system. Most gangliosides contain invariable tetrasaccharide backbones and a variable number of sialic acid residues. Native species are difficult to characterize in positive ion LSIMS and MALDI-TOFMS because the molecular ion-related peaks are relatively small and only little structural information is available. This may become a problem when mixtures are investigated, especially if the contribution from the background is high. Sensitivity and selectivity problems can be addressed by using derivatization, chromatography prior to mass spectral analysis and MS/MS. We report on three derivatization methods that yield more sensitivity and structural information in the positive ion mode and on MS/MS characterization of specific fragments. We also show that chromatographic methods such as HPLC can help to clean up samples in order to facilitate mass spectral analysis.

EXPERIMENTAL LSIMS and MS/MS spectra were recorded with a JEOL HX110/HX110 (E1B1-E2B2) instrument, operated at +10 kV accelerating voltage. The Cs^+ ion gun was operated at 25 kV. High energy collisions were induced at 7 keV in a collision cell (helium) located between MS-1 and MS-2. MALDI-TOFMS experiments were conducted with a modified VT2000 (Vestec Corp.) time-of-flight mass spectrometer. A nitrogen laser source (337 nm) was used. Peracetylated (PAC), permethylated (PME) and perbenzoylated (1) gangliosides derivatives were prepared. The gangliosides studied were obtained from human brain extracts and from commercial sources.

RESULTS For large gangliosides, direct permethylation is not possible because the native species are not soluble in the reaction solvent. Peracetylated derivatives are good intermediates because they are easily dissolved in organic solvents and also easily permethylated in the conditions that are routinely used for native material. The positive ion LSIMS and MALDI-TOFMS spectra of PAC gangliosides indicate that the formation of lactones occurs upon derivatization. These lactones do not interfere with subsequent permethylation, as the products are fully methylated according to the LSIMS and MALDI-TOFMS spectra of PAC-PME compounds. The positive ion LSIMS spectra of the PME derivatives of gangliosides have abundant (relative to the native species) $(M+H)^+$ and/or $(M+Na)^+$ and structure-related fragment ions (2), that include ceramide-related ions. When subjected to high energy collisions, the latter yield CID spectra which can denote heterogeneity in the structure of the ceramide in certain cases.
Mixtures of native gangliosides are conventionally separated by high performance thin layer chromatography (HPTLC) (3). HPLC can be substituted for HPTLC if substantial amounts of native material are available, but the UV detection becomes restricted if only nanomoles of gangliosides are to be analyzed. In the latter case, perbenzoyl derivatives (1) provide a substantial increase in sensitivity since benzoyl groups strongly absorb at 230 nm. Post-derivatization cleanup or separation can be conducted either in normal or reversed phase HPLC; Figure 1 shown the normal phase chromatogram obtained for the cleanup of PBZ GD1b. In our hands, the normal phase method provided no separation between individual species and thus was used as a cleanup

method after the PBZ reaction. The reversed phase HPLC method offered better resolution and individual species were eluted at different times. However, no separation between homologs of the same species was obtained. PBZ gangliosides, like PME species, show a substantial increase in sensitivity in LSIMS relative to the native species. Figure 2 shows the molecular ion region of the LSIMS spectrum obtained for PBZ GD1b. This region shows a high lability of the benzoyl groups as they are ejected from the molecular ion and from the $(W\text{-}NH)^+$ fragment (partial loss of the base chain). The low and middle-mass region of the LSIMS spectra of PBZ derivatives contains abundant ions that CID experiments indicate are related to the sugar and ceramide structures. The assignments of these ions are not yet complete.

Introduction

There has been a growing interest in the synthesis of C-glucopyranosides due to their biological activity and possible use in biochemical, medical, and plant physiological studies. Electron impact (EI) mass spectrometry has been shown to be an efficient method for the structural characterization of acetylated derivatives of C-alkyl and C-aryl glucopyranosides (1,2). Recently we reported the synthesis of several 3,4,6-tri-o-benzyl-c-glucopyranosides modified at the C-2 position with XC_6H_4S, where X=CH_3 or Cl (3). The objective of this study was to access the use of EI and electron attachment negative chemical ionization (NCI) mass spectrometry for the structural characterization of these benzylated 2-thio modified C-glucosides.

Experimental

Low resolution mass spectra were recorded on a Finnigan-MAT model 4500 mass spectrometer using a desorption direct sample introduction probe. EI ionization energy was 70eV. NCI spectra were obtained with Argon at 0.5-1.0 Torr. Elemental composition was determined using a Finnigan-MAT model 95 operating at 7000 resolution.

Results

The benzyl ion (m/z 91) was found to be the base ion for each compound studied by EI. However, the molecular ion was significantly intense to allow molecular weight determination. Fragmentation was interpreted in terms of positive charge localization of the molecular ion (4) and proceeded according to rules for normal carbohydrates (5). The proposed fragmentation pathways are shown in schemes I-IV below. Electron attachment spectra and subsequent disassociation produced molecular anions and fragment anions diagnostic of the thio moiety at C-2.

Conclusion

EI and NCI mass spectra are highly sensitive toward and diagnostic of benzyl derivatives of C-2 thio modified glucopyranosides.

Analysis of Heterogeneity of Native α_1-Acid Glycoprotein

Simin D. Maleknia[1], Micheal J. Trueheit[2], James E. Carlson[2], H. Brian Halsall[2] and Catherine E. Costello[1]
Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139-4307
Department of Chemistry, University of Cincinnati, Cincinnati, OH 45221-0172

Introduction Human α_1-acid glycoprotein (orosomucoid; OMD) is an acute phase reactant present in blood. OMD contains five *N*-asparaginyl-linked glycan chains with variations in the branch numbers and in the sialic acid and/or fucose content.[1-3] The concentrations of the glycoforms differ at each site with disease state.[4] Mapping the sialic content at each site may prove useful to the study of glycosyl transferase activity. An earlier investigation described the glycoform heterogeneity of the glycoprotein after desialylation. This was achieved by analyzing the glycopeptides from a proteolytic digest (*Staph* V-8) using HPLC and affinity chromatography in conjunction with matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOFMS).[2] A similar approach has been applied to analyze the sialic acid content of the individual glycopeptides. An ultimate goal is to differentiate the various isomers (glycomers).

Experimental A Modified VT2000 (VESTEC) linear time-of-flight mass spectrometer was operated at an accelerating voltage of ± 30 kV. The laser source was a nitrogen laser (337 nm) with a 3 ns pulse width. A Lecroy 9540A digitizing oscilloscope with a 400 MHz sampling rate was used. The matrix consisted of the 2:1 mixture of *o*-aminobenzoic acid and nicotinic acid at a concentration of 12 g/l. Total sample applied was in the range of 5 to 10 pmoles.

Results & Discussion The technique of MALDI-TOF has been applied to show the higher order heterogeneity induced by the presence of sialic acids. The sialic acid pattern is unique to the individual sites. The glycoform heterogeneity at site III is indicated in Figure 1A. The maximum number of sialic acids (two through four) is observed for each carbohydrate structure. Separation of tetra-, tri-, di- and mono-sialylated glycoforms was achieved by HPLC purification (column:C_{18}, gradient: 100% H_2O to 60% acetonitrile at 1ml/min.). Glycopeptides with the highest number of sialic acids showed the lowest retention time. The higher order effect of sialic acids was removed by neuraminidase digestion (Figure 1B). At this site, more branching is observed with tetrantennary form predominating. Similarly, tri- and terta-antennary structures are more abundant at sites IV and V. Several glycoforms with an additional *N*-acetyllactosamine are also observed. Additionally, fucosylated glycoforms are detected for tri- and tetra-antennary structures. The relative abundances of glycoforms are presently being compared to chromatographic data. A sialic acid content of 15.0 per mole has been reported for human α_1-acid glycoprotein by acid hydrolysis and high-pH anion exchange chromatography (HPAE).[5] Future goals include complete mapping of the sialic acid content at each site and detailed structural elucidation of glycomers by application of oxidation, reduction and alkylation reactions.

In soft ionization mass spectrometric analysis of underivatized carbohydrates, molecular ions can undergo three kinds of fragmentation: cleavage of the glycosidic bond between two monosaccharide units, breakdown of one of the sugar rings at the extremities of the molecule, and loss of substituents, if any.

Negative Ionization is able to promote sugar ring fragmentation in reducing underivatizated oligosaccharides.

This fragmentation starts from the reducing end producing fragments that are characteristic of the linkage positions present in the oligosaccharide.

In the sugar ring fragmentation, the negative charge is retained on the non-reducing end of the molecule. The peculiarity of negative ionization is supposed to be the selective deprotonation of the anomeric hydroxyl, which is more acidic with respect to the alcoholic groups, with formation of an ion bearing the negative charge on the reducing end. In this way, fragmentation starts from the reducing end, and a progressive erosion of monosaccharide units towards the non reducing end of the oligosaccharide occurs. This "peeling" of monosaccharide units results in the formation of a saccharide containing one sugar unit less then the molecular ion and with the new anomeric hydroxyl negatively charged, thus reproducing the initial situation at the reducing end.

On the other hand, fragmentation of the glycosidic bond can, in some cases, produce ions with retention of the negative charge on the reducing end of the oligosaccharide.

This is the case when a 3-O linkage is present; fragmentations observed in a trisaccharide, b trisaccharide and 3-fucosyllactose are reported in scheme 1a, b and c respectively.

The fragmentation pattern outlined in scheme 1 shows that, after the elimination of the monosaccharide linked at the 3-O position, the reducing sugar ring looses the hydroxyl or the substituent group at the C4 together with an hydrogen atom, as well as the C5-C6 moiety. This allows, in principle, to establish the molecular weight of substituents of the reducing unit not only at the 3-O position but also at the remaining linkage sites using a combination of MS and tandem MS experiments.

Sugar ring fragmentations can be suitable for the differentation of monosaccharides if a substitution at one OH is present (i.e. N-acetamido glucose, deoxyglucose). In Fact, the negative ion FAB mass spectra of three x N-Acetamido x- deoxy glucose (x=2,3,6) permit easily differentiation between the monosaccharides; in fact peak at m/z 119 (loss of C1-C2) is present only in 2 N-Acetamido glucose, peak at m/z 160 (loss of C1-C2) is present only in 6 N-Acetamido glucose, and these peaks are absent in the spectrum of 3 N-Acetamido glucose.

An analog situation is present in 2- and 3-deoxyglucose.

Oligosaccharides in aqueous solution can exist as an equilibrium mixture of conformers, each with a distinct local energy minimum and barrier to interconversion. The desorption process in mass spectrometry supplies excess kinetic energy to the oligosaccharides and as a result, the conversion between various conformers is expected to be more rapid in the gaseous phase as compared to the aqueous phase. In spite of this, we observe a similarity in the gas phase unimolecular decomposition behavior of sialosides that are known to have similar conformational properties in aqueous solution.

The unimolecular decomposition behavior of α-D-NeuAc-(2-6)-β-D-Gal sialoside (1) which represents the terminal units of many glycoproteins and glycolipids was compared to two C-6 methyl analogs which exists as the *gt* (2) and *tg* (4) rotamers. From nmr studies, it has been established that the natural sialoside 1 exists predominantly in the *gt* orientation. In the unimolecular decay of the analogs, the *gt* rotamer has a prominent fragment ion at m/z 558 (loss of ethylene), while the *tg* rotamer does not. The natural sialoside also has a prominent loss of an ethylene unit, which suggests that during the desorption process the *gt* orientation is favored.

To explain the fragmentation behavior, a hydrogen bonded complex and proton migration model is proposed. The protonation of the sialosidic oxygen may take place *via* the carboxylate group. If the C-6 arm of the galactose is maintained in the *gt* rotamer orientation, this proton can then be stablized by three hydrogen bonds involving O-6, O-5, and O-4 of the galactose. This proton is in very close proximity to the trimethyl silyl ethyl aglycone, therefore, it can migrate to the aglycone oxygen and result in the loss of the ethylene unit. For the *tg* rotamer, there can only be weak hydrogen bond stabilization involving O-6 and O-4.

The unimolecular decay of β-D-NeuAc-(2-6)-β-D-Gal sialoside (10) as compared to the methyl C-6 analogs which by design are in the *gt* (11) and *tg* (12) conformation is less conclusive. The natural β-sialoside gave less fragmentation than the natural α-sialoside but more the the *gt* and *tg* β-sialosides.

In the fragmentation of the isopropylidiene derivatives, the *tg* sialoside (8) favored the loss of acetone and the *gt* sialoside (5) produced abundant N-acetylneuraminyl (m/z 292) fragment. The unimolecular decay of the natural sialoside (3) gave a very prominent m/z 292 ion suggesting the *gt* orientation was favored during the desorption process.

The isopropyliediene thio analogs appear to follow a similar fragmentation mechansim as the natural sialoside. The *gt* sialoside (6) favors the formation of the m/z 292 fragments more than the *tg* sialoside (9). The fragmentation of the natural sialoside (3) is simlar to the *tg* sialosides suggesting that 3 is predominantly in the *tg* orientation during the desorption process.

In conclusion, the oligosaccharides appear to maintain their aqueous conformation during the desorption process, the fragmentation process is conformation mediated, and an excess energy are required to overcome interconversion barrier.

Comparative Study of Carbohydrate Structures of Recombinant Human Platelet Derived Growth Factor Expressed in Chinese Hamster Ovary and in Saccharomyces Cerevisiae

Eric Watson, Anjali Bhide, Bhavanna Shah, William C. Kenney and *Herman van Halbeek.

Amgen Inc., Amgen Center, Thousand Oaks, CA 91320.

Platelet-derived growth factor (PDGF) is a major mitogen in serum for connective tissue and glial cells (1,2). There are two homologuous chains, termed A and B, that are disulfide bonded and as a result three different dimeric forms are present : AA, AB, BB. Recombinant glycoproteins produced by different cell lines and eukaryotic organisms have been the subject of much interest in recent years. Recombinant glycoproteins are most frequently expressed in either Chinese hamster cells or in Saccharomyces cerevisiae as hosts for their biotechnological production on a commercial scale. While both types are capable of producing N-and O-linked glycans, there are structural differences between these glycans. The availability of recombinantly produced PDGF in CHO and yeast cells provided sufficient amounts for characterisation by chemical techniques and allowed us to compare the different glycosylation produced by CHO cells and in yeast.
In this report, glycans of recombinant PDGF-BB produced both in yeast and in CHO cells are described. . Structure determination was

carried out using carbohydrate composition, methylation analysis, MALDI and 500-MHz H-NMR spectroscopy. The carbohydrate structures of rhPDGF expressed in CHO cells comprised O-linked oligosaccharides that were linear tri- and tetra-oligosaccharides with one and two sialic acids respectively. The major N-linked oligosaccharides were complex type di-, tri and tetra-antennary N-acetyllactosamine that contained one, two and three sialic acids. All complex type oligosaccharides contained fucose α(1-6) linked to the proximal N-acetylglucosamine residue. Mature human PDGF-BB does not contain consensus sites for N-linked glycosylation and the presence of N-linked glycosylation as shown here arises from incomplete removal of the precursor sequence.

The presence of several substituted neuraminic acids, NeuGC, Neu5Ac2en, Neu5,9Ac2 and Neu2,7-anhydro5Ac in minor amounts were identified by GC-MS as their trimethylsilyl derivatives under electron impact ionization conditions Figure shows these EI-MS.

The carbohydrate structures in yeast cells were much less diverse and consisted solely of mannose in monosaccharide and dissacharide forms in approximately equal amounts. Both of these are typical yeast O-glycans. There was no evidence from chromatographic separations for other glycans such as trisaccharides being present.

Electrospray Mass Spectrometry of Heparin Oligosaccharides

*W. Chai[1], B.N. Green[2] and A.M. Lawson[1]

[1]MRC Clinical Research Centre, Watford Road, Harrow, Middlesex HA1 3UJ, UK
and [2]VG Bio Tech, Tudor Road, Altrincham, Cheshire WA14 5RZ, UK

Introduction

Despite the widespread use of heparin in medicine as an anticoagulant, and the increased interest in its possible role in cellular recognition, the assignment of the precise structures of the biologically active regions in the polysaccharide chains of heparin remains a difficult task.

Mass spectrometry, particularly FABMS (and L-SIMS), has been used for analysis of heparin oligosaccharides with either thioglycerol (1) or triethanolamine (2) as matrix. Ion-spray mass spectrometry has been demonstrated for analysis of oligomer fragments of hyaluronic acid and chondroitin 6-sulphate (3), members of the same glycosaminoglycan (GAG) family as heparin, but having none or only one sulphate group per disaccharide repeat unit, respectively. Among the GAGs, heparin is the most heavily sulphated with highly heterogeneous regions which represent a major challenge to structural analysis.

In the present study, five disaccharide fragments derived from heparin and three from chondroitin sulphate were analysed by ESI-MS using a triple-stage quadrupole instrument (VG-Quattro-BQ, VG Biotech, Altrincham, U.K.), in order to assess the sensitivity of the technique and its ability to give structural information on these anionic oligosaccharides.

Results and Discussion

Good quality negative-ion spectra were obtained from all eight GAG-derived disaccharides examined using less than 0.6 nmol of material with low nozzle-skimmer voltage. The nozzle-skimmer voltage has a strong affect on the fragmentation (desulphation) and charge states, and it can be optimized to give essentially no fragmentation in the normal ESI mass spectra. Isomeric structures having the same number of sulphates gave similar ESI spectra. As representative, the spectrum of disaccharide I-S, ΔUA(2S)1-4GlcNS(6S) (MW 577, with 3 sulphates), and the data transformed onto a true molecular mass scale are shown in Fig. 1.

The ESI spectra are dominated by $[M-nH]^{n-}$, where M represents the mass of the free acid and the charge (n) is largely dependent on the number of sulphate groups present. Molecular mass and composition (in terms of uronic acid, hexosamine and sulphate groups) can be easily derived. Although less abundant sodium adduct ions are also present, sulphate loss and other fragmentations were not observed at the low nozzle-skimmer voltage used.

Collision-induced ESI-MS/MS experiments were carried out to determine if more detailed structure could be deduced since, depending on conditions, fragmentation was only either limited or dominated by losses of sulphate substituents in the normal ESI spectra.

In ESI-CID-MS/MS spectra of the singly charged $[M-H]^-$ precursors, both glycosidic and ring fragmentation occurs to give useful information on the glycosidic linkages and sulphate positions. The ESI-CID-MS/MS spectra of heparin disaccharides II-A and III-A (Fig. 2) demonstrate the significant differences in the spectra of isomeric structures which would allow unambiguous differentiation of possible isomers. Interestingly, the four monosulphated disaccharides examined here by low energy argon collisional activation showed very similar fragmentation patterns to those produced by high energy FAB-CID-MIKE (4).

Doubly and triply charged, and sodiated quasi-molecular ions were also selected as precursors, but complicated and less informative daughter-ion spectra were obtained (not shown). Further work is needed to optimize conditions for ESI-MS/MS of multiply sulphated and higher oligomers.

Introduction

Anemia is a major complication arising from chronic renal failure and a reduction in EPO production is the cause for this disease. Studies have since shown that anemia can be corrected following the administration of recombinant EPO (1,2).

Structural characterisation of oligosaccharides in EPO produced in CHO, Baby hamster kidney (BHK) and HeLa cells has been described (3-6). These EPOs have been shown to contain about 40 % N-linked carbohydrates with the major structures being di-,tri-, and tetra-antennary oligosaccharides. O-Linked structures are also present but in much smaller amounts. In only one of these studies was the identity of intact N-linked sialylated oligosaccharides considered (3) where it was shown that one, two and three sialic acids were present on the di-, tri- and tetra-antennary structures respectively.

However comparison of retention times with authentic carbohydrates and carbohydrate composition of the separated oligosaccharides indicated that there was one additional sialic acid present as compared to the results by Sasaki et al(3).

Results and Discussion

Asparagine linked oligosaccharides were released enzymatically with N-glycanase and fractionated by anion-exchange chromatography O-Linked oligosaccharides were released under alkaline borohydride conditions. The primary structures of the major O- and N-linked oligosaccharides were unambiguously established by permethylation analysis, FAB-MS and 500-MHz H-NMR spectroscopy The most abundant N-linked oligosaccharides were diantennary, 2,4-branched tri-antennary, 2,6-branched tri-antennary, and tetra-antennary with the latter having zero, one, two, and three N-acetyllactosamine repeating units. Figure shows FAB-MS of the ABEE derivatives of the major N-linked oligosaccharides. The major di-,tri- and tetra-antennary structures are fully sialylated having two,three and four sialic acids linked exclusively α(2-3) to galactose The majority of N-linked structures (>95%) contain α(1-6) linked fucose at the proximal GlcNAc residue The primary structures of two O-linked oligosaccharides, determined to be mono-and disialyl oligosaccharide alditols, is also reported.

Structural Characterization of the Carbohydrate Chains of Saponins by FAB-MS/MS

Douglas M. Sheeley[1], Lewis K. Pannell[2], Henry M. Fales[1],
Marie-Genevieve Dijoux[3], and Georges Massiot[3].

[1]NHLBI, [2]NIDDK, NIH Bethesda, MD 20892, and
[3]Universite de Reims, France

Saponins are a broad class of compounds which are found in a number of plants, most notably alfalfa and many of the legumes. They exhibit a variety of activities, depending upon their specific structure. Many have a strong hemolytic activity, and are extremely toxic to cold blooded animals, with a diminished effect on mammals. These compounds also bind cholesterol and bile acids, and have consequently been examined as possible treatments for hypercholesterolemia. Saponin structures vary widely but share some basic features. All consist of a hydrophobic core made up of a sterol or triterpene, and one or more carbohydrate chains attached to this core structure through a variety of linkages.

In this study, some of the mass spectrometric techniques used in the sequence analysis of a single saponin structure **(Figure 1)** have been summarized. ^{252}Cf PDMS provides molecular weight assignment and several fragment ions indicative of glycan sequence. One ion, however, at mass 489 could be not be assigned unambiguously. It is either a sequence ion from the long chain, or a loss of acetic acid from the 549 ion of the short chain. The mass resolution of the instrument is not adequate to distinguish 487 from 489. For the tetrasaccharide, linear and branched chains cannot be distinguished from this spectrum.

Pyranoxonium fragment ions representing each carbohydrate chain were generated by FAB and subjected to MS/MS by B/E linked scan in order to sequence each chain individually. Results for the **Xyl-Glc-Glc** chain (m/z 835) were consistent with the structure determined earlier by PDMS. Results for the **Xyl-(Ara)-Rha-Ara** chain (m/z 921) were more complex. MS/MS of the 921 ion gives a much broader peak at 489 than would ordinarily be expected **(Figure 2)**. This has been identified as a second field free region metastable ion, whose actual mass is 139 (two acetic acid losses from the very strong 259 ion). This type of metastable ion is detected when a fragment ion generated in the ion source (rather than by collision) is transmitted through the magnetic sector, and undergoes a unimolecular decomposition in the second field free region during a B/E linked scan[1]. The presence of this metastable peak obscures the region around m/z 489. By looking at the MS/MS spectrum of the 705 fragment, this problem was eliminated. The 2nd FFR metastable was detected because the B/E spectrum was acquired in profile mode. If the spectrum had been centroided automatically, this peak could have easily been mistaken for a sequence ion.

MS/MS of the 705 ion from the series 921-->705-->259 shows a strong ion at 259 as expected, with a strong ion at 429, and a weak one at 489. The 429 and 489 ions are due to glycosidic cleavage with charge retention on the reducing end of the molecule (i.e., loss of a terminal xylose), either with or without acetyl transfer. These data are supportive of a branched structure. This assignment could have been altered if a sequence ion at m/z 489 had been assigned. The assignment can be confirmed by methylation analysis, because there is only one deoxyhexose present in the molecule. The alditol acetates of doubly or singly linked rhamnose residues should be easily distinguishable by GC-MS.

Structural studies on the glycosylation of the rabbit gastric H^+, K^+-ATPase

*P H Lipniunas[1], K Tyagarajan[2], D Chow[2], J G Forte[2] and R R Townsend[1].
[1]*Department of Pharmaceutical Chemistry, University of California, San Francisco, CA 94143-0446.*
[2]*Department of Molecular and Cell Biology, University of California, Berkeley, CA 94720.*

The H^+, K^+-ATPase is the membrane protein which is responsible for the acidity of gastric secretions. The protein is a heterodimer consisting of a catalytic α subunit of 110 kDa and a β subunit which migrates as a broad band at 60-80 kDa on SDS PAGE. Only the β subunit is glycosylated. From the primary peptide sequence the β subunit contains seven potential *N*-glycosylation sites. Both *N*- and *O*-linked oligosaccharides have been found (Weitzhandler et al., *J. Biol. Chem.* (1993) **268**, 5121-5130) and the *N*-linked chains are apparently novel asialo-structures, based on chromatographic studies.

We have begun studies to determine i) which peptide loci are glycosylated ii) the molecular weight profile of oligosaccharides at each glycosylation site and iii) the presence of unique structural features, all using pmol quantities of the H^+, K^+-ATPase β subunit. From HPLC electrospray mass spectrometric analyses (LC-ES-MS), (which utilized 6-8 pmols of a tryptic digest injected into the mass spectrometer), we observed glycopeptides containing five of the seven potential *N*-linked sequons. They were all occupied by asialo-complex structures, some of which were apparently elongated by lactosamine repeats. In addition we observed a series of ions which were consistent with the respective peptides containing *N*-linked polylactosamine structures with 1-3 additional Hex residues. We surmise that these additional Hex residues are terminal non-reducing α-linked Gal. The Asn-99 and/or Asn-103 sites gave ions consistent with fucosylated species. A tryptic glycopeptide containing Asn-222 was consistent with a biantennary series with up to two lactosamine repeats. A tri- or tetra-antennary series with up to five or six lactosamine repeats, respectively, was consistent with the observed ions from the Asn-161 containing glycopeptide. A greater proportion of Hex:HexNAc residues, possibly indicating α-Gal structures, was also observed at this site. The tryptic fragment containing Asn-146 produced ions suggesting tri- or tetra-antennary structures with two or three lactosamine repeats, respectively, and a surfeit of Hex residues. Glycopeptides containing both Asn-99 and Asn-103 produced ions suggesting that only one of these two sites is occupied in the same glycopeptide. A tryptic cleavage at Arg-104, which is adjacent to the Asn-103 glycosylation site supports that Asp-103 is unoccupied. Interestingly, the consensus sequence at Asn-103 in the pig gastric H^+, K^+-ATPase β subunit is missing (Toh et al. *Proc. Natl. Acad. Sci. USA* (1990) 87, 6418-6422). The ions arising from the glycopeptides containing both the Asn-99 and Asn-103 sites indicated fucosylated asialo-complex structures ranging from biantennary to tetraantennary structures which seemed to be capped with Hex residues. Eighty percent of the peptide sequence was identified during analysis of the tryptic peptides by LC-ES-MS.

The average molecular mass of the intact glycosylated β subunit was determined, by Matrix Assisted Laser Desorption Mass Spectrometry, to be 55750 Da. Since the open

reading frame for the full length rabbit cDNA clone predicts that the gastric β subunit contains 291 amino acids giving a molecular weight of 34002 Da, the β subunit is approximately 37 % carbohydrate by weight. Studies are under way to ascertain which other potential *N*-linked sequons are glycosylated and the location(s) of the *O*-linked chains.

Structural determination of the O-linked oligosaccharides of recombinant human granulocyte-colony stimulating factor.

E. Watson, T. Arakawa ,W. C. Kenney.and *Herman van Halbeek
Amgen Inc., Amgen Center, Thousand Oaks, CA 91320

*Complex Carbohydrate Research Center and Department of Biochemistry, The University of Georgia,Athens, GA 30602

Colony stimulating factors or haematopoietic hormones comprise a group of growth factors that are responsible for regulating the formation of blood cells in the stem cells of bone marrow. Human granulocyte-colony stimulating factor (G-CSF) is one of a group of glycoproteins that are now known to be responsible for controlling the growth and differentiation of hematopoietic progenitor cells (1-3). G-CSF differs from other members of this family largely as a result of its cellular specificity for neutrophilic granulocytes and their precursors, and also because of its ability to induce terminal differentiation in certain lines of myeloid leukemic cells (4-6).

Carbohydrate structures of human granulocyte-colony stimulating factor (rhG-CSF), expressed in Chinese hamster ovary cells (CHO), have been determined. rhG-CSF was found to contain ~4% carbohydrate by weight, representing two O-linked oligosaccacharides. These structures were released by alkaline borohydride reductive cleavage and separated by ion exchange chromatography into two fractions that were shown to contain one and two sialic acids, respectively. Figure 1.shows the chromatogram of the oligosaccharides released from rhGCSF.

Structure determination was carried out using carbohydrate composition, methylation analysis, fast atom bombardment-mass spectrometry, and 500-MHz ^{1}H-NMR spectroscopy Figure 2 shows the negative ion FAB-MS 0f the isolated oligosaccharides The structures of these oligosaccharides are as follows:

Neu5Acα(2-3)Galβ(1-3)GalNAc-ol

and

Neu5Acα(2-3)Galβ(1-3)
Neu5Acα(2-6) GalNAc-ol

The presence of the substituted sialic acid, N-glycolylneuraminic acid has previously been reported on N-linked oligossacharides obtained from human recombinant glycoproteins that were expressed in Chinese hamster ovary CHO cells (7) We report here that N-glycolylneuraminic acid is also present on O-linked oligosaccharides of thus obtained glycoproteins. HPLC analysis of the sialic acids released from rhG-CSF shows N-acetylneuraminic acid and N-glycolylneuraminic acid present in the ratio of ~96:4. N-glycolylneuraminic acid was unambiguously identified by electron impact mass-spectrometry of its trimethylsilyl derivative

Structural Determination of a Sulphated Tetrasaccharide Ligand for the Cell Adhesion Molecule E-Selectin by LSIMS

A.M. Lawson, W. Chai, C.T. Yuen and T. Feizi.

MRC Clinical Research Centre, Watford Road,
Harrow, Middlesex, HA1 3UJ, UK.

Introduction

There has been intense interest in the oligosaccharide structures that interact with selectins, a small class of recently discovered cell adhesion proteins involved in normal and pathological biology of blood cells. One of these proteins, E-selectin which is implicated in the first stage of recruiting neutrophils to sites of inflammation has been shown to recognise oligosaccharides having the 3-sialylated 3'-fucosyl-N-acetyllactosamine sequence of the type found on leucocytes. In the present study by using a TLC plate binding technique with neoglycolipids derived from O-linked acidic oligosaccharides, obtained from a human ovarian cystadenoma glycoprotein preparation, it was shown that a series of neoglycolipid bands were recognised by E-selectin. Among these, a novel class of oligosaccharide ligand was identified by mass spectrometry that is sulphated rather than sialylated (1).

Results and Discussion

A number of active bands were detected from among the neoglycolipids derived from the glycoprotein preparation. Of most interest were structures from the lower molecular weight fractions which might be expected to contain the minimum epitope being bound by E-selectin. The spectrum of a highly active neoglycolipid band showed a $[M-H]^-$ ion at *m/z* 1465 which suggested a dHex.Hex_2.HexNAc composition with an additional 80Da equivalent to a sulphate or phosphate group. Glycosidic fragment ions *m/z* 1365, 1219, 1203 and 854 allowed the sequence to be assigned as (80)-Hex-(dHex)HexNAc-Hex.

The combined positive and negative spectra supported the presence of sulphate and not phosphate. The extent to which neoglycolipid spectra could be used to distinguish these substituents was investigated using neoglycolipids of the model oligosaccharides, HSO_3-GlcNAc-Gal and H_2PO_3-Man_5 (Figs 1 and 2). They show characteristics, particularly in positive mode, which reflect the difference in chemical stability to acid conditions. Proton attachement leads to facile loss of sulphite and gives rise to $[MH-SO_3]^+$ as the most abundant ion and absence of MH^+ in the sulphated disaccharide. Man_5-phosphate in contrast shows only a small ion for HPO_3 loss and an intense MH^+. The negative ion spectra of each are similar although from the sulphated structure sulphite loss is again prominent.

Methylation analysis, to determine linkage positions of the active oligosaccharide required modification to take account of the water solubility of permethylated oligosaccharide sulphates. Purification of the aqueous layer following permethylation by the NaOH/DMSO slurry method (3) can be achieved by AG50WX8 chromatography. The E-selectin saccharide ligand was deduced to be a mixture of the isomeric structures

HSO_3-3Gal1-4/3(Fuc1-3/4)GlcNAc1-3Gal

The permethylated spectrum of this mixture was less useful than its neoglycolipid spectrum. While $[M-H]^-$ is produced no fragmentation of the sulphate occurs and hence no indication of sulphate substitution is given. The positive ion spectrum in contrast shows loss of sulphite (ie $[M-SO_3+Na]^+$) with MH^+ being replaced by intense salt adduct ions which make interpretation of an unknown spectrum difficult. In addition the expected glycosidic fragmentation of normal glycans was absent.

Structural Analysis of Glycosylation on the HIV Envelope Glycoprotein gp120

*John Caesar, Steve Chan, Bruce Reinhold, Tun-Hou Lee and Vernon Reinhold,
Harvard School of Public Health, Boston, MA 02115

The envelope glycoprotein gp120 expressed on the surface of the human immunodeficiency virus (HIV) functions as a ligand for the CD4 receptor glycoprotein on human T cells. Oligosaccharides were implicated in the infectious process by studies utilizing endoglycosidase inhibitors (1) and glycosylation site mutagenesis (2,3). In particular, the inhibitor study implied that high mannose glycosylation on gp120 was sufficient for viral infectivity (1). Efforts to analyze the gp120 glycan structures in greater detail have focused on recombinant material expressed in different cell lines. Insect cell (Sf9)-expressed gp120 was used for the work described in this poster, based on its in vitro biological activity (4).

The glycans from this Sf9-expressed gp120 were profiled by supercritical fluid chromatography (SFC)-negative chemical ionization (NCI)-MS (5). Electrospray ionization (ESI)-MS has been used in the present study to confirm the SFC-MS profile and HPLC-ESI interfacing was developed to continue the preliminary investigation of glycoform distributions at gp120 glycosylation sites.

ESI-MS: We used a Finnigan MAT TSQ700 triple quadrupole mass spectrometer operated either in the direct infusion mode or interfaced with HPLC. For direct infusion, unless otherwise specified, samples were dissolved in 70% methanol/water, 0.5 mM sodium acetate, and pumped into the ESI source at 0.75 µl/min. The operating needle voltage was roughly -4 kV, and nitrogen drying gas flow was maintained at 15 psi and a temperature of 220 degrees C. A nitrogen sheath gas flow was maintained at 25 psi.

HPLC INTERFACING: *The HPLC-MS runs that were done with an acetonitrile/ water/TFA* mobile phase used 2-methoxyethanol as a sheath liquid. However, it became clear that continued use of the methoxyethanol sheath caused a loss of sensitivity, most noticable when operating under infusion conditions. The standard buffer used for the direct liquid infusion of dissolved peptides into the Analytica ESI source is 50% methanol/water with 0.5% acetic acid. Since the infusion conditions required no liquid sheath flow, it seemed plausible that if the HPLC elution was done with a water/ methanol/acetic acid mobile phase, a liquid sheath might be unnecessary.

Glycans were released from gp120 using either hydrazinolysis or N-Glycanase (Genzyme Corp., Cambridge, MA). Glycan hydrazides were first analyzed by ESI-MS as underivatized protonated species. Improved sensitivity and collision (CID) experiments were possible for permethylated samples, analyzed as metal ion adducts (6). Figure 1 shows the ESI spectrum on enzymatically released glycans that were permethylated following periodate oxidation and aldehyde reduction.

Table 1 presents glycoform distributions, calculated from the peak intensities in the mass spectra of the ion chromatogram of a Lys C digest of gp120. The asterisks refer to the HPLC-MS run under sheathless conditions.

The Sf9 cells synthesized gp120 with high mannose glycans ranging in size from M_3GN_2 to M_9GN_2, with at least two isomers each of M_4GN_2, M_5GN_2, M_6GN_2 and M_7GN_2. One fucosylated structure was identified: M_3FucGN_2. Figure 2 shows this glycoform in high abundance on fragment L17. It is probable that the Endo H-resistant glycoforms from the Sf9 cell line were not complex glycans as reported (7), but the branched trimannose structures found in this study, based on the inactivity of Endo-H toward substrates containing the branched trimannose glycan (8).

The glycoform distributions were found to vary dramatically with glycosylation site. In particular, two sites possessed the M_3FucGN_2 in high abundance, and one of these sites was critical for viral infectivity in assays performed on a glycosylation site mutant (3).

Structural Elucidation of Branched Oligosaccharides: Isotope Labeling Studies

*Zhongrui Zhou and Julie Leary, University of California, Berkeley, CA 94720

We have previously shown that MS/MS of divalent metal ion coordinated oligosaccharides can be used to determine the linkage position in branched oligosaccharides. To apply the methodology to higher and more complicated oligomers, a clearer understanding on the dissociation process of branched oligosaccharides is required.

In this study, isotope labeling experiments were conducted in order to elucidate detailed fragmentation processes. Branched trisaccharides, 3-fucosyllactose, B-trisaccharide, and the linear isomer 2'-fucosyllactose, were either labeled with ^{18}O at their anomeric positions, or perdeuterated at all their hydroxyl groups. MS/MS of $^{26}MgCl^+$ coordinated precursors, in combination with semiempirical calculations, reveal the origins of ring cleavage neutral losses, thereby allowing us to propose mechanisms for the dissociation processes, and to make unambiguous assignments as to the linkages.

3-Fucosyllactose. By studing the product ion spectrum of 3-fucosyllactose, we are able to make corresponding ion assignments and identify a 1,4 linkage between fucose and glucose rings. Figure 1 shows the product ion spectrum of ^{18}O labeled 3-fucosyllactose. The ions at m/z 453 and 393, which correspond to two and four carbon chain neutral losses from $[M-H+^{26}Mg]^+$ at m/z 515 respectively, involve loss of the ^{18}O-labeled portion of the molecule, thus supporting our reducing ring cleavage assignment. Futhermore, the presence of ion at m/z 453 allows us to assign the two carbon chain neutral loss to C1/C2 position of the reducing ring, therefore eliminationg the possible linkage location for fucose ring at C2 position. The doublet at m/z 307 and 309 clearly suggests the presence of two different reaction pathways, one of which involves the anomeric ^{18}O which is included in the two carbon chain neutral loss from m/z 369. Deuterium labeling study is in agreement with the ^{18}O labeling study. Important information is that the ions at m/z 460 and 399 are due to two and four carbon chain neutral losses from m/z 515, respectively. The 61 AMU difference between two and four carbon chain neutral losses tells us that the second two carbon neutral loss is an aldehyde, and that the only origin of this aldehyde is C5/C6 of the reducing ring. This fact actually eliminates another possible linkage location for fucose ring at C6 of the reducing ring, and leads to the assignment of 1,3 linkage between fucose and glucose ring.

B-trisaccharide. The product ion spectrum of B-trisaccharide shows dramatic differences from that of 3-fucosyllactose. The characteristic three carbon chain neutral loss, which only occurs after fucose ring is cleaved off (it is observed from m/z 367, but not m/z 513), suggests a 1,3 linkage between two galactose rings and a 1,2 linkage between fucose ring and reducing galactose rings. Product ion spectrum of ^{18}O B-trisaccharide (Figure 2) supports the assignments. In contrast to 3-fucosyllactose, the two carbon chain neutral loss from $[M-H+^{26}Mg]^+$ gives rise to an ion at m/z 455, i.e., the ^{18}O labeling on anomeric position retaines, indicating that the loss occurs at C5/C6 posion of the reducing ring. This fact clearly rules out the possibility of 1,6 linkage between galactose and fucose rings. On the other hand, a 1,4 linkage is also not suggested, since we should have seen two carbon unit loss from C1/C2 position based on what we have learned from 3-fucosyllactose. Then the only posibility left is a 1,2 linkage between reducing galactose and fucose rings. The data obtained from deuterium labeling study is also in agreement with the assignments. For example, the two carbon chain

neutral loss from $[M-D+^{26}Mg]^+$ (m/z 522) gives rise to an ion at m/z 461. The 61 AMU difference clearly indicates that the loss is an aldehyde, coming from C5/C6 position of the reducing ring.

2'-Fucosyllactose. It is interesting to consider whether and how there are differences between 2'-fucosyllactose and its branched isomer 3-fucosyllactose. In contrast to 3-fucosyllactose which has fucose ring linked to reducing glucose, 2'-fucosyllactose is a linear trisaccharide and has fucose ring linked to non-reducing galactose via 1,2 linkage. The product ion spectrum of $^{26}MgCl^+$ coordinated 2'-fucosyllactose shows diagnostic ions at m/z 291 and 259, which assign a 1,2 linkage between fucose and non-reducing galactose rings. The ^{18}O and ^{2}H labeling experiments support our assignments, and again, they provide more detailed information on dissociation process.

On the basis of the information described above, in combination with semiempirical data, we have suggested dissociation processes for these $^{26}MgCl^+$ coordinated trisaccharides.

Detailed Structural Characterization of an Exopolysaccharide from Rhizobium Meliloti by ESI and Low Energy CID.

Bruce B. Reinhold, Siu Y. Chan and Vernon N. Reinhold, Harvard University School of Public Health, Boston, MA 02115.

Nitrogen fixing soil bacteria of the genus Rhizobium colonize specific host plants through the induction and invasion of root hair nodules. Successful colonization requires a number of chemical messages to control this complex, multistep process and extracellular polysaccharides are required for these signaling steps. Mutation studies have demonstrated that specific oligosaccharide structural features are necessary. As an example, mutants of *R. meliloti* strain Rm1021 produces an EPS (EPS I) that induces nodule formation 'pseudonodules' but lacks the ability to invade. A spontaneous mutant of the same strain has also been isolated that has the cryptic capacity to synthesize a second exopolysaccharide of considerably different structure (EPS II) which makes and invades nodules, and fixes nitrogen. This mutant was able to overcome the defects of EPS I in alfalfa, but not on four other plants that are normally hosts for Rm1021. The structural features of bacterial exopolysaccharides are thus directly involved in determining host range and have little influence on nodulation since both the succinoglycan producing wildtype strains and galactoglucan producing mutant strains of *R. meliloti* are able to infect their host plant properly

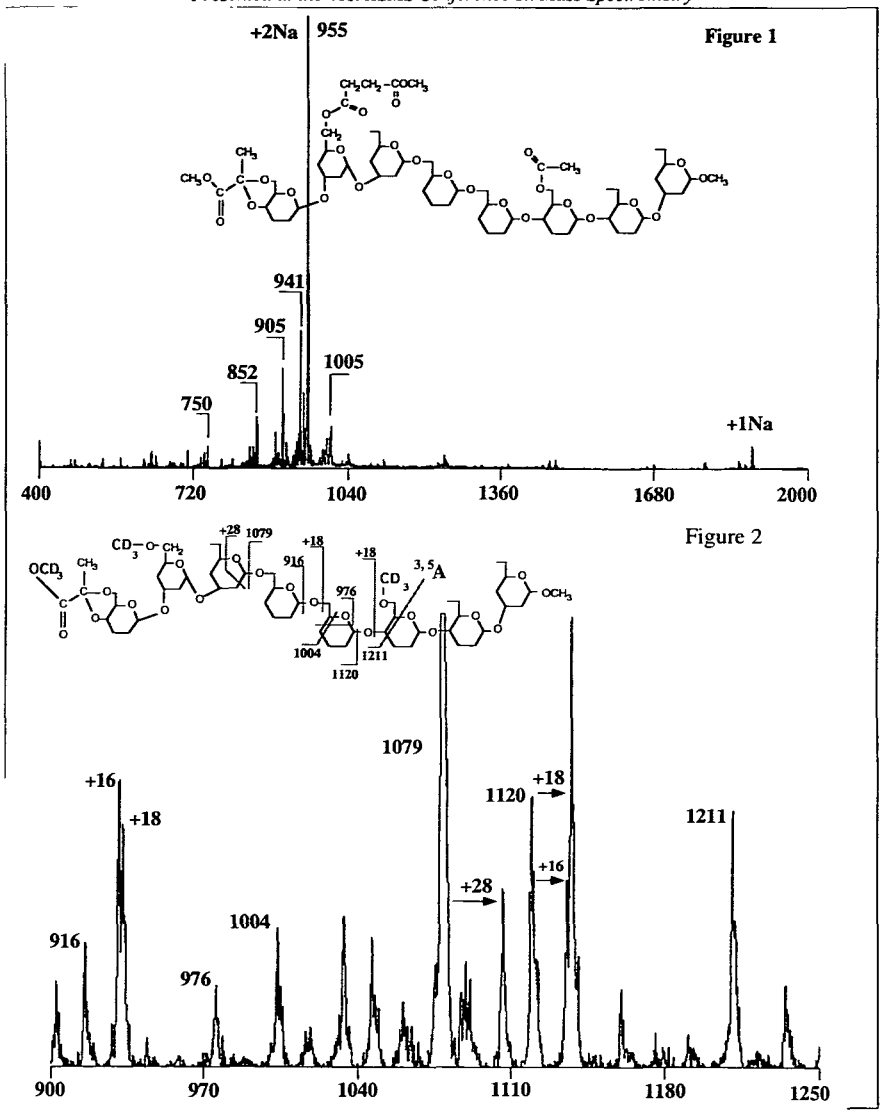
A biotechnology that would extend the range of host species offers great economic potential and consequently this system has been intensively researched in order to elucidate the complex signaling mechanism between the bacterium and plant host. A classic paper (Aman et. al. 1981) has detailed many aspects of the exopolysaccharide structure including the glycosyl composition, linkage and sequence. Proton NMR had revealed the presence of succinate and acetate moieties of the core oligosaccharide, although the location of the residues containing these functional groups and the site of derivatization were not determined. This succinyl moiety was subsequently shown to be essential for functional activity of the exopolysaccharide.

The ability to efficiently ionize and effectively fragment large oligosaccharides in a triple quadrupole with ESI and alkali metal cationization opens new doors in the structural biology of carbohydrates. The simplicity and sensitivity of this technique stands in stark contrast with the labor and material required of previous methodology.

In the current study the residue positions of the acetyl and succinyl groups were determined by a single ESI CID spectrum of the (neutral) permethylated oligosaccharide. Subsequent permethylation under basic conditions replaced the succinyl and acetyl modifications with deuterated methyl groups. The CID spectrum of this molecule verifies the residue locations determined in the previous spectrum, supports much of the backbone linkage assignment of Aman et. al. by specific ring-opening fragmentations, and determines the specific site of the acetyl modification. Location of the succinyl group The site of the succinyl modification was determined by clasical methylation analysis and GC MS of the methylated alditol acetates.

Figure 1 Electrospray MS of extracellular polysaccharide from Rhizobium meliloti. The oligosaccharide was (neutral) permethylated without cleaving the acetyl or succinyl esters. [Carb Res 78, 372-374 (1980) 145, 247-265 (1986)] The intense peak at 955 Th is the molecular ion adducted with two sodium cations and this ion was collided to identify the location of the acetyl and succinyl esters.

Figure 2 Expanded view of part of the CID spectrum of the neutral then base permethylated exopolysaccharide. The precursor was the doubly-natriated molecular ion. The substitution position of the acetyl ester is identified by a 3 Da shift in the ^{3,5}A ring-opening fragment.



Sequencing of Glycopeptides Using Sequential Digestion Followed by Microbore HPLC/Electrospray Mass Spectrometry

Christine A. Settineri and Alma L. Burlingame
Department of Pharmaceutical Chemistry and Mass Spectrometry Facility
University of California, San Francisco, CA 94143-0446

A method has been developed for sequencing oligosaccharides attached to partially purified glycopeptide mixtures using sequential digestion with highly specific glycolytic enzymes (glycosidases). This method involves digestion of glycopeptides with one to three glycosidases at a time, followed by purification with microbore HPLC coupled directly to an electrospray mass spectrometer for analysis of the products. Less than 5% of the sample injected onto the HPLC enters the mass spectrometer, therefore, approximately 95% of the sample can be recovered and digested with more glycosidase(s). Since different glycosidases require different buffer and pH conditions, this is an ideal method for removing the buffer salts as well as for further purifying the glycopeptides before each subsequent digestion step.

Glycopeptides were isolated by microbore HPLC separation of trypsin and endoproteinase glu-C digests of one nanomole of bovine fetuin and recombinant human nerve growth factor receptor (NGF-R), respectively. *N*-linked glycopeptide-containing fractions were identified in both digests by on-line HPLC/electrospray ionization mass spectrometry (LC-ESIMS). These fractions were isolated and digested with a series of exoglycosidases (shown in Table I) to identify and distinguish the different glycoforms present and where possible, determine the exact linkages between the monosaccharides. The fetuin glycopeptides [residues (54-85) and (127-142)] contain known carbohydrate structures and were used as standards to confirm the expected specificity of the enzymes and optimize reaction conditions. The NGF-R glycopeptide ^{24}GVAQPXGANQTVXEPXLD^{41} was then investigated to determine the sequence and linkages of the glycoforms attached at Asn-32 of this peptide.

Enzymes (in sequencing order)	*Enzyme Source*	*Conc. (U/ml or mU/ml)*	*pH optimum*	*Digestion Buffer*	*Digest Time (hours)*

Buffer A - 30 mM Sodium Acetate, pH 5.0
Buffer B - 100 mM Sodium Citrate Phosphate, pH 4.0 w/ 250 mg/ml Bovine Serum Albumin (BSA)
Buffer C - 100 mM Sodium Citrate Phosphate, pH 6.0 w/ 250 mg/ml Bovine Serum Albumin (BSA)

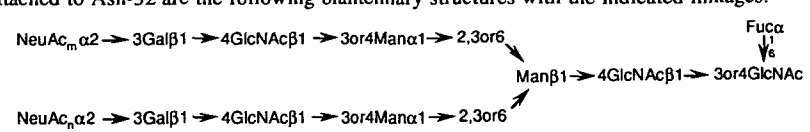
TABLE I - Exoglycosidase reaction mixtures used for sequencing glycopeptides.

The LC-ESIMS spectrum of the undigested NGF-R N-linked glycopeptide mixture showed considerable heterogeneity in the attached oligosaccharides. The molecular ions present in this spectrum correspond to NGF-R residues (24-41) containing fucosylated bi-, tri- and tetraantennary (or polylactosaminyl) complex structures containing zero, one and two sialic acids. This heterogeneity was considerably reduced by treatment with Newcastle disease virus sialidase, which removed all the sialic acid residues. Since this enzyme cleaves only α2-3 and α2-8 linkages, the linkage of the sialic acid to the next monosaccharide, galactose (determined by the next reaction with β-galactosidase), must be α2-3 (as expected with a Chinese hamster ovary cell-derived protein) since galactose contains only six carbons. With the fetuin glycopeptides, the Newcastle disease virus sialidase removed only some of the sialic acids present, as expected, since these bovine-derived glycopeptides are known to contain both α2-3 and α2-6 linked sialic acid residues.

The asialo spectrum showed evidence of a pentaantennary (or polylactosaminyl) oligosaccharide as well. The highly branched structures can be distinguished from less branched polylactosaminyl structures using exoglycosidase sequencing. β-galactosidase treatment of the glycopeptide mixture will only cleave the terminal galactose residues, so treatment of a bi- or triantennary polylactosaminyl structure will result in fewer galactose residues being cleaved than a tetra- or pentaantennary structure of the same mass. In fact, β-galactosidase treatment of the NGF-R glycopeptide resulted in cleavage of a maximum of three galactose residues, indicating the presence of triantennary structures with one and two additional lactosaminyl groups attached at the non-reducing termini. Similar rationale were used to determine the remaining sequence and linkages by combining the specificities of the glycosidases. For example, by combining the specificities of *S. pneumoniae* β-galactosidase and Chicken liver β-N-Acetylhexosaminidase, one can prove that a hexose-N-acetylhexosamine disaccharide unit is Galactose linked β1-4 to N-acetylglucosamine. Not all the glycosidases are specific enough to determine the exact linkage between every monosaccharide in the entire structure, however, they are specific enough that one can determine the exact sequence of specific monosaccharide residues in the carbohydrate structure.

The HPLC separation step with each ESIMS analysis was helpful due to side reactions that can occur from low level contaminants in the glycosidases. For example, the β-galactosidase contains protease activity which caused about 10% of the fetuin glycopeptide (54-85) to be cleaved down to (61-85) in the reaction mixtures which contained this enzyme. The two other glycopeptides were not proteolytically cleaved when using the *same concentration* of the β-galactosidase. However, if a two times greater concentration of the β-galactosidase was used, some protease activity was seen with all three glycopeptides. Therefore, we found it best to always try to use the minimum concentration of glycosidase in the reactions.

In conclusion, sequential exoglycosidase digestion of the NGF-R N-linked glycopeptide ^{24}GVAQPXGANQTVXEPXLD^{41} was used to determine three major carbohydrate glycoforms attached to Asn-32 are the following biantennary structures with the indicated linkages:



where m + n = 0-2.

In addition, mono- and disialo fucosylated triantennary structures containing 0, 1, and 2 additional polylactosaminyl groups were also found.

This work was supported by NIH grant DRR 01614 and NSF grant DIR 8700766.

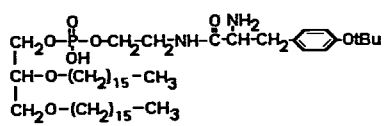
Microcolumn HPLC-CF-LSIMS of UV-absorbing Neoglycolipids Derived from Oligosaccharides

P. Verner, W. Chai, J. Rosankiewicz and A. M. Lawson
Medical Research Council, Clinical Research Centre, Harrow, Middlesex, HA1 3UJ, United Kingdom

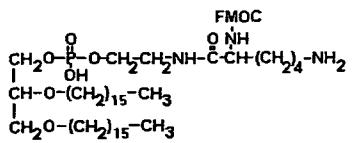
Dipalmitoyl phosphatidylethanolamine (DPPE) is currently used as a reducing terminal derivatization agent for oligosaccharides and their mass spectrometry (1). The resulting neoglycolipids formed from oligosaccharide and DPPE by reductive amination give particularly abundant molecular ions in liquid secondary ion mass spectrometry (LSIMS) and their fragmentation reflects the composition, sequence and branching of the oligosaccharide moiety. Typically, HPTLC separation of neoglycolipid mixtures is carried out with analysis by LSIMS directly from the plate.

We prepared a range of UV chromophore-containing derivatization agents based on DPPE or 2-dihexadecyl-glycero-3-phosphoethanolamine (DHPE). These reagents are comparatively straightforward to synthesise and their stability is similar to that of DPPE and DHPE.

Two of these derivatives, namely DHPET and DHPEL, were more fully investigated to examine their suitability for HPLC, LSIMS and biological studies.



DHPET



DHPEL

Neoglycolipids were prepared from various oligosaccharides with DHPET and DHPEL. These compounds retained the favourable LSI mass spectral features of DHPE and DPPE based oligosaccharide derivatives [Fig.1].

Analytical and microcolumn HPLC separation of these neoglycolipids was attempted on silica, amino, ODS-silica and ODS-polymer reversed phase columns using various mobile phases and modifiers. An ODS-silica reversed phase column with chloroform-methanol-water-TFA mobile phase was selected for separation of these conjugates prior to introduction to MS. Neoglycolipids separate according to their polarity on this phase with the reagent eluting last [Fig.2].

A coaxial flow interface was constructed for continuous flow LSIMS delivering the HPLC column effluent and the matrix separately to the probe tip. This has permitted different matrix compositions and mobile phase:matrix ratios to be easily tested. A matrix composed of diethanolamine-tetramethylurea-nitrobenzylalcohol added in a ratio of 1:20 to column effluent gave the best signal-to-noise ratio in continuous flow LSIMS experiments. Complete mass spectra were obtained from 2 pmol of neoglycolipid using continuous multichannel analysis mode.

Electrospray Ionization of Divalent Metal Chloride Coordinated Oligosaccharides.

Aberra Fura and Julie A. Leary, Department of Chemistry,
University of California, Berkeley CA 94720.

Previous reports[1] indicated that as oligosaccharides becomes larger and more structurally complex, coordination of more lithium ions is necessary for the unambiguous determination of linkage positions. In this study, the analytical usefulness of coordination of divalent metals, calcium and magnesium to three branched trisaccharides, 3-fucosyllactose, B-trisaccharide and 2'-fucosyllactose has been investigated using electrospray ionization (ESI) and tandem mass spectrometry (MS/MS).

The ESI of these trisaccharides, upon coordination with the above divalent metal ions, yielded several cluster ions. The relative abundance of these ions was found to depend on the concentration of the saccharide and the metal, their relative concentration ratio and the skimmer voltage. Thus when the molar concentration of the metal salt was less than that of the saccharide there was a relative increase in the abundance of the ions which represent $[M_n + Metal]^{2+}$ (where n is 1,2,3 etc. and M is the trisaccharide). The opposite trend is observed when the concentration of the metal ion is increased. However, this phenomenon is dependent on the concentration of the oligosaccharide and the coordinating metal. For instance, at the 3-fucosyllactose concentrations of 1500, 100, 50, 12 pmol/µl, the ion at m/z 563, $[M+CaCl]^+$, is maximized at a 1:1, 2:1, 5:1, and 10:1 metal to trisaccharide concentration ratios respectively.

The relative intensity was also observed to depend on the sampling skimmer voltage. Thus at lower skimmer voltages, solvent molecules remain attached to the metal due to lack of complete dissolvation. At higher voltage the spectra were dominated by fragment ions, resulting from the collisional dissociation in the low pressure region of the source.

The singly charged ions, $[M+CaCl]^+$ and $[M+MgCl]^+$, enhanced the sensitivity and led to analytically useful fragmentation upon collisional dissociation. MS/MS and MS/MS/MS of these ions produced ions due to glycosidic cleavages as well as ions resulting from the cleavage of the reducing ring. The MS/MS spectrum of the complex, $[M+CaCl]^+$, (Figure 1A) where M is 3-fucosyllactose showed ions at m/z 527,321,261, in addition to the precursor ion at m/z 563. The ion at m/z 527 is due to the loss of the fucose residue and two consecutive two carbon chain neutral losses at m/z 321 and 261. The first two carbon chain loss comes from C-1 and C-2 of the reducing ring. The ion at m/z 261, which represents a second two carbon chain neutral loss from C-5 and C-6 of m/z 321, as also confirmed by MS/MS/MS indicates that the linkage of the remaining disaccharide portion at m/z 321 must be 1,4, since these kinds of losses are characteristic of this linkage type as observed previously.[1] The C-3 is therefore the only logical place where fucose ring can be attached. The corresponding MS/MS spectrum of $[M+MgCl]^+$ also showed the above dissociation ions. In addition, it also indicated the presence of less abundant ions at m/z 451 and 391, due to the direct loss of two and four carbon chain neutrals along with HCl from the precursor ion at m/z 511. For B-trisaccharide, the corresponding MS/MS spectrum of $[M+CaCl]^+$ (Figure 1B) showed ions at m/z 545, 381, 291 and 261, in addition to the precursor ion at m/z 563. The ion at m/z 545 arise from the loss of H_2O and the ion at m/z 381 is due to the simultaneous loss of HCl and fucose ring. The ion at m/z 291 and 261 represents a three and four carbon chain neutral losses respectively, from the ion at m/z 381 as also confirmed by MS/MS/MS. These losses are specific for 1,3-linkage type in the disaccharide portion of the molecule having free

hydroxyl groups on C-4 and C-6 carbons of the reducing ring. Additionally, no two carbon chain loss is observed, thus narrowing down the possibility of the fucose ring attachment to C-2 of the reducing ring. The MS/MS of the corresponding $[M+MgCl]^+$ was also studied but found to show several more ions produced by more than one dissociation pathways. The MS/MS spectrum of $[M+CaCl]^+$ (Figure 1C) of the third isomer, 2'-fucosyllactose, showed ions at m/z 467 and 407 due to the loss of $C_2H_4O_2$ and $C_4H_8O_4$, respectively, from the precursor with simultaneous loss of fucose moiety indicating that the fucose ring is now attached to the non-reducing ring. However, definite information as to which carbon the fucose ring is bonded to was lacking.

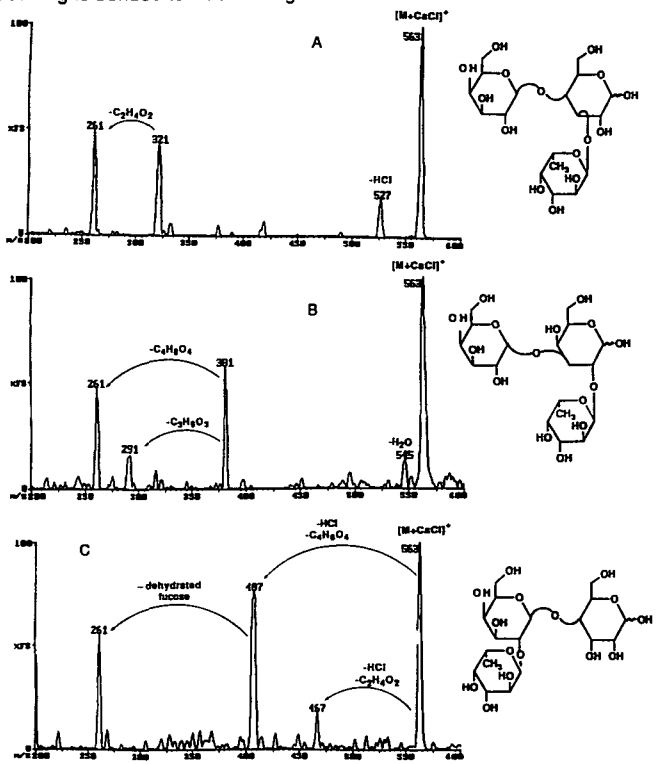

Figure 1. MS/MS spectra of $[M+CaCl]^+$ at 50% transmittance of Argon.

An Analysis of Mono- and Oligosaccharides by Electrospray Mass Spectrometry

Jennifer M. Duker and Edward W. Sheehan
Millipore/Extrel Mass Spectrometry, 575 Epsilon Drive, Pittsburgh, PA 15238

Simple sugars, or monosaccharides, are single polyhydroxy aldehyde or ketone units that provide the building block foundations for the larger covalently linked oligo- and polysaccharides. As bioorganic molecules, carbohydrates serve important biological functions in both the animal and plant worlds. In the form of sugar and starch they represent a large part of the total caloric intake for animals, while in plants, they are central to metabolism and the utilization of solar energy.

Based on the size of the saccharide of interest, the structural elucidation can often be complex. NMR (nuclear magnetic resonance) is commonly used to analyze sugars, however, in general these results are hindered by the complexity of larger molecular weight compounds. A more definitive means of analysis is provided by mass spectrometry. Mass spectrometry serves as an additional analytical tool for the analysis of carbohydrates and other compounds varying in molecular weight and structural complexity.

A series of mono- and oligosaccharides have been previously evaluated by particle beam LC/MS at various detection limits. This investigation looks at the use of electrospray for the evaluation of these same compounds. Negative electrospray was used to look at these compounds due to the resulting increase in sensitivity and response. In addition, collisonally induced dissociation (CID) was used to partially elucidate the structures of some complex oligosaccharides. This investigation, along with previous EI and CI spectra, allows us to fully characterize the compounds of interest. Further analysis of the data provided response factors at given injection volumes as well as multiple point calibration curves.

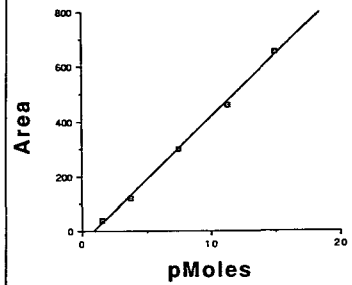
EXPERIMENTAL

This study evaluates the feasibility of utilizing a benchtop LC/MS with Particle Beam and Electrospray interfaces for the analysis of simple sugars. The compounds evaluated consist of monosaccharides up to 4 units in length.

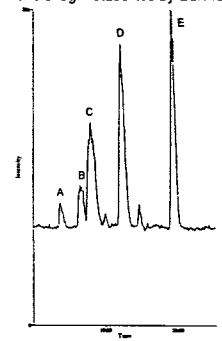
MASS SPECTROMETER
- EXTREL benchmark™ mass spectrometer
- ThermaBeam™ Particle Beam interface
- Electrospray interface

LIQUID CHROMATOGRAPHY
- WATERS 600MS LC pump and controller
- Particle Beam
  - Solvents: (A) Methanol (B) H_2O
  - Mobile Phase: 80% A / 20% B
  - Flow Rate: 0.5ml min
- Electrospray
  - Quenching Gases: O_2 and SF_6
  - Solvents: (A) Methanol/Isopropanol (70/30) (B) H2O
  - Mobile Phase: 85% A / 15% B
  - Flow Rate: 0.2ml min, 100:1 split

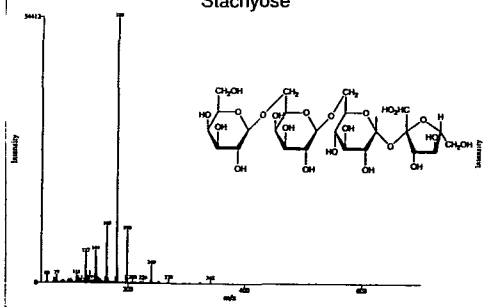
Calibration Curve for Stachyose
The response is linear, r=0.998



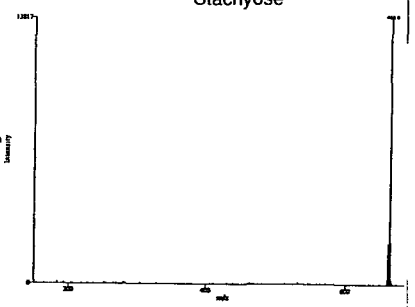
Total Selected Ion Chromatogram of 5 Drug Metabolites by LC/MS



Positive Chemical Impact Stachyose



Negative Electrospray Stachyose



CONCLUSIONS

ThermaBeam™ LC/MS Analysis of Sugars:
- Sugars up to tetrasaccharide's yield the same characteristic EI spectra
- PCI of sugars provides molecular weight information as well as some structural information
- PCI was sensitive to all analyzed sugars
- PCI provided limited quantitative information but extensive qualitative information

Negative Electrospray LC/MS analysis of sugars:
- [M-H]- for some analyzed sugars
- Sensitivity and detection limits for high molecular weight compounds
- Linear calibration and extensive quantitative information

Use of matrix-assisted laser desorption mass spectrometry for examination of oligosaccharide mixtures.

D. J. Harvey

Glycobiology Institute, Department of Biochemistry, University of Oxford, South Parks Road, Oxford, OX1 3QU, UK.

Introduction

Matrix-assisted laser desorption mass spectrometry using substituted benzoic acids as matrices has been shown to produce abundant $[M + Na]^+$ ions from complex oligosaccharides[1,2]. 2,5-Dihydroxybenzoic acid (2,5-DHB) generally gives the strongest signal. This paper examines the use of the technique for examination of *N*-linked oligosaccharides released from glycoproteins.

Experimental

Materials. Reference oligosaccharides and sugar mixtures were obtained from IgG, ovalbumin, transferrin, ribonuclease, thyroglobulin, ovomucoid, fetuin and horseradish peroxidase by hydrazinolysis. 2,5-DHB was obtained from Aldrich Chemical Co. Ltd.,

Sample preparation. The matrix solution was prepared by dissolving 50 µmol (7 mg) of 2,5-DHB in acetonitrile (0.7 ml) and water (0.3 ml). 1.0 µl of this solution was placed on the target followed by about 0.2 µl of the solution of oligosaccharide (containing about 100 pmol of oligosaccharide). These solutions were allowed to mix and evaporate to dryness at room temperature. The deposit was then recrystallised on the target by the addition of about 0.2 µl of ethanol, allowed to dry, and the target was introduced into the mass spectrometer.

Mass Spectrometry. LD spectra were acquired with VG TOFSpec and Finnigan Lasermat TOF mass spectrometers, and with a VG Autospec mass spectrometer fitted with an array detector. All three instruments were fitted with a nitrogen laser operating at 337 nM. Spectra were obtained using multiple laser shots to give a good signal:noise ratio. Oligosaccharide compositions were assigned using a computer program written for the Windows 3.1 environment.

Results and Discussion.

2,5-DHB has been shown to give a concentration-dependent, signal from reference oligosaccharides (1 - 2 KDa range) and this matrix produced good spectra from all oligosaccharide mixtures examined. Representative profiles are shown in Figs 1 - 4. Oligosaccharide profiles could be obtained in less than 5 mins with higher resolution than by the existing method using Bio-Gel P4 chromatography (16 hours). With all of the mixtures examined, the known oligosaccharides were characterised and mass measured, usually to within ± 2 Daltons on the TOF instruments and to 0.5 Daltons on the sector instrument (low resolution mode). This was sufficient, to assign a composition in terms of isobaric sugars. In several cases, particularly with ovalbumin (Fig. 3), a number of unreported oligosaccharides were detected (unfilled peaks).

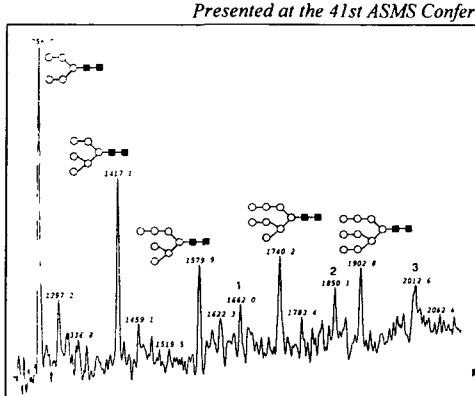


Fig. 1. LDMS of ribonuclease oligosaccharides.

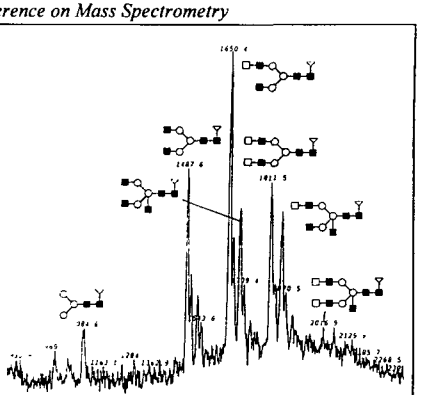

Fig. 2. LDMS of IgG oligosaccharides.

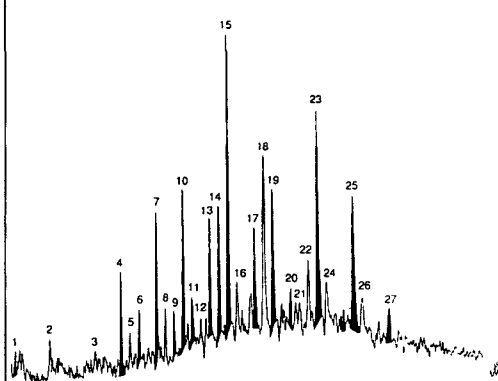

Fig. 3. LDMS of ovalbumin oligosaccharides.

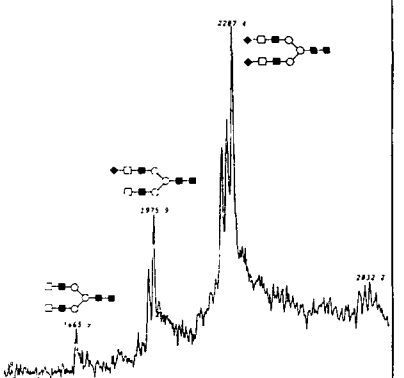

Fig. 4. LDMS of transferrin oligosaccharides.

Transferrin contained predominantly sialylated sugars (Fig. 4); these gave a mixture of ions in the positive ion mode in which each carboxylic acid group could acquire a sodium ion; the fully sodiated form predominated. In the negative ion mode, only one peak was observed suggesting that this is a more appropriate mode for anionic sugars.

Identification of Glycoalkaloids in A Crude Mixture by Tandem Mass Spectrometry With Scanning-Array Detection

Su Chen[1], Peter J. Derrick[1], Fred A. Mellon[2] and Keith R. Price[2]
[1]Institute of Mass Spectrometry and Department of Chemistry, University of Warwick, Coventry CV4 7AL, and [2]AFRC Institute of Food Research, Norwich Laboratory, Norwich Research Park, Colney, Norwich NR4 7UA, UK

The glycoalkaloids (GA) are a group of nitrogenous, steroidal glycosides found in some common food plants of the *solanum* species, including potatoes, tomatoes and aubergines (eggplant). Although the chemical structures of these biomolecules have been known for years, common procedures for the identification of various aglycones and monosaccharides (mainly L-rhamnose,D-glucose,D-galactose and D-xylose) in the glycoalkaloids are time-consuming and require significant quantities of sample. MS/MS method has been used for analyzing a wide range of GA, including GA crude mixtures (1). In this communication, the identification of GA in a crude mixture by positive ion LSIMS and MS/MS is reported.

Experimental: The potato extract was isolated from etiolated potato shoots and prepared by a previously described method (2). All spectra were obtained on a Kratos CONCEPT II HH four-sector tandem mass spectrometer equipped with a scanning-array detection system (3). The acquisition-time of 10 seconds was made possible by using a charged-coupled device (CCD) to register the signal. Experimental parameters were controlled by a MACH 3 data system which recorded and processed mass spectra in an identical manner to that used with a conventional point detector. CID of precursor ions was conducted in a flexicell which was floated at a potential of 4 kV related to the earth. Helium was used as collision gas and was set to a pressure sufficient to attenuate the precursor ion beam by 60%. The samples were dissolved in a 2:1 mixture of MeOH/TFA and the solution was transferred to the LSIMS probe tip and dried, after which NBA was added. The amount of sample loaded for positive ion analysis was 200 ng for conventional mass spectrometry and 200-2,000 ng for tandem mass spectrometry.

Results: CID MS/MS spectra of the $[M+H]^+$ ions, generated by LSIMS of a crude mixture (fig.1a), induces three major fragmentation processes, Z-, Y- and ^{1,5}X-cleavages, which are structurally informative. Signals resulting from X0-, Y0- and ^{1,5}X0-cleavages provide information on structures of various aglycone moieties in all GA. Linkages and positions of the sugars in trisaccharide- and tetrasaccharide-containing GA can be identified depending on the presence or absence of the ions due to Zα+β- and Yα+β-cleavages and intensity differences of the peaks due to ^{1,5}Xα- and ^{1,5}Xβ-cleavages (fig. 1b and 1c), respectively. The positive ion method has the advantage of i) lower detection limit in the conventional mass spectrometry; ii) numerous and intense fragment ions that are structurally informative; and iii) the capability of analysing minor components (fig. 1b) in crude extracts. Comparable analysis by other analytical means would not have provided the amount of structural information on the compounds of the glycoalkaloid mixture.

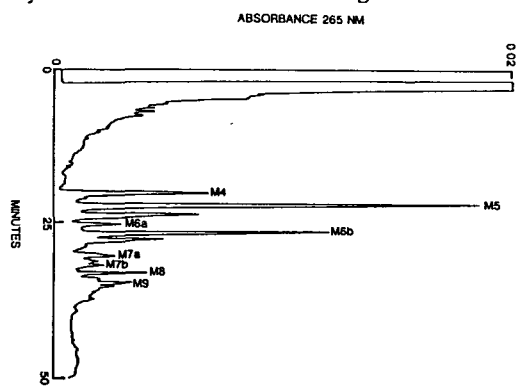
Oligosaccharide Profiling by LC-ESI-MS: Focus on Mucins.

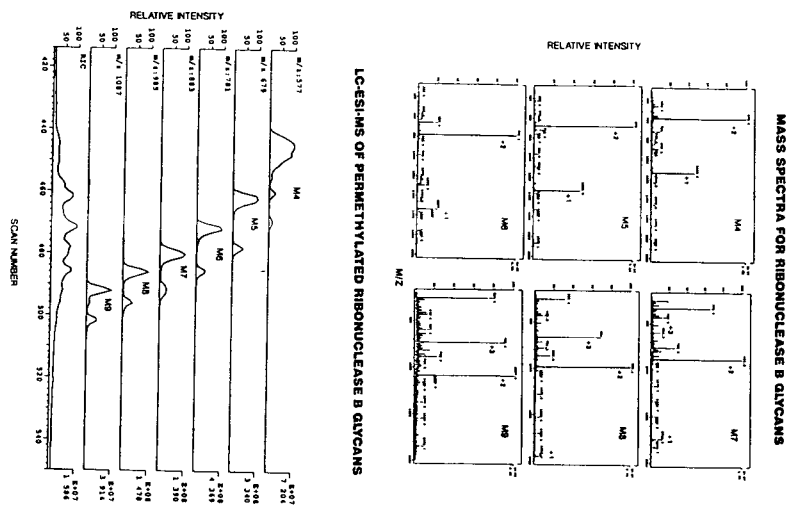
Rene Mora, Jeffrey M. Drazen and Vernon N. Reinhold.
Harvard University School of Public Health,
665 Huntington Avenue, Boston, MA 02115.

Carbohydrates fulfill important structural and functional roles within tracheobronchial mucins, and there is increasing evidence that changes in mucin carbohydrates may have profound pathophysiological consequences. With an eye toward the structural analysis of mucin glycans, we have been investigating methods for the chemical release of O-linked oligosaccharides from mucin glycoproteins, the derivatization and chromatographic separation of these oligosacharides, and the interfacing of such chromatography with electrospray mass spectrometry.

Our results to date indicate the following: (i) O-linked glycans can be released from mucins in intact form and with a yield of greater than 85% by hydrazinolysis at 75C for six hours. The distribution of O-linked glycans found in fetuin as well as in bovine submaxillary mucin by hydrazinolytic release matches closely with those profiles previously obtained by reductive elimination.
(ii) Both N- and O-linked glycans containing a reducing end group, whether released by hydrazinolysis or enzymatic means, may be subjected to end-group labeling by hydrazine and PITC. Such labeling greatly enhances the spectrophotometric detection of these glycans. When combined with the resolving power of normal-phase chromatography of glycans on aminosilica columns, complex mixtures of oligosaccharides present in relatively small amounts may be chromatographically purified as individual species. The chromatogram shown below represents the separation of less than 10 ug of ribonuclease b glycans, and it suggests that there is separation not only on the basis of size but also among different isomers.



(iii) Such released glycans are amenable to permethylation and mass spectrometric detection by ESI-MS, with sodium adduction. As previously demonstrated, this approach provides sensitivity in the low picomolar range (1). When hydrazino-PITC-labeled glycans are subjected to basic permethylation, there is full derivatization of all glycan hydroxyl groups as well as the amine moieties on the hydrazine and the phenylisothiocyanate. Glycans derivatized in this manner, when subjected to electrospray ionization, may appear either as the protonated or the sodiated species, depending on the solvent conditions . (iv) Complex mixtures of permethylated glycans may be subjected to capillary reverse-phase HPLC separation, coupled with on-line ESI-MS, using water and methanol as the eluants The inclusion of 0.5 mM NaAc in both the iorganic and organic solvents provides the needed alkali metal ion for adduction and electrospray ionization. The chromatogram shown below, generated with 200 ng of ribonuclease b glycans, demonstrates the sensitivity of this technique.



The longer term goal of these efforts is to combine these and other methodologies under development into a general approach to the structural analysis of mucin glycans.

GLYCOFORM DETECTION IN CHO - DERIVED INTERLEUKIN-4 BY LC - CID - ELECTROSPRAY MASS SPECTROMETRY.

***A. Tsarbopoulos, B.N. Pramanik, E. Huang and T. Covey[1].**

Schering-Plough Research Institute, Kenilworth, NJ 07033 and [1]Sciex, Thornhill, Ontario L3T 1P2, Canada.

Human interleukin-4 (IL-4), previously known as B-cell stimulatory factor, is a T-cell derived lymphokine which mediates the proliferation and differentiation of B-cells, and also stimulates mature T-cell proliferation. The gene encoding human IL-4 has been cloned and expressed in Chinese Hamster Ovary (CHO) cells. The mature polypeptide sequence is 129 amino acid residue long and contains two asparagine residues in the consensus sequence Asn-X-Ser/Thr which is required for N-linked glycosylation.

Several mass spectrometric (MS) techniques have been recently developed for identifying glycopeptides in chromatographically separated fractions from complex digest mixtures of glycoproteins, mainly by mapping prior to and after enzymatic digestion with peptide:N-glycosidase F (N-Glycanase). In this report, we assess the utility of the electrospray (ES) ionization method in combination with enhanced ion-source fragmentation towards the identification of the glycopeptides in the LC chromatogram and the early indication for the various glycoforms present in the chromatographic fractions.

Analysis of CHO IL-4 by electrospray MS, using a Sciex API III triple quadrupole mass spectrometer, generated three envelopes of multiply charged ions from 8+ to 10+ each comprising several peaks corresponding to the individual glycoforms of the glycoprotein (Fig. 1). Then the CHO IL-4 glycoprotein and its deglycosylated (*E. coli*-derived) counterpart were cleaved enzymatically by either trypsin or V8 protease and the resulting peptide digest mixtures were analyzed by reversed-phase HPLC in conjunction with ES MS. This approach provided information on the glycopeptide fragments along with protein mapping. ES MS analysis of the tryptic digest of CHO IL-4 provided mapping of the protein backbone including confirmation of the existing disulfide pattern in the protein molecule. It should be noted that ES analysis of the *E. coli* IL-4 tryptic digest yielded only signals corresponding to the average mass of the disulfide-paired peptides $T_{1,2}$-T_{22}, T_6-T_{16} and T_4-T_{10}, i.e., 1734.4, 2124.7 and 2943.1 Da, respectively. This is in contrast to the LSI and PD MS analysis, where additional signals corresponding to the cysteine-containing constituent peptides were observed. In the analysis of the CHO IL-4 tryptic digest these disulfide-indicative ES signals were shifted to higher m/z values due to incomplete cleavage at the lysine residues near the glycosylation site, thus resulting to the incorporation of the T_5-CHO glycopeptide on the adjacent disulfide-linked peptides T_4 and T_6.

Comparative LC-ES tryptic mapping of the CHO and *E. coli* IL-4 allowed the identification of peaks 11 and 14 in the total ion chromatogram of CHO IL-4 as the ones containing the glycopeptide fragments (Fig. 2). The ES mass spectrum of the *E. coli* IL-4 peak 11 exhibited multiply charged ions corresponding to the $T_{5,6}$-T_{16} disulfide (Fig. 3), whereas that of CHO IL-4 showed two ion envelopes corresponding to triply and quadruply charged glycopeptides (Fig. 4). The m/z spacing between the peaks in each ion envelope revealed the variations in the NeuAc and Hex-HexNAc content, and the corresponding glycopeptide mass values were 4921, 5286, 5577 and 5868. It should be noted that low mass ions indicative of the carbohydrate units were either very weak or absent in the ES spectrum of Fig. 4. The presence of these sugar-specific ions (m/z 162 for Hex^+, m/z 204 for $HexNAc^+$, m/z 292 and 274 for $NeuAc^+$ and m/z 366 for $Hex\text{-}HexNAc^+$) was enhanced by increasing the orifice (OR) potential, which controls the extent of fragmentation in the declustering region (the region before the first mass filter, Q1) of the API III mass spectrometer (HIGH SOURCE FRAGMENTATION). The ES mass spectrum of peak 11 at elevated OR potential (110 V) is shown in Fig. 5, where all sugar-specific oxonium ions are clearly observed. Moreover, this spectrum shows that the intact glycopeptide signals tend to shift to lower m/z values within the ion envelope of the same charge state, due to the partial loss of carbohydrate units such as the NeuAc end cap units. Although this is only happening to a small extent, it can be eliminated by stepping the OR potential with mass as it was recently shown by Carr et al. (Protein Sci. 1993, 2, 183-196). Even

though this enhanced fragmentation in the ion declustering region lacks mass selectivity, it yields the same structural information as fragmentation in the second quadrupole with much higher sensitivity and product ion resolution. These carbohydrate screening results agreed with those deduced from the PD MS analysis of the isolated and derivatized carbohydrate components (See Proceedings of the 38th ASMS Conference, pp. 1341-2).

Enhanced Carbohydrate Detection by Multiple Ion Monitoring (MIM) of HPLC Effluents

Stephen Chan, Bruce Reinhold and Vernon Reinhold
Department of Nutrition, Harvard University School of Public Health, Boston, MA 02115

Understanding the structure-functional relationship of carbohydrates in biological systems has been recognized as a vital aspect in biomedical research. Although the details of carbohydrate structure are still rarely pursued, and only then, when relatively large amounts of sample become available. With new attention to the role carbohydrates play in lymphocyte trafficking, modulation of the immune response, nitrogen fixation and their well established roles in cellular differentiation, a greater effort must be directed to supporting full characterization at the biological amounts frequently available.

Carbohydrates or glycans derived from extracts of biological samples could be in a matrix containing many other species even after extensive sample clean-up. We have demonstrated the utility of the permethylation technique to enhance sample clean-up and improve electrospray ionization (ESI) efficiency [1]. Even so, for analyzing glycans in a complex matrix, separating the glycans from the matrix would enhance not only the ESI efficiency of the glycans, but also produce cleaner and more interpretable mass spectra. In this research, on-line HPLC separation prior to ESI analysis is used to separate glycans from matrixes and, with an appropriate solvent gradient, separate the different glycoforms among the glycans. If the detection of a specific glycoform is the only interest, the sensitivity of the analysis could be greatly improved if only the ions associated with the glycoform are monitored during the HPLC run. The identity of the glycoform would be unambiguous if more than one ion characteristic of the glycoform are monitored. The multiple ion monitoring (MIM) technique is accomplished by collisional induced dissociation (CID) which produces characteristic fragment ions associated with the interested glycoform.

Both high-mannose and complex type glycans were used in this research in order to demonstrate the feasibility of the (MIM) technique. High-mannose glycans were enzymatically released from Ribonuclease B by means of endoglycosidase F. This protein is known to contain a single N-linked site of high-mannose glycans. Complex glycans were enzymatically deglycosylated from recombinant erythropoietin (EPO) using N-glycosidase F. All the released glycans were permethylated prior HPLC injection. This would remove all hydrophilic residues because the last step of permethylation involves several stages of water/ chloroform extraction. The HPLC separations were performed using a C4 capillary column with a pre-column (1: 600) solvent splitting. Effluents eluded from the column were directly infused into an eletrospray ionization source (ESI) at a flow rate of about 1 ul/min. The solvent gradient contains water and methanol with 0.5 mM of sodium acetate. During MS/MS scannings, the collision offset voltage of a Finnigan TSQ-700 triple stage mass spectrometer was maintained at between 27 to 35 V, depending on the type of glycans being monitored. The collision pressure of argon was set at about 3.5 mtorr.

All five known high-mannose glycoforms were separated under our HPLC conditions (Figure 1). Anomers and selected isobers appear to separate well under these conditions. The chromatrograph derived from monitoring a single characteristic ions of Man_9 glycans reveals remarkable improvement in signal to noise ratio. This allows the anomers to be better baseline separated. By monitoring more than one characteristic ions associated with the glycoform, the MIM chromatrograph allow further structure identities of the glycoform to be exposed.

The HPLC conditions used for separating the high-mannose glycoforms did not allows the complex glycan to be well separated. However, the MIM chromatrograph derived from monitoring the loss sialic acids from a tetraantennary complex glycan provides additional identity for the compound with enhanced signal to noise ratio. In case of monitoring a specific structure from a very complex mixture, MIM is needed to reduce ambiguity for the positive identification.

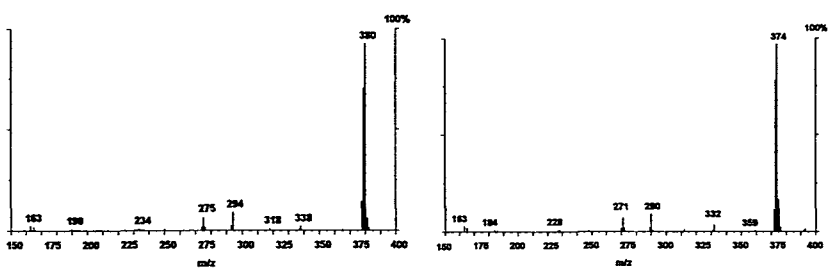
QUANTITATION OF GLUCOSE AND $^{13}C_6$-(U)-D-GLUCOSE METHYLBORONATE PENTAFLUOROPROPIONATES IN HUMAN PLASMA BY METHANE NCI GC-MS.

Jiri Zamecnik, Garry Seabrook, Defence and Civil Institute of Environmental Medicine, Operational Medicine Division, North York, Ontario, M3M 3B9, Canada.

Introduction and Methods

For our study of substrate utilization in humans exposed to cold we needed a method which would allow us to measure both $^{13}C_6$-(U)-D-glucose ($^{13}C_6G$) and D-glucose (G) in a single small volume sample, with a simple sample preparation. We have developed a methane NCI GC-MS method based on cyclic methylboronate-pentafluoropropionate derivatization using $^2H_3$-(5,6,6)-D-glucose (D_3G) as an internal standard (IS). Two calibration curves were produced, one for G was prepared in water in duplicates (500, 1000, 1500 and 2000 µg/mL), the second calibration curve for $^{13}C_6G$ was prepared in duplicates in human plasma (1, 5, 10, 50 and 100 ng/mL of plasma). The samples of heparinized frozen human plasma and control plasma pool samples were allowed to thaw and aliquots of 10 µL undiluted or 100 µL of diluted (1:10) plasma were used. The IS (100 ng/100µL of D_3G in water) was added to all samples and calibrators. All tubes were vortexed and freeze-dried overnight. The freshly prepared solution of methyl boronic acid (MBA - 100 µL of 1 mg/mL solution in dry pyridine) was added to all tubes, heated at 95°C for 1 h, pyridine was then removed under a stream of nitrogen. Pentafluoropropionic anhydride (PFPA, 100 µL) was added and tubes were heated for an additional 45 min at 75 °C; 1 µL aliquots were injected into GC/MS (Finnigan MAT TSQ-70). The samples were stable for up to 5 days. The GC conditions: injector in split mode (1:30) at 280°C, GC oven 160°C to 260°C at 15°C/min; separator 280°C, capillary DB-5 J&W Scientific 30 m column, 0.25 mm I.D. The ion source temperature was 110°C, filament current 200 µA, electron multiplier 1600V, scanning a single quadrupole in a selective ion monitoring mode (SIM) using methane as CI gas in negative mode. Masses 374 m/z (G), 377 m/z (D_3G) and 380 m/z ($^{13}C_6G$) were monitored with a dwell time of 100 µsec. The typical retention time was 3.5 min, with D_3G eluting slightly ahead of the other two glucoses. There were no interfering peaks in all the three monitored channels.



$^{13}C_6$-(U) D-glucose and D-glucose methylboronate-pentafluoropropinates methane NCI

Results and Discussion

We have developed G and $^{13}C_6G$ assays using MBA derivatization because the derivatives had good stability and excellent GLC properties (1-5). To increase the sensitivity we used PFPA and methane NCI. The sample size was typically 1-10 µL of plasma. Small lumps of insoluble material were observed in all sample tubes after the last derivatization step, with the derivatized glucoses remaining dissolved in PFPA. The small sample size, impurity precipitation and use of split injection (1:30) allowed us to skip any pre-purification steps. The crude derivatized plasma extracts were injected directly into the GC-MS. Other hexoses present in human plasma samples eluted from the GLC column at different retention times than glucose. This simple workup allowed us to complete a batch of 60 samples in one and a half days. The contribution of D_3G IS into either of the sample channels (0.351% into 374 and 0.436% into 380 m/z) at 100 ng/tube did not affect the results. The calibration curves were calculated by least square fitting of all points and plotted, as a ratio of areas for (377 m/z and 374 m/z over 380 m/z) against the glucoses plasma concentrations (r>0.998). The precision calculations were done on pooled plasmas used for the quality control (5.1 ng/mL of $^{13}C_6G$ and 750 µg/mL of G). The within assay coefficients of variation (%CV) assays were 3.79% for G and 2.33% for $^{13}C_6G$ (n=10). The between assays %CV were 5.05% and 3.91% (n=10). The limits of detection (3x SD of baseline, 6) were 3.7 pg/mL, the limits of quantitation (10x SD of baseline, 7) were 12.5 pg/mL, for both assays. In conclusion, the method of assaying both glucoses was reliable, fast and proved most applicable to kinetic studies of glucose utilization in humans.

QUANTIZATION STUDIES OF POLYMETHYLATED β-CYCLODEXTRINS BY ESMS

Leize E.[1], Dupont A.[1], Le Tavernier J.F.[2] and Van Dorsselaer A.[1]
[1]Laboratoire de Spectrométrie de Masse Bio-Organique, URA 31 CNRS-Université Louis Pasteur, 1 rue Blaise Pascal, 67000 Strasbourg. [2] Centre de Recherche en Biotechnologie ORSAN, Courtaboeuf, France.

INTRODUCTION:

β-cyclodextrins present attractive properties: for example, they are good pharmacological carriers and they can be used as stationary phases for liquid chromatography. Unfortunately, β-cyclodextrins are characterized by a low solubility. This drawback is circumvented by using modified β-cyclodextrins (methylated, ethylated and hydroxypropylated) which exhibit the properties of native β-cyclodextrins without their inconveniences. There is an analytical need to determine the degree of alkylation and the purity of these derivatized β-cyclodextrins which are often produced as mixtures of several states of *methylation usually ranging from 13 to 18. Using conventional analytical tools (RP-HPLC, NMR)*, accurate characterization of modified β-cyclodextrins is difficult to achieve.

We have already described the characterization of PolyMethylated β-CycloDextrins (PMCD) by ESMS, using NH_4^+ adducts [1]. This method does not lead to fragmentations and is characterized by an easy preparation of samples, short times of analysis and very high sensitivity (picomole scale). Unfortunately, in this former work, the percentage of each methylation state could not be determined because we had no access to the response factors.

We show here that ESMS can be used for an accurate quantization of the methylation degree in a PMCD mixture. We evaluate also the possibilities of dodecylamine to replace NH_4^+ for ionisation.

RESULTS:

Determination of the best ionization agent:

ESMS Spectra with NH_4^+ (Fig.1): Only molecular ions $[M+NH_4]^+$ were produced for each number of methylations. The presence of small doubly-charged ions $[M+2NH_4]^{2+}$ did not interfere with quantization, as the profiles of the mono-charged and the doubly-charged ions were identical. Therefore, only the mono-charged ions were used for quantization.

ESMS Spectra with dodecylamine (Fig.2): We observed almost exclusively the mono-charged ions [M+dodecylamine]. Comparing to the NH_4^+ spectra, the peaks were more intense and sharper. The doubly-charged ions were smaller than with NH_4^+. Surprisingly, for the same sample of PMCD, the different peaks did not display the same relative intensity with dodecylamine than with NH_4^+. Moreover, the pattern of the mono-charged and that of the doubly-charged ions were very different.

Conclusion: The mono-charged ion profile observed for NH_4^+ and dodecylamine are different. The quantization study have been designed to determine which profile is closer from the actual distribution.

Quantitative study:

In this study, we have used trimethyl β-cyclodextrin as an internal standard.

To prove that the intensities of the peaks corresponding to the different numbers of methylation represent accurately the proportions of the species present in solution, we have to demonstrate the linearity of the response and the equality of the response factors.

Linearity of the response: We have to prove that the experimental values of the relative intensities of the peaks, for each methylation number, can be deduced by calculation from the combination of A and B values.

Identity of the response factors: We have to prove that the sum of the relative intensities of each methylation degree is the same for different PMCD preparation with the same total concentration. For that purpose, we used several PMCD preparations:

- preparation A containing PMCD with 14 to 18 methylations

- preparation B containing PMCD with 13 to 15 methylations

and 3 mixtures of A and B in different ratios: 1/1 (sol.C), 2/1 (sol.D), 1/2 (sol.E).

Conclusion: The results are summarized in table 1:

In the case of NH_4^+: The correlation between experimental and calculated values is well established. This demonstrates the **linearity** of the response.between the concentration and the peak height. Moreover, the sums of the relative intensities are very close; eg. the A/B ratio is about 1.2. Therefore, **quantization** of the PMCD with NH_4^+ as charging salt **is then possible.**

In the case of dodecylamine: The agreement between the calculated values and the experimental ones is poor, and the sums of the relative intensities are quite different between the 5 solutions studied; eg. the A/B ratio is close to 1.6. This two points show that quantization can not be obtained with dodecylamine probably because of the discrimination by the degrees of methylation due to the size of the guest molecule.

CONCLUSION:

ESMS allowed us to determine the relative repartition of methylations with a good accuracy in several mixtures of PMCD, containing from 13 to 18 methylation number, provided that NH_4^+ is used as charging salt. This method is all the more interesting as it is simple, fast and accurate.

Matrix Additives to Enhance Signal Intensity of Gangliosides in Negative FAB-MS Analysis

Shyong, B. J., Huang, Z. H., Gage, D. A., Hollingsworth,R. I., and Sweeley, C. C.
Michigan State University, East Lansing, MI 48824

In order to characterize low levels of acidic carbohydrates and glycosphingolipids from biological materials by FAB-MS, we have investigated the effect of adding cationic surfactants and crown ethers to the FAB matrix forln order to characterize low levels of acidic carbohydrates the analysis of several standard gangliosides and carbohydrates containing sialic acid. In addition to commercial surfactants, we have synthesized a series of quaternary ammonium-type surfactants for this study.

Our approach for this study was to compare the spectra of analytes in the concentration range 10-100 pmol/ml by negative FAB-MS with standard matrices (TEA or glycerol) with and without the addition of surfactants or additives. With surfactant assistance, the molecular ion intensity of acidic carbohydrates and glycoconjugates was increased up to 10 fold.

Interest in the role of glycosphingolipids (GSLs), gangliosides, and related carbohydrate compounds has increased due to their multiple biological functions. Enzymatic, immunological, and spectroscopic techniques have been developed to structurally characterize these compounds. In practice, mass spectrometry has proven to be one of the most sensitive analytical approach. However, the sensitivity available with standard methods is often insufficient to analyze the quantities of glycoconjugates that can be isolated from biological sources. To characterize picomole levels of gangliosides and acidic carbohydrates from biological materials by FAB/MS, we have evaluated the signal enhancement effect of adding cationic surfactants or crown ethers into the matrix for the analysis of several standard gangliosides and related carbohydrates.

The examined analytes are dissolved in chloroform:methanol (1:2) (1μg/μl) to prepare stock solutions. Serial dilutions were made as needed. The additives (cationic surfactants or crown ethers) were prepared with as aqueous methanolic (1:1) solution (10 μg/μl) to facilitate quantitative handling. The additive solutions were also diluted as needed. Applied matrices (TEA or Gly) were diluted with equal volumes of methanol. Samples were prepared for analysis by loading on the probe tip 1 μl of the diluted analyte solution, 1 μl additive solution, and 1 μl of the matrix solution without mixing.

A JEOL HX-110 double focusing mass spectrometer was utilized for this study and operated in the negative mode at 10-kV accelerating voltage and 1:1000 resolution. Single scans were acquired by scanning the mass range in about 30 seconds. Spectral data were shown from a single scan while the numerical values for the absolute intensities were obtained from an average of three scans.

The results from this study could be concluded as following:

1. The relative intensity of the $[M-H]^-$ signals in the negative FAB spectra of gangliosides and acidic carbohydrates was increased by the addition of surfactants or crown ethers, except for the trisialo compound GT_{1b}.
2. The signal-to-noise ratio in the spectra obtained with surfactant assistance was improved, so that in some cases low abundance fragments were more readily detected.
3. The enhancement was quite specific to the combination of analyte and additive used.
4. Adding surfactants to the matrix increased the persistence of the signal under NI-FAB.

Analyte/matrix	Employed additives	Intensity ± STD (Analyte + matrix)	Gain (fold)
G_{T1b}(46 pmol)/TEA	aza15C5 10 μg	49,591 ± 1,019 (104,830 ± 13,739)	0.47

The ability to detect and quantify exogenous drug and toxin molecules introduced into cells and tissues is crucial for drug design, preclinical and clinical pharmacology, and toxicology. Current methods for identification and quantitative analysis of exogenous molecules in cells and tissues include scintillation counting of radiolabelled molecules, fluorimetry, HPLC and secondary ion mass spectrometry (SIMS). However, these methods have considerable limitations including disposal problems associated with radiolabeling and SIMS' requirement that a drug contain an element not present at competing concentrations. Consequently, the application of matrix-assisted laser desorption/ionization mass spectroscopy (MALD-MS) toward the analysis of intracellular drugs may be a viable alternative.

We initially tested the effect of crude mammalian cell lysate on the ability of MALD-MS to quantify aqueous tetraphenylphosphonium (TPP), a molecule that preferentially inhibits the proliferation of carcinoma cells. The TPP cation was readily identified and quantified (using methyl triphenyl phosphonium chloride, MTPP, as an internal stanard) at subpicomole levels in crude lysate, **Figure 1**. A quantitative MALD-MS time course for TPP cation accumulation

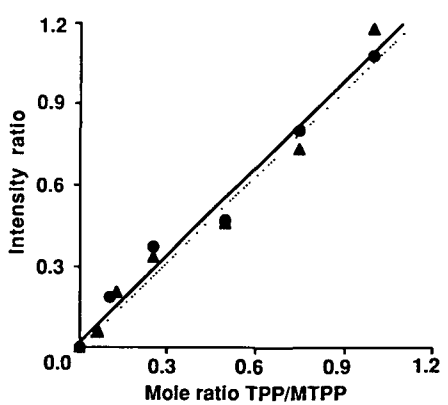

Figure 1. Effect of FaDu carcinoma cell hypotonic lysis on linear correlation between intensity ratio (TPP/MTPP) and the mole ratio (TPP/MTPP), 10.0 μM MTPP internal standard. The points, ● and ▲, represent analyses performed with and without cell lysate present.

into FaDu cells was comparable with a time course using scintillation counting. MALD-MS was also capable of demonstrating the reduced accumulation of the cationic drug rhodamine-123 by Dox^R MCF7, a multiply drug resistant breast adenocarcinoma cell line, relative to the nonresistant parent line MCF7. In addition, MALD-MS was used to follow a chemical reaction inside intact FaDu cells: the formation of a hydrazone, II-51, from benzaldehyde and an acylhydrazide, II-25, **Figure 2**. Cells were exposed to II-25 at 10mM for one hour followed by three washings with cold phosphate buffered saline (PBS).The intact cells were then exposed to benzaldehyde and also washed three times with cold PBS. The peak corresponding to II-51 (m/z=594) was readily observed upon mass analysis of the cell lysate from cells treated with II-25 followed by benzaldehyde (**Fig. 5D**). In control experiments, cells treated with II-25 alone or benzaldehyde alone produced no evidence of the II-51 ion (**Figs. 5A and 5B**). These results suggest that MALD-MS will be useful for the study of other chemical reactions, including the metabolism of cationic drugs and toxins in cells and tissues.

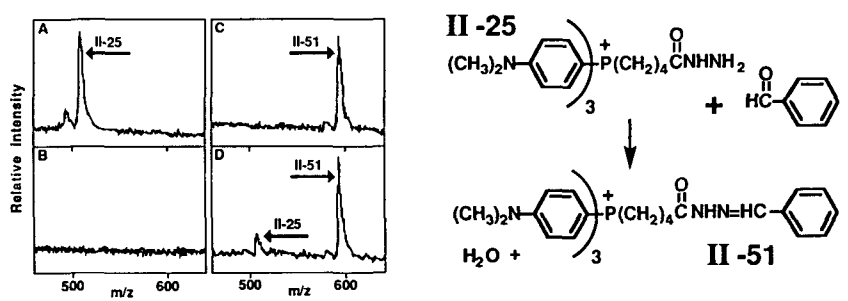

Figure 2. Observing intracell interactions through MALD mass spectra of FaDu cells exposed to: (A) II-25, (B) benzaldehyde, (C) II-51, and (D) II-25 followed by benzaldehyde.

These studies demonstrate the potential applications of MALD-MS for the study of cationic drugs in cultured cells and suggests its prospect for quantification of drugs, toxins, and their metabolites in plasma, tissue biopsies, and other biological matter. MALD-MS is superior to other methods in terms of analytical feasibility and specificity through the ease of sample preparation and the ability to provide molecular weight information. Recent quantitative results with heterogeneous mixtures of uncharged carbohydrates (1) and the ability to observe picomole quantities of anionic molecules (2) suggest that detection of uncharged and anionic drugs and toxins in cells may also be possible with MALD/MS.

Optimisation of Identification of Oligosacchardies by Matrix-assisted Laser Desorption Mass Spectrometry

Walter Blackstock, Glaxo Group Research Ltd, Greenford, Middlesex, UK.
Anne Maisey, John Hoyes, VG Analytical, Fisons Instruments, Wythenshawe, Manchester, M23 9LE, UK.

Introduction

Complex oligosaccharides may be linked to proteins via Asparagine (N-linked) or Serine/Threonine (O-linked); the former are known to be implicated in a variety of recognition processes, including host-pathogen interaction, cell-cell adhesion and protein targeting and are now the subject of intense research interest.

The full characterisation of a glycoprotein is complex and the depth of structural determination may ultimately be limited by the small amount of material usually available. Not only does the site of glycosylation have to be determined, but the oligosaccharide portion is invariably heterogeneous and the heterogeneity may depend on the expression vector and its maturity.

Two approaches to characterising N-linked glycoproteins are in use. The first is to cleave off the intact oligosaccharides by hydrazinolysis and to characterise the oligosaccharide pool. As the protein is destroyed, information regarding the sites, and extent of attachment of the oligosaccharide chains can only be surmised. In addition mass spectrometry techniques for characterising underivatised oligosaccharides are not particularly sensitive, when compared to the levels reached for peptides. The second approach, which we favour, is to characterise the glycopeptide pool resulting from standard enzymatic cleavages and to use the specificity of exo-glycosidases to determine the extent and type of glycosylation. In this way, information regarding the site of glycosylation is retained.

Carr (1) and others have convincingly shown that electrospray ionisation is able to locate the glycopeptides in an enzyme digest by scanned orifice LC/MS. As a complement to this approach, we have sought to use matrix assisted laser desorption time of flight mass spectrometry firstly to locate glycosylated peptides in an enzyme digest (2), and secondly, to determine as far as possible the nature of the glycosylation by trimming away the sugars with specific glycosidases (3,4). The emphasis has been to shorten analysis time, and to work with as little material as possible.

Methods

To develop our strategy for dealing with complex glycoproteins, we are working with bovine alpha-1 acid glycoprotein (Sigma). As far as we are able to ascertain, the sequence of this protein is not listed in the protein data bases, but some homology with other well characterised alpha-1 acid glycoproteins may be presumed. Further characterisation is in hand.

Alpha-1 acid glycoprotein was treated with sialidase (C. perfringens) to remove sialic acid, and then reduced and pyridinethylated by standard techniques. Cleavage of the above with Glu-C (Boehringer), and subsequent separation of the digest by reverse phase FPLC (Pharmacia) yielded fractions further analysis. For the present discussion, work on fraction 6 (Fn6), a glycopeptide, is presented.

Matrix assisted laser desorption time-of-flight (MALDI-TOF) mass spectrometry was carried out on a TofSpec (VG Analytical), in linear flight mode. A nitrogen laser operating at 337nm desorbed the ions (and neutrals), from the sample applied to a multi-position stainless steel disposable target. Detection was by dual micro-channel plates. Sampling rate was 500 MHz and data were processed on a VAXstation using Opus software.

The matrix employed was alpha-cyano-4-hydroxy cinnamic acid which yields excellent sensitivity and resolution for 200fmol to 1pmol of sample. Exoglycosidases were purchased from Oxford GlycoSystems and used as directed. For composite digests using the reagent array method of Edge (3), the enzymes were mixed immediately prior to use.

The ease of use of the laser has allowed many enzyme reactions to be followed in 'real-time' and our observation is that, at least for glycopeptides, the seemingly obligatory 24 hour digest times are not required, and that some reactions are complete in 30 minutes! Clearly, this is important, and a complex sequence of digests and their analysis, can often be completed in a day, rather than a week.

Results

Separation of a Glu-C digest of the reduced and pyridinethylated desialylated protein allowed the glycopeptides to be identified by their characteristic pattern. Fig. 1a shows a characteristic example Fn6. The characteristic "fingerprint" may be attributed to mixtures of tri- and tetra-antennary forms admixed with fucosylation. It serves to easily distinguish peptides from glycopeptides.

Treatment of Fn6 with exoglycosidases specifically removes individual sugars, progressively reducing the molecular weight (Figs 1b-d). Indeed the difference in the peak top data corresponds to the loss of multiples of hexose and N-acetylhexose indicated.

Conclusions

Matrix assisted laser desorption time-of-flight mass spectrometry combined with the specificity of enzymes offers a very powerful and rapid way of making inroads into the structure of glycopeptides and thereby glycoproteins. We have observed that many enzyme cleavages are fast and combined with the sensitivity of MALDI-TOF, this makes for fast analysis on small amounts of protein. We find this approach more useful than hydrazinolysis, as the linkage information to the protein is retained. As with most scientific endeavours, no single technique should be pushed to provide all the answers and we suggest that intelligent use of this approach combined with electrospray and gas phase sequencing, is an efficient way of characterising glycoproteins.

Matrix-Assisted Laser Desorption of O-Glycopeptides Using Linear and Reflectron Time-of-flight Instruments

Marc R. Chevrier* and Robert J. Cotter

Department of Pharmacology and Molecular Sciences
The Johns Hopkins University School of Medicine
Baltimore, MD 21205

INTRODUCTION. The classification of carbohydrates linked to a protein depends on the type of attachment and the structure of the sugar chain. O-linked sugars are linked to the hydroxyl group of serine or threonine. There are three types of O-linkages:

- Ser(Thr)-GalNAc {Labile to mild alkaline treatment}
- Ser-Xyl {Labile to mild alkaline treatment}
- Ser(Thr)-GlcNAc {Very labile to mild alkaline treatment}

O-linked N-acetylglucoseamine [O-GlcNAc] are a particularly interesting type of O-glycosylation. This type of glycosylation occurs intracellularly and as a mono-substituted sugar with no additional branching Analogous to phosphorylation, O-GlcNAc may serve to activate enzymes. It may also function to "cap" phosphorylation sites [1]

In contrast, N-linked sugars are linked to the free amino group of asparagine residues. The linkage [Asn-GlcNAc] is stable to mild alkaline treatment. N-linked sugars are either complex or high-mannose, a classification based on their branching and composition after synthesis and processing in the rough endoplasmic reticulum and Golgi apparatus There are numerous glycosidases and transferases which have been characterized for N-glycans. N-glycans are generally attached to Asn in a well characterized consensus sequence [2]

O-linked carbohydrates are generally more difficult to analyze than N-linked carbohydrates for several reasons:

- O-linked sugars do not have a distinct consensus sequence
- O-specific glycosidases or glycosyltransferases are less available
- O-linked sugars are more labile to basic treatment

We developed techniques using MALDI/MS to allow high sensitivity determination of carbohydrate sites and microheterogeneity for O-glycopeptides. Sialyl glycopeptide A and tryptic glycopeptides from human glycophorins were used to select matrices and crystallization conditions which would result in high sensitivity observation of intact O-linked glycopeptides. We then used these techniques to identify O-GlcNAc sites on simian alpha crystallins and rat neurofilaments The mass spectra were obtained using two instruments, a custom linear TOF described previously[3] and a commercial linear/reflectron TOF [Kratos MALDI III]

EXPERIMENTAL. Sialyl glycopeptide A [SGA], a dipeptide carrying three sugars including a sialic acid, was used to screen matrices for efficacy at 337nm. Five matrices (α-cyano-4-hydroxycinnamic acid, caffeic acid, ferulic acid, gentisic acid, and sinipinic acid) were all utilized to analyze titrations of SGA. In addition, tryptic glycopeptides from human glycophorins were prepared and analyzed by MALDI/MS using the matrices found to be optimal for SGA. In order to reduce the complexity of the digest mixtures, a single dimension of HPLC [Vydac C_{18} / TFA.ACN] was employed. A synthetic peptide YSDSPSTST was glysosylated *in vitro* with β-N-Acetylglucosamnyl transferase. This peptide then served as a substrate in a number of glycosidase and glycosyltransferase experiments prior to MALDI/MS analysis. Using similar methodology, peptides with O-linked GlcNAc from simian crystallins and rat neurofilaments were

subsequently analyzed. Confirmations were provided by chemical deglycosylation[4], specific enzymatic glycosylation[4], and radiolabeling in conjunction with manual Edman microsequencing.[5]

RESULTS AND DISCUSSION. 337 nm MALDI/MS sucessfully analyzed numerous O-linked glycopeptides in femtomolar quantity This additional sensitivity was much higher than afforded by Edman microsequencing and also permitted a reduction in preparative chromatography since unfractionated or partially fractionated digest mixtures could be analyzed directly In our experience, α-cyano-4-hydroxycinnamic acid and gentisic acid yielded the best sensitivities. For glycopeptides with sialic acids, gentisic acid consistently offered higher sensitivities than any other of the five matrices In general, the linear mode of operation offered higher sensitivities, whereas the reflectron mode could offer significantly higher resolutions (circa 2000 versus 450 for glycopeptides < 3 kDa) This additional resolution was exploited to reduce preparative chromatography by analyzing proteolytic digest mixtures which were only partially fractionated.

The Role of Lipooligosaccharides in Pathogenesis of *Haemophilus* Species and Possible Strategies for Therapeutic Intervention.

W. Melaugh, N. Phillips, J. Engstrom, M. Tullius and B. W. Gibson.
University of California, San Francisco, CA 94143-0446

Pathogenic *Haemophilus* species, such as *Haemophilus influenzae* which causes pneumonia and meningitis, and *Haemophilus ducreyi* which is responsible for chancroid, display on their outer membranes surface antigens that enable these organisms to adhere to and invade host cells. The focus of our research is investigating the role of lipooligosaccharides (LOS), one of the most abundant and structurally diverse of the surface antigens.

LOS consist of a lipid portion (lipid A) which is embedded in the outer membrane and a carbohydrate region which projects out into the environment of the cell. The amphipathic nature of LOS makes it difficult to directly analyse these molecules by mass spectrometric techniques since they tend to aggregate in solution and exhibit low solubility in most solvents. The traditional approach has been to take advantage of the susceptibility of the ketosidic linkage between the lipid A portion of the molecule and the oligosaccharide moiety to mild acid hydrolysis and to study the two parts separately. Structural studies by liquid secondary ion mass spectrometry and tandem mass spectrometry of the oligosaccharide fraction thus obtained have shown that many *Haemophilus* strains contain epitopes that mimic blood group antigens, allowing these organisms to evade the host immune system.

While such an approach has been useful, the hydrolysis conditions required to rupture the ketosidic bond cause chemical modification of the LOS molecule and critical structural information is lost during the hydrolysis step. For example, a phosphate group on KDO undergoes β-elimination during the mild acid hydrolysis leaving an anhydro KDO species. We have also found using electrospray ionization mass spectrometry (ESI-MS) that many *Haemophilus* strains are sialylated on a terminal lactosamine but the sialic acid is lost during the hydrolysis step. *O*-deacylation of the LOS using mild hydrazine renders the molecule water-soluble and amenable to analysis by ESI-MS. Figure 1 shows the negative-ion ESI-MS of *H. ducreyi* 35000 *O*-deacylated LOS in the triply-charged $[(M-3H)^{3-}]$ molecular ion region from m/z 800-1000, before and after neuraminidase treatment.

The significance of sialic acid is not completely understood, but it is believed to be crucial to the organism's ability to cause disease since it is known that in other bacteria the removal of sialic acid renders the pathogens vulnerable to lysis by serum. We know for example that a mutant strain of *H. ducreyi*, 188-2 which lacks terminal lactosamine and sialolactosamine, shows lower adherence to human cells of the genital epithelia than that of the parent strain. One of our goals is to develop inhibitors to the sialyltransferase since infectious agents lacking this critical sugar may be less virulent. Figure 2 shows on the left a schematic of the outer membrane sialyltransferase adding the activated sugar nucleotide to the lactosamine acceptor of the LOS. On the right is a potential bi-substrate analog which we propose as an inhibitor of this sialyltransferase.

Cyclodextrins, readily available degradation products of starch by an amylase of *Bacillus Macerans* [1], have been extensively studied due to their ability to form inclusion complexes with a range of small organic molecules. The three natural cyclodextrins, macrocycles consisting of six (alpha CD), seven (beta CD) or eight (gamma CD) alpha-(1,4)-linked glucose residues, are bucket shaped molecules with a hydrophobic cavity and a hydrophilic exterior which gives rise to their unique binding characteristics. The complexes formed by cyclodextrins have found industrial uses in areas as diverse as pharmaceuticals, agrochemicals and food additives [2].

Since the cyclodextrins are chiral molecules they can exhibit chiral preference when binding, encapsulating one enantiomer of a guest more favourably than the other. This has led to the exploitation of cyclodextrins as stationary phases for chiral HPLC systems [3]. Traditional techniques (e.g. NMR) can be either time consuming or inaccurate so there is a need for facile techniques for assessing both the stoichiometry of binding and the association constant for the complex. Mass spectrometry can play a valuable role in this analysis.

The detection of crown ether alkali metal complexes by fast atom bombardment mass spectrometry (FAB-MS) was first demonstrated by Johnstone and Rose in 1982. More recently Stoddart and others have shown that the mass spectral intensities of the ions corresponding to the cyclodextrin guest complex indicate the amount of species present in each solution.

We demonstrate the potential of FAB-MS as a powerful tool for the detection of enantioselective binding by cyclodextrins of amino acid methyl esters. It is well documented that cyclodextrins preferentially bind the D-enantiomers of amino acids [4] and this is supported by the spectra we have obtained. Accordingly our results show that a 1:1 mixture of phenylalanine and permethylated alpha cyclodextrin will preferentially bind the D-isomer by a factor of eight. This is apparent for all the permethylated cyclodextrins and the same phenomenon is observed with tryptophan. Results to date indicate that this does not occur to the same extent with the perbenzyl cyclodextrin, although the D-isomer preference is still observed, the magnitude of the preference is markedly reduced.

The fragmentation of the species observed in the FAB mass spectrum show losses of methanol from the protonated complex ion and of permethyl from the protonated cyclodextrin ion. Attempts to obtain tandem mass spectra have proved difficult but the data so far suggests that the predominant fragmentation is not the loss of the amino acid species from the complex.

To date we have characterised the complexes of four cyclodextrins with six amino acid isomers. Work is ongoing to obtain MS/MS data for these experiments and also to provide explanations for the complexation of these molecules.

Peptidoglycan (PG) or murein can be envisaged as a giant macromolecule surrounding the cytoplasmic membrane. PG is a heteropolymer unique to bacterial cell walls that consists of a glycan backbone with short peptide side chains linked via a lactyl moiety to the sugar unit The peptides are cross-linking the glycan chains of various length (up to 200 disaccharide units). This network provides stress-bearing mechanical strength, enormous fexibility and structural dynamics simultaneously Nature has provided numerous subtle variants in the chemical composition of murein among microorganisms. The first molecular target of the still most important group of antibiotics, β-lactams, is a group of unique proteins, called penicillin-binding-proteins (PBP), which are involved in several stages of PG biosynthesis. A complete understanding of the complicated chain of events leading from inhibition of PBPs to bacteriolysis is now accelerated by some recent progress in PG structural analysis based on new chromatographic [1] and mass spectrometric [2 - 4] techniques. The majority of studies aiming at the structural characterization of PGs is based on muramidase digest of the macromolecule, fractionation of the PG fragments by LC and subsequent amino acid / amino sugar analysis. But in more or less all cases the chromatographic separation of the PG fragment mixture turned out to be relative complex. Because of small, but for the understanding of the biosynthesis important variations of the PG fragment pattern it is desirable to monitor complete PG digest profiles, which is a formidable task by classical biochemical techniques in any respect.

Our integrated mass spectrometric approach is based on screening the entire muramidase-cleaved and

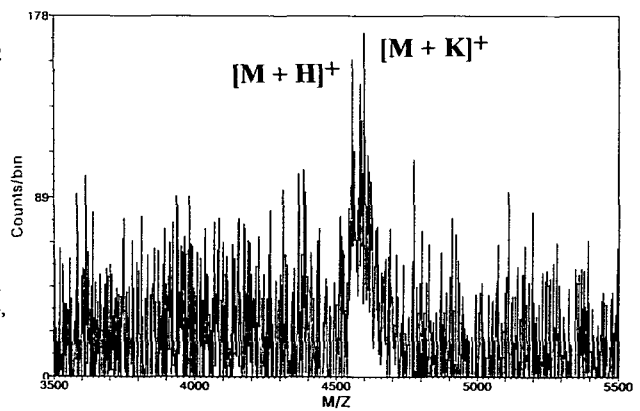

Fig. 1. Positive ion Cf-252 PD mass spectrum of a peptidoglycan pentamer [tetrakis (disaccharide tetrapeptide) disaccharide tripeptide] isolated from *Synecococcus spec.*, showing a protonated and potassiated molecular ion at m/z 4556 2 (calculated 4557.7, Δm = - 1 5 u) and 4597.1 (calculated 4595 8, Δm = + 1.3 u).

$NaBH_4$-reduced PG after RP-18 HPLC separation with a water/acetonitrile/TFA gradient by positive and negative ion PD mass spectrometry [3, 4]. Molecular weight information was obtained for simple PG

monomers to complex PG oligomers (Fig 1) of various origin Based on these values of the individual PG fragments and on determined amino acids and amino sugars in the total hydrolysate of the murein sacculus, the primary structure could be assigned in most cases In case of doubtful or uncorrelated PD mass spectrometric data, an aliquot of the same fraction was analyzed by ESI [4] (Fig 2) or FAB mass spectrometry with analyzer systems exhibiting higher resolving power If the structure can not be determined unequivocally even by these means, tandem mass spectrometry has to be applied. A hybrid instrument (BEqQ) combined with FAB was used to obtain low energy CID spectra which exhibited a high content of structural information [6]. Alternatively, the use of ESI as source for single or double charged precursor ions in combination with a triple quadrupole instrument was evaluated for generating of CID spectra [4] Especially this set-up offers the possibility of on-line LC/MS/MS for screening of complex PG digests Structural modifications (e g , N-acetyl putrescine coupled to D-Glu in *Cyanophora paradoxa* [6] or amino acid exchange in PG by a biosynthetic technique in *E. coli* [5]) and subtle variations (e.g , amidation or linkage inversion) of the PG could be determined by combining various MS techniques and amino acid analysis The outlined strategy was applied for the characterization of PG digests of *E. coli*, *Cyanophora paradoxa*, *Synecoccus spec.*, *Enterococcus faecium* and *Staphylococcus aureus*

STRATEGIES FOR THE IDENTIFICATION OF COMPOUNDS CAUSING ODORS IN WATER. A STUDY OF CREOSOTE SPILLS.

*J. Rivera[1], F. Ventura[2], J. Romero[2], R. Boleda[2], R. Lloret[2], J. Martin[2] and L. Mohedano[1].

1-Mass Spectrometry Lab. CID-CSIC; J. Girona 18. 08034-Barcelona (Spain).
2-Aigües de Barcelona; P. Sant Joan 39. 08009-Barcelona (Spain).

Tastes and odors in water is frequently one of the major complaints of consumers. Volatile organic compounds from both anthropogenic and natural sources are usually associated with these effects. In most cases, routine closed-loop stripping analysis (CLSA) which is suitable for the identification of compounds at trace levels (ppt), gives account of the responsible compounds.

Recently, we were surprised to find high abundance of 2-3 ring PAH in CLSA extracts identified by GC/MS from river water with odor problems. We associated such unexpected results to the presence of creosote, a complex mixture obtained from distillation of coal tar which constituents are 85-90% PAHs. Two creosote wood-preserving factories located in the upper course of the river might be responsible for the spills.

Liquid-liquid-extraction (LLE) and analysis by HPLC using a fluorescence detector (FL), corroborated our suspition after giving close results for river water extracts and creosote from each one of the factories. In addition, the presence of heavier PAH no detected by the CLSA method was observed. This confirmed that creosote was the responsible for the intense odor but no conclusions about which factory dumped it.

The comparison of the GC profiles of the creosotes used by both factories during the first episode, showed similar profiles and only the relationship naphtalene/isoquinoline (N/I) was dramatically different (15.7 and 0.55 respectively) for each creosote. Then, this ratio could be potentially useful in this case for the univocal identification of the responsible of dumping.

However, during the last episode both creosotes showed the same profile. There is only one supplier of creosote in Spain, but depending occasionally on market prices, **B** factory imported it from France.

The two creosotes were spiked in Milli-Q water, extracted by the CLSA and LLE methods and analyzed by GC. The results showed that recoveries of PAH by the CLSA method decreased dramatically for compounds heavier than fluorene, whereas good recoveries were obtained using the LLE method even for the heavier PAH.

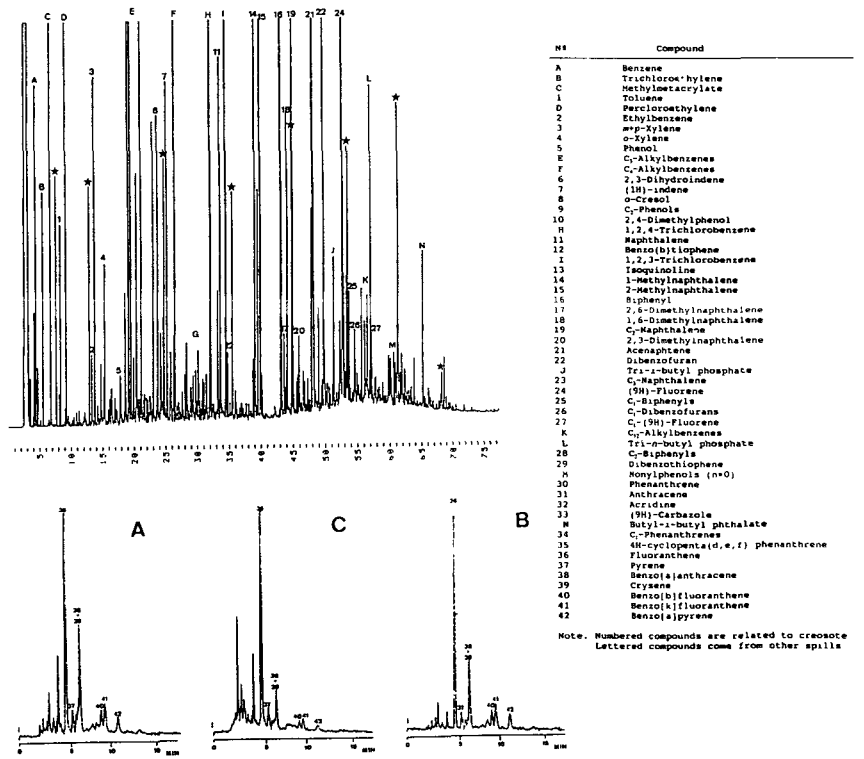
Table: Mean recoveries of selected compounds from creosote by CLSA and LLE.

Compound	CLSA	LLE
Naphthalene	91	74
Isoquinoline	0	67
1-methylnaphthalene	91	109
Acenaphthene	54	94
(9H)-Fluorene	25	112
Phenanthrene	3	104
Fluoranthene	0	90
Benzo[*a*]pyrene	0	88

The main disadvantage of CLSA, arises for its unability to recover three or more rings PAH and isoquinoline. Therefore, it was insuitable for tracing which was the origin of the spill. However, the CLSA method is the most useful technique for the identification of creosote spills at the ppt level and particularly suitable when no odor problems are detected by consumers.

On the other hand, LLE and GC/MS is the method of choice for the individual characterization of compounds and in this case to prove which factory dumped into the river. HPLC-FL is useful to determine the level of PAH listed as priority pollutants.

From levels of PAH priority pollutants measured in river water and their chromatographic profiles it can be inferred that **A** factory was responsible for the first creosote spill and **B** for the second.



Top: GC profile of raw water polluted by creosote. Bottom: HPLC/Fl profiles of left: creosote A; middle: raw water; right: creosote B.

Tandem Mass Spectrometry of Human Skin Emanations for the Determination of Mosquito Attractants

Ulrich R. Bernier and Richard A. Yost
Department of Chemistry, University of Florida, Gainesville FL 32611
Carl E. Schreck and Don R. Barnard
USDA Medical and Veterinary Entomology Research Laboratory, Gainesville, FL 32604

Introduction

Identification of volatile compounds which emanate from the skin and attract mosquitoes will provide for an understanding of the basis for chemical attraction of mosquitoes to hosts. Additionally, this information may be used to better control these insects, and these attractants may be incorporated into a form of pest control relying on attractants rather than repellents. This work is centered upon the identification of attractants from the human skin; additional compounds are being tested which have not yet been identified as emanating from the skin. Insight into the differences in attractiveness among hosts may be gained by studying factors which change attractiveness. The underlying premise of this work is that sample analysis by mass spectrometry should allow for sample detection in a fashion similar to that which mosquitoes encounter: a volatilized sample in the gas phase.

Experimental

Bio-assays are conducted in an olfactometer which allows quantitation of the proportion of mosquitoes attracted to a (sample) compound. Sample introduction for all mass spectrometric analyses is accomplished via a transfer line with either a deactivated 1 m x 0.10 mm i.d. fused silica open tubular (FSOT) column or a 7 m x 0.18 mm i.d. DB-1 FSOT column fitted directly into the ion source of the Finnigan MAT TSQ70 triple quadrupole mass spectrometer. Human samples are collected by rubbing five 3 mm diameter glass beads for five minutes. The beads are then placed in a 5 cm x 0.25" o.d. glass vial fitted with a 0.25" inch Swagelok cross inside a Varian 3400 GC oven. During analysis, the temperature is typically ramped from 30°C to 210°C over 5 minutes, with the transfer line held at 210°C. Chemical ionization using methane at an indicated source pressure of 1700 mtorr was used in all cases; MS/MS was performed with argon collision gas at an indicated pressure of 1.4-1.5 mtorr. The Q2 collision offset was -15 V for positive ions and +15 V for negative ions.

Results

The most suitable introduction technique is direct thermal desorption of deposited components off of glass beads enclosed in a small vial. Although adequate sensitivity is achieved from sampling 5 beads, temporal resolution is poor. Identification of lower molecular weight components, such as lactic acid, pyruvic acid, and propanoic acid is still straightforward due to the limited number of possible isomers for each molecular weight. *Figure 1* demonstrates the identification of ethylene glycol by comparison of sample and standard daughter spectra of the $[M+H]^+$ ion (m/z 63). Several carboxylic acids have been found to be slightly attractive to mosquitoes; neutral loss scans of 44 u from positive and more so negative ions can be used to screen samples for this class of compounds.

Lactic acid is the only widely-recognized attractant for *Aedes aegypti* [Takken, W., *Insect Sci. Applic.*, 1991, **12**, 287-295]; thus, this compound was used as the model for single compound studies involving altering attraction of mosquitoes to a sample. It should be noted that lactic acid alone is not as attractive to mosquitoes as is a human sample deposited by rubbing glass beads in the palm of the hand. Since lactic acid is a carboxylic acid, its volatility should be susceptible to acid/base effects. The expected result is that at a pH above the pK_a, most of the lactic acid will be dissociated to lactate,

reducing the amount of lactic acid in the gas phase. This agrees with the decreased attractiveness observed for lactic acid at higher pH, as shown in *Figure 2*.

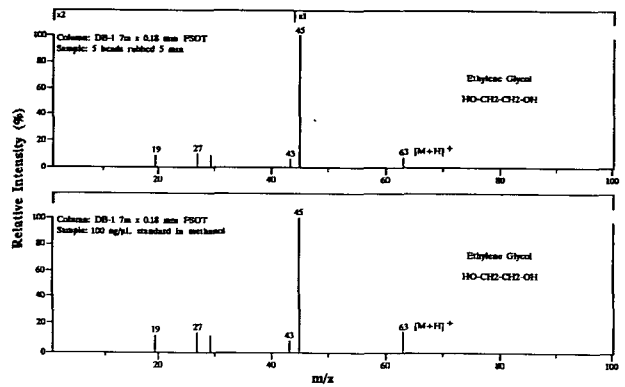


Figure 1. Comparison of Ethylene Glycol Daughter Spectra of Hand Sample (Top) and Standard (Bottom)

Conclusions

Direct thermal desorption of samples deposited on glass beads allows for detection of volatile compounds of interest; however, temporal resolution is poor, therefore cryo-focussing will be used in future work. Neutral loss spectra (such as neutral loss of 44 for carboxylic acids) allow for targeting compound classes of interest. Identification of compounds from MS/MS spectra is possible both by spectral interpretation (for low molecular weight species) and by comparison to standards. Lactic acid is of particular interest since it is the sole compound previously confirmed to be attractive for *Aedes Aegypti*. However, additional acids as well as alcohols have been found to be attractive. Sample matrix conditions (including pH) play a role in attractiveness; future studies will consist of bio-assay and MS/MS studies of the esters of lactic acid as well as studies involving acidified and basicified rubbed glass beads.

DIRECT SCREENING OF PAHs IN AIRBORNE PARTICULATE MATTER BY LASER TIME-OF-FLIGHT MASS SPECTROMETRY

Catherine H. Smith and Peter B. Kelly, Department of Chemistry;
Daniel P.Y. Chang, Department of Civil Engineering; and
A. Daniel Jones, Facility for Advanced Instrumentation,
University of California, Davis CA 95616.

Polycyclic aromatic hydrocarbons (PAHs) are formed during combustion of organic material and readily condense on particulate matter to become airborne. Current methods for the screening of PAHs in soot and fly-ash samples are labor-intensive and time-consuming. A two-step laser desorption laser photoionization mass spectrometry (LDLPMS) technique has been developed which provides a means for rapidly screening particulate matter samples for PAHs, with no prior extraction or separation steps.

Experimental:

The laser mass spectrometry experiments are performed with a custom-built linear time-of-flight instrument. The particulate sample is mounted on the flattened face of a metal probe tip using double-sided sticky tape. Pulsed IR radiation at 10.6 μ generated by a CO_2 laser is focussed to a 1 mm^2 spot size on the sample. Pulsed UV radiation at 266 nm produced by a Q-switched Nd:YAG laser is focussed into the plume of desorbed neutral molecules to effect resonance enhanced multiphoton ionization of the PAHs.

Results:

The response curves for PAHs doped into silica gel, Figure 1, indicate that the LDLPMS method is semi-quantitative and calibration curves can be constructed over several orders of magnitude. The sensitivity of the technique lies in the 10 ppm range, with an absolute sensitivity on the order of 20 picograms. The best response factors were obtained for phenanthrene and pyrene. The response factors for PAHs in the mass range 228 to 278 were 75% lower. The higher boiling point compounds may not be as efficiently removed from the particulate matter in the thermal desorption step. Only a very small portion of a sample can be analyzed using the LDLPMS method, thus the reproducibility is influenced by sample inhomogeneity. Several samples should be screened to obtain representative values.

The application of the LDLPMS technique to NIST SRM 1650 Diesel Particulate Matter, Figure 2, indicates the presence of PAHs ranging in ring size from two to four. NIST SRM 1650 material contains 71 ppm phenanthrene (m/z 178) and 50 ppm each of fluoranthene and pyrene (m/z 202).

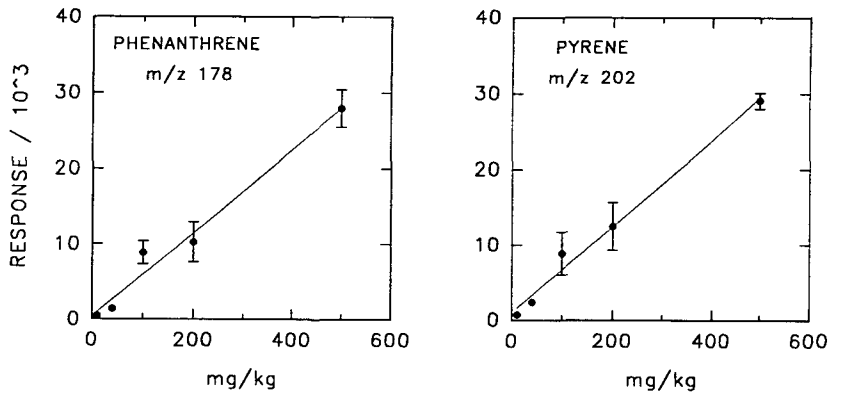

FIGURE 1. Response curves for PAHs doped into silica gel using the LDLPMS method. IR power: 5 MW/cm^2; UV power: 10 μJ/pulse; 500 shots averaged.

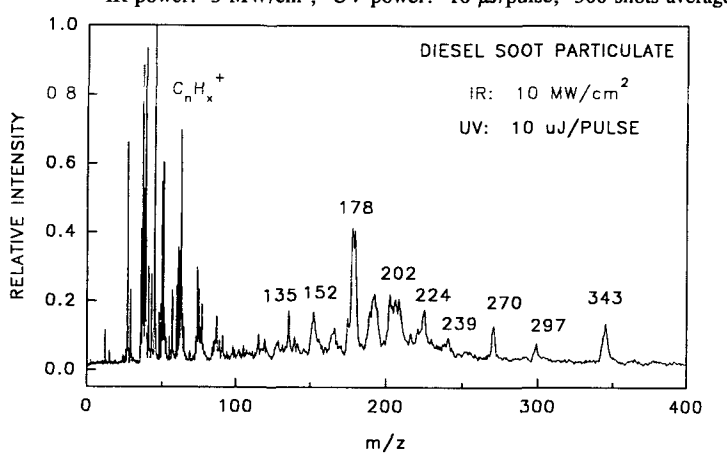

FIGURE 2. Application of the LDLPMS method to NIST SRM 1650.

LASER PHOTOIONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY APPLIED TO NITRATED POLYCYCLIC AROMATIC HYDROCARBONS AND NITROBENZOCOUMARIN DERIVATIVES

Rae A. Noyes, Catherine H. Smith and Peter B. Kelly, Department of Chemistry;
Daniel P.Y. Chang, Department of Civil Engineering; and
A. Daniel Jones, Facility for Advanced Instrumentation,
University of California, Davis CA 95616.

The analytical chemistry of nitrated polycyclic aromatic hydrocarbons (nitro-PAHs) is of widespread interest due to the highly mutagenic properties of this chemical class and their ubiquitous presence in the environment. Nitro-PAH can readily condense on respirable particulate matter. Nitro-PAH have been identified in diesel particulate, urban and indoor air particulate, wood and cigarette smoke condensates, and many other environmental samples.

In our laboratory, we are studying the application of laser photoionization time-of-flight mass spectrometry (TOF-MS) to the detection and identification of atmospheric pollutants in particulate samples. Laser photoionization mass spectra were obtained using 266 nm and 213 nm irradiation for four nitro-PAH compounds: 9-nitroanthracene, 1-nitropyrene, 2-nitrofluorene, and 2-nitro-9-fluorenone. Two nitrated heterocyclic compounds, 6- and 7-nitrobenzocoumarin, were investigated at 213 nm.

Experimental:

The experiments are performed with a custom-built linear TOF-MS instrument. A sample is typically prepared by depositing a small aliquot of the sample solution on the flattened face of a metal probe tip. The sample is allowed to air-dry, forming a thin solid layer. Pulsed UV radiation is generated by a Q-switched Nd:YAG laser and focussed into the source region perpendicular to the flight tube axis, such that the beam grazes the surface of the sample probe. Spectra are usually obtained with a UV laser energy of 10-20 μJ/pulse.

Results:

Photoionization of nitro-PAHs at 266 nm or 213 nm yields positive molecular ion for each of the standards studied. Characteristic photofragments include $[M\text{-}NO]^+$, $[M\text{-}NO_2]^+$, $[M\text{-}NO\text{-}CO]^+$, and NO^+, as shown in Figure 1. A very strong $[M\text{-}NO]^+$ ion peak was observed in all spectra and was often the base peak. An intense NO^+ ion peak accompanies the $[M\text{-}NO]^+$ peak at 213 nm, but is only weakly present at 266 nm. These observations suggest that the $[M\text{-}NO]^+$ radical is formed via an excited state nitro-nitrite photorearrangement, Figure 2, followed by dissociation to the observed odd-electron ion. The NO fragment is subsequently ionized by a multiphoton ionization process. The photofragmentation of the nitrobenzocoumarins initially follows the same pathway as the nitro-PAHs. These photorearrangement reactions may play a significant role in the atmospheric transformation of nitro-PAHs.

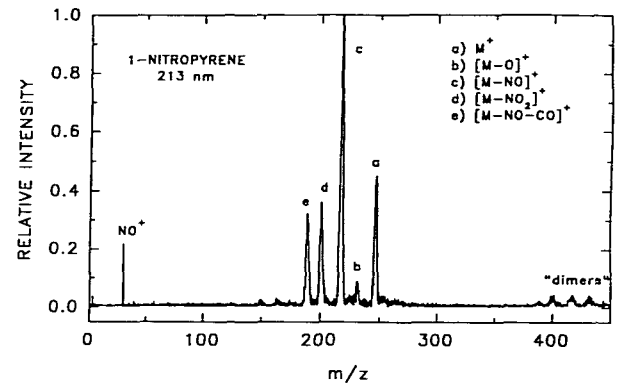

FIGURE 1. Laser photoionization mass spectrum of 1-nitropyrene at 213 nm.

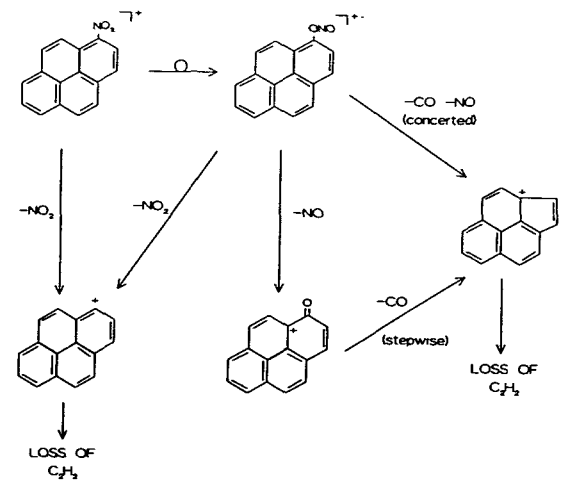

FIGURE 2. Photofragmentation pathways in nitro-PAH.

The support of the National Institutes of Health "Superfund" program (Grant 2-P42-ES04699) and the California Air Resources Board (Grant A9-32-099) is gratefully acknowledged. LASER PHOTOIONIZATION TIME-OF-FLIGHT MASS SPECTROMETRY OF ARSENIC AND CHROMIUM COMPOUNDS

Catherine H. Smith, Rae A. Noyes and Peter B. Kelly, Department of Chemistry;
Daniel P.Y. Chang, Department of Civil Engineering; and
A. Daniel Jones, Facility for Advanced Instrumentation,
University of California, Davis CA 95616.

The formation of volatile metal compounds during incineration results in atmospheric emission of toxic heavy metals associated with flyash. Analysis of metals present in airborne particulate matter usually involves aqueous extraction, which may alter the oxidation state of some metal species, followed by determination of the total metal content. The toxic properties of a metal may often depend on its oxidation state, e.g. Cr(III) vs. Cr(VI), consequently knowledge of not only the metal content but also the speciation of the metal is essential to assessing the hazards associated with the products of incineration. In our laboratory, we are studying the application of laser photoionization time-of-flight mass spectrometry (TOF-MS) to the detection and identification of atmospheric pollutants in particulate samples. Laser photoionization mass spectra were obtained using 266 nm and 213 nm irradiation for inorganic and organic As(III), As(V), Cr(III), and Cr(VI) compounds.

Experimental:

The experiments are performed with a custom-built linear TOF-MS instrument. A sample is typically prepared by depositing a small aliquot of the sample solution on the flattened face of a metal probe tip. The sample is allowed to air-dry, forming a thin solid layer. Crystalline samples are mounted using sticky tape. Pulsed UV radiation is generated by a Q-switched Nd:YAG laser and focussed into the source region perpendicular to the flight tube axis, such that the beam grazes the surface of the sample probe. Spectra are usually obtained with a UV laser energy of 10-20 μJ/pulse.

Results:

Laser photoionization mass spectrometry of both inorganic and organic arsenic compounds yields structurally significant fragment or cluster ion peaks, as shown in Figure 1. The arsenic ion is only weakly observed at 213 nm and is not observed at 266 nm. The AsO^+ ion is observed in oxygen-containing compounds. The laser photoionization mass spectra of the As(III) and As(V) oxide compounds are significantly different and may allow determination of arsenic speciation in environmental samples.

Photoionization of organic chromium compounds yields intense Cr^+ peaks as well as structurally significant fragment ion peaks. Covalent chromium oxide compounds such as CrO_3 and Cr_2O_3 also yield intense Cr^+ peaks. A wide range of Cr-O cluster ions are observed for CrO_3. The Cr^+ ion is not observed in the photoionization of the ionic compound $K_2Cr_2O_7$, and Cr-O cations are only weakly observed. Certain inorganic chromium compounds may yield more structurally significant fragment ions in negative ion mode.

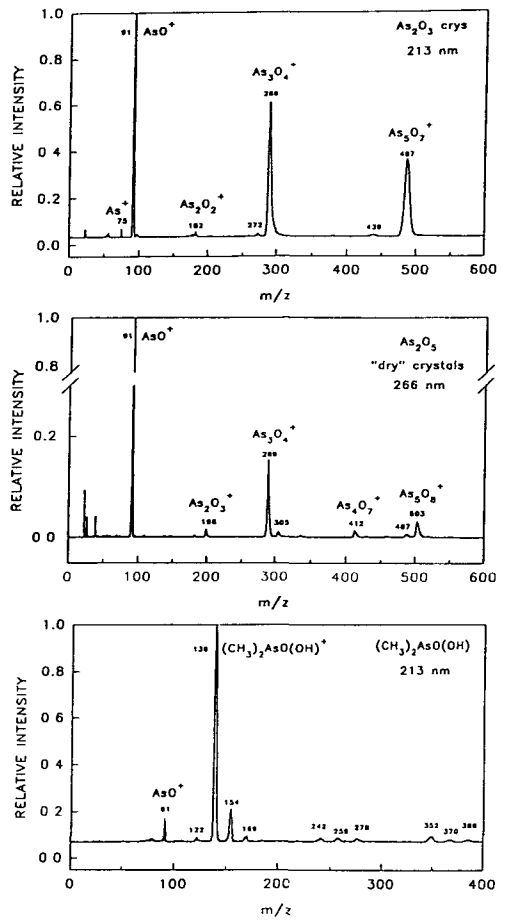

Figure 1. Laser photoionization mass spectra of As(III) and As(V) compounds.

The support of the National Institutes of Health "Superfund" program (Grant 2-P42-ES04699) and the California Air Resources Board (Grant A9-32-099) is gratefully acknowledged. Analysis of Sulfonated Azo Dyes as Their *tert*-Butyldimethylsilyl Derivatives

Samuel A. Testino, Jr. and Kenneth L. Busch, School of Chemistry and Biochemistry, Georgia Institute of Technology, Atlanta, Georgia 30332-0400

Sulfonated azo dyes are used extensively in the textile industry as pigments and coloring agents. Some of these dyes are discharged into the environment during the manufacturing and applications process. This is of concern because azo dyes and their aromatic amine metabolites have been shown to cause cancer in test studies.

Until now, the involatile nature of sulfonated azo dyes has required them to be analyzed by FAB mass spectrometry[1] and various LC/MS techniques, including thermospray[2] and electrospray.[3] Here, we demonstrate the ability to characterize some sulfonated azo dyes by direct inlet EI and CI and GC/MS of their *tert*-butyldimethylsilyl (tBDMS) derivatives.

Derivatization reactions. A procedure for tBDMS derivatization has been previously described.[4] Sulfonate groups, as well as polar -OH and $-NH_2$ substituents, are derivatized in a single step procedure.

$$RSO_3^- \xrightarrow[\text{tBDMCS}]{\text{MTBSTFA}} RSO_3tBDMS$$

To a solution of 2-3 mg of the sulfonated azo dye in acetonitrile was added 18 mg of *tert*-butyldimethylchlorosilane (tBDMCS) and 100 μL of N-methyl-N-(*tert*-butyldimethylsilyl)-trifluoroacetamide (MTBSTFA). The mixture was then heated at 70°C for 3 hours prior to analysis.

Direct inlet MS. The molecular ion is observed for the tBDMS derivative of each azo dye studied under EI conditions, except for acid orange 10, which required "softer" isobutane CI to keep the molecular ion intact. A spectrum of the tBDMS derivative of acid orange 7 is shown in Figure 1. Characteristic fragments of the tBDMS derivatives include $[M-15]^+$ (loss of methyl) and $[M-57]^+$ (loss of t-butyl) ions, as well as ions resulting from cleavage of the azo linkage.

GC/MS. A typical chromatogram of a tBDMS- derivatized sulfonated azo dye obtained on a DB-5 column is shown in Figure 2. Many of the extraneous peaks in the chromatogram can be attributed to decomposition products formed upon thermolysis of the labile azo linkage in the GC injection port and can be used to help characterize the azo dye being analyzed. The temperature limit of the available DB-5 column (350°C) limited the number of dyes that we could analyze; however, it should be possible to analyze all of the dyes using a specially-coated high temperature column (temp. limit, 400°C).

GC/MS DETECTION OF THIODIGLYCOL AND THIODIGLYCOL SULFONE USING TRIMETHYLSILYLATION DERIVATIZATION

Dennis K. Rohrbaugh and Stephen G. Pleva
U.S. Army Edgewood RD&E Center, APG, MD 21010-5423

Multinational chemical weapon treaty verification efforts have created renewed interest in the detection of scheduled compounds and their degradation products. Two degradation products of mustard gas, thiodidiglycol (TDG) and thiodiglycol sulfone, are difficult to analyze at low levels in the original state by GC/MS. In this study these compounds were converted to their trimethylsilyl (TMS) derivatives and analyzed by EI and methane CI GC/MS as part of 2 round robin exercises.

TDG and TDG sulfone were derivatized by addition of 300 µl THF and 180 µl N,O-Bis(trimethylsilyl) trifluoroacetamide (BSTFA) to the freeze-dried extract of 25 ml water. EI spectra were obtained on an HP 5970A (30m x .25mm DB-5 column). Methane CI (0.6 Torr) spectra were obtained on a Finnigan 5100 equipped with a 15m x 0.25mm DB-5 column. Injection temp was 200°C and the oven was programmed from 60-260°C at 10°C/min.

The first study was a national round robin exercise consisting of 15 water samples containing TDG, TDG sulfone and 10 other compounds spiked at 20, 90 and 160 ppb. Using BSTFA derivatization, both compounds were reliably detected at the 20 ppb level. Typical full scan chromatograms and CI spectra are shown in Figures 1 and 2. Neither molecular ion was observed under EI conditions. Small amounts of the ion resulting from loss of a methyl group were observed (m/z 251 for TDG and m/z 283 for TDG sulfone). The base peak for TDG sulfone under methane CI conditions was the potonated molecular ion at m/z 299, with the only major ion fragment resulting from loss of a methyl group (m/z 283). No molecular ion was observed for the TMS derivative of TDG but the methane adducts at m/z 295 and 307 were observed. Major fragments are m/z 177 from loss of the OTMS group (base peak) and m/z 251 from loss of a methyl group (40% of base). Selected ion monitoring under methane CI conditions using m/z 177 for TDG and m/z 299 for TDG sulfone can be used to provide increased sensitivity.

The second study involved the detection of schedule 1 compounds and their degradation products in three matrices, concrete, rubber and paint, as part of the third United Nations International Round Robin Exercise. A diesel fuel background was also added to the samples in addition to the spikes. TDG and TDG sulfone were detected in the concrete samples after extraction with water, freeze-drying and BSTFA derivatization. A methane CI total ion chromatogram is shown in Figure 3.

When the above concrete samples were extracted with D_2O (for NMR analysis), it was noted that deuteration of TDG sulfone but not TDG occurred. A comparison of spectra obtained for the TMS derivative of TDG sulfone when using water vs. D_2O is shown in Figure 4. This emphasizes the importance of avoiding deuterated solvents for mass spectral analysis or being aware that deuteration reactions can occur which complicate mass spectral interpretation.

R. E. Eibling
Westinghouse Savannah River Company, Savannah River Laboratory, Aiken, South Carolina 29808, USA

The Savannah River Site has generated approximately 83 million gallons of high-level radioactive waste. The existing inventory has been reduced to 35 million gallons by evaporation and is stored in underground tanks. The Site is planning to process this highly radioactive liquid waste by concentrating the radioactive species and encapsulating them in a borosilicate glass. The process uses sodium tetraphenylborate and sodium titanate to precipitate the radioactive cesium-137 and absorb the radioactive strontium-90 and most of the plutonium. Any remaining organic compounds in the precipitated aqueous slurry must be removed for compatibility with the borosilicate glass formation. Acid hydrolysis (with a copper (II) catalyst) is used to generate benzene. Unfortunately, during this process, several undesirable byproducts are formed. Identification of the remaining organic and inorganic byproducts in the aqueous slurry and the mechanisms by which they form is desired.

Several analytical methods, including mass spectrometry, are being used to identify organic and inorganic products in a simulated nonradioactive feedstock. We have used GC-MS to identify several organic species in the feedstock including phenol, biphenyl, 2-phenylphenol, 3-phenylphenol, 4-phenylphenol, and some nitrogen-containing compounds (see Figure 1). These identifications have been confirmed using LC - UV/VIS. Cyclohexane was used in initial studies as the solvent against which the basic aqueous extract was partitioned. Use of ethyl acetate provides a more complete extraction that provides evidence for approximately twice the number of organic compounds. Ion chromatography has been used to identify several anionic species in the sample. Figure 2 contains an ion chromatogram with labeled ion peaks for an aliquot of the slurry analyzed directly. The ions identified are consistent with the additives and catalysts known to be present in the mixture.

Capillary electrophoresis, more sophisticated LC separations, and high-resolution Particle Beam LC-MS analysis are currently being used to analyze the simulated feedstock. The LC and CE results indicate the presence of a far greater array of organic compounds than expected. Over 60 individual organic compounds can be identified in individual chromatographic traces. Many of these are present at levels currently too low for positive mass spectral identification. Consequently, new methods of sample collection and concentration are being devised. Since sample is not limited in this case, these methods include solvent/solvent partitioning followed by sample concentration.

Real-time Measurement of Reactive and Toxic Hydrocarbons in Auto Exhaust: Methods Development.

Mark A. Dearth and T. J. Korniski, Ford Motor Co., Scientific Laboratory, Maildrop SRL 3061, P.O. Box 2053, Dearborn, MI 48121-2053.

Hydrocarbon analysis in vehicle exhaust becomes ever more difficult as emissions control systems and engines become more efficient. Also, State and Federal regulators are mandating that more chemical information be reported on the composition of these emissions. In an effort to reduce both the instrumentation and the manpower required to meet these testing needs, on-line methods of analysis are actively being sought.

One potential method is based on atmospheric pressure corona discharge ionization (APCDI) and tandem mass spectrometry (MS/MS), and uses nitric oxide (NO) as a reagent gas. Nitric oxide is a proven reagent gas in low pressure CI (1-3), and it was a logical next step to use NO as a reagent gas in APCDI. Nitric oxide is favored because: 1) it has an ionization potential of 9.25 eV; 2) it will not ionize N_2, O_2, CO_2, and small alkanes; 3) it will ionize alkenes, aromatics, and oxygenates.

This report describes some of the various instrumental and sample parameters that effect ionization by NO, and its potential for the real-time analysis of hydrocarbons in auto exhaust.

Experimental

All experiments were conducted using an Sciex API-III tandem mass spectrometer. The ion source region was heated to 100°C and tightly sealed, to reduce interference effects due to extraneous water The glass interface supplied by the manufacturer was modified to allow heating of the sample gases to 350°C. A ceramic sleeve was fitted to the end of the glass interface to contain the sample gases in a narrow region around the discharge needle (data not shown).

Synthetic blends of hydrocarbon gases (Scott Specialty Gases) were diluted to volume with nitrogen. Nitric oxide (9000 ppm; Airco) was diluted with N_2, air (99.999) and with the sample gases. Typical dilutions resulted in a 3000 ppm mixture of nitric oxide and a factor of 200 dilution of the sample gases.

Results

Nitric oxide reacts with various hydrocarbons in the manner previously documented under low pressure CI conditions. Representative parent and daughter ion spectra for various hydrocarbon classes can be seen in Figure 1.

Nitric oxide strongly enhances the ionization of most species, either by adduct formation or charge exchange, as depicted in the plot in Figure 2. The aromatic compounds strongly associate with NO, but can be induced to lose neutral NO by increasing the extraction voltage potential difference between the orifice (OR) and the first quadrupole lens (RO) of the API-III instrument.

The robustness of this ionization process to water, a major component of the exhaust matrix, was a major concern. Even traces of water dramatically reduce the response for all compounds, as shown in Figure 3. Average signals (ion counts per second or ICPS) drop by

almost 90% at 450 ppm water in the sample gas However, the effect of water can be reduced by heating the sample stream. Water at 100 ppm reduces compound responses by 60% at a sample gas temperature of 110°C, but only by 15% with heating (@ 350°C) With water's interference minimized, this real-time method can measure a variety of previously untenable hydrocarbons at the ppb-pptr level While developed for automotive emissions measurement, this technique has equal potential for process or ambient air monitoring applications.

THERMAL STUDY OF RUTIN BY ON-LINE THERMOGRAVIMETRY/ GAS CHROMATOGRAPHY/MASS SPECTROMETRY

Henry L. Chung*, John C. Aldridge, and Jessie M. Rivers

R. J. Reynolds Tobacco Company, Bowman Gray Technical Center, Winston-Salem, NC 27102

Thermal analysis has become an important analytical technique with the introduction of modern thermal analytical instruments. An on-line thermogravimetry/gas chromatography/mass spectrometry (TG/GC/MS) system (1) was used to study the stabilbity, weight loss, and thermal degradation products of rutin. The on-line TG/GC/MS system employed a Du Pont 951 thermogravimetric analyzer equipped with a 9000 thermal analysis system interfaced to a Hewlett-Packard 5890 GC/5970 MSD system. The TG/GC interface consisted of a heated transfer line, an adsorbent trap packed with Tenax and a six-way valve. Rutin was heated and purged with air at a flow rate of 30 ml/min during the heating and purging process. The TG temperature was programed from 30°C to 900°C at 20°C/min. The volatile compounds generated in the TG were swept into an adsorbent trap. The purge gas, after passing through the trap, was vented to the atmosphere. After the heating and purging process, the trap was rapidly heated to 200°C and the volatile compounds in the trap were swept into the GC/MS system by helium at a flow rate of 35 ml/min. The volatile compounds were separated by GC. A 60 m X 0.25 mm ID DB-1701 (0.25 μm film thickness) fused silica capillary column was used for compound separation. The GC injection temperature was 250°C. The column head pressure was 25 psi. The column temperature was held at 35°C for 10 minutes, programmed to 220°C at 3°C/min and held for 48 minutes. An open-split GC/MS interface was used and the temperature was at 275°C. The mass spectrometer was operated at 70 eV in the EI mode. The ion source of the mass spectrometer was maintained at 250°C. The mass range scanned was from 29-500 amu. The volatile compounds were identified by mass spectra. The on-line TG/GC/MS system permits evolution of thermal degradation products of rutin by

TG, separation of the volatile thermal degradation products by GC, and identification by MS. The thermogram of rutin depicts a curve with four plateaus showing sample weight loss as a function of increasing temperature. The first decomposition occurred over a temperature range of 82-159°C with a weight loss of 5%. The second decomposition was between 275-374°C with 29% weight loss. The third decomposition occurred over a temperature range of 374-669°C with 62% weight loss. The fourth decomposition was between 669-900°C, and involved a further 4% weight loss. Thus, a temperature profile of stability and weight loss from rutin was obtained. The total ion chromatogram showed that a number of thermally degraded compounds were formed from rutin under the conditions studied. The volatile compounds were identified by mass spectra. The volatile degradation products were identified as ketones, furan derivatives, benzene derivatives, acids, aldehydes, furanone derivatives, pyranone derivative and phenol derivatives.

Interpretation of the Distribution of Environmental Contaminants in Gulf of Mexico Oysters using Log-Normal Distribution Functions

*T.J. Jackson, T.L. Wade, T.J. McDonald, J.L. Sericano, and J.M. Brooks, Geochemical and Environmental Research Group, College of Geosciences and Maritime Studies, Texas A&M University, College Station, TX 77845

In the National Status and Trends Mussel Watch Program, over 80 sites in the Gulf of Mexico have been sampled for oysters and analyzed for trace organic contaminants during the first seven years of this program. The contaminant concentration found in oysters reflects the current contaminant burden of the ecosystem. The PAHs were analyzed by SIM-GC-MS using a HP5890 GC interfaced to a HP5970MSD, and the organochlorines by GC-ECD.

The cumulative frequency distribution function was used to deconvolute the distribution for contaminant concentrations (PAHs, PCBs, DDTs, Chlordanes and Dieldrin) into two log-normal probability density functions and calculate summary statistics for each population. This approach has the advantage of examining the Gulf of Mexico as a single heterogeneous environmental system and provide information for environmental evaluation. The lower concentration level population (Pop 1) is associated with sites whose source of contaminants is probably due to chronic contamination (i.e., water runoff, atmospheric deposition). The higher level contaminant concentration population (Pop 2) is associated with local point sources of input. The temporal pattern for the mean concentration for some contaminants is consistent with large-scale climatic factors such as the El Niño cycles which affect the precipitation regime

The two log-normal probability density functions are controlled by changing the mean and spread for each population. The probability density functions are then summed using the proportion of each population, which is also a controllable variable. The sum of the probability density functions is then compared to the actual cumulative frequency distribution. The best fit for the modeled cumulative frequency distribution is determined by the minimum in the sum of the absolute deviations between the actual data and the model data (Figure 1).

The model uses a spreadsheet to calculate and compare the data which is generated. The inputs to the model are, a table of log values versus cumulative percent for a particular analyte, the mean value and spread for each population and the percent of the data in population 1, which are used to generate a table for each population, which contains the values for the mean minus 3s to the mean plus 3s versus the value for the gaussian function. The model table compares the analyte data with the model data using the lookup function with the appropriate population table to compute the cumulative distribution from the model data.

The model determines, the median concentration for each population, the percent of the data in Population 1 and the concentration above which Population 2 samples dominate the distribution (Figure 2).

Dieldrin displays a general decrease in concentration with time, as does the Chlordanes concentration. DDTs, PCBs and PAHs display a cyclic distribution which is consistent with large-scale climatic factors such as the El Niño cycle (Figure 3).

SUPERCRITICAL FLUID EXTRACTION IN THE ANALYSIS OF ENVIRONMENTAL ORGANIC POLLUTANTS

Iddys Figueroa, Arturo Hornedo and Osvaldo Rosario
University of Puerto Rico, Rio Piedras, Puerto Rico, 00931.

It is very important in environmental analysis, to remove the compounds of interest as efficiently as posible from the matrix being studied in such a way that artifacts are minimized and sample integrity is mantained. There are several methods of extraction for non-volatile and semi-volatile organic compounds from liquid and solid matrices. The most comonly used methods of extracting organic compounds from liquids are liquid-liquid extraction, solid-phase extraction and Dean Stark, from solids are Soxhlet extraction and ultrasonic extraction. The use of one technique or another depends on the matrix, the efficiency and the time available to perform the analysis. The majority of these methods require the use of organic solvents that present problems of sample dilution, disposal and toxicity.

Recently, interest has emerged in a relatively new technique of extraction for environmental analysis called Supercritical Fluid Extraction (SFE). A supercritical fluid is a substance that is over its critical temperature and critical pressure. By changing the pressure and temperature of this fluid, its properties change continuously from liquid-like to gas-like and hence its physical properties of viscosity and diffusivity change continuosly between those of a liquid and those of a gas, improving the solvating power of this fluid. The fluid most commonly used is CO_2 which eliminates the use of organic solvents and sample dilution. A modifier can also be added such as methanol to increase the polarity of the fluid.

The purpose of this work is to develop a methodology based on supercritical fluid to exract non-volatile semi-volatile and thermally labile compounds from diverse matrices such as adsorbents, filters, soil and biological matrices. The SFE systems commercially available are made for specific aplications and do not offer sufficient flexibility for changing the working conditions. For this reason a system of extraction was constructed. This SFE system allows changing conditions such as the size of the extraction cell,

collection mode, restrictor type and possibilities of using the system on-line or off-line.

After the equipment was assembled, all the unions, seals and valves were submitted to 10,000 psi of CO_2 and once demonstrated to withstand these pressures, experiments to optimize the extraction conditions were performed. The analytical technique used to monitor the efficiency of the extraction was HPLC with U.V. detector. Previous to the extraction experiments, the chromatographic parameters were optimized for a selection of standards representatives of a broad range of chemical properties as is the case with environmental samples.

Mixtures of the standard compounds were loaded onto a cartridge packed with glass wool and the optimum parameters such as pressure, temperature and volume of CO_2 were determined. The optimum parameters are 500 atm,50°C and 50 mL of CO_2. The same mixture was loaded into a cartridge packed with Tenax adsorbent, already preconditioned, and the extraction was performed using the parameters optimized using the glass wool. The recovery was compared with the injection of the mixture directly in the HPLC and the recovery percent was higher than 85% for most of the standard compounds but for 2,3-dichlorophenoxy acetic acid, 1-(2-chlorophenyl)-2-thiourea, monuron and bromacil.

Selectivity and Sensitivity Enhancements of Halogen Detection Utilizing Microwave-Induced Plasma/Chemical Reaction Interface Mass Spectrometry and Negative Chemical Ionization

Jeffrey T. Morre' and Mehdi Moini*
Department of Chemistry and Biochemistry
The University of Texas at Austin,, Texas 78712

Recently [1,2] we applied the GC-MIP-CRIMS technique to the selective detection of chlorine-containing compounds in complex mixtures utilizing MIP-CRIMS using electron impact ionization. Here we report the MIP-CRIMS detection of chlorinated and brominated compounds in complex mixtures using negative chemical ionization (NCI). The mass spectrometer used was a Finnigan MAT TSQ-70. In this study, SO_2 has been found highly effective as a reaction gas for selective detection of chlorine- and bromine-containing compounds using GC-MIP-CRIMS.

WHY NEGATIVE CHEMICAL IONIZATION

1) Inherent higher sensitivity of NCI for for halogen containing compounds: It has been shown that electron capture chemical ionization (negative chemical ionization) for many halogenated compounds is more sensitive compared to other forms of CI or to EI. This is because for many halogenated compounds electron capture rate constant is greater than, e g., proton transfer rate constant.

2) Less background chemical noise: In the SO_2 containing helium plasma environment, chlorine and bromine of the Cl- and Br-containing compounds predominantly form HCl and HBr, respectively. In EI mode of ionization $H^{35}Cl$ m/z 36 was the most abundant ion that was completely selective for chlorine-containing compounds, i.e., only chlorine-containing compounds produced peaks in the m/z 36 mass chromatogram However, the most sensitive selective mass chromatograms for bromine in the electron impact ionization mode are $(H^{79}Br)^+$ m/z 80 and $(H^{81}Br)^+$ m/z 82, but these channels were saturated because of the $^{32}SO_3$ m/z 80 and $^{34}SO_3$ m/z 82 formation in this plasma Therefore, the second most sensitive bromine mass chromatogram, $S^{79}Br$ m/z 111, has to be used for bromine detection. As a result, the minimum detectable amount of bromine was higher than it would have been if m/z 80 could have been used.

In the negative chemical ionization mode the most sensitive selective mass chromatograms for bromine is $(^{79}Br)^-$ and $(^{81}Br)^-$ that have no interference with $(^{32}SO_3)^-$ m/z 80 and $(^{34}SO_3)^-$ m/z 82 m/z. For this reason, the detection limits of bromine containing compounds improve significantly under NCI condition.

Selectivity and Dynamic Range. The selectivity of the GC-MIP-CRIMS of chlorine-containing compounds in complex mixtures is demonstrated using a mixtures of PCBs (Figure 1), and chlorinated pesticides (Figure 2). M/z 35 represents a selective mass chromatogram

for chlorine, m/z 81 represents a selective bromine mass chromatogram The linear dynamic range is at least three orders of magnitude.

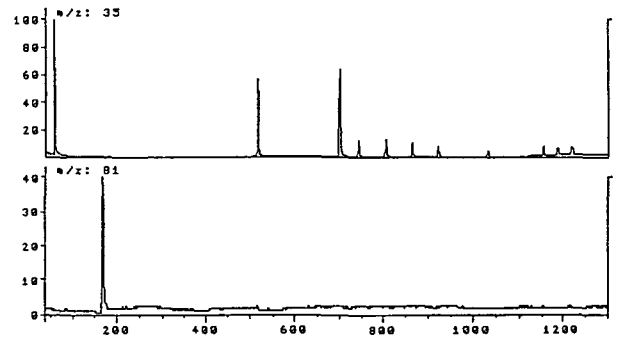

Figure 1. Selectivity of chlorinated compounds for a mixture of PCBs. Cl^- m/z 35 represents the selective mass chromatogram for chlorine-containing compounds. The PCBs concentrations were: 2-chlorobiphenyl (100 μg/mL), 3,3'-dichlorobiphenyl (100 μg/mL), 2,4,5-trichlorobiphenyl (10 μg/mL), 2,2',4,4'-tetrachlorobiphenyl (10 μg/mL), 2,3',4,5',6-pentachlorobiphenyl (10 μg/mL), 2,2',3,3',6,6'-hexachlorobiphenyl (10 μg/mL), 2,2',3,4,5,5',6-heptachlorobiphenyl (5 μg/mL), 2,2',3,3',4,4',5,5'-octachlorobiphenyl (5 μg/mL), 2,2',3,3',4,4',5,5',6-nonachlorobiphenyl (5 μg/mL), 2,2',3,3',4,4',5,5',6,6'-decachlorobiphenyl (5 μg/mL).

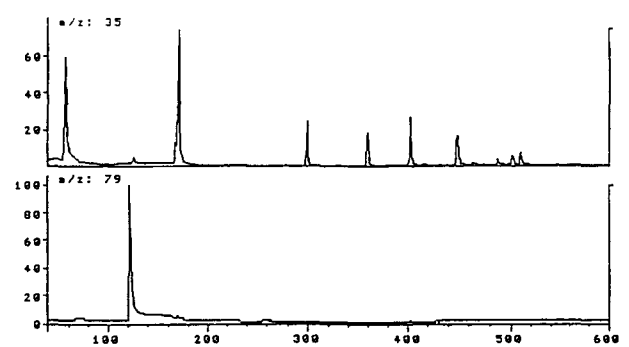

Figure 2. Selective detection of a chlorine-containing pesticide mixture. 500 μg/mL of the following pesticides: Atrazine, Endrin, Heptachlor, Heptachor epoxide, Hexachlorobenzene, hexachlorocyclopentadiene, Methoxychlor. 1 μL injected.

DETERMINATION OF BENZENE IN FOOD BY DIRECT SAMPLING ION TRAP MASS SPECTROMETRY

S.A. Barshick, S.M. Smith, M.V. Buchanan, and M.R. Guerin, Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Two methods, purge & trap GC/MS and Direct Sampling Ion Trap Mass Spectrometry (DSITMS), were developed and evaluated for the determination of benzene in food. DSITMS involves the direct introduction of purged volatile organic compounds (VOCs) into an ion trap mass spectrometer with no trapping or chromatographic separation prior to detection. Compared to a conventional purge & trap GC/MS method (such as EPA method 624), this amounts to a significant reduction in analysis time and cost per sample analysis.

In this work, a purge and trap GC/MS approach was developed based upon EPA method 624 (VOCs in environmental samples) and adapted for the determination of benzene in food. In this approach, volatiles are purged from a sample using a helium purge flow of 40 mL/minute for 11 minutes. The volatiles are trapped on a OV-1/Tenax/silica gel resin trap and then desorbed for 4 minutes at 180°C. The volatile components are then separated on a 30 m, 0.25 mm i.d., 1.0 μm film RTX-5 column that is heated from 25 to 225°C resulting in a total GC/MS analysis time of 35 minutes per sample. The components are ionized using 70 eV electron ionization. Benzene and its internal standard, fluorobenzene are selectively detected using selected ion monitoring. In the DSITMS approach, volatiles are purged directly into the mass spectrometer without trapping or chromatographic separation. A helium purge flow rate of 50 ml/minute is used and data is collected for 3 minutes. Water, introduced in the helium purge gas stream, is used as the chemical ionization reagent to provide proton transfer from H_3O^+ to neutral benzene producing an $(M+H)^+$ ion at m/z 79. Using the unique software capabilities of the ITMS, fullscan and MS/MS data are collected over the same purge profile. This allows the detection of an internal standard and identification of other components in the sample using the fullscan mode and adequate sensitivity and selectivity for the detection of benzene using the MS/MS mode.

Initial studies were performed to determine detection limits for benzene in water by purge & trap GC/MS and DSITMS. Both methods were shown to be linear (correlation coefficents of 0.9977 for DSITMS and 0.9957 for GC/MS) from 0 to 800 ppb benzene in water. Assuming a target concentration between 0 and 25 ppb, EPA method detection limits (MDLs) were less than or equal to the EPA criteria of 5 ppb in drinking water for both methods. Overall, the DSITMS approach has slightly lower detection limits (1.3 ppb) than purge & trap GC/MS (4.9 ppb) for the determination of benzene in water.

Table 1 summarizes the results for the analysis of 3 types of blind QA/QC samples (water, water + VOCs, and milk). Unknown sample concentrations were calculated using the water calibration lines and by single standard addition. For the DSITMS approach, the standard addition calculation had lower percent errors than the calibration plot because the standard addition method takes into account matrix effects. Chemical interferents were not a problem in the GC/MS method because they could be separated chromatographically from benzene. The calculated concentrations of benzene using the linear regression line determined from the water calibration data were low for the milk samples for both instruments. These low results were due to the matrix and the less than 100% purge efficiency of benzene in milk relative to water. The standard addition approach, however, eliminates any matrix effects and the need to run calibration lines for each of the food matrices. Overall, confidence intervals and percent errors using the standard addition approach

were similar for both instruments for all matrix types analyzed and were more accurate than the linear regression method using water calibration data.

A preliminary study was conducted for six targeted foods using the standard addition approach and both instrumental methods. Each food type was analyzed as is (blank) and fortified with two levels of benzene so that a 3 point standard addition line could be plotted. A fortified water sample was also analyzed to determine relative recoveries of benzene from the different food matrices. Benzene recoveries relative to water in all foods except coffee were typically less than 50% and were comparable for both instrumental methods. Using the standard addition plot the amount of benzene in each food was determined. In all six foods, the amounts of benzene found by the purge & trap GC/MS method were below the method detection limits. The amounts of benzene found using the DSITMS approach were also below the method detection limits for all foods except tomatoes and roast chicken. Based on 95% confidence intervals, however, it can be concluded that no significant amount of benzene was found in any of the six foods analyzed by either technique.

In this study, it was shown that comparable results (detection limits, accuracies, and percent recoveries) can be obtained for DSITMS and purge & trap GC/MS. Overall, the DSITMS approach had slightly lower detection limits than purge & trap GC/MS, although comparable results were obtained for the quantification of benzene in blind QA/QC samples (percent errors ranging from 0 to 60% with acceptable errors based on EPA QA acceptance criteria ranging from 37 - 151%). Purge efficiencies and amounts of benzene found for each of the six foods relative to water were also comparable for the two methods. In terms of time and cost-effectiveness, however, the DSITMS method was much faster, requiring only 3 minutes per sample compared to 35 minutes per sample by purge & trap GC/MS.

Table 1: Results for Triplicate Analyses of Benzene in Blind Samples

Target Concentration (Sample)	Method	Mean	95% Confidence Interval
7.2 ppb (water)	GC/MS	4.5	+/- 2.3
7.2 ppb (water)	ITMS	8.3	+/- 4.5
6.3 ppb (VOC mix)	GC/MS	5.3	+/- 2.2
6.3 ppb (VOC mix)	ITMS	6.3	+/- 3.0
201 ppb (milk)	GC/MS	156	+/- 19
402 ppb (milk)	ITMS	332*	+/- 259*

Oak Ridge, TN, 37831-6120.

Introduction

Direct Sampling Ion Trap Mass Spectrometry (DSITMS) has been under development in our laboratory for a number of years as a means of rapidly detecting and quantifying volatile organic compounds (VOCs) in environmental samples. Over the past years, efforts have focused primarily on the development and modification of instrumentation for field and laboratory applications of DSITMS. Early data generation efforts were mostly aimed at the acquisition of pilot data which demonstrated the utility of the DSITMS technique. As this technology has started to mature and gain acceptance among other users, it has become necessary to develop concise analytical procedures and generate the validation data to support regulatory acceptance of DSITMS methods.

Method

At this time, a method has been developed for the screening of 34 EPA TCL volatile organics in water samples by direct purge into the ion trap. This method is designed to detect the presence of one or more of the VOCs at or above a threshold level of 5 ppb with a total analysis time of 3 minutes. The method utilizes a helium purge with a flow rate of 100 mL/min. Approximately 1% of the effluent is directed to the ion trap through a capillary restrictor and the remaining 99% is vented to atmosphere or can be collected on a sorbent tube for sample archival purposes. The ion trap is operated over a scan range of 45 to 300 amu using fixed ionization times for improved detection limits. Alternating electron ionization and chemical ionization scans are routinely employed. This provides enhanced compound selectivity for compounds such as alkyl-aromatics and also improves the detection limits for water soluble analytes such as aldehydes and ketones. The CI reagent is water, which is introduced into the ion trap at a constant rate along with the analytes. Quantification is performed by integrating the purge profile area for m/z values corresponding to the target analytes. The objective is to minimize the occurrence of false negatives.

Results

Method detection limits (MDL) and Certified reporting limits (CRL) have been determined for each of the volatile organics based on criteria of EPA and Army Environmental Center, respectively. Standard spectra have been generated under EI and CI conditions and potential interferences have been identified and noted where appropriate. Linearity has been established over a range of at least 1 ppb to 100 ppb and response factors for each compound have been established relative to internal standards. Appropriate QA/QC has been incorporated in the analytical method including steps for mass calibration and detailed instrument performance checks.

Conclusion

A screening method has been successfully developed for VOCs in water based on direct purge into an ion trap mass spectrometer. A draft of this method has been submitted to the Department of Energy and also to the Environmental Protection Agency for consideration for inclusion in the SW-846 manual. As a laboratory or field screening method, it will be possible to process in excess of 100

water samples per day. This high throughput will greatly improve the ability to perform site characterizations in an efficient and timely manner. Furthermore, additional cost savings will be realized by eliminating the non-contaminated samples from the sample load submitted for complete analysis by conventional purge and trap GC/MS.

Example DSITMS Detection Limits for Volatile Organic Compounds in Water

Compound	Ionization Mode[a]	MDL[b] (ng/mL)	CRL[c] (ng/mL)	Quant Mass (m/z)

Multispectral Identification of Chlorine Dioxide Disinfection By-products in Drinking Water

*Susan D. Richardson, Alfred D. Thruston, Jr., and Timothy W. Collette, U.S. Environmental Protection Agency, Athens, GA 30605-2720.

Kathleen Schenck Patterson and Benjamin W. Lykins, Jr., U.S. Environmental Protection Agency, Cincinnati, Ohio 45268.

Introduction

Due to concern over the presence of trihalomethanes (THMs) and other chlorinated by-products in chlorinated drinking water, alternative disinfection methods are being explored. Chlorine dioxide (ClO_2) has been considered as an alternative to chlorine because it produces fewer THMs than chlorine and has other desirable properties, such as providing excellent disinfection, controlling odor and taste, and removing manganese and iron from water. However, very little is known about the identity of organic disinfection by-products (DBPs) that are produced by chlorine dioxide treatment.

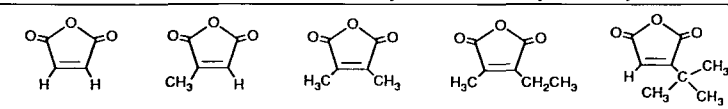
Using multispectral identification techniques (combination of mass spectral and infrared methods), we identified more than 40 DBPs produced by chlorine dioxide treatment at a pilot plant in Evansville, Indiana. This is the first such comprehensive study of chlorine dioxide DBPs. Among the more interesting compounds identified were a series of maleic anhydrides and halopropanones.

Experimental

Multispectral identification techniques included gas chromatography coupled with low and high resolution electron-impact mass spectrometry (GC/EI-MS), low resolution chemical ionization mass spectrometry (GC/CI-MS), and Fourier transform infrared spectroscopy (GC/FT-IR). CI-MS experiments utilized methane gas, and GC/MS analyses were performed on either a VG 70-SEQ high resolution hybrid mass spectrometer or a Finnigan 4500 quadrupole mass spectrometer. GC/FT-IR experiments were performed on a Hewlett Packard Model 5965B IRD. Water samples were collected from a pilot-scale drinking water treatment plant in Evansville, IN, where the following treatment variations were applied: 1) liquid ClO_2, 2) liquid ClO_2 + $FeCl_2$ + Cl_2 + dual media filtration (sand and anthracite), 3) gaseous ClO_2, and 4) gaseous ClO_2 + $FeCl_2$ + Cl_2 + dual media filtration. Water samples (90 L) were concentrated by adsorption on Amberlite XAD resins, and the ethyl acetate eluents were then concentrated to 2 ml by Kuderna-Danish.

Results and Discussion

Rather than attempting to identify a few expected target by-products, our objective was to identify every compound that was detected in the sample extracts. In most cases, the multispectral techniques afforded very precise identifications for the semi-volatile by-products. Of the 40+ DBPs identified, the most unusual compounds were a series of maleic anhydrides, whose structures are shown below. The basic ring structure of these maleic anhydrides is similar to MX, 3-chloro-4-(dichloromethyl)-5-hydroxy-2(5H)-furanone, the controversial mutagenic chlorination by-product. Compound **5**, 2-*tert*-butyl maleic anhydride (which was one of the most concentrated by-products), was particularly difficult to identify, as there was nothing remotely similar in the mass spectral library databases (NIST or Wiley), there were no EI-MS ions characteristic for maleic anhydrides, and there was no molecular ion present in the EI mass



1 **2** **3** **4** **5**

spectrum. Methane CI-MS provided the molecular weight, high resolution EI-MS provided empirical formula information on fragments, and GC/FT-IR provided functional group information. Because the maleic anhydrides exhibit an extremely unusual infrared absorbance characteristic of the furandione functional group present in their structures, GC/FT-IR was key to identifying the maleic anhydrides. The EI mass spectrum and IR spectrum for Compound **5** are shown below.

When DBPs for the different treatment variations were compared, we discovered that the form of ClO_2 used was not important; both liquid and gaseous ClO_2 have the same effect. However, added reducing agent ($FeCl_2$), along with residual chlorine and dual media filtration, do cause a greater variety of by-products to be formed. Finally, although many DBPs were identified, all appear to be of extremely low concentration (1 to 10 ng/L, ppt). These levels are 1000 to 1,000,000X lower than those levels typically found for chlorinated drinking water. Chlorine dioxide appears to be a promising alternative to chlorine for treatment of drinking water, based on the levels of semi-volatile DBPs produced.

Identification of PCB Degradation Products in Gamma-Ray Irradiated Solutions of PCB's in Isopropanol. W. B. Knighton and L. J. Sears, Department of Chemistry, Montana State University, Bozeman, Montana 59717. R. E. Arbon, B. J. Mincher and D. H. Meikrantz, EG&G Idaho Inc., Chemical Sciences Group, Idaho National Engineering Laboratory, Idaho Falls, Idaho 83415.

Destruction of polychlorinated biphenyls (PCB's) and other halogenated wastes by incineration is meeting with increasingly stronger public opposition. As a result, significant effort is being directed at the development of alternative disposal methods for the PCB's. Towards this end, we have explored gamma-ray irradiation as a method for detoxifying halogenated wastes. Radiolysis offers numerous advantages over incineration, including minimization of gaseous and particulate effluents and the ability to verify that the hazardous materials have been reduced to acceptable limits prior to being discharged.

We report here the results of gamma radiolysis of octachlorobiphenyl (OCB) in aerated neutral isopropanol solutions. Unlike radiolysis under alkaline conditions, where PCB's undergo stoichiometric dechlorination to free chloride and lower chlorinated biphenyls (1,2), the degradation of OCB in neutral isopropanol produces not only the expected less chlorinated PCB species, but also a series of solvent altered PCB congeners. The identity of these altered PCB compounds is reported and a mechanism is proposed for the radiolytic degradation of OCB in neutral isopropanol.

Samples were gamma irradiated with spent nuclear fuel at the Advanced Test Reactor (EG&G Idaho) as described previously (3) at a dose rate of approximately 1 MRad/hr. Absorbed doses were measured using a FWT-60 radiochromic dye dosimeter (Far West Technology, Goleta, CA). Samples were analyzed by GC/MS (VG 7070-EHF) operated in the EI mode using a J&W 60m DB-1 column.

Figure 1 shows an EI total ion chromatogram for a solution of OCB in neutral isopropanol after receiving a 12 Mrad dose The large envelope of peaks having retention times shorter than that of OCB starting material consists of a series of less chlorinated congeners ranging from trichloro- to heptachlorobiphenyl. The peaks having retention times longer than that of OCB are due to the presence of a series of solvent altered compounds. The mass spectrum of the most predominant member of this series is shown in Figure 2. The proposed structure of this compound is also shown in Figure 2. Chemical derivatization techniques verified that the isopropanol group was bound to the biphenyl ring via a carbon linkage.

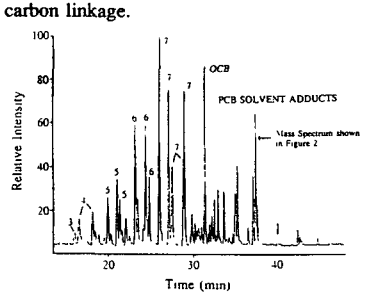

Figure 1 GC/MS EI total ion chromatogram for an octachlorobiphenyl in isopropanol solution after receiving a 12 Mrad dose Peaks are labelled to indicate the level of chlorination on the biphenyl ring

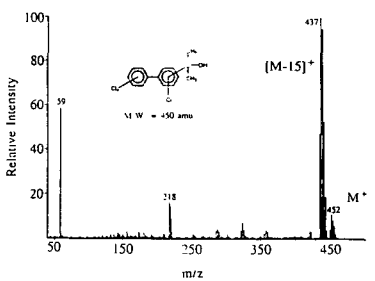

Figure 2. EI mass spectrum for the indicated peak in Figure 1 Insert shows the tentative structure of the isopropanol substituted PCB assigned to this mass spectrum

The following mechanism is proposed for the radiolytic recomposition of OCB.

$$(CH_3)_2CHOH + \gamma \rightarrow [(CH_3)_2CHOH]^* \quad (1)$$
$$[(CH_3)_2CHOH]^* \rightarrow e^- + [(CH_3)_2CHOH]^+ \quad (2)$$
$$[(CH_3)_2CHOH]^+ \rightarrow (CH_3)_2\dot{C}OH + H^+ \quad (3)$$
$$OCB + e^- \rightarrow HCB^\cdot + Cl^- \quad (4)$$
$$HCB^\cdot + (CH_3)_2CHOH \rightarrow HCB + (CH_3)_2\dot{C}OH \quad (5)$$
$$HCB^\cdot + (CH_3)_2\dot{C}OH \rightarrow HCB[(CH_3)_2\dot{C}OH] \quad (6)$$
$$OCB + (CH_3)_2\dot{C}OH \rightarrow HCB^\cdot + (CH_3)_2CO + HCl \quad (7)$$

The first three reactions provide a simplified scheme of the gamma radiolysis of isopropanol. The production of the α-hydroxyisopropanol radical is generalized via Reaction 3. While other solvent radicals are produced, these undergo H abstraction with the solvent and ultimately lead to the formation of the α-hydroxy radical. It is the products of the solvent radiolysis that are thought to be responsible for the radiolytic degradation of OCB. Direct action on OCB by the gamma radiation is not significant.

The presence of substances which are both efficient electron and radical scavengers, CCl_4 or nitrobenzene, in the irradiated solution virtually inhibits the destruction of OCB. This eliminates positive ions as being reactive towards OCB. Irradiation of OCB solutions saturated with SF_6, an efficient electron scavenger, reduces the radiolytic decomposition efficiency about 95%. SF_6 is thought to be unreactive towards the α-hydroxy solvent radical. These results indicate that solvated electrons, Reaction 4, are the primarily responsible for the destruction of OCB, but that reaction with the α-hydroxy solvent radical, Reaction 7, occurs to a measurable extent.

Heptachlorobiphenyl or other less chlorinated PCB's observed in the degradation of OCB are formed via a sequence of reactions starting with Reaction 4 or 7 followed by H abstraction with the solvent, Reaction 5. The production of the isopropanol PCB adduct is thought to be produced via the radical-radical reaction in Reaction 6. However, a series of radical neutral reactions could also lead to the observed product.

The Analysis of TCDD in Human Serum using Very High Resolution SIR

***Jeremy R. Hart[1] and Donald G. Patterson Jr.[2]**
1 – VG Analytical, Fisons Instruments, Manchester, M23 9LE
2 – Centers for Disease Control, Atlanta, GA 30333

INTRODUCTION

The analysis of polychlorinated dibenzo-*p*-dioxin and dibenzo-furans in human serum samples has often presented difficulties due to the limited amount of source material available for adequate clean-up In addition, the need to provide improved statistical information in epidemiological studies of human exposure requires that quality data is obtained from lower sample quantities and on a more cost effective basis.

As part of an evaluation of an experimental clean-up technique[1], 5 samples were prepared for analysis, including one extracted from 2.4 grams of human serum. This paper describes the results obtained from the analysis of TCDD (tetra-chloro-dibenzo-dioxin) using conventional, 10,000 resolution GC–MS and shows the improvements observed at 22,000 resolution.

METHODS

From their final dry state, each sample was re-constituted in a make-up solution containing $^{13}C_6{}^{12}C_6$–1,2,3,4–TCDD as a recovery and resolution check[2] standard in 5µl of toluene

Each sample was analysed using a VG AutoSpec–Ultima mass spectrometer and HP 5890A GC fitted with a J&W 60 metre DB–5MS column. All data was acquired in the SIR mode monitoring 7 ions (including lock mass and check channel).

Due to their low volume, manual injections of 2 µl were used for all samples and an autosampler used for calibration standards.

Data Review and Quality Control

The data from the analyses of TCDD at 10,000 resolution clearly indicated a problem due to chemical interferences. This is marked by the presence of some peaks in only one of the mass channels and an unstable baseline Some peaks of interest were also masked thus preventing accurate quantification

Data from the sample make-up showed a small (<5 fg) 1,2,3,4–TCDD peak only The use of separate syringes for all samples and checks on solvent blanks following a standard's injection confirmed that there was no measurable carry-over.

These and additional performance checks based on the calibration standards, i e isotope ratios, dynamic resolution and the lock-mass-check channel stability, confirmed that the interferences were due to components, present only in the samples, that were unresolved at 10,000 resolution

Sources of Interference and the need for Higher Resolution

There are several polychlorinated-biphenyl and related compounds that are possible sources of interference. The NIST library lists 113 chlorinated compounds that include mass 322 in their spectrum, of these 39 are biphenyls. For example, 4,4'–Biphenyldiol, 3,3'5,5'–tetrachloro–, m/z 321.9122 would require > 18,000 resolution for 10% valley separation Also, at these detection levels, the consideration of abundant sensitivity is important.

As there was only sufficient sample for one further set of analyses, it was decided to perform this with the mass spectrometer tuned to 22,000 resolution.

RESULTS

The resulting data showed that the chemical interferences were largely eliminated (figure 2), *and that high sensitivity was still maintained with a DL < 10 fg The analysis was repeated for* the remaining samples in the series; each showing significant improvement in data quality.

A calibration curve was generated, at 22,000 resolution, using 5 standards to cover the range 10 fg to 200 fg The 20 fg calibration standard has maintained an excellent signal to noise ratio of greater than 20 1 (based on a 4σ noise definition, smoothed data), and an isotope ratio of 0.80

The new data could now be quantified using fully automated procedures, OPUSquan results for the 2.4 gram serum sample are shown here for the confirmed TCDD peaks

Figure 1 Sample 906-29E 10,000 RP

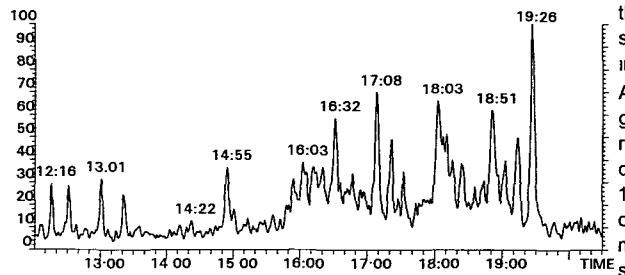

Figure 2 Sample 906-29E 22,000 RP

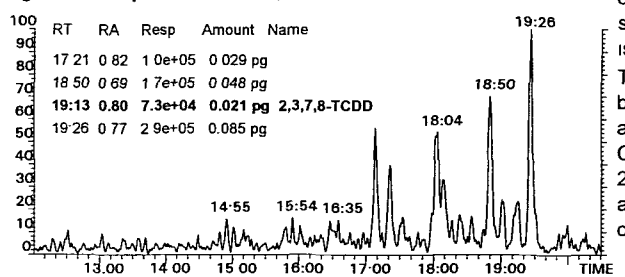

CONCLUSIONS

Without the ability to acquire very high resolution SIR data at this level of sensitivity it would have been necessary to re-extract the samples using an improved method — as in the example illustrated, that possibility does not always exist.

This paper has shown that, with current instrumentation, very high resolution SIR is a practical option where femtogram detection limits are required of samples obtained from serum or other difficult matrices.

Investigations into Interferences in Dioxin Analysis by HRGC-HRMS

T. Takasuga[1], T. Inoue[1], P. Ireland[2] and C. Moore[2]

[1] Shimadzu Techno Research Inc., Kyoto 604, Japan

[2] Kratos Analytical, Manchester M31 2LD, UK

Introduction

Current methodology for dioxin analysis utilises high resolution capillary gas chromatography coupled with high resolution mass spectrometry (HRGC-HRMS). In order to maintain the highest sensitivity at the same time as increasing the selectivity, the mass spectrometer is operated in the selected ion monitoring (SIM) mode at 10,000 resolution. Additionally, as the samples are often complex matrices containing many potential interferences at much higher levels, an extensive clean-up procedure also precedes the HRGC-HRMS analytical step. Despite this extensive clean-up and the use of HRGC-HRMS, interferences can still occur, especially when a large variety of samples are analysed on a regular basis. Identification of these interferences can yield valuable information on their likely source, and also indicate possible alternative clean-up strategies.

Air Sample - I

The chromatograms of the ions monitored for pentachlorodibenzofurans (PeCDFs) and the $^{13}C_{12}$-labelled internal standards in the standard, peak top SIM analysis of an ambient air sample are shown in Figure 1. A number of components are observed which do not have relative retention times that correspond to PeCDFs, even though the observed isotope ratios are within accepted limits for PeCDFs.

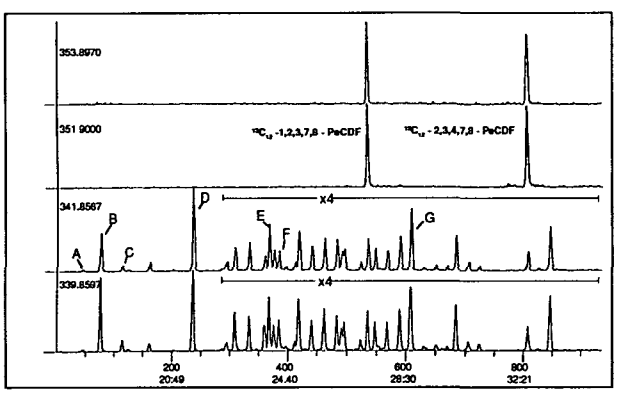

Figure 1: Ion chromatograms for PeCDFs and $^{13}C_{12}$-PeCDFs from a standard, peak top SIM analysis of an ambient air sample. Resolution: 10,000; GC column: SP-2331. A selection of the suspected interferences are labelled A to G

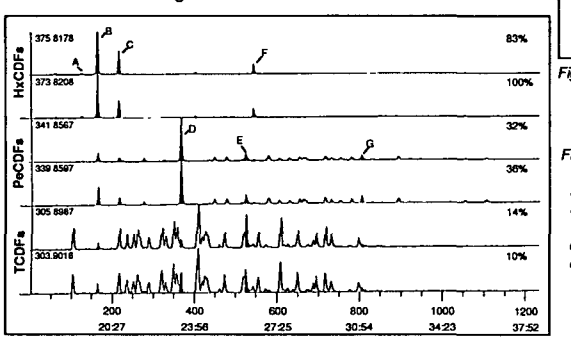
The peak profiles of two of these interferences, together with that of a component presumed to be a PeCDF, can also be seen. Clearly from the accurate masses and isotope ratios the two interferences appear to be different. A standard scanning analysis was also performed on this sample and the spectrum for the component labelled B is shown identifying this compound as chlordane, with the other interferences being related compounds. A scanning analysis of a sample of technical chlordane, coupled with comparison to previously published data,[1] enabled the identification of γ-(*trans*)-chlordane, α-(*cis*)-chlordane, *trans*-nonachlor and octachlordane, as well as dihydroheptachlors.

Air Sample - II

As a consequence of the identification of the interfering species, an additional carbon column chromatography clean-up step was added to the original multilayer silica column chromatography (silica, 10% $AgNO_3$/silica, 22% H_2SO_4/ silica, 2% KOH silica, silica) and alumina column chromatography stages. Interferences due to chlordane and related compounds can also be seen in the ion chromatograms for TCDFs and hexachlorodibenzofurans (HxCDFs) as well as the PeCDFs of this ambient air sample using the original clean-up strategy.

Addition of the extra carbon column clean-up step results in the removal of most of these interfering species as can be seen in the lower chromatogram.



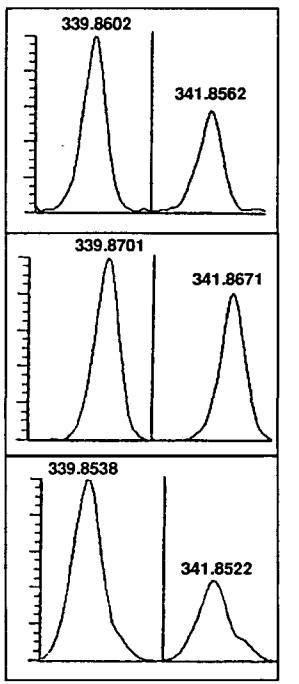


Figure 2: Ion peak profiles of PeCDF (top), interference G (middle) and interference B (bottom)

Figure 4a: Ion chromatograms for TCDFs, PeCDFs and HxCDFs from the standard, peak top SIM analysis of an ambient air sample. Resolution: 10,000; GC column: SP-2331, mixed silica column chromatography and alumina column chromatography clean step.

Mass Profile Monitoring in Trace Analysis: Polychlorinated Dibenzo-p-dioxins and Dibenzofurans in Crab Tissues From Raritan/Newark Bay System

Zongwei Cai[1], V. M. S. Ramanujam[1], M. L. Gross[1] and A. Cristini [2] (1) Midwest Center for Mass Spectrometry, Department of Chemistry, University of Nebraska, Lincoln, NE 68588, (2) Biology Department, Ramapo College of New Jersey, Mahwah, NJ 07430.

In 1983, several species of fish from Newark Bay, New Jersey, were reported to contain elevated levels of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD) (1). The data have resulted in the placement of restrictions on the consumption of crustaceans from Newark Bay, Arthur Kill and Kill van Kull, but not those from Raritan Bay. These earlier data, however, suggest that an additional study should be performed to establish further the levels of polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDD/Fs) in the tissues of these species of crustaceans from the system.

During September 1991 and June 1992, 30 - 40 adult, legal size blue crabs (Callinectes Sapidus) were collected from each of the following four stations in the Raritan/Newark Bay system: Station 1 - Sandy Hook Bay; Station 2 - East Reach of Raritan Bay; Station 3 - Newark Bay; Station 4 - Wards Point. The crabs were dissected and the tissues from 5 - 7 male and female animals were composited for muscle and pancreas samples, respectively. The samples were analyzed for 17 selected 2,3,7,8-substituted PCDD/Fs.

The sample preparation of the crab muscles and pancreas tissues included basic digestion, liquid-liquid extraction with hexane, acid wash and multiple column chromatographic clean-up. Quantification of PCDD/Fs in the sample extracts was performed by using capillary gas chromatography/high resolution mass spectrometry (GC/HRMS) and selected ion monitoring in the mass profile mode (2).

Application of the mass profile monitoring offers high certainty of identification, especially in trace analysis, because it has high diagnostic capability (2). In addition to the two dimensions of information, chromatographic retention time and intensity of signals obtained from conventional peak top monitoring mode, the mass profile mode provides a third dimension of information - accurate mass measurement. Figure 2 shows mass chromatograms and mass profile data for the analysis of TCDD in a crab pancreas sample collected from station 3. The mass profiles (right side of the figure) were acquired for 2,3,7,8-TCDD (A) by the mass profile technique. The isotope ratio that comes from the peak intensities of the two selected ions (M and M + 2) for TCDD, the accurate masses of the selected ions, and the retention time of the GC peak result in a reliable identification of 2,3,7,8-TCDD. Moreover, analysis of mass profile data for peaks (B) has resulted in the identification of a tetrachlorodibenzothiophene (TCDT), a sulphur analogue of TCDF, because mass profile provides accurate masses for the selected ions of this interesting interference.

The concentration levels of 2,3,7,8-TCDD in pancreas samples are listed in Table 1. 2,3,7,8-TCDD/F were found not only in muscle and pancreas samples collected from station 3 but also in pancreas samples from three other stations. The levels of 2,3,7,8-TCDD in pancreas tissues of the crabs from station 3 (up to 1 ppb) are elevated by a factor of 5 to 10 times those of samples from other stations. Even the muscle samples from animals taken from station 3 have detectable levels of 2,3,7,8-TCDD (less than 50 ppt) whereas those from other stations have "no detectable" levels of 2,3,7,8-TCDD (detection limit 0.5 to 1.0 ppt). Other selected 2,3,7,8-substituted PCDD/Fs were at lower levels (less than 100 ppt) or, for most samples, not detected.

The analytical results support the suggestion that the source of dioxin contamination in the system is a chemical manufacturing plant located on the Passaic River, approximately three kilometers upstream of Newark Bay (3).

Comparison of Pre-operational and Post-operational PCDD/F in Milk Samples Taken from Farms Located Near a New Resource Recovery Incinerator by HRGC/HRMS.

*Brian D. Eitzer and Mary Jane Incorvia Mattina, The Connecticut Agricultural Experiment Station, P. O. Box 1106, New Haven, CT 06504.

It has been well documented that polychlorinated dibenzo-p-dioxins and polychlorinated dibenzofurans (PCDD/F) are produced by the combustion of municipal solid waste (MSW) (1). These highly toxic compounds have been reported in cow's milk, with areas close to incineration sources showing higher concentration levels than more rural areas. It is therefore of interest to examine how the PCDD/F concentrations in cow's milk taken from the same set of farms located a short distance from a newly constructed resource recovery MSW incinerator change over time.

Samples of cow's milk were obtained once a week for three weeks from each of five farms located between two and eight miles from a newly constructed resource recovery incinerator. Two sets of samples were collected, one in November 1991, prior to incinerator start-up, the other in March of 1993, approximately one year after the incinerator went into operation. Portions of five of the pre-operational samples were initially examined by high resolution gas chromatography/high resolution mass spectrometry (HRGC/HRMS). The remainder were frozen at -4°C to be analyzed at the same time as the post-operational samples, reducing errors in the comparison of the sample sets from altered instrumental conditions.

Milk samples were analyzed as follows: 200 mL of raw milk was spiked with a set of 9 C 13 PCDD/F standards and extracted with 900 mL of 2:1 acetone:hexane in a large separatory funnel. The aqueous portion was washed twice with 200 mL of hexane. All hexane fractions were combined and the extracts were passed through sodium sulfate. The combined hexane fractions were reduced in volume to 75 mL, washed with 30 mL of distilled water and slurried for two hours with acid silica (40 g sulfuric acid/60 g neutral silica) The hexane solutions were then subjected to a semi-automated column chromatographic clean-up procedure described elsewhere (1) The extracts were analyzed by HRGC/HRMS on a Kratos Concept 1S. The GC was temperature programmed from 200°C to 330°C with selected ion monitoring of five groups of ten ions (two ions for each homolog) at a resolution of 10,000. Only the 2,3,7,8-substituted PCDD/F congeners were quantified.

The results are summarized in Table I which shows the average value and standard deviation for each of the three groups of data; pre-operational analyzed in 1991, pre-operational analyzed in 1993, and post-operational analyzed in 1993. As can be seen in the table the method is quite sensitive with detection limits at the fg/g concentration level. Although the standard deviations are on the high side, the data are quite acceptable given the ultra-trace levels reported. The results seem to indicate that the incinerator has not caused any significant increase in the concentrations of PCDD/F in the milk samples taken from these farms to date.

National Marine Fisheries Service, NOAA. 2725 Montlake Blvd. E., Seattle, WA 98112.
* Infometrix, Inc. 2200 Sixth Ave., Suite 833, Seattle, WA 98121

The *Exxon Valdez* ran aground on Bligh Reef in Alaska's Prince William Sound on March 24, 1989, and spilled ca. 11 million gallons of Prudhoe Bay crude oil. In a survey to determine if the spill had contaminated the fisheries resources used by the natives for subsistence, hundreds of samples of biota were taken from many harvesting locations inside and outside the Sound, and analyzed for aromatic compounds (U. Varanasi, D.W. Brown, T. Hom, D.G. Burrows, C.A. Wigren, L.J. Field, J.E Stein, K.L. Tilbury, J T. Landahl, B.B. McCain, and S-L. Chan. Survey of Alaskan Subsistence Fish, Marine Mammal, and Invertebrate Samples Collected 1989 - 1991 for Exposure to Oil Spilled from the *Exxon Valdez*., in preparation).

The purpose of this paper was to use the GC/MS-derived patterns of aromatic hydrocarbons (AHs) to evaluate the possible sources of the contaminants found in invertebrates and to compare patterns of AHs from different sampling areas. The chemometric tools of Hierarchical Cluster Analysis (HCA) and Principal Component Analysis (PCA) offer an objective approach to characterize the similarities and differences. The results from the PCA and HCA analyses were compared to manually classifying the samples into different groups based on visual analysis of their patterns.

The GC/MS ion peak areas were collected for each compound of interest and were normalized to focus on pattern differences and not concentration differences between samples. For visual comparisons, the pattern graphs were prepared by normalizing the compound peak areas to a particular C_2 phenanthrene that was present in all the samples. These ratios were then plotted as bar graphs with the same vertical scale. The pattern graphs for all the samples were visually divided into groups.

For HCA and PCA analysis, the peak areas normalized by using the sum of the areas of all the compounds measured in a sample, were analyzed using the Pirouette® data analysis software on a PC. HCA analysis divided the samples into groups (Figure 1) based on similarities in their compound profiles. PCA was used to calculate the factors (linear combinations of the compound ratios) which were responsible for the differences between the samples. The first three factors account for more than 80% of the variability between the samples. By plotting these factors on a 3-D scatter graph (Figure 2) it is possible to view the groupings of and linear distances between sample points. Simultaneous examination of the HCA and PCA results helped to achieve an optimal division of samples into groups.

Another result of PCA is a measure of the contribution of each compound to the PCA factors. It is possible to correlate certain sample groups with groups of compounds based on the compound contributions to the PCA scores. For example, the Windy Bay samples (**A**) are distinguishable from other sample groups based on the C_3-dibenzothiophenes, C_3-phenanthrenes/anthracenes and C_1-benzanthracenes/chrysenes (C_1-BAA/CHR), while the oil and fuel samples (group **G**) are distinguishable by the higher peak ratios of C_1-, C_2- and C_3-naphthalenes (recognizing that such comparisons may not include factors such as exposure, metabolic processes, depuration, etc.). The group **E** samples are distinguishable by higher peak ratios of parent PAHs, C_1-fluoranthenes/pyrenes and C_1-BAA/CHR, indicative of combustion products.

The visual analysis of the pattern graphs shows that the *Exxon Valdez* crude oil (EVCO) is characterized by high ratios of alkyl naphthalenes relative to the reference C_2-phenanthrene, and moderate ratios of alkyl dibenzothiophenes, alkyl phenanthrenes, some high molecular weight aromatic compounds (HACs), and low ratios of anthracene. The patterns of the samples from the Kodiak sites and the Old Harbor site (**J**) are a similar to the pattern of weathered EVCO with some parent HACs superimposed on it. The patterns of two samples (**E1-2**) from Tatitlek did not show signs of oil contamination probably because the spilled EVCO flowed away from this area. However, these patterns are similar to that of the urban sediment from Puget Sound (**E3**) which had higher peak ratios of parent AHs relative to alkyl substituted components (typical of combustion products). The Chenega Bay 7 (**E4-5**) site sample patterns show similar high peak ratios of parent hydrocarbons with some oil contamination. The Windy Bay site sample patterns (**A**) resemble that of weathered EVCO, but with some increased HAC ratios. The patterns of the less volatile alkyl phenanthrenes and dibenzothiophenes are similar to those patterns in weathered EVCO from

Snug Harbor 15 months after the spill; however, the patterns of ACs in Windy Bay mussels appear even more weathered, possibly resulting from many variables such as weathering, exposure, depuration, etc.

The visual analysis divided the samples into more groups than PCA and HCA, but there are only a few major differences between the two methods that couldn't be explained by moving the group separation line further down the cluster analysis dendrogram. The HCA-PCA analysis is much faster than visual analysis, gives quantifiable separations and can be easily reapplied to some subset of the data set (i.e., using fewer compounds or only certain compound groups).

GC Inlet Modifications Improving the Analysis of Aromatic Hydrocarbon Metabolites in Fish Bile

Jennie L. Bolton, *Douglas G. Burrows,
Marc Nishimoto, Donald W. Brown

Environmental Conservation Division, Northwest Fisheries Science Center,
National Marine Fisheries Service, NOAA, Seattle, WA 98112

Introduction

Derivatization is often necessary when analyzing polar compounds by GC/MS to insure good chromatographic behavior.[1,2] Studies of metabolites of polycyclic aromatic hydrocarbons (PAHs) from the ß-glucuronidase-hydrolyzed bile of fish exposed to individual PAHs[5], and to extracts of contaminated marine sediments or other complex mixtures[3,4], have shown that many of these polar metabolites could only be analyzed as derivatives. In fish species, for example, the primary metabolite of phenanthrene was shown to be a dihydrodiol[5], however, due to dehydration of this dihydrodiol in the GC inlet, only a mixture of hydroxyphenanthrenes was seen in underivatized samples. We present improvements in GC inlet parameters enabling the direct analysis of a wide range of polar metabolites without prior sample derivatization.

Experimental

Hydrolyzed bile of English sole which had been exposed to a sediment extract from a site highly contaminated by PAHs, was analyzed in full scan mode. Metabolites were identified, and a selected ion monitoring (SIM) method was devised to quantitate compounds of interest. The effects of GC insert material and diameter, insert deactivation, and injector temperature were evaluated in SIM mode. Peak shape and arene-dihydrodiol decomposition were monitored, and relative standard deviations of analyte responses were analyzed for several inlet configurations.

Results and Discussion

Tailing of arenols and breakdown of dihydrodiols was lessened by decreasing the injector temperature from 300°C to 250°C. Use of a 4 mm i.d Vycor® insert, instead of 2 mm i.d. Pyrex® glass, allowed larger injections with improved column loading. When the Vycor® insert and its fused silica wool plug were carefully silanized[6] and kept from air and moisture until placed in the heated block of the GC injector, % RSDs of analyte responses, calculated against an internal standard, were further reduced. In addition, metabolites of 5-ring PAHs were identified,

which was not possible in previous studies without sample derivatization, due to the extreme tailing exhibited by these compounds when GC conditions were not optimized.

Conclusion

GC injector temperature, injection volume, insert diameter and inlet deactivation are variables affecting the analysis of polar compounds such as arenols. When these GC inlet parameters are optimized, many metabolites which previously could only be detected as various derivatives can now be directly, reproducibly quantified in hydrolyzed bile extracts.

COMPREHENSIVE ANALYSIS OF MISSISSIPPI RIVER SAMPLES BY GAS CHROMATOGRAPHY/POSITIVE CHEMICAL IONIZATION/ TANDEM MASS SPECTROMETRY AND GAS CHROMATOGRAPHY/ NEGATIVE CHEMICAL IONIZATION/MASS SPECTROMETRY

Colleen E. Rostad and Thomas J. Leiker
U.S. Geological Survey
5293 Ward Road, Mail Stop 408
Arvada, Colorado 80002

Anthropogenic organic compounds in water and suspended sediment phases were identified by mass spectrometry and used as a basis for characterizing the transport and fate of these organic contaminants in a large river system. The samples included suspended sediment and water from sixteen sites on the Mississippi River and some of its major tributaries from above St. Louis, Missouri, to below New Orleans, Louisiana. In addition to the typical GC/electron impact/MS analysis, extracts of the complex sample matrices were analyzed for selected herbicides by gas chromatography/positive chemical ionization/tandem mass spectrometry (GC/PCI/MS/MS) and for halogenated compounds by GC/negative chemical ionization/mass spectrometry (GC/NCI/MS).

Organic compounds present in the aqueous and sediment phases were initially identified by GC/electron impact/MS analysis. The aqueous phase contained some very water-soluble organic compounds which were unique to particular tributaries. The Illinois River uniquely contained tris(2-chloroethyl)phosphate, and three isomers of tris(chloropropyl)phosphate. The Ohio River uniquely contained trimethyltriazinetrione.

A technique was developed to rapidly analyze and quantitate in 20 minutes these specific compounds in the sample extracts by GC/isobutane-PCI/MS/MS. An automatic sampler was used to inject samples continuously to increase efficiency and reproducibility. Terbuthylazine was used as the internal standard. These tributary-specific compounds were found in all samples taken from the tributary, and downstream in the Mississippi River from the source tributary, but not in samples from upstream. Analysis of water samples taken from 15 verticals evenly-spaced across the Mississippi River at sites below tributary confluences indicated that the distributions across the river, of these very water-soluble compounds, were not uniform.

The sample extracts were then reanalyzed for halogenated organic compounds by GC/methane-NCI/MS. Compounds identified to be associated with the sediment included PCBs, chlordane, nonachlor, DCPA (dacthal), pentachlorobenzene, hexachlorobenzene, and trifluralin, among others. Decaflurobiphenyl and 4,4-dibromooctafluorobiphenyl were used for internal standards. Because of their low water solubility and high partition coefficients, few of these compounds were identified in the aqueous phase.

The specificity of the NCI analysis minimized the need for extensive sample cleanup. However, the complex, concentrated sample extracts still entered the ion source, contaminating the ion volume and significantly reducing the life of the filament. NCI requires colder source temperatures, so the ion volume had to be changed often to maintain sensitivity. The removable ion volumes enable quick replacement with very little retuning required. The linear range of the electron multiplier (EM) was less for NCI than for electron impact (EI), because the number of ion counts resulting in EM saturation was much less for NCI than for EI. Whether this was a fault of the conversion dynode electron multiplier is unknown. The EM was changed twice during this study, and the limited range of the EM occurred with new EMs also. Because of the specific response of NCI, the NCI data files required less disk space than EI data files from the same sample. Hence, more samples could be analyzed before the data system disk space approached capacity and required immediate quantitative and archival processing.

The aqueous and sediment extracts were then reanalyzed by GC/isobutane-PCI/MS/MS for water-soluble herbicides. These herbicides included atrazine, simazine, alachlor, metolachlor, and some of their degradation products. Terbuthylazine was used as the internal standard. The analysis took only 12 minutes per sample because the GC was temperature-ramped as rapidly as possible (20 degrees per minute) and simultaneous parent/daughter ion pairs were used. The hydrophilic herbicides were detected in both the water and the suspended sediment phase, which enabled calculation of their sediment-water partition coefficients. Detection of these compounds in the suspended sediment phase in very complex sample extracts required extreme specificity and sensitivity, which was provided by the GC/isobutane-PCI/MS/MS technique. These agricultural herbicides are widely used in the Mississippi River Basin on various crops.

Between each type of analysis, the ion volume was changed, reagent gas stabilized, and the system retuned, while the GC column parameters remained unchanged. The turbomolecular pumps handled the high manifold pressure, resulting from the reagent gas required for chemical ionization and the collision gas required for collision activated decomposition, very well for extensive periods of time. Dual terminal access to the data system, even during complex computer-controlled acquisitions, optimized the efficiency of data processing.

Given a maximum number of samples and minimum time frame, the versatility of the mass spectrometer provided extensive quantitative information on a variety of compound classes. Compounds unique to each river were identified and the data served as a basis for studying the mixing of contaminants at the confluences of the major rivers. The information obtained from the non-standard mass spectrometric techniques provided a technical base for assessing the contaminant transport and fate in the Mississippi River and its tributaries.

ALKYLBIS(TRIFLUOROMETHYL)PHOSPHINE SULPHIDE HOMOLOGUES AS MULTI-DETECTION RETENTION STANDARD IN GC/MS AND GC/MS/MS

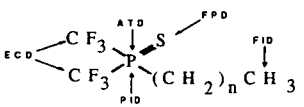
Antti Hesso [1,2], Jarkko Tornaeus [1], Heikki Björk [2]
1) Institute of Occupational Health, Topeliuksenkatu 41 aA, SF-00250 Helsinki, Finland
2) University of Helsinki, Dept. of Organic Chemistry, Vuorikatu 20, SF-00100 Helsinki, Finland

INTRODUCTION

The use of relative retention times or retention indices in GC/MS offers an independent identification method by which the reliability of the analyte identification can be improved in complex environmental samples.

METHODS

Alkylbis(trifluoromethyl)phosphine sulphides ($M_3...M_{20}$) meet the demands for good gas chromatographic behaviour and the demand of multidetector detectability in gas chromatography [Scheme 1].



SCHEME 1. M-sesie and sites of interaction with GC-detectors

The chemical structure of alkyl bis(trifluoromethyl)phosphinesulphides (n=3-20) forms homologue serie and possesses functional groups suitable for use flame ionization detection (FID), electron capture detection (ECD), alkaline thermoionization detection (ATD) [N,P], photoionization detection (PID) and flame photometric detection (FPD)[P,S]. The standard solution (2.5 10^{-4}M) including even number homologuos (M3, M4-M20) was obtained from HNU-Nordion, Helsinki, Finland.
GC-MS analysis were performed by VG Autospec Q instrument (VG Analytical, Manchester UK.) interfaced with HP 5890 Series II gas chromatograph. The used fused silica capillary columns were NB-54 and NB-1701 (HNU-Nordion, Helsinki, Finland).

RESULTS

The mass spectrometric behaviour of alkyl bis(trifluoromethyl)phosphine sulphides (M-serie) were characterized by EI, HR-EI, PCI, NCI and by low energy tandem mass spectrometry.
The positive ion chemical ionization shows effective protonation by isobutane and methane (FIG 1. resp. FIG 3.). The formation of $[MH-102]^+$ -ions is significant under CI/CH_4 conditions for all members of the serie.The proton affinity of alkyl bis(trifluoromethyl) phosphine sulphides seems to be too low for effective protonation by ammonia.
M-serie shows excellent sensitivity by NCI (CH_4, NH_3), spectra are shown in FIG 2. resp. FIG 4. The characteristic ions are $[201]^-$, $[101]^-$ and $[M-69]^-$.
Under electron ionization conditions extensive formation of compound and group specific ions are characteristic. Ions at m/z 273^+ and m/z 241^+ are compoud specific for M_{10} corresponding loss of [M-69] and [M-101] respectively from molecular ion . Ions at m/z 147^+, $[C_2H_3F_3PS]$, m/z 202^+ $[C_2F_6PS]$ and m/z 229^+ $[C_4H_5F_6PS]$ are group specific ions for whole M-serie (FIG. 5).
The group specific ion at m/z 201^- formed under NCI conditions fragments extensively under low energy MS/MS analysis giving ion at m/z 132^-.

CONCLUSIONS

according the results, the behaviour of alkylbis(trifluoromethyl)phosphine sulphides under electron ionization and under positive and negative chemical ionization fulfill the characteristics of good retention marker compounds in GC/MS and GC/MS/MS analysis of complex environmental samples. Under ammonia positive ion chemical ionization conditions M-serie will not protonate, but by using pulsed PICI/NICI techniques and combining the retention information from NICI with the environmentally sensitive method of PICI, the full sensitivity of retention markers can br gained.

IDENTIFICATION AND QUANTIFICATION OF 2,4,6-TRIBROMOANILINE IN THE COLOR ADDITIVE D&C RED No. 22 (EOSIN Y) BY GC/MS

Adrian Weisz[a] and Denis Andrzejewski[b]

[a]Office of Cosmetics and Colors and [b]Office of Scientific Analysis and Support, U.S. Food and Drug Administration, Washington, D.C. 20204

INTRODUCTION: D&C Red No. 21 (R21, mainly 2',4',5',7'-tetrabromofluorescein, **1**) and its disodium salt, D&C Red No. 22 (R22, Colour Index No. 45380, **2**), are U.S.-certified color additives listed for use in drugs and cosmetics. (R22 has an additional important use as a biological stain, under the name Eosin Y). They are batch certified by the U.S. Food and Drug Administration (FDA) to ensure compliance with specifications described in the Code of Federal Regulations (CFR) [1]. These color additives are synthetically prepared by the bromination of fluorescein. GC/MS analyses of several extracts of D&C Red No. 22 revealed the presence of 2,4,6-tribromoaniline (TBA). Because current regulations for D&C Red No. 22 do not specify a limit for TBA, it was of interest to determine the extent and level of contamination of certified lots of the color.

EXPERIMENTAL: **Identification:** Each test portion (45-61 g) was Soxhlet-extracted with chloroform for approximately 50 h. The solvent was eliminated by rotary evaporation. The residue was redissolved in 1 ml chloroform and 0.5 μl was injected into a Hewlett-Packard 5890 gas chromatograph, which was interfaced with an HP-5971 mass selective detector. Full scan data were acquired. The GC was equipped with a Supelcowax 10 fused silica capillary column, 30 m x 0.25 mm ID and 0.25 μm film thickness. The column temperature was increased from 40 to 100°C at 15°C/min. and from 100 to 250°C at 10°C/min. The total ion chromatogram of an extract of a test portion from sample 4 (Table 1) is shown in Fig. 1.

Quantification: GC/MS quantification of TBA was performed on a 9610 Finnigan Mat gas chromatograph interfaced to a 4023 Finnigan Mat quadrupole mass spectrometer (MS) with an Incos 2300 data system. Electron ionization data were obtained at 70 eV electron energy and 0.25 mA emission current at a source temperature of 240°C. The MS was operated in the selected ion monitoring (SIM) mode. The GC was equipped with a SPB-5 fused silica capillary column, 30 m x 0.25 mm I.D. and 0.25 μm film thickness. GC parameters were: injection port temperature 220°C; transfer line temperature 250°C; initial temperature 40°C (1 min.) ramp to 80°C and increase to 250°C at 10°C/min. Helium was the carrier gas at a linear velocity of 35 cm/sec. TBA was quantified by measuring the ion area ratios of m/z 329 for TBA and m/z 357 for the N,N-dimethyl-TBA that was co-injected as the internal standard. TBA was quantified using a six-point calibration curve based on analyses of standard solutions that contained internal standard and 1, 10, 25, 50, 100 and 200 ng/μl TBA. The instrument response was linear over this range (Fig. 2).

RESULTS AND DISCUSSION: Samples from 22 certified lots of commercial D&C Red Nos. 21 and 22 were analyzed for TBA. These lots represent (5) domestic and (1) foreign manufacturers that requested certification for these color additives in the past 3 years. The study includes a lot of D&C Red No. 21 (sample 1, Table 1) used in the animal feeding studies upon which FDA based its safety evaluation. Recovery of TBA from fortified samples was quantitative. Eight samples (36.4%) have been found to contain TBA (range 0.6-14 ppm, as shown in Table 1). Specifically, all the batches submitted by manufacturer A were found to contain TBA while all those submitted by manufacturer D did not contain TBA.

CONCLUSION: These findings suggest that the presence of 2,4,6-tribromoaniline as an impurity in D&C Red No. 22 may be avoided through modification of the manufacturing process.

The Photolytic Degradation of Pentachlorophenol in Organic Solvents

Michael T. Walsh and Leonard L. Ingram, Jr.
Mississippi Forest Products Laboratory
Mississippi State, MS 39762

Pentachlorophenol (PCP) is widely used as a wood preservative for the treatment of utility poles, fence posts, lumber and structural wood components of buildings that may be in ground contact. Recent statistics show that in one year 21.6 million pounds of PCP and 29 million gallons of petroleum solvents were used in the wood treating industry.[1] Two major routes of transformation of PCP in the environment are microbial and photolytic degradation. Previous research has been done on the photodegradation rate and photoproducts of PCP in water under different conditions and of PCP in hexane at 254 nm.[2,3,4] Our objectives were to study the rate of photolysis of PCP in different organic solvents at a wavelength simulating sunlight and to identify the products formed.

A 125-Watt medium pressure mercury lamp located in a double-walled immersion well was used to photolyze 100 ppm PCP solutions in selected solvents. The 313 nm line of the lamp was isolated by circulating a solution of potassium chromate and sodium carbonate between the lamp and the samples.[5] A Tracor 560 gas chromatograph was used to determine the amount of PCP remaining in each sample. Identification of photoproducts was accomplished with a Kratos MS80RFA GC/MS system with a J&W DB-5 capillary column (0.625 mm by 30 m).

Pseudo first-order reaction rates were calculated as the slope of the line from the plot of $\ln(C_t/C_0 x100)$ versus photolysis time; where C_t is the concentration of the sample at time t and C_0 is the initial concentration. Figure 1 illustrates the reaction rate for PCP in hexane, cyclohexane, cyclohexene and benzene. The photodegradation rate of PCP in hexane was 4.5 times faster than that of PCP in benzene. The 2,3,4,5- isomer of tetrachlorophenol was the major product formed under these test conditions. Solvent addition products were found in all solvents. Figure 2 shows mass spectra of solvent addition products found in a) hexane and b) benzene. No products were found where two solvent molecules dimerized. The photolysis of PCP in 100% hexane also produced the 3,4,5- isomer of trichlorophenol.

Results from this study showed that the rate of photolysis of PCP was affected by the surrounding medium. Organic solvents tested did not affect the preference for hydrogen substitution on the tetrachlorophenol radical. PCP in the organic solvents tested followed reductive dechlorination at 313 nm with a loss of chlorine from the <u>ortho</u>- position. The major photoproducts under these conditions were 2,3,4,5-tetrachlorophenol, 3,4,5-trichlorophenol and solvent addition products. The pseudo first-order rate constants indicated the presence of different solvents affected the rate of photolysis.

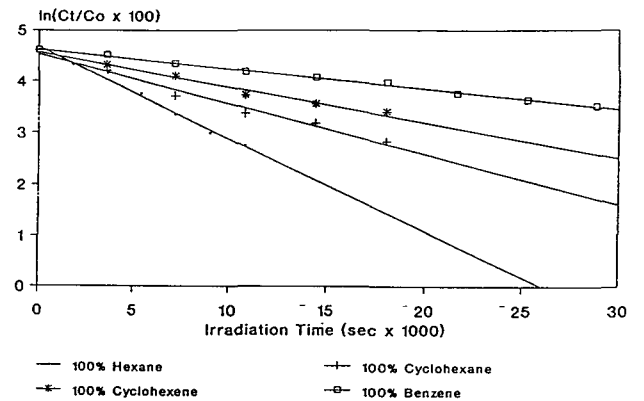

Figure 1 First-order plots for the photodegradation of PCP (100 ppm) in selected solvents

A Sample/Calibration "Pipeline" for the Analysis of Hazardous Cylinder Gases

Jeremiah D. Hogan
Texas Instruments Inc., Dallas, TX

The need to analyze a wide variety of hazardous gas cylinders with an equally large variety of analytical instruments presents a formidable challenge. Analysis of gases such as WF_6, HBr, HCl, HF, NF_3, BCl_3, NH_3, BF_3, and other such hazardous and/or corrosive species causes several immediate problems in the area of sampling. Safety guidelines dictate that these gas cylinders be isolated in high-airflow gas cabinets, which further complicates the sampling process. It is also inadvisable to incorporate lengthy runs of tubing, or a large number of fittings in order to connect each of these cabinets to an analytical instrument.

Development of a novel tubing/valving arrangement has led to the construction of a tubing "pipeline" which enables any of eight analytical workstations to access each of six gas cabinets with a minimal risk of cross-contamination, and with a minimum amount of tubing and fittings. The six gas cabinets are interconnected such that they form three "loops", with two cabinets on each loop. These loops are arranged such that the gases for which these cabinets are designated are interconnected with cabinets containing gases which present a minimized risk, should cross-contamination occur. For example, the HCl cabinet is connected to the HBr cabinet, not to the NH_3 cabinet, and so forth. This network also provides purging of each sample line with inert house-gas when the line is not in use. Each loop is accessible via a manifold located adjacent to the analytical instruments in the lab. Figure 1 is a schematic representation of the one of the loops in the pipeline network, all of which are similar.

There is an additional loop which is designated as a calibration loop. This loop is not tied to any of the cabinets, but provides custom blended calibration gases to each instrument through the same manifolding system as the sample loops. Calibration gas is supplied to this loop from a custom-made gas blending unit which is capable of multiple dilutions of a premixed standard calibration gas used for calibrating the analytical instrumentation.

All four loops were manufactured from electropolished stainless steel tubing, and all joints were orbitally welded to insure integrity and to maintain cleanliness. All valves are ultraclean and contain all-metal seals to prevent valve damaged due to exposure to corrosive gases.

Figure 2 depicts the time required to fill a loop with sample gas, and then to purge the sample from that loop completely, after the analysis is completed. Overall cycle times of less than three minutes are routinely achieved using this system

MICROVOLUME GAS ANALYSIS

Julius Perel, Stephen A. Ruatta and John F. Mahoney
Phrasor Scientific, Inc. 1536 Highland Ave, Duarte, CA 91010

The presence of moisture or gases in a sealed atmosphere can be an important factor in the premature failure of semiconductor and other devices[1,2]. Determining the concentration of moisture in the ambient atmosphere of a package volume is complex. Compared to most gases, water has a relatively low vapor pressure which makes extracting it out of a package and into an analyzer challenging. It is well known that measuring the concentration of any compound requires reference materials be available during analyses. Standards covering a range of concentrations have been used for the calibration of samples. Ideally, the standards should be as similar to the sample as possible. In the case of semiconductor package analysis, the internal volume, internal pressure and temperature should be matched and the standard be readily available for both interlab comparisons and blind standards.

A system for the mass spectrometric analysis of the gaseous components contained within a small volume package has been constructed and tested. The key features of the interface between the package and the mass spectrometer is shown schematically in figure 1. This design minimizes the surface area exposed to the analyte water vapor thus reducing adsorption and outgassing effects that could lead to systematic errors. The system exposes a very small surface area to the water containing gas, thus minimizing contamination and loss of analyte water.

As illustrated schematically in figure 1, puncturing of a package releases the gas into about a $0.05cm^3$ volume connected to a fused silica transfer line. This transfer line (40μmID) utilizes viscous (laminar) flow to reduce contact of the analyte vapors with the walls of the tubing as it flows into the Millipore/Extrel Questor III quadrupole mass spectrometer source. The gas is then ionized by electron bombardment and the resulting ions up to 200 Daltons(amu) mass analyzed and detected by a Faraday cup and/or an electron multiplier. Data is collected automatically by a computer which also controls the mass spectrometer operation.

Gas flow in a tube can be characterized as one of two basically different types. At low pressures where few molecules are present, the mean free path between gas molecules is long compared with the dimension of its container. In this molecular flow regime, there are many interactions between a gas species and the container walls as shown in figure 2a. As the pressure increases, the mean free path decreases, eventually becoming less than the distance to the walls of the tubing through which it is flowing. When the mean free path is much less than this distance, the character of the gas flow is determined mainly by gas-gas interactions while gas-wall interactions occur relatively infrequently. This viscous flow regime is shown schematically in figure 2b.

A major problem in the analysis of moisture inside of semiconductor packages is the lack of standards used in calibration. While samples are available for certification purposes, it would be ideal for laboratories to have a standard that could be utilized daily. One possibility which we have begun to investigate is to utilize saturated salt solutions to generate known moisture levels in air or nitrogen inside of small metal and/or Teflon packages. The use of saturated salt solutions to provide constant humidity gases is not new and has been used commercially as secondary standards for calibrating solid state hygrometers in the field. Adapting the idea to the production of a useful calibration tool requires that the design look as much as possible like the package under test. A schematic diagram of a reference device is shown in figure 3. This device is based on a stainless steel Whitey valve, with the addition of a glass salt solution holder and a stainless steel or aluminum reference volume. When the valve is in the open position, the vapor above the solution can easily equilibrate throughout the valve and the gas chamber. This results in all the surfaces being wetted so as to be in equilibrium with the moisture containing gas. Just prior to sampling, the valve is closed, isolating the gas chamber from the salt solution, without moving the solution containing bulb. Using this technique, we have generated concentrations of moisture ranging from 1590 ppmV to 18300 ppmV to compare with results using a two pressure humidity generator and measurements of the humidity in the calibration flow with a solid state sensor.

INTRODUCTION:

Fusarium moniliforme Sheldon, which occurs worldwide on grains, is a common contaminant of corn. Fumonisins B_1 and B_2, which are mycotoxins produced by *F. moniliforme*, have been shown to promote cancer in rats. Isolates of *F. moniliforme* from corn have been shown to produce higher concentrations of fumonisins B_1 and B_2 than similar isolates from other substrates.

We grew cultures of a toxigenic strain of *F. moniliforme* on five different substrates (corn, unmilled rice, rodent feed, peanuts, and soybeans) and analyzed them for fumonisins by FAB MS as well as FAB MS/MS and quantitated by gradient HPLC. Corn was used as a positive control for determining if proper conditions were used for fumonisin production. Rodent feed cultures were of particular interest since the National Center for Toxicological Research (NCTR) maintains a rodent colony for research purposes and any toxin in the feed could affect research results.

This study was to determine if FAB MS and FAB MS/MS analysis could be utilized for the determination of both fumonisins B_1 and B_2 in culture extracts. The fumonisins were quantitated by a modified gradient elution HPLC method with fluorescence detection after derivatization with fluorescamine.

EXPERIMENTAL:

FAB MS Analysis. The FAB MS system consisted of a Finnigan MAT TSQ 70 triple quadrupole mass spectrometer, equipped with a Finnigan fast atom bombardment (FAB) source and an Ion Tech fast atom gun. Xenon was utilized in the primary atom beam at energies of 8 to 10 KeV and thioglycerol was used as the matrix. Typically, the matrix was applied to the FAB probe tip followed by 1 μL of the sample. The mass spectrometer was scanned from m/z 200 to m/z 800 at 1 scan/sec.

FAB MS/MS Analysis. The FAB MS/MS analyses were performed under the same conditions as FAB MS, except that the collision gas, argon, was set to about 0.5 mtorr and the collision energy was either 30 or 50 eV. To obtain daughter ion spectra, MS1 (Q1) was set to pass the selected parent ion and MS2 (Q3) was operated under full scanning conditions.

HPLC Analysis. The gradient HPLC system consisted of two Shimadzu model LC-600 pumps (Shimadzu Scientific Instruments, Columbia, MD), a Shimadzu model SIL-9A autoinjector, a Shimadzu model C-R3A integrator, a Waters model 470 fluorescence detector (Waters Chromatography Division), and a Microsorb C_8 column (25 cm x 4.6 mm i.d., 5 μm particle size, Rainin Instrument Co., Woburn, MA).

RESULTS AND DISCUSSION

As expected, the corn cultures produced the highest concentration of fumonisins B_1 and B_2. Significant levels of fumonisins B_1 and B_2 were also observed in the unmilled rice culture extract.

The mass spectra obtained for the FAB MS analyses of the unmilled rice and corn culture extracts showed $[M+H]^+$ ions at m/z 722 and m/z 706 for fumonisins B_1 and B_2, respectively. Additional peaks can be attributed to the K adduct ions; peaks at m/z 760 and m/z 744 correspond to the $[M+K]^+$ ions for fumonisins B_1 and B_2, respectively.

FAB MS/MS analysis was performed on the fumonisins B_1 and B_2 standards as well as the culture extracts. Figure 1 shows the collisionally activated dissociation (CAD) of the $[M+H]^+$ ions for fumonisin B_2 for the standard and the corn culture extract, confirming the presence of fumonisin B_2 in the extract.

FAB MS together with FAB MS/MS was found to be a sensitive technique for the detection of both fumonisin B_1 and B_2 in culture extracts. Also, a modification of an existing HPLC procedure using fluorescence detection after derivatization with fluorescamine has resulted in a sensitive method for quantitating the fumonisins.

The Use of Internal Standards to Improve Linearity and Reproducibility in the Thermospray LC/MS Analysis of Chlorinated Phenoxyacetic Herbicides

*Jeffery S. Hollis, The Hewlett Packard Company, Cincinnati, OH 45242
Alexander B Schilling, The Hewlett Packard Company, Naperville, IL 60566

Introduction.

The EPA Method 8321A recommends the use of thermospray (TS) LC/MS for the identification and quantification of chlorinated phenoxyacid herbicides. Earlier work[1] had examined the use of negative ion TS LC/MS in SIM mode to quantify a series of these herbicides Although good sensitivity and linearity were observed, during the use of thermospray one can observe small source pressure fluctuations under normal operating conditions that can be sources of non-linearity and affect reproducibility This could be a problem using an external standard based assay The use of internal standards might help to compensate for these fluctuations and improve the reproducibility and linearity over the calibration range. Ideally, internal standards should be stable isotope labeled analogs of the compounds being analyzed However since stable isotope labeled standards are not always readily available, structurally similar analogs may be employed One requirement of any internal standard in an LC/MS assay is that it ionize under the conditions employed A variety of alkyl esters of the chlorinated phenoxyacid herbicides are readily available but yielded poor sensitivity under the discharge negative ion conditions employed in this study Dinoseb (2,4-Dinitro-6-sec-butylphenol) is included in the 8321A method and yields the largest response in negative ion mode for the compounds studied previously. This is presumably due to electron capture facilitated by the nitro-functional groups Thus compounds possessing nitro functional groups may be suitable as internal standards for this assay

Experimental

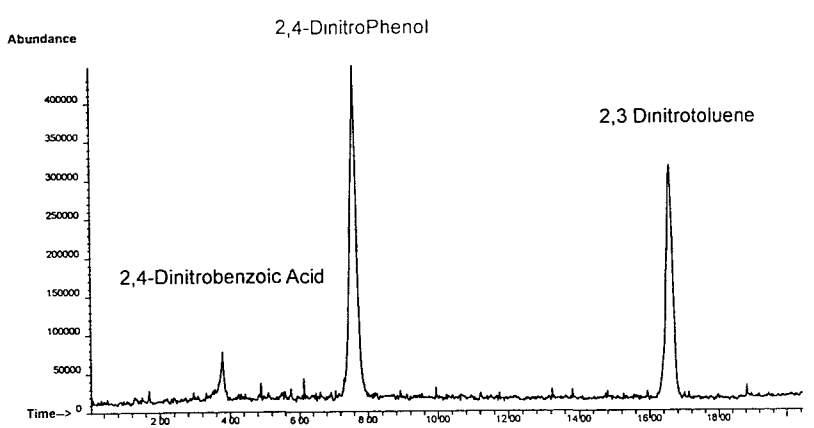
A series of nitro-functionalized phenols, benzenes, toluenes and phenylacetic acids were analyzed using TS/LC/MS using the method protocol. A HP 5989A LC/MS/DS with a thermospray interface and a HP 1090L HPLC with a diode array detector were used to chromatograph the compounds Negative ion mode employing discharge ionization was used in all cases Chromatography was performed on a Zorbax Rx 4 6 x 250 mm column using a solvent system as follows Solvent A 0 1 M NH_4Ac pH 4 5, Solvent B. 0 1 M NH_4Ac in methanol, with gradient elution starting (%A %B) 50.50, hold 2 minutes then to 40.60 at 12 minutes, then to 10 90 at 20 minutes, hold to 25 minutes, then to 50.50 at 30 minutes. The column was at ambient temperature. SIM acquisition was used, monitoring the most intense ion for each compound The internal standards were added at 50 ng each on column. A series of six calibration levels were run with a 3 uL injection volume All samples were made up in acetonitrile

[1]Hollis and Schilling, 40th ASMS Conf on Mass Spec and Allied Topics, 1992, 1699-1700.

Results and Discussion.

Several mono and dinitro-functionalized analogs of Dinoseb and the chlorinated phenoxy acids were examined for suitability as internal standards Amongst these only the dinitro-phenols and toluenes were found to have both a good response and useful retention times with the current chromatographic system These compounds presumably ionize in discharge negative ion mode in a manner analogous to the chlorophenoxy herbicides By using the internal standard based assay an improvement in the reproducibility over the calibration range (3 0 ng-400 ng on column) of the assay was observed There is a possibility that typical hazardous waste samples being examined for herbicide residues may contain one or more of the internal standards as an unexpected but likely trace contaminant Nitrophenols and nitrotoluenes are listed on several EPA RCRA/CERCLA lists as target analytes. Therefore the use of labeled analogs of these compounds, which are commercially available and would yield similar results are recommeded.

LC/MS Chromatogram Of Three Selected Internal Standard Candidates



LIQUID CHROMATOGRAPHY/PLASMASPRAY MASS SPECTROMETRY FOR CHARACTERIZATION OF A COMMERCIAL CHLORINATED *n*-PARAFFIN MIXTURE.

G.T.Tomy [a,b], D.C.G.Muir[a], J.B.Westmore[b] and G.A.Stern[a].
[a]Fisheries and Oceans, Winnipeg, MB. R3T-2N6, Canada.
[b]Department of Chemistry, University of Manitoba, Winnipeg, MB. R3T-2N2, Canada.

Introduction. Chlorinated *n*-paraffins (CPs) are used as fire retardants, plasticizers in PVC, adhesives, and as extreme pressure additives in lubricants and cutting oils. They have also found use as replacement chemicals for more toxic and persistent chemicals such as PCB's.

Currently there is limited information on the fate and impact of CPs in the environment, and this is due, in part, to the complexity of CP mixtures and also to the difficulties in measuring low levels.

This report describes preliminary results on the application of liquid chromatography-negative ion plasmaspray ionization (NPI) mass spectrometry to the qualitative determination of a commercial *n*-paraffin mixture.

Mass Spectrometry. A Trio 1000 (VG/Fisons Analytical Ltd.) quadrupole mass spectrometer equipped with a thermospray/plasmaspray interface was used. Ionization was achieved using the plasmaspray interface. Mass spectra were recorded in the negative ion mode with a plasmaspray current of 150μA, a source temperature of 200°C, a nozzle temperature of 170°C, a repeller voltage of 225V and an ion source pressure of 1×10^{-4} mbar. The mass spectrum was scanned from 350 to 650 daltons.

Chromatography. HPLC separations were performed on a Waters Novapak™ 150mm × 3.9mm C_{18} column with 3μm packings at a temperature of 30°C. A gradient elution using tetrahydrofuran (A) and water (B) was used. The initial condition 50%A : 50%B was held for 3 minutes, ramped linearly to 51%A : 49%B over 5 minutes, held there for 15 minutes, and then ramped linearly to 52%A : 48%B over 5 minutes, and held 15 minutes. A constant flow rate of 0.75mL/min was used throughout the gradient.

Results and Discussion. Chloroparaffin huls 70C (CP huls 70C) is a mixture of isomers and congeners with C_{10} to C_{13} chain lengths and chlorine content of 70% by weight. The total ion chromatogram of CP huls 70C separated with the reverse phase column is shown in Figure 1. The broad hill-like shape of the chromatogram is due to the large number of congeners and isomers present in the mixture. Congeners and isomers present in low concentrations cause the rise in the baseline, while congeners and isomers present in higher concentrations give rise to the peaks[1].

The mass spectrum of signal* is shown in Figure 2. The highest mass ion cluster starts at m/z 510, and corresponds to ten chlorine atoms, indicating the molecular formula $C_{12}H_{16}Cl_{10}^{-\cdot}$. The odd-mass peaks in this cluster correspond to loss of a hydrogen atom from the molecular ion. The ion clusters around m/z 496, m/z 476 and m/z 462 correspond to the molecular ions $C_{11}H_{14}Cl_{10}^{-}$, $C_{12}H_{17}Cl_{9}^{-}$ and $C_{11}H_{15}Cl_{9}^{-\cdot}$ respectively. Upon each of these ions is superimposed, at odd-mass, the cluster corresponding to a loss of a hydrogen atom from the molecular ion.

The two isotopic patterns of low abundance are probably fragment ion clusters. The ion cluster starting at m/z 440 corresponds to the formula $C_{12}H_{16}Cl_{8}^{-}$ and could be derived by a loss of Cl_2 from the molecular ion $C_{12}H_{16}Cl_{10}^{-\cdot}$. The ion cluster starting at m/z 441 corresponds to the formula $C_{12}H_{17}Cl_{8}^{-}$ and is derived from dechlorination of the molecular ion $C_{12}H_{17}Cl_{9}^{-\cdot}$.

The isotopic pattern starting at m/z 426 corresponds to eight chlorine atoms and can only be derived from dehydrochlorination of the molecular ion $C_{11}H_{15}Cl_{9}^{-\cdot}$. The ion cluster starting at m/z 425 corresponds to the molecular formula $C_{11}H_{13}Cl_{8}^{-}$ and is derived from dechlorination of the molecular ion $C_{11}H_{13}Cl_{9}^{-}$.

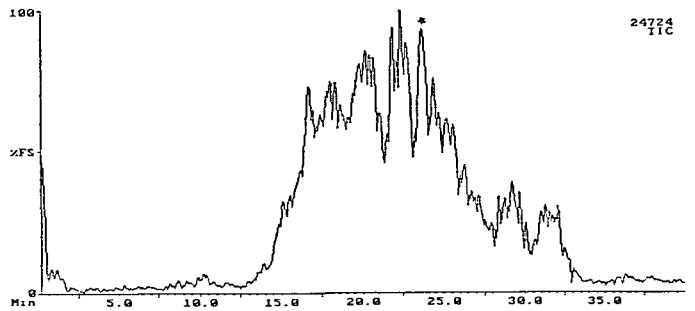


Figure 1. NPI-LC/MS total ion chromatogram of CP huls 70C.

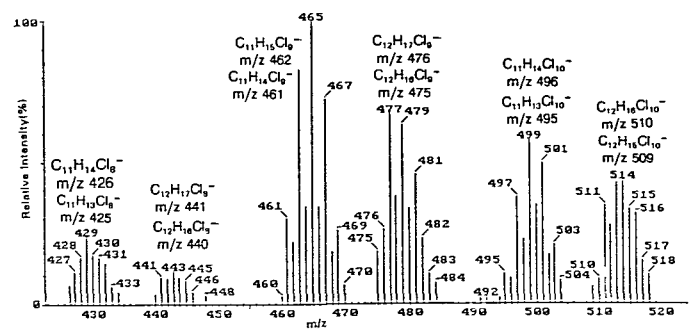

Figure 2. NPI mass spectrum of signal*

Conclusion. These results demonstrate that negative ion plasmaspray ionization (NPI) mass spectrometry is a suitable analytical technique for studying chlorinated *n*-paraffins. Mass spectra are dominated by molecular ions, but also contain ions corresponding to $[M-H]^-$, $[M-Cl]^-$ and $[M-HCl]^{-\cdot}$.

CHEMOMETRIC ASSESSMENT OF GC/MS AND GC/MS/MS DATA OF NAPHTHENIC BIOMARKERS

C. S. Hsu(1), A. Lorber(1), S. C. Blum(1),
A. G. Requejo(2), G. Isaksen(2) and G. Hieshima(2)
(1) Exxon Research and Engineering Co., Annandale, NJ 08807
(2) Exxon Production Research Co., Houston, TX

GC/MS has been commonly used to characterize biomarkers to obtain important geochemical information, such as organic matter input (source), geological age, thermal maturity, molecular alteration (such as biodegradation), etc. The use of tandem mass spectrometry further resolves overlapping isomers, particularly for steranes, that are difficult to analyze by GC/MS. We have used chemometric approaches to assess GC/MS and GC/MS/MS data for marine-source rock extracts and oils in Western Canadian sedimentary basin.

The age of the source rocks studied range from Cretaceous (100 million years) to Devonian (400 million years). Principal component regression (PCR) was used to regress age with sterane distribution. Figure 1 represents the regression coefficients obtained by applyting PCR. the magnitude and direction of the regression cofficients are indicative of the importance and direction of the correlation for the particular biomarker. Close look at the figure shows that odd carbon number steranes (except αββ isomers) are positively correlated, while even carbon number steranes are negatively correlated with the geological age of the source rocks. This result is consistent with the results found by Grantham and Wakefield over a wide range of marine-source rocks that the ratio of C_{28} steranes to C_{29} steranes increases with decreasing geological age of the source rocks.[1] In order to improve age modeling, applicability of a neural network model was tested The neural network model succeeded to reduce the prediction error (estimated by cross validation) from 20 million years to 12 million years. Neural network using four principal components and two nodes in the hidden layer (see Figure 2) improves age correlation among the source rocks and between source rocks and oils. Figures 3 and 4 compare the predicted and measured age of the source rocks with and without neural network. The samples coded with a letter O at the beginning are oils. The codes for rocks are K for Cretaceous, J for Jurassic, T for Triassic, etc. With neural network, rock samples are distributed in clusters with smaller ranges. Close scrutiny of Figure 4 reveals that only predicated ages of oils do not agree with the assessed ages based on geological information. OM4, which was thought to be an oil derived from Cretaceous rocks, should be derived from Mississippian rocks. OM3, another outlier, was re-analyzed and found to be indeed a Mississippian oil (as OM3').

For the maturity assessment, PCR shows that 5β and αααR steranes are negatively correlated with T_{max} of Rock-Eval pyrolysis measurement, as shown in Figure 5. This is consistent with the fact that these sterane isomers have configurations similar to their biological origins, and therefore represent low maturity of the sediment. There are redundancies found by PCR between C_{27} and C_{29} steranes and between C_{28} and C_{30} steranes in the maturity assessment. Preganane, a C_{21} βαα sterane, is found to be positively correlated with T_{max} and should be included in the maturity assessment.

Table 1 shows the comparison of age and maturity assessments between using sterane data only and using both sterane and terpane data. For the age assessment, three factors (i.e. principal components) are needed to describe over 90% of variance using only sterane data. At least five factors are needed for over 90% variance if both sterane and terpane data are used. For the maturity assessment, only one factor can describe over 90% of variance if only sterane data is used and at least three factors are needed if both sterane and terpane data are used. Therefore, in the data set studied the addition of terpane data does not help age and maturity prediction by principal component regression based on steranes.

Thus, the utility of principal component regression and neural network for the assessment of GC/MS and GC/MS/MS data of naphthenic biomarkers is demonstrated.

Computer Program for Interpreting Peptide Mass Spectra Utilizing Hydrogen-Deuterium Exchange Information

D.C. Stahl and T.D. Lee, Beckman Research Institute of the City of Hope, Duarte, CA 91010
N.F. Sepetov, O.L. Issakova, and M. Lebl, The Selectide Corp., Tucson, AZ 85737

Recently we reported the use of hydrogen/deuterium exchange to facilitate peptide sequence analysis by mass spectrometry [1]. Information about the number of exchangeable hydrogens can be used to filter the list of candidate sequences obtained from computer interpretation programs, thereby significantly decreasing the number of possible sequences to be considered. We have since developed an efficient peptide sequencing algorithm which utilizes the experimentally determined number of exchangeable protons as a key input parameter. The basic approach is to first calculate possible compositions that are consistent with the molecular weight. A novel method reduces the customary list of 20 amino acids to nine groups and dramatically decreases the time needed to do the calculations. By using information about the number of exchangeable hydrogens, the final list of possible compositions is reduced to a manageable size. Possible compositions are then calculated for each significant ion in the mass spectrum. These subcompositions are then combined to yield a final list of possible sequences. The program was written in the C programming language in conformance with the ANSI programming standard to ensure code portability. The code was generated and tested on a Dell 433DE desktop computer using the Microsoft Quick C compiler version 2.5. Future work will optimize the process of building sequences from composition data and to analyze deuterium exchanged fragment ion spectra.

Quantitative Aspects of Maximum Entropy Applied to Multiply Charged Electrospray Data.

J.C Cottrell and B.N. Green, Fisons Instruments, VG BioTech, Tudor Road, Altrincham, Cheshire, UK. and J. Skilling, Cavendish Laboratory, Madingley Road, Cambridge, CB3 0HE, UK.

Introduction. The maximum entropy technique known as MaxEnt has been successfully applied to multiply charged electrospray data giving improved resolution and signal to noise ratio (1). However the quantitative aspects of the technique were not demonstrated. Furthermore, discussion of a different, though entropy based, algorithm (2) implied that this technique would not be quantitative

Here we examine, by way of two examples, the quantitative aspects of the MaxEnt algorithm when applied to mixtures of proteins In the first example, mixtures of two proteins which were resolved in the original m/z data, were examined In the second example, there were three proteins which were unresolved in the original data

Resolved Data. A series of acquisitions was made (m/z 600-1600) on mixtures of horse (16951 5) and whale myoglobins, in which the horse myoglobin concentration was kept constant at 1 pM/µl and the whale myoglobin concentration was varied from 0.1 to 80 pM/µl After baseline subtraction, the m/z data were processed by two methods .-

1 By the transform method. This simply sums all the intensity data from each component in the m/z spectrum and presents it on a true molecular mass scale Thus the transformed spectrum gives a true representation of the intensities of the two myoglobins as they occurred in the m/z spectrum. After smoothing, the heights of the myoglobin peaks above baseline were taken to represent their intensities.

2 By MaxEnt. In this case, the areas under the peaks in the MaxEnt output spectrum (profile spectrum) were taken as measures of their intensities

When the whale to horse myoglobin intensity ratios produced by the two methods were compared, they were within 5% of one another except for the solutions containing 0 1, 0 2 pM/µl of whale myoglobin. The 80 pm/µl data were rejected (the S/N ratio was only 2:1) Fig. 1 is a plot of MaxEnt intensity ratio vs concentration ratio of whale / horse myoglobin from 1 10 to 20 1 Linear regression analysis gave comparable results for the two methods, as shown in Fig 1

Unresolved Data. A series of analyses was made on mixtures of horse and human haemoglobins (Hbs) in which the concentration ratio of horse to human Hb was varied from 1.10 to 10 1 In this case, there are 3 α-globins with molecular masses of 15098 3 (horse α1), 15114 3 (horse α2) and 15126.4 (human α) with mass differences of 16 and 12 Da. They were insufficiently resolved for quantification without the resolution enhancement given by MaxEnt

The m/z data were processed by MaxEnt to obtain intensity data on all three globins and also by the transform method to illustrate the resolution before enhancement by MaxEnt. Two examples are shown in Figs. 2 & 3 for the cases where the horse to human Hb ratios were 1 5 & 1 1 Plots of the intensity ratios of horse α1 and horse α2-globins to human α-globin gave correlation coefficients of 0 9993 & 0.9998 resp. over the concentration ratio range from 1 10 to 5.1 At higher ratios, interferences between horse α1 sodium adduct and human α became significant

Curve-Fitting for Resolution of Overlapping Chromatography Peaks in High Precision Gas Chromatography-Combustion Isotope Ratio Mass Spectrometry (GCC-IRMS)

Keith J Goodman and & J. Thomas Brenna
Division of Nutritional Sciences
Cornell University
Ithaca, New York

INTRODUCTION:

In Gas Chromatography Combustion Isotope Ratio Mass Spectrometry (GCC-IRMS) it is general practice to report isotope ratio data only from peaks for which baseline resolution has been achieved because of the stringent requirements for precision and accuracy. GCC-IRMS is increasingly used for biological tracer experiments, chromatography of highly complex mixtures usually results in some overlapping peaks. This is particularly a problem for GCC-IRMS for two reasons First, the system requires plumbing in addition to that required for conventional GC detectors. Second, the carrier gas is restricted to Helium. These factors combine to produce increased peak tailing and somewhat reduced chromatographic resolution, respectively. We have investigated experimentally the effects of overlap using a model system, and the correction of isotope ratios using curve fitting

EXPERIMENTAL:

Isotopically calibrated binary mixtures of methyltridecanoate (Me 13:0) and butylated hydroxytolulene (BHT) were prepared with mass ratios of 1:1, 1:10, and 10:1. Gas Chromatograph conditions were adjusted to produce graded degrees of overlap (10-70% (peak height - % valley)) Chromatograms from each detection channel were fitted using the Marquardt-Levenberg algorithm, implemented in batch processing mode using a commercial computer program Peakfit 3.0 (Jandel Scientific) Isotope ratios were calculated from integrated peak areas. The technique currently employed for peak integration is an automated sequence of peak detection and integration. Peaks are first detected by calculating the slope of a regression line drawn through five consecutive data points and comparing the result to a user defined minimum value. This method is used to define the peak start and stop. Peak areas are calculated as the difference between baseline and signal for the region defined by the peak start and stop.

RESULTS & DISCUSION:

Three functions which model asymmetric chromatography peaks were evaluated for goodness-of-fit Giddings, exponentially modified Gaussian (EMG), and Haarhoff-Van der Linde (HVL) In general, the tail of the peak was poorly modeled for all three functions resulting in an R squared <= 0.996. Modeling the peak with two functions simultaneously resulted in an R squared of 0.9999 Modeling single components with two peaks, however, did not produce accurate peak areas when used for overlapping peaks. The nine possible combinations (three functions, two peaks) were evaluated for fitting of

the 1:1 40% overlap data This screening process revealed that the combinations of EMG/EMG and HVL/EMG gave the best R squared and F statistic.

To further test the resiliency of the fits, both combinations were applied to 1:1 70% overlap. The EMG/EMG fit resulted in a better R squared and F statistic but the shape of the first EMG function distorts and tails into the second peak. This fit resulted in inaccurate (unequal) peak areas. This error would result in inaccurate isotope ratios. The fit achieved using the HVL/EMG combination yielded a poorer R squared but better estimates the peak areas. Based on these data, the HVL/EMG combination was used to model all overlapping peaks

Figure 1 compares R45 obtained for fit and non fit peaks. Each data point represents a mean of at least three replicates chromatographed and fit independently. The non fit data results in 45/44 ratios (R45) that systematically underestimate R45 for Me13 0 and overestimate R45 for BHT The curve fit data preserves accuracy for all peaks >=10% overlap. Similar results were obtained for 1:10 and 10:1 ratio experiments.

CONCLUSIONS:

Overlapping peaks detected by simple algorithms are systematically distorted in isotope ratio even for compounds with closely matched isotope ratios. Curve fitting is effective in restoring isotope ratios for overlaps as high as 70% valley. The quality of ratio restoration depends on relative peak heights.

Analysis of Natural and Adulterated Essential Oils by MDGC/FTIR/MS

Kevin A. Krock, N. Ragunathan, and Charles L. Wilkins
Department of Chemistry, University of California, Riverside
Riverside, CA 92521-0403

Introduction:

Gas chromatography has been the analytical tool of choice for the separation and identification of essential oil components for many years. Traditionally, oil analysis has been performed mainly with flame ionization detection (FID) or with a mass spectrometer. However, there are several potential difficulties with both of these methods of analysis. In general, the FID can not provide the specificity required for identifications, and a mass spectrometer is limited in its ability to differentiate isomeric groups. One method to overcome the difficulty of isomeric differentiation is to couple infrared spectroscopy to the analytical system. With the complementary detection scheme, the reliability of the component identity assignments is greatly enhanced. However, the identification process is only as accurate as the separation can provide. In many cases, total component separation is difficult or impossible with a single separation stage, so a solution to this is multidimensional gas chromatography (MDGC). With MDGC, separation efficiencies can be achieved far greater than a single stage separation provides, and when coupled to an infrared/mass spectral detection scheme, accurate identifications are only limited by the library against which the sample spectra are compared.

In the recent past, the use of optical rotation measurements to differentiate between adulterated and natural oils has become obsolete because the adulterated oils now contain a mixture of optical isomers of compounds that occur naturally in the oil to provide an optical rotation similar to that of natural oils. Since the concentration of many components varies somewhat from batch to batch, differentiation between adulterated and natural oils is difficult by either FID or spectroscopic detection. Fortunately, in most cases, the oils that are adulterated to simulate natural oils contain some traces of their true origin, but these traces are usually minimized or masked by high concentrations of compounds that occur naturally. In the research presented here, both natural eucalyptus and adulterated eucalyptus oils, were examined by combined MDGC-IR-MS. Two different known natural eucalyptus oils and a known adulterated oil which derives from camphor oil were analyzed, and compounds present in the adulterated sample but not the natural samples were taken to be "marker" compounds. Using these compounds as a reference point, a suspected adulterated oil and an oil of unknown origin were analyzed to determine the true origin of the oil.

Methods:

The analytical system utilized in this study is a Hewlett-Packard (HP) 5890 Series II Gas Chromatograph-5965B IRD-5970B MSD system modified for multidimensional gas chromatography with multiple cryogenic traps and analytical columns. Each of the five oil samples were separated on each of the three stationary phases by utilizing a *looping* sequence to retrap the column eluents following detection, and then each of the chromatograms were compared with one another. Differences between the natural and known adulterated sample were spectrally identified and considered marker compounds, and in cases where separation was not good, multidimensional separations were employed. The remaining two unknown oils were then analyzed for the presence of the marker compounds using MDGC when required.

Results and Discussion:

The initial separation of the samples on the various stationary phases provided a very rapid and accurate representation of the components in each of the oils (See Figure 1). There were some differences between the two natural oils, but it has been well established in the literature that variations in components and component concentrations vary considerably with several variables such as time of year, geographic location, and tree type. These variations were taken to be a fair representation of components that naturally occur in eucalyptus oils. The known adulterated sample was then compared to each of the natural oil samples, and obvious areas of difference were subjected to an MDGC analysis. The MDGC separations were performed much like the initial examinations. Each of the three chromatographic precolumn areas identified as potential adulterants were trapped and independently reinjected onto one of the analytical columns. The sample

emerging from the infrared lightpipe was then retrapped in an empty cryogenic trap and subsequently separated on the other analytical column after the separation was completed. Thus, with a single sample injection into the GC, three heart cuts were collected, and each heart cut was then separated on both a polar and non-polar analytical column.

After all of the separation steps were completed, the spectroscopic data was examined for differences between all of the components. From these comparisons, the following compounds were identified as adulteration markers for eucalyptus oil: camphor, α-thujene, decane, sabinene, β-phellandrene, and γ-terpinene. Since adulterated eucalyptus oil generally derives from natural camphor oil, camphor is expected to be, and is, the main marker compound. Upon completing the identification of the markers, the unknowns were analyzed for the presence or absence of those compounds. In the analysis of the unknowns, the presence of camphor and/or α-thujene in any concentration was taken to be an immediate indication of adulteration, and absence of camphor or α-thujene but presence of others was considered a strong indication of adulteration of the oil. However, the latter case was not encountered in this study. The results of the examination of the unknowns were that the suspected adulterated oil was indeed an adulterated oil, and the other unknown sample was determined to be a true eucalyptus oil. The suspected oil contained a both camphor and α-thujene as well as small amounts of the other marker compounds. As for the unknown, none of the marker compounds were present at any level.

Conclusions:

- Combined IR-MS systems provide more powerful identification possibilities than mass spectrometry alone, especially for complex isomeric mixtures such as essential oils.
- Multidimensional separations when coupled with spectroscopic detection and the ability to retrap heart cuts provide fast and powerful methods to accurately analyze complex mixtures.

THE APPLICATION OF SELF-MODELLING MIXTURE ANALYSIS TO AUTOMATED MASS SPECTROMETRY

Alan W Payne, Kodak Limited, Harrow, U.K.
Willem Windig, Eastman Kodak, Rochester, U.S.A.

We are engaged in a programme to automate the process of structure characterisation by mass spectrometry for samples synthesised in a typical industrial research laboratory[1,2] One of the central issues that we are confronting is that many "real world" samples contain mixtures of components. We are using a probe inlet analysis (actually a "DCI" -type probe), and we record mass spectra every second whilst the sample is being temperature programmed; this typically gives us 150 separate mass spectra for one sample. The components of a mixture will generally have different evaporation profiles but the separation with time is invariably incomplete. Traditionally background subtraction techniques are used to attempt to obtain the "pure" spectra. This is of variable success, particularly when applied to any other than binary mixtures, and when applied in an automated procedure.

We have explored the application of self-modelling mixture analysis to this problem[3]. The mathematical technique used for this study is a pure variable method. For this, it is assumed that each component in a mixture has a variable (m/z value) that is unique for that component. With the large number of peaks typically produced in an EI spectrum, this assumption is valid. As has been shown previously[3], a pure variable is basically the variable having the maximum ratio of the standard deviation and the mean (this ratio is termed the "purity") of all the intensities at a given variable (m/z value). The purity values are calculated for each m/z value in the total data set. This shows which masses have varied the most with time as the sample has evaporated. The mass with the maximum value of purity corresponds to the first pure variable. The proportion of the peak intensity that is correlated with the 1st pure variable is then subtracted from every peak in the spectrum, after which the second pure variable can be found. This process is continued until no information is left. In practice, the number of pure variables extracted invariably exceeds the number of components actually present because of noise in the system. However, this is readily obvious both from a noticeable fall-off in the numerical purity values, and also from the appearance of the spectra extracted for these "non-existent" components!

Once the pure variables have been determined, the data set can be resolved into the pure components and the individual spectra extracted. Extraction of the complete spectra , i.e. all peaks relating to the pure variables determined as above, is performed using a least-squares solution, and has been described fully previously[4].

To test the process, data sets were obtained from three separate components, and a mixture of the components. Figs. 1(a), 2(a) and 3(a) show the spectra of the components extracted using the self-modelling approach. Figs 1(b), 2(b) and 3(b) show the reference spectra obtained by analysing the components separately. The comparisons show excellent agreement between the extracted and reference spectra. It was not possible to obtain such "clean" spectra using background subtraction routines, which were of necessity for such a data set, highly interactive and not compatible with our automation scheme.

EVOLVING FACTOR ANALYSIS AND GC/MS - AN IDEAL COMBINATION.

*Lisa Roach and Michael Guilhaus, School of Chemistry, The University of New South Wales, PO Box 1 Kensington NSW 2033 AUSTRALIA.
Marcel Maeder, Dept. of Chemistry, The University of Newcastle, Newcastle NSW 2308.

Evolving Factor Analysis (EFA) is a recently developed "pattern-matching" deconvolution method which makes use of the intrinsicly ordered nature of chromatographic data. The large amount of uniquely "patterned" information in a mass spectrum makes the combination of EFA and GC/MS data ideal. It offers advantages for the mathematical separation of components in an unknown mixture as it makes no assumptions about the number of components, their identities or their chromatographic behaviour.

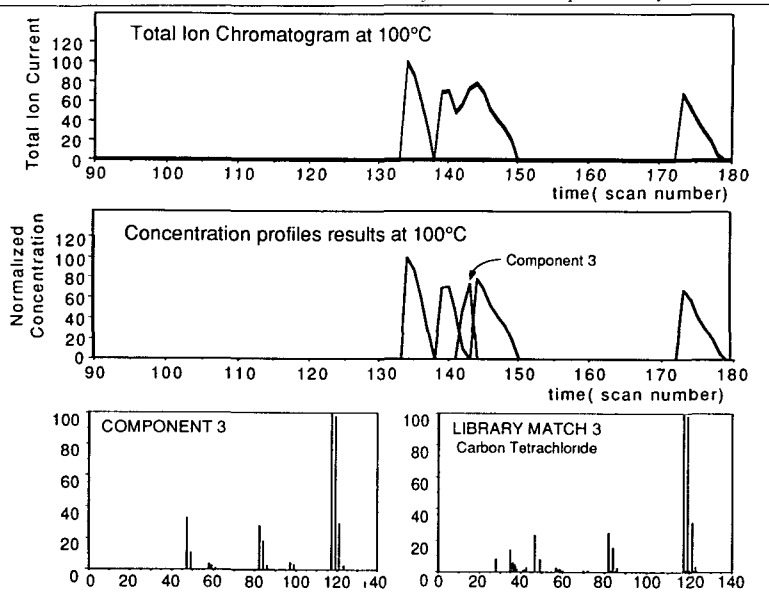
EFA is an extension of the classical factor analysis matrix-algebra based methods. Using the EFA method, severely overlapped data from a GC/MS run can be deconvoluted into the concentration profile and pure mass spectrum of each component. This is achieved by performing a forward and backward rank analysis of the data, and plotting the resultant eigenvalues to determine the appearance and disappearance of each component Eigenvalues are intermediate indicators of the significance of the presence of each component or pattern in the data. The larger the eigenvalue, the greater the certainity that the component/pattern is in the data. The number of components in the system can be determined by deciding which of the eigenvalue lines are significant(indicating components) and which derive from noise. The intrinsic fixed elution order of chromatographic components allows the assumption to be made that the order of the onset of elution is the same as the order of the components' finishing elution. i.e. the first component to elute is the first to finish elution, the second to start is the second to finish, and so on. Thus "positive concentration windows" can be formed, which are then used to retrieve the pure mass spectrum of each component. The identity of the resultant spectra can then be ascertained by matching them with the reference spectra in a computerised mass spectral library, such as the Wiley Mass Spectral Database.

EXPERIMENTAL

A system of five organochlorines was studied. A Pye-Unicam Series 204 gas chromatograph with a DB-164, 1.8μm fused silica capillary column(30m x 0.317mmID) was used. A VG-16F single-focussing mass spectrometer was used(70eV spectra, trap current 50μA, accelerating voltage 4kV). The maximum scan speed of the VG-16F was used(0.3 s/scan for a mass range of 40-150 mass units), resulting in 5 -6 scans per GC peak. A series of experiments were run with column oven temperatures ranging between 100°C and 120°C. The data was automatically collected using the Schrader GC/MS data acquisition system on a 286 IBM-PC.

RESULTS

As the following diagram shows, the results produced by the EFA program are accurate and identifiable. The deconvoluted elution profiles retrieved are the correct shape and occur at the correct retention times. The mass spectra are the EFA resultant spectrum and the library-matched spectrum for the most severely overlapped component. The only significant differences between the two are the mass spectral lines in the library spectrum between 20 and 40 mass units, caused by scan's low-mass limit of 40 mass units.



CONCLUSION

The EFA method works successfully with capillary GC/MS data. The elution profiles and mass spectra extracted from severely overlapped GC/MS data are remarkably accurate (in almost all cases, correct matches were given when automated library search procedures were used). The match was incorrect only when the components had precisely co-eluted and a single composite mass spectral pattern of the two components emerged. The limitation of the method at present is the data acquisition speed of the computer software used and the scanning speed of the mass spectrometer. GC/MS/EFA can be used in the analysis of unknown mixtures since no prior knowledge of the system is required. Applications are envisaged such as large-scale pollutant and drug screening where the sample throughput is a problem and accelerated GC/MS followed by automated deconvolution, identification and flagging of target compounds would be efficient as well as cost-effective. Further testing of this method will include data collected from a quadrupole mass spectrometer (faster scan speeds) and fast-spectral acquisition non-scanning instruments.

INTRODUCTION

Discrimination and Quantitation of Geometric Isomers by Mass Spectrometry; A Model for Chiral Analysis

Aubrey McIntosh and Jennifer Brodbelt, Department of Chemistry
University of Texas at Austin, Austin, Texas 78712

Introduction

One focus of our research is the development of novel methods of analysis in mass spectrometry that allow the chiral specific analysis of bioactive molecules. Many theraputic agents differ in activity based on their chirality. Thalidomide, for example, gained notariety and fueled the growth in power of the FDA in 1960, due to the tetratogenic properties of an enantiomeric impurity.

Realization of this effort requires significant advances in several distinct areas of Analytical chemistry. Typically, research in Mass Spectrometry has emphasized Apparatus Design. In a few specific instances, such as FT/ICR, the application of existing data analysis methods have been important as well We are exploring the largely underutilized novel reagent development area as it applies to mass spectrometry for this project. The Brodbelt group is developing a suite of novel reagent ions which are typically generated in situ within the instrument and which may have site–selective properties or functional group specificity. Ancillary to the main group effort, this poster reports on post–run data analysis methods that aid in mixture analysis, as applied to a simplified model of the chiral analysis problem.

Data Analysis Concerns

Strong similarities exist between the mass spectra of chiral molecules. However, although there may not be universally a unique mass channel that can be monitored for the presence or absence of an ion, there may be qualitative distinctions that are immediately recognized on inspection. One requirement is to find a mathematical formalism that allows the manipulation of these differences to obtain quantitative results. Two problems present themselves. One is the production of distinct spectra for the enantiomers, and the other is the manipulation of these spectra. The development course that we chose was to use geometric isomers as a model of the ultimate chiral mixture problem, and to develop the data manipulation tools in this known analytical setting. Subsequently, the search for resolving reagents could be accelerated by having the appropriate data analysis tools.

Factor Analysis

Factor analysis, in its most general form, is simply a method to factor a matrix into two more easily interpreted matrices that multiply together to provide the original matrix. This is essentially similar to the elementary algebra operation of factoring a polynomial into more easily interpreted monomial terms. The matrix in question is the covariance matrix formed by multiplying a set of data by itself. In general, this matrix contains all the statistical information about the experiment, and is a rich source of information.

A covariance matrix has certain vectors associated with it that have special properties. The most important property is that the matrix multiplied by this vector gives back a scaled copy of the vector itself. This is simply the familar eigenvector property that plays such a familar and important role in quantum mechanics. In fact, we expect all chemist to recognize the standard eigenvalue equation: $H\psi = E\psi$. In our application, mass spectrum of a pure component are a linear combination of these eigenvectors (and vice versa).

The correspondance between the mass spectrum and the (linear combination of) eigenvectors suggests that it is valuable to "view" the vector as a graphic, rather than a column of numbers. This allows intuitive manipulation of the data during the investigation phase with an economy of programming effort. Decision are often made by the chemist based on interpretations of these graphics. We have reported a tool that does present the factor analysis information graphically, and allows the chemist to manipulate the graphs with a mouse. The graphs may be copied directly into

documents or user as input to additional principle component analysis or other computer processing. The direct visualization of the target factors, as well as the ability to edit them and iterate through the target factor evaluation phase is essential for rapid development of target factors.

Factor analysis is an emerging area of data interpretation, and was not widely known to analytical chemists prior to the Malinowski article in Analy. Chem., April 1977. An entire block of this poster gives an intuitive example of factor analysis targeted toward a mass spectrometrist audience.

Data Manipulation Results

The ultimate goal for the post–run analysis is to accept a data–file which has an evolving series of spectra for a mixture of chiral isomers, modeled in this work as geometric isomers, and produce a list of pure–component mass spectra and corresponding concentration evolution. An additional goal is to have this operation be sufficiently fast that the results are available to evaluate at the conclusion of the experiment. It is convenient language to call this data file a Mass Spectra Chromatogram, although the evolving dimension is not typically a chromatographic separation. Indeed, we envision that many experimental manipulations available to the ion–trapping mass spectrometers may be used as the evolving dimension. In particular, ion–molecule reaction time, pro–chiral reagent concentration, and collisional energy are expected to be key dimensions in the chiral analysis problem. This work, however, reports on initial results verifying the data system.

In this work, we use thermal desorption curves from a temperature programmed solids probe. Responses from various total microgram amounts of 2–Bromobenzoic acid are shown. The 2–Bromobenzoic acid was deposited from solution to a standard glass solids probe vial. After introduction of the probe, a temperature desorption run was effected at 60o/min. Additionally, temperature desorption runs of 4–Bromobenzoic acid and 2–Bromobenzoic acid mixtures are run. Known spectra are compared against the reconstructed spectra. Work continues to address the effects of space charging, charge transfer, and other mechanisms that make the linear model break down.

Improving Performance of Mass Spectral Search Algorithms

***Craig A. Walla, Hitachi Instruments, Inc., San Jose, CA 95134**
Stephen Bradshaw, Teledyne MEC, Mountain View, CA 94039

INTRODUCTION

Comparing an unknown mass spectrum with a database of known mass spectra is commonly referred to as library searching To be of use in industry, library searching must be both fast and accurate There are many library searching algorithms available to determine how well two spectra may match each other. One method, the dot product, has been shown to give the best results[1]. Unfortunately, this method is not practical in all applications because of the amount of time it takes to compare an unknown with each entry in the library. To solve this problem, pre-search methods are used that can select a relatively small number of spectra These spectra are then compared using the dot product method One commonly used pre-search method, INCOS[2], uses the absence / presence of a mass to narrow the number of spectra. Two additional pre-search methods were developed.

METHODS

The NIST Mass Spectral Database was reduced in size from 35.2 Mbytes to 4 2 Mbytes to allow the entire library to reside in RAM for very fast searches The work was done on a 66Mhz, 486 PC with 16 Mbytes of RAM. To reduce the size of the library, each spectrum was limited to include only the most significant 16 masses. These masses were determined by the following steps:

- $I_w(m) = \sqrt{m \times I(m)}$ where $I_w(m)$ is the weighted peak intensity[2]
- normalize the spectrum by setting the maximum peak intensity to 10000
- save only the most significant 16 peaks

To test the results of the 3 pre-search algorithms, the top 10 spectra and top 100 spectra are sent to the main search for further comparison The main search algorithm uses the dot product of the two spectra as a measure of closeness and is described as the Purity[2]

Pre-search Algorithms

INCOS is a widely used algorithm that is based on the number of common masses in both the unknown and the library spectrum. For each unknown mass that is also in the library spectrum a value of 1 is added to the mass total.

We developed two additional methods which expand on the INCOS algorithm by including information about the importance of a peak in the spectrum.

Method #1 - Ranking the Unknown Spectrum

This algorithm is based on the importance of the unknown peak and its existence in the library Each of the 16 or fewer peaks in the unknown is given a ranking based on its weighted intensity. 16 signifies the most important peak while 1 signifies the least important peak If there are fewer than 16 peaks in the spectrum then the remaining positions in the reduced library are set to 0 which signify that there are no more peaks in this spectrum. These rankings are then accumulated as the corresponding peak in the library is found.

Method #2 - Ranking both the Unknown and Library Spectrum

This algorithm is based on the importance of both the unknown and library peak. The library peaks are ranked using the same method as in the previous example. The product of the rankings of common peaks is accumulated. The rank total is doubled if a common peak is found to further distinguish between spectra. The rank total in this example has been scaled to avoid exceeding a 16 bit integer

RESULTS

Ethylbenzene was used as the unknown for comparison of these pre-search methods and was searched against over 62000 compounds in the reduced NIST library. The INCOS method is very fast (0 39 sec) because of the small amount of calculations required to generate a mass total. However, the mass total alone can not discriminate between spectra because this method groups many spectra by assigning an identical mass total While this method selected some very good candidates, a very poor choice was also made. Method #1 is slightly slower (0 49 sec) than INCOS because of the additional calculations required to generate a rank total. However, this rank total is more discriminating than the mass total from INCOS. Method #2 is the slowest (0.55 sec) of all the methods tested because of the multiplications needed to generate a rank total. However, this rank total is much more discriminating than the previous two methods. Unfortunately, this method also selected some very poor choices as possible candidates. The results are shown in the following table. The numbers 1-5 indicate the same 5 best hits

INCOS			Method #1			Method #2		
Mass Total	Purity		Rank Total	Purity		Rank Total	Purity	
16	**.943**	1	136	**.943**	1	1460	**.943**	1
15	840	5	135	896	3	1055	231	
15	865	4	133	840	5	717	897	2
15	896	3	133	865	4	706	896	3
15	897	2	133	897	2	701	865	4
14	750		131	651		679	840	5
14	651		130	.553		660	369	
14	.789		130	712		653	.384	
14	231		129	789		622	189	
13	614		128	.701		547	.553	

CONCLUSION

1) All three methods successfully passed the same 5 spectra to the main search. These 5 spectra appear to be the best matches for the unknown used

2) All three methods are relatively fast. In all cases the pre-search task was completed in less than 1 second This is important for applications where the speed of the library search can affect system throughput.

3) The Ranking methods discriminate between similar spectra

4) Further work needs to be done with specific families of compounds to determine how well a particular method can discriminate between spectra

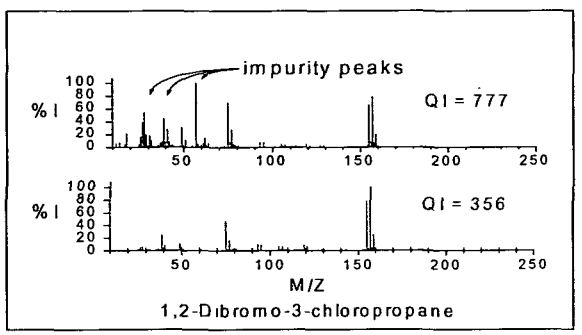
THE CONTROL OF QUALITY IN A COMPREHENSIVE MASS SPECTRAL LIBRARY

A.I. Mikaya*, P.J. Ausloos, S.G. Lias, S.E. Stein, A260/222, NIST Mass Spectrometry Data Center, Gaithersburg, MD 20899

Spectra in comprehensive mass spectral collections come from diverse sources and therefore possess a diverse range of quality. Until recently, spectral quality in the NIST/EPA/NIH Database was monitored solely by a computer-generated "Quality Index," [1,2] which assigned to each spectrum a numerical rating based on selected spectral features and analytical conditions. When multiple spectra of a compound were available, only the one with the highest quality index was included in the distributed library. However, because such algorithms cannot detect a large proportion of serious spectral errors, we found that over a period of time this policy could reduce the overall quality of spectra in the library by replacing good quality older spectra with lower quality, recently-measured spectra that were fortuitously assigned higher Quality Index values. An example of such a replacement is given below.

Here, the spectrum of a pesticide containing major impurity peaks replaced a good quality spectrum of the pure compound. The higher number of peaks in the former spectrum led to a higher Quality Index value.



In addition, chemical structure information is not used in the Quality Index. It cannot, therefore, discern many serious errors evident through straightforward application of structure/spectral correlation rules.

For these reasons, we have abandoned the use of the Quality Index for selecting spectra. To deal with quality we have undertaken a program to manually examine all spectra in the database. Suspect spectra are first examined to find the likely origin of the problem. Then, when possible, corrective action is taken. Some correctable errors are name/formula/molecular weight inconsistencies, identifiable impurities and single mass unit displacement of a spectrum. Remeasurements are done for commercially-available compounds and erroneous or seriously deficient spectra are deleted. If a spectrum is not suitable for distribution, but of possible use in later evaluations, it is marked as having low quality and stored in an internal file.

Computer methods, some of which are components of the original Quality Index, are employed only to aid this evaluation process. The accompanying table lists the most commonly encountered varieties of errors.

PC-based Modular Data System for Time-of-Flight Mass Spectrometry

*** M. Hubert**
Chips at Work GmbH, Argelanderstr. 36, D-5300 Bonn 1, Germany

A versatile data system for transient recorder based time-of-flight mass analysis is presented.
"ULISSES" originally was developed for matrix-assisted laser desorption mass spectrometry, but is applicable to any ionization method using transient recorders for time-of-flight analysis, such as laser postionization or laser ionization.
The program performes all tasks usually necessary for system control:
laser trigger, transient recorder setup, universal stepper motor control, and allows data handling like: spectra storage, data compression, file managing and offline printing.
The ULISSES-Software supports data manipulation functions like averaging, background subtraction, smoothing, labelling, normalization and line spectra generation Various data analysis features as mass calibration, peak detection, peak integration, peak analysis can be performed

Spectra can be presented by hardcopy-printouts, high-quality postscript or HPGL-plots and exported into PICT-graphics.
The package is written in PASCAL and can be combined with other PASCAL-applications Computer code is optimized for high-speed data acquisition and high-speed display. Data transfer rates to the computer are in the range of 300kByte/s (with digital scopes, such as LeCroy 9450) to 1 MByte/s (using PC-cards, such as Precision Instruments 9825).
Total screen refresh rate can be as high as 10 Hz (depending of the computer and the complexity of display).
Of special importance is the possibility to include user-written routines or units, and to append additional user data to spectra files.

The ULISSES-Software can be run on a MS-DOS-machine, which should be a 386 or higher. The computer should support VGA-graphics-standard. The software works together with various transient recorders. Data transfer can be perfomed via IEEE-interface.
ULISSES runs in an DOS-Box under MS-WINDOWS 3.1. Using this method, the user can drag spectra from the ULISSES-screen and drop into any other WINDOW-application.

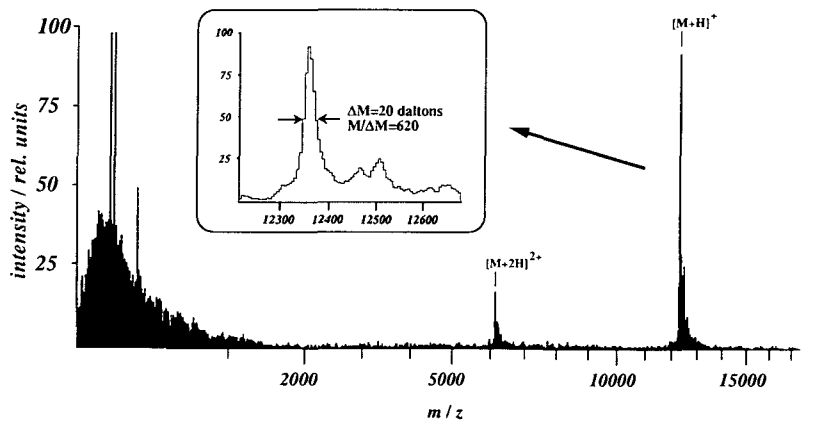

Fig. Matrix-assisted laser desorption mass spectrum of cytochrome c (MW=12360), analysed in a linear instrument with a bare channel plate detector at λ=337nm, at 34keV acceleration energy and a residual gas pressure of $2*10^{-7}$ mbar. Matrix was 2,5-dihydroxybenzoic acid. The from calculated mass resolving power (FWHM) was $M/\Delta M \approx 620$. Data acquisition and peak analysis has been done by ULISSES.

Software for Acquisition and Analysis of TPEPICO - TOF - MS

Bibi Teklehaimanot and Gerry G. Meisels
Department of Chemistry
University of South Florida
Tampa, FL 33620-5250

TPEPICO-TOF-MS, (Threshold photoelectron photoion coincidence time of flight mass spectrometry) is a valuable experimental tool that allows the preparation and study of molecular cations formed in coincidence with zero kinetic energy electrons. It furnishes important information on such diverse areas as thermochemistry, kinetics, unimolecular reaction mechanisms, and on the inter conversion of internal energy among the various degrees of freedom. It is also an invaluable tool for testing theoretical models of ionic decomposition phenomena and for gathering mass spectrometric information on gas phase ion chemistry.

Unfortunately TPEPICO experiments are inherently demanding and tedious. Compounding this inconvenience is the lack of commercially available software for data acquisition and processing specifically suited to TPEPICO.

We have developed TCMS, (Threshold coincidence TOF MS data analysis system) a comprehensive integrated software package, customized for TPEPICO. Major considerations in developing the package were reliability, convenience and ease of data manipulation. TCMS runs optimally on 386/486 series PC compatibles, under the MS - DOS(R) 5.0 operating environment. TCMS is a menu driven, procedure oriented software, consisting of a control module (Fig. 1) and four separate modules each capable of operating in conjunction with the control module or as an independent application. The control module serves as an entry point to the integrated environment. It allows the user to select a particular application.

Module 1 consists of routines for acquiring data, displaying the spectrum on the computer screen, analysis of regions of interest (ROE) such as background subtraction, data smoothing and data deconvolution. Module 2 deals with kinetic energy release analysis based on the shape and width of peaks. Module 3 includes routines for decay rate fitting with one or two component dissociation rates. Module 4 contains routines for the theoretical analysis of data.

Although TCMS was developed to be used with TPEPICO-TOF-MS, the TOF peak analysis routines in modules 1 - 4 can be applied directly with no or minimal modification to analyze TOF MS data from other systems. TCMS has been tested and used extensively in our laboratory for acquiring and analyzing data on the unimolecular dissociation of a number of molecular samples including dimethyl sulfide and furan.

Networking a Laboratory Information Management System (LIMS) with Mass Spectrometer Data Systems

*K. Straub and G. Witkop
Syntex Discovery Research, Palo Alto, CA 94304

While the use of autosampling devices on mass spectrometers has become commonplace, procedures for efficient instrument scheduling and sample tracking are still at an early stage of development Most central analytical laboratories make use of a database manager, usually referred to as a Laboratory Information Management System or "LIMS", to facilitate sample tracking and to store final analysis results. The type of information that is stored on a LIMS system includes elements that are normally part of an MS datafile, such as the sample title, notebook reference, project number, and requested analysis. Information stored in a LIMS system prior to actual analysis also includes items that can be useful for instrument scheduling such as expected molecular weight, type of structure, and desired ionization techniques. The practice in most laboratory environments is to use a LIMS for sample tracking and test status, but does not include a physical link between the LIMS and the MS data systems.

Our laboratory operates a number of diverse instruments, including a MAT 8230 high resolution system equipped with an automated solids probe (Audevap™), and several Finnigan TSQ70/700 triple stage quadrupole spectrometers set up for LSIMS and LCMS. The instruments are located in physically distant sites The data systems are based on DEC microPDP-11/73's that use RSX-11M or RSX-11M+ as an operating system (MAT 8230, TSQ70) or Unix-based workstations (TSQ700). All of these spectrometers are connected to the corporate network via ethernet, using either DecNet or TCP/IP.

The large number of samples that are processed by the MS laboratory prompted us to examine methods for achieving a greater degree of integration between the spectrometer data systems and the department LIMS (Beckman Lab Manager, running on a Vax 4000/600). Much of the information that is manually entered into a spectrometer data system prior to data acquisition is already present in the LIMS database We therefore undertook development of a suite of programs to facilitate transfer of this information directly between the LIMS and the various spectrometer systems. We have also explored the complementary process, in which analysis results are automatically entered into the LIMS database following completion of an analysis by the spectrometer data system. The resulting system, when combined with software for analysis and plotting of spectra, permits unattended operation of the instruments for analyzing large numbers of disparate samples.

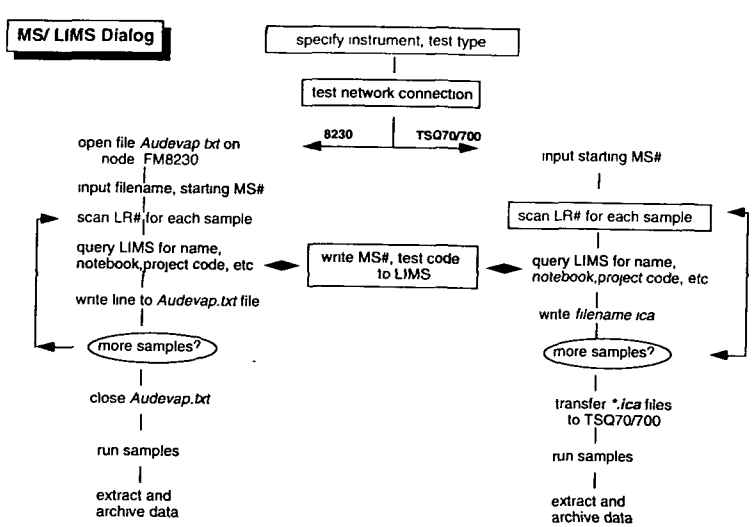
Lab Manager provides a transaction processing function, LBTRNS, which can be used to transfer information in and out of the LIMS database. The input and output functions are encoded in two 2048 character strings, CRECV and CSEND Specific items of information about a particular sample can be requested by specifying the laboratory reference number for that sample, and then parsing the returned CRECV string. A VAX fortran program was written that, for a given sample reference number, queries the LIMS database and outputs a file containing the requested information In actual practice, each sample submission form is scanned with a barcode reader, and the program retrieves the data and writes a file appropriate for the type of spectrometer that is going to be used Two different file types are constructed, one for the MAT 8230 and another for the TSQ70/700. A flowchart for this process is shown in figure 1.

The MAT 8230 Audevap control program uses a simple text file, in which each line specifies a turret position number, file name, header comment, and instrument parameter file. The latter file contains settings for the instrument such as scan rate, resolution, and other acquisition parameters. The Audevap turret assembly accommodates up to 46 samples, and the normal procedure is to create the control file for a full set of samples. The control text file is actually opened across the network and written directly on the MAT 8230 data system. The samples are then loaded into crucibles and analyzed by EI or CI. After each datafile is acquired, the most intense spectra are automatically selected and plotted. These spectra are then extracted from the original datafile and transferred over the network to magneto-optical disks on the VAX for archival storage.

The TSQ70/700 series instruments make use of a special file, referred to as an "instrument analysis" or ICA file that must be present in a specific subdirectory. This is a 512 byte file specified as *filename.ICA* that contains information about the analysis in a special format. For the TSQ70 this file must reside in UIC [1,102], while on the TSQ700 it resides in the subdirectory */usr/users/finnigan/msi*. In addition to containing the sample description and header comments, these files reference the names of other files that specify the autosampler, instrument control and data analysis methods, and other useful information. The high degree of automation that is implemented on these particular instruments makes it feasible to link the sample with standard data analysis and reduction methods as well as LC or GC programs on the LIMS. For sample scheduling, the VAX fortran program creates the required ICA file after retrieving the appropriate information about each sample from the LIMS. The ICA files are then transferred over the network to the TSQ70 or TSQ700 data system. Following analysis, spectra marked for archival storage are extracted and transferred over the network to magneto-optical disks for permanent storage.

Information flow between the LIMS and MS data systems in this scheme can be bidirectional, since the LIMS system contains an entry for the MS filename, ionization technique, and comments describing the results of the analysis. The MS filename and ionization technique are automatically entered into the LIMS, while the test results are manually entered by the analyst following review of the data.

Retrieval of archived mass spectra data for review is accomplished by transferring a copy of the archived file across the network to the spectrometer data system. Since all of the spectrometers are linked to the corporate network, they can be accessed from any location using PC's with appropriate emulation software.



An Instructional HyperCard Stack for Users of the Mass Spectrometry Laboratory at the University of Illinois

Steven L. Mullen, University of Illinois at Urbana-Champaign, School of Chemical Sciences, 505 South Mathews Avenue, Urbana, IL 61801

Why Write a HyperCard Stack?

For many years we have had a lab brochure that explains to our customers how to use the lab and what the lab can do for them. The availability of Macintosh computers and laser printers has made the brochure much more attractive and readable. However, the linear organization of printed text is not always the best way to convey information.

HyperCard 2.1 is a program for the Macintosh computer that allows one to create a stack of cross-referenced index cards. The author of the stack can create cards and link them as he sees fit. Thus, instead of flipping through pages, the reader can jump from card to card in a logical manner and find the required information more readily. The stack also has the advantage of being on a hard disk instead of somewhere in an endless stack of papers.

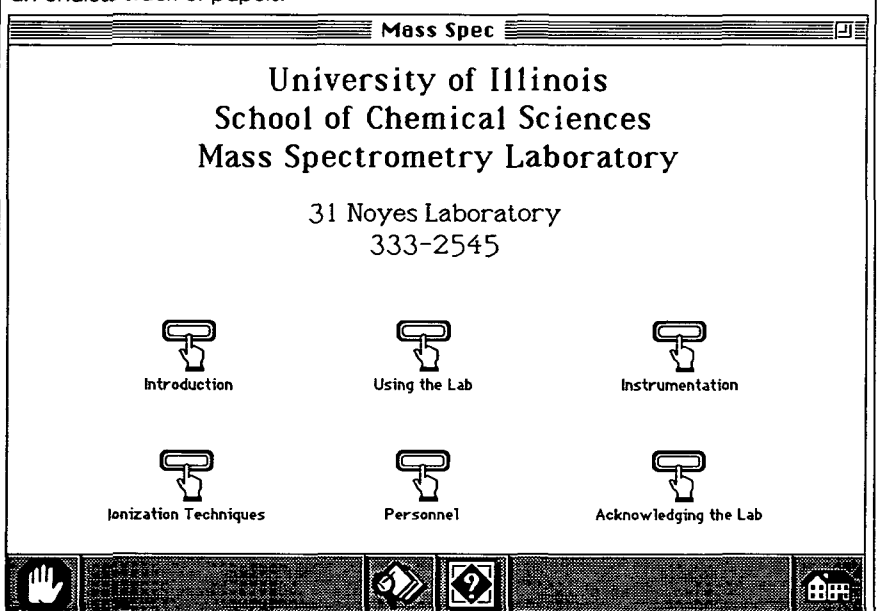


Figure 1. Main card of the Mass Spec stack.

What is in the Stack?

The Mass Spectrometry Laboratory Stack, like the printed brochure upon which it is based, is divided into six main sections. The main card of the stack is shown in Figure 1. By clicking the buttons on the cards, it is easy to move between sections and subsections. The text of the stack is identical to that of the brochure so that users of the printed and HyperCard versions have the same information. Only the means of accessing it is different. However, the stack does have some features that cannot be duplicated in the printed version. For example, clicking on any part of the sample submission form shows instructions on filling out that part. There is also a companion help stack accessible from the main stack and a "Read Me First" stack for novice users. The stack has been distributed to interested research groups in the School of Chemical Sciences.

Construction of the Stack

To be most visually effective, the stack should have a consistent layout. HyperCard allows the creation of a background layer that appears on every card of the stack. Graphics, title and text fields, and the one button that appears on every card were placed on the background. Once the background was in place, buttons and titles were added and text was pasted from the brochure. Buttons that look the same, but perform slightly different functions on each card, were carefully placed at the same position on each card.

Another place where consistency is important is in the visual effect when moving from one card to the next. All cards on the same hierarchal level use the same effect, either a slide right/left or wipe right/left.

Although complex programs can be written in HyperCard, this stack mostly uses simple links between cards. Very little scripting was necessary, and that which was necessary relates to the linking of the cards. For example, information on ionization techniques is accessible from two places in the stack. Pop/push card was used to return the reader to the proper point of origin.

Future Work

There are several additional features that could be incorporated into the stack. More links could be added. A stack can never have too many links. These links could include clicking on key words to go to a card showing more detail. Digitized pictures of the instruments and staff could be added. An index in which the reader could click on the entry of interest to go to that card could also be useful.

Acknowledgements

The printed brochure upon which this stack is based was originally written by Richard Milberg. It has since been modified by this author in collaboration with Dr. Milberg. Beta testing of the stack was done by Furong Sun and Anthony Thompson.

Ion Optical Study of Low Acceleration Ion Source

[1]M. Ishihara and [2]T. Matsuo
[1] Analytical Instrument Division, JEOL Ltd, Akishima, Japan.
[2] Institute of Physics, College of General Education, Osaka University, Japan.

INTRODUCTION

Recent studies have demonstrated the production of large metal clusters (m/z 300,000) by the use of Cs^+ bombardment [1]. In order to extend the mass range of sector mass spectrometers to allow analysis of such massive species, a number of possibilities exist: (i) increase the magnetic sector radius, (ii) increase the magnetic field strength, and (iii) decrease the acceleration voltage. Technical limitations exist for the first two options (we already have a 1.25m radius magnet weighing 9t, and there are limits to the generation of homogeneous, high strength magnetic fields), therefore our only option is to reduce the acceleration voltage. We have previously reported spectra obtained with an acceleration voltage of 70V, but this was severely hampered by the drop-off in ion extraction from the ion source. We have investigated the extraction optics of the ion source region for a unit operating at low accelerating voltage, using computer simulations derived from the computer code 'ELECTRA' [2].

CALCULATION

The block diagram of the prototype ion source used for the calculations is shown in Figure 1. Calculations were performed on an HP-9000-730 and typical computing time was 7 min. It was assumed that ion beam was emitted normal to the target surface, and two parameters (initial energy of the ions, U_0, and target inclination angle, θ_0) were varied.

1. Target angle, θ_0, is fixed (45°) and initial energy, U_0, is varied. (Figure 2a,2b)
2. Initial energy, U_0, is fixed (0 eV) and target angle, θ_0, is varied.
3. Initial energy, U_0, is fixed (5 eV) and target angle, θ_0, is varied.
4. Target angle, θ_0, is fixed (45°) and initial energy, U_0, is fixed (5 eV). Voltage to intermediate plates were varied. (Figure 3a,3b)

DISCUSSION

1. Ion extraction decreases as the initial energy of the ions is increased. Therefore, special attention should be given to very low acceleration voltages (<50V) since the average initial energy of a SIMS-type ion source is of the order of 20-30 eV.

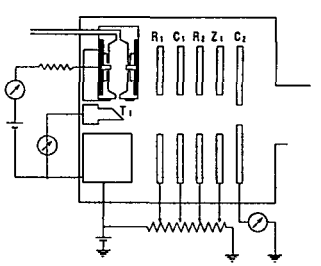

Figure 1: Block diagram of calculated ion source
T1: Target(+50 volt), R_1,R_2.: horizontal lenes (-5v,-80v), C_1,C_2: cylindrical lens (-120v,0v), Z_1: vertical lens (-80v) respectively

2. A smaller inclination angle, θ_0, gives rise to better ion extraction, at low acceleration potentials, but this influence is greatly reduced for sources operating in higher voltage (5-10 kV) régimes.
3. Even in the situation with an inclined target and a larger initial energy, the ion extraction can be improved by changing the potential of intermediate focusing lenses.
4. We are currently verifying the optimized theoretical models by experiment.

Identification of Proteins by their Peptide Masses in DNA Databases

Matthias Mann[1], Peter Mortensen[1], Peter Højrup[2] and Peter Roepstorff[2]

[1]Protein & Peptide Group, European Molecular Biology Laboratory, Heidelberg, Germany
[2]Dept. of Molecular Biology, Odense University, DK-5230 Odense M, Denmark

Previously, we have investigated the possibility of correlating partial mass spectral data of proteins with protein databases [1]. It was possible in most circumstances to identify proteins even with very few peptide masses, with moderate mass accuracy (0.1%) and in the presence of masses which were not obviously correlated to the sequence.

In this contribution we wish to extend those investigations to the searching of DNA databases. Such an extension is desirable because virtually all new sequence data that is entered into databases today is DNA data and because projects like the Human Genome Project will yield a wealth of DNA sequence information. For the biological mass spectrometrist these developments represent an opportunity to convert the challenging task of primary structure determination of an unknown protein into the more tractable one of correlating MS measurements to "proposed" sequences in the data banks.

We have adapted the program "PeptideScan" written in C++ and running on the Macintosh family of computers to the task of reading and translating DNA sequences. Figure 1 shows the user interface and a search result from scanning SWISS PROT, a protein database. The user interface was not modified and the main changes to the program were the addition of an "object" (software module) embodying the rules for DNA translation.

Between one and all six reading frame of a DNA sequence can be searched with the program. Digestion (i.e. calculation of peptide masses) is done "on the fly" in all the specified reading frames in contrast to the searches on SWISS PROT which was "pre-digested" to the hard disk according to user specified conditions. In searching DNA sequences open reading frames of a certain length are first determined. A protein match must have all matching peptides in one open reading frame (see below).

The program was furthermore modified to search the 84061 entries of the PIR system of data bases, again using digestion "on the fly". Currently only the search on SWISS PROT is optimized, taking typically 10 seconds or less on a Macintosh Centris 650. The PIR search takes about 10 minutes and DNA database search of the primate division about 12 minutes when specifying all six reading frames (27524 entries and 24 Mbyte sequence).

There are some limitations in the current algorithm that will have to be addressed. They mainly stem from the way the data base is organized. There are some entries where different exons of a gene are separate entries. In such cases a straightforward search might miss a match because some peptides may match in one entry and some in another. Thus it will be necessary to be able to parse (read) the feature table automatically and count up peptide matches across different entries for the same gene. Being able to parse the feature table automatically will in any case be advantageous because it allows the option to use more information about the sequence.

Using the techniques developed for this communication we can now search three categories of databases. (i) Well annotated and established amino acid sequences (i.e. SWISS PROT). (ii) Less certain, mostly auto translated sequences such as PIR III and Patch X. (iii) DNA data bases. The probability for false hits was not found to be very much higher than in amino acid sequence data bases. In particular, there was no need to specify the correct reading frame in advance because wrong reading frames contain enough stop codons to prevent false positives. However, it will in the future be benificial to be able to parse the feature table.

On the basis of our preliminary experience we suggest that MS information be checked against data bases in the order of certainty of entries given above (i.e. (i) to (iii)).

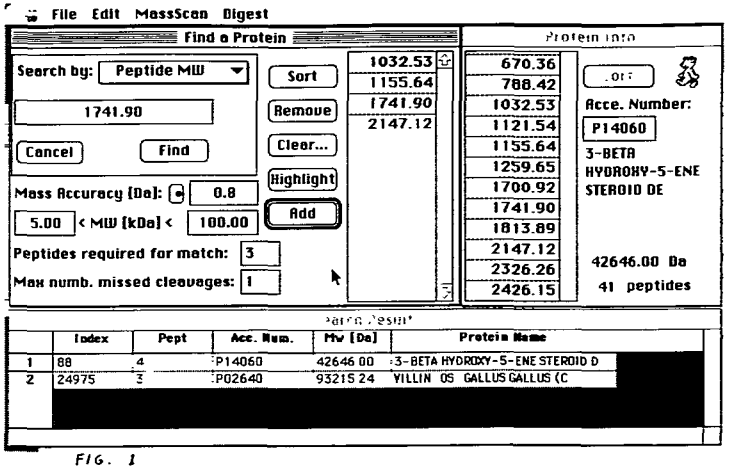

FIG. 1

COMPLEXATION SELECTIVITY OF METAL CATIONS TOWARD ORGANIC MOLECULES BY FAB MASS SPECTROMETRY

D. Giraud, *O. Laprévote and B. C. Das

Laboratoire de spectrométrie de Masse, Institut de Chimie des Substances Naturelles, C.N.R.S., Av. de la Terrasse, 91198 Gif-sur-Yvette, France.

Mass spectrometry using a fast-atom bombardment or a cesium ion beam as ionizing agent (FAB and L-SIMS) has gained increasing success since a dozen of years by virtue of its ability to transfer in the gas phase polar and involatile chemical substances introduced into a liquid matrix. A special feature of the FAB desorption is the generation of ions by attachment of alkali metal cations on various organic compounds (glycosides, oligosaccharides, antibiotics, peptides, etc.). Although the "cationisation" mechanism is not fully understood, some experimental results suggest that the mass spectra may reflect the equilibrium established in the matrix solution (1). This assumption has been developed for studying crown-ethers and other macrocyclic ligands of metallic cations allowing metal cation selectivity measurements and, in some cases, an evaluation of the corresponding stability constants.

Fundamentally, our strategy is based on the study of the variation in concentration of ligand/cation complexes of three different metal ions (M_1^+, M_2^+, M_3^+) competing for a defined amount of ligand (L).

The first step of the work consists in the determination of the theoretical concentration of each complex (LM_1^+, LM_2^+, LM_3^+) starting from fixed stability constants (K_1, K_2, K_3, respectively). The solutions of the three corresponding interdependent equations are obtained by successive iterations. When these calculations are carried out with different values of the ratio R = (total salt concentration)/(ligand concentration), characteristic variations in the relative concentrations ($LM_i^+{}_{calc}$) of the different complexes are observed.

In the presence of an excess of ligand (R<1) almost all the alkali cations are complexed, thus leading to equal complex concentrations and suggesting that, in the initial regions of the curves, the differences in relative intensities of the observed LM_i^+ ion peaks are due to different desorption rates. In order to relate the ion peak heights to each complex concentration in the matrix, the relative intensity values must be corrected by a "desorption coefficient" $D_i = LM_i^+{}_{obs}/LM_i^+{}_{calc.}$ calculated in the initial segments of the curves. Thus, the division of the relative intensities of all the LM_i^+ ion peaks by their corresponding desorption coefficients D_i should draw the observed values nearer to the theoretical curves.

For a ratio R=5, the experimental values LM_i^+ corrected by D_i are very close to the theoretical curves and they can be used directly for calculating new stability constants K_2 and K_3, with only a fixed

value of K_1. The variations in the theoretical curves due to a change of K_2 and K_3 (slightly different from the initial values) lead to new D_i coefficients, then to new LM_i^+ corrected values, and consequently to other K_2 and K_3 values which can be used for the calculation of the theoretical concentrations LM_i^+.

Thus, by fixing one stability constant value, it is possible to determine the stability constants of the two other complexes, and then to measure the selectivity of a particular ligand toward different cations. The reliability of this method is simply demonstrated by the fact that an increase (or decrease) of K_1 by a factor 10 allows only a variation of 0.05-0.1 in terms of $\Delta \log K$ (= selectivity measurement).

The stability constant measurements of a ligand toward different alkali cations are achieved in the same way as for the relative affinities. This is obtained simply by determining the best fit between the experimental data corrected by the desorption coefficients and the theoretical values. Minimisation of the chi-square value is obtained by using the Microsoft® Excel software for searching the best K_1 values. The Figure illustrates the results obtained for various compounds with lithium, sodium and potassium cations, after the complete set of iteration, chi-square minimisation and stability constants determination.

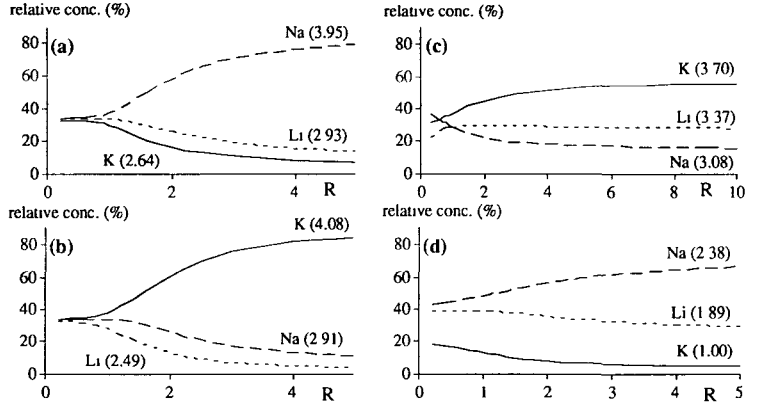

Figure. Relative concentrations (%) calculated for (a) 15-crown-5, (b) 18-crown-6 (c) lasalocid A, and (d) taxotere complexes with Li^+, Na^+, and K^+, along with their log K values. [R = (total salt concentration)/(ligand concentration)].

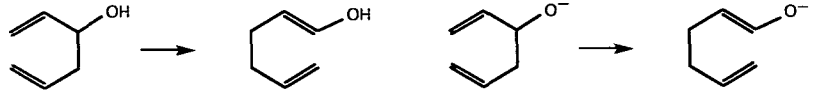
MECHANISTIC INVESTIGATIONS INTO THE ANIONIC OXY-COPE REARRANGEMENT IN THE GAS-PHASE

Jeehiun Lee† and Joseph J. Grabowski‡
Departments of Chemistry
†Harvard University, Cambridge MA 02138
‡University of Pittsburgh, Pittsburgh, PA 15260

[3,3]-sigmatropic rearrangements such as the Cope rearrangement have long been of interest to physical-organic and synthetic chemists alike. The discovery by Evans and Golub[1] that the rate of the oxy-Cope rearrangement (eq 1) could be accelerated by 10^{10}-10^{17} by deprotonation of the hydroxyl substiuent (the aptly named *anionic* oxy-Cope rearrangement, eq 2) led to its widespread use in synthetic chemistry, and to studies to probe the root of the



(1) (2)

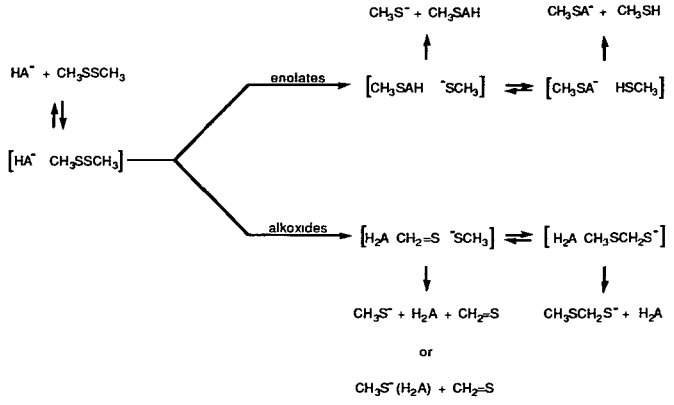
acceleration. One such theoretical study[2] employed *ab initio* methods to calculate the carbon-hydrogen bond strengths for methanol (H–CH_2OH), sodium methoxide (H–CH_2ONa), potassium methoxide (H–CH_2OK), and the methoxide anion (H–CH_2O^-). It was found that as the substiuent became more "anionic," the C-H bond became weaker (bond dissociation energies of 90.7, 80.6, 79.0, and 74.2 kcal mol^{-1} respectively). This bond weakening effect was suggested as a possible reason for the marked rate enhancements observed. The study of the rearrangement in the gas-phase, where solvent and counterion effects are absent, could potentially provide further insight into the acceleration question.

The greatest challenge in studying any rearrangement in the gas-phase is finding a viable method for discerning whether or not rearrangement has occurred. Since the starting material is an alkoxide and the product is an enolate, methods can be used which capitalize on these structural differences. One such method involves using a reagent, or probe, which can differentiate between the two structures. A well-known example of such a structural probe is the family of deuterated solvents: enolates can exchange protons, alkoxides cannot. A probe of greatest utility would react quickly and efficiently with both alkoxides and enolates, and more importantly, would yield a *unique* product for each.

In our search for the ideal probe, we examined the reactions of alkoxides and enolates with dimethyl disulfide, which is known to undergo fast reactions with both localized and delocalized bases, producing a unique product for each (see scheme). Experiments with

1. Evans, D.A.; Golob, A.M. *J. Am. Chem. Soc.* **1975**, *97*, 4765-4766.
2. Steigerwald, M.L.; Goddard, W.A., III; Evans, D.A. *J. Am. Chem. Soc.* **1979**, *101*, 1994-1997.

model compounds (propoxide and propanal enolate to mimic a secondary alkoxide; isopropoxide and acetone enolate to mimic a tertiary alkoxide) indicated that dimethyl disulfide would be an ideal probe. The alkoxides react efficiently to produce mostly $CH_3SCH_2^-$ (*m/z* 93) while the enolates produce mostly thiomethoxylated product CH_3SA^-.



Our experiments were carried out under thermally equilibrated (298 K) conditions attainable in the flowing afterglow. The following procedure was used for both parent alcohols **1a** and **1b**: first, the parent alcohol is deprotonated with a base B^-; then the $(M\text{-}H)^-$ is allowed to react with CH_3SSCH_3. Both alcohols were found to yield thiomethoxylated product upon deprotonation (eq 3), indicating that both the parent secondary and tertiary alkoxides **2a** and **2b** rearrange to the corresponding enolate in our flowing afterglow.

Complexation Of Alkaline Earth And Transition Metal Ions With Polyethers In A Quadrupole Ion Trap

Hui-Fen Wu, Jeff Liou and Jennifer S. Brodbelt
Department of Chemistry, University of Texas, Austin, TX 78712-1167

The study of molecular recognition has become an increasingly active area of research over the past two decades due to its fundamental importance in many biological and chemical phenomena . The process of complexation, in which a host and guest selectively bind through various types of interactions, is one particularly intriguing aspect of molecular recognition because many different types of binding interactions, including electrostatic, hydrogen-bonding, and covalent, may be involved, and these forces ultimately direct the stability and structures of the resulting complexes.

In the present study, we have undertaken an examination of the types of complexes formed from reactions of metal ions with a variety of crown ethers and their acyclic analogs in a quadrupole ion trap mass spectrometer. The metal ions are generated by laser desorption from a metal foil or metal salts (calcium, magnesium, gold, iron, copper, zinc, cobalt, nickel, silver, tin), and the complexes are formed by subsequent ion-molecule reactions with neutral ethers. Various collision-activated dissociation (CAD) techniques are used to evaluate the structures of both the metal/polyether complexes and sandwich type complexes which contain two polyethers bound to a single metal ion. Ligand-exchange methods were performed to establish the relative order of ligand binding energies for the polyethers. Finally, a comparison of the behavior of transition metal complexes to alkali and alkaline earth metal complexes is made with respect to aspects of host-guest binding.

All experiments were performed in a Finnigan quadrupole ion trap mass spectrometer (ITMS) equipped with a probe-mounted fiber optic laser desorption assembly. Metal ions were generated by pulsed laser desorption of a metal foil or of metal salts applied to a stainless steel sample tip. A Nd: YAG laser operated in the Q-switch mode at 532 nm and 1064 nm provided the desorption pulse. The metal ions are stored in the ion trap and allowed to undergo reactions with neutral polyethers. The metal/polyether complexes are mass-analyzed by operating the ion trap in the mass selective instability mode. A helium buffer gas pressure of 2 mtorr is used to assist in collisional cooling of the complexes The CAD spectra of the metal complexes were obtained by applying a small AC voltage (500 - 1000 mV_{p-p}) across the end-cap electrodes at a q value of 0.3 for 5 - 10 ms.

I: Formation of Metal$^+$/Polyether complexes

In order to compare the reactions of metal ions with polyethers, ion-molecule reactions between metal ions and the polyethers were examined. Typical product spectra are shown in Figures 1-2.

Reactions with Magnesium and Calcium Ions

Many of the reactions between Mg^+ and the crown ethers or glymes result in incorporation of H_2O or a small organic neutral. The C_2H_4O unit is a common skeletal portion of the polyethers Interestingly, reactions of Mg^+ ions with the glycols do not result in hydrated adducts. The lack of H_2O incorporation and general absence of the diverse array of products noted for the crown ethers and glymes may be attributed to the different binding nature of the terminal hydroxy groups.

The results for the reactions of Ca^+ with the polyethers demonstrates that hydration of the complexes does not occur. This absence of hydration may reflect the reduced charge density of Ca^+ ions relative to Mg^+ ions, such that a water molecule is not as strongly electrostatically bound to Ca^+ as to Mg^+.

Reactions with Copper Ions

The major product ions include $(M + Cu)^+$ and $(2M + Cu)^+$, but fragments ions from these complexes are not observed. The dimer ion $(2M + Cu)^+$ is only observed for those crown ethers that have cavity diameters smaller than the diameter of the Cu^+ ion. This result is attributed to a cavity size effect in which the addition of a second polyether ligand can not occur for those $(M + Cu)^+$ complexes in which the copper ion may be completely encircled by the crown ether skeletal, making the coordination of another ether molecule to the copper ion unfavorable.

Reactions with Iron Ions

Many more types of product ions are formed from the reactions with iron ions, and some of these are best rationalized as involving iron insertion into C-C or C-O bonds. Interestingly, the simple dimer ion, $(2M + Fe)^+$, is not observed for several of the polyethers, but instead a dissociation product, $(2M + Fe - C_2H_4)^+$, is formed.

II: CAD spectra of Metal/Polyether Complexes

Each metal/polyether complex was subjected to collisional activation in order to evaluate the types of dissociation reactions that the complexes undergo. The CAD spectrum of the $(12\text{-crown-}4 + Mg^+ + H_2O)$ ions is shown in Figure 3 as one example. Common losses from the complexes of the crown ethers and glymes include losses of several C_2H_4O units.

III: Comparison of Polyether Complexes With Alkali vs. Alkaline Earth Metals

Collisionally activated dissociation of the $(M + Alkali)^+$ complexes results in production of the bare alkali metal ion. These CAD results underscore the fact that the alkali metal/ether complexes are bound by weak electrostatic forces only. CAD of the polyether/alkaline earth complexes shows that the metal ion always remains attached to the polyether fragment. Thus, the alkaline earth metal/ether complexes are bound by very strong electrostatic and/or partially covalent forces. The difference is that the alkali metal ions have inert np6 electronic configurations. For the alkaline earth metal ions, the ionic ns1 configurations promote very strong ion-dipole electrostatic forces and may allow some partial covalent bond development.

HYDROGEN BONDING INTERACTIONS AND SELECTIVE ION-MOLECULE REACTIONS IN HOST/GUEST CHEMISTRY IN A QUADRUPOLE ION TRAP

Jennifer S. Brodbelt, Hui-Fen Wu, and Chien-Chung Liou, Department of Chemistry, University of Texas, Austin, TX 78712-1167

The ability to examine host-guest chemistry without the influence of solvent effects opens up new avenues for understanding some of the fundamental details of molecular recognition. Intermolecular and intramolecular hydrogen-bonds are arguably the most important interactions in molecular self assembly and molecular recognition. Recently we have undertaken a comprehensive study of hydrogen-bonding interactions in host-guest chemistry in the gas phase with a series of polyethers as model hosts. The model of hosts of interest include the simple crown ethers and their acyclic analogs: the polyethylene glycols and their di-ether counterparts, the glymes, and the more complex "lariat" dibenzo crown ethers with pendant side groups. The latter class of polyethers not only prove to be an interesting set of models for evaluation of multi-site binding interactions but also allow detailed studies of site-selective ion-molecule reactions.

I. Evaluation of Hydrogen-Bonding Interactions

To study the effects of hydrogen-bonding interactions in gas-phase host-guest complexes, proton-bound complexes between a crown ether and amine were formed in a quadrupole ion trap and then probed by CAD. The extent of fragmentation attributed to polyether C-C and C-O bond cleavages is related to the strength and number of hydrogen-bonding interactions of the complexes. Dissociation of many of the ammonium and 2-ethanolammonium ion complexes results in extensive fragmentation of the polyether ligands, especially for the larger crown ethers and glymes. The relative extent of polyether skeletal cleavage increases with the number of oxygen binding sites of the ether. The observation of extensive fragmentation of the acyclic ether ligands supports the idea that the flexible acyclic ligands may participate in the types of multiple bonding interactions already described for the pre-organized crown ethers.

Most interestingly, some of the crown ethers show less extensive fragmentation overall than their acyclic counterparts. For example, the ammonium ion complex involving tetraglyme shows an abundance ratio for $(M + H)^+$: Σ (Fragment ions) equal to 4:5, whereas the ratio is only 5:4 for 15-crown-5 and 7:3 for tetraglycol. The hydrogen-bonds in the tetraglyme complex may be collectively more favorable than those in the 15-crown-5 complex because tetraglyme is a more flexible ligand which can wrap around ammonia whereas ammonia is too large to fit in the cavity of the more rigid 15-crown-5. Also, the kinetics for dissociation may be sufficiently slower for the floppy acyclic ligands, allowing correspondingly more energy accumulation during collisional activation and permitting greater competition from slower dissociation pathways.

In general, the glycols show the lowest extent of skeletal cleavage. This result may be related to the fact that glycols have terminal hydroxyl groups which participate in different types and/or strengths of hydrogen-bonds than do the ether functional groups, thus altering the dissociation dynamics of the complexes. Clearly, the fact that glycols don't exhibit the same extent of skeletal fragmentation as either the crown ethers or glymes indicates that kinetics alone cannot explain the differences in fragmentation patterns because the glycols are also floppy ligands which would be expected to promote slower dissociation kinetics (and thus a corresponding increase in skeletal decomposition).

II. Orders of Gas-Phase Basicities and Ammonium Ion Affinities of Lariat Ethers

There has been great interest recently in the design and evaluation of new and more structurally complex polyethers as ligands for size-selective metal binding. For example, a new class of proton-ionizable macrocycles with pendant groups, termed "lariat ethers" have been synthesized (see Table 1). It is believed that the addition of the pendant groups onto the macrocyclic structures assists in the selectivity and strength of cation complexation due to the ability of the pendant group to stablize the resulting complex in solution via secondary electrostatic interactions. We have measured by ligand exchange methods the gas-phase basicities and ammonium ion affinities of a series of these interesting lariat ethers. The order of increasing is: 7 > 3 > 8 > 6 > 1 > 5 > 2 > 4. The ethers with carboxylic acid pendant groups typically show the lowest gas-phase basicities, whereas the ones with

ester pendant groups show higher basicities. Generally, the ethers with two pendant groups demonstrate higher affinities than those with one or no pendant groups.

III. Site-Selective Ion-Molecule Reactions of Lariat Ethers

The products from reactions of dimethyl ether ions, $(CH_3OCH_3)H^+$ and $CH_3OCH_2^+$, with the lariat ethers are shown in Table 2. Each lariat ether is protonated by protonated dimethyl ether, but only those ethers with a β-hydrogen at the center methylene position may form the diagnostic $(M + 13)^+$ product ion. Those with two pendant substituents, such as compounds **3**, **5**, and **7**, do not form these products. Interestingly, only those macrocycles with phenyl substituents may undergo this reaction. The phenyl groups are inductively electron with-drawing, thus making the methylene carbon atoms more acidic and facilitating the necessary proton migration.

CONCLUSIONS

1) The nature of hydrogen-bonding interactions can be evaluated by examination of CAD spectra for polyether/ammonium complexes. The collective binding interactions of complexes involving acyclic ethers are greater than those involving crown ethers for bulky ammonium ions.

2) The formation of multiple hydrogen-bonds can have striking effects on the dissociation behavior of polyether/ammonium ion-complexes because the multiple hydrogen-bonding interactions allow formation of strongly-bound complexes with relatively large barriers to dissociation.

3) Lariat ethers provide additional information about the structural features which enhance complexation of model hosts in the gas phase. Macrocycles with pendant side groups assist in stabilization of the ionic complexes.

4) Site-selective ion-molecule reactions occur at the methylene position of substituted lariat ethers only if a β-hydrogen is available, thus specifically identifying the nature of this portion of the macrocycle.

RECOGNITION OF CHIRAL AMMONIUM SALTS USING CHIRAL CROWN ETHER HOSTS IN THE GAS PHASE[1]

David V. Dearden, In-Hou Chu, and XueJun Yu
Department of Chemistry and Biochemistry, Box 19065
The University of Texas at Arlington, Arlington, Texas 76019-0065

Introduction. Although mass spectrometry is an excellent technique for determining molecular weights and atom connectivities, it is still a poor means of determining 3-dimensional molecular conformations. Our research group is exploring ion-molecule interactions from the perspective of host-guest chemistry, in hopes of finding ion-molecule reactions which can be used as conformational probes. In this quest, the ability to recognize chiral molecules, and to distinguish enantiomers, is an important and long-sought goal. Although our previous work has successfully shown that host-guest size relationships are important in ion-molecule chemistry, most of those studies have involved atomic ions as guests. Herein we describe some of our efforts to extend our studies into the realm of molecular recognition, using small molecular ion guests. In particular, we note a chiral host-guest system which displays molecular recognition in its ion-molecule chemistry.

Experimental. These experiments employed a Fourier transform ion cyclotron resonance mass spectrometer (Extrel FTMS-1000) equipped with two temperature-controlled direct-exposure solid sample probes. Ligands such as 18-crown-6 or its chiral analog dimethyldiketopyridino-18-crown-6 were introduced into the vacuum chamber on the solid probes. In most experiments, the probes were left at ambient temperature, although the chiral ligands were heated to about 90° C to achieve adequate vapor pressures. Volatile guests and guest precursors (such as water and ammonia) were introduced using precision variable leak valves Guest ions were formed using 70 eV electron impact, followed by a delay to allow proton transfer to generate the hydronium or ammonium ions of interest. The relative initial rates of proton attachment to the two ligands being compared were determined and used to obtain the relative vapor pressures of the two ligands. Equilibrium constants for transfer of guest molecules between two hosts were determined using the host pressure ratios and equilibrium signal intensities for the host-guest complexes. Equilibria were approached from both directions to ensure attainment of true equilibrium conditions.

Results and Discussion. Equilibrium constants for transfer of a number of ammonium ions, as well as H_3O^+, from 18-crown-6 to 21-crown-7 are as follows. ammonium, 11.8 ± 1.9; methylammonium, 2 0 ± 0.2, n-butylammonium, 1.5 ± 0.2; benzylammonium, 0.64 ± 0.03; 2-propylammonium, 0 28 ± 0.04; *t*-butylammonium, 0.07 ± 0.01; hydronium, < 0.01 (transfer was observed in the forward direction only). Among the ammonium ions, a clear trend emerges: as steric bulk increases, *K* for transfer from the smaller host to the larger host decreases. This is a counterintuitive result, especially in light of the fact that *K* is smallest for the sterically smallest guest, hydronium. It is possible that *K* is sensitively dependent on the H-X-H bond angle of the guest (X = N or O). Molecular modeling studies and earlier experimental work suggest that 18-crown-6•H_3O^+ complexes are especially stable due to the C_3 symmetry axes present in both host and guest which allow formation of 3 linear hydrogen bonds

Equilibria for transfer of *R*- and *S*-α-(1-naphthyl)ethylammonium ($NapEt^+$) ions between achiral 18-crown-6 and the chiral analog *S,S*-dimethyldiketopyridino-18-crown-6 were also characterized. Both guests bind more strongly to 18-crown-6 than to the chiral ligand, probably because of greater conformational flexibility and the lack of electron-withdrawing substituents in the case of 18-crown-6. There is a large difference in equilibrium constants for the *R*- and *S* enantiomers (130 ± 15, and 570 ± 70, respectively), indicating a high degree of chiral recognition in this system. If a temperature of 350 K is assumed, this corresponds to a free energy difference of 4.2 ± 0.4 kJ mol^{-1} between the complexes of the two enantiomers with the chiral host, the *R*-$NapEt^+$ complex being more stable. This compares with free energy differences of 2.3 ± 0.5 and 4.6 ± 0.8 kJ mol^{-1}, respectively, in methanol and CD_2Cl_2 solutions,[2] suggesting that strongly solvating achiral solvents such as methanol disfavor the interactions which lead to recognition, while weakly-solvating media give results similar to those observed in the gas phase.

FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRIC INVESTIGATION OF GAS PHASE CRYPTATE COMPLEXES

Qizhu Chen and David V. Dearden, Department of Chemistry and Biochemistry,
The University of Texas at Arlington, Arlington, Texas 76019

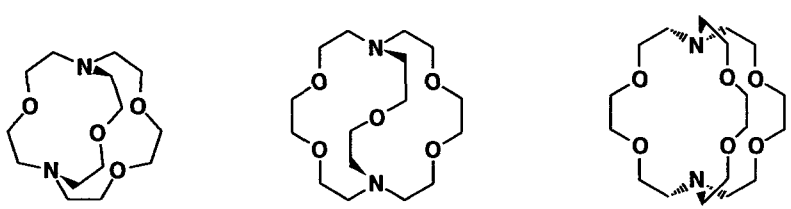
Introduction

Cryptands are well known host-guest ionophores. These 3-dimensional ligands are capable of ion encapsulation, because they have cage-like structures. The complexation of cryptands with mono- and divalent cations in solution has been extensively studied. However, there is little or no information about the attachment of alkali metal cations to multidentate cryptand ligands in the gas phase. In the present work, we investigate the underlying factors governing the complexation of alkali metal cations by cryptands. These studies provide evidence that non-covalent attachment can be crucially dependent on the size relationship between the cation and the binding site of an organic host molecule. Fourier transform ion cyclotron resonance mass spectrometry was used to probe the thermochemistry of cation transfer between multidentate macrocyclic crown ethers and cryptand ligands with systematically varying binding cavity size. The relative cation affinities of cryptands and crown ethers of similar size were determined.

Experimental

All measurements in this study were performed using a Fourier transform ion cyclotron resonance mass spectrometer (Extrel FTMS-1000). Alkali metal cations were introduced into the trapping cell via laser desorption using an excimer-pumped dye laser (Lambda Physik LPX 205i/FL 3002). The neutral ligands were introduced into the vacuum chamber through a variable leak valve or by using a mini-tube set in the center of a solid sample probe. Figure 1 shows the structures of cryptands used in this work. Initial rates of proton attachment to the two ligands being compared were measured to determine the relative pressures of the ligands, and this information was used to determine equilibrium constants for cation transfer between the ligands.

Cryptands



[2.1.1] [2.2.1] [2.2.2]

Results and Discussion

The complexation of cryptands with alkali metal ions in the gas phase has been studied. "Sandwich" 2:1 ligand:metal complexes were observed for cryptand[2.1.1] with K^+, Rb^+ and Cs^+, but only 1:1 complexes were seen for Li^+ and Na^+, suggesting that the latter two small cations enter the binding cavity of cryptand[2.1.1].

As shown in Table 1, among the cryptands, cation affinities were found to be in the following sequences: [2.2.2] > [2.1.1] > [2.2.1] for Li^+, [2.2.1] > [2.2.2.] > [2.1.1] for Na^+, and [2.2.2] > [2.2.1] > [2.1.1] for K^+, Rb^+ and Cs^+ ions. These results can be rationalized on the basis of size-selective complexation by the ligands.

Table 1

Thermodynamic parameters for alkali metal ion transfer reactions between cryptands.

Reaction	Cations	log*K*	ΔG / kJ mol^{-1}
$[M(C_{211})]^+ + C_{221} \rightleftharpoons [M(C_{221})]^+ + C_{211}$	Li^+	-0.18(0.08)	1.17
	Na^+	1.63 (0.09)	-10.9
	K^+	2.51 (0.07)	-16.8
	Rb^+	1.43 (0.10)	-9.58
	Cs^+	1.23 (0.03)	-8.24
$[M(C_{211})]^+ + C_{222} \rightleftharpoons [M(C_{222})]^+ + C_{211}$	Li^+	0.23(0.12)	-1.53
$[M(C_{221})]^+ + C_{222} \rightleftharpoons [M(C_{222})]^+ + C_{221}$	Na^+	-0.02 (0.03)	0.15
	K^+	1.67 (0.20)	-11.2
	Rb^+	1.71 (0.13)	-11.5
	Cs^+	1.94 (0.05)	-13.0

Standard deviations for repeated measurements in parentheses. T = 350 K.

The spatial arrangement of the donor groups was also be observed to be important, in that the 3-dimensional cryptands were observed to have larger cation affinities than crown ethers with the same number of donor atoms. For example, complex stabilities were observed in the following orders: (Na^+[2.1.1]) > (Na^+18C6), and (K^+[2.2.1]) > (K^+21C7).

INFLUENCE OF LIGAND POLARIZABILITY AND LIGAND FLEXIBILITY ON MULTIDENTATE ATTACHMENT OF ALKALI METAL CATIONS: KINETICS AND THERMOCHEMISTRY OF CATION BINDING BY ISOMERS OF DICYCLOHEXANO-18-CROWN-6

In-Hou Chu and David V. Dearden, Department of Chemistry and Biochemistry, The University of Texas at Arlington, Arlington, TX 76019-0065

Introduction:

This work extends our earlier studies of molecular recognition in gas-phase ion-molecule reactions, which have shown that size relationships between neutral hosts and alkali metal ion guests can have profound influences on the kinetics and thermochemistry of the host-guest interactions.[1] For maximum cation binding, the ligand must be flexible enough to allow optimum arrangement of the electronegative heteroatoms around the bound ion. Further, in the gas phase, increasing the number of donor groups in a simple ligand such as a crown ether increases its ability to strongly bind cations. In solution, on the other hand, a much more complicated model is required to predict relative binding affinities due to trade-offs between the intrinsic host-guest interactions and increased solvation energy as the size of the ligand and number of donor groups increases. In addition, kinetic studies imply that ligand polarizability plays a large role in gas phase cation attachment processes.[1] To further explore the relationship between ligand polarizability, ligand flexibility, and cation binding affinity, we have undertaken a study comparing the cation binding properties of 18-crown-6 (18C6) and two isomers of the alkyl substituted ligand dicyclohexano-18-crown-6 (DC18C6). The latter two isomers have the same number of donor groups as the unsubstituted crown, but are less flexible than 18C6 due to addition of the cyclohexyl groups. If ligand flexibility is the determining factor, we would predict that the DC18C6 isomers should bind alkali metal ions less strongly than 18C6. On the other hand, alkyl substitution greatly increases the polarizability of these ligands relative to 18C6 (DC18C6, 39.1 $Å^3$; 18C6, 25.9 $Å^3$, both estimated using the method of atomic hybride components[2]), so if polarizability dominates, we expect the substituted ligands to bind the ions more strongly. Finally, the two DC18C6 isomers, *cis*-syn-*cis* and *cis*-anti-*cis* (referred to hereafter as "syn" and "anti", respectively), differ in the arrangement of the cyclohexyl substituents around the plane of the ligand. It is of interest to determine whether the two isomers can be distinguished mass spectrometrically through their ion-molecule chemistry, and whether guest cation size effects play a role.

Experimental:

Alkali metal cations were generated by laser desorption from salts inside a Fourier transform ion cyclotron resonance mass spectrometer (Extrel FTMS-1000) The two ligands to be compared were introduced into the vacuum chamber on direct-exposure probes, and their relative pressures were determined by measuring the relative rates of proton attachment.[1,3] Crown ether-alkali metal complexes were isolated, and the metal transfer reaction between the two ligands was allowed to come to equilibrium. Equilibria were approached starting from both of the isolated ligand-metal complexes to ensure the attainment of true equilibrium conditions. Equilibrium constants were determined from the product of the ratio of the two ligand pressures times the relative intensities of the two complex ion peaks.

Results and Discussion:

Equilibrium constants for cation exchange reactions between DC18C6 and 18C6 or 21C7 are summarized in Tables 1 and 2. Both DC18C6 isomers have higher alkali metal

cation affinities than 18C6, and in some cases, even the extra donor atom of 21C7 cannot provide it with higher Li^+ or Na^+ affinities than the DC18C6 isomers. These observations clearly indicate that ligand polarizability is more important than flexibility for these ligands. The syn isomer forms more stable alkali metal complexes than the anti isomer, which is consistent with solution results[4] and suggests that the spatial arrangement of the donor groups and ligand flexibility do play a significant role.

Rate constants for cation transfer from 18C6 to DC18C6 were also determined (Table 3). The constants are always larger for the syn isomer than for the anti isomer, suggesting that the arrangement of donor atoms in the syn isomer is better suited for metal binding than in the anti isomer. In general the smaller cations transfer more readily than the larger ones. We are currently performing molecular modeling studies of these systems to gain further insight.

Table 1. Equilibrium constants for $18C6M^+ + DC18C6 \rightleftharpoons DC18C6M^+ + 18C6$

	Li^+	Na^+	K^+	Rb^+	Cs^+
(*cis*-syn-*cis*)DC18C6	*	552 ± 48	7.3 ± 0.6	6.6 ± 0.6	3.4 ± 0.2

FOURIER TRANSFORM ION CYCLOTRON RESONANCE MASS SPECTROMETRIC INVESTIGATION OF CALIXARENES AND THEIR COMPLEXES WITH METAL AND ORGANIC CATIONS IN THE GAS PHASE

Xuejun Yu, Qizhu Chen, Philip Wong and David V. Dearden, Department of Chemistry and Biochemistry, The University of Texas at Arlington, Arlington, Texas 76019-0065.

Introduction

Calixarenes are cyclic ligands consisting of ortho-linked phenol units, which are often studied in solution as biomimetic molecules capable of selective cation binding and as model agents for drug delivery. In a search for gas phase systems exhibiting molecular recognition, we have investigated para-tert-butylcalix[4]arene (PTBC4), shown in Fig.1, and its binding properties using Fourier transform ion cyclotron resonance mass spectrometry. To probe the intrinsic guest-host chemistry between PTBC4 and metal or organic cations, we have undertaken a study of these complexes. For organic cations, the kinetics and thermochemistry of complexation with PTBC4 were investigated. The relative cation affinities of PTBC4 and crown ethers of similar size were also determined.

Calixarene macrocycles serve as receptor models because of their conformational flexibility and the presence of multiple binding sites. These conformations are very important to the study of their host-guest chemistry. PTBC4 has four conformations which are referred to as "cone," "partial cone," "1,2-alternate," and "1,3-alternate" conformations. Due to very favorable electrostatic interactions, only the cone conformation (Fig. 2) is observed for PTBC4 in the solid state. There are at least two cation binding sites (endo and exo).

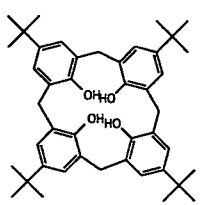

Fig. 1. *p*-tert-butylcalix[4]arene (PTBC4)

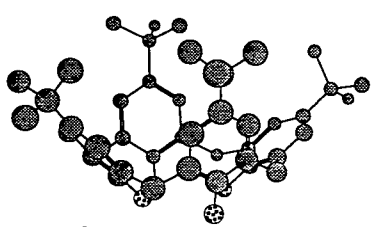

Fig. 2. Cone conformation of PTBC4.

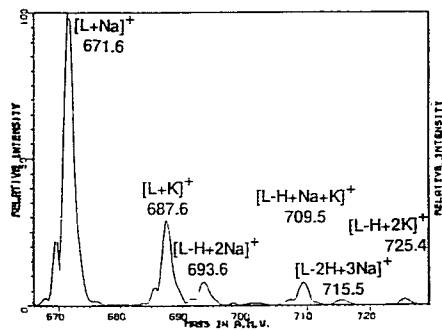
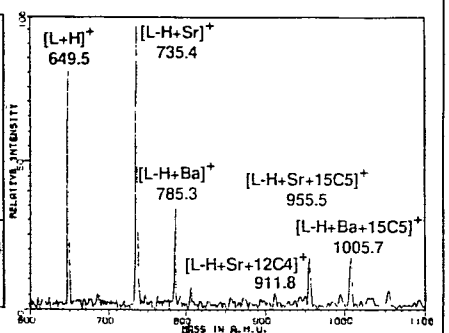
Experimental

All experiments were performed using a Fourier transform ion cyclotron resonance mass spectrometer (Extrel FTMS-1000). Metal cations were desorbed into the gas phase using an excimer pumped dye laser (Lambda Physik LPX 205i/FL 3002). Organic cation precursors and PTBC4 were introduced separately into the chamber via small capillary tubes mounted in the center of a temperature-controlled probe tip. Volatile ligands were introduced into the chamber through a variable leak valve. The relative pressures of the two receptors being compared were determined by measuring the initial rates of proton attachment to them. This information was used with the relative intensities of the two host-guest complex peaks to determine equilibrium constants for guest transfer reactions between the two hosts.

Results

The mass spectra of Fig.3 and Fig.4 show that thermally desorbed PTBC4 can complex with laser-desorbed alkali or divalent metal cations to form mono-metal and bis-metal PTBC4 ion complexes. Complexes of PTBC4 with Na^+, K^+, Rb^+, Cs^+, Ba^{2+}, Sr^{2+}, and Fe^{2+} were observed in 1:1 stoichiometry. In the case of the divalent cations, complexation was accompanied by loss of a proton, such that the overall charge of the complex was +1. Similarly, complexes consisting of two alkali metal ions bound to PTBC4 with loss of one proton were seen, as was a complex involving three Na^+ ions with the loss of two protons.





Reactions of PTBC4 with benzylammonium cation were of particular interest, since in this case "ditopic" binding, involving interactions between the ammonium group and the phenolic oxygens of the calixarene, as well as π-π stacking interactions between the calixarene and the guest, is possible. From competition experiments involving cation transfer between PTBC4 and crown ether receptors of similar size, it was observed that the benzylammonium affinity of 15-crown-5 is larger than that of PTBC4, but that the benzylammonium affinity of PTBC4 is similar to that of 12-crown-4.

Acknowledgments

We are grateful for the support of the Robert A. Welch Foundation (Y-1214); the donors of the Petroleum Research Fund, administered by American Chemical Society (24657-G5); and the National Science Foundation (CHE-9221224).

CHIRAL FAB MASS SPECTROMETRY

Masami Sawada, Yasuo Okumura, Yoshio Takai, Hitoshi Yamada, Takahiro Kaneda, and Shigetoshi Takahashi
Material Analysis Center, the Institutue of Scientific and Industrial Research, Osaka University, Ibaraki, Osaka 567, Japan

Enantioselective host-guest complexation has been demonstrated using FAB mass spectrometry. Among several crown ethers, modified chiral crowns **1** and **3** differentiate a chiral alkyl ammonium ion guest such as 1-(1-naphtyl)ethylammonium ion **4** or phenylalanyl ion **5**. On the other hand, chiral crown **2** does not differentiate it.

Relative peak intensity (RPI) method has been principally applied to the evaluation of such host-guest complexations, where the peak intensity of the target host (M)-guest (A^+) complex ion, $[I(M+A^+)]$, is compared to that of the internal standard host (R)-guest (A^+) one, $[I(R+A^+)]$.

$$M + (R+A)^+ \rightleftharpoons (M+A)^+ + R \qquad (1)$$

Here, R is a selected internal standard achiral host, and is added to an equimolar amount of M. Therefore, these two host-guest complex ion peaks appear simultaneously in a FAB mass spectrum. The RPI value is defined as $[I(M+A)^+/I(R+A)^+]$, and might be regarded as a measure of the degree of the ammonium ion transfer equilibrium (eq. 1).

$$M + (R+A_{(R)})^+ \rightleftharpoons (M+A_{(R)})^+ + R \qquad (2)$$
$$M + (R+A_{(S)})^+ \rightleftharpoons (M+A_{(S)})^+ + R \qquad (3)$$

The present enantioselectivity is characterized by the RPI ratio value, $RPI_{(R)}/RPI_{(S)} = [I(M+A_{(R)})^+/I(M+A_{(S)})^+]$, in the range of 1.2 to 1.6, as shown in Table 1 and Fig. 1. The RPI ratio value of 1.0±0.1 is regarded as non-enantioselectivity of the target host. The observed preference of the (*R*)-enantiomer guest ((*R*)-**4** or (*R*)-**5**) is compatible with (i) CPK model examinations toward chiral crown **3** and (ii) related coloration results.

With chiral crown **3**, a close correspondence exists between the enantioselections of FABMS/RPI values and strictly related solution phase energetics

in association equilibria, indicating the potential applicability of the FABMS/RPI approach. The usefulness of this RPI method for searching a new type of enantioselective host compounds has been demonstrated.

Table 1.

GAS PHASE REACTIONS OF THE GROUP 11 IONS WITH SMALL ALKANES

E.E. Ward and W.S. Taylor
Department of Chemistry, University of Central Arkansas, Conway AR 72035
Lucia M. Babcock and Tonya L. McNeal
Department of Chemistry, University of Georgia, Athens, GA 30602

INTRODUCTION

The gas phase reactions of metal ions with small organic species have been the subject of much discussion.[1,2] In the reactions of metal ions with alkanes, an excited association complex is initially formed which can subsequently eliminate small molecules such as H_2 or CH_4. Alternatively, sufficient numbers of collisions between the excited complex and an inert third-body can result in the formation of a stabilized adduct. Access to both the bimolecular and three-body product channels is strongly influenced by the electronic configuration of the metal.[3,4] Significant variation in reactivity can also occur among ions possessing analogous electron configurations.[5] In this work, we have carried out the reactions of Ag^+ and Au^+ with C_2H_6, C_3H_8, and n-C_4H_{10}; and Cu^+ with C_2H_6. The focus of this work is to examine trends in the reactivity of isovalent ions in an environment where both bimolecular and three-body chemistry can occur.

EXPERIMENTAL

The reactions listed above were carried out at room temperature in a flowing afterglow reactor (FA) equipped with a glow discharge ion source.[6] Reactant ions were produced in the discharge as a result of a sputter-bombardment process and injected into the FA along with a carrier gas (He). The reaction environment in the FA is one in which the reactants experience many collisions with the carrier gas. Thus, three-body product channels can be observed as well as bimolecular channels. Further, this environment is one in which only exothermic reactions can occur.

RESULTS AND DISCUSSION

The reactions described here display significant variation, with Au^+ exhibiting facile elimination chemistry not observed with Cu^+ or Ag^+. The systems involving Cu^+ and Ag^+ form the adduct exclusively, while only the reaction with C_2H_6 produces the adduct when Au^+ is the reactant ion. Interaction of Au^+ with all three alkanes yields bimolecular products. In the reaction of Au^+ with C_2H_6, the bimolecular ionic product is $Au^+ \cdot C_2H_4$, which indicates the elimination of H_2. Reaction of this ion with both C_3H_8 and n-C_4H_{10} yields $C_3H_7^+$ and $C_4H_9^+$ respectively - both consistent with the formation of AuH. This product channel has been observed previously for reactions involving Au^+ using ICR techniques.[7] Overall second-order rate constants for the reactions involving Cu^+ and Ag^+ display pressure dependencies (see Figure 1), whereas the Au^+ rate constants are pressure-independent. For reaction with a given alkane, the rate constants

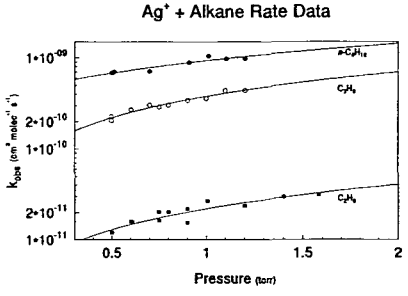

Figure 1

for Ag^+ are approximately an order of magnitude lower than those for Cu^+. In addition, the overall rate constants for Ag^+ increase with the size of the alkane.

Using readily available thermochemical data, it can be shown that formation of the neutral metal hydride is exothermic only for the reactions of Au^+ with C_3H_8 and n-C_4H_{10}, and only when the product ions are i-$C_3H_7^+$ and sec-$C_4H_9^+$ respectively. In the reaction of Au^+ with C_2H_6, AuH formation

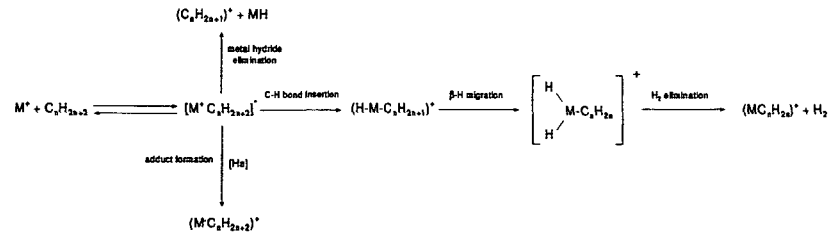

Figure 2

is endothermic, but H_2 elimination is observed in addition to formation of a three-body product. This product channel is also exothermic for the reaction of Cu^+ with C_2H_6 but is not observed in the FA due to the presence of a kinetic barrier most likely arising from C-H bond insertion.[8] Our results suggest a similar situation exists when Ag^+ is the reactant ion. Elimination of H_2 in the Au^+ reaction indicates that this kinetic barrier is lower for this ion; however, some barrier to reaction must exist since H_2 elimination competes with adduct formation. Thus, access to the H_2 elimination channel appears to subject to *kinetic* control, whereas formation of the neutral metal hydride is subject to *thermodynamic* control. The behavior of the systems discussed here can be described by the mechanism shown in Figure 2, which incorporates all observed product channels. It is probable that MH formation occurs directly from the initial association complex, since C-H bond insertion represents a barrier to reaction. Formation of MH after this step would likely result in a competition between this channel and formation of the adduct.

Transition Metal Ion Reactions with Laser Desorbed Amino Acid and Peptide Neutrals in a Fourier Transform Mass Spectrometer

Ping P. Wang, Cindy C. Pitsenberger, J. Paul Speir, Gregory S. Gorman*, I Jonathan Amster
Department of Chemistry, University of Georgia
Athens, Georgia, 30602

INTRODUCTION

We have previously reported the reactions of transition metal ions with laser desorbed amino acids neutrals in a Fourier transform mass spectrometer.[1] For these prior experiments, the metal ions were formed by laser ablation of a suitable metal target and were allowed to undergo thermalizing collisions with a single pulse of a bath gas (Ar) resulting in 40-60 collisions/ion. Since many of the metal ions possess long lived excited states, this relatively low number of collisions proved to be insufficient for collisional thermalization of the metal ions to their ground state. Attempts to increase the number of collisions resulted in substantial ion loss due to the expansion of the ions' magnetron radius. Here we report the application of a new technique, quadrupolar excitation,[2] in which the metal ions are subjected to tens of thousands of thermalizing collisions with a bath gas thereby significantly reducing the population of excited state ions with less than a 1% loss in ion intensity

EXPERIMENTAL

All experiments were performed in a Fourier transform mass spectrometer designed and constructed in this laboratory and equipped with an electromagnet operated at a field strength of 1 tesla. Neutral amino acid molecules were produced using the substrate-assisted technique in which 248 nm (KrF) light from an excimer laser is focused onto the sample probe at an irradiance of approximately 1 MW/cm^2.[3] Transition metal ions were produced by laser ablation of a metal target using multiple pulses of 248 nm light at irradiances $\geq$ 10 MW/cm^2 Pulsed valves were used for introduction of the collision gas into the vacuum system. Quadrupolar excitation was performed by applying a r.f quadrupolar electric field to cause interconversion of magnetron and cyclotron motion resulting in tens of thousands of thermalizing collisions between the metal ions and the collision gas. Additionally, this technique axializes the metal ions, moving them to the center of the ICR cell, directly in front of the sample probe, which enhances overlap between the laser desorbed neutrals and the metal ions.

RESULTS

Figure 1 shows the effects of quadrupolar cooling on the reaction of mass selected $^{65}Cu^+$ with laser desorbed phenylalanine molecules. In Figure 1a, in which quadrupolar cooling was not used, the reaction between the metal ions and the amino acid neutrals results exclusively in charge exchange. In Figure 1b, in which quadrupolar cooling was used, we observe metal ion attachment with subsequent loss of the elements of formic acid. The absence of any charge exchange products in Figure 1b suggests that quadrupolar cooling effectively reduces the internal energy of the metal

ions. Figure 2 shows the reaction of quadrupolar cooled, mass selected $^{63}Cu^+$ with phenylalanine neutrals. This spectrum is identical to that in Figure 1b, except that all the peaks appear two mass units lower confirming Cu ion attachment to these ions

Chemistry of NO and CO Ligands on MCo_n^+ clusters

Yongqing Huang and Ben S. Freiser*
H. C. Brown Laboratory of Chemistry
Purdue University
West Lafayette, IN 47907

The highly reactive nature of small gas-phase transition metal clusters is not only reflected by their abilities to activate a variety of chemical species in the gas-phase, but also by the rich chemistry of their ligated systems where uniquely interesting ligand structures are sometimes observed. One such example is a chemisorbed nitrosyl ligand in Co_nNO^+.[1] This study examines the chemistry of CO and NO coordinated to small heterodinuclear and trinuclear cluster ions with one of the constituent metal atoms being an early transition metal ion, whose strong M-O bond is expected to facilitate dissociated ligand structures.

A. Oxidation of Carbon Monoxide to Carbon Dioxide by Vanadium Oxide Ion

A heterodinuclear complex ion with a CO_2 ligand is formed upon reacting $Co(CO)_3NO$ with VO^+, which is prepared from the reaction of laser desorbed V^+ with O_2, reaction 1. The

(1) $VO^+ + Co(CO)_3NO \longrightarrow VCo(NO)(OCO)^+ + 2CO$ 100% [2]

presence of a CO_2 ligand structure is supported by CID on the isolated product ion from reaction 1, reactions 2-6. The loss of a distinct CO_2 molecule from reaction 3, as opposed to

(2) $VCo(NO)(OCO)^+ \xrightarrow{CID} VCoO(NO)^+ + CO$
(3) $\longrightarrow VCo(NO)^+ + CO_2$
(4) $\longrightarrow VCoO^+ + CO + NO$
(5) $\longrightarrow VO^+ + (Co + NO + CO)$
(6) $\longrightarrow Co^+ + (VO + NO + CO)$

the consecutive loss of CO and an oxygen atom, is verified by the lack of a $VCoNO^+$ fragment upon isolating the product ion from reaction 2 and performing further CID on it. The concurrent loss of CO_2 in reaction 3 and CO elimination in reaction 2 suggest the likelihood of two distinct species for the product ion from reaction 1, with each giving different fragmentation products. Intuitively, an ion with the structure $VCo(NO)(O)(CO)^+$ is expected to give CO elimination readily, reaction 2, while an ion with the structure $VCo(NO)(CO_2)$ is expected to eliminate CO_2 upon CID. Alternatively, the two structures might be very close in energy and interconvert from one structure to the other under CID activation.

Ion-molecule reactions were used to provide further support for the CO_2 structure. Reactions 7-9 were observed upon reacting CH_3CN with the product ion from reaction 1.

(7) $VCo(NO)(OCO) + CH_3CN \longrightarrow VCo(NO)(CH_3CN)^+ + CO_2$ 9%
(8) $\longrightarrow VCo(NO)(O)(CH_3CN) + CO$ 10%
(9) $\longrightarrow VCo(NO)(OCO)(CH_3CN)^+$ 81%

Isolation and subsequent CID of the condensation product ion in reaction 9 gives 19% $VCoNO(CH_3CN)^+$, 13% $VCoNO^+$ and 68% $VCo(NO)(OCO)^+$, suggesting the competitive loss of the acetonitrile ligand.

B. The Structures and Reactivities of NO Ligands

Evidence was presented in an earlier study that the nitrosyl ligand actually exists in both molecularly adsorbed and the dissociated forms in the species Co_2NO^+.[1] This study indicates that this structure may be the favored structure, as opposed to a simple two-electron or three-electron NO ligand for quite a few dinuclear complexes of the ligand. For example, $MCoNO^+$ (M = Sc, Y, La) ions were formed upon reacting $Co(CO)_3NO$ with the respective metal ions. CID on these dinuclear species give MO^+, exclusively, indicating the spliting of the NO ligand under activation. The ion-molecule reactions of several neutral species with $ScCoNO^+$ provided further evidence for the dissociated NO ligand structure. For example, reactions 10 and 11 were observed upon reacting $ScCoNO^+$ with ethylene. Reaction 12 provides another

(10) $ScCoNO^+ + C_2X_4 \longrightarrow ScCoOX^+ + C_2X_3N$ X = H, D
(11) $\longrightarrow ScCoC_2X_3N^+ + OX$

interesting example of a series of unique reactions that give products involving the breaking of the N-O bond.

(12) $ScCoNO^+ + CH_3CN \longrightarrow ScCoOCN^+ + (CH_3N)$

C. Reductive Coupling of Two Nitrosyl Ligands

Simultaneous reduction of two adjacent NO ligands coordinated to small heteronuclear transition metal cluster species occurs. For example, reaction 13 proceeds efficiently upon low energy CID on on $ScCo_2(NO)_2CO^+$, which is prepared from the reaction of $ScCoNO^+$ with

(13) $ScCo_2(NO)_2CO^+ \longrightarrow ScCo_2O_2^+ + CO + N_2$

$Co(CO)_3NO$. Of the two nitrosyl ligands present, only one NO ligand displays reactivity similar to reaction 10-11. For example, the reaction of propene with $ScCo_2(NO)_2CO^+$ gives both ligand displacement of the carbonyl ligand, reaction 14, and products indicating the spliting of the NO ligand, reaction 15.

(14) $ScCo_2(NO)_2CO^+ + C_3H_6 \longrightarrow ScCo_2(NO)_2(C_3H_6)^+ + CO$
(15) $\longrightarrow ScCo_2(NO)(CO)(OH)^+ + C_3H_5N$

The coupled reduction of two NO ligands also occurs for the polynuclear species $ScCo_3(NO)_3(CO)^+$, which is prepared from the reaction of $ScCo_2(NO)_2(CO)^+$ with $Co(CO)_3NO$. $ScCo_3(NO)_3(CO)^+$ readily loses a NO ligand upon CID, with the remaining two NO ligands undergoing reductive coupling and CO elimination to give $ScCo_3O_2^+$. Based on the CID results, it it obvious that multiple patterns of coordination exist for these NO ligands.

In summary, Interesting structures and reactivities are associated with CO and NO ligands coordinated to MCo_n^+ systems with M being an early transition metal atom. The highly reactive nature of the cluster centers definitely plays a key role in promoting these structures and reactivities. Future efforts will focus on using specific ion-molecule reactions to probe unique ligand structures.

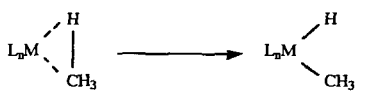
FORMATION OF STRONGLY BOUND TRANSITION-METAL MOLECULAR SILANE COMPLEXES. η^2-COORDINATION OF Si-H

R. Bakhtiar and D. B. Jacobson

Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

The oxidative addition of a Si-H bond to a transition-metal center is an obligatory step in many transition metal-mediated transformations of organosilanes including hydrosilation[1] and silane alcoholysis. Formation of an η^2-Si-H coordination complex (three-center two-electron bond, **1**) is a prerequisite step for formal oxidative addition to yield **2**. Several examples of coordination complexes of **1** have been generated and characterized in solution.[2]



1 **2**

1 is important because it is intermediate toward formal Si-H oxidative addition and is related to the corresponding H-H and C-H three-center two-electron bond complexes.[3] Although Fe^+ reacts with methylsilanes by elimination of simple molecules (H_2 or CH_4),[4] methylsilane adducts can be generated by displacement of CO from $FeCO^+$,

$$FeCO^+ + Me_xSiH_{4-x} \longrightarrow (FeMe_xSiH_{4-x})^+ + CO \qquad (1)$$
$$(x = 0\text{-}4) \qquad \mathbf{3}$$

reaction 1, and it is the exclusive process observed for methylsilanes. **3** may exist either as a molecularly bound iron-silane complex or as an insertion species (e.g., $(HFe\text{-}SiMe_2H)^+$ or $(H_2Fe{=}SiMe_2)^+$ for Me_2SiH_2).

Insight into the structure of **3** can be obtained by studying specific ion/molecule reactions. Ethene and ethene-d_4 react with the silane adducts ($(FeSiH_4)^+$, $(FeMeSiH_3)^+$, and $(FeMe_4Si)^+$) to yield exclusive silane displacement with *no* H/D scrambling observed with ethene-d_4. The silane adduct $(FeMe_2H_2)^+$ yields both adduct formation and silane displacement, reaction 2. Similar results were obtained for reaction with ethene-d_4 with *no* H/D

$$(FeMe_2SiH_2)^+ + C_2H_2 \xrightarrow{0.10} (FeMe_2SiH_2)C_2H_4^+ \qquad (2a)$$
$$(FeMe_2SiH_2)^+ + C_2H_2 \xrightarrow{0.90} FeC_2H_2^+ + Me_2SiH_2 \qquad (2b)$$

exchange. Me_2SiH_2 reacts with $Fe(CH_2CH_2)^+$ to yield both ethene displacement (0.57) and adduct formation (0.43). CAD of the adduct, $(FeMe_2SiH_2)C_2H_4^+$, yields competitive Me_2SiH_2 (0.78) and ethene (0.22) losses at low collision energy. In contrast to the above silane displacement reactions, the $(FeMe_3SiH)^+$ adduct reacts with ethene to yield both silane displacement and formation of $FeSiC_3H_8^+$ (formally a dehydrogenation process), reaction

$$(FeMe_3SiH)^+ + C_2H_4 \xrightarrow{0.74} FeC_2H_4^+ + Me_3SiH \qquad (3a)$$
$$(FeMe_3SiH)^+ + C_2H_4 \xrightarrow{0.23} FeSiC_3H_8^+ + C_2H_6 \qquad (3b)$$
$$(FeMe_3SiH)^+ + C_2H_4 \xrightarrow{0.03} (FeMe_3SiH)C_2H_4^+ \qquad (3c)$$

3. Ethene-d_4 yields similar results with ethane loss exclusively as $C_2D_4H_2$. Reaction of Me_3SiH with $FeC_2H_4^+$ yields competitive adduct formation (0.33) and ethane loss (0.67).

The complete absence of H/D exchange for reaction of the $(Fe\text{-silane})^+$ adducts with ethene-d_4 suggests that insertion into the Si-H bond has *not* occurred. Consequently, the $(Fe\text{-silane})^+$ adducts are believed to consist of molecular silane bound to Fe^+. The displacement of CO from $FeCO^+$ combined with silane displacement from the $(Fe\text{-silane})^+$ adducts by ethene indicate that $D^o(Fe^+\text{-}CO) = 31.3 \pm 1.4$ kcal/mol[5] $< D^o(Fe^+\text{-silane}) \leq D^o(Fe^+\text{-}CH_2CH_2) = 39.9 \pm 1.4$ kcal/mol.[6] The results for Me_2SiH_2 suggest that $D^o(Fe^+\text{-}Me_2SiH_2) \approx D^o(Fe^+\text{-}C_2H_4)$. Hence, Fe^+ forms strongly bound molecular silane complexes with Fe^+! The relative binding energy of the silanes to Fe^+ was determined by silane/silane displacement reactions (e.g., reaction 4).

$$Fe(Me_3SiH)^+ + Me_2SiH_2 \longrightarrow Fe(Me_2SiH_2)^+ + Me_3SiH \qquad (4)$$

These results reveal the following order of relative silane binding energies:

$$\boxed{Me_2SiH_2 > Me_3SiH > MeSiH_3 > Me_4Si > SiH_4}$$

Reaction with mixed deuterated silanes (e.g., $Fe(Me_3SiH)^+$ with Me_2SiD_2) revealed *no* H/D exchange, again consistent with formation of molecular silane-Fe^+ complexes.

We now consider the structure of the $Fe(silane)^+$ adducts. The binding energy of Fe^+ to propane has recently been found to be 19 ± 2 kcal/mol.[7] This binding energy is considerably less than that for the above silanes (> 31 kcal/mol). The strong binding energy suggests that Fe^+ interacts with a Si-H bond instead of a C-H bond of methylsilanes. It has been found that metals that display a weak interaction with C-H bonds may display strong interactions with Si-H bonds. This interaction is presumably in the form of a three-center two-electron bond complex similar to **1**. If the nature of the interaction of the silane with Fe^+ is purely electrostatic, then the binding energy should follow silane polarizability with Me_4Si the strongest bound silane. The above relative order of silane binding energies clearly indicates that the interaction is more complicated than that of a simple ion-dipole model.

Fe-L$^+$ (L = c-C_5H_6, C_4H_6) MEDIATED EXTRUSION OF CO FROM FURAN. A MODEL STUDY RELEVANT TO CATALYTIC HYDRODESULFURIZATION

R. Bakhtiar and D. B. Jacobson

Department of Chemistry, North Dakota State University
Fargo, North Dakota 58105-5516

Catalytic hydrodesulfurization (HDS), hydrodeoxygenation (HDO), and hydrodenitrogenation (HDN) are important processes for hydrotreatment of liquid fuels.[1] HDS of thiophene and sulfides is particularly significant due to the large sulfur content of many petroleum feedstocks The catalyzed removal of heteroatoms from heterocycles typically involves hydroprocessing petroleum feedstocks over an alumina supported cobalt-molybdenum sulfide catalyst. Model systems have been studied involving thiophene, furan, and pyrrole to better understand the mechanism of heteroatom removal. These species were selected for study because they require the most severe conditions for reaction (i.e , heteroatom removal). The reaction of Fe(L)$^+$ (L = C_4H_6, c-C_5H_5, c-C_5H_6, C_6H_6, and O) with thiophene, furan, and pyrrole was studied by using Fourier transform mass spectrometry (FTMS)

Fe^+, Fe(c-C_5H_5)$^+$, and Fe(C_6H_6)$^+$ yield exclusive adduct formation with thiophene, furan, and pyrrole. The chemistry of the iron-diene complexes, $FeC_4H_6^+$ and Fe(c-C_5H_6)$^+$, is considerably more complicated The most intriguing reaction is the predominant, direct extrusion of CO from furan, reactions 1 and 2. A proposed

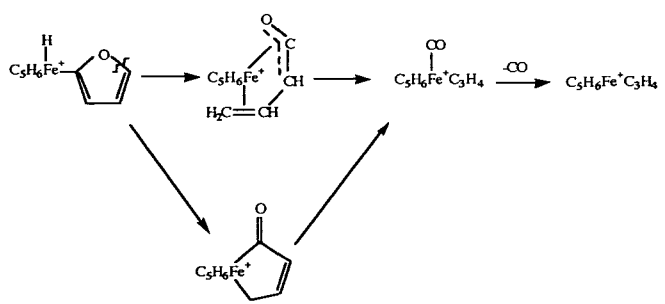
$$FeC_4H_6^+ + C_4H_4O \longrightarrow FeC_7H_{10}^+ + CO \quad (1a)$$

$$FeC_4H_6^+ + C_4H_4O \longrightarrow FeC_7H_8^+ + (H_2CO) \quad (1b)$$

$$Fe(c\text{-}C_5H_6)^+ + C_4H_4O \longrightarrow FeC_8H_{10}^+ + CO \quad (2)$$

mechanism for reaction 2 is presented in Scheme I and involves initial C-H bond insertion. Initial C-O bond insertion is also possible.

Scheme I



The predominant reaction of both thiophene and pyrrole with Fe(c-C_5H_6)$^+$ is displacement of a hydrogen atom which implies D^o(FeC_5H_5)$^+$-L) (L=thiophene, pyrrole) > D^o(Fe$C_5H_5^+$-H) = 46±5 kcal/mol.[2] Thiophene and pyrrole yield predominant adduct formation and C_4H_6 displacement with $FeC_4H_6^+$. CAD of the adduct, Fe(C_4H_6)$C_4H_4S^+$, yields competitive C_4H_6 (ca. 64%) and C_4H_4S (ca. 36%) loses with an analogous distribution

seen for SORI-CAD.[3] These results suggest that D^o(Fe$^+$-C_4H_4S) ≈ D^o(Fe$^+$-C_4H_6) = 48±5 kcal/mol [4] Finally, CAD of the adducts, Fe(C_6H_6)$C_4H_4O^+$ and Fe(C_6H_6)$C_4H_5N^+$, yield exclusive loss of the heterocycle indicating that D^o(Fe$^+$-C_4H_4O) and D^o(Fe$^+$-C_4H_5N) are less than D^o(Fe$^+$-C_6H_6) = 55±5 kcal/mol.[4]

FeO^+ reacts with C_4H_4X (X = S, O, NH) to yield initial CO elimination followed by loss of CO (furan), C_2H_4 (thiophene), and C_2H_4 (pyrrole), reactions 3-5 A general mechanism for CO extrusion for these heterocycles

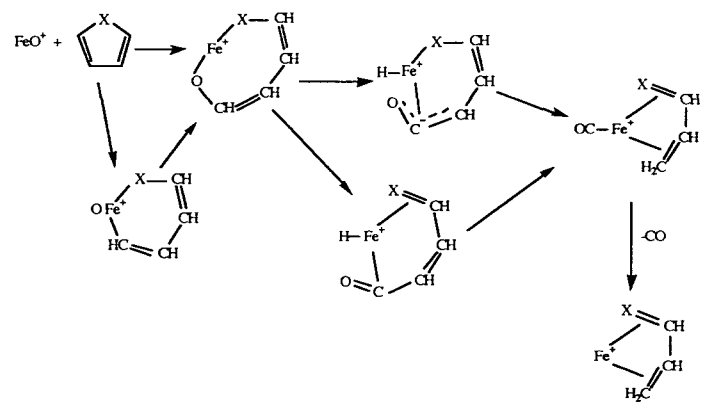
$$FeO^+ + C_4H_4O \xrightarrow{-CO} FeC_3H_4O^+ \xrightarrow{-CO} FeC_2H_4^+ \quad (3)$$

$$FeO^+ + C_4H_4S \xrightarrow{-CO} FeC_3H_4S^+ \xrightarrow{-C_2H_4} FeCS^+ \quad (4)$$

$$FeO^+ + C_4H_5N \xrightarrow{-CO} FeC_3H_5N^+ \xrightarrow{-C_2H_4} FeHCN^+ \quad (5)$$

by FeO^+ is presented in Scheme II and involves initial C-X insertion.

Scheme II



These results indicate that simple iron ion complexes can readily remove the heteroatom from model heterocycles.

Hydrogenolysis Rates of Group 4 Methyl Metallocenes

*N.G. Alameddin, M.F. Ryan, J.R. Eyler, and D.E. Richardson
Department of Chemistry, University of Florida
Gainesville, FL 32611-2046

The chemistry of organometallic molecules in solution has been extensively studied, while in contrast, the gas-phase reactivity of analogous compounds is just beginning to be explored. Our group at the University of Florida has several projects underway to determine the kinetic and thermodynamic properties of organometallic ions in the gas-phase using Fourier Transform Ion Cyclotron Resonance Mass Spectrometry (FTICR-MS). One array of compounds of particular interest is the Group 4 methyl metallocenes. These complexes have been shown to behave as Ziegler-Natta catalysts in solution, where the presence of the solvent can significantly affect the rate of reaction. The goal of this study is to ascertain the intrinsic reactivity of these important compounds in the absence of the solvent.

In the present work the rates of hydrogenolysis (k_H) for a set of cationic complexes of the general formula, $L_2MCH_3^+$ (M = Ti, Zr, and Hf; L = cyclopentadienyl derivatives) are being measured by FTICR-MS. The least sterically demanding reaction possible, the reaction with dihydrogen to produce the hydride and methane (Fig. 1), was chosen to separate the electronic and steric properties of this system. The compounds were synthesized by A.R. Siedle (3M). A glove box is used for all subsequent sample handling and storage of these air- and water-sensitive complexes

In a typical experiment, a sample is attached to the end of a solids probe and inserted into the main chamber, so that the sample is 3-5 cm from the ICR cell. After setting the sample pressure (~1-5 x 10^{-7} torr), a partial pressure of H_2 (~5-10 x 10^{-7} torr) is established. On electron impact, the neutral, $L_2M(CH_3)_2$, loses a methyl group to form the desired ion, $L_2MCH_3^+$ (Fig. 2). Following a thermalization period, all other ions are

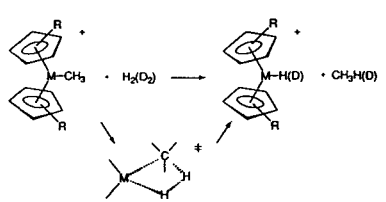

Figure 1

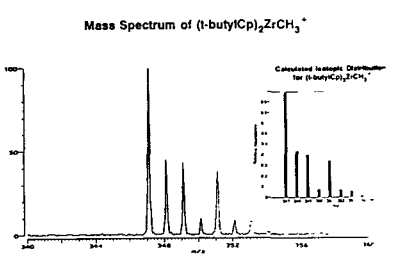

Figure 2

ejected and the substrate is allowed to react with H_2 for a variable time followed by excitation and detection. A pseudo-first order rate constant can be determined by monitoring the disappearance of the reactant and the appearance of the product, L_2MH^+, as a function of time (Fig. 3).

The rate constants are plotted against the sum of the γ parameters [1], a dimensionless parameter quantifying the relative metal-ligand electronic interaction for substituents on cyclopentadienyl (Cp) ligands (Fig. 4). The trend which is becoming apparent (albeit from four points) is that the rate decreases with decreasing γ values. The γ parameters from the ruthenocene study show a decrease in ionization potential with decreasing γ values. Electron-rich substituents (negative γ values) stabilize the oxidation of the substituted ruthenocenes relative to Cp_2Ru. The reactivity of the Zr complexes depends on the electrophilicity of the metal center, and the hydrogenolysis rate is expected to increase with increasingly positive γ values This prediction is illustrated by the three additional points plotted on Fig. 4.

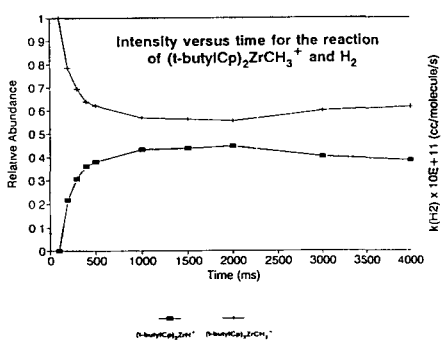

Figure 3

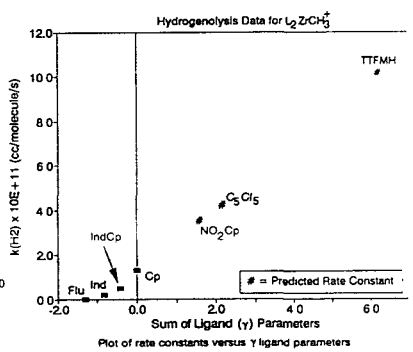

Figure 4

In summary, the hydrogenolysis rate constants for a set of Group 4 methyl metallocenes have been determined. The trend thus far is as expected based on the previously derived ligand parameters In the future, besides continuing the work on the reactivity with H_2, we will explore the reactivity of these complexes with various alkenes and alkynes.

Support for this work by the NSF and the ONR is gratefully acknowledged.

THE CHANGE IN REACTIVITY OF THE $FeCp^+$ ION AFTER COLLISIONAL THERMALIZATION USING QUADRUPOLAR EXCITATION WITH FOURIER TRANSFORM MASS SPECTROMETRY

Cheryl A. Turner, Charles R. Kutal, I. J. Amster
Department of Chemistry, University of Georgia, Athens Georgia, 30602

INTRODUCTION

We are interested in studying the gas-phase ion chemistry of $FeCp^+$ and its thermal reactions with ethylene oxide and other heterocyclic compounds in order to gain a better understanding of its role in the cationic polymerization of epoxides. We previously reported evidence of two channels for the reaction of $FeCp^+$ and ethylene oxide.[1] Electron transfer yields the radical cation, $C_2H_4O^+$, which rapidly abstracts a hydrogen from a second epoxide molecule to form the observed product, $C_2H_5O^+$; oxygen abstraction forms the metal-containing products, $FeCpO^+$ and $FeCpO_2^+$. There are also two reaction pathways for the reaction of tetrahydrofuran (THF) with $FeCp^+$. Coordination forms $FeCpTHF^+$, while electron transfer, followed by hydrogen transfer with a second molecule of THF, yields $C_4H_7O^+$ and $C_4H_9O^+$. We found that the two reaction pathways could be individually enhanced by changing the internal energy of the $FeCp^+$ ion. However, there was not enough physical data on $FeCp^+$ to determine whether the electron transfer reactions were exothermic or endothermic for $FeCp^+$ in its ground electronic state. Recently, Dunbar et. al. determined the bond dissociation energy of $FeCp_2^+ \rightarrow FeCp^+ + Cp$ to be 3.7 eV,[2] thereby allowing a calculation of the recombination energy of $FeCp^+$ (6.7 eV). As a result, the electron transfer reaction between $FeCp^+$ and ethylene oxide or THF is endothermic by more than 2 eV, which suggests that the $FeCp^+$ ion is formed in an electronically excited state. Recently, we have examined the ratio of the two reaction pathways for both of the heterocyles with $FeCp^+$ as a function of the number of thermalizing collisions using quadrupolar excitation,[3,4] and the results of these studies will be discussed here.

EXPERIMENTAL

A Fourier transform mass spectrometer, equipped with a 1-3/4" cubic cell, a 1 Tesla electromagnet, and an IonSpec Omega data system is used in these studies. The gas/liquid inlet system is equipped with three pulsed valves and a sapphire sealed leak valve which are used for introducing volatile samples into the main vacuum chamber. The gas/liquid inlet system is pumped with a diffusion pump and the main vacuum chamber is pumped with a 330 l/s turbomolecular pump to a base pressure of 2×10^{-10} Torr.

The $FeCp^+$ ion used in these experiments is formed by electron ionization of ferrocene, which is pulsed into the main chamber at a peak pressure of 10^{-7} to 10^{-6} torr. The cation is then collisionally thermalized with a pulse of carbon dioxide for 1200 ms using quadrupolar excitation.[3,4] This technique uses an r.f. quadrupolar electric field to cause the interconversion of magnetron and cyclotron motion. If this interconversion is rapid compared to the collision frequency of an ion with neutrals in the ICR cell, then the ion follows a trajectory that pushes it to the center of the cell. Once at the center of the cell, quadrupolar excitation can be used to allow an ion to undergo thermalizing collisions without the occurrence of radial diffusion. Following thermalization of $FeCp^+$, ethylene oxide or other nucleophiles are pulsed into the system and allowed to react for 2500 ms before ionic reaction products are detected.

RESULTS

Figure 1 shows the ratio of products resulting from the reaction of $FeCp^+$ with ethylene oxide, plotted versus the number of thermalizing collisions $FeCp^+$ experiences with CO_2 prior to reaction. The main reaction pathway for no thermalizing collisions or for a large number of thermalizing collisions is oxygen abstraction, however, electron transfer dominates at every point in between those two extremes. The reaction of $FeCp^+$ with THF is found to have a similar response, except that coordination of the THF molecule, not oxygen abstraction, is the main reaction channel for high and low numbers of thermalizing collisions. Since electron transfer is an endothermic reaction for both of the heterocyclic ethers, and should therefore be a slow reaction for the ground state species, its observation shows that $FeCp^+$ is present in an excited state, even after hundreds of thermalizing collisions with a molecular gas. In conclusion, the results show that thousands of thermalizing collisions are required to relax the $FeCp^+$ ion to its ground state. Therefore, methods for trapping ions while they undergo a large number of collisions, such as quadrupolar excitation or a QUISTOR-type event,[5] are needed to quench the surprisingly long lifetimes of the metal complex's excited states.

Gas-Phase Ion Molecule Chemistry of η^4-c-$C_8H_8Fe(CO)_3$: Reactivity and Structure

Ziyi Kan and Melvin B. Comisarow, Department of Chemistry, University of British Columbia
Vancouver, B. C., Canada, V6T 1Z1

Introduction. It has been shown that the fully coordinated aromatic hydrocarbon ligands in (η^4-c-C_5H_5)M^+ and (η^6-c-C_6H_6)M^+ from different sources retain their structural integrity in the gas phase [1]. Our ion reactivity study of organometallic complexes bearing non-aromatic olefin ligands, such as (η^6-c-C_7H_8)$Cr(CO)_3$ [2], (η^4-c-C_6H_6O)$Fe(CO)_3$ and (η^4-c-C_6H_8)$Fe(CO)_3$, has revealed an intramolecular β-hydride transfer process from olefin to metal that lowers ion reactivity. An example is the reaction of (c-C_7H_8)Cr^+ shown in Eqn. (1). In this study, the uncoordinated free diene portion of the cyclooctatetraene in (η^4-c-C_8H_8)$Fe(CO)_3$ is demonstrated to be able to lower ion reactivity by fully or partially coordinating to metal center(s). These observations are of importance to a better understanding of the mass spectra of organometallic complexes.

$$(\eta^6\text{-}C_7H_8)Cr^+ \Leftrightarrow (\eta^7\text{-}C_7H_7)Cr\text{-}H^+ \qquad (1)$$

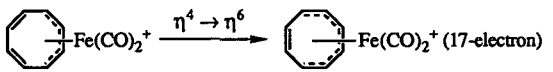
Experimental. A home-built Fourier transform ion cyclotron resonance mass spectrometer equipped with a Nicolet FTMS-1000 console, 2.54 cm cubic trapping cell and 1.9 Tesla electromagnet is used in this study. Sample pressure is maintained at 6.0 x 10^{-7} Torr and monitored by a Varian dual range ionization gauge. 25 eV x 20 millisecond and 2.5 eV x 5 millisecond electron beam pulses are used to generate positive and negative fragment ions, respectively. FT-ICR multiple resonance techniques are used to isolate a single reactant ion to study its reaction pathways. Rate constants for the pseudo-first order reactions between reactive ions and $C_8H_8Fe(CO)_3$ are determined by following the variations of ion intensities with reaction times.

Results and Discussion. The measured rate constants of the major positive fragment ions and ionic products are listed in Table 1. ED in the table is the calculated electron deficiency from an 18-electron closed shell, assuming η^4-C_8H_8 coordination and single metal-metal bonding in polymetallic ions. ED* is the adjusted electron deficiency of rearranged ion structures. The ion reactivity shows increasing trend with increasing electron deficiency of the central metal atoms. Eqn. (2) to (7) summarize the major positive ion molecule reactions determined by ion ejection experiments.

$$C_6H_6Fe^+ + C_8H_8Fe(CO)_3 \rightarrow C_8H_8Fe_2(CO)_2^+ (1) + CO + C_6H_6 \qquad (2)$$
$$\rightarrow C_8H_8Fe_2C_6H_6^+ (2) + 3CO \qquad (3)$$
$$C_8H_8Fe^+ + C_8H_8Fe(CO)_3 \rightarrow C_8H_8Fe_2(CO)_2^+ (1) + CO + C_8H_8 \qquad (4)$$
$$\rightarrow (C_8H_8Fe)_2^+ (3) + 3CO \qquad (5)$$
$$C_8H_8Fe_2(CO)_2^+ (1) + C_8H_8Fe(CO)_3 \rightarrow (C_8H_8)_2Fe_2(CO)_2^+ (4) + Fe(CO)_3 \qquad (6)$$
$$\rightarrow (C_8H_8)_2Fe_3(CO)_2^+ (5) + 3CO \qquad (7)$$

As given in Table 1, the fragment ion $C_8H_8Fe(CO)_2^+$ and the product ions **2-5** in the above reactions are unreactive. As it has been observed repeatedly that 17-electron molecular ions of transition

metal complexes are generally unreactive, we believe that in $C_8H_8Fe(CO)_2^+$, the C_8H_8 ring donates 6 electrons to the metal atom, as shown below.



Since this conversion is driven by the electron unsaturation of the central metal atom, the η^6 coordination mode will remain in the fragment ions $C_8H_8Fe(CO)^+$ and $C_8H_8Fe^+$, which explains why $C_8H_8Fe^+$ and $C_6H_6Fe^+$ have the same reactivity. Similarly, the structures of the ionic products **1-5** are proposed to have partial double metal-metal bonds and η^6-C_8H_8 bonding to one Fe or η^4,η^4-C_8H_8 bonding to two Fe atoms, as appropriate to satisfy the measured ion reactivity. All these coordination forms of C_8H_8 to Fe have been observed directly in neutral complexes [3].

The negative mass spectrum of $C_8H_8Fe(CO)_3$ shows two fragment ions, $C_8H_8Fe(CO)_2^-$ and $C_8H_8Fe(CO)^-$. The reactions of $C_8H_8Fe(CO)^-$ with $C_8H_8Fe(CO)_3$ produce two stable ionic products, $(C_8H_8)_2Fe_2(CO)_3^-$ (**6**) and $C_8H_8Fe_2(CO)_3^-$ (**7**). Their structures are proposed in the following reaction sequence in analogy to the structures of neutral complexes $Cp_2Fe_2(CO)_4$ [4] and (η^4,η^4-C_8H_8)$Fe_2(CO)_5$ [3(b)]. Both **6** and **7** have 17-electron stable anion structures [5].

ACTIVATION OF METAL CARBONYLS BY CHARGE TRANSFER REACTION

Tianlan Zhang and Douglas P. Ridge
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Introduction

Metal carbonyls are interesting as prototypical transition metal coordination compounds and are also used as thermometer molecules in mass spectrometry. Their extent of decomposition following activation is used to measure the efficiency of various activation schemes. One method of activation that has not been thoroughly examined is charge transfer. We outline briefly here experiments intended to probe the effect of activating metal carbonyls by charge transfer. Two types of charge transfer processes have been considered. First we consider process where electronic excitation of the neutral product is not possible (eg. $Ar^+ + M(CO)_n$). Second we consider process where electronic excitation (or decomposition) of neutral product is possible ($N_2^+ + M(CO)_n$).

All measurements were made using a double-cell Fourier transform ion cyclotron resonance instrument (FTMS-2000, Extrel, Madison, WI).

Results and discussion

1. Activation of $Cr(CO)_6$ and $Fe(CO)_5$ by charge transfer reaction with NO^+, CS_2^+, OCS^+, Xe^+, CO_2^+, CO^+ and Ar^+. Rate constants and Branching ratios for these reactions have been obtained. Table 1 and Figure 1 show the rate constants and breakdown plot for $Fe(CO)_5$. These curves are consistent with the best data in the literature on appearance potentials. Comparison with the breakdown plot obtained from PEPICO suggests that nearly all of the reaction exothermicity is deposited in the metal carbonyl ions. The total reaction rate constants are fast (10^{-9} cm^3 $molecule^{-1}$ s^{-1}) consistent with an efficient electron transfer.

2. Charge transfer reaction of $Cr(CO)_6$ and $Fe(CO)_5$ with N_2^+, N_2O^+, O_2^+, Br_2^+, ICN^+ and $BrCN^+$. In these cases electronic excitation of the neutral products is possible. The distribution of $M(CO)_n^+$ products suggests a bimodal reaction. Products corresponding to n=0, 1, 2, 4 and 5 may be observed, for example, but the n=3 products is absent. In one mode the reaction exothermicity ΔH is all deposited in $M(CO)_n^{+\bullet}$ which then decomposes to give the distribution of products expected from PEPICO experiments for internal energy $E^* = -\Delta H$. In the second mode a specific product neutral excited state (N_2 $a^3\Sigma_u$) or specific decomposition products ($N_2(X^1\Sigma_g^+) + O(^1D)$) are formed depositing in $M(CO)_n^{+\bullet}$ the difference between $-\Delta H$ and the excitation or decomposition energy, E. The $M(CO)_n^{+\bullet}$ then decomposes to give the distribution of products expected from PEPICO experiments for internal energy $E^* = -\Delta H-E$. this dramatic bimodal behavior is also observed in the reactions of O_2^+, Br_2^+, ICN^+ and $BrCN^+$. The observed products of the N_2^+ and N_2O^+ reactions are consistent with (though not uniquely consistent with) (1) and (2) below.

$$N_2^+(^2\Sigma_g^+) + Fe(CO)_5 \text{ ---> } Fe(CO)_5^{+\bullet}(E^*) + N_2(X^1\Sigma_g^+, v=3) \qquad E^*=-\Delta H-3h\nu=7.0 \text{ eV}$$
$$\text{---> } Fe(CO)_5^{+\bullet}(E^*) + N_2(a^3\Sigma_u, v=3) \qquad E^*=-\Delta H-E-3h\nu=0.8 \text{ eV} \qquad (1)$$

$$N_2O^+(^2\Pi) + Fe(CO)_5 \text{ ---> } Fe(CO)_5^{+\bullet}(E^*) + N_2O(X^1\Sigma_g) \qquad E^*=\Delta H=4.99\text{eV}$$
$$\text{---> } Fe(CO)_5^{+\bullet}(E^*) + N_2(X^1\Sigma g^+, v=2) + O(^1D) \qquad (2)$$
$$E^*=-\Delta H-E-2h\nu=0.8 \text{ eV}$$

Table 1. Rate Constants of Charge Transfer Reaction

Charge Transfer Reaction	$-\Delta H$(eV)	k/k_{no}
$NO^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + NO$	1.36	1
$CS_2^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + CS_2$	2.20	0.287
$OCS^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + OCS$	3.27	0.269
$Xe^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + Xe$	4.28	0.157
$N_2O^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + N_2O$	4.99	0.364
$CO_2^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + CO_2$	5.87	0.303
$CO^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + CO$	6.11	0.610
$Ar^+ + Fe(CO)_5$ -----> $Fe(CO)_5^+ + Ar$	7.86	0.373

$k_{no} = 6.74*10^{-10}$ cm^3 $molecule^{-1}$ s^{-1} for reaction of NO^+ with $Fe(CO)^5$

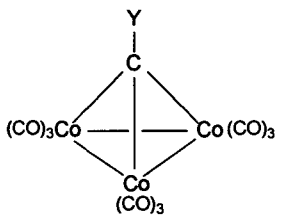
The Chemistry of Methinyltricobalt Enneacarbonyls Radical Anions : Unimolecular and Bimolecular Reactions

David L. Vollmer and M. L. Gross, University of Nebraska-Lincoln, Lincoln, NE 68588
R. Waugh, M. Bruce and J. Bowie, University of Adelaide, Adelaide, South Australia, 5000.



Methinyltricobalt enneacarbonyls are the first examples of heteronuclear cobalt carbonyl clusters[1]. Their stability is indicated by the numerous and facile synthetic routes[2] and can be attributed to the high symmetry of the complexes. The complexes have also been used as catalysts in the reduction of aromatic nitro compounds[3], the hydroformylation of alkenes[4], and the hydrogenation of CO[5].

The synthesis of methinyltricobalt enneacarbonyls was previously shown as the reaction of cobalt tetracarbonyl anion with polyhalogenomethane in the presence of a polar solvent[3]. The mechanism of formation of the cobalt-complexes, however, is not well-understood. Thus, the aim of this study is to investigate the formation of these and higher-order complexes via gas-phase radical anions. The methods for this study are full-scan mass spectrometry, tandem mass spectrometry (MS/MS) and Fourier transform mass spectrometry (FTMS).

The molecular negative ions are absent in the full-scan mass spectra. The principal ions, formed via dissociative electron capture by loss of CO groups, account for nearly 100% of the fragment ions. Each compound shows sequential losses of varying numbers of CO groups; the -Cl derivative loses from one to nine CO groups. The $-CH_3$ derivative, however, has two different fragmentation processes. The first process, similar to the other derivatives, is sequential loss of four CO groups. The second process begins after the loss of three CO groups and involves loss of [nCO + 2H (or H_2)].

CAD spectra of the $[M - 2CO]^-$ for the -H and $-C_6H_5$ derivatives and the $[M - 3CO]^-$ for the -Cl derivative are comparable to those of the negative-ion mass spectra; each shows sequential loss of carbonyl groups with little fragmentation of the YCo_3 moiety (See **Figure 2**). The metastable ion (MI) spectra of $[M - nCO]^-$, where n = 1 - 4, for the $-CH_3$ derivative establish the mechanism of [nCO + 2H] loss to be from $[M - 3CO]^-$ (See **Scheme 1**).

Similar to the negative-ion mass spectrometry experiments, no molecular anions are detected in a normal FTMS experiment, even at low ionizing energy. The principal ions are $[M - 2CO]^-$ for the -H, $-CH_3$, and $-C_6H_5$ derivatives and $[M - 3CO]^-$ and $[M - 4CO]^-$ for the -Cl derivative. Isolation of these radical anions by ion ejection and subsequent reaction delays show that they react with their neutral precursor to form higher-order cobalt

complexes (See **Scheme 2**). The anions also undergo C_2H_2 ligand substitution with one or two CO groups (See **Scheme 3**).

The gas-phase reactions of coordinatively unsaturated metal carbonyl anions ($M(CO)_n^-$; M = Cr, Mn, Fe and Co; n = 0 - 3 and $Co(CO)_nNO^-$; n = 0 - 2) with methyl formate have been studied with Fourier Transform Ion Cyclotron Resonance Mass Spectrometry. The $M(CO)_n^-$ ions were formed either i) in the FT-ICR cell by low-energy electron ionization (EI) on the neutral metal carbonyl compound or ii) by collision-induced loss of one or more CO ligands from the ions generated in an external ion source by EI. The ions formed by collision-induced dissociation were allowed to undergo non-reactive collisions with Ar in order to remove possible excess kinetic/internal energy prior to the reaction with methyl formate.

The products formed in the reactions of the metal carbonyl anions with unlabelled methyl formate are given in **Table I**. No reactions were observed with the $M(CO)_n^-$ (n = 0 , 1) ions and the ions with more than 15 valence electrons. Reactions proceeded in most instances by loss of one or more CO ligands from the collision complex. With the $Mn(CO)_3^-$, $Fe(CO)_2^-$ and $Co(CO)_2^-$ ions, CH_3OH and $[C,H_2,O]$ were also expelled.

Table I. Products formed in the reaction of metal carbonyl anions with unlabelled methyl formate[a)]

Ion	#[b)]	Products[c)]	Losses[b)]	%	Ion	#[b)]	Products[c)]	Losses[c)]	%
$Cr(CO)_2^-$	11	$HCr(OCH_3)^-$	3 CO	<15	$Fe(CO)_2^-$	13	$HFe(CO)(OCH_3)^-$	2 CO	35
		$HCr(CO)(OCH_3)^-$	2 CO	>85			$Fe(CO)_3^-$	CH_3OH	25
$Cr(CO)_3^-$	13	$HCr(CO)_2(OCH_3)^-$	2 CO	95			$Fe(CO)_2(OCH_2)^-$	$[C,H_2,O]$	40
		$Cr(CO)_3(OCH_3)^-$	$HCO^\cdot$	5	$Fe(CO)_3^-$	15	$HFe(CO)_3(OCH_3)^-$	CO	100
$Mn(CO)_2^-$	12	$HMn(OCH_3)^-$	3 CO	<15	$Co(CO)_2^-$	14	$Co(CO)_3^-$	CH_3OH	30
		$HMn(CO)(OCH_3)^-$	2 CO	>85			$Co(CO)_2(OCH_2)^-$	$[C,H_2,O]$	70
$Mn(CO)_3^-$	14	$HMn(CO)_2(OCH_3)^-$	2 CO	50	$Co(CO)(NO)^-$	15	$HCo(NO)(OCH_3)^-$	2 CO	<15
		$Mn(CO)_4^-$	CH_3OH	10			$HCo(CO)(NO)(OCH_3)^-$	CO	>85
		$Mn(CO)_3(OCH_2)^-$	$[C,H_2,O]$	40					

a) No reactions were observed with Cr^-, $Mn(CO)^-$, Fe^-, $Fe(CO)^-$, Co^-, $Co(CO)^-$, $Co(CO)_3^-$, $Co(NO)^-$ and $Co(CO)_2(NO)^-$.
b) Number of valence electrons. c) Assumed structures.

In the reactions of the $M(CO)_n^-$ ions with ^{13}C-labelled methyl formate ($H^{13}CO_2CH_3$), CO as well as ^{13}CO were eliminated. This may be explained as a result of insertion of the metal into both the H-CO and the C(O)-OCH_3 bond of the substrate, forming a five- or six-coordinated intermediate (**Figure I**) which may then expel one or two labelled or unlabelled CO molecules in a statistical ratio as indicated in **Table II**.

Table II. Neutrals formed in reactions with $H^{13}CO_2CH_3$

Ion	Neutrals Lost	Expected	Found	Neutrals Lost	Expected	Found
$Cr(CO)_2^-$	$CO+^{13}CO$ / 2 CO	2/1	1 8/1			
$Cr(CO)_3^-$	$CO+^{13}CO$ / 2 CO	1/1	1.1/1			
$Mn(CO)_2^-$	$CO+^{13}CO$ / 2 CO	2/1	1.8/1			
$Mn(CO)_3^-$	$CO+^{13}CO$ / 2 CO	1/1	1/1	$[^{13}C,H_2,O]$ / $[C,H_2,O]$	1/3	1/2
$Fe(CO)_2^-$	$CO+^{13}CO$ / 2 CO	2/1	1/1	$[^{13}C,H_2,O]$ / $[C,H_2,O]$	1/2	>1/2
$Fe(CO)_3^-$	^{13}CO / CO	1/3	1/3			
$Co(CO)_2^-$				$[^{13}C,H_2,O]$ / $[C,H_2,O]$	1/2	1/1
$Co(CO)(NO)^-$	^{13}CO / CO	1/1	0.25/1			

In the reaction of the ions with $DCOOCH_3$ expulsion of [C,D,H,O] occurred, whereas the reaction with $H^{13}CO_2CH_3$ resulted in a more pronounced loss of $[^{13}C,H_2,O]$ than expected for a statistical process (see **Table II**). This result suggests the occurrence of one reaction leading to the loss of formaldehyde and a competing process in which H_2 and CO are expelled. Moreover, the loss of formaldehyde cannot be explained by a conventional reductive elimination mechanism.

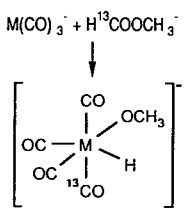

Figure I. Formation of a six-coordinated intermediate

In the reaction of $Fe(CO)_3^-$ with $H^{13}CO_2CH_3$ facile consecutive exchange of all three CO ligands for ^{13}CO was observed in addition to loss of CO/^{13}CO from the collision complex (**Figure II**). This is a unique reaction, which is unlikely to involve formation of a six-coordinated 19-electron intermediate (**Figure I**). The mechanism may be explained for example as oxidative addition to the $^{13}C(O)$-OCH_3 bond and rapid migration of the hydride ligand between the different CO-groups followed by reductive elimination of a methyl formate molecule. The formation of other neutral species is not likely either because of endothermicity, or for kinetic reasons. A possible reason that this novel reaction only takes place with $Fe(CO)_3^-$ may be that initial insertion is very rapid whereas loss of CO, the "exit channel" for the system, is slightly endothermic or has a high kinetic barrier.

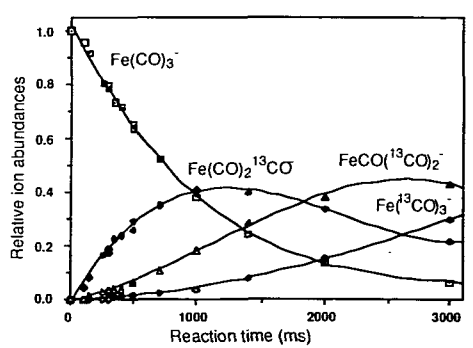

Figure II. Exchange of ligands with ^{13}C-labelled methyl formate

Gas-Phase Ion-Molecule Reactions of $Cr_2(CO)_5^-$ with Ketones and Alkenes

*Larry Sallans, Kelley R. Lane, Robert R. Squires and Ben S. Freiser, Department of Chemistry, Purdue University, West Lafayette, Indiana, 47907

Gas-phase ion-molecule reactions of transition-metal ions and complexes have received significant attention during the last decade. While producing a wealth of important and useful thermodynamic data, these studies have centered predominantly on the reactions of cationic metal species. Nevertheless, anionic species such as atomic metal anions also yield important information (e.g. heterolytic and homolytic metal-hydrogen bond energies).

Previously, we reported the production and proposed structure of $Cr_2(CO)_5^-$ created in the reaction of Cr^- with chromium hexacarbonyl[1]. This study focusses on the reactions of $Cr_2(CO)_5^-$ with ketones, alkenes and other unsaturated compounds. A comparison with $V_2(CO)_3^-$ is also presented.

The reaction between $Cr_2(CO)_5^-$ and 2-pentanone exemplifies the general reaction of the dinuclear species with ketones. Through the use

$$Cr_2(CO)_5^- + CH_3COCH_2CH_2CH_3 \longrightarrow (C_5H_{10}O)Cr_2(CO)_4^- + CO \qquad \text{(eq1)}$$

of deuterated ketone samples and comparisons with alkene reactions, the neutral loss in eq1 originates by CO loss from the ligated chromium. The product ion may represent a simple adduct bound to the bare chromium or, as CID results demonstrate, may involve C-H insertion for additional coordination to the metal. A summary of the reaction and CID results for various ketone reactants are given in Table 1.

TABLE 1. Reaction of $Cr_2(CO)_5^-$ with ketones and CID of the product.

Ketone Reactant (N)	Product $(N)Cr_2(CO)_4^-$	CID of $(N)Cr_2(CO)_4^-$ -CO	-H_2	$OCr_2(CO)_x^-$
Acetone	Yes	1	0	x = 2-4
Butanone	Yes	1-3	1	3,4
2-Pentanone	Yes	1-4	1,2	3
3-Methylbutanone	Yes	1,2	1,2	3
4-Heptanone	Yes	---	---	---

Collision-induced dissociation, CID, of the ketonetetracarbonyldichromium species resulted in losses of CO and H_2, and formation of species presumably involving a strong metal-oxygen bond, $OCr_2(CO)_{2-4}^-$. Secondary reactions of $(N)Cr_2(CO)_4^-$ with ketones yield product ions resembling adduct formation stabilized by CO loss, $(N)_2Cr_2(CO)_3^-$. The reaction of $Cr_2(CO)_5^-$ with 2,4-pentanedione yielded product ions corresponding to two and even three carbonyl ligand losses.

Another group of π-donor ligands, alkenes, are also observed to undergo addition to $Cr_2(CO)_5^-$ followed by CO loss. These results are summarized in Table 2. It is interesting to note that

Table 2. Reaction of $Cr_2(CO)_5^-$ with alkenes and related compounds

Alkene Reactant (N)	Product $(N)Cr_2(CO)_4^-$	CID of $(N)Cr_2(CO)_4^-$ -CO	-H_2
Propene	No	---	---
1-Butene	Yes	1	1,2
Methylpropene	Yes	1	1,2
3-Methyl-1-butene	Yes	1,2	1,2
1-Pentene	Yes	1	1,2
2,3,3-Trimethylbutene	No	---	---
trans-2,4-Pentadiene	Yes	1,2	1,2
Cyclohexene	slow	1,2	1[a]
Cyclooctene	No	---	---
1,3-Cyclooctadiene	Yes	1-3	1-3
1,5-Cyclooctadiene	Yes	1-3	1-3
Benzene	No	---	---
Propyne	Yes	1	1

[a]Loss of C_6H_8 and C_6H_{10} also observed

a number of alkenes are unreactive. There is no explanation that easily rationalizes this observation, however, the π-bonding energy of the ligand in relation to the metal-carbonyl bond strength is currently being investigated.

In comparison, the dinuclear species, $V_2(CO)_3^-$, reacts more vigorously with 2-pentanone (eq2). It appears that these reactions are

$$V_2(CO)_3^- + CH_3COCH_2CH_2CH_3 \longrightarrow \begin{cases} (C_5H_6O)V_2(CO)_2^- + 2H_2 + CO \\ (C_5H_6O)V_2(CO)^- + 2H_2 + 2CO \\ OV_2(CO)_2^- + CO + (C_5H_{10}) \end{cases} \qquad \text{(eq2)}$$

more energetic than the corresponding $Cr_2(CO)_5^-$ reactions since the products in the vanadium system correspond to similar reaction products in the chromium system upon collisional activation. In analogy to ketones, $V_2(CO)_3^-$ reacts with 1-pentene to form products that are characterized by CO loss and extensive dehydrogenation.

Correlation Between Gas Phase Electron Affinities, Reduction Potentials and Catalytic Activities of Halogenated Metalloporphyrins

H. L. Chen, P. E. Ellis, Jr., T. Wijesekera, T. E. Hagan, S. E. Groh, J. E. Lyons and D. P. Ridge
Department of Chemistry and Biochemistry and Center for Catalytic Sciense and Technology, University of Delaware, Newark, DE 19716. Sun Refining and Marketing Co. P. O. Box 1135, PA 19061

Polyhalogenated metalloporphyrins have been the object of a number of recent studies because of their potential as selective oxidation catalysts. The activity of such heme-based biological oxidation catalysts as cytochrome P-450, suggested that metalloporphyrins might be effective homogeneous oxidation catalysts. Readily available iron tetraphenylporphyrin (FeTPP) is essentially ineffective as a catalyst for air oxidation of alkanes to alcohols, but halogenated FeTPPs have been found to be effective and selective catalysts for conversion of isobutane to t-butanol. Both the stability and activity of the catalysts increase with extent of halogenation. In probing the origin of the dependence of catalytic activity on halogenation it was found that catalytic activity increase with the Fe(III) to Fe(II) reduction potential of the catalyst. The importance of the reduction potentials of halogenated FeTPPs led us to measure their gas phase electron affinities. We give a preliminary report of the results of those measurements here.

A FT-ICR was employed to do all the experiments. The measurements were done using the same methods that were used to measure the electron affinities of nickel porphyrins[1]. Syntheses of the halogenated porphyrins have been described elsewhere[2]. Electron affinities of halogenated FeTPPs are listed in table 1. Also listed are the condensed phase reduction potentials for the halogenated FeTPPCl (Fe(III) to Fe(II)) and the halogenated FeTPP (Fe(II) to Fe(I)). It is evident from table 1 that the electron affinities and the reduction potentials vary together. The electron affinities are plotted against the reduction potentials in Figure 1. The Fe(II) to Fe(I) reduction potentials vary approximately linearly with the electron affinities of the neutral halogenated FeTPP. The data for Ni(II) to Ni(I) reduction potentials and the corresponding electron affinities from our earlier study fall approximately on the same line. The Fe(III) to Fe(II) reduction potentials vary approximately linearly with the halogenated FeTPPCl electron affinities, but the line through the III-II data is not collinear with the line through the II-I data. Several of the Fe(III) porphyrins are more easily reduced in solution than would be expected from the gas phase electron affinities. This suggests that reduction of the Fe(III) species is mediated by some solvent effect. One possibility is that on reduction the Fe(III) species reversibly lose the axial chlorine as Cl^- which as an atomic ion has a high energy solvation. The solvent effect also decreases the range of reduction potentials for Fe(III) species (0.50 V) relative to their electron affinities (1.25 eV). The gas phase electron affinities thus uniquely provide an unambiguous measure of the intrinsic electrophilicity of the Fe(III) porphyrin complexes. Finally we note that for those cases for which we have the III-II reduction potential, the electron affinity and the catalytic activity, all three quantities are listed in table 1. The three quantities are clearly covariant.

Photoinduced Gas Phase Ligand Switching

R. M. Pope* and S. W.Buckner, University of Arizona

The gas phase photoinitiated ligand switching reaction of $VC_6H_6^+$ with CH_3CN at 604 nm to generate VCH_3CN^+ has been monitored by FTICR. The $V(C_6H_6)^+$ dehydrogenation product of the reaction between thermalized bare vanadium cation and a pulse of cyclohexene was isolated by swept double resonance excitations. Dissociation of the coordinated benzene occurs by a two photon process in the 585-615 nm region. If, prior to the absorption of a second photon, a $V(C_6H_6)^+$ cation with sufficient internal energy encounters a molecule of CH_3CN (used here as a static buffer gas), competitive elimination from the excited collision complex is possible (scheme I). In spite of the fact that $V(C_6H_6)^+$ is energetically more stable than VCH_3CN^+, a .2 branching ratio for C_6H_6 elimination was recorded. The isolated complex $V(C_6H_6)(CH_3CN)^+$ dissociates exclusively to form $V(C_6H_6)^+$ when irradiated with 585-615 nm light. Photodissociation measurements indicate the reaction proceeds on a single minimum potential surface with an endothermic activation barrier.

The mechanism for the associative ligand switching reaction shown in scheme I can be best understood by reference to a simplified potential surface for the reaction, shown in Figure 1. At thermal energies, CH_3CN does not displace benzene from $V(C_6H_6)^+$ ($k^I I < 10^{-13}$ cm^3/mol-sec) because the reaction is endothermic. The adduct, $V(CH_3CN)(C_6H_6)^+$, does form slowly by collisional and/or radiative stabilization. $V(C_6H_6)(CH_3CN)^+$ undergoes photodissociation

$V(C_6H_6)(CH_3CN)^+ + h\nu$ (488, 514 nm) -> $V(C_6H_6)^+ + CH_3CN$ 80% (1)
-> $V(CH_3CN)^+ + C_6H_6$ 20% (2)

with output from the Ar^+ laser via two channels, reactions (1) and (2). The loss of acetonitrile is the main pathway due to its lower activation energy. Photoexcitation of $V(C_6H_6)(CH_3CN)^+$ with 585 to 615 nm light results in exclusive loss of CH_3CN, as previously stated. This is because the activation energy for benzene loss is greater than the photon energy (46-48 kcal/mol). Initial photoexcitation of trapped $V(C_6H_6)^+$ generates an excited ion (~47 kcal/mol internal excitation) which undergoes interconversion to a vibrationally excited level of the ground electronic state. In the low density environment of the ICR trap, this ion can relax by sequential infrared fluorescence or collisional quenching[1]. Absorption of a second photon induces dissociation to form V^+. However, if the vibrationally excited ion collides with CH_3CN, a highly excited $V(C_6H_6)(CH_3CN)^+$ complex is formed. This ion has internal energy equal to the photoexcitation energy plus the energy of coordination of acetonitrile to $V(C_6H_6)^+$, internal energy A in Figure 1. The highly excited $V(C_6H_6)(CH_3CN)^+$ can then partition between the benzene and acetonitrile loss pathways. The benzene loss pathway effectively results in an associative ligand displacement.

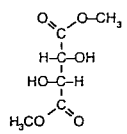
Moscow, Russian Federation

INTRODUCTION

As mass spectrometry extends its mass range to larger and more complex species, the question arises whether previously observed ion/molecule behavior and concepts can be extended to larger systems. In this study, three very different ion/molecule reactions involving the neutral Dimethyltartrate (DMT) were studied. This compound approaches a size where geometric factors could be affecting ion/molecule processes. This may be reflected in the fact that the DMT dimer has been found to exhibit an interesting chirality effect.



Dimethyl-L-tartrate

EXPERIMENTAL

A Brucker CMX-47 ICR mass spectrometer equipped with a 4.7 T magnet was utilized. The 3cm cell was of cylindrical symmetry and V_t= 3V. The DMT sample was commercially obtained (Fluka AG) while the deuturated (DMTd6) form was synthesized by a reesterfication with CD_3OH. The samples, introduced by separate leak valves, were thoroughly pumped by the high vacuum so as to remove any condensed gases and to fully saturated the vacuum system. A Balzers IMR-132 ionization gauge was utilized for pressure determination. Effort was made to keep ion densities low and comparable for all pressures. Ion ejection was by short (1-10ms) fixed frequency pulses. At the end of the kinetic reaction period the ion of interest was excited by a single frequency pulse and detected in a narrow band heterodyne mode. Repeat experiments with a different excitation pulse were made for each monitored ion. Kinetic delay times were sampled cyclically to give a large number of accumulated transients which allowed an averaging over slow signal variations. Peak heights were taken as proportional to ion intensities.

PROCEDURE

Preliminary Ion: All three reactions of interest are preceded by the electron impact ionization of DMT (or DMTd6) to form ions of presumed formula $C_3H_6O_3$ ($C_3H_3D_3O_3$).

$$\text{DMT (DMTd6)} \quad \text{---}(e^-)\text{--)} \quad 90^+ \ (93^+)$$

Reaction 1: Fragment ions m/e 90 reacts with precursor DMT neutrals to form the protonated DMT species ("self CI").

$$90^+ + \text{DMT} \ \text{---}k_1\text{--)} \ 179^+ \qquad \text{rxn. 1}$$

In the case of the deuterated sample

$$90^+(93^+) + \text{DMTd6} \ \text{--}k_1\text{-)} \ 185^+$$

Reaction 1 is presumed an exothermic process occurring with unit efficiency and is used to determine the collision rate (k_c=k_1/Pt).

Reaction 2: The protonated DMT species undergo proton exchange with the neutral precursor bath gas.

$$185^+ + \text{DMT} \ \text{---}k_2\text{--)} \ 179^+ \qquad \text{rxn.2a}$$
$$179^+ + \text{DMTd6} \ \text{---}k_2\text{--)} \ 185^+ \qquad \text{rxn.2b}$$

To follow the exchange process one of the ion species is ejected from the cell by a double resonace pulse. The original ratio (R_i) will be reestablished as follows

$$R(t) = R_i(1-e^{-kPt}) \qquad \text{eqn.1}$$

Reaction 3: Protonated DMT ions can also react to form proton bound dimers by a combination of collisional and radiative stabilization. The three possible dimer species (m/e 357,363,369) then undergo ligand exchange reactions. The mixed dimer is formed as follows.

$$357^+ + \text{DMTd6} \ \text{---}k_3\text{--)} \ 363^+ \qquad \text{rxn.3a}$$
$$369^+ + \text{DMT} \ \text{---}k_3\text{--)} \ 363^+ \qquad \text{rxn.3a}$$

The mixed dimer reacts as follows.

$$363^+ + \text{DMT} \ \text{---}k_3\text{--)} \ 357^+ \qquad \text{rxn.3b}$$
$$363^+ + \text{DMTd6} \ \text{---}k_3\text{--)} \ 369^+ \qquad \text{rxn.3b}$$

When the fraction of deuterated neutrals (f_d) is around .5 the reestablishment of the ion ratios after ejection of either mixed dimer (m/e 363) or both homodimers (357,369) is given by eqn.2.

$$R(t) = 2f_d(1-f_d)(1-e^{-kPt}) \qquad \text{eqn.2}$$

RESULTS AND DISCUSSION

Column 1 of Table 1 summarizes the determined rate constants.

TABLE 1
Experimental and theoretical rate constants

	$k_i(10^{-10}cm^3s^{-1})$	k_i/k_1	R(calc)
rxn.1	1.14	1	1
rxn.2a	.60	.53	.41
rxn.2b	.69	.61	.41
rxn.3	.71	.62	.48

Absolute values are reported assuming no correction for ionization gauge sensitivity - this is unimportant since only relative values are considered. The normalized values relative to reaction 1 are presented in column 2. Column 3 gives theoretical ratios taking into account the statistical factors (1:1/2:2/3) and the reduced mass effect (1:.81:.7) on the collision rate. Within error limits (+-10%) there is reasonable agreement and correlation between the columns. This suggests that all three reactions are occurring at (or near) the upper limit governed by the collision rate. To presume that three very different reactions would proceed at similar less than unit efficiencies is not reasonable. This would be consistant with reactions 2 and 3 forming a long-lived complex on each collision allowing complete randomization before redissociation. This is the same type of behavior as that observed for smaller organic species such as proton transfer with methanol.

A Redermination of the Proton Affinity Scale from Nitrogen to t-Butylamine by Variable Temperature High Pressure Mass Spectrometry.

*J.E. Szulejko and T.B. McMahon

Guelph-Waterloo Centre for Graduate Work in Chemistry, Department of Chemistry, University of Waterloo, Waterloo, Ontario, CANADA N2L 3G1

In 1991, Meot-Ner and Sieck[1] published a High Pressure Mass Spectrometric based Proton Affinity scale which linked several Proton Affinity "primary standards", viz, C_3H_6, i-C_4H_8 and NH_3. The main finding was that the i-C_4H_8...NH_3 Proton Affinity difference was larger by 4.3 kcal mol^{-1} than previously assigned in the NIST[2] database. This finding was subsequently verified by this work (see TABLE). However, the present work Proton Affinity difference of 13.5 kcal mol^{-1} does not support the Meot-Ner Sieck ΔPA of 16.7 kcal mol^{-1} or the NIST ΔPA of 16.4 kcal mol^{-1} between C_3H_6 and i-C_4H_8. The agreement between the Meot-Ner Sieck and present work ΔG^0_{600} scales is excellent from C_3H_6 to about $(C_2H_5)_2CO$. The agreement is only fair between $(C_2H_5)_2CO$ to $(CH_3)_3CNH_2$. The relative Proton Affinity scales are in excellent agreement from i-C_4H_8 to $(CH_3)_2NH$, but are in rather poor agreement elsewhere.

A completely revised PA scale[3] from N_2 to $(CH_3)_3CNH_2$ is presented in the TABLE. The absolute PA of CO, 141.9 kcal mol^{-1} based on Appearance Energy measurements was used as the *Single* PA reference standard for the entire PA scale. Also presented in the TABLE are, (i) most recent G2 *ab initio* Proton Affinity calculations by Smith and Radom[4] (average deviation 0.6 kcal mol^{-1}), (ii) other recent high quality *ab initio* PA calculations, (iii) the NIST PA values and (iv) Proton Affinities derived from Appearance Energy measurements. One of the main findings of this work is that the PA of i-C_4H_8 has to be revised downward by *ca* 4.0 kcal mol^{-1} compared to the NIST PA table which is in part based on the photoionization AE data of Traeger[5]. The earlier photoionization AE study by Ingraham[6] and an electron monochromator study by Lossing[7] on neo pentane are in excellent agreement with the present finding. The present work leaves the PA for NH_3 (203.5 kcal mol^{-1}) very close to the NIST value of 204.0 kcal mol^{-1}, prior ab initio PA calculations and AE data unlike the Meot-Ner Sieck finding of 208.3 kcal mol^{-1}.

Isomers of $CHNO^+$ and the Proton Affinity of NCO at N

Murray J. McEwan, Mark Morrison and Colin G. Freeman
Department of Chemistry, University of Canterbury, Christchurch, New Zealand

Introduction. Four of the most common elements found in the interstellar medium are H, C, O and N. The simplest compound formed from all four is isocyanic acid, HNCO, which has been detected in interstellar clouds and comets, and which is one of several isomeric forms. The radical cations of CHNO, $CHNO^+$ also exist in isomeric forms and at least five structures have been proposed: four acyclic and one cyclic. The order of stability based on ab initio calculations is (ΔH°_f in kJ mol^{-1} in parenthesis)

$HNCO^+$	>	$HOCN^+$	>	c-$HNCO^+$	>	$HCNO^+$	>	$HONC^+$
(1015)		(1165)		(1236)		(1250)		(1407)

This study was undertaken in part to help elucidate the $CHNO^+$ structure of the ion products of the reactions:

$$HNC^+ + O_2 \rightarrow CHNO^+ + O$$
$$HNC^+ + N_2O \rightarrow CHNO^+ + N_2$$

and in part to characterise the reactivity of isomeric $CHNO^+$ ions.

Experimental. A selected ion flow tube (SIFT) was used to investigate the ion-molecule chemistry of $CHNO^+$. Electron impact on one of the species, $H_2NCONHNO_2$, CH_3OCONH_2, $HCONH_2$, HNCO and HNCO polymer generated the $CHNO^+$ ion at m/z = 43. In most cases a mixture of isomeric ions at m/z = 43 were produced as was seen from their decay with appropriate reactants (Figs. 1 and 2).

Results. The $CHNO^+$ ion produced from pure HNCO produced one isomer only which we attribute to $HNCO^+$ (Fig. 1). The curved decay seen in Figure 2 is due to a difference in reactivity between the isomeric forms. The initial fast decay is due to $HNCO^+$ as its proton transfer behaviour with the reactants CH_3Br (PA = 693 kJ mol^{-1}), CS_2 (688 kJ mol^{-1}), CH_3Cl (682 kJ mol^{-1}) and CS_2 (680 kJ mol^{-1}) was identical to that of $HNCO^+$ produced from pure HNCO. The proton affinity of NCO at N established from these reactions was 680 < PA(NCO) < 688 kJ mol^{-1}, which is consistent with tabulated thermochemical data (PA = 669 ± 20 kJ mol^{-1}) and ab initio calculations at the G2 level of theory (PA = 654 kJ mol^{-1}) (Table 1).

The less reactive $CHNO^+$ which was formed by electron impact on all species tried (with the exception of unpolymerised HNCO) exhibited proton transfer with NH_3, $(C_2H_5)_2O$, CH_3COCH_3 but not C_2H_5CN. We conclude from these results that this less reactive isomer will transfer its proton to reactants with PA's in the range 806 – 812 kJ mol^{-1}. None of the known isomers of $CHNO^+$ satisfy these constraints and this isomer has not yet been identified.

The $CHNO^+$ products of the ion-molecule reactions $HNC^+ + O_2$ and $HNC^+ + N_2O$ were each identified as $HNCO^+$.

Table 1. Selected Reactions of $HNCO^+$

			k/(10^{-9} cm^3 s^{-1})
$HNCO^+ + NH_3$	$\xrightarrow{1.0}$	$NH_4^+ + HNCO$	2.2
$HNCO^+ + CH_3Br$	$\xrightarrow{0.85}$	$CH_3Br^+ + HNCO$	1.3
	$\xrightarrow{0.15}$	$CH_3BrH^+ + NCO$

State-Selected Ion-Molecule Reactions in a Quadrupole-Octopole-Quadrupole Mass Spectrometer: Mode-Specific Effects in the Reaction $NH_3^+ + ND_3$

Robert D. Guettler, Glenn C. Jones, Jr., and Richard N. Zare

Department of Chemistry, Stanford University, Stanford, CA 94305-5080

The main goal of our research is to better understand the effect of reactant energy on ion-molecule reactions. In these experiments both the ion vibrational state and kinetic energy are controlled while their effect on product formation is monitored. We have looked in-depth at the ion-molecule reaction system of $NH_3^+ + ND_3$. We have found that product formation in this system has a complex dependence on the ion vibrational state. Distinct differences have been observed between not only ion kinetic and vibrational energy, but also between excitation of differing ion vibrational modes.

This work has been carried out in our quadrupole-octopole-quadrupole mass spectrometer. Ions are generated by intersecting a molecular beam containing the species to be ionized with the frequency-doubled output of a Nd:YAG-pumped dye laser. This ~300-nm laser light prepares the ions in specific vibrational states via (2+1) resonance-enhanced multiphoton ionization (REMPI).[1] The ions are extracted from the molecular beam by a DC quadrupole turning element and focused into a quadrupole mass filter which mass selects the reactant ion. The ions then enter an octopole ion-guide that passes through a collision cell containing the neutral reactant molecule. A second quadrupole mass filter then selects the ion mass to be detected. The octopole ion-guide is essential in insuring that all product ions are collected with nearly uniform efficiency, regardless of their scattered direction and kinetic energy, thus allowing for the direct comparison of product channel intensities. The ratios of the various intensities allow us to calculate product branching ratios and relative cross sections.

The reaction of $NH_3^+ + ND_3$ is seen to have a very interesting dependence on ion reactant energy. By varying both the ion reactant kinetic energy and vibrational state, detailed information regarding the subtle interplay between these two forms of energy is obtained. The three primary product channels of this reaction system are:

$\mathbf{NH_3^+}(v_1,v_2) + ND_3 \rightarrow$	$\mathbf{NH_3D^+} + ND_2$	Deuterium Abstraction
	$NH_3 + \mathbf{ND_3^+}$	Charge Transfer
	$NH_2 + \mathbf{ND_3H^+}$	Proton Transfer

The ammonia reactant ions can be prepared with umbrella bending mode excitation (v_2, symmetric out-of-plane bend) or with combined umbrella and breathing mode excitation (v_1+v_2). We have observed the

[1] W.E Conaway, R.J.S. Morrison, and R N Zare, Chem Phys. Lett 113, 429 (1985).

product channels to show significant sensitivity to the amount of umbrella mode excitation placed into the reactant ion. As the amount of umbrella mode excitation was increased from 0 to 7 quanta, the relative cross sections changed by nearly a factor of two for both deuterium abstraction (enhanced) and proton transfer (attenuated). The same trends were seen with increasing kinetic energy, although the vibrational energy was nearly four times more effective at shifting the reactant intensities.

Of special interest for state-selection of the ammonia ion is a set of nearly isoenergetic vibrational states in which differing amounts of umbrella and breathing motion are excited. The pure umbrella mode ($v_2 = 5$) yields ions with 0.60 eV of vibration energy, while a combination band of umbrella and breathing mode ($v_1 = 1$, $v_2 = 2$) yields ions with 0.66 eV. In addition to depending on the quantity of energy placed into vibration, these experiments show that the intensities of the product channels also depend on the vibrational mode that is excited. At a center-of-mass collision energy of 1.0 eV, the branching ratio for charge transfer decreases from 48 to 37% with stretch excitation, while proton transfer increases from 44 to 57%. The deuterium abstraction branching ratio is slightly attenuated with the stretch excitation.

Although the collection efficiency of the octopole ion-guide is expected to be nearly uniform over the collision energy ranges investigated (1.0-10.0 eV center-of-mass), this cannot be true at all energies. There will be some low collision energy at which the inherent energy spread in the ion beam along with changing collection efficiency will lead to distortions in the measured product intensities. To determine this limit and to rigorously verify our collection efficiencies, we have studied the reaction system of $N^+ + O_2$:

$N^+ + O_2 \rightarrow$	$\mathbf{NO^+} + O$	Oxygen Abstraction
	$N + \mathbf{O_2^+}$	Charge Transfer
	$NO + \mathbf{O^+}$	Anion Abstraction

Electron impact (0.25 mA, 50 eV electrons) was used to generate the N^+ from a beam of N_2. Measuring branching ratios and relative cross sections of the three product channels of this reaction system provides a good test of the instrumental collection efficiency. Comparison of our results to those obtained by techniques that do not utilize RF devices[2] shows that there are no significant biases to collection and detection of the three rather diverse product channels.

The $NH_3^+ + ND_3$ system has demonstrated that vibrational excitation can play an active role in determining product formation in ion-molecule reactions. This influence depends on more than just the amount of vibrational energy, it also depends upon the mode or type of vibration that is excited in the reactant ion. We believe complete interpretation of these results will provide glimpses into the dynamics involved in formation of the different product channels.

Electrophilic Bromination of Gaseous Aromatic Compounds: Mechanism and Linear Free Energy Effects on Reaction Rates

Olga Bortolini
Universita Di Ferrara, Dipartimento Di Chimica, Via Borsari 46, Ferrara 44100 Italy.

Sheng Sheng Yang* and R Graham Cooks
Purdue University, Department of Chemistry, West Lafayette, IN 47907, U. S.A.

Electrophilic bromine cation addition to monosubstituted benzenes is studied using $BrCO^+$ and $CH_3NH_2Br^+$ as reagent ions in a pentaquadrupole mass spectrometer[1]. One aim of this study is to seek a correlation between substituent effects and the extent of gas phase ion/molecule reactions under the non-equilibrium, low pressure and solvent free conditions which pertain in quadrupole collision cells. The electrophile $BrCO^+$ was created by electron ionization of acetyl bromide. The protonated electrophile $CH_3NH_2Br^+$ was generated by chemical ionization of CH_3NHBr introduced via a membrane introduction system[2]. The reactions of monosubstituted benzenes with mass selected $BrCO^+$ are dominated by the addition of Br^+. Reaction normally occurs at the ring and the brominated product fragments by Br loss upon collision induced dissociation (Scheme 1). A linear correlation ($r=0.96$, $\rho=-0.23$) between relative reaction rates of bromine cation addition against Brown's substituent constant σ^+ is reported (Table 1 and Figure 1). Nitrobenzene displays unique behavior, NO_2 substitution by Br^+ occurring (Scheme 2). The reactions of $CH_3NH_2Br^+$ with monosubstituted benzenes are characterized by both bromine cation and proton addition (Scheme 3). A good linear correlation ($r=0.98$, $\rho=-0.56$) is observed between the relative reaction rates of bromine cation addition and the σ^+ value (Table 2 and Figure 2). A Hammett type of correlation for protonation is not observed and this suggests that protonation occurs at the ring in some cases and at the substituent in others. Protonation is shown to take place at the substituent for acetophenone, benzonitrile and nitrobenzene. A linear correlation is observed between the relative rate of protonation and proton affinity of the monosubstituted benzenes (Table 3 and Figure 3). Ion/molecule reaction products were characterized by recording sequential product ion mass spectra (MS^3). Electrophilc reaction proceeds via a σ-complex to the ring as suggested by MS^3 spectra. The greater reactivity of $BrCO^+$ is consistent with its weak Br-CO bond and is evidenced by the fact that it reacts even with the strongly deactivated substrates. The much less negative reaction constants in these reactions ($\rho=-0.23$ and -0.56), compared with the reaction constants in solution[3] ($\rho=-12.14$ in acetic acid and -5.78 in hypobromous), is consistent with the much greater reactivity of the electrophiles ($BrCO^+$ and $CH_3NH_2Br^+$) due to the absence of solvation and counterion effects. .

A Study of the Temperature Dependence of the S_N2 Reactions of Cl^- with Methyl Bromide, Ethyl Bromide and n-Butyl Bromide at Atmospheric Pressure using an Ion Mobility - Mass Spectrometer.

*W. B. Knighton, P. M. O'Connor, J. A. Bognar and E. P. Grimsrud, Department of Chemistry, Montana State University, Bozeman, Montana, 59717.

The study of gas phase ion-molecule (IM) reactions at atmospheric pressure is important, because, in conjunction with parallel low pressure measurements insight can be gained into the factors which control the rates of slow IM reactions. In addition, the nature of the potential energy surface for a given reaction system can sometimes be more easily deduced from measurements performed at higher pressures. For instance, in the high pressure limit, if the rate-determining step of a slow gas phase IM reaction is passage over the transition state of interest, theoretical analysis of the rate data requires only knowledge of the reactants and the rate-limiting transition state - no specific knowledge of the reaction intermediates or other minor transition states along the reaction coordinate is then required. Unfortunately, only a modest level of attention has been given to the development of instrumental methods for the measurement of IM reactions under conditions of very high buffer gas pressures, where essentially any IM reaction would be forced into it's high pressure limit of kinetic behavior.

We have recently constructed an instrument called the Kinetic Ion Mobility - Mass Spectrometer (KIMMS) which provides a means for measuring the rate constants of IM reactions at ambient pressure. In this poster, we describe the application of a temperature-variable version of this instrument to the study of a series of nucleophilic displacement S_N2 reactions between Cl^- and three primary alkylbromides (methylbromide, ethylbromide and n-butylbromide), Reaction 1. Measurements of these reactions at 3 torr using a pulsed high pressure mass spectrometer (PHPMS) are also reported.

$$Cl^- + RBr \rightarrow Br^- + RCl \qquad (1)$$

The KIMMS instrument has been previously been described in detail (K. Giles and E.P. Grimsrud, *J. Phys. Chem.* **1992**, *96*, 6680). Ion-molecule reactions occur in the drift tube between the pulses of ions and the reagent molecules that are seeded in the drift gas. If the mobility of the product ions differ from the reagent ions then the ion arrival time spectrum at the Faraday plate will be modified by the reaction. Analysis of these modified spectra as a function of reagent neutral concentration yields a reaction rate coefficient.

The rate constants (k_1) determined here by the KIMMS for the reactions of Cl^- with EtBr, n-BuBr and MeBr are shown in Figures 1-3, respectively. Also, shown in these figures are measurements obtained in the present study in 3 torr methane buffer gas by PHPMS, along with previous measurements by several other groups using a variety of techniques and buffer gas pressures. For EtBr and n-BuBr both the magnitude of and the temperature dependence of the rate constants do not differ over the pressure range of 3 torr to 1.0 Atm. For MeBr it is noted that the measurements of k_1 obtained at 1.0 Atm are significantly greater than all other measurements at lower pressures.

An approximate representation of the reaction coordinates for the reactions of Cl^- with primary alkylbromides is shown in Figure 4. In the reactions of EtBr and n-BuBr with Cl^- (Figures 1 and 2), it is believed that the initially-formed, chemically-activated intermediate, $Cl^-.RBr^*$, is sufficiently long lived that it suffers numerous collisions with the buffer gas at pressures of 3 torr or above, thereby forming a thermalized intermediate, $Cl^-.RBr$. Therefore, the high pressure limit of kinetic behavior is operative at

both 3.0 torr and 1 Atm for these two reaction systems and k_1 is the same at both pressures. For the reaction of MeBr with Cl^-, however, the chemically-activated intermediate, $Cl^-.RBr^*$, is not believed to be efficiently thermalized at pressures of 3 torr or lower. Therefore, at these low pressures, this system appears to be operating within or near its low pressure limit of kinetic behavior. At 1.0 Atm pressure, the distinctly different (higher) k_1 values indicated by the KIMMS measurements in Figure 3 suggest this reaction system has moved towards its high pressure limit of behavior.

The determination of Transition State (TS) energies ($\Delta E^\ddagger$ in Figure 4) from the rate data obtained in the low pressure limit for the reaction of Cl^- with MeBr is difficult using conventional statistical rate theories because simple S_N2 intermediates, including $Cl^-.MeBr^*$, have recently been shown to behave in an non-statistical manner. However, if the buffer gas pressure is made sufficiently high, so that the reaction of interest is moved into it's high pressure limit, where the intermediate is brought into a state of thermal equilibrium with the buffer gas and reactants, then the rate measurements can be interpreted in terms of conventional TS Theory $k_{TST} = \left(\frac{kT}{h}\right)\left(\frac{Q^\ddagger}{Q_{Cl^-}Q_{CH_3Br}}\right)\exp^{\left(\frac{-\Delta E^\ddagger}{RT}\right)}$ (2). By calculation of the partition functions (Q) for the reactants and the envisioned TS, the T-dependence for the combined preexponential factors in Equation 2 can be predicted. If expressed in the form, $\exp(-\alpha/RT)$, this contribution to the T-dependence of k_1 is found to be α = -0.8 kcal/mol. The magnitude of $\Delta E^\ddagger$, where $\Delta E^\ddagger = E_a - \alpha$, can then be deduced from the experimental Arrhenius activation energies, E_a, derived from plot of ln k versus 1/T (Figures 1-3). The $\Delta E^\ddagger$'s thereby determined for each reaction studied here are included in Figures 1-3. Using $\Delta E^\ddagger$ = -2.3 kcal/mol, predictions of k_{TST} for the reaction of Cl^- with MeBr over the temperature range of 35 to 150°C, are shown in Figure 3 to be within a factor of 2 of the KIMMS measurements.

KINETIC ISOTOPE EFFECTS FOR THE S_N2 REACTIONS OF SOLVATED ANIONS WITH METHYL HALIDES.

Thuy Thanh Dang, Charles H. DePuy,
Richard A. J. O'Hair and Veronica M. Bierbaum,

Department of Chemistry and Biochemistry,
University of Colorado,
Boulder, Colorado 80309-0215.

Bimolecular nucleophilic substitution reactions have been the focus of numerous theoretical and experimental studies in recent years due to their central importance in organic chemistry. Nevertheless, there has been relatively little experimental work on the gas phase reactions of solvated nucleophiles and no experimental studies of solvent kinetic isotope effects.

We have studied the S_N2 reactions of F^-, $F^-(H_2O)$, and $F^-(D_2O)$ with CH_3X and CD_3X, where X = I, Br and Cl, using the tandem flowing afterglow-selected ion flow tube technique. The displaced halide ion X^- is the sole product in the reactions of F^-, and the major product in the reactions of $F^-(H_2O)$ and $F^-(D_2O)$, where solvated X^- is also formed. The rate coefficients for these reactions are summarized in Table I.

Table I: Rate Coefficients for S_N2 Reactions

	F^-	$F^-(H_2O)$	$F^-(D_2O)$
CH_3I	2.16 (-9)[a]	1.01 (-9)	1.02 (-9)
CD_3I	2.22 (-9)	9.93 (-10)	1.05 (-9)
CH_3Br	2.02 (-9)	5.31 (-10)	6.06 (-10)
CD_3Br	2.04 (-9)	5.73 (-10)	6.68 (-10)
CH_3Cl	1.44 (-9)	1.45 (-11)	2.04 (-11)
CD_3Cl	1.60 (-9)	1.75 (-11)	2.68 (-11)

[a] 2.16 (-9) represents 2.16×10^{-9} cm^3 $molecule^{-1}$ s^{-1}

These results demonstrate that:

1) S_N2 reactivity decreases as the reaction exothermicity decreases, i.e., for a given nucleophile, the rate coefficients decrease in the sequence $CH_3I > CH_3Br > CH_3Cl$.

2) Reactivity decreases with solvation; this effect is most dramatic for CH_3Cl where solvation lowers the rate coefficient by two orders of magnitude.

3) Kinetic isotope effects are absent for extremely rapid reactions but become evident for slower processes where the height of the central barrier is important.

4) Inverse kinetic isotope effects are observed for deuteration of the methyl halide with k_H/k_D as small as 0.76 ($k[F^-(D_2O) + CH_3Cl]/k[F^-(D_2O) + CD_3Cl]$).

5) Inverse kinetic isotope effects are observed for deuteration of the solvent molecule with k_H/k_D as small as 0.65 ($k[F^-(H_2O) + CD_3Cl]/k[F^-(D_2O) + CD_3Cl]$).

These inverse kinetic isotope effects indicate that the zero point energy difference between hydrogen and deuterium is greater in the transition state than it is in the ground state. Future studies will explore the kinetic isotope effects in reactions of nucleophiles involving higher degrees of hydration as well as other solvent molecules.

COMPETITIVE S_N2/S_Ni REACTIONS OCCURING IN THE COLLISION CELL OF TRIPLE QUADRUPOLE FROM LOW KINETIC ENERGY MH^+ AND $[M+NH_4]^+$ IONS PREPARED FROM THE DIASTEREOMERIC 1,2-INDANEDIOLS.

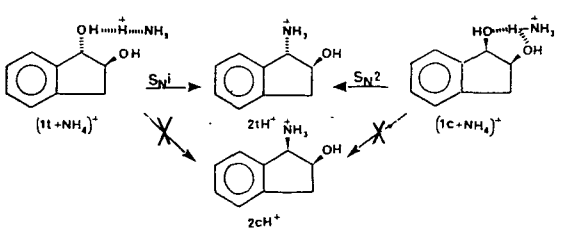
Bourhis, C., Perlat, M.C., Fournier, F. and Tabet, J.C.*

Laboratoire de Chimie organique Structurale,
Department of Molecular Chemistry, U.P.M.C., Paris, FRANCE.

In the gas phase, ion-molécule réactions were commonly investigated by using either FT-ICR and ITMS (more recently) or Pulsed High Pressure Source Mass Spectrometer and Flowing-Afterglow (and SIFT)[1]. Furthermore, these bimolecular processes can be studied under chemical ionization in high pressure source of tandem mass spectrometer and also in collision cell from selected ions having a low kinetic energy (CAR spectra)[2]. Among the different ion-molecule reactions studied by this approach, proton transfer and nucleophilic substitution are typically generated when the basicity of substrat is lower than of ammonia by less 10 kcal/mol. These réactions can compete from alcohols[3] and esters[4] submitted to CI-NH_3.

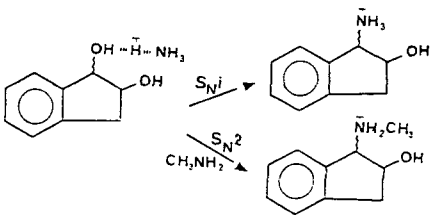
$$\text{i.e.}\quad R\text{-}OH + NH_4^+ \rightleftharpoons [R\text{-}OH...NH_4^+] \begin{cases} \rightarrow R\text{-}OH_2^+ + NH_3 & (a) \\ \rightarrow R\text{-}NH_3^+ + H_2O & (b) \end{cases}$$

Different investigations demonstrated that such adduct $[M+NH_4]^+$ ions in ion source lead to the substituted $[M+NH_4\text{-}H_2O]^+$ ions (case of alcohols) *via* nucleophilic substitution which accompanies the unfavored MH^+ formation. The former process occurs from adduct ions either *via* unimolecular S_Ni mechanism (decomposition with retention of stereochemistry) or bimolecular substitution as the "like S_N2" pathway accompanied by Walden inversion of function configuration.



In the present work, the Nucleophilic Substitution is investigated in collision cell of triple quadripole instrument from adduct $[M+NH_4]^+$ ions prepared from *cis* and *trans* epimers of 1,2-indanediol. Methylamine was used as nucleophilic reagent in the cell in order to react with adduct ions under low collision energy. Dissociation (e.g. S_Ni pattern) and ion-molecule reactions take place in competition at E_{lab}=7 eV as well as at lower E_{lab} values. Among the different

bimolecular processes, $NH_3/MeNH_2$ exchange, proton transfer and S_N2 from $[M+NH_4]^+$ are the major bimolecular reactions. Competition occuring between S_Ni and S_N2 processes is influenced by the experimental conditions according to the collision energy used : laboratory energy, methylamine pressure in collision cell etc... The Reaction products of methylamine on the epimeric MH^+ ions is compared to those observed from the adduct ions but mainly proton transfer occurs and the SN appears inefficient. In particular, orientation of competitive reaction such as SN_2 process and proton transfer to nucleophilic reagent, studied according to similar experimental conditions shows that it is strongly influenced by the energy level of the initial state. On the other hand this means that stabilizing collisions are inefficient in collision cell.



ERMS breakdown from adduct ions $[M+NH_4]^+$ with $MeNH_2$ in collision cell (multiple collision conditions).

INTRODUCTION

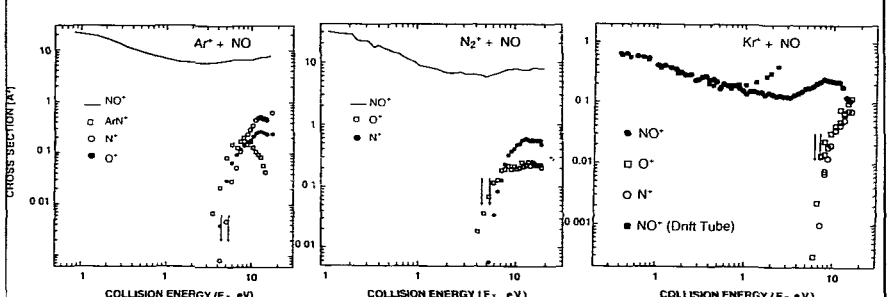
As a consequence of its very low ionization potential (9.26 eV), NO can undergo charge transfer with most atmospheric ions at thermal translational energies. In systems where the charge transfer reaction is very exothermic, the thermal energy reaction rate constant may nonetheless be very small ($k < 10^{-12}$ cm^3-sec^{-1}), which is inconsistent with statistical models for kineticcs of bimolecular reactions. For these charge-transfer reactions where the assumption of energy randomization within a long-lived complex does not apply, alternative models can be considered. The simplest of these invokes two criteria that govern reaction rate constants: *energy resonance* and *Franck-Condon overlap* between reactant and product states. In the present work, we examine the reactions of Ar^+, N_2^+, and Kr^+ with NO at hyperthermal energies, and consider which model best describes the reaction dynamics.

EXPERIMENT

These studies are carried out in a guided-ion beam apparatus.[1] Reactant ions are mass-selected at a Wien filter and injected into an double-octopole beam guide, which runs through a collision cell, where a low pressure of NO gas is maintained. Ionic products are mass-analyzed in a quadrupole mass filter. Time-of-flight distributions are measured by pulsing the reactant ion into the octopole and monitoring flight times of product ions.

RESULTS

Cross sections for the reactions of Ar^+, N_2^+, and Kr^+ with NO are shown below. The total charge-transfer cross sections are significantly less than the Langevin cross section, but below about 1 eV relative translational energy, the energy dependences are similar. In each reaction, N^+ and O^+ fragment ions are also observed at energies above the respective thermodynamic thresholds for dissociative charge transfer.



In the Ar^+ + NO reaction, an additional product is observed, corresponding to ArN^+ or ArO^+ (the mass resolution is not adequate to distinguish these products under the high transmission conditions required to detect this channel).

The TOF distributions are transformed to axial velocity distributions using the methodology of Gerlich.[2] Velocity distributions are shown below for the NO^+ product from Ar^+ + NO at a relative translational energy of 1.16 eV. The distributions on the left is obtained with a low octopole guiding field, such that product ions with large components of radial velocity are not trapped. This distribution can be compared with the one obtained for high octopole guiding field (on the right), in which case all product ions are collected. Inspection of these distributions reveals that while most of the NO^+ product ions are formed with very little axial velocity, there is a significant fraction of products that have velocities equal to or greater than the center-of-mass velocity.

The distributions can be analyzed in terms of an "osculating complex" model, in which collisions result in formation of transient complexes. The angular distribution of the products is determined by the lifetime of the complex relative to its rotational period. In addition to momentum transfer, conversion of translational to internal energy. The experimental distributions are compared to distributions calculated for various complex lifetimes and differing amounts of converted energy, until acceptable agreement between the distributions is obtained. The solid and dashed lines in the figures below are the calculated distributions for the internal energy distribution of NO^+ shown.

Most of the NO^+ product ions that are formed with small velocities are likely due to long-range charge transfer reactions, in which little or no momentum transfer occurs. The faster, forward-scattered NO^+ ions are formed in large-impact parameter orbiting collisions, in which varying amounts of energy are converted from translation to internal energy. It is particularly interesting to note that the NO^+ product ions are all highly excited, with internal energies in excess of 6 eV. These ions are probably formed in the excited electronic *a* state.

Effects Of Reactant Ion Kinetic Energy On Both Endothermic And Exothermic Ion/Molecule Reactions In A Quadrupole Ion Trap Mass Spectrometer

Hui-Fen Wu and Jennifer S. Brodbelt
Department of Chemistry, University of Texas, Austin, TX 78712-1167

Stemming from the first discovery of ion/molecule reactions and the landmark development of chemical ionization, the use of ion/molecule reactions to solve a diverse range of ion structural problems in analytical and organic mass spectrometry has become increasingly widespread. There has been ongoing interest in evaluating the application of endothermic ion/molecule reactions for both fundamental thermochemical and analytical applications. In the gas phase, endothermic ion/molecule reactions require an alternate driving force, and this is typically supplied by accelerating a reactant ion of interest to some particular kinetic energy prior to an ion/molecule collision with a neutral substrate. When sufficient kinetic energy is converted to internal energy during the collision, the barrier to reaction may be surpassed, and product ions may be formed from the intermediate collision complex.

In this study, we have examined a variety of reactions of known endothermicity to determine the feasibility of driving endothermic ion/molecule reactions in a quadrupole ion trap. Both proton-transfer and charge exchange reactions are investigated, and such factors as the activation time, activation voltage, and trapping conditions are described in the context of their effects on the outcomes and efficiencies of endothermic ion/molecule reactions. Additionally, the effects of supplementary activation on the outcomes of exothermic proton-transfer and charge exchange reactions are studied.

All experiments were performed in a Finnigan quadrupole ion trap mass spectrometer. Compounds were admitted into the vacuum chamber to nominally 2 - 5 x 10^{-6} torr. Helium buffer gas was admitted to 1 mtorr. For the reactions, the molecular type ions of one compound were isolated by application of an appropriate combination of dc and rf voltages in order to eject all other ions from the trap. Then during a subsequent reaction interval, the ions were activated by application of a supplementary ac voltage of 0 - 1000 mV_{p-p} across the end-cap electrodes (q_z = 0.2 - 0.6) for 0 - 1000 ms.

Effects of Reactant Ion Kinetic Energy on Endothermic Ion/Molecule Reactions

A survey of various charge-exchange and proton-transfer reactions was performed in order to obtain an initial evaluation of the feasibility of driving endothermic ion/molecule reactions in a quadrupole ion trap. Collisions with either helium or reactant neutrals may lead to two important competing processes, dissociation or neutralization, of the activated reactant ion.

In Figure 1 is shown the endothermic charge-exchange between naphthalene molecular ions (m/z 128) and phenol (net 0.33 eV endothermic). For this experiment, the conditions found to optimize the endothermic reaction consisted of a 20 ms activation period at q_z = 0.35 (600 mV_{p-p} activation at 136,100 Hz). Activation of the naphthalene ions leads to both collisionally-activated dissociation by elimination of C_2H_2 and charge exchange to form phenol molecular ions at m/z 94. The naphthalene fragment ions at m/z 102 do not undergo observable exothermic or endothermic charge transfer reactions with phenol, so evidently the phenol ions must be due to endothermic charge exchange from the naphthalene ions.

Shown in Figure 2 are the spectra illustrating endothermic proton-transfer (18.7 kcal/mole) of protonated propylamine with tetrahydrofuran. Upon activation by a 350 mV_{p-p} voltage (116,700 Hz), protonated propylamine transfers a proton to tetrahydrofuran and does not undergo extensive collisionally-activated dissociation. The conditions found to optimize the formation of endothermic ion/molecule reaction products consisted of a 20 ms activation period at q_z = 0.3.

The effects of activation conditions on competing endothermic ion/molecule reaction and dissociation processes is illustrated in Figure 3 for the case of protonated n-butyl ether. Both n-butyl ether and dimethyl ether were admitted to the vacuum chamber to nominally 4 x 10^{-6} torr. Protonated

n-butyl ether was isolated and activated (q_z = 0.3) by applying a supplementary ac voltage of 0 - 1000 mV_{p-p} for 5 ms. The proton-transfer reaction to dimethyl ether is 11.6 kcal/mole endothermic. The conversion efficiency increases with voltage, reaching a maximum of 6.5 % at 300 mV. At higher voltages, there is a steady decrease in the conversion efficiency, indicating that other competitive dissociation, neutralization and ion ejection processes become more favored.

Effects of Reactant Ion Kinetic Energy on Exothermic Ion/Molecule Reactions

Many exothermic reactions are disfavored as the kinetic energy of the reactant ion increases because the higher velocity of the reactant ion perturbs formation of the collision complex necessary for a successful ion/molecule reaction. Thus, it was of interest to determine whether an increase in the kinetic energy of reactant ions in the ion trap caused observable changes in proton-transfer and charge exchange reactions. For example, shown in Figure 4 is a plot of the relative abundances of the protonated dimethyl ether and protonated n-butyl ether as a function of activation voltage. First protonated dimethyl ether was isolated, then accelerated for 5 ms by application of a supplementary ac voltage (156,000 Hz) from 0 - 800 mV_{p-p}. When protonated dimethyl ether is not activated, it rapidly transfers a proton to n-butyl ether (11.6 kcal/mole exothermic) in the 5 ms interval, and this is represented in Figure 4 by the points of nearly equal intensity at 0 mV activation. With application of a 200 mV supplementary voltage, the abundance of protonated dimethyl ether increases while the abundance of protonated n-butyl ether decreases. At higher voltages, both the abundances of protonated dimethyl ether and n-butyl ether decrease, because the formation of the proton-bound collision complex is disfavored and other ion loss processes occur.

H/D EXCHANGE IN LOW ENERGY COLLISIONS BETWEEN PROTONATED AROMATICS AND D_2O OR CD_3OD

John A. Stone, Department of Chemistry, Queen's University
Kingston, Ontario, Canada K7L 3N6

H/D exchange can be used to count the number of "active" H atoms in a molecule. The use of both a chemical ionization source[1] and the central quadrupole in a triple quadrupole instrument[2] for this purpose have been demonstrated. We have examined H/D exchange in the hexapole collision cell of a Fisons quadrupole/hexapole/quadrupole triple sector instrument to explore the advantages and limitations of using a triple sector instrument.

A grounded chemical ionization source with grounded ion repeller produced protonated molecular ions MH^+ using CH_4 as reagent gas. The MH^+ ions from the first quadrupole were directed into the hexapole RF only cell which can be set at zero or negative integral voltages with respect to the source. The collision gases employed were D_2O, CD_3OD and C_6D_6. Transmitted ions were analysed by the second quadrupole.

The results demonstrate that the extent of isotope exchange depends on the gas pressure, the difference in proton affinity between M and the collision gas, and the translational energy of the ion.

Table 1 shows the extent of deuteration of various MH^+ by D_2O with 0 V on the collision cell. The extent of deuteration decreases in the order benzene >> toluene > xylene with no deuteration observed for mesitylene. This is the order of increasing proton affinity (PA), i.e. the increasing difference in PA between D_2O (167 kcal mol^{-1}) and M. The pattern of M-d_x ions is not as expected from a statistical point of view since their relative intensities do not fall continuously with increasing extent of deuteration. For benzene there is a minimum intensity at M-d_3^+ and for toluene, p-xylene and 2-F-toluene at M-d_2^+. These patterns does not change drastically over the pressure range 1 to 5 x 10^{-3} mm Hg.

Tables 2 and 3 show the results for similar experiments using CD_3OD and C_6D_6 as collision gases. The same behaviour and conclusions apply as for D_2O. Protonated benzene cannot be studied since it proton transfers to CD_3OD and charge exchanges with C_6D_6.

When a negative potential is applied to the collision cell to accelerate the MH^+ ions, the total ion intensity increases, mainly because the intensity of MH^+ increases. However with D_2O the relative intensities of the M-d_x^+ ions show little change until greater than -4 volts is applied to the collision cell, when their intensities fall to essentially zero (Figure 1). For protonated toluene colliding with C_6D_6, most H/D exchange vanishes at -1 volt; for ethanediol this occurs at -3 volts.

Conclusions

The patterns of M-d_x peaks with changes of pressure and voltage difference between ion source and cell show that some MH^+ ions can survive transmission through the collision cell without exchange while others exchange completely under the same conditions. The dependence on PA(M) can be explained in terms of the change in ion/neutral collision complex lifetime with Δ(PA)[1]. The invariance of the pattern of M-d_3^+ ions with collision energy shows that once an ion is slowed down

by collision inside the cell, its further behaviour is independent of its initial energy. There are, however, cut-off energies above which ions cannot be slowed down sufficiently to take part in any exchange reactions. The intensity of the transmitted MH^+ beam changes little with cell potential from -5 to -200 V.

Target Capture and Ion/Molecule Reactions in High Energy Collisions between Protonated Peptides and Hydrogen-Containing Targets

Xueheng Cheng* and Catherine Fenselau

Department of Chemistry and Biochemistry, University of Maryland Baltimore County, Baltimore, MD 21228

* Present address: Battelle Pacific Northwest Laboratory, Richland, WA 99352

Recent progress in the methods of ionizing large biomolecules has raised expectations for the application of collision-induced dissociation (CID) in the structural analysis of large biomolecules using mass spectrometry. One limitation of CID is the low efficiency for dissociating large ions. A better understanding of the dynamics and mechanism of CID involving large ions is very important for improving dissociation efficiency and extending applications of CID. Recently, target-capture in high energy CID has been observed for fullerene ions colliding with small target gases and the dynamics of such a process were discussed.[1]

We will present evidence showing that target-capture in high energy CID is likely to be a more general phenomenon and ion/molecule reactions can take place in such a high energy collision. Using a JEOL HX110/HX100 four-sector tandem mass spectrometer (EBEB geometry) modified for the study of variable-collision energy (0 eV-10 keV) ion/molecule reactions, we have studied collisions between protonated peptides MH^+ (generated from FAB ionization) and hydrogen-containing target gases (XH_n) such as ammonia and methane. Peptides (MW, Da) studied include leucine enkephalin (555), leucine enkephalin-arginine (711), valinomycin (1111), renin substrate (1758), ACTH(22-39) (1985) and melittin (2845). Product ions with mass above that of the precursor ion have been observed for all the peptide systems studied and the yield increases with an increase in the MW of the peptides. A major product ion observed had a mass corresponding to elimination of two hydrogens from the ion/target complex $[MH + XH_n - 2H]^+$ (Fig. 1b). The collision energy (E_{cm}) at which maximum yield observed was shown to depend directly on the mass and the thickness of the peptide ions and span from 12 eV to 24 eV (E_{cm}) (Fig. 2). The ion/target complex $[MH + XH_n]^+$ were also observed with a lower yield and lower optimal collision energies (Fig. 3). Isotope labeling experiments established the origin of the two hydrogens eliminated from the ion/target complex with one from the target and the other from the precursor ion (Fig. 1c). Incorporation of 14 Da, $[CH_4 - 2H]$ or 17 Da, $[CD_4 - H - D]$ into some of the fragment ions was observed in CID experiments with renin substrate and CH_4 or CD_4, respectively.

The collision energy dependence showed similarities to the fullerene system. This work renders experimental support to the analysis of collision dynamics of large peptide ions by Derrick and coworkers[2] and suggests that the transition point in target scattering is convergent with the formation of target-capture complexes and maximum kinetic-to-internal energy conversion (Fig. 4).

A model of "loose-woollen-ball" conformation for gas-phase protonated peptides is proposed in which the peptide back-bone wraps around to solvate the proton (Fig. 4). A mechanism based on homolytic bond breaking and reformation in the ion/target complex formed by target-capture is proposed to account for the experimental observations. This work shows that chemical reactions can take place in high energy collisional processes under target-capture conditions.

GAS PHASE BASICITIES OF GUANIDINE AND UREA

R. D. Kinser, G. R. Nicol, and D. P. Ridge
Department of Chemistry and Biochemistry
University of Delaware
Newark, DE 19716

Measurements of gas phase basicities (GBs) of the 20 essential amino acids have been the subject of several recent publications.[1,2] Our interest has been focused on the GBs of amino acid amides, since the amide structure incorporates the components of the peptide bond. Studies in our laboratory of proton transfer from the laser desorbed protonated amino acid amide arginamide (ArgA) yielded results indicative of a lower than expected GB for ArgA. Both ArgA and the highly basic amino acid arginine have as R-groups an amino-alkylated guanidine. FTMS studies of proton transfers to the diaminoimine guanidine and its ketone analog, urea, were conducted to increase our understanding of the relationship between structure and GB.

Bracketing techniques were used to establish a proton affinity of urea of 221.0 ± 6.6 kcal/mol. The relevant reactions are:

$$(2,5\text{-diMefuran}+H)^+ + \text{urea} \rightarrow (\text{urea}+H)^+ + 2,5\text{-diMefuran} \quad (1)$$

$$(\text{urea} + H)^+ + \text{pyridine} \rightarrow \text{urea} + (\text{pyridine} + H)^+ \quad (2)$$

$$(\text{urea}+H)^+ + MeNH_2 \rightarrow \text{urea} - MeNH_3^+ \quad (3)$$

Bracketing techniques also were used to establish a proton affinity of 239.6 ± 1.5 kcal/mol for guanidine. Reactions indicative of this are (2,6 - lut = 2,6-lutidine):

$$(2,6\text{-lut}+H)^+ + \text{guan} \rightarrow (\text{guan}+H)^+ + 2,6\text{-lut} \quad (4)$$

$$(\text{guan}+H)^+ + Et_3N \rightleftharpoons \text{guan} + Et_3NH^+ \quad (5)$$

$$(\text{guan}+H)^+ + Pr_3N \rightarrow \text{guan} + Pr_3NH^+ \quad (6)$$

The K_{eq} for Eq. 5 was determined to be 4.22, with $\Delta G° = -0.86$ kcal/mol. From this equilibrium constant, the proton affinity of guanidine was determined to be 240.5 kcal/mol. These values are consistent with the reported GB for arginine and support the need for further refinements in the measurement of the GB for ArgA. Plans for continuing these investigations include measurements of the GBs for N-methyl- and N-ethylguanidine.

BREAKDOWN CURVES FOR THE DISSOCIATION OF PROTONATED PEPTIDE IONS BY LASER DESORPTION/CHEMICAL IONIZATION

J. Paul Speir, I. Jonathan Amster
Department of Chemistry, University of Georgia, Athens, Georgia 30602

INTRODUCTION

The technique of of laser desorption/chemical ionization (LD/CI) has allowed us to obtain fundamental information about the gas-phase properties of peptides and amino acids as well as gain insight into the energetics of fragmentation of peptide ions.[1,2] Here, LD/CI is used to probe the energy dependence of the dissociation pathways of peptides. This technique allows a discrete amount of energy to be placed in the parent ion. By using different reagent species, the exothermicity of the proton transfer reaction can be changed. This allows the product ion distribution to be measured as a function of the reactions's enthalpy, thus producing the breakdown graph. The results of RRKM/QET computations are compared to experimentally obtained breakdown curves in an effort to better understand the dissociation mechanisms of protonated peptide ions.

EXPERIMENTAL

The experiments were performed using a Fourier transform mass spectrometer equipped with a 4.4 cm cubic analyzer cell, a 1 Tesla electromagnet, and an IonSpec data system.[1] For peptide samples desorbed using the substrate-assisted methodology, a 500 monolayer coverage of sinapinic acid, a uv absorbing compound, is first electrosprayed onto the metal substrate. The peptide sample is then electrosprayed on top of the sinapinic acid layer producing an analyte coverage of 500 monolayers.[3] Intact *neutral* peptide molecules are desorbed from a sample stub using either the 248 nm (KrF) or 337 nm (N_2) output of an excimer laser. Proton transfer reagent ions are generated by electron ionization of a high pressure burst of a reagent gas which is admitted through a pulsed valve

The RRKM computer program used for calculating the unimolecular rate constants for the dissociation of peptide ions was written in-house using *Turbo Pascal* ™ The algorithm utilizes the method of steepest-descent for evaluating the reduced energy level densities and sum of states.[4] The vibrational frequencies of the protonated peptide val-pro, used in the RRKM calculations, were obtained by semiemperical (AM1) calculations.

RESULTS AND DISCUSSION

The complete breakdown curve for val-pro (VP), shown in Figure 1, has recently been completed and encompasses the energy range of 16.1 to 136.1 kcal/mol. The dominating fragmentation pathways in this energy range, as a result of proton transfer reactions, is the formation of the y_1 and a_1 fragments. The y_1 is more prominent at the lower energy range (27.7-92.2 kcal/mol) while the a_1 dominates at energies above 99.1 kcal/mol. A plot of the unimolecular rate constant (k(E)) versus internal energy (E), obtained by RRKM calculations, for the formation of the a_1 and y_1 fragments which best model the experimental data is shown in Figure 2. This data is used to produce the theoretically derived breakdown curve which is compared to that obtained

experimentally, as shown in Figure 3 The parameters adjusted to enhance overlap between the theoretical and experimental breakdown curves are the critical energies of the fragments and the degree of 'looseness' or 'tightness' of the transition state. Both the theoretical and experimental data for the formation of the y_1 suggest passage through a tight transition state. This is consistent with a hydrogen rearrangement reaction mechanism for the formation of the y_1 as shown by Orlando etal.[5] The best fit between the theoretical and experimental data for the a_1 was made by assuming that the transition state to form the a_1 gained a rotational degree of freedom, which suggests passage through a loose transition state resulting in direct bond cleavage.

Proton Transfer Rate Constant Measurements of Amino Acids and Dipeptides in a Fourier Transform Mass Spectrometer.

*Gregory S. Gorman, I Jonathan Amster
Department of Chemistry, University of Georgia
Athens, Georgia, 30602

INTRODUCTION

We have previously reported the application of the bracketing method to measurements of the gas-phase basicities (ΔG of protonation) for the 20 common α-amino acids and 22 valine containing dipeptides.[1,2] The basis for assigning gas-phase basicities is the occurrence or nonoccurrence of a proton transfer reaction between a brief pulse of neutral biomolecules with reference base ions previously stored in an ICR cell. When no reaction is observed to occur in the experimental time frame the reaction is considered to be slow and endoergic, while observed reactions are considered to be fast and exoergic. For gas-phase proton transfer reactions, the rate of proton transfer depends on the free energy of the reaction. To determine the thermodynamic value being measured by the bracketing method, a series of kinetic experiments in which the rate of proton transfer is measured under various conditions of free energy and enthalpy were made. Additionally, the transition region between a slow, endoergic reaction and a fast, exothermic reaction, when $\Delta G = 0$, can also be determined.

EXPERIMENTAL

All experiments were preformed in a Fourier transform mass spectrometer designed and constructed in this laboratory and equipped with an electromagnet operated at a field strength of 1 tesla. Protonated amino acid and dipeptide ions were produced by matrix assisted laser desorption/ionization (MALDI) by focusing 337 nm light onto a stainless steel sample probe at an irradiance of 1-10 MW/cm^2. Double resonance eject pulses were used to isolate the protonated molecule ion species from other ions formed in the desorption/ionization procedure. The resulting protonated molecular ions were then collisionally thermalized with Ar, (40-60 collisions), admitted through a pulsed valve, and then allowed to react with reference base, admitted through a leak valve at a static background pressure. The background pressure was measured with an ion gauge, which was corrected for placement and gas sensitivity.[3] Triplicate ion intensity measurements were made at 500 ms intervals from 1 to 5 seconds.

RESULTS

The gas-phase basicity of lysine was determined to lie between that of diethylamine (224.1 kcal/mol) and di-n-propylamine (227.9 kcal/mol) by the bracketing experiments. The proton transfer reaction between di-n-propylamine with protonated lysine (ΔG = -1.9 kcal/mol, ΔH = +5.3 kcal/mol) is both endothermic and exoergic. The measured rate constant was $1.2 \pm .1 \times 10^{-9}$ cm^{3}molec^{-1}s^{-1}, which is essentially the same as the calculated collision frequency of $k_{Langevin} = 1.4 \times 10^{-9}$ cm^{3}molec^{-1}s^{-1}. This entropy-drive reaction is observed to occur essentially at the calculated

collision rate because of the substantial entropy change associated with deprotonation of the cyclic form of protonated lysine. For the reaction with diethylamine (ΔG = +1.9 kcal/mol), the rate constant was measured to be $1.7 \pm .3 \times 10^{-10}$ cm^{3}molec^{-1}s^{-1}, which is approximately an order of magnitude slower than the calculated collision rate of 1.4×10^{-9} cm^{3}molec^{-1}s^{-1}. Since proton transfer was not observed with diethylamine in the bracketing experiments, these results indicate that the free energy (ΔG) of the reaction controls the rate of proton transfer. Table 2 is a comparison between the assigned basicity values of lysine and leucine with those of mono- and diaminoalkane. The upper portion shows the difference between these values assuming the bracketing method is sensitive to free energy, while the lower portion assumes sensitivity to enthalpy. These results indicate that the best agreement between the values is obtained by assuming the bracketing method is sensitive to free energy rather than enthalpy.

GAS-PHASE BASICITIES OF SMALL CARBOHYDRATES

Carolyn J. Cassady
Department of Chemistry
Miami University
Oxford, OH 45056

The formation of protonated molecular ions is dominant ionization pathway in the analysis of carbohydrates by mass spectrometry. Little is known, however, about the fundamental gas-phase proton transfer properties of carbohydrates. The present study probes the gas-phase basicities (GB) of several disaccharides and glucose by deprotonation reactions with a series of reference compounds in a Fourier transform mass spectrometer.

Gas-phase basicity is the negative of the free energy change for a molecule's protonation reaction:

$$M + H^+ \rightarrow MH^+ \qquad \Delta G_{rxn} = -GB(M).$$

Experimental studies involved bracketing the GBs of glucose, lactose, sucrose, maltose, and cellobiose, using deprotonation reactions in a Bruker CMS 47X Fourier transform mass spectrometer (FTMS). Ions were produced from the carbohydrates by fast atom bombardment (FAB) using a glycerol matrix in an external ion source. The ions were moved into the cell region of the FTMS by electrostatic focusing and then were collisionally cooled. Ion ejection techniques were used to isolate the protonated molecular ions of the carbohydrates. These ions were then allowed to proton transfer to a reference compound of known GB, which was present at a static pressure in the ICR cell:

$$MH^+ + Base \rightarrow M + (Base)H^+.$$

Reaction rate constants were measured, and reaction efficiencies were obtained by comparing these experimental values to the theoretical collision rate constants. For efficiencies of less than 0.10 (less than 10% of all collisions resulting in a reaction), GB(Sugar) was considered to be greater than GB(Base). For faster reactions with efficiencies of greater than 0.10, the reference compound was considered to be the most basic.

Glucose, maltose (two glucose units with an $\alpha(1\rightarrow4)$ linkage) and cellobiose (two glucose units with a $\beta(1\rightarrow4)$ linkage) produced very low abundances of MH^+ by FAB. In particularly, cellobiose was not studied extensively because of difficulties resulting from the low ion yield. (This may be related to its solubility in glycerol.) β-Glucose was found to have a GB between t-butanol and ethyl acetate, bracketing it at 189 ± 5 kcal/mol. This is below the GB of glycerol (196 kcal/mol[1]), which may account for the low formation of MH^+ for glucose by FAB. The GB of mixed anomers of maltose was bracketed between pyrrole and 3-methylaniline, giving a value of 201 ± 6 kcal/mol. All GBs are referenced to the scale of Lias and coworkers[2].

Sucrose and individual anomers of lactose were also studied. The GBs of both sucrose and α-lactose were found to be 203 ± 5 kcal/mol and are bracketed between pyrrole and 3-methylaniline. While in-depth studies have not yet been performed, our preliminary results also suggest that these disaccharides, which have the highest GBs, also form the most intense MH^+ by FAB. β-Lactose was found to be slightly less basic, with a GB of 199 ± 3 kcal/mol, bracketed between i-propyl ether and pyrrole. The higher basicity of α-lactose relative to β-lactose may be the result of enhanced intramolecular H-bonding. α-Lactose contains two sets of OHs that are in proximity in the folded structure, versus one set in the β-form. Intramolecular bonding is known to greatly influence the GBs of crown ethers.[3,4]

Attempts were also made to study galactose and fructose, the monmers which (in addition to glucose) comprise sucrose and lactose. These studies were hindered by low MH^+ formation. Prevous FAB and chemical ionization studies[5,6] have also found that monosaccharides give low MH^+ yields, with H_2O loss dominating. However, the GB of galactose does appear to be near the GB of glucose. As noted above for glucose, this low GB relative to the glycerol matrix may contribute to the poor production of MH^+ by FAB on galactose.

GAS-PHASE BASICITY STUDIES OF GLYCINE AND DIGLCYINE BY MASS SPECTROMETRY AND AB INITIO CALCULATIONS

Kui Zhang, Alice Chung-Phillips, and Carolyn J. Cassady
Department of Chemistry
Miami University
Oxford, OH 45056

In solution, proton transfer influences the 3-D structure and biological activity of peptides. In the gas-phase, protonation is the dominant ionization pathway during the analysis of peptides by mass spectrometry, with the location of the proton influencing ion intensities and fragmentation patterns. However, very little is known about fundamental thermochemical aspects of the proton transfer process. The present study provides this information for the simples amino acid, glycine, and the simplest peptide, diglycine. The gas-phase basicities (GB) of these species have been determined experimentally and theoretically.

Gas-phase basicity is the negative of the free energy change for a molecule's protonation reaction: $M + H^+ \rightarrow MH^+$ $\Delta G_{rxn} = -GB(M)$.
Experimental studies involved bracketing the GBs of glycine, Gly, and diglycine, Gly_2, using deprotonation reactions in a Bruker CMS 47X Fourier transform mass spectrometer (FTMS). Ions were produced from Gly and Gly_2 by fast atom bombardment (FAB) in an external ion source and moved into the cell region of the FTMS by electrostatic focusing. The ions were collisionally cooled and ion ejection techniques were used to isolate the protonated molecular ions $GlyH^+$ or Gly_2H^+. These ions were then allowed to proton transfer to a reference compound of known GB, which was present at a static pressure in the ICR cell: $Gly_xH^+ + Base \rightarrow Gly_x + (Base)H^+$.
Reaction rate constants were measured, and reaction efficiencies were obtained by comparing these experimental values to the theoretical collision rate constants. For efficiencies of less than 0.10 (less than 10% of all collisions resulting in a reaction), $GB(Gly_x)$ was considered to be greater than GB(Base). For faster reactions with efficiencies of greater than 0.10, the reference compound was considered to be the most basic.

Using this experimental technique, the GB of glycine was found to be 206.2 ± 2.2 kcal/mol and the GB of diglycine was found to be 215.2 ± 2.5 kcal/mol. These values are referenced to the basicity ladder of Meot-Ner and Sieck[1]. The GB value for glycine is in good agreement with previous mass spectral studies that place it between 204 and 209 kcal/mol.[2-5]

Theoretical studies involved high level ab initio calculations using the Gaussian 90 and 92 programs. These studies were primarily performed using the Cray Y-MP8/864 supercomputer at the Ohio Supercomputer Center. In obtaining structures, all geometries were fully optimized. For glycine and protonated glycine, 6-31G* and 6-31 + G(d,p) basis sets were used with MP4 electron correlation. For diglycine and its protonated form, the 6-31G* basis set was used with partial fourth order (MP4SDQ) electron correlation. Gas-phase basicities were calculated from zero-point energies for 298.15 K and 1 atm. Several other levels of ab initio calculations were also performed, but the higher level calculations gave the greatest agreement with experimental results.

For glycine, ab initio research indicates that the preferred protonation site is the terminal amino nitrogen. The calculated GB for this structure is 206.3 kcal/mol, which is in excellent agreement with the experimental results. In addition, a second stable structure, with carboxyl carbonyl oxygen protonation, was found to have a GB of 191.5 kcal/mol.

For diglycine, ab initio research revealed five stable protonated structures. The two most stable structures also involve protonation of the amino nitrogen, differing only in their N13-C12-C9-N6 dihedral angle. Structure I shows the most stable structure. Both structures give strong intramolecular H-bonding from the terminal NH_3^+ to the amide oxygen. This interaction is significantly stronger for diglycine than for glycine and results in a large increase in GB. The calculated GB for the most stable Gly_2H^+ is 215.2 kcal/mol, which is again in excellent agreement with the experimental results.

Trends in gas-phase basicities of linear oligopeptides Gly_n, Ala_n, and Val_n (n=1-4)

Jiangyue Wu, Carlito B. Lebrilla, Chemistry Department, University of California, Davis. California 95616

The study of the inherent basicities of peptides is important in both chemistry and biochemistry. Basicity is a fundamental property and it affects directly the chemical reactivity and the physical characteristics of peptides. The acid-base properties of various oligomeric peptides in aqueous solution have been studied. It was observed that increasing the peptide length from mono- to di- greatly changes pKa values. Further lengthening the chain from di- to tri- changes the pKa values moderately while tri- to tetra- produces no significant change. In addition, the functional groups on side chains can significantly modify the basicity of peptides.[1] Recently, we reported the gas-phase basicities(GB) of glycine oligomers.[2] Here, we present the continuation of a systemic study of the gas-phase basicities of linear oligopeptides with alkyl side chains.

The gas-phases basicities of peptides are measured in an external source FTMS by using a bracketing method which has been described in earlier pubication.[2] The rate constants and the efficiencies of all the proton exchange reactions are obtained through a kinetic analysis. The efficiencies are large (~ 50%) for the reactions in which the GBs of peptides are lower than that of reference base. The GB values of peptides are assigned according to the efficiencies of the reactions The efficiencies of the reaction are listed for alanine (Table 1) and valine (Table 2). The GB values are listed in Table 3. For comparison, the values for glycine from an earlier study are also shown. The GB values of reference base are assigned from the scale developed by Lias, Liebman and Levin.[3]

In the earlier publication, we reported that the GB values increase from glycine, diglycine to triglycine. However, for the alanine and valine series, the GB values change from amino acid to dipeptide but do not change from dipeptide to tripeptide.

Semi-empirical AM1 calculations show that the increase in GB values between amino acids and dipeptides is due to the hydrogen bonding between the terminal amine and the adjacent amide carbonyl oxygen. The increase in basicity from diglycine to triglycine is due to the second hydrogen bonding between terminal amine with the second amide carbonyl oxygen. This structure is not observed in trialanine due to the Steric interaction of alkyl group and similar behavior is expected for trivaline.

Lowest Energy Structure of Protonated triglycine

Analysis of High Molecular Weight Hydrocarbons by Short Column Gas Chromatography Mass Spectrometry. James G. Moncur, Lockheed Missiles and Space Co. 3251 Hanover St., Palo Alto, CA, 94304.

High molecular weight aliphatic hydrocarbons have been analyzed by high temperature gas chromatographic/MS methods (Ref. 1) in search of "biomarker" up to molecular size C_{60}. In the current study, a commercial oil used as a low volatility lubricant was analyzed by short column gas chromatography mass spectrometry with electron ionization up to molecular size C_{89}. The oil consisted of numerous minor low molecular weight additives and three hydrocarbon components with the following tentative molecular ions and empirical formulas:

644 = $C_{46}H_{92}$ with 1 degree of unsaturation.
910 = $C_{65}H_{130}$ with 1 degree of unsaturation.
1246 = $C_{89}H_{178}$ with 1 degree of unsaturation.

It is possible that the oil was manufactured synthetically, although information on this product was not readily available.

A short length of DB-5 phase capillary column taken from a previously used 30 meter column was used for this work, (3 meter long, 0.25 mm ID, with 0.25μm film thickness). The helium carrier gas pressure was programmed from 10 to 20 psi seconds after sample injection. The current data was obtained using a cool on-column injection technique. The column oven was heated from ambient to 400C at 50C per minute. The injector was set to heat as fast as possible from ambient to 350C soon after injection of the oil. The standard capillary interface of the Fisons VG model 70VSEQ mass spectrometer was operated at 330C and the column was inserted into the ion source for efficient transfer of organics to the 70 eV electron beam.

The mass spectrometer was scanned from 1300 to 50 amu every 5.6 seconds with a 1 second inter-scan delay. A total ion chromatogram is shown in Figure 1. The mass spectrum of $C_{89}H_{178}$ is shown in Figure 2. Low molecular weight additives triphenyl phosphate, tertbutylphenyl diphenyl phosphate, and an unidentified compound were also observed as well separated peaks. A total ion chromatogram of the oil analyzed by direct probe mass spectrometry under the same temperature conditions is shown in Figure 3.

In conclusion, separation of medium to high molecular hydrocarbons by short column GC/MS was found to be much more efficient than direct probe analysis.

CHARATERIZATION OF WAX FRACTIONS FROM LUBE OIL BASESTOCKS BY THERMAL EXTRACTION-GAS CHROMATOGRAPHY/MASS SPECTROMETRY

J. W. Fedora, S. G. Roussis and T. R. Ashe
Imperial Oil, Sarnia Research Centre, Sarnia, Ontario, Canada , N7T 7M1

The low temperature performance of lube oils is related to the basestock composition, of which wax is a major component. Analytical methods are therefore required for the compositional analysis of wax fractions from lube oil basestocks in order to obtain a better understanding of the relationship between wax composition and low temperature lube oil performance characteristics. GC/MS methods originally developed for conventional lube oil basestock wax characterization proved ineffective when applied to wax fractions from nonconventional lubes (NCL). NCL's are highly complex mixtures of isomeric paraffins and the usual chromatographic procedures cannot provide adequate chromatographic separation which is essential for the correct identification and quantification of the components, due to the similarity of their mass spectra. Consequently, a new characterization approach utilizing thermal extraction prior to gas chromatographic separation (TE-GC/MS) has been examined for use with wax fractions from nonconventional lubes. The study was initially undertaken to examine whether subdivision of the wax fraction into smaller fractions (thermal slices) could improve the chromatographic separation and simplify the mass spectrometric analysis.

The experimental setup used in this work is shown in Figure 1. It consists of a thermal extraction unit (Thermex from Ruska, Houston, TX) coupled, by a heated transfer line, to a conventional HP GC/MS system. The sample is placed into a quartz ampoule with a fritted glass bottom. The ampoule is positioned into a temperature programmable pyrocell which is heated at a controlled rate. The vapourized material is swept through the heated transfer line to the head of the GC column, where it is cold trapped. The thermal extraction step is followed by conventional 70eV EI GC/MS analysis.

The thermal extraction procedure consists of a series of 6 thermal slices, of 30°C widths, taken across a wider boiling range (50° to 200°C). The extraction profiles and optimum chromatographic conditions were determined experimentally, then standardized for all subsequent analyses. Subdivision of the wax fraction into thermal slices allows the large unresolved chromatograms produced by conventional GC/MS to be resolved into simpler chromatograms, shown in Figure 2. The thermal extraction GC/MS system is calibrated using a C5 to C60 blend of n-alkanes. For each thermal slice, a range of n-alkanes of known b.p.'s is vapourized and swept through the GC/MS. The thermex temperature parameters are calibrated by comparison with the actual b.p.'s for the eluted n-alkanes.

The thermal slicing of the wax into smaller fractions has allowed for the identification and quantification of 11 homologous series representing normal, various methyl, dimethylalkanes, naphthenes and alkylbenzenes, across a carbon number range of approximately C10 to C45. Differentiation of waxes based on the isomeric types and their respective carbon number distributions have been obtained (Figures 3 and 4). Correlations of the molecular composition with several physical properties of the lube oil basestock, can now be obtained.

The method developed here, can be applied in a general fashion, in situations where conventional GC/MS experiments are not adequate for the analysis. Complex mixtures of very similar components can be selectively analysed by the on-line thermal slicing procedures reported here. Future work will concentrate on the identification and quantification of other petroleum samples consisting of very similar components (lube oils). Thermal extraction experiments may be coupled with selective separation procedures based on polarity or molecular size.

THE ANALYSIS OF A COMPLEX MIXTURE OF ACIDIC MATERIALS DERIVED FROM PETROLEUM BY CAPILLARY ELECTROPHORESIS (CE) AND ELECTROSPRAY IONIZATION-MS(ESI-MS): A PRELIMINARY OFF-LINE INVESTIGATION.*

AI MALLET, INSTITUTE OF DERMATOLOGY, UMDS, UNIVERSITY OF LONDON, , LONDON SE1 7EH. SAUL PARRY*, CF SIMPSON, DEPT. OF CHEMISTRY, BIRKBECK COLLEGE, 29 GORDON SQUARE, LONDON WC1H OPP. .MJC SMITH, BP INTERNATIONAL Ltd, CHERTSEY Rd, SUNBURY ON THAMES, MIDDLESEX, UK.

INTRODUCTION.

A complex Mixture of Mono- and Di-Basic Acids (MMDBA) has been analyzed using ESI-MS . MMDBA is derived from the production of a low molecular weight carboxylic acid, and comprises 25-35% of the production stream. A detailed knowledge of the composition is required to investigate utilization of MMDBA which is currently a waste stream.

EXPERIMENTAL.

ESI-MS: VGTrio-2 quadrupole equipped with a Biotech ESI source (Fisons Ltd,UK). An Isco SFC500 pump delivered buffer at 7.5uL/minute. Standards and MMDBA were dissolved in acetonitrile: methanol (ratios dependant upon sample) . MMDBA was analyzed as solid and liquid fractions , as heating to 100C is required for homogenisation, which might affect sample composition. Results are compared to negative ion CI spectra acquired on an ICR-MS instrument (Nicolet FTMS 2000), using a probe heated to 140C.

*CE: Due to a hardware problem no electropherograms can be shown.

RESULTS.

In contrast to initial experiments with +ve ionization, negative ESI-MS of standards produced strong signals at (M-H)-. Single species were ionized with high efficiency, however equimolar mixtures resulted in reduced ion currents. As the mixture became more complex, individual ion currents were reduced.

In general, acid concentrations were ~0.00001M, resulting in approximately 150,000 counts per 10uL injection of a single standard for the acids studied. When mixtures of different composition were electrosprayed differing response factors were obtained for individual components. Ion counts of standards in mixtures varied from thousands to ten's of thousands dependent upon mixture composition. We ascribed this result to the existence of suppression effects, observing the same effects in the TIC traces.

Succinic acid was retained in the ESI-MS manifold, and may be detected in subsequent injections of other standards. Presumably, this retention results from adsorption on metallic components. The presence of succinic acid in certain mixtures resulted in apparent suppression of some components, whilst other mixtures resulted in increased ion counts. Analysis of an equimolar mixture of di-acids and hydroxy acids resulted in suppression of succinic acid, indicating di-carboxylic and hydroxy acids may act as strong suppressants of succinic acid.

The analysis of MMDBA by ESI-MS resulted in spectra which were comparable to those obtained by distillation from a heated probe by ICR-MS(-ve CI spectra). The major components were present at ratio's consistent with the proposed composition. The ESI-MS results obtained with MMDBA are at present tentative on account of the complexity of response vs composition of standard mixtures. Further work to verify the relationships will be required. The range of mixture compositions studied so far does, however, support the conclusion that the spectra were representative; the components that appear to suppress the major MMDBA components (succinic,adipic,glutaric, and the n-carboxylic acids) were either not present in MMDBA ,or were present at non-interfering concentrations. Suppression effects associated with succinic acid were, however, indicated in the solid fraction sample of MMDBA. Presumably, succinic acid was present at higher levels in the solid fraction. Co-components involved with suppression or enhancement of analyte signals may be present in both fractions, however utilizing ESI-MS alone we are unable to determine this.

CONCLUSIONS.

The present study has demonstrated the potential of ESI-MS for the analysis of complex mixtures; a wide range of carboxylic acids and related compounds having been examined and these produce primarily (M-H)- ions. Despite the suppression effects associated with certain MMDBA components, experimental conditions have been achieved under which ESI-MS spectra reflect the proposed composition of MMDBA. In order to define the molecular composition, including components at the same nominal mass, considerably enhanced resolution will be required. The problem may be simplified if an on-line separation with CE is employed, as this has been shown to be effective in the analysis of complex mixtures. In addition, if employed in the coupled column mode of isotachophoresis(ITP), this could provide a means of selective removal of suppressants from the mixture.

CHARACTERIZATION OF ASPHALTS AND ESTIMATION OF BOND STRENGTHS BETWEEN ORGANIC COMPONENTS AND AGGREGATES BY PROBE MICRODISTILLATION/MASS SPECTROMETRY

Ronald D.Grigsby

IIT Research Institute
National Institute for Petroleum and Energy Research
P.O. Box 2128, Bartlesville, OK 74005

Arnulf P. Hagen and William D. Lee

Department of Chemistry and Biochemistry
The University of Oklahoma, Norman, OK 73019

The long-term performance of asphaltic concrete as a road-building material is, in part, determined by the bond strengths between components of the organic binder and the surface of the aggregate. To characterize organics and estimate bond strengths, selected whole asphalts and fractions are being analyzed by high resolution mass spectrometry. In addition, pure model compounds and those adsorbed from solution onto aggregates are being studied. Desorption of the mixtures and model compounds from a direct-introduction probe, as a function of linearly increasing temperature, provides apparent activation energies and frequency factors as calculated from first-order kinetics. These parameters are related to bond strengths between organic components themselves and between the components and surface of the aggregate. Binder-aggregate combinations have been selected based on parameters obtained from whole asphalt solubility profile data and zeta potentials of the n-pentane insoluble asphaltenes as well as from the zeta potentials and chemical constitutions of the aggregates.

All data were acquired with a Kratos MS-50 high resolution mass spectrometer. The samples were introduced into the mass spectrometer via a cooled/heated quartz probe with linear temperature programming at 10 ^{o}C/min over a temperature range from ambient to 350 ^{o}C. Ions were generated by low energy (12 eV) and 70 eV electron ionization and by field ionization. A mixture of halogenated compounds was used for calibrating masses in the low eV spectra. Resolving powers up to 20,000 were used.

The mass spectrum of a whole asphalt (without aggregate), obtained at a probe temperature of 346 ^{o}C, is shown in Figure 1. The data were acquired by low energy electron ionization at 14,000 resolving power. Molecular-ion peaks are visible from about m/z 370 to m/z 900 . Intense peaks in the low region of the spectrum are mostly molecular ions from the reference compounds.

Analysis of the data shows that volatiles from the whole asphalt up to a probe temperature of about 350 ^{o}C consist primarily of aromatic hydrocarbons having elemental formulas from C_nH_{2n-26} to C_nH_{2n-38}. Only about 25% of the asphalt is volatile at this temperature. Presumably, the residue consists of higher molecular-weight hydrocarbons and polar compounds.

Figure 2 shows experimental ion intensities vs. absolute temperature for m/z 450, C_nH_{2n-26}, recorded for the whole asphalt (without aggregate). The elimination curve was calculated from least-squares parameters obtained by analyzing intensities as a function of linearly increasing temperature. A four-parameter skewed-gaussian equation was used. From the parameters for the curve shown and for other curves, typical activation energies in the range from 25 to 35 Kcal/mol and frequency factors of about 1 x 10^{10} sec^{-1} are obtained. The relatively low value of the frequency factor is consistent with a model for diffusion of volatile components through a non-volatile matrix, as expected from the theory of asphalt structure.

In contrast, desorption of a model compound such as quinquephenyl from the surface of a solid with a large surface area provides a higher activation energy and a frequency factor in the range of 1 x 10^{14} sec^{-1}. See Figure 3. These values are anticipated from a first-order kinetics model for simple desorption of a volatile substance from a surface.

EVALUATION OF MASS SPECTROMETRIC METHODS FOR DETERMINATION OF SULFUR TYPES IN PETROLEUM SAMPLES

S. G. Roussis, J. W. Fedora and W. P. Fitzgerald
Imperial Oil, Sarnia Research Centre, Sarnia, Canada, N7T 7M1

Sulfur compounds of different types such as: mercaptans, sulfides, disulfides, thiophenes and others, are found in petroleum samples in concentrations varying from the percent (%) to the low ppm levels. The presence of sulfur compounds in crude oil and finished products is considered harmful with undesirable metallurgical and environmental consequences. Determination of the individual sulfur types in such samples is therefore important for mechanistic studies and quality assurance. Early mass spectrometric methods utilizing 70 eV Electron Ionization allow for the analysis of aromatic sulfur compounds (1,2). More recently Chemical Ionization GC/MS has also been applied for the identification and quantification of aromatic sulfur compounds (3). However, routine methods for the direct analysis of alkyl sulfur species are not yet available. The present study investigates two different methods for their suitability to analyze both aromatic and saturate alkyl sulfur species in a routine manner. First, 70 eV EI HR by dynamic batch sample introduction, and second, low voltage EI HR GC/MS, are examined using standard sulfur compounds and samples spiked with known sulfur mixtures. The advantages and disadvantages of each method are presented.

High resolution mass spectrometry has the advantage of separating structures with different exact masses. Unfortunately, the resolution required for the separation of ions increases with higher masses. In addition, in sector instruments, where resolution increases by closing the instrument slits, higher resolution usually results in lower sensitivity. Using, however, low mass fragment ions characteristic of the various parent structures, allows detection of different chemical classes with lower resolving power demands. The technique has been used previously (4) to identify sulfur species in complex petroleum samples monitoring the fragment CHS^+ (44.9799 m/z). However, ion CHS^+ can be produced by almost any sulfur compound and cannot be used alone for type analysis. Here, we have used a dynamic batch type introduction system (5) and a set of characteristic sulfur type fragments with known relative abundances and response factors (Figures 1, 2). This set of ions: SH^+ (32.9799), CHS^+ (44.9799), $C_2H_5S^+$ (61.0112), and $H_2S_2^+$ (65.9598) has been found to be produced by the sulfur species under investigation. The concentrations **{Ci}** of the various sulfur types are obtained by HR measurement of the abundances of these ions **{Ai}** and subsequent solution of the equation: (**[M]** is a calibration matrix determined from known sulfur mixtures).

$$\{Ci\} = [M]^{-1}\{Ai\}$$

Low voltage electron ionization is usually employed for selective analysis of aromatic compounds in complex hydrocarbon mixtures. Appropriate selection of the electron kinetic energy (ca. 10 eV) allows ionization of the sulfur types considered in the present study. The advantage of this method is that it forms primarily molecular ions. Low voltage ionization has been studied here, using the same standard mixtures and spiked sample solutions as those used in the study of the 70eV ionization technique. LV ionization produces molecular ions with approximately equal response factors and is an attractive method for the analysis of sulfur species. However, it was found in this study, that analysis using the previous 70 eV EI method is more preferable. This is shown in Figure 3 which displays calibration curves covering typical sulfur concentration ranges found in petroleum samples. Similar results were difficult to obtain using LV GC/MS experiments (Fig. 4). This can be attributed to the fast scanning requirements for GC/MS and the increasing resolution requirements with higher molecular weights.

The Determination of 2-Aminonaphthalene in Petroleum Products By High-Performance Liquid Chromatography and Mass Spectrometry

*Nero, V P., D'Antono, J A. and Drinkwater, D. E.

Texaco Research and Development, Beacon, NY 12508

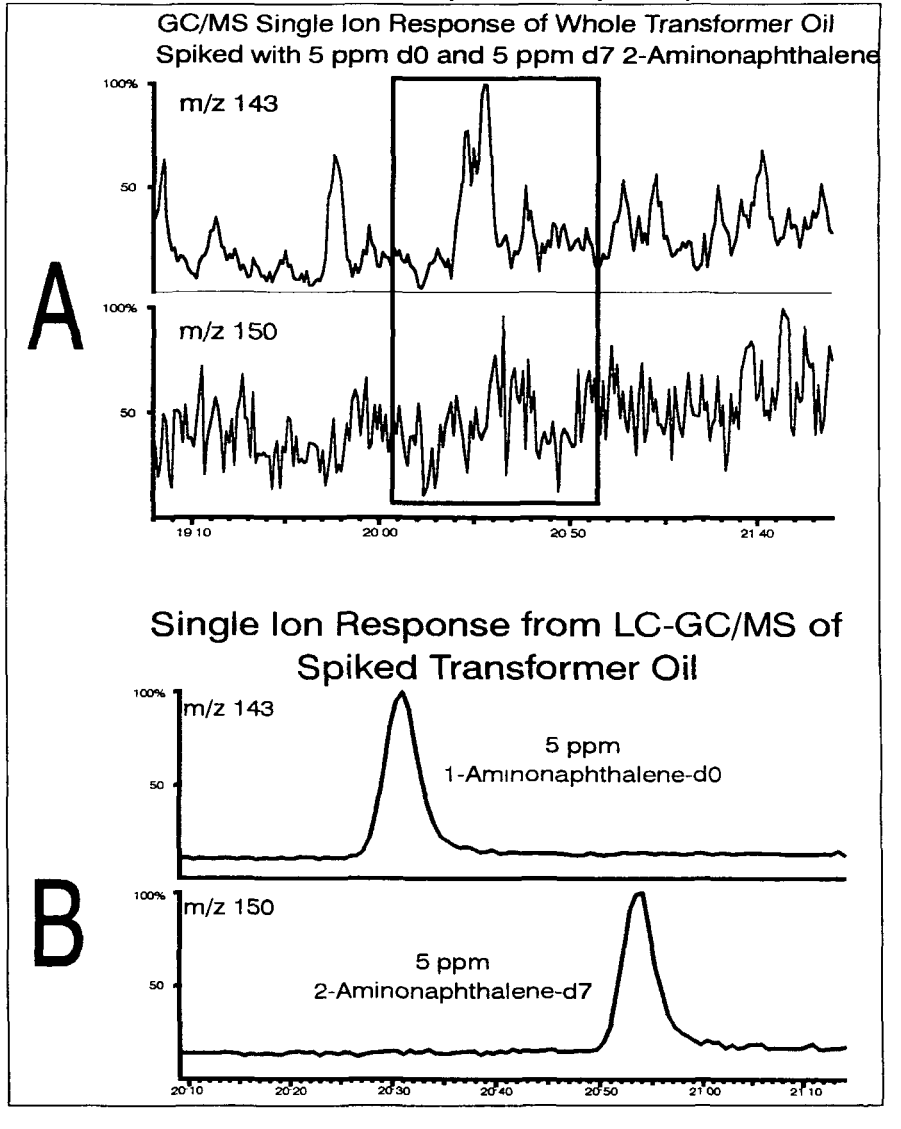
2-Aminonaphthalene has long been recognized as a human carcinogen and as a toxic chemical. It is crucial to establish that it is not present in petroleum products which may come into contact with potable water or food packaging equipment Since these oils are complex matrices containing vast numbers of saturated, unsaturated and aromatic hydrocarbons, their quantitative analyses present a formidable analytical problem. Additionally, these matrices often have many compounds with similar boiling points and molecular weights, making their analyses by GC/MS alone difficult.

The traditional method for quantitative determination of 2-aminonaphthalene is single-ion monitoring of 1-3 major ions in the mass spectrum, preceded by complicated multistep separation procedures to eliminate interferences with similar retention properties and ionic fragments A high-performance liquid chromatography and gas chromatography/mass spectrometry procedure was developed to quickly and unambiguously determine 2-aminonaphthalene in refined oils as well as crude oils at a 1 ppm detection limit. This procedure involves spiking the oil with a deuterated surrogate, removing interferences using an initial HPLC cleanup procedure and then analyzing by selected ion detection

25 uL of a light vacuum gas oil spiked with a deuterated internal standard at the low ppm level is injected onto an Alltech Econosil 5 micron Cyano column 250 mm x 4 6 mm ID. The fraction containing the aminonaphthalene is evaporated to 10-50 uL and 1 uL injected onto a 30 m , 0 25 mm ID, 0.25 um phase thickness fused silica capillary DB-5 capillary column running at a flow rate of 40 cm/sec. The analyte is detected by a Finnigan-MAT SSQ 710 quadrupole mass spectrometer running in electron impact mode with 70 eV electron energy.

The internal standard, 2-Aminonaphthalene, is found to have some interesting H-D exchange properties. One of the labeled aromatic ring positions (but only one, as determined by MS and NMR) can exchange on extended storage in methylene chloride or while passing through an older GC column A 6 week old solution of this compound in methylene chloride is shown to have >80% D6 and <3% D7 in contrast to the expected molecular ion envelope if all aromatic positions exchange with equal ease. It is crucial, therefore, to examine carefully all sample handling, storage and analysis operations to ensure the integrity of this internal standard The undeuterated 1-Aminonaphthalene can also be used as an internal standard since the retention times for this species is well before that of 2-Aminonaphthalene

The Figure shows the response for m/z 143 (aminonaphthalene-d0) and m/z 150 (aminonaphthalene-d7) for **A** GC/MS of the whole oil spiked at 5 ppm D0 and 5 ppm D7, and **B** GC/MS of the HPLC fraction from this oil



GEOPORPHYRIN ANALYSIS USING ELECTROSPRAY IONIZATION-MASS SPECTROMETRY

G.J. Van Berkel,[1] Miguel A. Quiñones[2] and J. Martin E. Quirke[2]
[1]Analytical Chemistry Division, Oak Ridge National Laboratory, Oak Ridge TN 37831-6365
[2]Department of Chemistry, Florida International University, Miami, FL 33199

Geoporphyrins are found as complex pseudohomologous series of numerous structural types in sediments, fossil fuels, and source rocks. Their potential use as biomarkers in fossil fuel exploration has provided stimulus for determining the relative distributions of the different carbon number species in such geological samples as well as the complete structures of the individual porphyrin species present. In this regard, MS has proven to be one of the more powerful analytical techniques available. EI-MS, which provides the porphyrin molecular weight, has been the most used. CI-MS is also often used because of the ability using this technique to pyrrole sequence a single porphyrin isomer. In a recent paper,[1] we demonstrated the general utility of electrospray ionization-mass spectrometry (ES-MS) for the analysis of a wide variety of porphyrins. In this paper, we examine ES-MS detection limits for geoporphyrins, the use of ES-MS for determination of relative porphyrin abundances within geoporphyrin mixtures, and on-line microbore-HPLC/ES/MS for geoporphyrin analysis. The mass spectrometer employed was a modified version of a Finnigan-MAT ion trap mass spectrometer (ITMS) adapted to sample ambient air. This is not of primary importance except that the ES detection limits that can be obtained with the ion trap might be better than those obtainable with other types of mass analyzers.

Geoporphyrin-like standards, e.g., free-base, nickel, and vanadyl chelates of octaethylporphyrin (OEP) and etioporphyrin-III (etio-III), as well as geoporphyrins isolated from Gilsonite bitumen were analyzed. A single molecular species was produced from these porphyrins and no ES produced fragment ions were observed. Detection limits using continuous infusion at 1-5 μL/min required sampling as little as 1 femtomole of material, while at these same flow-rates, 18 femtomoles of OEP could be detected via flow injection. However, because of sample impurities, spectra with suitable signal-to-background for unambiguous identification of unknowns required injection of about 400 femtomoles. Detection of 500 femtomoles of mesoporphyrin IX dimethyl ester was demonstrated using on-line reverse-phase microbore-HPLC at solvent flow rates of 40 μL/min.

The ability using ES-MS to accurately determine the relative abundances of the porphyrins within geoporphyrin mixtures was demonstrated using standard solutions containing known molar ratios of OEP and etio-III as determined by weighing and UV/visible spectrophotometry (Figure 1). With this methodology established, the porphyrin distribution in Gilsonite Bitumen was determined via three sequential flow injection experiments (Figure 2(a)). Averaged, isotopically corrected and renormalized data from these injections (Figure 2(b)) matched literature values for the porphyrin distribution within this sample (E = etio, D = DPEP or CAP).[2] The major advantages of ES-MS for this determination are the sensitive, rapid and reproducible nature of the measurement.

A reverse-phase separation (300 Å ODS (1 mm X 100 mm), 40 μL/min, 75% MeOH/25% H_2O/0.1% TFA to 95% MeOH/5% H_2O/0.1% TFA in 15 min) was used in the on-line HPLC/ES/MS analysis of the total free-base porphyrin mixture isolated from Gilsonite bitumen (Figure 3). The two porphyrin structural types in the mixture, etio and cycloalkanoporphyrins (CAP) were completely separated from one another. Within each structural type the porphyrins separated by carbon number. All the known porphyrins in the mixture were detected. In addition, minor CAP components of high carbon number (> C_{33}) were also detected in the mixture. Nickel Gilsonite porphyrins separated on-line using different reverse-phase conditions showed similar elution behavior.

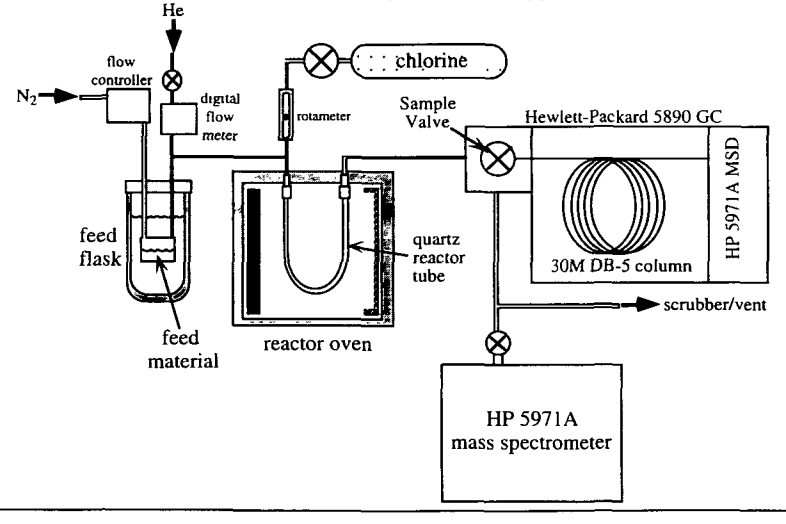
Using in-situ mass spectrometry to study the chemistry of a small scale benchtop minireactor.

J.R. Gilbert, M.A. DesJardin, S.J. Doherty, The Dow Chemical Company
Health and Environmental Sciences Laboratory, Midland, Michigan 48674.

The need for real-time pilot plant data to develop new chemical processes or improve existing production facilities is becoming increasingly important for successful process commercialization. The amount of time spent in the costly pilot plant stage can be greatly reduced through the use of real-time compositional analysis. The application of conventional spectroscopic and chromatographic process instruments often requires some compromise in sensitivity, specificity, or sampling rate. In-situ mass spectrometry offers the advantages of high sampling rate, high sensitivity, wide dynamic range, and good specificity. These characteristics are especially important when evaluating high-speed reactions for product output, catalyst efficiency, catalyst deactivation, and reaction kinetics. We present the application of both in-situ mass spectrometry and off-line GC/MS to study the products of a small scale minireactor.

Several of the trace impurities in thermal chlorination feed streams are oxygen containing compounds. The presence of these impurities in the feed streams may be linked to high corrosion rates in large scale plants. One potential product resulting from the chlorination of these impurities is water, which could be responsible for the observed corrosion. A research study was initiated to determine the fate of these oxygen containing impurities in a thermal chlorination reactor. The products from several different feed streams were studied using the benchtop minireactor system shown in Figure 1.

Figure 1. A schematic diagram of the benchtop minireactor apparatus.



Gaseous oxygenate streams were produced by passing a controlled flow of nitrogen across the liquid oxygenate feed material. The feed material was held at a controlled temperature, producing a constant vapor pressure of the feed material in the nitrogen stream. This stream was combined with fixed flows of ultra-pure helium and chlorine at the reactor inlet tube. The composition of the feed stream entering the reactor was controlled by adjusting the flow rates of these combined streams and the temperature of the oxygenate feed flask. Reaction products were sampled with a heated GC/MS Valco sampling valve and a leak valve coupled to the on-line mass spectrometer. The bulk of the product gases were finally neutralized by bubbling through a caustic bath housed in a fume hood.

Several oxygen containing compounds were studied with the mini-reactor apparatus, the products of these reactions are shown in Table 1. The major oxygen containing products in these systems were CO, CO_2, and phosgene. Carbon tetrachloride, perchloroethylene, and hexachloroethane were also detected as chlorination products. The high concentrations of chlorine in the system produced a large Cl^{2+} signal (m/z 17.5 and 18.5) which interfered with the direct observation of water. Isotopically (^{18}O) labeled methanol was used to determine if water was generated as a product of thermal chlorination. The m/z 20 region of the in-situ mass spectrometer was relatively clear of interfering ions, allowing the direct observation of water ($H_2{}^{18}O^+$) produced from the feed. In all of the systems studied, water was detected at only background levels in the product stream. **These results indicate that the corrosion observed in the large scale plants is <u>not</u> caused by water produced through the chlorination of oxygen-containing impurities in the feed stream.**.

The combination of high-speed acquisition via on-line mass spectrometry with the specificity of GC/MS was ideally matched with the mini-reactor system. The mini-reactor allowed the rapid evaluation of several chemical systems under a variety of reaction conditions. The on-line MS provided rapid response to follow the changing composition of the reactor effluent, and the on-line GC/MS provided sufficient specificity to allow the positive identification of the effluent stream components.

Table 1. A summary of the results from each of the oxygenate systems studied.
The integrated results for GC/MS injections for each compound at a reactor temperature of 600°C. For comparison purposes the peak areas were scaled to account for the percent of oxygenate in the stream. (example: scaled response = (area counts)/(% oxygenate in feed)).

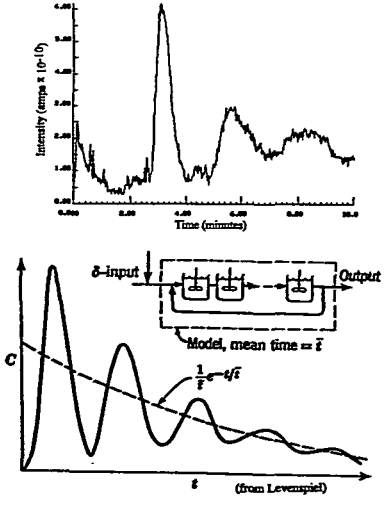
IN SITU MASS SPECTROMETRY FOR PROCESS MONITORING IN CHEMICAL PLANTS

Steve Doherty, Mike DesJardin, Michael Mann
Dow North America, Western R&D Labs, Pittsburg, CA 94565.

In situ mass spectrometry has proven to be an invaluable tool in the characterization of process streams in a chemical plant. Three applications are described, and each highlights a particular strength of mass spectrometry for process analysis.

The first application is a tracer experiment on a large production-scale reactor. In a tracer experiment, an inert compound is injected into a reactor, and its elution profile is obtained (in the form of a selected-ion chromatogram) as it exits the reactor. A mass spectrometer, with argon gas as a tracer compound, is well suited for this type of study on vapor-phase reactors. In the experiments to be described, less than two pounds of argon gas provided a readily discernible signal at the sample point. The real-time data acquisition capabilities of the mass spectrometer allow for continuous monitoring of the tracer compound, making it possible to fully characterize the elution profile. Results from such a study make it possible to describe the macromixing behavior of the reactor or unit operation, which in turn allows for much more accurate reactor modeling calculations. **Figure 1** illustrates how an experimentally obtained trace can be compared to a well characterized macromixing model.

Figure 1



The second application employed the mass spectrometer vacuum system to ensure that a representative sample was obtained. A chemical plant was experiencing operational upsets when it was run at high feedrates. As a result, the plant was facing a substantial loss in capacity. The problem was traced to a vacuum flash separator, but it proved difficult to obtain a sample for off-line analysis, since the process was run at sub-ambient

pressures. Since the mass spectrometer was operated at even lower pressure, there was sufficient pressure drop to draw analyte into the ion source. A calibrated flow of argon gas was introduced into the process as an internal standard, and the mass spectrometer was able to provide real-time composition and flow rate data. Using this method, the source of the capacity problem was deduced.

The last set of experiments describe the apparatus for transfer-line GC/MS of process gases. This combination provides a robust analytical method for unattended operation of catalyst screening reactors and process streams where rapid turnaround and complete sample identification is required. Short lengths of narrow-bore (10-100 micron I.D.) capillary GC column are used to provide pressure drop into the mass spectrometer and to transport the sample from an external sample injector. Separations typically take from thirty seconds to a few minutes (10-100 times faster than conventional GC/MS), with RSD's on replicate injections consistently less than 5%. The apparatus is conducive to automation, making possible unattended operation for runs of up to a week in duration. **Figure 2** demonstrates a typical separation from a catalyst screening reactor for a process that has very high water content and contains corrosive gases. This process has been monitored using this method for several months, without requiring any maintenance on the mass spectrometer system.

Two Improved Probe Designs and a Modified Source for Desorption Chemical Ionization on the HP5989A Mass Spectrometer

Christopher W. Baker[1] and William J. Jones[2] John A Masucci[2]

[1]Scientific Instrument Services, Inc., [2]R.W. Johnson Pharmaceutical Research Institute

Analysis of samples by direct introduction of the sample into a mass spectrometer via a direct probe is a routinely used analytical tool. Through the years, direct probes have been used on many different mass spectrometers including magnetic sector instruments as well as quadrupoles and ion traps. There have been various designs utilized, many of which have been made available commercially by the mass spectrometer manufacturers.

This article details the design of two new probes for use on the Hewlett-Packard 5989 MS Engine mass spectrometer and demonstrates the usefulness of these two probes for solving analytical problems. The first probe described is a Direct Probe (DP) and the second probe discussed is a Direct Exposure Probe (DEP). The work on the new direct probe design was begun in an attempt to improve on the design of the standard direct probe manufactured by Hewlett-Packard. The standard HP probe has a very slow heating rate which makes it more difficult to use for the analysis of some compounds. The DEP probe is designed and manufactured to provide an additional probe technique which is not currently available from Hewlett-Packard.

Experimental

All experiments were performed on a Hewlett-Packard 5989 MS Engine. The two new probes described below, both designed by Scientific Instrument Services, were utilized to introduce the sample into the mass spectrometer. The standard HP direct probe inlet port was used as the introduction port for insertion of the probes. The probes were ramped at the highest temperature rate that the probe design would allow. All data was acquired using the chemical ionization mode of operation using ammonia as the reagent gas.

Direct Probe

In the new Direct Probe (DP), the heater coil is actually wrapped around the sample vial holder, providing direct heating of the sample. This design eliminates the problem of heat transfer to the sample. Also the probe tip is manufactured from a small, low mass piece of silver which provides good thermal heat transfer to the sample being analyzed. The location of the heater coupled with the relatively small thermal mass of the probe tip allows for ballistic heating of the sample. Control of the temperature in the new designed Direct Probe can be accomplished through the HP data system since the probe is equipped with the same electrical connections and power requirements as the HP original. The thermocouple has also been moved up to the base of the sample cup holder providing the user with an accurate measurement of the sample temperature. The rapid heating rates combined with accurate measurement of the sample temperature provide for more accurate and reproducible results.

The Direct Probe can be used in two different configurations which allows the user to optimize the analysis depending on the type of samples being analyzed. In the standard mode of operation the DP can be used with glass capillary sample vials which are inserted into the end of the probe. They are held in place by a small spring. Quartz sample vials could also be used. Samples are dissolved in a solvent and then the resulting mixture is injected into the sample vial where the solvent can be allowed to evaporate leaving the solid or liquid residue of the sample of interest. Solid samples can also be analyzed directly by placing small amounts of the solid sample directly in the vial. An alternative technique uses a gold plated stainless steel probe tip as a sample cup in place of the glass sample vial. The sample is placed on the very end of the gold plated tip as described earlier. Although the sample is not directly heated in this experiment the relatively short length of the probe tip and the gold plating used on the tip allow for adequate volatilization of the sample when inserted into the mass spectrometer. With both direct probe techniques, control of the temperature can be achieved through the HP data system. Both techniques are used to acquire the data presented in this paper as shown below.

Direct Exposure Probe

A new DEP Probe was also designed for use on the HP 5989A mass spec. This type of probe design is not currently available from Hewlett-Packard. This probe technique has been called direct exposure probe (DEP) mass spectrometry as well as direct chemical ionization (DCI) probe mass spectrometry. In this style of probe, a replaceable probe tip is used which has a small resistance heating wire filament loop which serves to hold the sample. The probe, with the sample in place on the filament heater wire, is inserted into the mass spectrometer placing the sample inside the mass spec source close to the electron beam. After the probe is inserted into the source of the mass spectrometer a small current is passed through the wire loop to directly heat the sample. Since the sample is sitting directly on the filament wire, which is heated to volatilize the sample, this probe design provides for the fastest temperature ramps and a very short analysis time.

Results and Discussion

Analysis of the Drug Topiramate via Direct Probe

The standard Hewlett-Packard Direct Probe (DP) was used to analyze a new drug called topiramate. In the total ion profile the sample comes off in a broad range over a two minute time frame starting at approximately one minute into the analysis. The broad and jagged appearance of the total ion profile is possibly due to thermal decomposition of the sample, created by the slow heating rate of the HP Direct Probe. Topiramate has a molecular weight of 339. The M+NH4 ion at 357 is the base peak, however a significant peak at mass/charge ratio 278 is also present. This is the ammonium adduct ion of the alcohol produced by the cleavage of the sulfamate group from the topiramate. It is theorized that this peak is the result of thermal decomposition of the parent drug due to the slow rate at which the topiramate is heated.

The same analysis for topiramate was done using the SIS designed Direct Probe using the gold plated insert described earlier. The total ion profile is a sharp, symmetrical peak and the sample is completely volatilized in just over 30 seconds. Improvement can be seen over both the standard HP probe as well as the SIS Direct Probe when used with a glass capillary sample vial. The mass spectrum again shows the 357 peak as the base peak, however the peak at 278, is nearly gone. The ratio of the 357 to 278 peaks is much greater due to the rapid heating of the sample which minimizes thermal degradation of the sample.

Analysis of Topiramate via Direct Exposure Probe

Topiramate was also analyzed using the SIS DEP which was used with the sample placed directly on the filament wire loop. The sample was inserted into the mass spec source and then volatilized. The mass spec was again used in the CI mode using ammonia as the reagent gas. The total ion profile shows the sample volatilizing in less than 1.5 minutes, however the peak shape is not as symmetrical as the profiles from the direct probe. The mass spectrum shows that 357 remains the base peak, however the 278 peak is slightly larger than was seen in the SIS Direct Probe data . This suggests that although the DEP probe produced less thermal decomposition than the HP direct probe, the SIS Direct Probe used with a gold plated stainless steel probe tip is the most effective direct probe mass spectrometry technique for the analysis of topiramate.

Conclusion

Analyses via Direct Probe mass spectrometry can be difficult on the Hewlett-Packard 5989 MS Engine with the HP designed direct probe due to the design limitations which do not provide for adequate heating ramp rates. Two new probe designs from Scientific Instrument Services, the Direct Probe and the Direct Exposure Probe, provide increased heating rates, greater flexibility of techniques and therefore allow the analysis of a wider range of compounds. A Direct Probe was designed and manufactured which provides fast heating rates and can be configured for use with either a glass capillary sample vial or a gold plated stainless steel probe tip. A Direct Exposure Probe was also designed and manufactured which allows the user to insert the sample directly into the mass spec source. This probe has replaceable probe tips providing great flexibility. The probe was used with both a filament wire loop and with a glass encapsulated filament loop for this paper.

The Analysis Of Alkylated Diphenylamines By High-Performance Liquid Chromatography / Particle-Beam / Mass Spectrometry

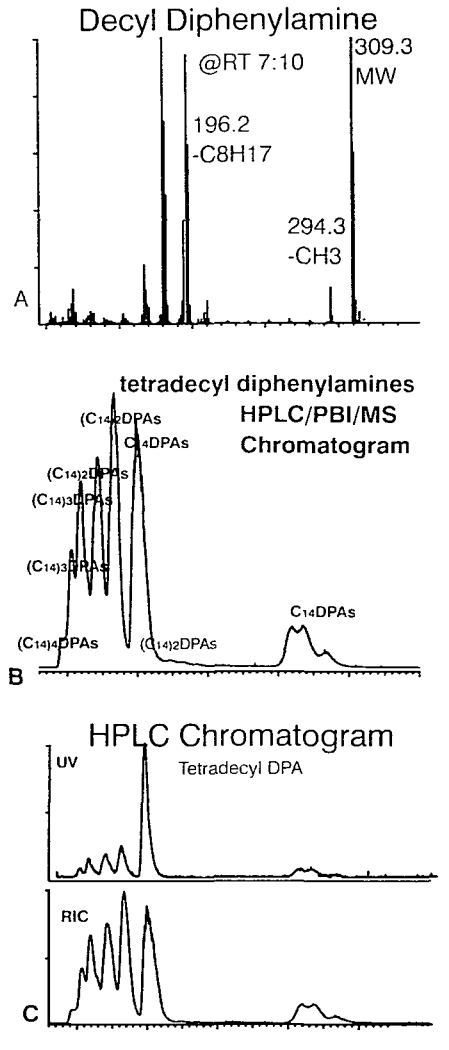
Nero, V. P. and D'Antono, J. A.
Texaco Research and Development, Beacon, NY 12508

Polyalkylated aromatic diphenylamines (DPAs)are commonly used antioxidants in lubricants. DPAs are complex mixtures in which the extent of alkylation, point of attachment of the DPA along the alkane chain, and the positions of the alkyl groups on the phenyl ring will vary. A high-performance liquid chromatograph (HPLC) coupled to a quadrupole mass spectrometer with a particle-beam interface (PBI) was used to resolve and analyze this mixture.

A 0.2% hexane solution of the various alkylated DPAs, ranging up to tetradecyl DPAs, were injected, using a loop injector, onto a Spherisorb 5 um Amino column (15cm X 2mm ID) and eluted with a methylene chloride / hexane gradient. The gradient started as 100% hexane and was increased linearly to 50% methylene chloride. The flow rate was held at 0.2ml /min. The HPLC was directly coupled first to an ultraviolet detector set at 280 nm. Next, a quadrupole mass spectrometer was coupled in series via a Finnigan-Mat particle-beam interface. The interface was held at 40°C and used helium as a nebulizing gas.

Eluting compounds were identified using a Finnigan-MAT SSQ710 mass spectrometer. This instrument was scanned from 100 to 900 amu at 1 scan per 0.8 sec. The source temperature was held at 250°C and was operated under electron impact conditions with an ion current of 200 uA at 70 eV. The mono-, di-, tri- and tetra- DPAs were readily separated and characterized by their mass spectra. (Figure A)

The less polar compounds eluted first, as expected for an amino column when using a non polar solvent. However, the elution sequence was more complex than initially anticipated; Unreacted alkenes, used in the manufacture of DPAs, eluted first. These olefins were transparent to HPLC ultraviolet detector. Next, the more alkylated DPAs eluted. The alkyl groups shield the functionality of the amino group and reduce the overall polarity of these molecules. Finally, the major components followed and were determined to be di- and mono-alkyl DPAs. (Figure B) The point of attachment of the DPA to the alkyl chain also effected its elution time. When the alkylation occurred close to the beta or gamma position on the alkane chain, the corresponding product eluted earlier. If the alkylation occurred towards the middle of the alkane chain, the corresponding product eluted later. Both the ultraviolet and mass spectral detection provide similar, but not identical quantitative results. It appears that the particle-beam interface might discriminate in favor of the heavier components. (Figure C)



COMPARISON OF FIELD DESORPTION AND THERMOSPRAY MASS SPECTROMETRY FOR THE ANALYSIS OF PETROLEUM RESIDUA

C. S. Hsu, R. V. Kadtke and G. J. Dechert
Exxon Research and Engineering Co., Annandale, NJ 08807

Mass spectrometry has been used in petroleum industry as a powerful analytical technique to characterize hydrocarbon mixtures at molecular levels. Various mass spectrometric techniques have been used to analyze different petroleum fractions, as illustrated in Figure 1. For high boiling petroleum residua, field desorption (FD) has been the method of choice, which does not require vaporization of the sample prior to ionization. In FD, the sample is deposited onto an activated emitter which is made of a fine wire. With a high voltage (10-13 kilovolts) across the emitter and a counter-electrode at a short distance, a high electric field is produced to ionize sample molecules near the surface of the emitter and expelled out of the sample matrix by Coulombic repulsion. If several layers of molecules are present between the surfaces of the emitter and the sample matrix, dimer ions can be formed via ion-molecule reactions. Figure 2 shows a FD spectrum of a 875-1026°F distillate from a vacuum residuum of a Californian crude oil. The average molecular weight of this fraction is near 500. However, the presence of dimers with molecular weights between 700 and 1300 is also apparent. With FD, it is also difficult to perform high/medium resolution mass measurements due to short duration of signals.

We have evaluated thermospray (TSP) as an alternative ionization technique to FD for the characterization of high boiling petroleum residua. In TSP, the sample is carried by a mobile phase which is sprayed out of a heated nebulizer and ionized by a heavy duty filament or a discharge electrode. Solvent molecules which are in excess are ionized preferentially by electron bombardment or discharge ionization. These solvent ions then ionize sample molecules via protonation or hydride abstraction. Since the sample molecules are not directly heated and ionized, intact protonated or hydride-abstracted molecular ions are formed in TSP.

The same distillate as in the FD experiment mentioned above was dissolved in a mobile phase of 75% methylene chloride and 25% hexane. A discharge electrode is used as an external ionization device for TSP, yielding a spectrum shown in Figure 3. The distribution of the ions in TSP is quite similar to that in FD. Most noticeable is the absence of a dimer cluster. However, TSP has a major disadvantage of not being able to ionize saturated hydrocarbons because all of the suitable solvents have similar or higher proton affinity than saturated hydrocarbons.

With TSP a hydrocarbon mixture can be separated by liquid chromatography (LC) and analyzed by MS on-line. Since TSP yields strong and more stable signals than FD, slower scans for high/medium resolution mass measurements are possible. The combination of on-line LC and high/medium resolution MS can provide not only molecular weight determination but also compound class identification. We have successfully applied this combination to a 1120-1305°F fraction of a vacuum residuum from a Middle East crude oil.[1]

Table 1 compares between field desorption and thermospray for the characterization of heavy hydrocarbons.

MULTI-SAMPLE PROBE FOR FAST ATOM BOMBARDMENT MASS SPECTROMETRY

Marshall M. Siegel*, Rushung Tsao, William Bouley, Theodore Kornas, Glen Brubaker
American Cyanamid Company, Medical Research Division,
Lederle Laboratories, Pearl River, New York 10965

INTRODUCTION

The traditional method for the analysis of samples by fast atom bombardment (FAB) is to load a single sample onto a probe target and then insert the probe into the mass spectrometer through a vacuum lock. In our laboratory environment, large numbers of FAB samples are analyzed to support pharmaceutical development. An inexpensive and routine method was needed to increase the productivity in generating large numbers of high quality low and high resolution FAB spectra. Flow-FAB and TLC-FAB were evaluated and found not to produce the same quality spectra as by probe analysis. We designed a multi-sample FAB probe for the consecutive analysis of five (or more) samples. With this probe, FAB spectra are produced with equal or better quality than those with the single sample probe but are generated with minimal effort and twice the speed. In addition, the design chosen requires no major modifications to the existing spectrometer system thereby minimizing implementation costs. The new multi-sample probe is an extension of the "reference" probe design introduced by VG for Flow-FAB.

DESIGN DETAILS

A VG ZAB-SE mass spectrometer equipped with an "open" FAB source, originally designed for Flow-FAB, and a vacuum lock perpendicular to the spectrometer beam axis was used. A schematic diagram of the multi-sample probe and source assembly is illustrated in Figure 1. A rectangular probe tip, 72 mm x 5 mm x 1.5 mm, containing five (or more) sample wells was fabricated from stainless steel and polished. A polished surface improves the adhesion of the sample and matrix to the surface and minimizes sample spreading from the confines of the well. The wells are 2.5 mm wide, 1 mm deep and spaced 5 mm apart. About 1 µl of dilute matrix and sample are respectively placed at the top of each well after the probe tip is rotated on its axis and held at about 45 degrees. The samples flow into the wells completely filling them. The multi-sample probe tip is introduced into the FAB source perpendicular to the spectrometer beam axis via the vacuum lock extension. The vacuum lock extension is 3 inches long to accommodate the elongated probe tip for evacuation before introduction to the high vacuum of the spectrometer. "O" rings at both ends of the inlet extension serve to seal the system upon insertion of the probe. After evacuation, the high vacuum valve is opened and the probe is pushed into the high vacuum region until constrained by the probe stop. At this point, the probe guide is locked into place with the thumb screw located on the probe guide extension. The translation of the probe and tip in the source region is controlled by a high performance Mitutoyo vernier dial (Model 297-201). As illustrated in Figures 2A and 3, when the probe tip enters the source block it makes electrical contact with a flexible stainless steel clip. This spring clip attaches securely around the screen plate which floats at the source potential. The clip can be easily disconnected from the screen plate without disassembling the source. (Exploded views of the spring clip and the multiple target tip are also illustrated in Figures 2A and B, respectively.) Each sample well is fully irradiated by the cesium ion beam without cross contamination. Transmission of the secondary ions is very efficient due to the closeness of the irradiated samples to the ion optics.

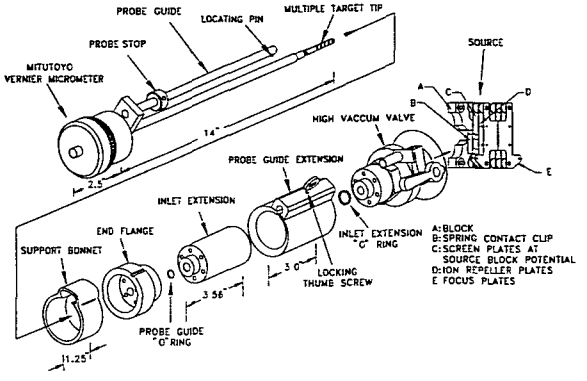

Figure 1. Exploded view of the multiple target FAB probe assembly. The original VG components are the end flange, high vacuum valve and FAB source (excluding the spring contact clip).

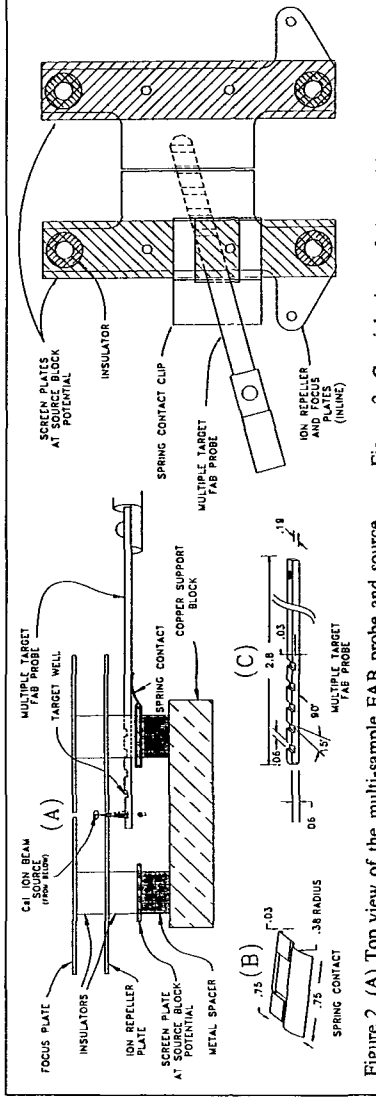

Figure 2. (A) Top view of the multi-sample FAB probe and source assembly. Exploded views of (B) the stainless steel spring clip, and, (C) multiple well target tip.

Figure 3. Coaxial view of the multisample probe tip, spring clip and FAB source assembly.

The multi-sample probe assembly has been in continuous use now in our laboratory for over nine months. The throughput of low resolution FAB samples has increased by about 50%. In the high resolution peak matching mode, pairs of adjacent samples, each with internal standards, can be rapidly analyzed without additional tuning. To maximize the number of samples analyzed, one does not use an excessive amount of FAB matrix so as to keep the source pressure as low as possible during the analysis but not too sparingly so that the matrix does not evaporate before the last analysis. For lengthier analyses, this can be achieved by using slightly more matrix for the later samples versus the earlier samples. The less volatile matrixes *m*-nitrobenzyl alcohol and a 5:1 (w:w) mixture of dithiothreitol:dithioerythritol have been found to work best with the multi-sample probe for a wide variety of pharmaceuticals.

Presently, the multi-sample probe is being automated. The design includes the following modifications. A stepper motor, which is software controlled, is being attached to the manual vernier dial. Rapidly interchangeable probe tips are being designed. With these modifications, up to ten FAB samples can be automatically analyzed without operator intervention. During the automatic operation of the probe, additional samples can be prepared and loaded on to the interchangeable multi-sample FAB probe tips. A net increase in sample throughput of 100% is anticipated upon installation of these improvements.

The Use of a Variable Focus Cesium Ion Source to Facilitate the On-line Generation of FAB Spectra with Particle Beam LC/MS

*Vicki Lanyon and Alexander B Schilling, The Hewlett Packard Company, Naperville, IL 60566

Introduction:

Particle Beam (PB) LC/MS operates by separating solvent from analyte molecules on the basis of differences in their momentum as they pass through a series of skimmers. The net result is an analyte enriched particle beam that enters the source and then is vaporized by source heat and ionized by electron impact or chemical ionization. This has limited the use of PB to compounds that exhibit some volatility The combination of PB with on-line FAB has been previously described using Xe ion sources[1] A focused Cesium ion source provides a higher current density at the sample platform as well as simplifying the alignment procedure needed to successfully interface PB and FAB

Experimental

A Phrasor Scientific cesium ion source was mounted to a HP 5989A MS by means of a clear Lexan(TM) plastic (1" thick) flange that facilitated visual inspection of the source alignment with the primary ion source The flange was tested with the source at 275 C for 2 weeks to ensure that radiant heat from the source would not damage it An inlet for the target probe was constructed to rigidly hold the probe and prevent contact with the repeller The holes on the repeller were enlarged to better accommodate the increase diameter of the target probe shaft The magnetic yoke was removed to give the cesium ion beam a clear path to the target probe tip When used in positive ion mode the target probe tip was allowed to float electrically with respect to the repeller Negative ion mode operation required that the tip carry a potential This was accomplished using either an external power supply or by coupling the tip to the repeller voltage. Two types of probe tips were studied, a bevel ended tip and a flat sectioned tip (referred to here as a spoon tip). Samples were introduced by means of a particle beam interface with a HP 1090L pumping system and methanol as the solvent (0 6 mL/min) using a 2 uL injection The Cesium ion source was operated at an acceleration voltage of 8 kv with a 1 0 uamp current The matrices used were glycerol, thioglycerol and 3-nitrobenzyl alcohol The source temperature was 40C and an HED was used at 9300 V A series of peptides such as the enkephalins, Substance P, Physalaemin and nucleotides such as AMP and GMP were used to evaluate the instruments performance.

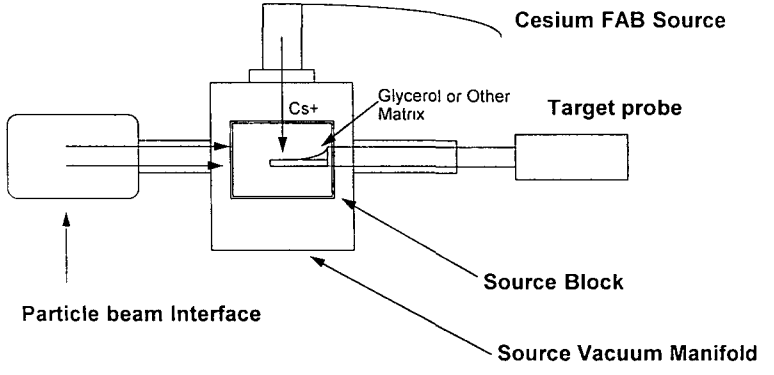
Results and Discussion

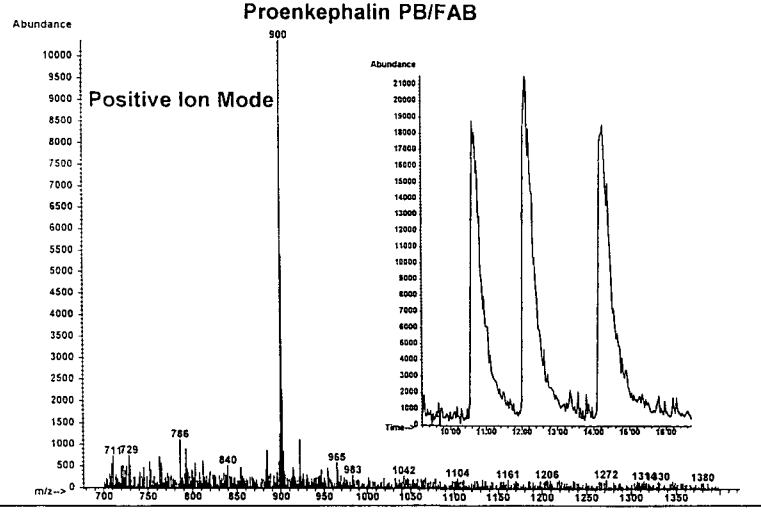
The work completed demonstrates that a variable focus cesium ion source can be successfully interfaced to a commercially available quadrupole mass spectrometer. The use of a cesium ion source results in lower operating vacuums than are attainable with Xe ion sources because of the increased gas loads produced by using Xe gas When used in conjunction with a particle beam LC/MS interface for sample introduction, the best results were obtained with beveled target probe tips of narrow shaft diameter with a circular depression cut into them These tips allowed continuos operation for an hour , with minimal carryover due to excessive glycerol matrix loading.

[1] Kirk and Browner, Biomed Environ Mass Spec., 18, 355-357 (1989) and references therein.

In order to prevent rapid depletion of the glycerol the source temperature must be maintained at less than or equal to 40 C. This effectively precludes chromatographic separation using buffers as the source fouls very quickly under these conditions The system therefore is currently optimized for flow injection analysis (automated FAB) Ongoing work utilizing a continuos flow probe to ensure the constant supply of glycerol matrix at the target probe tip is underway.

How Particle Beam FAB Is Done





Selective Enhancement of Cationic Surfactant Ion Signal in Fast Atom Bombardment Mass Spectrometry

Yu-Chie Chen and Jentaie Shiea*
Department of Chemistry, National Sun Yat-sen University,
Kaohsiung, Taiwan, 804

The FAB signal of quaternary amines with different surface activity was found to vary with the concentration of sodium dodecylsulfate (SDS) present in the glycerol matrix. By controlling the concentration of SDS in the matrix, the signal of a series of equal concentration of quaternary amines with different alkyl chain can be selectively enhanced. Figure 1 shows the FAB spectra obtained from such samples which contain different concentration of SDS added in the matrix. The spectra show that with increasing SDS concentration, the signal of the less surface active compound increasing gradually. The changes of TIC of C_{16}-trimethylamines with irradiation time is very stable and decreasing with increasing amount of SDS in the matrix. The change of TIC of C_8-trimethylamine with irradiation time shows the reverse trend as that of C_{16}-trimethylamine. The explanation of this observation can be explained as the differences in the rate of formation of ion-pair precipitate from the reaction of SDS with the opposite charged surfactants (quaternary amines) in the matrix.

As we know, the trend to form ion-pair precipitate depends on the chemical properties of the surfactant. For their lower solubility in the aqueous solution and stronger van der waals forces with SDS, longer alkyl chain quaternary amines should form precipitate with SDS faster than that of shorter alkyl chain quaternary amines[2]. The FAB signal of the analyte will decrease when the precipitate was formed by this ion pair reaction. This is the reason why the signal of more surface active amines decrease with adding of SDS. In another word, after adding SDS, the increasing signal intensity of short chain quaternary amines on FAB spectra is not due to increasing of absolute concentration in the matrix. This is actually due to the suppression of the signals intensity of longer alkyl chain quaternary amines by the increasing of precipitate form (with SDS) in the matrix. This explation can be supported by the results from the experiments described below. Equal concentration of SDS was added into the aqueous solution each contained one species of solvated quaternary amines (from C_8 to C_{16} trimethylamines individually). The turbidity of each solution was measured by a turbidimeter. In Figure 2, we can see that the turbidity of the solution which contained C_{16} quaternary amines and SDS shows the highest turbidity. The turbidity of the solution which contained C_8 quaternary amines did not changed even in the solution which contained high concentration of the analyte and SDS. Since the formation of ion-pair precipitate will consume free SDS molecules, we should expect that the signal of SDS decreases for the solution which contain longer alkyl chain quaternary amines. This is clearly showing in Figure 3 where the intensity of SDS signal (obtained by negative FAB analysis) decrease with increasing of the alkyl chain in the quaternary amines.

One of the practice of using the matrix system described in this paper is to properly determining the species of charged surfactants with different surface activity. Figure 4 shows the FAB spectra from a emulsifying agent used in dye industry. The sample is comprised mainly of alkyldimethylbenzene ammonium chloride. It can be seen that, without adding SDS, only one series of peaks (m/z 304-388, m/z 388 as the prominent peak) can be observed in the FAB spectrum (Figure 4a). As the concentration of SDS increasing to 0.3 mM, the peak with m/z 304 turns to be the prominent peak (Figure 4b). When 5mM of SDS was added, a new series of peaks (m/z 248 and 276) were observed on the FAB spectrum (Figure 4c).

FAB MS OF NON-VOLATILE COMPOUNDS IN THE TRANSITION RANGE BETWEEN LIQUID AND SOLID

K. Anheuser, E. Junker and F.W. Röllgen
Institute of Physical and Theoretical Chemistry, University of Bonn
Wegelerstr. 12, D-53115 Bonn 1, FRG

In Fast Atom Bombardment Mass Spectrometry (FAB MS) molecules are ionized from liquids under conditions of continuous erosion of layers by sputtering. We have investigated the limits of this mode of ionization in the transition range between the liquid and solid state of samples for ammonium nitrate and raffinose.

EXPERIMENTAL

The experiments were performed with a double focusing AEI MS902 mass spectrometer. The Xenon primary particle beam was produced in a saddle field discharge source operated at 6 kV anode potential and 1 mA discharge current. The current density of the Xenon atom beam was 5-10 $\mu A/cm^{-2}$. The probe surface was in a horizontal position allowing the deposition of thick layers.

The change of the physical state of the sample solutions under bombarding conditions was monitored by optical microscopy in a separate experimental setup.

RESULTS

For a concentrated solution of ammonium nitrate in glycerol (molar ratio 1:3) and the onset of Xe atom bombardment immediately after introduction of the solution into the vacuum a steep increase of the intensity of the $[(NH_4NO_3)NH_4]^+$ cluster ion is observed after 10 min (Fig. 1). This intensity increase coincides with an optically observable formation of small crystallites of the salt in solution.

For a concentrated solution of raffinose and ammonium nitrate in glycerol (molar ratio 1:17:54) the same effect of a steep increase of the ammonium nitrate cluster ion signals upon crystallization of the salt in solution is observed. The time dependence of the molecular ion signal of raffinose was similar to that reported before [1] for a raffinose solution of similar concentration without ammonium nitrate.

Abundant and long lasting cluster ion signals are obtained from a "solid" surface layer of ammonium nitrate formed by exposing a concentrated solution of ammonium nitrate in glycerol (molar ratio 1:3) to vacuum for several hours prior to the onset of bombardment.

Long lasting and abundant cluster ion signals with a delayed steep increase during the first minutes of bombardment are also observed for a thick layer (about 1 mm) of ammonium nitrate, with residual water retained in the layer (Fig. 3).

For solvent free solid ammonium nitrate the cluster ion intensities decay within several minutes as shown in Fig. 3. The decay of the cluster ion signal and an increase of the chemical noise level indicate the accumulation of radiation damage during sputtering of the solid layer.

In contrast to ammonium nitrate sputtering of solid ammonium cloride yields an abundant long lasting $[(NH_4Cl)NH_4)]^+$ cluster ion signal with a delayed intensity increase after onset of sputtering [2] (Fig. 4). The delay indicates the effect of loosing the structure of the solid by particle bombardment [3] and the long lasting cluster ion signal shows that no radiation damage accumulates.

CONCLUSIONS

Solutions with precipitated small particles and solid deposits with solvent molecules retained are amenable to FAB MS (dynamic SIMS).

The extent to which FAB MS (dyn. SIMS) can be applied to solutions with precipitated solid particles, or to solids containing solvent residues depends on the decomposition of molecules into volatile products upon sputtering and the accumulation of radiation damage.

The dependence of the sputtering of cluster ions of the ammonium salts from a loose structure of the solid, which is also induced by preirradiation of salts [3], strongly supports a mechanism of pressure pulse sputtering for the formation of the cluster ions. In this mechanism a high pressure (≈10 kbar) generated within about 2 ps in the area of the dense cascade by the incident particle leads to the desorption of neutral and ionized intact molecules and clusters [4].

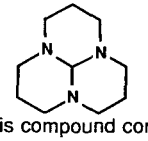
INVESTIGATION OF [M-H]+ FORMATION IN FAB/LSIMS FOR A COMPOUND WITH HIGH PROTON AFFINITY

G. J. C. Paul, T. Rendon and M. J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, P.Q. H3C 3J7

Recently numerous compounds have been shown to yield $[M-H]^+$ in FAB/LSIMS in addition to the $[M+H]^+$ species normally associated with these techniques A new compound which forms $[M-H]^+$ in FAB/LSIMS is perhydro-3a,6a,9a-triazaphenalene (PHTAP) shown below.



What is especially interesting is that this compound contains three basic amine groups giving it a large proton affinity and exclusive $[M+H]^+$ formation in FAB/LSIMS would be expected. However, the presence of a -CH group α– to three nitrogen atoms is sufficient to provide a site for hydride abstraction in FAB/LSIMS. PHTAP was studied by FAB/LSIMS using several liquid matrices; 1,2,4-butanetriol (BUT), diethanolamine (DEA), glycerol (GLY), 2-hydroxyethyl disulfide (HEDS), 3-nitrobenzyl alcohol (NBA), thiodiglycol (TDG) and thioglycerol (THIO), to gain insight into the ionization processes occurring. CI and electrospray data were taken to complement this study.

A typical FAB mass spectrum for PHTAP is shown in Figure 1. The only significant analyte peaks are in the molecular ion region with $[M-H]^+$ dominant. The relative molecular ion intensities for PHTAP are given in Table 1 for each liquid matrix. For five matrices a dramatic time effect is observed as the relative intensity of $[M-H]^+$ increases relative to $[M+H]^+$. For HEDS and NBA, the duration of fast atom bombardment does not have a significant effect on the $[M-H]^+/[M+H]^+$ ratio. LSIMS experiments have also been performed for PHTAP in TDG and NBA. Similar molecular ion intensity trends to those in FAB are observed (Table 1). The CI (NH_3) mass spectrum for PHTAP is shown in Figure 2. The molecular ions are again dominant but here $[M+H]^+$ is the major species with $[M-H]^+$ weak (Table 1) The CI data makes it difficult to rationalize strong $[M-H]^+$ formation in FAB/LSIMS for PHTAP purely in terms of gas phase ionization processes where the protonated matix is assumed the major reactant species. This is because the hydride ion affinity of NH_4^+ is greater than those estimated for protonated BUT, DEA, GLY and THIO yet the relative intensity of $[M-H]^+$ in FAB in those matrices is greater than in CI (NH_3) (Table 1).

Hence, condensed phase ionization processes appear to be at least partially responsible for $[M-H]^+$ formation in FAB/LSIMS. The time dependence exhibited by the molecular ion intensities in FAB/LSIMS for PHTAP with certain matrices is consistent with this interpretation. In the condensed phase ionization model for FAB/LSIMS a build-up of reactant electrophilic species responsible for hydride abstraction with increasing time of fast atom/ion bombardment would explain the increase of $[M-H]^+$ relative to $[M+H]^+$. The time effect thus suggests the importance of fast atom/ion beam-induced processes in the condensed phase ionization model. It is interesting that a significant time dependence is not observed for PHTAP in HEDS and NBA. These matrices have been seen to inhibit fast atom/ion beam-

induced reduction processes through their proposed electron/radical scavenging properties. These properties may similarly be responsible for the lack of a time dependence for PHTAP in HEDS and NBA as fast atom/ion beam-induced processes are believed responsible for this effect. Indeed, in this work it is seen through negative ion FAB that HEDS and NBA are the only matrices capable of forming radical anions through electron capture.

The ESI mass spectrum for PHTAP is shown in Figure 3. In ESI, ionization occurs predominantly through condensed phase equilibrium processes with no fast atom/ion bombardment taking place. The $[M+H]^+$ is dominant with only a small $[M-H]^+$ peak present, possibly through unimolecular decomposition (Table 1). This again suggests that fast atom/ion beam-induced processes are responsible for the strong $[M-H]^+$ peaks observed in FAB/LSIMS for PHTAP.

IMPROVED DYNAMIC (CONTINUOUS FLOW) LSIMS (FAB) SENSITIVITY USING A COLD FINGER TO ENHANCE PUMPING

Klaus Eckart, Adrian R. Woolfitt§, Robert S. Bordoli§ and Joachim Spiess
Department of Molecular Neuroendocrinology, Max Planck Institute for Experimental Medicine, Hermann-Rein-Str. 3, D-3400 Goettingen, § VG Analytical, Wythenshawe, Manchester M23 9LE, UK

Dynamic or continuous flow LSIMS (FAB) has a number of advantages compared with static LSIMS, such as improved detection limits, reduced suppression effects, shorter analysis time, and LCMS capability. In favourable cases, such as the peptide substance P (MW 1347), a 200-fold sensitivity improvement has been reported. However, higher mass compounds such as glucagon and the insulin B chain exhibit a weaker response when analyzed with Dynamic rather than Static LSIMS (1). This has been attributed to the adverse effects of source housing pressure on the transmission of such ions. Indeed during experiments with a prototype electrospray interface on a sector instrument (VG AutoSpec) a clear relationship between source housing pressure and ion transmission was established; the effect was most marked for larger proteins such as bovine serum albumin (66 kDA).

We have designed a cold finger in order to overcome the transmission problems associated with the high solvent vapor pressure from the dynamic probe. The factors affecting the performance of the system are investigated and the best operating conditions are presented.

All experiments were carried out on a VG Analytical AutoSpec-T tandem mass spectrometer. LSIMS spectra were obtained using standard LSIMS conditions. The design of the dynamic screen/wick probe has been described in detail (2). The probe was used with a 10μm screen. Samples were continuously delivered in 49.5% water, 49.5% acetonitrile, 1% glycerol, and 0.1% TFA through a 50μm inside diameter capillary. The measurements of the molecular ion intensities were carried out using the peptides Xenopsin in 10ng/μl concentration and the ACTH (18-39) fragment in 100ng/μl concentration. The cold finger was manufactured from stainless steel. It replaces the glass lid above the ion source and incorporates a circular glass window for visual inspection of the ion source under operation. The pumping speed of the cold finger is calculated to be approximately 1000 l/second for water.

Two peptides with molecular weights of 1000 and 2500 dalton were used to establish the dependence of sensitivity and molecular ion intensity (response) from flow rate. A part of these results is displayed in Figure 1. The following aspects should be noted: as expected, the *molecular ion intensity is increased in any case when the cold finger is operated. This increase* amounts to a factor of 1.3 for xenopsin at 1μl/minute and 2.3 at 5μl/minute. For ACTH 19-38 we obtained factors of 2.5 and 8.0, respectively. In addition for glucagon a molecular ion was only detected with cold finger operation. This increase in cross section with increasing mass for collisionally activation observed in these experiments is confirmed by the same behaviour using a collision cell in MSMS experiments.

The sensitivity expressed in coulomb/μg is reduced when the flow rate is increased. This must be attributed to an increasing source housing pressure but it cannot be excluded that the conditions are changing on the probe with the amount of matrix delivered. Independently of the molecular weight the best sensitivity is obtained at the lowest possible flow rate in conjunction with the cold finger operation. We found in addition that reduction of the flow rate from 1.0 to 0.5 μl/min decreases the molecular ion intensity by more than 90%. This indicates that not sufficient glycerol is delivered for LSIMS operation. Earlier experiments showed that

1% glycerol is the best concentration to obtain maximum sensitivity. This finding is in agreement with the results obtained by another group (3).

Increasing pressure reduces the transmission through the ion source housing by scattering and collisionally activated decompositions. This effect is investigated in the linked scan spectra of substance P (data not shown). The operation of the cold finger reduces significantly the amount of collisionally activated fragmentation, but the presence of d-ions even with the cold finger operation indicates a significant amount of high energy collision induced fragmentation. This is completely removed in the linked scan spectrum using the static probe (DTT/DTE matrix). These results support the conclusion that the changes in sensitivity are mainly due to changes in source housing pressure. It should be noted that the molecular ion beam of substance P is more than tripled by the cold finger operation. Nevertheless the linked scan spectrum is less intense compared to the spectrum obtained using 70% reduction with a collision gas in the collision cell. This leads to the conclusion that most of the ions are lost in the acceleration region.

The cold finger enables a sensitivity improvement by a factor of 2 to 10 depending on the sample and operating conditions. Linked scan spectra had shown that even under cold finger operation the ion beam is significantly decreased by collisions with solvent vapor. Highest sensitivity was achieved in all cases by operating the probe with a flow rate of 1μl/min. The cold finger needs five minutes to achieve maximum pumping and is operative for one hour when filled with liquid nitrogen. The advantage compared to a cold trap is that it can be made easily in a machinery workshop and it can be taken out when it is cooled down in order to protect the pumps from acid. The pumping speed of a cold trap which is limited by the diameter of the throat is expected to be in the same range of the cold finger.

The Effects of Analyte and Matrix Properties on the True Reduction-Oxidation Extents Observed in FAB/LSIMS Analysis of Peptides

J. Visentini*, M.Allard, D. Zidarov and M.J. Bertrand,
Regional Center for Mass Spectrometry, Department of Chemistry,
University of Montreal, Montreal, Canada H3C 3J7

Reduction-oxidation processes which may occur during FAB/LSIMS analysis of peptides are believed to be responsible for the frequent observation of elevated A±n peak intensities [A=(M+H)+, n≥1]. Early work in this area attributed the discrepancy between expected and measured peak intensities entirely to redox products. The reduction extents determined by isotopic peak ratio measurements alone, however, may contain contributions from radiation-induced background signal which may sometimes mask trends in true redox processes. A deconvolution procedure recently developed in our laboratory[1] has proven to be useful for the isolation of actual redox extents and background level from overall measured signals. With the aid of this new tool, the effects of the analyte structure, matrix composition, time of irradiation and sample concentration on the actual redox extents can be studied. All isotopic peak ratio measurements were made using narrow voltage scanning and multi-channel acquisition on a VG Autospec-Q mass spectrometer equipped with a variable energy caesium ion gun. The instrument was operated at an accelerating voltage of 8 kV and maintained at a mass resolution of 2000. Integrated peak areas were averaged over a 5 minute period in order to maximize reproducibility. The computer program SIMBROC[1] (Simulated Background and Reduction-Oxidation Calculations) used to evaluate the individual contributions of redox extents and background signal was written in Fortran 77 and requires only a few seconds for execution. The Red_n and Ox_n values given by SIMBROC represent the extents of those reduction and oxidation processes, respectively, by which *n* hydrogens/electrons are transferred. The redox extents are given as percentages of the sum of all redox processes. The $Back_1$ and $Back_2$ values, however, represent the background level as percentages of the base peak intensity in the molecular ion cluster.

In order to study the effect of analyte structure on redox extents, a series of peptides were analysed under similar conditions and the SIMBROC results are given in Table I. The lack of correlation between redox extents with the hydrophobicity/hydrophilicity indices (ΔF values), indicates that the redox extents are not dependent on the solubility or distribution of analyte in the liquid matrix. The relationship between structural features of the analyte and the redox extents was also examined. Possible reduction sites found in peptides include disulfide bridges which reduce extensively in glycerol or thioglycerol matrices, phenyl rings or other unsaturated sites, and carbonyl groups which are found in the backbone structure of all peptides. The data presented in Table I indicate that as the number of unsaturated sites in the peptide increases, the extent of two-electron reduction also increases. In fact, Figure 1 illustrates that the extent of two-electron reduction varies linearly with the number of unsaturated sites and that each unsaturated site contributes approximately 0.18% of two-electron reduction. The Red_2 values were also found to increase with increasing number of phenyl rings although the relationship was not a linear one. Moreover, SIMBROC results indicated that the redox extents do not vary linearly with the number of carbonyl groups present in the peptide chain. The carbonyl groups and phenyl rings therefore provide sites for reduction without being preferentially reduced. In the cases of substance P and pentaalanine, oxidation processes seemed to be favoured probably due to the presence of more aliphatic groups in the side chains of these peptides. Besides structural features of the analyte, the matrix composition may also play an intimate role in the redox processes. Table II presents data obtained for pressinoic acid and met-enkephalin

in six different matrices. Thioglycerol causes extensive two-electron reduction in pressinoic acid and significant one-electron oxidation in met-enkephalin. Since its behaviour is unpredictable, its routine use is not recommended. When 2-HEDS, 3-NBA and 4-HBSA were used as matrices, the extent of two-electron reduction was significantly decreased while the oxidation extents increase. These results indicate that these matrices are not only inhibiting reduction processes but are also actively involved in promoting oxidation. Results from this study also indicated that actual redox extents do not generally increase with sampling time. Instead, the time dependence often observed in isotopic peak ratio measurements is due moreso to increased radiation-induced background signal with continued bombardment. Measured isotopic ratios typically increase as the concentration is lowered. When the data were treated with SIMBROC however, it was found that the concentration effect remains and cannot thus be explained solely by background interferences at the lower concentrations. By simulating concentration curves, it was found that the extent of reduction observed in peptide samples is proportional to the number of matrix molecules surrounding the analyte species.

The Effect of Functional Groups on the Reduction Behaviour of Phenothiazine-related Dyes in LSIMS/FAB Mass Spectrometry.

* M. Allard, J. Visentini, D. Zidarov and M.J. Bertrand, Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, Canada H3C 3J7

Reduction/oxidation processes in FAB/LSIMS mass spectrometry are frequent for several classes of compound, as for organic dyes. The experimental parameters shown to affect reduction extent include the nature of matrix, the beam density and the analyte concentration. The redox processes manifest themselves by an excess signal in the peaks $(M \pm n)^+$ $(n \geq 1)$ of the isotopic distribution. The real effect of experimental conditions on redox extents can only be seen once the contributions from the background and the other redox species have been isolated. The true rather than the apparent reduction/oxidation extents can be evaluated using the deconvolution program SIMBROC developed in our laboratory. SIMBROC is based on a mathematical model which assumes that each redox process affecting the isotopic distribution occurs by an hydrogen/electron exchange. For a preformed ion in solution, the redox processes are characterized as follow:

Ox_2	M^+	-	$2H^\bullet$	-->	$(M-2H)^+$	[1]
Ox_1	M^+	-	$H^\bullet$	-->	$(M-H)^{+\bullet}$	[2]
Red_0	M^+	-->	M^+			[3]
Red_1	M^+	+	$H^\bullet$	-->	$(M+H)^{+\bullet}$	[4]
Red_2	M^+	+	$2H^\bullet$	-->	$(M+2H)^+$	[5]

Equation 1 and 2 respectively represent the two and one-electron oxidation while equation 4 and 5 define the one and two-electron reduction processes. Results obtained using the SIMBROC deconvolution program are given as Ox_n and Red_n values. These data indicate the extents of oxidation and reduction respectively where n denotes the number of electrons/hydrogens transferred in the process. As for the $Back_1$ and $Back_2$ values, they represent the alternating background levels calculated by the program. Earlier work[1] conducted in our laboratory with Methylene Blue indicated that changes in the experimental parameters affect the true two-electron reduction more significantly than the one-electron reduction process. This would suggest that those two processes are occuring by different mechanisms. Two other dyes, Thionin and Azure A, have been used to monitor the extents of one and two-electron redox processes and to verify the conclusions drawn from the Methylene Blue study Table 1 shows the matrix effect on the redox processes for Methylene Blue, Thionin and Azure A. Glycerol seems to inhibit the oxidation processes for the three dyes while 3-NBA seems to inhibit the extent of reduction. The three compounds gave similar results, thereby suggesting that analyte structure doesn't play an important role in the redox

mechanisms. Figure 1 shows the concentration effect on the redox processes of the Azure A dye. The two reduction processes are increasing with decreasing concentration, while the oxidation processes increase with increasing concentration.

BEAM-INDUCED DEHALOGENATION of ORGANIC COMPOUNDS in LSIMS: EFFECT of ANALYTE STRUCTURE, HALOGEN TYPE, and MATRIX CHEMISTRY.

R. Théberge* and M.J. Bertrand, Regional Center for Mass spectrometry
Department of Chemistry, University of Montreal, Montreal, Canada, H3C 3J7

Dehalogenation reactions of organic compounds during their FAB/LSIMS analysis have been the object of several studies. The importance of these reactions lie in the fact that they can cause the presence of artefacts in the mass spectra. Althought it was suggested that specific experimental parameters influence these reactions, there have been no systematic study of these factors. In a previous study conducted in our laboratory, it was observed that matrix chemistry and analyte structure were the main factors controlling the extent of beam-induced dehalogenation of organic compounds. In our continuing investigation of beam-induced dehalogenation, we have focused on the effect of analyte structure, halogen type, and matrix chemistry. The compounds chosen for this study were the 4-halo-phenylalanine methyl esters (F, Cl, Br, I) 1 and the chlorinated herbicide atrazine 2. The variety of matrices used allowed the elaboration of a rough matrix structure dehalogenation inhibiting efficiency correlation. This correlation can be used to gain insight in the mechanism(s) involved in the beam-induced dehalogenation of organic compounds in FAB/LSIMS. Mass spectra were obtained using an Autospec-Q equipped with a caesium ion gun. The caesium ion beam had an energy of 22 keV and beam density of 2μA. The matrices used were glycerol (GLY), thioglycerol (THIOGLY), thiodiglycol (TDG), , 2-hydroxyethyl disulfide (HEDS), 2-hydroxyphenethyl alcohol (HPEA), 3,4-dimethoxybenzyl alcohol (DMBA), 4-hydroxybenzene sulfonic acid (HBSA), 3-nitrobenzyl alcohol (NBA), 2-mercaptoethyl sulfide (MES), 2-benzyloxy-1,3-propanediol (BOP), 1,4-anhydroerythritol (AET). The last three being new matrix compounds.The extent of dehalogenation was expressed in % as shown in eq (1).

$$\%\text{Dehalogenation} = 100 \times \frac{(M_H+H)^+}{(M_H+H)^+ + (M_X+H)^+} \qquad (1)$$

Where $(M_H+H)^+$ is the relative abundance of dehalogenated molecule (protonated) and $(M_X+H)^+$ is the relative abundance of the intact protonated molecule. As expected, the %dehalogenation observed in glycerol increases in the order I > Br > Cl > F, reflecting the respective leaving group ability of the halogens (Table 1). In fact, the trends presented in table 1 are coherent with the matrix dehalogenation-inhibiting efficiency scale established in our previous study on the LSIMS beam-induced dehalogenation of chlorpromazine. The basis for the rationalization used to explain the dehalogenation-inhibiting efficiency of the respective matrix compounds rests on the premise that keV particle impacts cause the production of electrons (via the ionization of the sample or matrix) and that these electrons can be effective reducing agents. However, the possibility that other beam-generated reactive species might contribute to the dehalogenation process cannot be ruled out. For aromatic matrices, their dehalogenation-inhibiting efficiency can be rationalized in terms of their relative electron affinities. It has been shown that substituted benzenes with electron withdrawing substituents have greater electron affinities than those with electron donating substituents[1]. It is important to note that electron affinitity (a gas phase property) appears to follow the same trend as reduction potentials (a condensed phase property)[2]. However, a dehalogenation mechanism based on beam-generated electrons is of limited use to rationalize the data obtained with the aliphatic matrices since little is known on their electron

affinities or the correlation between their structural features and that physical property. It appears that sulfur plays a role in inhibiting the dehalogenation process since sulfur-containing matrices consistently exhibit a relatively low % dehalogenation with respect to glycerol. The lower extent of dehalogenation observed in sulfur-containing matrices may be explained by the bombardment-induced formation of thiyl radicals which are known to have oxidizing properties. Sulfur compounds are known to be involved in the protection mechanism for biological systems subjected to ionizing radiation or other forms of free radical damage. That sulfur plays a role in inhibiting the dehalogenation process appears undeniable since MES, which has three sulfurs and no other heteroatom, exhibits a low %dehalogenation value.The other new matrices, AET and BOP, exhibit dehalogenation inhibiting trends similar to their structural analogs, glycerol and HPEA respectively.

The effect of the aromatic moiety of the analyte is illustrated by the %dehalogenation obtained for atrazine with respect to the chlorinated phenylalanine compound. Since the capture of an electron is thought to be the cause of dehalogenation, the ability of a molecule to form the radical anion should be commensurate to its propensity to dehalogenate. The one electron reduction potential of s-triazine (-2.0V) is much more positive than that of the chlorobenzene moiety (-2.78V). This is in agreement with the extent of dehalogenation observed in the LSIMS spectra of the compounds.

Sample Charge Compensation on a Large Sample Ion Microprobe

R. T. Short, J. M. McMahon and P. J. Todd
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

We have developed a triple quadrupole-based microprobe suitable for secondary ion imaging of biological tissue samples as large as 1 cm diameter. Tissue samples this large, however, are often insulators. Positive charge accumulates on insulating samples, when a positive primary ion beam strikes the surface. Charge compensation is then needed for the analysis of such samples. A charge compensation scheme for large biological samples is necessarily subject to several constraints. The technique must neither damage the sample, nor interfere with secondary ion emission. Spatial resolution cannot be degraded and charge neutralization must be self regulating for variations in sample conductivity across the surface.

One method, which meets these criteria and works well with the large sample microprobe, is described in Figure 1. The secondary ion extraction field is synchronized with a periodic primary Cs^+ beam. A sheet-like beam of 5 eV electrons passes over the sample surface when the extraction field is zeroed. Electrons are attracted to and neutralize any points on the sample which have charged. When the primary ion beam is turned on, the extraction field deflects most electrons away from the sample.

Figure 2 demonstrates the effectiveness of charge compensation on Teflon^R, a well known insulator. Positive secondary ion images were obtained from a 4 mm x 4 mm piece of Teflon^R tape placed on a copper target. The necessity of the periodic extraction field is indicated by the dramatic improvement in secondary ion yield from the Teflon^R in Figure 2c compared to 2b. Figure 3 displays positive secondary ion images obtained from a 50 μm thick slice of dried chicken liver placed on a copper target. The liver sample was spiked with 40 ng of acetylcholine and then analyzed for the acetylcholine secondary ion, *m/z* 146. The location of acetylcholine is easily discernable. This charge compensation technique has worked well with a variety of samples and requires little or no change in operational parameters from sample to sample.

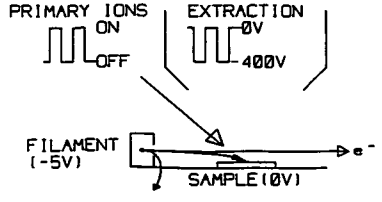

Figure 1. Charge compensation scheme. Electrons strike a charging spot on the sample when the extraction field is zeroed. The primary beam is turned off during charge compensation period (1 ms) to reduce primary ion damage. Data are acquired only during the (3.5 ms) period that the primary beam is turned on. The process is repeated for each spot on the sample to produce an image.

Determination of Flux from a Saddle Field Fast Atom Bombardment Gun

Bill Boggess and Kelsey D. Cook, Department of Chemistry, University of Tennessee, Knoxville, TN 37996-1600.

Users of FAB generally list at most the nominal beam energy and "emission current" (load on the FAB gun power supply). Even in LSIMS, it is common to report primary *current* without assessing the beam diameter, thus leaving the *flux* (current/area) undetermined and unreported. The relationship between FAB emission current and particle flux is presumed to be linear, but is not at all well-characterized. Because flux correlates with sensitivity[1] and with the extent of beam-induced damage,[2] it would be useful to have an accurate and simple measure of primary beam flux at the target. Such a measure should improve reproducibility and facilitate interlaboratory comparisons of FAB and LSIMS data. While flux determination using a faraday cup detector with a known entrance aperture is relatively straightforward for primary *ion* beams,[1] a corresponding experiment with the *neutral* primary FAB beam is not possible. This study evaluates the use of the flux-dependent beam-induced reduction of methylene blue[2] as an alternative, indirect measure of flux.

A 15 mM solution of methylene blue (molecular cation, M^+, at m/z 284) in glycerol was exposed to an 8 keV cesium ion beam at various levels of flux (measured using a faraday cup with a 1 mm diameter entrance aperture). The extent of reduction (Fig. 1) was estimated from the excess intensity at $[M+1]^+$ using the enrichment ratio, E, given below:[3]

$$E = \frac{i_m - i_c}{i_c}$$

where i_m is the measured peak intensity for the $[M+1]^+$ ion at m/z 285 and i_c is the corresponding calculated peak intensity based on natural isotopic abundances for M^+. Using the ion at $[M-2]^+$ (m/z 282) as a measure of the peak-at-every-mass background, the estimated signal-to-background ratio exceeds 30; thus, no correction for background[4] was necessary. In a subsequent experiment, E was determined using a FAB gun operating at 8 kV at various emission currents (Fig. 2). During the course of this study, the FAB gun performance deteriorated, requiring higher Xe gas pressure to achieve a given emission current. Electrodes were cleaned, and ultimately replaced. Figure 2 shows data for each set of electrodes. Comparison of Figures 1 and 2 provide an estimate of equivalent flux for each FAB gun operating condition (Table 1). In order to estimate the equivalent particle current emanating from the FAB gun, this flux was multiplied by the area illuminated by the FAB beam, as estimated by viewing the beam-induced luminescence on a flat FAB target coated with CsI. These "currents" are also summarized in Table 1. From Figure 2, it is clear that FAB gun output depended on the condition of the electrodes, even when the emission current and nominal energy indicated on the power supply were constant. The changes are significant in light of the substantial effect of flux on the appearance of FAB spectra.[3] It is obvious that appearance of FAB spectra will depend upon the physical condition of the gun, affecting reproducibility, unless flux is calibrated using a parameter like E.

The decline in FAB gun performance occurs over the matter of months as a result of contamination of the electrodes during use. An investigation into this slow aging process is currently underway.

TIME-OF FLIGHT SECONDARY ION MASS SPECTROMETRIC ANALYSIS AND IMAGING OF AVIAN EGG MEMBRANES

C. M. John and R. W. Odom, Charles Evans & Associates
301 Chesapeake Drive, Redwood City, CA 94063

Development of biological applications for surface analysis by time-of-flight secondary ion mass spectrometry (TOF-SIMS) is our goal. The avian egg contains three membranes, inner and outer shell membranes and the yolk membrane These membranes are fibrous, between 20 and 60 μm in diameter and are mainly composed of proteins. A number of minor lipid components of avian egg membranes have been identified.[1] The egg shell membranes are easily prepared in an ordered, intact state for TOF-SIMS.

Positive ion TOF-SIMS analysis and ion imaging of avian egg membranes was performed using a microfocused 25 keV Ga^+ primary ion beam The most abundant ions in the mass spectra were Na^+ and K^+ and various low molecular weight organic fragment ions. Figure 1 presents portions of the positive ion mass spectra of 6 avian egg membranes. Some higher molecular weight ion peaks (> m/z 300), likely fragment and molecular ions from lipids such as cholesterol and cholesterol esters, were also prominent in the spectra Characteristic peaks for cholesterol in positive ion TOF-SIMS spectra have been observed at m/z 369 and 385 The peaks at m/z 413 and 441 are 28 and 56 Da higher than the peak at m/z 385.

Differences were observed in the relative intensities of some of these higher molecular weight ion peaks in spectra from the two sides of an outer shell membrane and the top side of the inner membrane. Spectra of the top side of the outer shell membrane of different birds of the same species and different species were slightly different.

Ion imaging analysis (see Figure 2) revealed topographical features. The Ca^+ and Mg^+ ion images exhibited distinct localization in an outer shell membrane. Organic ion images were obtained from low molecular weight fragment ions. Also, low intensity ion images were obtained of the higher molecular weight peaks such as at m/z 413 and 435, but these images did not reveal localization We are currently working on techniques to increase the secondary ion yield of higher mass molecular ions in TOF-SIMS analysis of biological samples.

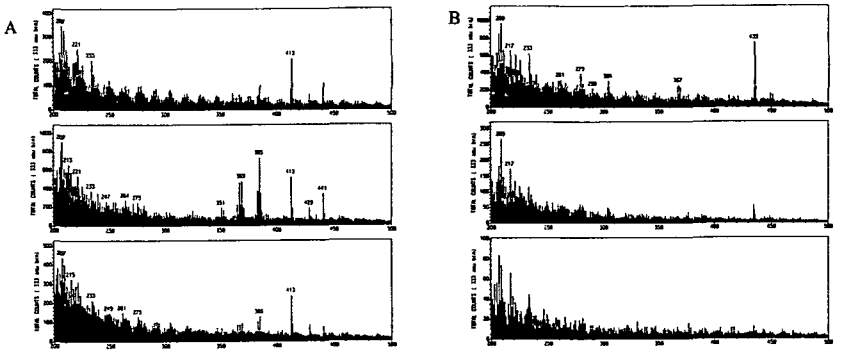

Figure 1 Portions of the positive ion spectra of the egg shell membranes of a chicken are shown in A; the top side of the outer shell membrane (top), the bottom side of the outer membrane (middle), and the top side of the inner membrane (bottom). Spectra from the top side of the outer shell membrane from avian eggs are presented in B, from two different chicken eggs (top and middle), and a quail egg (bottom).

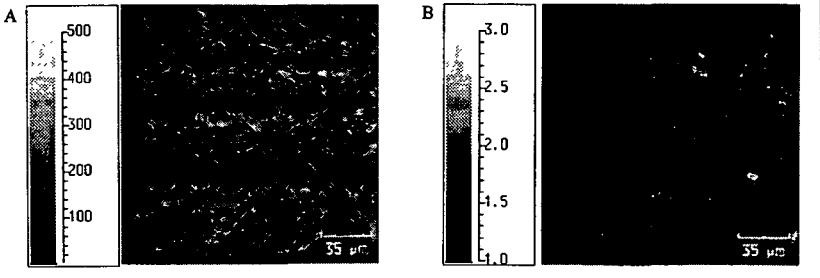

Figure 2 Total ion image (A) and a Ca+ ion image (B) from the top side of the outer shell membrane of a chicken egg are presented.

LIQUID SECONDARY ION MASS SPECTROMETRY OF HYPERVALENT SILICONATES

J. Greaves*, J. H. Small and K. J. Shea. Department of Chemistry, University of California, Irvine, Irvine CA 92717-2025

Introduction

Hypervalent polysiliconates are novel materials that are of interest because of their physical (mechanical and solution), electrical and optical properties. These are due to the dynamic stereochemistry of the silicon, the ion:counterion structure, and the type of organic bridge between the silicon (ionic) components of the compounds. Model building blocks of these ionomeric materials have been synthesized by condensation of catechol with alkoxy silyl derivatives in the presence of triethylamine[1-3]. Penta- and hexacoordinated species with triethyl ammonium counterions have been prepared by this method. Negative ion LSIMS spectra of a related series of compounds - nearly all hexacoordinated compounds with alkali metals as counterions - have been reported[4]. These authors noted rapid interaction between the analytes and glycerol and some interaction with mNBA[5]. The objective of the current study was to use LSIMS to characterise the mass spectrometric behaviour of the model compounds in both positive and negative ion modes and to see if this information would assist in the characterisation of an oligomer whose structure is currently uncertain.

Experimental

The compounds investigated were arylene- (4,4'-biphenylene- [1], 1,4- and 1,3-phenylene- [2,3], and 9,10-anthracylene [4]) and alkylene-bridged (1,2-ethylene- [5], and 1,6-hexylene- [6]) dicatechol siliconates of the form $(C_6H_4O_2)_2SiRSi(C_6H_4O_2)_2^{2-}.\{(C_2H_5)_3NH\}_2^+$ where R = the bridging moiety, and a tricatechol siliconate $(C_6H_4O_2)_3Si^{2-}.\{(C_2H_5)_3NH\}_2^+$ [7]. In all cases the hypervalent silicons are bound with triethylammonium counterions. In addition, an oligomeric compound in which there was assumed to be a spirocatechol:phenyl-silicon triethyl ammonium counterion repeating unit, $\{Si(C_6H_5).(O_2C_6H_2.C_9H_{16}.C_6H_2O_2)\}^-.\{(C_2H_5)_3NH\}^+$ [8], was investigated. The number of repeating units in the structure was uncertain. For compounds 1-6 and 8 the silicon was pentavalent while for compound 7 it was hexavalent. LSIMS was carried out on a Fisons Autospec trisector high resolution mass spectrometer. Cesium ions were used as the bombarding species at either 25 or 35 kV. The cesium ion current was approximately 3 μA. The matrix was mNBA. For accurate mass measurement the matrix was supplemented with 2% polyethylene glycol. For full spectra the instrument was scanned from 2100 - 100 amu (3 second scans) with resolution set at 2000. Accurate mass measurement was performed at 10,000 resolution using voltage scanning over a short mass range.

Results and Discussion

Compounds 1-7. Molecular ions were obtained in both positive and negative ion modes. In the positive spectrum the triethylammonium counterion remained in place and an additional proton was attached to form the charged species. Accurate mass determinations for these ions are given in Table 1. In some cases the positive spectra also showed triethylammonium adduct ions and an ion corresponding to the replacement of a triethylammonium with a proton. In the negative spectrum both triethylammonium groups were lost and replaced with a single proton thus giving a net negative charge. Compounds 5, 6 and 7 also showed a number of interactions with mNBA. Products included a) replacing a catechol with mNBA and b) cleaving the silicon-carbon bond and replacing it with either mNBA or another catechol. NMR studies showed that there were extensive reactions between compounds 5, 6 and 7 and mNBA in solution and, therefore, that the compounds observed in the LSIMS spectra were probably created independently of the ionization process. This does not, however, preclude the possibility that the energy of the cesium ions contributes to these processes in the LSIMS source. The reaction between Compound 7 (with alkali metals as the counterions) and mNBA has been reported previously[5]. These situations do not occur for compounds 1 - 4 which have arylene-bridging.

Compound 8. The positive ion spectrum for Compound 8 showed ions at m/z 1870 and m/z 1768. The major high mass ion in the negative ion spectrum was m/z 1767. The repeating covalently bonded unit has a mass of 441 daltons and triethylammonium is 102 daltons. Assuming that the triethylammonium counterions remain in place in the positive ion mode but are not present in the negative ion mode, as occurred for the other compounds, then the logical structure is a cyclic tetramer with one triethylammonium group and protons as the counterions at the other silicons. Independent confirmation of this structure is currently being sought.

Table 1. Accurate mass values for protonated molecular ions (including two triethylammonium counterions). LSIMS - positive ion mode.

Compound	$[M+H]^+$ calculated	$[M+H]^+$ observed	Δ mmu

Massive Cluster Impact Mass Spectrometry: Source Design and Performance

J.F. Mahoney and E.S. Parilis, Phrasor Scientific, Inc., Duarte CA 91010 USA
T.D. Lee and S. McCullough-Catalano, Beckman Research Institute of the City of Hope, Duarte, CA 91010 USA

Previously we reported on a new method for desorbing large biomolecules that uses a primary beam of massive, multiply charged clusters for sputtering ion from a liquid matrix [1]. A comparison of the MCI spectrum of bovine insulin (Fig. 2) with that of a conventional Xe FAB spectrum (Fig. 1) dramatically illustrates the features of MCI desorption. Abundant ions are observed for the intact insulin molecule (MH^{+1}, MH_2^{+2}, MH_3^{+3}, $M_2H_3^{+3}$) and the B chain fragment (MH^{+1}, MH_2^{+2}). The "chemical noise" background evident in the FAB spectrum is virtually eliminated in the MCI spectrum. Low mass ions in the MCI spectrum are largely the result of debris from the primary cluster beam (obtained by electrohydrodynamic atomization of 1.5M ammonium acetate in glycerol). The proposed mechanism for initiating sputtering events is by shock wave propagation in matrix material subjected to hypervelocity cluster impacts [2]. Cluster which impact liquid matrices with specific energies <5 eV/nucleon (compared to ~75 eV/nucleon for 10 keV Xe atom beams) provide an extremely soft method for sputtering intact biomolecules.

An estimate has been made of the cluster charge-to-mass ratio threshold δ_{tr} for molecular damage. The estimate assumes fragmentation occurs by knocking out target atoms from their positions in the molecule via collions with atoms of the cluster projectile. Spectra for clusters with $\delta > \delta_{tr}$ (Fig. 3) and $\delta < \delta_{tr}$ (Fig. 4) support this model. Different charge to mass ratios were obtained by controlling the flowrate of the glycerol solution. The low flowrate (0.02 µl/min vs. 0.2 µl/min for the high flow rate) favors smaller clusters with higher δ values.

Modifications in the design of the MCI source have resulted in greatly improved performance and more consistent operation. The source is equipped with a focusing lens and an electrostatic deflection system for beam positioning. Depending on the polarity of the applied voltage, primary beams of either positively or negatively charged cluster can be formed. The angle of the sample stage was found to have a significant effect on the strength and character of the spectra. Preliminary studies show that higher desorption yields and more stable operation is achieved using clusters compared to those formed from higher volatility solutions. The primary disadvantage of the MCI mode of operation is that the secondary ion source must be cleaned more frequently (weekly).

A KINETIC MODEL FOR SENSITIVITY ENHANCEMENT BY SURFACTANT-ANALYTE ION PAIRING IN PARTICLE INDUCED DESORPTION MASS SPECTROMETRY

James G. Pavlovich and Douglas F. Barofsky,
Department of Agricultural Chemistry, Oregon State University,
Corvallis, Oregon 97331

In particle induced desorption-ionization mass spectrometry the strength of an analytes signal under a given set of bombardment conditions is usually considered to be representative of the analyte's relative surface activity. This is the rationale generally used to explain differences in sensitivity between and within various classes of compound under these techniques.

Sensitivity enhancement of ionic analytes in FABMS by ion-pairing with a surface active counterion has been demonstrated by Ligon and Dorn (ref. 1). Previously, we have reported a 10,000 fold increase in sensitivity for adenosine triphosphate using hexadecylpyridinium acetate (HDPAc) in a glycerol matrix. This technique has been utilized in conjunction with a liquid matrix assisted SIMS/time-of-flight instrument to allow detection of femtomole quantities of nucleoside monophosphates (ref. 2). The analyte signal, however, is primarily dependent on the surfactant's bulk concentration (figure 1) and only minimally on that of the analyte. Additionally, the optimum surfactant concentration changes with the analyte concentration indicating that the surface activity of the hexadecylpyridinium ion is not independent of the counterion.

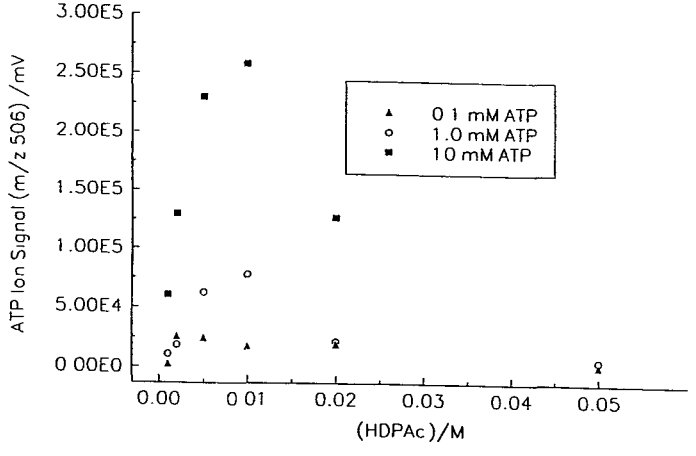

Figure 1. Dependence of ATP ion signal intensity on HDPAc concentration.

We have undertaken to model this phenomenon in terms of conventional solution equilibria and surface chemical principles under the assumption that the initial surface composition and the bulk concentration are the boundary conditions of a steady state established by the competing processes of surface sputtering and surface replenishment from the bulk during analysis.

Fundamentally, the system can be described in terms of two surface active species, the surfactant-

acetate ion pair (HDPAc) and the surfactant-nucleotide ion pair (HDPN), competing for a fixed number of surface sites. The bulk-surface equilibrium for each species is described in terms of a Langmuir type isotherm. In addition, the finite dissociation of each ion pair must be taken into account. The relative stability constants are estimated here from the relative selectivity for each anion on a strong basic anion exchanger. Since the nucleotide is introduced into solution as the free acid, the acid-base equilibrium is also taken into account. Acidity constants in glycerol are estimated based on data reported by Caprioli (ref.3). Equilibrium calculations were carried out using a program called MICROQL (ref. 4).

Figure 2 illustrates the comparison of the MICROQL calculations with the mass spectral data for the dGMP/HDPAc system. Good agreement is seen for the relative abundances of the $(M-H)^-$ ion of dGMP and the calculated surface concentrations of the surfactant-nucleotide ion pair at concentrations below the optimum. At higher concentrations the observed signal decreases faster than expected from the calculations.

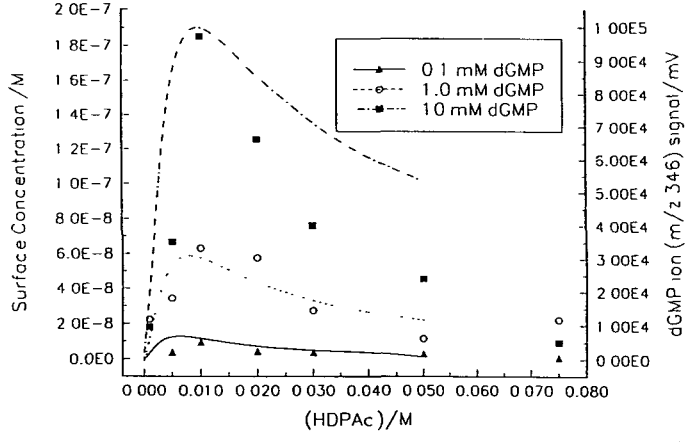

Figure 2. Calculated nucleotide surface activity and relative dGMP ion signal intensity.

TOF-SIMS STUDIES OF ION FORMATION AND FRAGMENTATION MECHANISMS IN POLYGLYCOLS

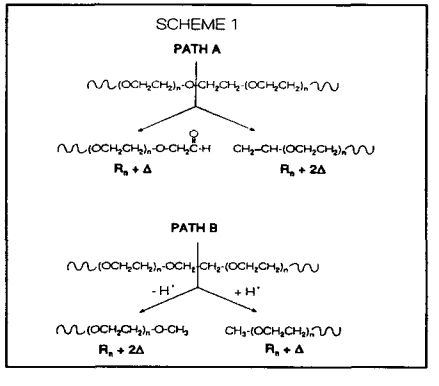
Lucinda R. Hittle, Paul A. Zimmerman and David M. Hercules
Department of Chemistry, University of Pittsburgh, Pittsburgh, PA 15260

Ion formation in SIMS typically follows two mechanisms: 1)Simple desorption of cationized oligomers or 2)Desorption of large polymer fragments cationized with a substrate ion (usually Ag). When the second mechanism occurs, it is not clear whether the Ag^+ is attached to the polymer fragment prior to sputtering, or if cation attachment occurs in the gas phase en route to the analyzer. Oligomers may also be cationized with ions from dopant salts such as NaCl, but only oligomers up to ~3000 Da have been detected using this sample preparation. In this study, both mechanisms of ion formation were observed, and the interrelation of polymer molecular weight and cations present to the extent of fragmentation was examined.

The instrument used in these studies was the TOF-SIMS III (Ion-Tof, GmbH, Munster, FRG). The samples were prepared by casting thin films on etched silver, or zinc. A series of poly(ethylene glycol) (PEG) and poly(propylene glycol) (PPG) polymers ranging in molecular weights from 450-100,000 Da were examined.

Fragmentation in Polyglycols

In general, it is possible to detect oligomers from polyglycols with molecular weights up to *ca.* 5000 Da. Main chain fragments in the mass range from 500-3000 Da are observed for samples with molecular weights above 5000 Da. For high molecular weight samples, the primary mode of fragment ion formation involves cleavage of the C-O bond between repeat units to yield fragments corresponding to the formula R_n. Some possible fragmentation modes are shown in Scheme 1. Path A indicates cleavage of the C-O bond within the repeat unit, which would produce 2 fragments, $R_n + \Delta$ and $R_n + 2\Delta$, where Δ corresponds to either an oxygen or CH_2 group. Fragmentation at the C-C bond within the repeat unit (shown in Path B) will also produce $R_n + \Delta$ and $R_n + 2\Delta$ fragments. Similar fragmentation mechanisms may be proposed for the PPGs, including scission of a pendant methyl group to produce $R_n + 3\Delta$ fragments.



The fragmentation pattern for PPG is shown in Figure 1. Each cluster within the fragmentation patterns contains several peaks, due in part to contribution from the 2 Ag isotopes. The relative intensities of the major fragment clusters were calculated for PEGs and PPGs with a range of molecular weights to determine if the fragmentation pattern will change as a function of polymer size. In general, the relative intensities within the fragmentation patterns of the PEGs were the same regardless of molecular weight.

However, the relative intensities of the fragments resulting from cleavage within the PPG repeat unit (such as $R_n + 3\Delta$) increased with increasing PPG molecular weight. The contribution of pendant groups within the polymer repeat unit must play an important role in fragmentation of high molecular weight polymers.

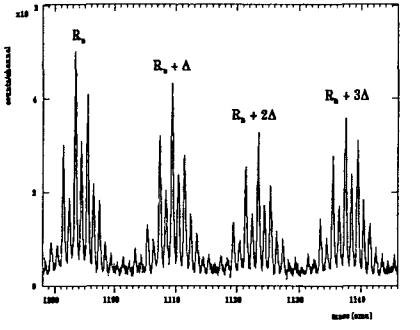


Figure 1. Fragmentation Pattern for PPG

Cationization Effects

Typical TOF-SIMS sample preparation involves casting the polymer film onto a silver substrate which cationizes the polymer samples. Another possible sample preparation method is to add dopant salts to the polymer on an inert metal substrate (e.g. Zn). Both alkali metal salts (Li, Na, K, Cs) and transition metal salts (Fe, Co, Mn, Cu) were examined to determine the optimal method of sample preparation. Directly mixing the polymer with the salt solution provided the best results, using a large excess of the salt in solution. In general, the highest yield of both fragments and oligomers was found for the silver cationized samples. No cationization of polymer species was observed for the other transition metal salts. Since all of the transition metals studied were in the M^{2+} state, the polymer may not be able to stabilize the +2 charge. It may be possible to see cationization with these metals in the M^+ state, similar to what was observed in laser desorption studies.[1-2]

The fragmentation patterns of PEG and PPG samples mixed with alkali metal salts were examined, and in general, the same patterns, containing the clusters R_n, $R_n + \Delta$, etc., were observed. The patterns from the alkali metal (Na^+ or Li^+) are simpler than those from Ag^+ due to the single isotopic contribution of the metal. Comparison of the spectra from several salts may make exact determination of fragments possible. For example, the $R_n + 2\Delta$ cluster may be assigned the formula $H\text{-}R_n\text{-}CH{=}CH_2$ (R_n + 28 Da) rather than $H\text{-}R_n\text{-}OCH_3$ (R_n + 31 Da). Although the choice of appropriate cation will affect the fragmentation pattern observed in the plasma desorption mass spectra[3], no effects on the SIMS fragmentation patterns were observed for different cations. The cations may be attaching to the polymer during the energy transfer from the primary ion impact, rather than in the gas phase, as is observed in PDMS.

Secondary Ion Mass Spectrometry Depth Profiling of Ti-Implanted AlInAs and InP at Room and at Elevated Temperatures

* P. H. Chi[1], D. S. Simons[1], R. K. Nadella[2], J. Vellanki[2], and M. V. Rao[2]
[1]Surface and Microanalysis Science Division
National Institute of Standards and Technology
Gaithersburg, MD 20899
[2]Department of Electrical and Computer Engineering
George Mason University
Fairfax, VA 22030

There has been considerable interest in the study of ion-implanted InP and AlInAs in recent years due to their potential applications in the fields of microwave, opto-electronic, and high speed microelectronic devices. Ion implantation is preferred over other techniques (MBE, CVD) for introducing a selected dopant at a specific depth with precise control of the implant concentration. Post-implantation treatment is needed to activate the implant and to reduce the radiation damage caused by the implantation[1]. However, the annealing can also lead to the redistribution of the implant in these materials that may hamper the intended applications[2]. In this study, we prepared InP and AlInAs by Ti implantation at room temperature, and at a temperature of 200^0 C. The samples were implanted at energies from 200 keV to 3 MeV with fluences up to 6 x10^{14} atoms/cm^2. These materials were cleaved and then subjected to rapid thermal annealing (RTA) at 825^{0}C, 850^{0}C, 875^{0}C or 900^{0}C. Secondary ion mass spectrometry (SIMS) was used to profile the Ti implant to check whether the Ti in these materials was redistributed after annealing.

Depth profiles of Ti-implanted AlInAs and InP were obtained with a secondary ion microscope using a focused and rastered oxygen primary ion beam. Secondary ions $^{48}Ti^+$ and the matrix signals $^{31}P^+$ (InP) and $^{75}As^+$ (AlInAs) were collected from a circular area 60 µm in diameter that was located at the center of the square raster. For the depth profile of Ti-implanted InP, a 50 V bias was applied to the sample to discriminate the interference at mass 48 from the molecular ion POH^+.

Figure 1 shows the overlay of Ti profiles for the 200 keV/2x10^{13} cm^{-2} room temperature Ti-implanted AlInAs, as-implanted and annealed at 850^{0}C and 900^{0}C. The two high temperature annealed samples show slightly redistributed Ti. There is no major difference between the two annealed samples. The overlaid profiles for the 200 keV/2x10^{13} cm^{-2} Ti implanted at 200^{0}C before and after annealing at 850^{0}C and 900^{0}C are plotted in Figure 2. As shown in this figure, the Ti profiles are similar to the Ti profiles in Figure 1 (room temperature implant) which shows slight in- and out-diffusion after annealing. The elevated temperature implantation at 200^{0}C did not have any significant effect on the redistribution of the Ti.

Figure 3 shows the overlay of plots for the 1 MeV/3 x10^{13} atoms/cm^2 room temperature Ti-implanted InP, as-implanted and then annealed at 825^0 and 875^{0}C. The Ti profiles are similar in all three samples, indicating that the Ti does not redistribute under these annealing conditions.

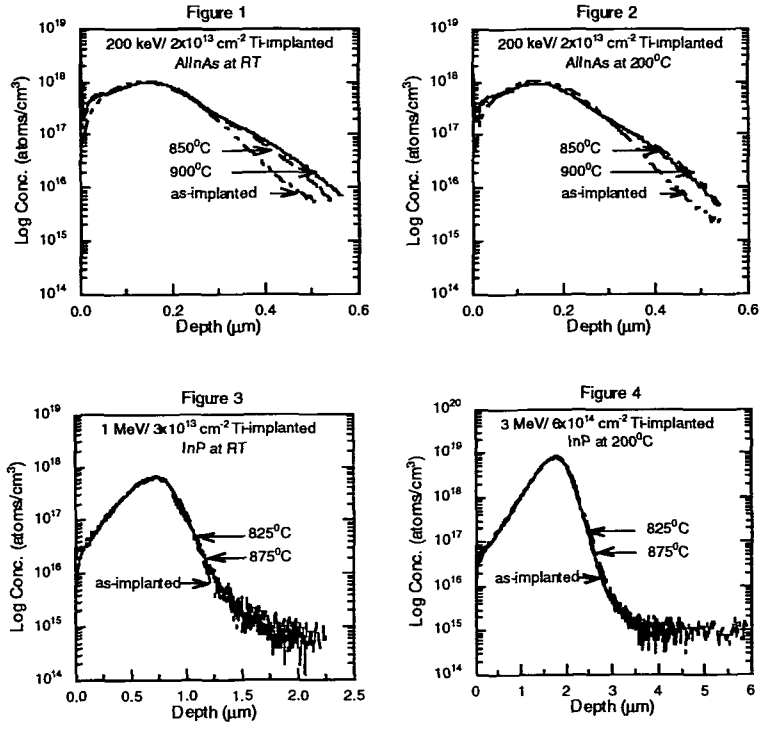

Figure 4 shows the Ti profiles for the 3 MeV/6x10^{14} cm^{-2} Ti-implanted InP at 200^{0}C before and after annealing at 825^{0}C and 875^{0}C. The three Ti profiles are similar, as seen in the room temperature implanted samples, which indicates that the Ti is thermally stable in InP under these annealing conditions.

In summary, SIMS results indicate that Ti-implanted InP is thermally stable but Ti-implanted AlInAs shows a small amount of redistribution under high temperature annealing.

Measurement of Secondary Emission from Various Materials

*Stephen A. Ruatta, Julius Perel, and John F. Mahoney, Phrasor Scientific, Inc., Duarte, CA 91010

Positive ion detection in mass spectrometry is often achieved by the use of ion/electron multipliers. These devices rely on the ejection of secondary electrons and/or ions upon the impact of the ion of interest on the detector surface. Secondary electron emission results mainly from one of two processes: Kinetic emission or Potential emission. For analysis and detection of very large and thus relatively slow-moving positive ions, the contribution from the kinetic processes to electron and ion emission will be small at energies below about 1eV/amu. Investigation of methods for increasing the potential emission contribution is continuing in our laboratory.

Our interest is in producing surfaces for high mass detection utilizing low work function surfaces to increase the potential electron emission contribution to the total secondary emission. We have also compared the effects of different materials on the kinetic emission and sputtering processes.

In order to compare the total secondary emission contribution from different materials, we have constructed an experiment that allows us to measure the total emission for 3 samples sequentially in situ. Three different samples are held in an insulating holder that can be moved from outside the chamber. The sample is the back surface of a Faraday cup and is isolated from the inner walls of the cup.

A schematic diagram of the potential emission apparatus is shown in Figure 1. Krypton ions (Kr pressure = 5×10^{-5} Torr) are produced by low energy electron impact and accelerated and focussed into the detector

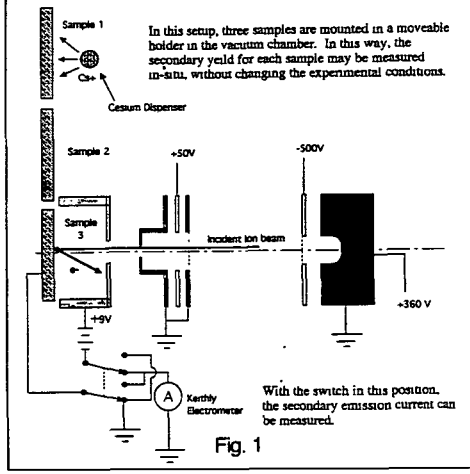

Fig. 1

The Kr^+ ion energy is about 160eV ± 30eV (FWHM) as determined by retarding potential analysis. The walls of the Faraday cup are biased positively to attract the negative secondary electrons and ions.

The kinetic emission experimental setup is shown in Figure 2 below. A cesium ion beam is used at different energies as the incident ion.

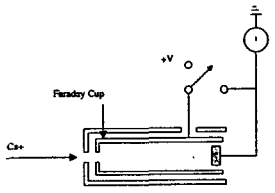

Fig. 2

Secondary electron yeilds can be predicted by Kishinevsky's equation:

$\gamma \approx (0.2/\varepsilon_F)(0.8E_i - 2\varphi)$

and selected results are shown in the Table below:

Material	ε_{Fermi}(eV)	φ[clean surface work function (eV)]	γ (predict)	γ (exp)
Mo	9.28	4.6	.043	.06
Ni	7.39	5.15	.024	.07
Al	11.66	4.28	.045	.06
Mg	7.11	3.66	.109	.06
Li	4.72	2.4	.271	----
W	9.20	4.55	.046	.06
Fe	11.18	4.7	.032	.06 (ss-304)
W/Cs^+	?	?	?	.08

There is no correlation between the expected and observed results. This points to at least 3 possibilities:

1) Experimental Malfunction (unlikely(?)):
   A) MacSimion trajectories indicate that some fraction of secondary electrons can escape the Faraday cup. On the other hand, relative differences between samples should still be observed.
   B) Dosing samples with cesium improves the secondary yield slightly, but only for a short time.
   C) The observed values are in the correct range.
2) Oxide formation at the surface (likely)
   A) Work functions and Fermi energies for oxides needed.
3) Surface dependent adsorbate coverage (likely):
   A) Chamber pressure is 5×10^{-5} Torr

Improvement of kinetic emission by a factor of 3x is easily produced by coating with a material such as NaI or CsI compared to stainless steel, magnesium, PbO glass, AlLi alloys or silicon. The increase should be due to the increased availability of an easily sputterable anion such as I^-.

Work along this line will continue. We need to:
1) Ensure collection of all secondary particles.
2) Operate at lower pressures to minimize adsorption.
3) Continue to try different materials.

Assuming our current setup is operating correctly, it certainly appears that the base material is independent of the actual surface at which the Auger neutralization occurs. In this case, it may be of more use to increase the kinetic contribution.

CHARACTERIZATION OF FINGERPRINT RESIDUES ON SURFACES USING NEUTRAL-BEAM SECONDARY ION MASS SPECTROMETRY (SIMS)

Bryan L. Bentz
David Sarnoff Research Center, CN 5300, Princeton, NJ 08543-5300

To many workers in the fields of spectroscopy and thin film preparation, a human fingerprint inadvertently placed on critical surfaces is a nuisance; it can result in unwanted spectral background, marred optical surfaces, and an inhibition of the condensation of metallic films prepared by vacuum deposition. In our surface analysis laboratory, we have often encountered fingerprint residue on samples submitted for characterization, deposited there accidentally by the submitter through less than careful handling. We became interested in studying fingerprints in their own right, and we have developed a method using static, neutral-beam SIMS for the sensitive detection and identification of trace organic materials that can be found in latent fingerprints. The experiments were conducted using the Sarnoff-developed triple stage quadrupole static SIMS instrument which incorporates a pA level, 3 keV neutral Xe primary beam. Static SIMS spectra in the positive ion and negative ion mode were obtained.

When a human finger touches a surface a sweat deposit - the fingerprint - remains on the surface. The deposited film generally consists of a mixture of natural secretions from eccrine and sebaceous glands in the body. Water, inorganic salts, fatty acids, amino acids, and glycerides are common components of natural fingerprints. In addition, foreign substance contamination picked up on the skin from the environment may be present in the fingerprint. Figure 1 highlights some physical observations concerning fingerprint analysis by our SIMS technique. The quantity of material in a fingerprint is extremely small (low to sub-μg) and it is dispersed over a large area. In view of this form of sample presentation, the response characteristic of our instrument to sub-, mono-, and multimolecular sample layers of a test substance (methylene blue) on silver was investigated. As shown in Fig. 2, quantitative detection of substances at trace levels on solid surfaces appears possible.

We find that the surface-sensitive nature of static SIMS can identify differences in surface composition that are characteristic of a fingerprint. Several metals (Ag, Al, SS) and polymers (PTFE, PP, PE) were studied as collection substrates for fingerprint deposition. Of these, acid-etched silver foil was found to be the most analytically useful for SIMS. Surface energy and wetting were found to play a role in fingerprint adsorption on the substrates.

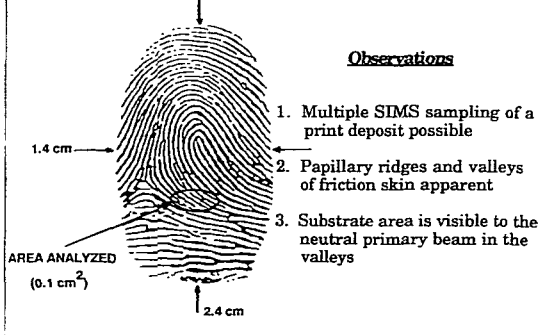

Figure 1

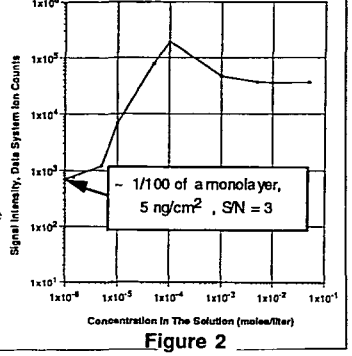

Figure 2

An example of the detection by SIMS of residue from an uncontrolled fingerprint on a silver substrate is presented in Fig. 3. The SIMS method developed can identify the minute amount of chemical constituents present in the deposit. Silicones were found to be a foreign substance contamination in many fingerprints. Additionally, it was observed that deposits from methanol-cleaned fingers and from sweat-rich fingers differed markedly in the amount and type of material (compare spectra of Fig. 4). Solvent cleansing produces dry friction skin and little material is contained in the fingerprint.

A survey analysis of fingerprints from a diverse population of donor individuals was undertaken, including prints from a chef, a machinist, a secretary, a reprographics worker, a plating engineer, and a lab scientist. Interestingly, differences in the amount and identity of foreign substance contamination on the fingers could be observed by SIMS. The contamination detected included species such as aliphatic hydrocarbons, fatty acids, silicones, inorganic salts, and handlotion. Acid-etched silver served as the deposition substrate for these experiments.

In other work, we find that deliberate substance contamination on the finger at the hundreds of nanogram level and greater can be detected in fingerprint residue deposited on a solid surface. Compounds examined for these tests included phenyltoloxamine and 5-methyltryptamine hydrochloride.

The test results of the exploratory studies described here suggest that our static Organic SIMS method has potential for trace substance detection in the fields of forensic science and criminology.

CORRELATION BETWEEN INITIAL RADIAL KINETIC ENERGIES AND CHEMICAL COMPOSITION OF SECONDARY IONS SPUTTERED ELECTRONICALLY FROM ORGANIC SOLIDS

***P.Demirev, R.Papaléo, H.-F.Kammer, B.Karlsson, G. Brinkmalm, D.Fenyö, J.Eriksson, P.Håkansson, C.Reimann, R. Zoubarev, B.U.R.Sundqvist, Dept. Rad. Sciences, Uppsala University, Box 535, Uppsala, 75121 SWEDEN**

When swift MeV atomic ions interact with organic solids, material is sputtered from the solid. That phenomenon, termed electronic sputtering [1], finds application in mass spectrometry of non-volatile compounds, and is known as plasma desorption. Studies of the properties of ions, ejected as a result of the MeV ion - solid interaction, allow clarification of the mechanisms of the electronic sputtering phenomenon. Systematic investigations of the initial radial energy of low mass positive and negative secondary ions (from 1 to 150 m/z), sputtered electronically from thin industrial polymer films (polyvinylidene difluoride - PVDF, and polystyrene - PS) are reported in this paper. The Uppsala Tandem accelerator provides 72.3 MeV I^{13+} heavy ions for target bombardment at 45° incidence angle. The use of a high resolution time-of-flight mass spectrometer allows separation of peaks, corresponding to ions with same integer m/z (Fig.1). Accurate mass measurements provide unequivocal determination of the chemical composition for different ions.

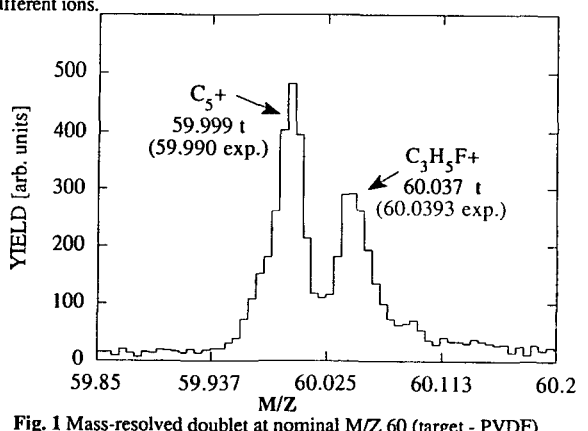

Fig. 1 Mass-resolved doublet at nominal M/Z 60 (target - PVDF).

The low mass ions form homologous series, C_nH_m and $C_nH_mF_p$. The secondary ion yield has been measured as a function of the voltage applied to a set of deflection plates parallel to the ion optical axis. The technique for extraction of the the *initial mean radial velocity* (<v>) *and mean radial kinetic* energy (~<v^2>, connected to the FWHM of the distribution) from the yield versus voltage distribution and the parameters of the experimental set-up has already been described [2]. A plot of <v> and <v^2> as a function of the positive secondary ion m/z results in "oscillating" behaviour due to a systematic repeat pattern (Fig. 2). This pattern is related to the chemical constitution homology of the ions, with 12 as a repeat unit. The degree of hydrogenation for different positive ion series is correlated to their initial mean radial velocity distributions: ions with lower hydrogen content exhibit wider velocity distributions (i.e. higher <v^2>), and they also have <v> directed towards the direction of the primary ion. In its turn ions with higher hydrogen content have lower mean kinetic energies and <v> directed away from the direction of the incident ions. The positive ions from the two targets exhibit somewhat different behaviour: while for

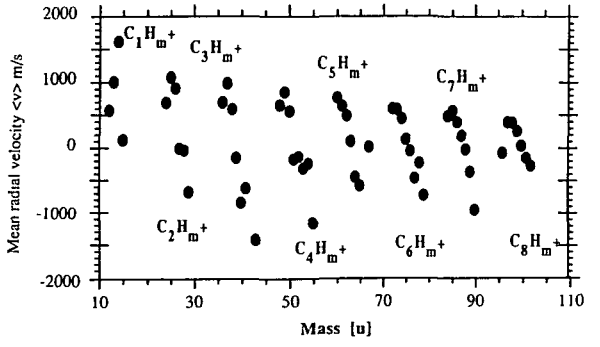

Fig.2 Mean radial velocities for the $C_nH_m^+$ ion series from PVDF.

ions from PVDF there is a dependence of both <v> and <v^2> on the m/z, ions ejected from PS have roughly the same <v^2>, but <v> shows the "oscillating" pattern (with absolute values roughly twice lower than those for the corresponding ions from PVDF). In contrast the negative C_nH_m ions from both PVDF and PS have <v> and <v^2> which does not depend on m/z (Fig. 3).

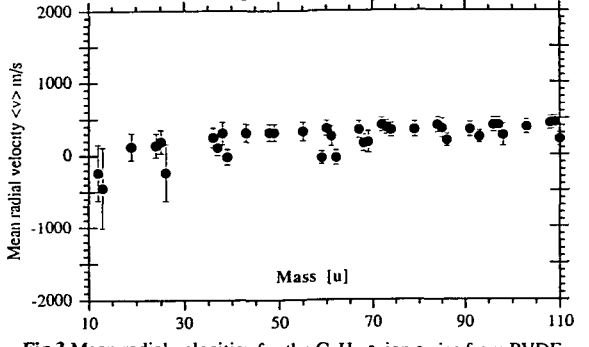

Fig.3 Mean radial velocities for the $C_nH_m^-$ ion series from PVDF.

We argue that these specific properties of the carbonaceous ions ejected in an MeV ion impact provide explicit information for e.g. the spatio-temporal evolution of the deposited energy density after the "big bang" event. The <v> and <v^2> behavior for the ejected positive ions reflects the local temperature (energy density) during the ion formation process thus supplying a specific example of subnanosecond chemistry on an Ångström scale in the MeV ion track. Our results bear also implications on the mechanism of ion ejection, caused by a hydrodynamic type pressure pulse (shock wave), propagating radially from the MeV ion infratrack [1].

COMPARISON OF PLASMA DESORPTION- AND THERMOSPRAY-MASS SPECTRA OF MERCAPTURIC ACIDS

*E. Pittenauer, M. Zollinger[1], E. R Schmid and G. Allmaier

Institute for Analytical Chemistry, University of Vienna, Währinger Straße 38, A-1090 Vienna, Austria
[1]Sandoz Pharma Ltd , CH-4002 Basel, Switzerland,
present address Brain Research Institute, University of Zürich, August Forel-Straße 1, CH-8029 Zurich, Switzerland

Detoxification of a wide variety of xenobiotics by conjugation with the tripeptide glutathione (= γ-Glu-Cys-Gly) represents an important metabolic pathway in liver. Hydrolysis of these S-conjugated tripeptides and subsequent N-acetylation of the remaining S-modified cysteines leads to the well known mercapturic acids (= N-acetylcysteine conjugates, S-substituted desaminoglycylcysteine dipeptides) The mass spectrometric characterization of such compounds by different desorption/ionization-techniques like EI, CI, FD, FAB and TS, as well as tandem mass spectrometry, has been subject of several papers. Recently, we could demonstrate the usefulness of positive- and negative-ion PD-MS for the analysis of nine synthetic, structurally simple mercapturic acids (1) In both ionization modes abundant $[M+H]^+$ and $[M-H]^-$ ions, respectively, and significant structurally diagnostic fragmentation of the desamino dipeptide backbone as well as cleavage around the sulfur atom in the side chain are observed. For assignment of these fragment ions we used a slightly modified nomenclature (1) from the one suggested by *Deterding et al.* (2) These spectra obtained by PD coupled to a time-of-flight instrument were compared with those obtained by TS using a triple-quadrupole instrument. In contrast to PD-mass spectra, positive- and negative-ion TS-mass spectra exhibit intense $[M+H]^+$ and $[M-H]^-$ ions, respectively, but little fragmentation in most cases indicating that PD-generated and TS-generated molecular ions contain different internal energies. Interestingly, low-energy CID-spectra (TS-MS/MS) obtained from protonated and deprotonated quasimolecular ions show close resemblance in their product ion patterns to the fragmentation observed in PD-mass spectra Fragmentation of peptides in positive-ion PD-MS was recently compared to fragmentation observed in their corresponding high-energy CID-spectra (3). In the case of the compounds investigated low-energy CID yields comparable product ion patterns as observed in fission fragment-induced decomposition of the molecular ions except that under low energy CID-conditions -C(R)H-C(R)H- bonds where R = -H, -alkyl or a heteroatom do not break apart easily. Finally, for evaluation of suppression effects due to potential competition during the desorption/ionization process of these compounds, an equimolar mixture of eight synthetic mercapturic acids was investigated by positive- and negative-ion PD-MS as well as positive- and negative-ion TS-MS.

A sensitive and selective method for the determination of glycinebetaine and choline is described. The method employs stable isotope dilution plasma desorption mass spectrometry in which a ^{252}Cf ionizing source produces fission fragments which interact with the sample (applied in methanol to a nitrocellulose coated aluminized-Mylar foil) to produce ions which are then mass analyzed by a time-of-flight mass spectrometer. Glycinebetaine is detected as the protonated molecular ion, $(M+H)^+$=118, and the internal standard, $^2H_9$-Glycinebetaine $(M+H)^+$=127 (Fig.1). Choline is detected as the molecular cation, M^+=104 and $^2H_9$-choline (M^+=113) serves as the internal standard (Fig.2). Glycinebetaine is quantified from the ratio of ion intensities at m/z 118 : 127, and choline from the ratio of ion intensities at m/z 104 : 113. The method is applied to the quantification of choline and glycinebetaine pools in two F_6-populations of ***Zea mays* L.** (maize) differing for alleles of a single locus conferring the presence or absence of glycinebetaine. The deficiency gene appears to confer a lesion in choline oxidation (X) to betaine aldehyde in the glycinebetaine biosynthetic pathway (Lerma et al., 1991).

$$(CH_3)_3N^+CH_2CH_2OH \xrightarrow{X,\ CMO} (CH_3)_3N^+CH_2CHO \xrightarrow{BADH} (CH_3)_3N^+CH_2COO^-$$

Choline — **Betaine aldehyde** — **Glycinebetaine**

CMO=Choline monooxygenase ***BADH=Betaine aldehyde dehydrogenase***

Glycinebetaine deficiency in maize is shown to result in a small (<2-fold) but statistically significant expansion of the free choline pool. Choline must down-regulate its own synthesis to prevent a large expansion of the free choline pool in salinized glycinebetaine-deficient plants (Lerma et al. 1991, Weretilnyk and Summers 1992). The results presented here demonstrate the utility of PD-MS in the routine quantification of glycinebetaine and choline in plant extracts.

THE CHARACTERIZATION OF TRI-NICKEL CLUSTER COMPOUNDS USING ^{252}Cf PLASMA DESORPTION AND FAB MASS SPECTROMETRY

**A.P. Rothwell, C.C. Bonham, K.V. Wood, D.A. Morgenstern and C.P. Kubiak, Campus-Wide Mass spectrometry Center, Department of Chemistry, Purdue University, West Lafayette, IN 47907.*

The study of metal cluster compounds (molecules containing at least three metal atoms plus coordinating ligands) is among the most active areas of Inorganic Chemistry. Of particular interest is the interaction between small unsaturated molecules and multiple metal centers.

Recently a series of nickel clusters $[Ni_3(\mu_3\text{-}L)(\mu_3\text{-}I)(dppm)_3]^{n+}$ were synthesized (where L = I, CO, $C{\equiv}NiC_3H_7$, etc; dppm = bis(diphenylphosphino)-methane and n = 0,1,2). These clusters were found to be efficient electro-catalysts for the reduction of carbon dioxide. The structural characterization of these new compounds proved difficult on account of their symmetry. Limited information was obtained from IR and NMR data. X-ray crystallography was not possible for several derivatives due to the non-crystalline nature of the materials.

Informative ^{252}Cf Plasma Desorption (PD) and Fast Atom Bombardment (FAB) mass spectral data were obtained. Intense molecular ions were generally observed for the neutral and monocationic tri-nickel clusters using both ionization modes (Figure 1). Fragmentation pathways for the tri-nickel clusters were similar (Scheme 1). The dicationic hexa-nickel clusters gave weak intensity monocations in FAB and ionic aggregates, MI^+, in the PD spectra (Figure 2).

Characterization of the tri-nickel clusters by mass spectrometry was a simple and cost-effective alternative to X-ray crystallography. For the novel, non-crystalline hexa-nickel clusters, molecular weight determinations enabled them to be identified and distinguished from the tri-nickel clusters.

LC-MS ANALYSIS OF SOME PHOTOGRAPHIC COLOUR-COUPLING COMPOUNDS USING A CONTINUOUS-FLOW FAB INTERFACE

Caroline D. Bradley and Alan W. Payne, Kodak Ltd., Harrow, U.K.

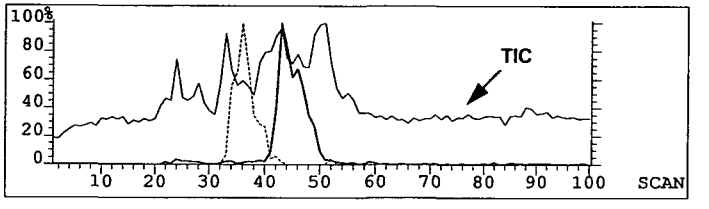
Photographic film and paper products employ a mixture of chemicals with one particularly important class being colour-coupling compounds which are the precursors of the colour dyes. Since a complex mixture is present, an analytical technique such as LC-MS is required which combines the ability to both separate and uniquely characterise. Until recently we have been using thermospray as our interface between the liquid chromatograph and mass spectrometer but this can have limitations for higher molecular weight compounds and also limited sensitivity. The nature of colour coupling compounds makes them particularly amenable to ionisation by fast atom bombardment (FAB); they typically have molecular weights of 500-1200 Da and are thermally labile. We have used static FAB for their characterisation with much success but have now combined the advantages of FAB ionisation with the capability of separation of the components immediately prior to analysis. This is achieved using continuous flow FAB as the interface between the HPLC system and a VG-70 mass spectrometer.

The HPLC set up comprises a Hewlett Packard 1050 quaternary pump system to deliver solvent at a flow of 0.3 ml per minute. This is reduced to a flow of 2.5 µl per minute passing through a 320 µm internal diameter (i.d.) LC capillary column by the use of a so-called balance column. The use of a 3 mm internal diameter reversed phase LC column to re-direct the majority of the flow away from the capillary system has been described previously by Balogh and Stacey[1]. Sample is introduced via a Valco C14W injector fitted with a 500 nl slot. Both LC columns and the injector are mounted onto the handle of the mass spectrometry probe. The probe tip is a modified version of the original VG dome design whereby the dome has been reduced in size to enable a wick to be fitted. Solvents used were HPLC grade with 2% glycerol added.

The following example illustrates the use of our LC-MS system in the analysis of a sample from part of a factory process to recover the silver from photographic materials. The final stage of this process results in a dry solid containing silver compounds and silicates but which is contaminated by various organics including colour-coupling compounds

Figure 1 shows the total ion current chromatogram for LC-MS of the sample. Careful analysis of the data revealed at least 10 clearly identifiable organic components. Figure 1 also shows mass chromatograms for two of these components which have MH^+ ions at m/z 909 and 508 (dashed and solid lines respectively).

Fig. 1



Figures 2 and 3 show the corresponding mass spectra of these two components. Both can be identified as colour coupling compounds with molecular weights 908 Da and 507 Da respectively. All of the major ions present in the spectra can be assigned to characteristic fragmentations of these species.

Fig. 2

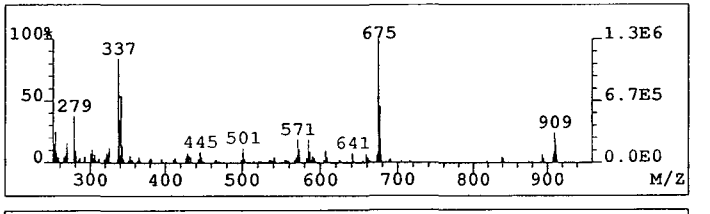


Fig. 3

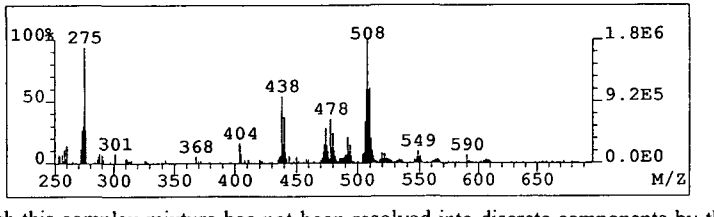

Although this complex mixture has not been resolved into discrete components by the LC, mass spectra of the individual components have either been obtained using background subtraction techniques or alternatively the discriminating ability of linked scanning was employed. We found an order of magnitude improvement in the overall sensitivity with continuous flow FAB as compared to our thermospray system.

INFORMATION ON THE IONIZATION PROCESSES INVOLVED IN FAB/LSIMS THROUGH ELECTROSPRAY IONIZATION

G. J. C. Paul, R. Feng[1] and M. J. Bertrand
Regional Center for Mass Spectrometry, Department of Chemistry, University of Montreal, Montreal, P.Q. H3C 3J7
[1]National Research Council of Canada, Biotechnology Research Institute, Montreal, P.Q. H4P 2R2

The formation of dominant $[M-H]^+$ molecular ions in FAB/LSIMS has been observed in our laboratory for two series of ether-type compounds; the cyclic acetals and derivatized monosaccharides.[1-3] This phenomena has been interpreted in terms of condensed phase ionization processes as a consequence of the major $[M+H]^+$ molecular ion formation observed under gas phase CI conditions.[1,3] A remaining question in the condensed phase FAB/LSIMS ionization model for these compounds is whether $[M-H]^+$ formation occurs through condensed phase equilibrium processes prior to fast atom/ion bombardment or through fast atom/ion beam-induced processes. One way to gain information on this subject is through the use of electrospray ionization (ESI). The ions sampled in this technique are formed predominantly through condensed phase equilibrium processes with no fast atom/ion bombardment taking place.

ESI studies have been conducted with two cyclic acetals and two derivatized monosaccharides, shown in Figure 1. The analytes were dissolved in methanol and the ESI experiments were run without and with glacial acetic acid (0.1 M). The ESI mass spectrum for 4-hexyl-2-phenyl-1,3-dioxolane (**1**) without acid is shown in Figure 2. The $[M+H]^+$ is dominant with no significant $[M-H]^+$ formation. Also present is a weak $[M+NH_4]^+$ adduct. The relative molecular ion intensities in ESI and FAB[1,2] for the acetals and monosaccharides are shown in Table 1. In each case, $[M+H]^+$ is the only significant molecular ion in ESI wheras in FAB the $[M-H/D]^+$ is the major ionic species. The absence of $[M-H]^+$ in ESI suggests that hydride abstraction occurs in FAB/LSIMS through fast atom/ion beam-induced ionization processes in the condensed phase. Consistent with this, $[M-H]^+$ was not observed for monosaccharides in either thermospray[4] or electrohydrodynamic ionization mass spectrometry (EHMS)[5] where both techniques rely on the preformation of ions in the condensed phase.

The ESI mass spectrum for α-methyl-2-deoxy-5-0-benzyl-D-ribofuranose (**3**) without acid is shown in Figure 3. In addition to $[M+H]^+$ the $[M+NH_4]^+$ adduct is present in large intensity. The formation of $[M+NH_4]^+$ in ESI (Figures 2 and 3) is through the presence of NH_4^+ in solution as an impurity. The presence of NH_4^+ probably leads to the preformation of $[M+H]^+$ in solution through proton transfer prior to electrospray. This would explain the intense absolute molecular ion signals obtained in ESI for cyclic acetals and derivatized monosaccharides without the presence of acid in solution. Due to the proposed preformed nature of $[M+H]^+$ in solution the addition of acid had little effect on the ESI mass spectra. It is anticipated that $[M+NH_4]^+$ and $[M+H]^+$ are in condensed phase equilibrium where the greater $[M+H]^+$:$[M+NH_4]^+$ ratio for the cyclic acetals (Figure 2) compared to the derivatized monosaccharides (Figure 3) in ESI reflects the greater proton affinity of the former species.

An intense $[M+Na]^+$ adduct was also observed in the ESI mass spectra of the derivatized monosaccharides (Figure 3). It is anticipated that Na^+ is present in solution as an impurity. The $[M+Na]^+$ adduct is also seen in the FAB/LSIMS mass spectra of monosaccharides where

thioglycerol and 2-hydroxyethyl disulfide are the liquid matrices.[2,3] The appearance of $[M+Na]^+$ in ESI indicates when Na^+ is present in the liquid matrix in FAB/LSIMS, preformation of $[M+Na]^+$ occurs through condensed phase equilibrium processes prior to fast atom/ion bombardment. It is believed that no $[M+Na]^+$ is seen for the cyclic acetals in ESI (Figure 2) due to the lower Na^+ affinity of these compounds compared to the monosaccharides.

FORMATION AND SPUTTERING OF FULLERENES BY MeV IONS

I.Bitensky, G.Brinkmalm, *P.Demirev, J.Eriksson, P. Håkansson, R.Papaleo, B.U.R. Sundqvist,
Div. Ion Physics, Dept. Rad. Sciences, Uppsala University, Box 535, 75121 SWEDEN

Swift (with velocities exceeding the Bohr velocity) MeV atomic ions from the Uppsala EN-tandem accelerator are used to bombard different carbon-containing organic solids. A reflectron time-of-flight mass spectrometer is used to analyze the ejected secondary ions in a single ion impact event, and typically several milion MeV ion impact events are collected. Most of the energy of an MeV ion is deposited in a solid target via ionization of the target atoms in times of the order of 10^{-15} s. The energy density in the solid around the MeV ion trajectory is of the order of 1 keV/Å, and thus an infratrack - a short-lived positive ion plasma region with characteristic radius of the order of a few Å - is formed. If the energy relaxation rates from that region are lower compared to the energy deposition rate, as in the case of insulators, material is ejected from the solid in a process termed "electronic sputtering" [1]. As has already been demonstrated [2,3] even-numbered carbon cluster ions (C_n^+, n= 40 to > 400) are ejected from poly(vinylidenedifluoride) - PVDF as a result of this electronic sputtering phenomenon. Both the experimental data [2,3] and a theoretical model [4] suggest that these fullerene ions are formed in the infratrack, resulting from the interaction of a single MeV atomic ion with the solid. So far the PVDF polymer has been unique among the carbon-containing organic solids that produce fullerenes as a result of an MeV ion impact. Here we report the ejection of higher mass positive fullerene ions (C_n^+, n = 40 to > 400) by MeV ions from synthetic $C_{60}F_{2m}$ targets with different degree of fluorination (m = 14 to 24) [5]. The similarity of the spectra from the two targets (Fig. 1) suggests a common formation mechanism. This is also confirmed by studies of the initial radial velocity distributions of the positive ions, ejected from the fluorinated fullerene target. In contrast, the negative ion spectra contain only peaks corresponding to $C_{60}F_{2m}^-$ ions (Fig 2).

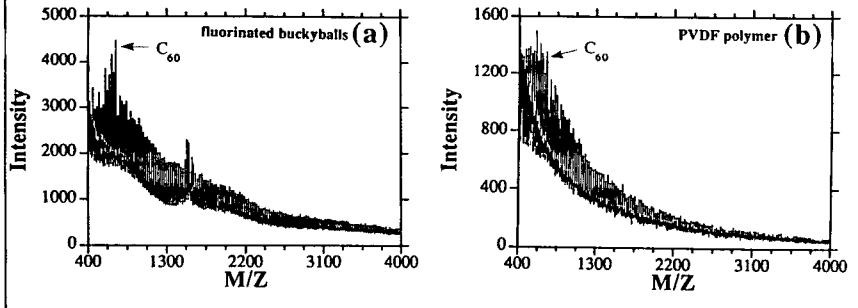

Fig. 1. Positive ion spectra from fluorinated buckyballs (a), and PVDF (b).

Spectra taken from thick films of pure synthetic C_{60} contain higher mass fullerene peaks with increased intensity around multiples of 60. Such peaks are not observed in the negative ion mode, which suggests that these higher mass fullerenes are formed as a result of coalescence reactions between sputtered ions and neutrals of C_{60} and its fragments (we note that the positive and negative ion yields from a film of preformed C_{60} and C_{70} fullerenes are the same [3]). Blends of pure C_{60} with polystyrene (PS) exhibit also higher mass - up to C_{100} - positive fullerene ions that are not present on the target surface (Fig. 2). No "modulation" of the ion intensity around multiples of 60 is observed in this case. The positive and negative ion spectra of a thin layer of pure C_{60} contain only the C_{60} ion peak, and so does the negative ion spectrum of the C_{60}/PS mixture.

Two types of reactions are observed in the electronic sputtering of fullerenes. The first type (as illustrated on the example of $C_{60}F_{2m}$) is the hot carbon atom "gas" condensation in an axially expanding infratrack plasma region, resulting from a single MeV ion impact. Another reaction regime is the coalescence to higher mass fullerenes from preformed C_{60} which occurs most probably in the gas-phase (selvedge). Three points in the electronic sputtering of fullerenes with implications to the fullerene

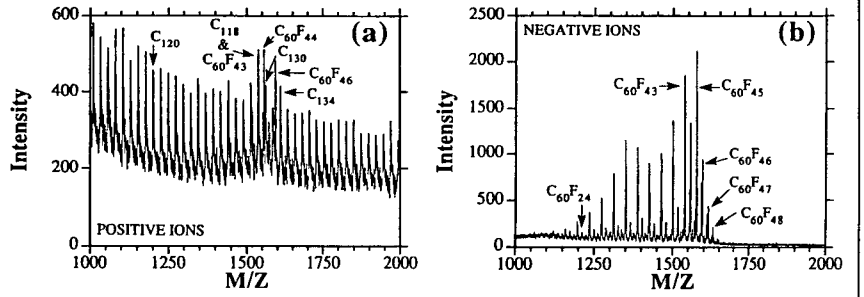

Fig. 2. Positive and negative ion spectra from fluorinated buckyballs in the 1000 to 2000 M/Z.

formation mechanism in general may be stressed: **1.** the typical time (subnanosecond) and spatial (tens of Å) scales for the MeV ion/solid interactions leading to fullerene ejection are orders of magnitude faster and smaller than the corresponding values in laser ablation; **2.** the observation of only positive fullerene ions (not present initially on the target) may be linked to the possible role of a cationic precursor in the fullerene formation pathway; **3.** at least in some instances fullerene growth proceeds through C_{2n} (n=1,2,...) addition to already existing three-dimensional pentagon-hexagon structure.

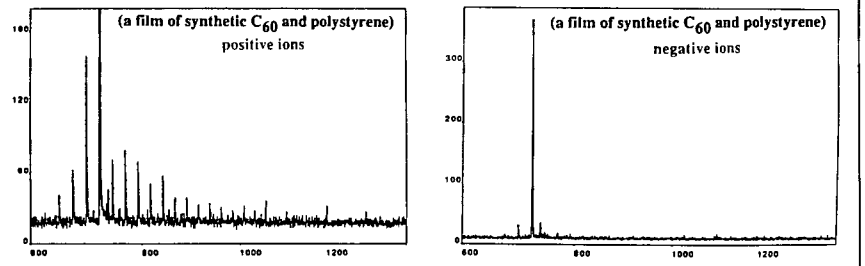

Fig. 3. Positive and negative ion spectra from a mixture of C_{60} and PS.

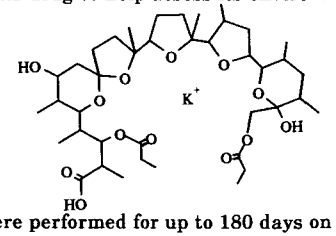
Identification of Degradation Products of the Antibiotic Laidlomycin Propionate by Mass Spectrometry

*David A. Lustig, Syntex Research, Palo Alto, CA 94304.

The ionophoric antibiotic laidlomycin propionate has been found to significantly improve cattle feedlot performance by favorably altering the intraruminal microbe balance and ultimately bovine metabolism. The purpose of this work is to identify the degradation products of this drug to help assess its environmental fate.



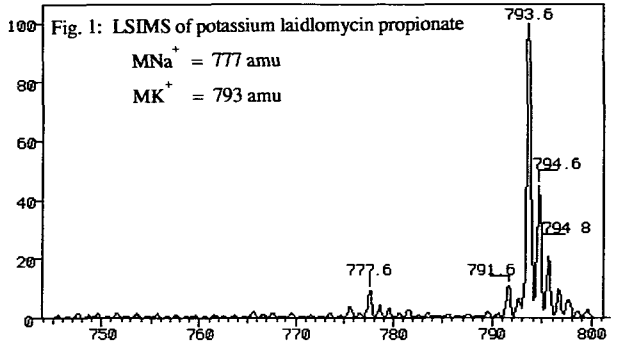
Biodegradation studies were performed for up to 180 days on ^{14}C radio labeled laidlomycin Propionate potassium salt in three regional soils (California, Texas and Mississippi).

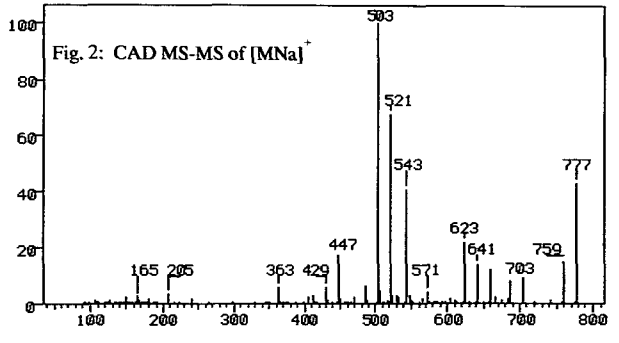
An initial separation of the raw soil extracts was performed and fractions were collected. These were further purified by extraction into methylene chloride and subsequently analyzed by HPLC with RAM detection. Phenomenex Ultremex C18 columns (5 µm particles, 4.6 mm x 250 mm) were employed with an acetonitrile / water / THF / acetic acid (70/30/0.5/0.1) mobile phase. Fractions containing the main peaks were collected.

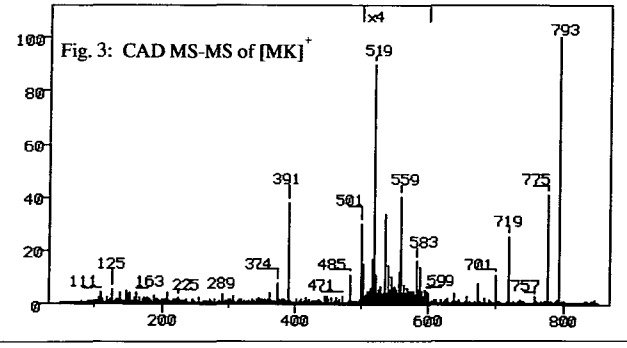
Mass spectral analysis of the HPLC fractions was performed with a Finnigan TSQ70 triple stage quadrupole mass spectrometer. Desorption ionization was accomplished from a glycerol matrix by Liquid Secondary Ion Mass Spectrometry (LSIMS) with 8 keV Cs^+ ions. MS-MS spectra were obtained for parent ions using 25-30 keV collision activated dissociation (CAD) with argon gas.

The ionization and fragmentation of the antibiotic and related models compounds was first studied. The mass spectra and tandem mass spectra were unique in that all molecular ions and fragment ions contained alkali metals, almost exclusively (see Figures 1-3).

It was found that typical fragmentation pathways were dominated by sequential ring cleavages and neutral losses. This information allowed for the identification of the degradation products of laidlomycin propionate. Confirmation was accomplished by comparison of the CAD MS-MS with known standards.







Quantification of malondialdehyde-deoxyguanosine (M_1G-dR) adduct by GC ECNCI MS.

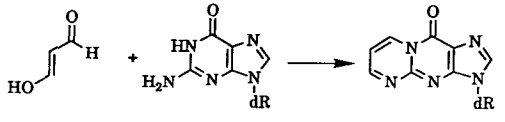
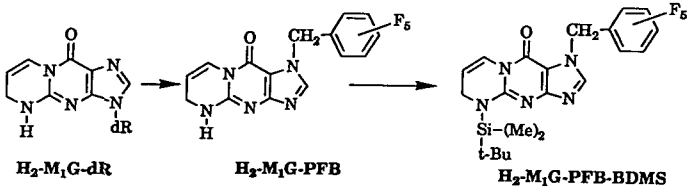
and Departments of Biochemistry[1] and Pharmacology[2]
Vanderbilt University School of Medicine, Nashville TN, 37232.

Exposure to environmental, nutritional and endogenous carcinogens leads to the formation of nucleic acid adducts which have been linked to the induction of mutations and cancer. High dietary fat intake is associated with the development of breast and colon cancer. Malondialdehyde (MDA), an endogenous product of lipid metabolism, causes mutation in bacterial and mammalian cells and cancer in rats. MDA reacts with deoxynucleosides *in vitro* with an order of reactivity guanine > adenine > cytosine > thymine. The monomeric adduct of MDA with guanine (M_1G) is the major adduct formed and induces mutations in bacteria. The possible involvement of MDA in the development of cancer requires a sensitive analytical method to characterize and quantitate the products formed by the exposure to this compound.



MDA **Deoxyguanosine** **M_1G-dR**

Reduction of M_1G-dR with sodium borohydride produces a dihydro derivative (H_2-M_1G-dR). H_2-M_1G-dR is more stable and exhibits a much improved HPLC profile facilitating the isolation from biological matrices. H_2-M_1G-dR is converted to a monopentafluorobenzyl (PFB) derivative by dissolving in 440 µL of acetone:acetonitrile (1:1), adding K_2C0_3 (2mg) and 35 µL of PFB.Br solution (35 µL PFB.Br in 465 µL acetone acetonitrile mixture) and heating to 60° for 60 min. Reaction proceeds with simultaneous depurination of the nucleoside and yields only one product which was characterized as 3-(2,3,4,5,6-pentafluorobenzyl)-5,6-dihydropyrimido[1,2a]purine-10(3H)-one (H_2M_1G-PFB) using LSI MS/MS and NMR. H_2-M_1G-PFB is converted to H_2-M_1G-PFB-BDMS derivative by heating with N-Methyl-N-t-butyldimethylsilyl trifluoroacetamide (MTBSTFA) containing 1% t-butyldimethylchlorosilane (TBDMCS):Pyridine mixture (1:1) at 120° for 20 min. The PFB-BDMS derivative is purified by SPE extraction and dissolved in n-decane for analysis by EC NCI GC/MS.



H_2-M_1G-dR **H_2-M_1G-PFB** **H_2-M_1G-PFB-BDMS**

EC NCI GC/MS was carried out on a Nermag R1010C instrument interfaced with a Varian Vista 6000 gas chromatograph using a 10 m SPB-1 fused silica capillary column (0.25 mm ID, 0.25µM film thickness; Supelco). Helium was used as carrier gas at a flow rate of 1 ml/min and methane was used as reagent gas at a pressure of 7 x 10^{-2} torr. Injections were made in splitless mode with the injector

temperature held at 250°C. The instrument was operated with an accelerating voltage of 70 eV, source temperature held at 260°C and emission current at 250 µA. The column temperature was programmed from 150°C (held for 1 min) to 320°C at 20°C/min. The EC NCI mass spectrum showed an intense [M-PFB] negative ion at m/z 302. [$^2H_2$-M_1G] was used as internal standard and exhibited an intense [M-PFB] negative ion at m/z 304. Quantitative analyses were carried out using SIM analysis of ions at m/z 302 and m/z 304. The limit of detection by this method is 10 pg (30 fmol) injected on column. The method was used to estimate M_1G-dR in normal rat liver. DNA was isolated from rat liver followed by enzymatic hydrolysis. The M_1G-dR was isolated by C_{18}SPE extraction, reduced to H_2-M_1G-dR and derivatized to PFB-BDMS derivative. A typical selected ion current profile obtained for analysis of M_1G-dR in rat liver is shown in Figure 1. A full scan mass spectrum of the same sample, to which no internal standard had been added was identical with an authentic standard of H_2-M_1G-PFB-BDMS (Figure 2). This confirms the structure of the isolated compound as M_1 G-dR.

In summary, we have characterized and quantitated M_1G-dR formed *in vivo* in DNA isolated from rat liver. This method is highly specific and sensitive for the analyses of M1G-dR from other biological matrices.

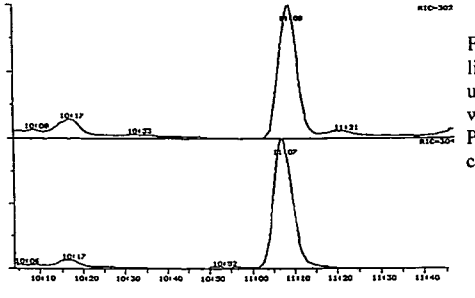


Figure 1. Selected ion current profile for rat liver DNA spiked with 2 ng of [$^2H_2$]-M_1G: upper panel shows H_2-M_1G-PFB-BDMS while lower panel depicts [$^2H_2$]-H_2-M_1G-PFB-BDMS. The concentration of M_1G-dR corresponds to 9 M_1G-dR per 10^7 bases.

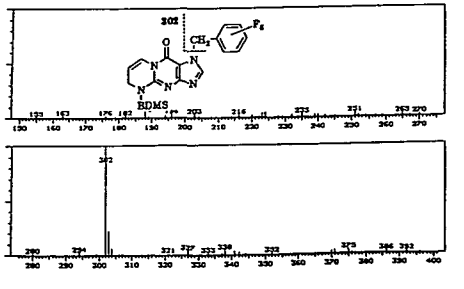

Figure 2. EC NCI MS of H_2-M_1G-PFB-BDMS isolated from rat liver DNA.

Differentiation of Isomeric C8-Substituted Dinitrotoluene Adducts of Guanine by FAB MS/MS

M. P. Chiarelli, R.D. Holland, K. E. Kirtley, and J. O. Lay, Jr., University of Arkansas-Little Rock, Little Rock, AR 72204 and The National Center for Toxicological Research, Jefferson, AR 72709.

Introduction

Mass spectrometric studies of carcinogen-modified DNA are motivated by the hypothesis that these compounds play a major role in the initiation of cancer. In this investigation product ion scans and fragment ion abundance ratios are used to differentiate three different isomeric C8-substituted dinitrotoluene adducts of guanine.

Experimental

All FAB MS/MS spectra were acquired on a Finnigan MAT TSQ70 triple quadrupole mass spectrometer equipped with an Ion Tech fast atom gun. Xenon was employed in the primary atom beam at energies of 8-10 KeV. Argon was employed as the collision gas in the second quadrupole at pressures of ca. 0.8 millitorr. Thioglycerol was used as a matrix for all compounds studied. CAD spectra of the protonated molecules and significant source-produced fragment ions were acquired using 50 eV collision energies. The three guanine adducts used in this study were synthesized using the procedure of Jacobson et al. (1).

Results and Discussion

The major difference between the product ion spectra of these guanine-C8-substituted bifunctional adducts and the product ion spectra of the guanine C8-adducts of simple arylamines (2) is that the primary ion formation processes proceed by fragmentation of the carcinogen, rather than the base, losing the nitro group to produce a distonic radical cation at m/z 256 (Figures 1-3). One aspect of these product ion spectra that distinguishes N-(guan-8-yl)-4-methyl-3-nitroaniline from the ortho-methylnitroaniline adducts is the formation of tropolyium and NH_2-substituted tropolyium ions at m/z 91 and m/z 106 (Figure 1). The two ortho-methylnitroaniline adducts yield an m/z 117 ion in their product ion spectra (Figures 2 and 3) not observed in Figure 1.

The mechanism of formation of the ortho-methyl isomer specific ion at m/z 117 is shown in Scheme 1. After the loss of the NO_2 group, methyl group transfer from the aniline C2 position to the N7 or N9 position of guanine may occur through a six-membered transition state driven by benzyne formation in the aniline ring. Cleavage of the guanine base may then produce the substituted benzyne ion at m/z 117. Alternatively, cleavage of the guanine C8-aniline N^1 bond may produce the methyl-substituted guanine ion observed at m/z 166. Product ion spectra of source-produced m/z 256 ions were acquired from all three isomers to support the proposed mechanisms. The product ion spectra of the source-produced m/z 256 ions from both the ortho-methylaniline adducts show substantial abundances of both m/z 117 and m/z 166, thereby supporting the mechanism of ion formation proposed in Scheme 1.

Although both product ion spectra of the ortho-methylaniline adduct isomers in Figures 2 and 3 show the same major fragment ions they can be differentiated by the comparison of ion abundance ratios of the most prominent fragment ions. Ion abundance ratios, (m/z 117)/(m/z 256), obtained from the product ion spectra of N-(guan-8-yl)-2-methyl-3-

nitroaniline and -5-nitroaniline, were found to be 0.76 ± 0.06 and 0.21 ± 0.02, respectively, when a set of eight consecutive determinations were averaged for each isomer.

DISTINGUISHING ISOMERIC MONOMETHYL GUANINES BY FAB MASS SPECTROMETRY COMBINED WITH PERMETHYLATION

M. George, *V.M. Sadagopa Ramanujam, R.L. Cerny and M.L. Gross, Midwest Center for Mass Spectrometry, University of Nebraska-Lincoln, NE 68588-0304.

Most of the minor purine constituents of both *transfer*-RNA and DNA consist of mono- and dimethyl derivatives of guanine (2-amino-6-oxypurine). The characterization of these compounds are important because carcinogenic methylating agents are known to cause methylation[1] of guanosine in DNA *in vivo* and can be isolated as methyl guanines. There are seven isomeric *mono*-methyl guanines and it is often difficult to distinguish them especially at submicrogram quantities. Due to high polarity and nonvolatility, the methyl guanines are unsuitable for conventional EI or CI mass spectral analysis. In addition, these compounds have poor sensitivity by fast atom bombardment (FAB) mass spectrometry. The objective of this study is to develop a good method for the characterization of *mono*-methyl guanines at submicrogram levels. In order to achieve this, we have investigated the permethylation of several methyl guanines using **CD_3I** followed by **FAB MS/MS** analysis.

All methyl guanines, except 8-methylguanine, are commercial samples. 8-Methylguanine is a synthetic sample. The permethylation reaction was carried out by reacting each methylguanine with excess CH_3I or CD_3I in DMSO in the presence of *t*-BuOK. The derivatized mixture was directly used for the FAB MS/MS analysis. The collisionally activated dissociation (CAD) experiments were performed by using a VG ZAB-T, a 4-sector tandem mass spectrometer (BEBE configuration), after precursor ion (MS1 resolution 2000) activation in the third field-free region by collision with helium. Sufficient helium was added to the collision cell to decrease the main beam intensity by 50%. Spectral acquisition and data work-up were performed by using a VAX 3100 workstation equipped with OPUS software. Typically 10-15 scans were signal-averaged for each spectrum.

Permethylation of the six isomeric 1-, N^2-, 3-, O-, 7-, and 9-methyl guanines using **CH_3I** yield preformed *tetra*-methyl quarternary ion (*m/z* 222), whereas 8-methylguanine produces a *penta*-methyl derivative (*m/z* 234). The CAD spectra of the *tetra*-methyl derivatives (*m/z* 222) are very similar giving fragments of *m/z* 207, 206, 192, 178, and 85, and hence not suitable for isomer distinction.

If the methylation is carried out with **CD_3I**, however, then the CAD spectra (**Figure 1**) of perdeuteromethyl derivatives (*m/z* 234) are specific for each isomeric *mono*-methylguanine. The changes in mass/charge ratios of the fragments depend upon the position of the original CH_3 group.

Conclusions: (1) The permethyl derivatives of *mono*-methyl guanines give abundant FAB-MS signals corresponding to quarternary ions at submicrogram levels. These quarternary salts are several orders more sensitive to FAB than the respective *mono*-methylguanine. (2) The FAB MS/MS spectra of the perdeuteromethyl derivatives are different from each other thus facilitating the identification of each isomer. (3) Methylation of 8-methylguanine is unique because it is the only isomer yielding a *penta*-methyl derivative.

LOW-ENERGY TANDEM MASS SPECTROMETRY OF PAH DIOL EPOXIDE-DEOXYNUCLEOSIDE ADDUCTS

Paula S. Branco, M. Paul Chiarelli, Frederick A. Beland and Jackson O. Lay, Jr.
National Center for Toxicological Research, Jefferson, AR 72079 and
University of Arkansas-Little Rock, Little Rock, AR 72204.

The structural elucidation of carcinogen-deoxynucleotide adducts by mass spectrometry (MS) is motivated in part by the belief that these compounds may serve as biochemical markers of exposure to environmental genotoxins. To date no systematic tandem MS studies of diol epoxide modified deoxynucleoside adducts of polycyclic aromatic hydrocarbons (PAH) have been undertaken. Here we report an analytical strategy using fast atom bombardment (FAB) ionization and tandem mass spectrometry, with collision energies on the order of 30-50 eV, for the characterization of these compounds. Our methodology combines three experimental approaches to charactertize low levels of carcinogen-deoxynucleoside adducts. These include the use of contrast neutral loss (CNL) scans (116 u and 313 u), products ion scans of the protonated molecule or the BH_2^+ ion, and parent ion scans.

Constant neutral loss scans: **The PAH diol epoxide adducts used in this study showed little or no signal for the loss of the deoxyribose by FAB, a fragmentation typically observed with other classes of deoxynucleoside adducts. Nonetheless CNL scans (116 u) were possible and fragments were observed from the mono and di-sodium containing molecule ions as well the protonated molecule. CNL scans of *anti*-benzo(*a*)pyrene diol epoxide (BaPDE) adducts of deoxyguanosine (dG), deoxyadenosine (dA), and deoxycytidine (dC) were acquired using as little as 25 ng applied to the FAB probe. We have also found that another type of CNL spectra (313 u) can be used as a very sensitive probe for dG adducts of PAH diol epoxides (Figure 1).**

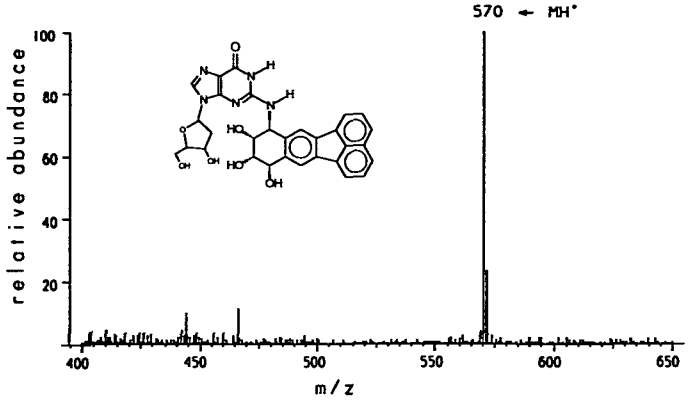

Figure 1. **The FAB constant neutral loss (313 u) spectrum of *anti*-benzo(*k*)fluoranthene diol epoxide-dG adduct.**

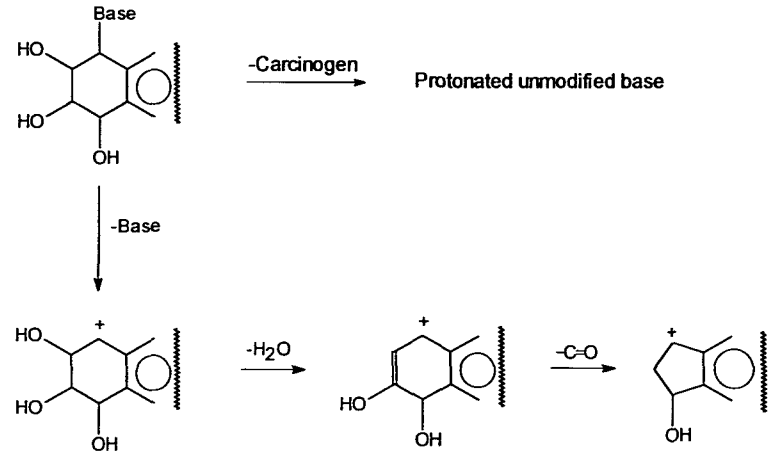
Product ion scans: **The $(M+H)^+$ ions of the synthesized PAH adducts showed product ion spectra dominated by fragments derived from the carcinogen group, as shown in the following scheme.**



Model compounds for the BH_2^+ ions were synthesized by reaction of BaPDE and the bases guanine, adenine, and cytidine. The major fragments are the same as those observed from the protonated deoxynucleoside adducts.

Parent ion scans: **Another approach can be used to detect PAH diol epoxide deoxynucleoside adducts if the PAH is known. The product ion spectra for the *anti*-benzo(*a*)-pyrene diol epoxide adducts of dG, dA and dC showed a common base peak ion at 257. When a parent ion spectrum (257 u) was recorded for these three compounds, the corresponding protonated molecule ions were observed. (This work was supported in part by the Center for Indoor Air Research, #92-002).**

CHARACTERIZATION OF MODIFIED OLIGODEOXYNUCLEOTIDES BY ELECTROSPRAY MASS SPECTROMETRY

Dasari M. Reddy, Robert A. Rieger, and Charles R. Iden

Department of Pharmacological Sciences, Health Sciences Center
State University of New York at Stony Brook, Stony Brook, NY 11794-8651

DNA may be structurally modified in living cells either by interacting with oxygen free radicals generated as by-products of cellular metabolism and ionizing radiation, or with genotoxic chemicals present in the environment. Recent evidence indicates that these modifications play an important role in degenerative processes such as carcinogenesis, mutagenesis and aging. Consequently, elucidation of the chemical nature of DNA damage is fundamental for understanding the nature of these processes. Mass spectrometry has played an important function in the analysis of modified DNA constituents, and various methodologies have been developed for the characterization of modified DNA constituents. While GC/MS procedures are useful, especially for low level quantitation of known adducts, these methods involve hydrolysis of native DNA to its constituent nucleosides followed by derivatization to increase the volatility and thermostability. New ionization techniques permit analysis of thermally labile and polar molecules and biopolymers at the nanogram level which is required for biological samples. Techniques based on desorption, such as FAB, SIMS and DCI have proven useful for small oligomers, but are often limited by the range of the mass analyzer. Electrospray ionization mass spectrometry (ESI/MS), a sensitive ionization technique useful for the analysis of biopolymers and charged species, provides an alternative method of analysis without need for enzymatic hydrolysis or chemical transformation. Moreover, the propensity of this technique to form multiply charged ions effectively extends the range of mass analyzers and permits accurate molecular weight determination at large molecular weights. We present our preliminary results on electrospray ionization of oligonucleotides containing modified deoxynucleotides.

Analysis was performed on a TRIO-2000 mass spectrometer equipped with an electrospray source. Samples were introduced into the ion source by a continuous flow of solvent (MeOH: H_2O, 90:10) at 6-8 μl/min using a syringe pump connected to a Reodyne injector with a 10 μl sample loop. Prior to analysis samples were dissolved in $MeOH:H_2O:NH_3$ (90:9:1) at a concentration range of 100-200 pmol/μl. An aliquot (10 μl) of each sample was injected into the continuous flow of solvent entering the source. The instrument was scanned in the multichannel analyzer mode (MCB) with a 8 sec dwell time over the mass range m/z 300 to 1200. The mass scale was calibrated in the positive ion mode using polyethylene glycol. Spectra are an average of ten to fifteen scans. Oligodeoxynucleotides were synthesized on a Dupont Coder 300 or Applied Biosystems 394 automated DNA synthesizer using the solid state phosphoramidite chemistry. Oligomers were released from the resin and deprotected by treating with 28% NH_3 at 55^{0}C for 18 h, and purified by HPLC on a reverse phase column (Hamilton PRP-1, 250 x 21.5 mm) using a gradient of 16% to 36% acetonitrile in 0.1M triethylammonium acetate (pH 7.5).

1a.

1b.

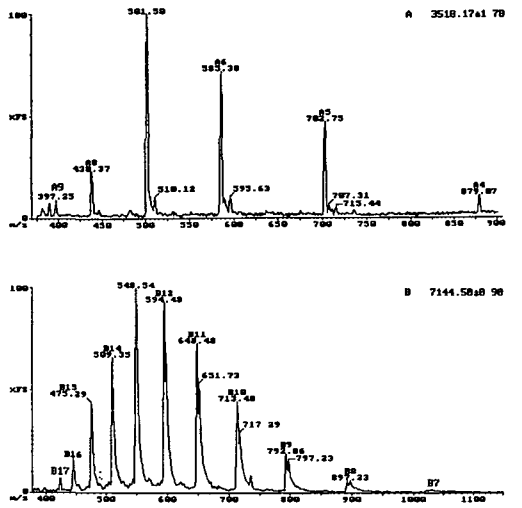


Figure 1. ESI mass spectrum for oligonucleotides a). 5′-GCATGCXTACAG-3′ and b). 5′-CCTTCXCTACTTTCCTCTCCATTT-3′ (see text for definition of X).

Figure 1a shows the negative ion ESI mass spectrum for the dodecaoligonucleotide 5′-GCATGCXTACAG-3′, where X is a tetrahydrofuran moiety, a model for the abasic site in which a nucleobase is replaced by a hydrogen atom. Electrospray ionization produces intact, multiply-charged, molecular ions which result from abstraction of protons from the phosphate bridges to yield even electron ions of the general formula $(M-nH)^{-n}$. This spectrum shows a distribution of multiply charged molecular ions ranging from $(M-9H)^{-9}$ to $(M-4H)^{-4}$. Because of the nature of the purification process, no ions corresponding to sodium or potassium adducts were formed, and well defined peak shapes were observed in the spectrum; however, weak ions corresponding to ammonia adducts are discernable. By increasing the concentration of ammonia in the sample, adduct ions will dominate the spectrum.

Figure 1b illustrates the negative ion ESI spectrum of an oligodeoxynucleotide (24-mer) with the sequence 5′-CCTTCXCTACTTTCCTCTCCATTT-3′, where X is the oxidative lesion 8-oxo-2′-deoxyguanosine. The spectrum exhibits the typical bell shaped molecular ion charge distribution ranging from $(M-8H)^{-8}$ to $(M-17H)^{-17}$. Low intensity ions corresponding to ammonia adducts were also observed. The number of adducts formed with ammonia tends to be greater for the lower charged states of the molecular ion.

Computer-Assisted Interpretation of Electrospray-Tandem Mass Spectra of Oligonucleotides

K.J. Hart, S. Habibi-Goudarzi and S.A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6120

A computer program is being developed to facilitate the analysis of oligonucleotides by tandem mass spectrometry of multiply charged molecular anions. The nucleotide sequencing program (NSP) currently handles naturally occurring DNA (i.e. deoxyribose & A,C,G,T bases) and RNA (i.e. ribose & A,U,G,T bases). The NSP is being developed in C without, for now, a graphical user interface to allow easy compilations on a variety of computer platforms.

Calculations for a given oligonucleotide sequence include:

- MW and isotopic mass of the neutral free acid
- Expected m/z (s) for ES-MS
- Expected m/z (s) for ES-MS/MS

Calculations for an unknown oligonucleotide sequence:

- Base composition given observed ES-MS m/z, charge state and a user defined mass tolerance (e.g. 1 u)
- Given a selected parent ion, charge state and MS/MS spectrum:
  - ⇒ Identify B- m/z's and -BH m/z's in the ES-MS/MS spectrum
  - ⇒ Identify sets of complementary ions in ES-MS/MS spectrum

The expected ES-MS ions for 5'-d(GTGGCCAC)-3' are:

Ion Desc.	m/z
(M - 7Na+)7-	343.20
(M - 7Na+ + 1H+)6-	400.57
(M - 6Na+)6-	404.23
(M - 7Na+ + 2H+)5-	480.88
(M - 6Na+ + 1H+)5-	485.28
(M - 5Na+)5-	489.67
(M - 7Na+ + 3H+)4-	601.35
(M - 6Na+ + 2H+)4-	606.85
(M - 5Na+ + 1H+)4-	612.34
(M - 4Na+)4-	617.84
(M - 7Na+ + 4H+)3-	802.14
(M - 6Na+ + 3H+)3-	809.47
(M - 5Na+ + 2H+)3-	816.79
(M - 4Na+ + 1H+)3-	824.12

Ion Desc.	m/z
(M - 3Na+)3-	831.45
(M - 7Na+ + 5H+)2-	1203.71
(M - 6Na+ + 4H+)2-	1214.71
(M - 5Na+ + 3H+)2-	1225.70
(M - 4Na+ + 2H+)2-	1236.69
(M - 3Na+ + 1H+)2-	1247.68
(M - 2Na+)2-	1258.67
(M - 7Na+ + 6H+)1-	2408.44
(M - 6Na+ + 5H+)1-	2430.42
(M - 5Na+ + 4H+)1-	2452.40
(M - 4Na+ + 3H+)1-	2474.38
(M - 3Na+ + 2H+)1-	2496.36
(M - 2Na+ + 1H+)1-	2518.35
(M - 1Na+)1-	2540.33

The largest ions observed in the ITMS electrospray mass spectrum are the ions corresponding to (M - 7Na+ + 1H+)6-, (M - 7Na+ + 2H+)5- and (M - 7Na+ + 3H+)4-. The sodiated species in the m/z range below 650 were also observed.

The NSP output for expected ES-MS/MS ions for the triply charged 5'-d(AAAA)-3' parent ion is provided below. The nomenclature used is defined elsewhere [1].

Ion Desc.	m/z
A-	134.05
w[1]2-	164.02
[w[1]-B[4](AH)]1-	195.01
[w[2]-B[3](AH)]2-	253.53
[w[3]-B[2](AH)]3-	273.37
w[3]3-	317.72
w[2]2-	320.55
w[1]1-	329.05
(P-(AH)) 3-	350.73
[a[3] - B[3](AH)]2-	361.07

Ion Desc.	m/z
Parent Ion 3-	395.75
[w[3]-B[2](A-)]2-	410.36
[a[2] - B[2](AH)]1-	410.09
w[3]2-	477.58
[w[2]-B[3](A-)]1-	508.06
(P-(A)-) 2-	526.60
w[2]1-	643.12
[a[3]-B[3](A-)]1-	723.14
[w[3]-B[2](A-)]1-	821.12

The interpretation of ES-MS/MS spectra of oligonucleotides of unknown sequence can also benefit from some simple calculations. There are several spectral features which are useful to recognize when interpreting these spectra. One feature is the presence of ions indicating B^- loss and/or BH loss. Another feature is to correlate complementary ions by using the fact that:

$$(m/z)_{p1} * z_{p1} + (m/z)_{p2} * z_{p2} = (m/z)_p * z_p \quad \text{and}$$

$$z_{p1} + z_{p2} = z_p$$

to derive the ratio of the charges of two complementary product ions:

$$z_{p2} / z_{p1} = ((m/z)_p - (m/z)_{p1}) / ((m/z)_{p2} - (m/z)_p)$$

where p refers to the parent ions and p1 and p2 refer respectively to product ion 1 and product ion 2 of a complementary pair of product ions [1]. The NSP first calculates possible z_{p2} / z_{p1} ratios based on the number of parent ion charges. After MS/MS product ions have been entered, a list of B^-, -BH ions and complementary ions found is displayed to the screen. Future additions to this program are expected to include calculations for neutral sugar loss, loss of PO_3^- and additional rules for interpreting ES-MS/MS spectra. Once sufficient interpretation rules are in place, generation of candidate sequences will be implemented. Also, direct input of spectral data from ITMS data files and a graphical user interface will be added to the program. This program represents a significant step towards achieving automatic candidate sequence generation from ES-MS/MS spectra of oligonucleotides. The authors wish to acknowledge the support of NIH grant number GM45372.

MALDI MASS SPECTROMETRY OF OLIGONUCLEOTIDES AND NUCLEIC ACIDS

Eckhard Nordhoff, Michael Karas, Franz Hillenkamp
Institute for Medical Physics and Biophysics, University of Münster, Robert-Koch-Str. 31, 48149 Münster, Germany

Finn Kirpekar, Karsten Kristiansen, Peter Roepstorff
Department of Molecular Biology, University of Odense, Campusvej 55 5230 Odense, Denmark

The few results on MALDI mass spectrometry for oligonucleotides and nucleic acids obtained and reported until now show a much lower quality of the mass spectra than typically achieved for peptides and proteins and seem to indicate some fundamental problems in the LDI of this class of compounds.

Formation and desorption of oligonucleotide salt ions with different and differing number of cations has been shown to be one factor responsible for the peak width and degrading signal quality; a simple and highly efficient cleaning of the applied matrix/analyte solution by cation exchange beads replacing metal cations against ammonium ions has been successfully used to overcome this problem (1); ammonium salts of the oligonucleotides enable to reconstitute the free acid in the gas phase and the formation of $[M-H]^-$-ions. DNA pieces of up to 26 mers can now be investigated with a quality and sensitivity comparable to those of peptides enabling e.g. routine analysis of antisense DNA. Susceptibility of larger DNA pieces to fragmentation poses the major problem in the higher mass range. Fragmentation by (multiple) base loss resolved for small pieces of DNA is responsible for the observed limits in performance such as mass range limit, broad molecule ion peaks and systematic errors in mass determination. DNA is much more susceptible to this fragmentation than RNA, enabling intact molecule ion desorption and accurate mass determination for RNAs up to 104 mers (see Figure 1) The advantages documented until now for IR-MALDI (using a succinic acid matrix) vs. UV-MALDI (using

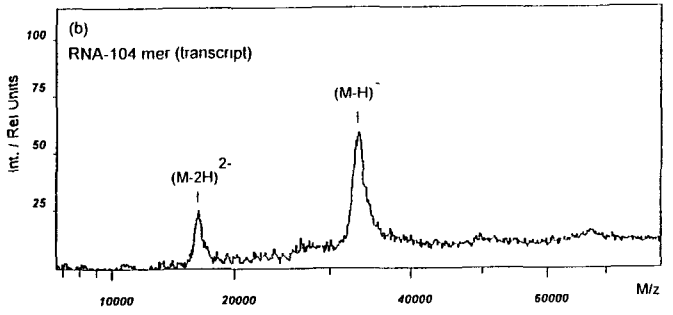

FIGURE 1 : IR-MALDI mass spectrum of a RNA-104 mer (transcript)
Matrix: succinic acid, Er:YAG-laser - 2.94 μm, sum of 10 single shots

typical protein matrices) have been overcome by the use of 3-hydroxypicolinic acid (2) as a UV-matrix.

IR-MALDI of DNA using a succinic acid matrix and working at increased irradiance induces (prompt) fragmentations; this kind of behaviour has never been observed in UV-MALDI. The fragment ions formed are highly specific and significant for the chemical structure; cleavages are observed from both ends of the oligonucleotide chain (X- and Y-series), allowing for a sequencing of the oligonucleotide (see Figure 2). As an explanation for this fragmentation an intramolecular proton-catalyzed elimination of the nucleobase followed by a cleavage of the 3'- or 5'- O-glycosidic bond by a second elimination reaction is proposed. This is substantiated by the fact that cleavages at thymine, the only base which cannot be protonated, are inhibited. Further work will concentrate on optimizing the experimental conditions, until now focused to the desorption of intact molecular ions, for this new aspect of MALDI.

Electrospray LC-MS of Modified Oligonucleotides

LeRoy B. Martin* and Cynthia S. Mamer
Fisons Instruments, 32 Commerce Center, Cherry Hill Drive Danvers, MA 01923

Robert A. Rieger and Charles R. Iden
Department of Pharmacological Sciences, Health Sciences Center, SUNY at Stony Brook, Stony Brook, NY 11794-8641

The purpose of this project was to develop a method for detection of oligonucleotides synthesized by phosphoramidite chemistry. As a chromatographic detector, a mass spectrometer using electrospray ionization can accurately determine the nature of modifications introduced into a sequence during synthesis. The methods developed here are adaptable to HPLC conditions often used in DNA purification.

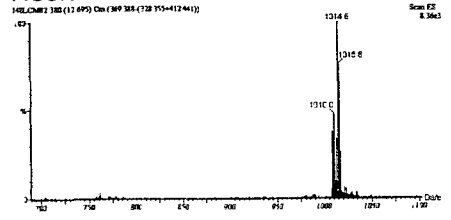
Detection of DNA from a chromatographic run presents two challenges. The first to overcome is electrospray ionization from highly aqueous, high ionic strength solutions that do not favor the negative ion formation often used in DNA detection. To accurately assign a molecular weight to a species measured by electrospray a strong series of multiply charged peaks is critical. Therefore, a second challenge is the detection of enough peaks in a series to accurately determine their charge state and hence the molecular weight of the measured oligomer. Simple additions after the column can enhance both sensitivity and selectivity by increasing volatility and affecting the ionic form of oligonucleotides. As examples, two modifications were examined by LC/MS. The modifications incorporated into these oligonucleotides have been developed as models for damage leading to carcinogenesis.

Modified phosphoramidites were synthesized in the labs at Stony Brook. Oligonucleotides were purified by HPLC collection of the DMT product. The column used was a Hamilton (Reno, NV) PRP-1 polystyrene divinyl benzene column. Subsequent removal of the DMT protection group afforded product in a state that could be used in the next HPLC separation. Oligonucleotides without DMT were quantitated by UV spectrometry and used directly for HPLC/MS experiments. An HP 1050 LC system was used with a Brownlee (ABI, San Jose, CA) 5µm 220x2.1mm Spheri-5 RP-18 column. The gradient used was 300µl/min 50mM triethylammonium acetate pH 6 in H_2O with 9-15% acetonitrile in 15min. Postcolumn additions were made at the electrospray probe tip and consisted of either 10mM triethylamine in acetonitrile or 50/50 isopropanol/2-methoxy ethanol (IPA/2-MeOEtOH) at 18µl/min using a Phoenix 20 syringe pump (Fisons Instruments SPA, Rodano, Italy). All mass spectra and mass chromatograms were acquired on a VG Platform single quadrupole mass spectrometer. (Fisons Instruments, VG Biotech, Altrincham, UK) operating in negative ion electrospray mode. Infusion experiments used a Harvard Apparatus (South Natick, MA) Model 22 syringe pump at 5µl/min. Dry nitrogen at 300l/hr was used for drying, and 50l/hr was used for nebulization The source was maintained at 30°C.

A series of oligonucleotides with the sequence GCTTXXTTGC was used where the central two nucleosides marked by X are nominally G and A, but have been replaced by one or the other of the derivatives, 8-oxo-2'-deoxyguanosine (8-oxo-dG) and 8-oxo-2'-deoxyadenosine (8-oxo-dA). This replacement increases the mass of the oligonucleotide by 16 corresponding to the addition of a single oxygen. The mass spectra of the 8-oxo-dG and 8-oxo-dA are essentially

identical. The 8-oxo derivatives and the unmodified oligonucleotide are not well resolved chromatographically; the two derivatives coelute. The relative amounts of modified *vs.* unmodified oligonucleotides can be observed by monitoring the triply charged $[M-3H]^{3-}$ ions of the respective sequences (Figure 1). Relative intensities of the two triply charged species at 1010 and 1015 from the coeluting 10-mer and 8-oxo derivatives are indicative of the amount of each species injected on column.

FIGURE 1



Spectra from coeluting GTTCXXTTGCand GTTCAGTTGC. The base peaks are the triply charged species.

In the second pair of oligonucleotides with the sequence GCTXCT, the adenosine has been eliminated leaving only the furan in the "X" marked site of the 6 base oligonucleotide. The sequence with and without the adenosine base can be easily separated chromatographically as shown in Figure 2. The spectra obtained from these chromatograms are presented in Figure 3. The base peak in each of these spectra are the $[M-2H]^{2-}$ from each of the oligonucleotides. The spectra do not, however, show the triply or quadruply charged species. In such a case, the presence of adduct ions help to confirm the charge state of the ion The spectra in Figure 3 were aquired with a postcolumn addition that enhanced ionization but did not suppress adduct formation. These can be compared with the spectra in Figure 1. If sodium adducts had not been supressed by the postcolumn addition of 10mM TEA in acetonitrile identification of these two coeluting species would be much more difficult.

FIGURE 2

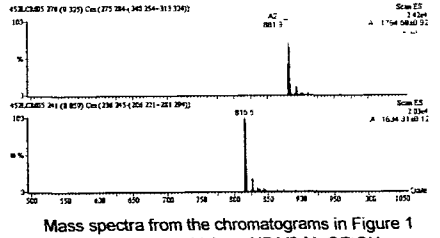
FIGURE 3



Mass spectra from the chromatograms in Figure 1 Postcolumn addition of IPA/2-MeOEtOH

Conclusions: The methods described here can be adapted for LC/MS analysis for many types of oligonucleotides. Postcolumn addition of volatile solvents facilitates ionization from HPLC systems that are currently in wide use. Volatile salts added after separation can reduce the level of adduct formation.

The Incorporation of Sample Stacking Techniques into the Capillary Electrophoresis-CFFAB-Mass Spectrometric Analysis of DNA Adducts

Susan Wolf and Paul Vouros; Department of Chemistry, Northeastern University, Boston, MA 02115

In previous work, we have examined the utility of CZE-CFFAB-MS for the characterization of DNA adduct mixtures and have observed high concentration detection limits associated with the well-known low injection volume requirement of CZE. Recent attempts to address this limitation have resulted in a number of innovations including a high volume sample stacking technique which is especially suited to the detection of negative ions (1). In this study, we investigated the ease with which this stacking technique could be interfaced with CZE-MS and determined the sensitivity with which a model adduct, AAF-C8-dGMP (the C8 N-acetyl-2-aminofluorene adduct of deoxyguanosine-5'-monophosphate), could be detected in the CZE-CFFAB-MS mode. This methodology was then applied to the analysis of AAF-DNA adducts generated *in vitro* to assess its usefulness for "real" sample analysis.

Experimental. Adaptation of the stacking technique to CZE-MS analysis required the inclusion of a true cathode buffer reservoir in the analytical set-up and the employment of off-line stacking prior to on-line CZE-MS analysis. A modified plexiglass liquid junction interface which relied upon the use of teflon tubing sleeves to allow for the rapid introduction and alignment of the capillaries in the interface was constructed to meet this requirement. A 40 cm x 50 um ID capillary was used to transfer materials eluting from the CE capillary (75 um ID X 75 cm) along with a make-up flow of CFFAB matrix solution present in the interface into the CF probe. A CFFAB solution of 1% glycerol, 39% MeOH, 60% 100mM NH_4OAc at a vacuum induced flow rate of ~ 2.5 uL/min was employed. Electrophoretic separations were conducted at 20kV (15uA) employing buffer of 0.01 M NH_4OAc adjusted with NH_4OH to pH 9.4. A VG Fisons Quattro triple quadrupole mass spectrometer, outfitted with a cesium ion gun, was employed for all mass spectrometric analyses. 1.0 mg of calf thymus DNA was reacted with 1.0 mg N-acetoxy-N-acetyl-2-aminofluorene after which the DNA was enzymatically cleaved to deoxynucleotide-5'-monophosphates (2). A centrifuge filter (MW 3000 cutoff) was employed to remove enzymes and undigested oligonucleotides. Adducts were then isolated using a polystyrene divinylbenzene solid phase extraction cartridge in fractions of low enough conductivity to permit analysis by stacking CZE-CFFAB-MS.

Results and Discussion. *Standard Analysis.* Under typical injection conditions, ~3.5 nL of 5 X 10^{-4}M (1 ng total) AAF-dGMP solution provided a good quality normal scan positive ion FAB spectrum by CZE-MS. With stacking, the concentration detection limit could be lowered by two orders of magnitude as shown in Figure 1. The ~100% recovery at 10^{-5}-10^{-6}M levels indicated that, for the conditions employed, the mobility of the adduct was high enough to prevent losses during the stacking process. When MRM detection was used (m/z 569→373, loss of dRMP from MH+), the signal response obtained was linear over a range from 25 pg (350 nL $1.25X10^{-7}$M injected) to 1.0 ng (35 nL $5X10^{-5}$M injected). Full column (3.3 uL) stacking of 117 pg of AAF-C8-dGMP from a $6.25X10^{-8}$M solution resulted in an 86% recovery of the injected adduct.

Adducts Isolated from DNA In Vitro. Constant neutral loss scanning of the loss of dRMP provided signals corresponding to the MH+ of the two expected dGMP adducts when a 175 nL injection of an adduct extract solution was made (Figure 2). Using the same injection volume, good detectability for the major adduct (AAF-C8-dGMP) was also achieved in full scan and CID (m/z 373) modes. It was not possible to obtain such information on the N^2 species, because mass spectral signals from this compound were obscured by a coeluting unknown related to the C8 adduct.

EXPERIMENTAL CONDITIONS FOR THE MATRIX-ASSISTED LASER DESORPTION FTMS ANALYSIS OF MODIFIED OLIGONUCLEOTIDES[a]

E.A. Stemmler*, R.L.Hettich, G.B. Hurst, and M.V. Buchanan**

**Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120.

Matrix-assisted laser desorption/ionization (MALDI)[1,2] Fourier transform ion cyclotron resonance mass spectrometry (FTMS) at 355 nm is being developed for the structural characterization of normal and modified oligonucleotides. Matrix-assisted studies on the FTMS are being duplicated on a newly constructed TOF mass spectrometer to help discriminate between factors influencing ion production (i.e. sample preparation) and ion trapping and detection on the FTMS.

We have found that efficient ion trapping, matrix selection, and laser conditions are critical to the desorption and detection of oligonucleotides by FTMS. The previous upper mass limit for MALDI-produced ions has been addressed by pulsed trapping plate ion deceleration experiments first described by Castoro et al[3]. Previous MALDI-FTMS studies of oligonucleotides were limited to hexamers[4]. By implementing the deceleration technique, the molecular ion for a mixed base 12-mer, 5'-CTGTACCGATTT-3' (MW = 3610.5), was observed in the negative ion mode. In addition, bovine insulin (MW = 5733.5) has been detected in the positive ion mode. The deceleration step used to observing these high mass ions involved setting the source trapping plate at 0 V and the conductance limit at -9.0 V (for negative ions) prior to the laser desorption event. Following the laser pulse a variable time delay (t_D) of 150 to 450 μs is inserted prior to setting both the conductance limit and source trapping plates at -1.5 V for ion detection. The detection of $[M-H]^-$ ions from an oligodeoxythymidylic acid mixture, at two ion deceleration times, is shown in Figure 1.

While ion deceleration methods have extended the FTMS mass range for MALDI-produced ions, the selection of an appropriate MALDI matrix is essential for the generation of intact $[M-H]^-$ oligonucleotide ions. Using dinucleotides as model compounds for preliminary screening experiments we found that basic matrices, such as 1,5-diaminonaphthalene and 9-aminophenanthrene, promoted extensive dinucleotide fragmentation. Fragmentation was reduced using 2,5-dihydroxybenzoic acid; however, the newly introduced matrix, 3-hydroxypicolinic acid[5], significantly improved our ability to detect unfragmented dinucleotides and mixed base oligomers. When FT and TOF mass spectra have been compared, fragmentation on the TOF is significantly reduced relative to that observed by FTMS. This may be a consequence of the longer times (milliseconds) required for FTMS detection.

The characterization of modified nucleic acid constituents in living systems is important for understanding the molecular basis of biological abnormalities, such as cancer. We have applied MALDI-FTMS to the analysis of modified nucleotides, nucleosides and oligonucleotides. For example, we have analyzed the modified hexamer 5'-GCATG^{Me}C-3' (G^{Me} = O^6-methyl substituted guanine), as well as its unmodified counterpart. Using 3-hydroxypicolinic acid, intact $[M-H]^-$ ions were measured for the modified and unmodified hexamers. In contrast, using 2,5-dihydroxybenzoic acid as a matrix, structurally significant negatively-charged fragment ions permit sequence verification. In the positive ion mode, protonated base ions permit further structural characterization of the modified guanine using the trapped ion capabilities of FTMS. While MS/MS of methylated guanine isomers is not sensitive to the site of methyl substitution,

studies by Nourse et al.[6] have shown that H/D exchange reactions can be used to distinguish sites of methyl group substitution. The O^6-methyl guanine isomer is expected to undergo one slow H/D exchange. Only one other isomer, 3-methyl guanine, undergoes one H/D exchange; however, the exchange for this isomer occurs at a faster rate. Experimentally, one slow H/D exchange reaction is observed for the $G^{Me}H_2^+$ ion that appears in the MALDI mass spectrum of the modified hexamer. This supports the assignment of methyl substitution at the O^6-position for the modified guanine in this oligonucleotide.

MALDI-FTMS and TOF have been applied to the structural characterization of deoxyguanosyl and deoxyadenosyl nucleoside and nucleotide PAH triol adducts. These highly polar molecules are difficult to detect by conventional mass spectrometric methods. Using MALDI, abundant $[M+H]^+$ and $[B+2H]^+$ ions were observed by TOFMS. On the FTMS, sodiated molecular and base fragments were more abundant for deoxyguanosyl adducts. Other fragments yield structural information about the nucleoside/nucleotide, nucleic base, and PAH triol.

MALDI-FTMS FOR THE CHARACTERIZATION OF ULTRAVIOLET AND X-RAY DAMAGE TO NUCLEIC ACID CONSTITUENTS *

Robert Hettich and Hiroko Yoshida
Oak Ridge National Laboratory, Oak Ridge, TN 37831-6120

Both low energy (far-ultraviolet) and high energy (x-ray) radiation can cause DNA damage by inducing strand breaks, base modifications, and sugar alterations. These changes may lead to mutations and ultimately cell death if they cannot be biologically repaired. It is therefore necessary to characterize both the identities (at the isomeric level) and the abundances of the radiation-induced products to probe the nature of DNA damage in these cases. Matrix-assisted laser desorption/ionization Fourier transform mass spectrometry (MALDI-FTMS) is well-suited for the direct detection and characterization of radiation-induced damage to nucleic acid constituents, including oligonucleotides. This technique eliminates the need to hydrolyze and derivatize the samples prior to mass analysis, thereby reducing the possibility of modifying the sample after irradiation. The accurate mass measurement and ion trapping capabilities of FTMS permit the detailed examination of the structures of these products. The experimental approach for these studies focusses on the development of MALDI-FTMS for the sensitive detection (picomole) and structural characterization of radiation-induced products. Reverse phase liquid chromatography (HPLC) is used to purify irradiated samples prior to mass analysis and to quantitate the dose dependent formation of products after they have been identified by mass spectrometry.

Hydroxylated thymines are a common product generated by x-ray irradiation of thymine-containing nucleic acid constituents. In particular, it is important to not only identify a hydroxylated product but also determine the site of hydroxylation on the thymine base. To address this issue, the collision-induced dissociation (CID) spectra of thymine glycol, 5-hydroxydihydrothymine, 6-hydroxydihydrothymine, and 5-hydroxymethyluracil standards were examined. Both thymine glycol and 5-hydroxymethyluracil reveal abundant fragment ions corresponding to loss of water from the $(M-H)^-$ ions. The two isomers of hydroxydihydrohthymine can also be differentiated by CID. Whereas 5-hydroxydihydrothymine fragments to generate NCO^- as the only fragment ion, 6-hydroxydihydrothymine also reveals a fragment ion corresponding to loss of HNCO. Examination of a ^{60}Co gamma ray irradiated sample of d(TpT) revealed the presence of hydroxylated thymines as well as a variety of other products. HPLC was used to purify fractions, and was found to be quite useful for separating the radiation-induced products from the unmodified d(TpT) prior to FTMS examination.

Pyrimidine photodimers are generated by the far-ultraviolet irradiation of DNA. These species consist of the cyclobutane pyrimidine dimers (for example, cis-syn and trans-syn) as well as the 6-4 and Dewar valence isomers. A series of these isomeric dimer standards were examined for d(UpT). MALDI-FTMS was used to generate characteristic negative ions, including $(M-H)^-$, for all of these species. CID of the cis-syn d(UpT) and the trans-syn d(UpT) revealed only one fragment ion, m/z 433 (loss of a sugar ring), and could not be differentiated from each other. In contrast, both the 6-4 d(UpT) and the Dewar valence d(UpT), fragmented to give an ion at m/z 432, loss of H_3PO_4. Figure 1 illustrates the CID of the cis-syn isomer and Figure 2 shows the CID of the Dewar valence isomer. Research is currently directed at development of other ion-molecule reactions which can be used to differentiate these isomers.

7 Day Low Level Dose Response Study of MeIQx in Rats using Accelerator Mass Spectrometry

CHRIS. FRANTZ[1], ESTER FULTZ[1], JOHN VOGEL[2], AND KEN TURTELTAUB[1]
BIOLOGY AND BIOTECHNOLOGY RESEARCH PROGRAM[1] AND CENTER FOR ACCELERATOR MASS SPECTROMETRY[2], LAWRENCE LIVERMORE NATIONAL LABORATORY, LIVERMORE, CA

2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx) is a heterocyclic amine that forms in meats during cooking and has been shown to cause cancer in laboratory animals at high doses. Structurally, MeIQx belongs to a class of heterocyclic amines often referred to as amino-imidazoazaarenes or AIA's. MeIQx, like all AIA-type compounds, is highly mutagenic in the Ames/*Salmonella* microsome-mediated assay, having a potency, depending on the bacterial tester strain, between 56,000 and 99,000 revertants/ ug (Felton and Knize 1990). MeIQx is also mutagenic in mammalian cell systems. Long-term feeding studies in mice (0.06% MeIQx in diet) show an 43% and 99% incidence of liver tumors in male and female CDF_1 mice, respectively (Ohgaki 1987). In F344 rats continuously fed MeIQx (0.04% in diet for 429 days) the incidence of liver tumors was 100% and 53% for males and females, respectively (Kato 1988). A high incidence of zymbal gland tumors in males and females, as well as clitoral gland tumors in female rats, were also found.

Although MeIQx is carcinogenic in rodents at high doses, the significance of these finding for humans is unclear since humans are exposed to much lower amounts of this compound (ngs/g meat) in the diet. We report here on the use of accelerator mass spectrometry (AMS) to trace the absorption, distribution, and elimination of human-relevant levels of [^{14}C]-MeIQx given to animals. We also report on the relationship between DNA binding and administered dose using [^{14}C]-MeIQx (sp. act.=10 mCi/mmol). Using this methodology, we were able to detect sub-pg levels of [^{14}C]-MeIQx in the tissues and DNA of the animals.

The effects of dose on tissue and DNA levels of MeIQx was examined in a sub-chronic feeding regimen by feeding Male Sprague Dawley rats [^{14}C]-MeIQx at concentrations ranging from 1 ng/kg/day up to 34 ug/kg/day in their diet for 7 days. A linear relationship between dose and tissue concentration was found for all tissues at the end of the 7 day exposure. At all dose levels the highest concentrations of [^{14}C]-MeIQx were found in the liver and kidney. The next highest levels were in the intestine, followed by the stomach, then the spleen, thymus, heart, pancreas, blood, and finally the brain.

The relationship between DNA damage and administered dose has also been examined. The dose response is linear ($y= 25.2 + 58302 x$ $R=0.99991$). A comparison of the biologically available [^{14}C]-MeIQx (liver tissue levels) to the biologically active [^{14}C]-MeIQx (bound to liver DNA) suggests that the percentage of MeIQx in the liver tissue that bound to DNA was slightly less at the high doses than the lower doses, though not significantly so. This relationship may be a function of metabolism or DNA repair kinetics.

In summary, AMS has been used to show that the biologically available dose (tissue concentration) decreases proportionally with decreasing administered dose from the high doses used in cancer assays to doses relevant for human exposure. The doses used in this study cover 3 orders of magnitude demonstrating the large dynamic range of the method.

This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract no. W-7405-ENG-48 and supported by NIH Grant CA55861.

DETECTION OF DNA ADDUCTS BY GC-ECNI-MS. Roger W. Giese, Manasi Saha, Samy Abdel-Baky, Kariman Allam and Amir Abushamaa. Bouve College of Pharmacy and Health Sciences, and Barnett Institute, Northeastern University, Boston, MA 02115.

Covalent damage to DNA by endogenous and exogeneous agents in vivo is termed "DNA adducts". The measurement of DNA adducts in human samples is important to help define the risks to health from exposure of people to carcinogens and mutagens. We are converting DNA adducts at a trace level via chemical transformation and electrophoric derivatization into products which can be detected with high sensitivity by GC-ECNI-MS. A Hewlett-Packard Model 5988A mass spectrometer is being used.

In Fig. 1 is shown a scheme for the detection in general of diolepoxide polyaromatic hydrocarbon DNA adducts, using benzo[a]pyrene as a model. Mild acid hydrolysis of the DNA releases the adduct as a tetrol. The latter is oxidized with potassium superoxide (1) to pyrene-2,3-dicarboxylic acid, which, in turn, is pentafluorobenzylated to DIESTER. The latter can be detected at the low attomole level, as a standard, by GC-ECNI-MS (2). Fig. 2 shows the detection of this particular adduct in human lymphocytes exposed in cell culture to benzo[a]pyrene: 5 adducts in 10^7 nucleotides were found.

Figure 1

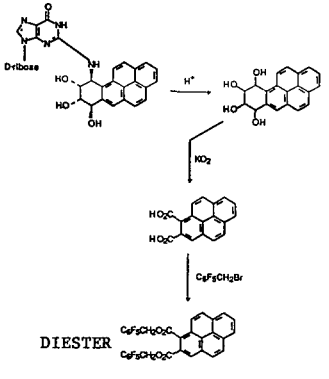

Figure 2

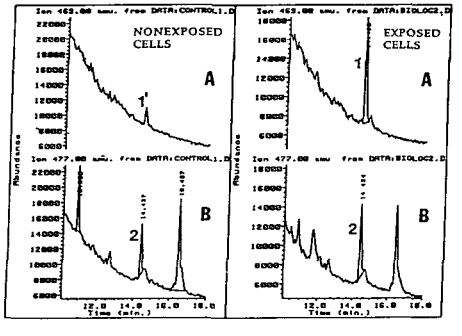
Selected Ion GC-ECNI-MS chromatograms from nonexposed and B(a)P-exposed cells. A. m/z 469 to detect Diester (peak 1) and apparent Diester (peak 1'). B. m/z 477 to detect d8-Diester (peak 2).



In Fig. 3 is shown a scheme for the detection in general of N7-G alkyl and hydroxyalkyl DNA adducts, using N7-(2-hydroxyethyl)guanine (an ethylene oxide DNA adduct) as a model, along with the detection of 7 fmol of a standard of the latter compound. This type of adduct can be recovered from DNA by neutral thermal hydrolysis. Conversion to a corresponding xanthine by nitrous acid, followed by pentafluorobenzylation, leads to the final derivative. Like the above product, this derivative can be detected as a standard at the low attomole level by GC-ECNI-MS. The detection of 165 pg of this adduct spiked into 100 ug of calf thymus DNA is shown in Fig. 4.

Spatial Distribution of Nucleic Bases using SIMS

J. M. McMahon, R. T. Short, W. B. Holland, and P. J. Todd
Analytical Chemistry Division
Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

The Human Genome Project will require rapid analytical throughput to obtain the extensive analytical data required to map the Human Genome. Selectivity, sensitivity, and reproducibility must be linked to rapid throughput for a technique to meet all the analytical demands of the project. Imaging SIMS easily meets these criteria.

Analysis by SIMS is rapid because the primary ion beam can be rastered quickly across the sample. In particular, we have developed a wide-angle secondary ion microprobe that is capable of producing images from samples 1 cm^2. If several thousand spots of nucleic bases were arrayed upon a target, all could be identified, and the DNA strand sequenced by deduction, in ten minutes.

Phase I of this study involves the molecular mapping of an array of one each of the four bases (adenine, cytosine, guanine, and thymine). Figures 1A through 1D illustrate the selective mapping of each base according to its mass-to-charge; Figure 1E is a composite of these four images, and reflects the actual spatial relationship of the spots. These figures demonstrate the ease with which Imaging SIMS can map the molecular distribution of several species and reconstruct the overall distribution.

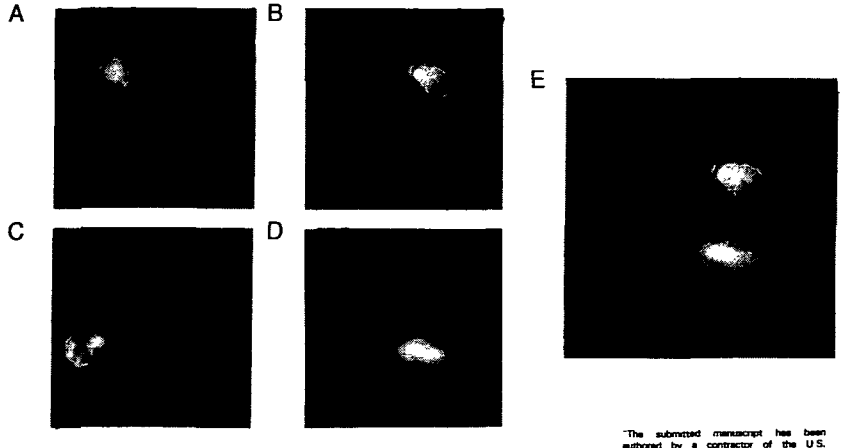

Figure 1. Secondary ion images of array of nucleic bases. A) Image showing position of guanine spot, B) adenine spot, C) thymine spot, D) cytosine spot, and E) composite image of all four spots.

"The submitted manuscript has been authored by a contractor of the U.S. Government under contract No. DE-AC05-84OR21400. Accordingly, the U.S. Government retains a nonexclusive, royalty-free license to publish or reproduce the published form of this contribution, or allow others to do so, for U.S. Government purposes."

As with SIMS in general the nature of the surface proved critical to analytical success, particularly for quantitation and reproducibility. After much experimenting with a variety of surfaces, best results were obtained with electropolished copper targets that were gold coated to inhibit complexation of analyte and metal, and then carbon coated to prevent sample spreading (see Figure 2). When the drop of sample analyte was applied, best results were seen when drying was done rapidly in vacuum. Figure 3 is an example of this surface preparation and sample drying technique.

The concentration profile of cytosine is shown in Figure 4. Using $3x10^{-7}$ liter of 10^{-5} M cytosine on a 1 mm diameter spot (rastered with a 100 µm diameter primary beam) results in a detection limit of $3x10^{-14}$ mol/pixel, or 30 femtomoles.

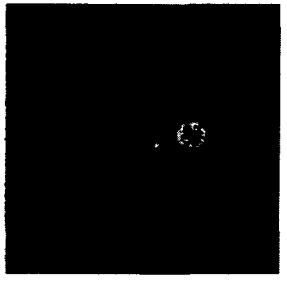

Figure 3. Image of sample prepared as described in Figure 2. Three spots of 10^{-5} M cytosine are easily seen; note even distribution in each circular spot.

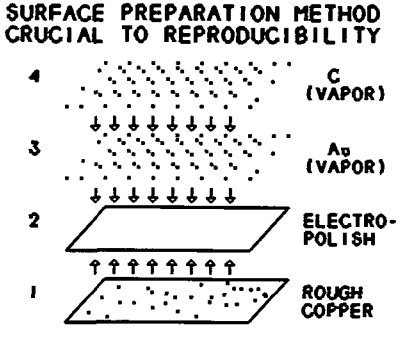

Figure 2. Schematic of surface preparation. An electropolished copper plate is gold coated followed by carbon coating. After applying sample drop to surface, rapid drying in vacuum is employed.

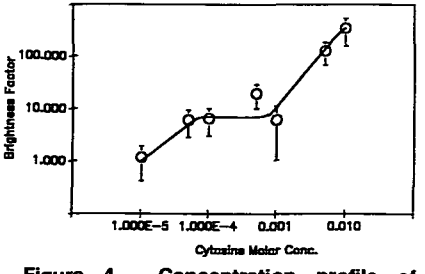

Figure 4. Concentration profile of cytosine. The Brightness Factor (comparable to intensity) vs. Concentration profile of cytosine. The 10^{-5} M concentration represents detection limits of 30 femtomoles.

MASS SPECTROMETRIC IDENTIFICATION OF 2'-DEOXYCYTIDINE ADDUCTS FROM REACTIONS WITH ACROLEIN AND 2-BROMOACROLEIN

Ahmed Chenna and Charles R. Iden

Department of Pharmacological Sciences, Health Sciences Center
State University of New York at Stony Brook, Stony Brook, NY 11794-8651

Acrolein is ubiquitous in the human environment, and a major source is the result of incomplete combustion of organic matter. Studies have shown that acrolein is mutagenic toward *Salmonella typhimurium* and can interact directly with DNA. Several investigators have characterized adducts of acrolein with deoxyguanosine, adenine and cytosine derivatives, deoxycytidine-5'-monophosphate, and thymidine. Halogen substitution at C-2 of acrolein should increase the rate of reaction with nucleobases in DNA; accordingly, 2-bromoacrolein and several chloroacroleins have displayed a higher mutagenic potency than acrolein. 2-Bromoacrolein is a genotoxic metabolite of *tris*(2,3-dibromopropyl)phosphate (Tris-BP) and the nematocide, 1,2-dibromo-3-chloropropane. Tris-BP may be activated by conversion to reactive electrophiles such as 2-bromoacrolein by cytochrome P_{450}. The chemical structure of the products from the reaction of 2-bromoacrolein with 2'-deoxyguanosine and thymidine have been determined, and reaction with DNA produces an unstable thymidine adduct. The goal of the present study was to determine the chemical structures of all major adducts formed in the reaction of 2'-deoxycytidine with 2-bromoacrolein and acrolein under physiological conditions.

2'-Deoxycytidine was permitted to react with either acrolein or 2-bromoacrolein in 0.1 M sodium acetate buffer (pH 4.4 or 7.4) at 37°C. After 38 h the solvent was evaporated under reduced pressure, and silica gel thin layer chromatography (20:80, methanol:methylene chloride) indicated that a single major product was present for each reaction. Flash chromatography on silica gel (15:85, methanol:methylene chloride) permitted separation from 2'-deoxycytidine, but the unknown products failed to crystalize from methanol. HPLC analysis of the reaction mixture separated 2'-deoxycytidine from a mixture of product stereoisomers.

The UV spectrum of the product of the reaction with acrolein was recorded at several pH values, and results are characteristic of 3,N^4-substitution on cytidine. The FAB mass spectrum (Fig. 1a) shows an MH^+ peak at *m/z* 284 (13.5%), a natriated molecular ion at *m/z 306* (17.9%) and a BH_2^+ peak of *m/z* 168 (100%). The 300 MHz ^1H NMR spectrum (Me_2SO-d_6) was compared to that for 2'-deoxycytidine and suggests the formation of a cyclic adduct; however, the position of the hydroxy group, whether at C-7 or C-9, cannot be determined from the spectral data. In order to determine the location of the hydroxy group, the product was hydrolyzed with sodium hydroxide to open the ring and then reduced with sodium borohydride to give the stable alcohol. This product, (N^3-(3"-hydroxypropyl)-2'-deoxyuridine), was identified by UV, FAB/MS and ^{1}NMR. Chemical transformation confirmed the position of the hydroxy at C-7, and the exocyclic adduct is 3-(2'-deoxyribosyl)-7,8,9-trihydro-7-hydroxypyrimido-[3,4-c]pyrimidin-2-one.

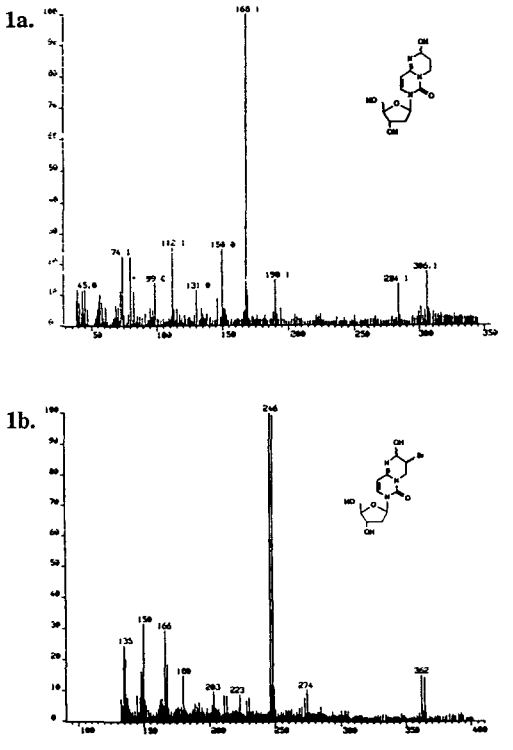

Figure 1. FAB mass spectrum of the exocyclic 2'-deoxycytidine adduct formed by a). acrolein and b). 2-bromoacrolein.

The reaction of 2'-deoxycytidine with 2-bromoacrolein at pH 4.4 gave a single major product which was purified by flash chromatography. The UV spectrum of this substance recorded at pH 2.3 and 4.2 shows λ_{max} at 288 nm, whereas at pH 10.8, λ_{max} of 228 and 274 nm are present. These changes in UV spectral character as a function of pH are characteristic of 3,N^4-substitution on a cytidine residue. The positive ion FAB mass spectrum of this compound (Fig. 1b) has an MH^+ at *m/z* 362 (15.0%) and a corresponding peak at *m/z* 364 (14.4%) containing the ^{81}Br isotope. BH_2^+ peaks at *m/z* 246 (100.0%) and 248 (98.9%) are formed by cleavage of the glycosidic bond. This important fragmentation shows that Br isotopes are present in the modified base moiety. In this reaction two new chiral centers are formed at C-7 and C-8 derived from C-2 and C-1 of 2-bromoacrolein. Because of these chiral centers and those of the sugar ring, the product exists as a mixture of diastereomers which were not separable by HPLC. Consequently, the ^1H NMR is complex and difficult to interpret. However, the spectrum of this mixture does not show any exchangeable protons in the region between 6.2 to 7.5 ppm indicating there is no NH_2 group in the compound. The spectral information did not allow the position of the hydroxy group to be uniquely determined; however, ring opening with sodium bicarbonate gave three N^3-substituted 2'-deoxyuridines which were characterized by UV, FAB/MS, ESI/MS, and ^{1} NMR and confirmed the position of the hydroxy at C-7. The 2-bromoacrolein adduct is 3-(2'-deoxyribosyl)-7,8,9-trihydro-7-hydroxy-8-bromopyrimido-[3,4-c]pyrimidin-2-one.

Enhanced Sensitivity in the Negative Ion FAB-MS Analysis of Polyanionic Organic Compounds Through the Use of Cationic Additives to the FAB Matrix

Zhi-Heng Huang[1], Bao-Jen Shyong[1], Kathleen Noon[2], John Allison[2], and Douglas A. Gage[1]

Departments of Biochemistry[1] and Chemistry[2], Michigan State University, East Lansing, MI 48824

Negative-ion (NI) FAB MS has been the method of choice for characterizing a variety of polyanionic compounds such as nucleotides, oligonucleotides (up to 10 mers), nucleotide sugars, cofactors, sugar phosphates and sulfates, and polar conjugates of xenobiotic substances. However, problems remain. First, the sensitivity is generally poor. Relatively large sample sizes (up to 10 nmoles or higher) are commonly required to obtain a good quality spectrum. Second, the spectra frequently exhibit a variety of pseudomolecular ions, containing various numbers of alkali ions.

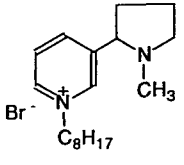
It has been proposed that addition of cationic surfactants to such samples can improve sensitivity. For example, it was shown by Ligon *et al.* [W.V. Ligon, Jr. and S.B. Dorn, *Fresenius Z. Anal. Chem.*, 325, 626-627 (1986)] and Barofsky *et al.* (J.P. Pavlovich, T.-Y. Yen, D.F. Barofsky, and B.U.R. Sundqvist, *Proc. 40th ASMS Conference on Mass Spectrom. Allied Topics*, pp. 543-544, 1992) that the $[M-H]^-$ signal for ATP was significantly enhanced when cetyl pyridinium acetate was added to the FAB matrix.

We have evaluated a large number of cationic surfactants for improving the NI-FAB analysis of the title compounds which respond poorly under ordinary conditions, and found that quaternary ammonium-type surfactants having an additional, basic center ("bifunctional" surfactants) increase analyte response more than the simple cationic surfactants that have been investigated previously.

The aims of this work are (1) evaluation of N-alkylnicotinium halides for their ability to enhance the signals of the model compound, coenzyme A; (2) study factors influencing the enhancement effect; and (3) study the scope of application for a potentially useful surfactant, N-octyl nicotinium bromide (ONBr).

RESULTS

Of the various N-alkyl nicotinium halides tested, the analog having a C-8 chain, ONBr, showed the most promising signal enhancement effect for the $[M-H]^-$ of the model compound, coenzyme A (Na salt). When ONBr is added to a polyanionic compound in dilute glycerol, the following phenomena are observed:



ONBr

- enhanced response of $[M-H]^-$ and the presence of fragment ion peaks in NI-FAB, shown in the spectra below for Coenzyme A, Na salt, FW=767 (for free acid = M);
- reduced tendency of cationization resulting in a much simplified spectral pattern.

Mechanisms have been proposed to explain the phenomena observed:

- Ionic forms of the analyte accumulate at the surface via ion-pair interactions with ON^+, or through establishment of an electrical double layer at the surface.
- ONBr alters the chemical environment from which the analyte desorbs.

CONCLUSION

N-Octyl nicotinium bromide has been shown to be an efficient reagent to assist in the desorption of compounds containing multiple acidic functionalities under NI-FAB conditions. The advantages include: (1) 1 - 2 orders of magnitude gain in intensities; (2) simplified spectra, mostly free of alkali ion clusters; and (3) simple to implement, without requiring other pretreatments like desalting and derivatization.

INTRODUCTION

Cyclic nucleotides are naturally occurring molecules composed of a heterocyclic base, a ribose ring and a cyclic phosphate group. In mammals one such cyclic nucleotide, adenosine 3',5'- cyclic monophosphate (cyclic AMP), acts as the intracellular mediator of the action of numerous hormones and neurotransmitters, this action leading to its description as a biochemical second messenger, transducing the primary extracellular message from the hormone or neurotransmitter. The response to this message is brought about by the action of a protein which is able to recognise and selectively bind cyclic AMP; this protein is one of two types of cyclic AMP-dependent protein kinase, and when it has bound cyclic AMP it is able to catalyse the phosphorylation of a wide range of substrate proteins:

$$\text{Protein} + \text{ATP} \xrightarrow[\text{Cyclic AMP}]{\text{Cyclic AMP-dependent protein kinase}} \text{Protein-PO}_4 + \text{ADP}$$

The protein so phosphorylated changes shape, resulting in a change in activity, for example in an enzyme or a membrane protein; this change in activity manifests itself as the physiological response to the hormone or neurotransmitter In view of the potency of cyclic AMP and ubiquity of this responsive kinase, this system is a significant potential pharmacological target.

While cyclic nucleotides were not readily amenable to mass spectrometric analysis by more established methods, the advent of fast atom bombardment (FAB) as a method of 'soft' ionization provided a means of generating mass spectra from underivatised cyclic nucleotides which contained a quasi-molecular ion of significant proportion[1,2]. The selection of this quasi-molecular ion and generation of a mass-analysed ion kinetic energy (MIKE) spectrum after its collisionally induced dissociation (CID) has been used successfully to differentiate cyclic nucleotide isomers[2] and to identify putative cyclic nucleotides in tissue extracts[3-5].

The application of FABMS to studies of cyclic nucleotide biochemistry has been extended from qualitative to quantitative analysis by examination of the kinetics of cyclic AMP- and cyclic CMP-phosphodiesterase activities[6,7], and to a protein kinase responsive to cyclic CMP[8]. The latter assay, based upon quantitation of the mass spectrum of enzyme incubate, had the advantage over the alternative radiometric assay in that several incubation components could be monitored in a single incubation. This same approach has now been successfully applied to type II cyclic AMP-dependent protein kinase.

PREPARATION OF CYCLIC AMP-DEPENDENT PROTEIN KINASE

Type II cyclic AMP dependent protein kinase was prepared from bovine heart muscle; a series of incubations were set up containing 1-25 nmol cyclic AMP, 50 μg histone 2A, 0.125 μmol magnesium acetate, 100 μg of protein kinase preparation in a total volume of 400 $\mu\ell$ 50 μM Tris-HCl pH 7.4. The mixture was incubated at 37°C for 10 minutes then the reaction stopped by the addition of TCA; precipitated protein was removed by centrifugation and the supernatant retained for mass

spectrometric analysis. Control incubations containing denatured protein kinase were simultaneously carried out.

EXPERIMENTAL PROCEDURE

Positive-ion FAB mass spectra were obtained on a ZAB-2F mass spectrometer from 5 $\mu\ell$ samples made up in glycerol-water, 1 : 1 v/v. Quantitation of the spectra were carried out by selecting the major ions arising from each component and incorporating their peak heights in the following:-

$$\Delta\ \text{conc} = \frac{\left[\left[\dfrac{\sum I_n\ \text{sample}}{\sum I_n\ \text{matrix}}\right]_{\text{control}} - \left[\dfrac{\sum I_n\ \text{sample}}{\sum I_n\ \text{matrix}}\right]_{\text{experimental}}\right]}{\left[\dfrac{\sum I_n\ \text{sample}}{\sum I_n\ \text{matrix}}\right]_{\text{control}}}$$

where $\sum I_n$ = sum of peak intensities relative to m/z 369 as characteristic ion for sample component or matrix

For cyclic nucleotides and ATP, the peak relative intensities utilized were those corresponding to $[MH]^+$, $[MNa]^+$, $[MNa + Na]^+$, $[M + Gro]^+$, $[MNa + Gro]^+$, $[MNa + GroNa]^+$, plus each of these less 17 mass units and less 18 mass units, corresponding to loss of NH_3 and loss of H_2O, respectively. For the matrix the peak relative intensities used were at $[3Gro + 2Na]^+$, $[4GroH]^+$, $[4GroNa]^+$, $[4GroNa + Na]^+$, $[5GroNa]^+$, $[5GroNa + Na]^+$, $[MH + Gro]^+$ and $[MNa + Gro]^+$, plus each of these minus 18 mass units, corresponding to a loss of H_2O. By this means of monitoring changes in peak heights of diagnostic ions emanating from cyclic nucleotides, it is possible to determine binding of cyclic nucleotides to the protein kinase by FAB analysis, by monitoring changes in the diagnostic ions of ATP and ADP it is also possible to monitor conversion of ATP and ADP and, by means of appropriate controls, to differentiate between ATP hydrolysis due to non-specific phosphorylase activity and that due to protein phosphorylation as a result of protein kinase activity. This approach provides an unique means of determining the specificity of the protein kinase in terms of its cyclic nucleotide-binding capacity and its protein substrate, but also enables the determination of any integral phosphodiesterase activity and the turnover of any low Mr effector molecules. The data obtained has shown that stimulation of cyclic AMP-dependent protein kinase occurred to a lesser extent with other cyclic nucleotides, indicating how the intercellular levels of these other compounds can potentially alter the potency of cyclic AMP in a cyclic AMP-regulated system.

ULTRA TRACE ANALYSIS OF OXIDIZED NUCLEOSIDES IN BIOLOGICAL MATRICES

A.J.R. Teixeira, G. van de Werken, J.G. Westra [1] and A.P.J.M. de Jong
National Institute of Public Health and Environmental Protection. Bilthoven, The Netherlands
[1]The Netherlands Cancer Institute, Anthonie van Leeuwenhoekhuis, Plesmanlaan 212, Amsterdam.

The study of oxidation of DNA contituents is receiving increasing interest, because they are suspected to be involved in ageing, mutagenesis, carcinogenesis and in a variety of other pathological processes.
Until now approx. 20 oxidized DNA base variants have been identified. Typical examples of oxidized base containing nucleosides are 8-hydroxy-2'-deoxyguanosine (8-OHdG), 5-hydroxymethyl-2'-deoxyuridine (HMdU) and thymidineglycol (dTg).

DNA base oxidation is caused by reactive oxygen species, including hydroxyl radicals and singlet oxygen, and ionizing radiation. Normal aerobic metabolic processes cause a background level of oxidized nucleobases in DNA. Enhanced levels of these compounds have been found in DNA and in urine after *in vivo* exposure to tobacco smoke and to hazardous compounds such as benzo[a]pyrene (PAHs), 2378-TCDD (dioxins), asbestos, phtalates, tobacco smoke and AZT. Reported DNA background levels of 8-OHdG are:

animal	organ	8-OHdG/10^5 dGs	ref.
rat	liver	1.4-1.5	1
	kidney	1.2-1.3	
rat	liver	3-5	2
hamster	liver	3-29*	3
	kidney	6-18*	

* depending on age

Normal urinary excretion rates in healthy adults range between 130–300 pmol/kg/day for 8–OHdG and approx. 100 pmol/kg/day for dTg (4). HPLC with Electrochemical Detection is the most commonly used determination method for base oxidized nucleosides.
Mass spectrometry combined with GC, LC or other separation techniques is becoming increasingly used. GC/MS requires chemical derivatization of nucleosides owing to their polar and thermolabile nature.
Here we report on a GC/MS method based on Electron Capture Negative Ion Chemical Ionization Mass Spectrometry (GC/ECNICI-MS) after acetylation and electrophoric labelling with pentafluorobenzyl groups (PFB).

Results of applications are shown for 8-OHdG in rat liver DNA obtained after in vivo exposure to nitropropane and for HMdU in genomic DNA extracted from Bacillus subtilus bacteriophage H1. Further, first experiences with standard dTg are shown as well as a GC/MS run of a sample containing the three mentioned compounds as a mixture of standards.

We have choosen for Gas Chromatochraphy combined with Electron Capture Negative Ion Chemical Ioniation Mass Spectrometry (GC/ECNICI-MS) as analysis technique as this technique generally provides ultimate sensisitivity when proper derivatives are prepared.
Quantification of 1 modified in excess of 10^6 non-modified nucleotides will require very high sensitivity and selectivity for the low µg DNA sample size range. The method uses nucleosides instead of nucleobases in order to prevent interference from RNA

The results of this show that the method developed is suitable to study the level of 8-OHdG occuring in DNA. This conclusion is supported by:
1. The sensitivity of the method which allowed the detection of background levels of 8-OHdG in DNA;
2. The results obtained with 2-nitropropane, which are in agreement with the findings of Adachi et al. (8) with HPLC-EC;
3. The good inter-assay precision for real samples (13%).

The sensitivity for other oxidized nucleosides is a good support for the development of a multicomponent method allowing analysis of several oxidative products in a single run.

Estimation of Quadruplex DNA T_M by Electrospray Ionization-Mass Spectrometry

David R. Goodlett[1], Charles C. Hardin[2], Matthew Corregan[2] and Richard D. Smith[3]
[1]Analytical Research, Immunobiology Research Institute, Annandale, NJ 08801
[2]Department of Biochemistry, North Carolina State University, Raleigh, NC 27695
[3]Chemical Methods and Separations, Pacific Northwest Laboratory, Richland, WA 99352

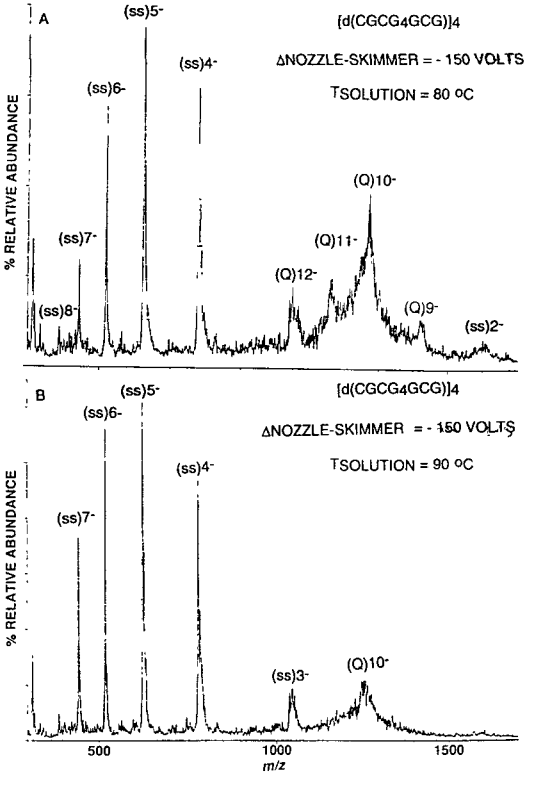
The use of electrospray ionization-mass spectrometry (ESI-MS) to detect non covalent biological complexes has become quite popular.[1-3] It appears to hold some promise in understanding 1) the interaction of subunits within a given structure in solution and 2) the electrospray process itself; in particular the process of ion desolvation. Guanine-rich DNA[4-6] can be found in the telomeric region of certain chromosomes. When removed from the chromosome and analyzed as small oligonucleotides in the presence of cations such as K^+, Ca^{2+}, and Na^+, these guanine-rich sequences form quadruple-stranded structures (quadruplexes); dissociation into single-stranded DNA occurs when all cations are removed from solution. ^{1}H-nmr, circular dichroism and electrophoresis have been used to study the thermal stability of quadruplex DNA. We recently published[1] the detection of quadruplex DNA by ESI-MS. We now present the results of experiments carried out using on-line thermal denaturation to dissociate quadruplex DNA structures in solution followed by observation of the effect of thermal perturbation on the solution structures using ESI-MS. This allowed us to estimate by ESI-MS the melting temperature (T_M); the temperature at which the quadruple-stranded structure dissociates in solution to the single-stranded structure.

For liquid phase thermal denaturation studies, 60 cm of an 80 cm length of 50 µm i.d. x 180 µm o.d. fused-silica capillary was wrapped in heating tape with segments of about 8 cm at the ESI source and 12 cm at the syringe remaining unheated. Temperature was measured with a thermal couple placed inside the heating tape. "On-line" thermal denaturation was conducted by filling a capillary with sample, incubating for ten minutes at a given temperature, then directly infusing (0.5 µl/min.) the sample. The single-stranded DNA oligomer d(CGCG$_4$GCG) was synthesized using phosporamidite chemistry on an Applied Biosystems Model 381A DNA synthesizer. The oligomer was purified from failure sequences using reversed-phase, high-performance liquid chromatography followed by treatment with Amicon Centricon-3 ultra filtration tubes to remove low-molecular weight impurities and residual salt. Quadruplex DNA, d[(CGCG$_4$GCG)]$_4$, was prepared in the presence of 10 mM sodium phosphate, pH 7.6, containing 0.1 mM ethylenediaminetetraacetic acid from single-stranded d(CGCG$_4$GCG) according to a published protocol.[4] All ESI-MS thermal denaturation experiments were done on DNA in this buffer solution.

The single-quadrupole mass spectrometer, operated by a Teknivent data system, was assembled at Pacific Northwest Laboratory from Extrel components and consists of a nozzle-skimmer (+300 V and 0 V) atmospheric pressure inlet, followed by an rf only quadrupole surrounded by a cryopumping surface. Operating pressures in the analysis quadrupole, which was separated from the rf only quadrupole in a second chamber, were typically 10^{-7} torr when a one mm nozzle and a two mm skimmer were used. The front plate was held at ambient temperature and the lens was at +1.0 kV. A counter-current stream of nitrogen gas at ambient room temperature was used to assist desolvation and a coaxial stream of SF_6 within the ESI source was used to prevent discharge when water was used as a sheath solution.

At a solution temperature of 29 °C and a low nozzle-skimmer bias (ΔNS) of -150 volts, unique charge states (e.g. 9- & 11-) for natriated ions of [d(CGCG$_4$GCG)]$_4$ can be observed by ESI-

MS. These ions are absent when ΔNS = -250 volts; presumably dissociated in the desolvation stage of ESI at a high ΔNS, but preserved at a low ΔNS. A solution of [d(CGCG$_4$GCG)]$_4$ incubated at 80 °C and then analyzed by ESI-MS at ΔNS = -150 volts (Figure A) showed the same unique ions of [d(CGCG$_4$GCG)]$_4$ as the solution incubated at 29 °C. However, [d(CGCG$_4$GCG)]$_4$ incubated at 90 °C and analyzed by ESI-MS at ΔNS = -150 volts showed no unique ions (Figure B) for [d(CGCG$_4$GCG)]$_4$. These results agree with circular dichroism experiments which show that [d(CGCG$_4$GCG)]$_4$ dissociates in solution to d(CGCG$_4$GCG) at 90 °C, but not 80 °C. In the mass spectra below "Q" stands for [d(CGCG$_4$GCG)]$_4$ ions and "ss" for d(CGCG$_4$GCG) ions. Also note that as a result of ESI-MS analysis in a sodium phosphate buffer, the 11- ion of [d(CGCG$_4$GCG)]$_4$ has 16 sodium ions attached to it and the 5- ion of d(CGCG$_4$GCG) has 3 sodium ions attached.



Pacific Northwest Laboratory is operated by Battelle Memorial Institute.

COLLISION-INDUCED DISSOCIATION OF PERMETHYLATED DERIVATIVES OF SITE-SPECIFICALLY ^{15}N- AND ^{18}O-LABELED GUANOSINES

John M. Gregson and James A. McCloskey
Departments of Medicinal Chemistry and Biochemistry
University of Utah, Salt Lake City, UT 84112

In previous reports (1, 2) we showed how permethylation MS/MS could be used to both increase the analytical sensitivity as well as to assign sites of alkylation in nucleosides related to guanosine. Ionic formulas were presented for structurally significant fragment ions that were consistent with — but not proven by — previous workers or by traditional chemical reasoning.

In this report we provide evidence for the veracity of these ionic compositions, based on the results obtained by low energy CID of the permethylated derivatives of guanosines labeled by ^{15}N at N-1, N^2, and N-3; and by ^{18}O labeling at O^6. Microgram level synthesis (10 — 100 nmol) was used for the selective implantation of ^{15}N and ^{18}O into the heteroaromatic ring. Levels of isotope incorporation were high, with [1-^{15}N]guanosine being generally the most difficult to prepare. The synthetic protocols employed (to be published separately) featured exclusive site specificity. Subsequent derivatization and mass analysis were conducted as described (1).

The following figure shows the CID mass spectra of four isotopically labeled perdeuteromethylated guanosines along with guanosine itself (product ion spectra for the base fragments BH_2^+; only the keto forms are shown). The observed patterns unanimously validate the compositions shown previously and help eliminate alternative structures, such as the hypothetical N-3 deammoniated analog of *m/z* 127.

There are several interesting outgrowths of this work. Most important of these is the discovery of widely different fragmentation channels between permethylated and underivatized guanosines. Within these categories is further noted the presence of hitherto unknown decomposition pathways (*e.g.* exclusive retention of N-1 in fragment 152 — not the case for underivatized nucleoside) as well as the absence of certain commonly reported ones (such as the near-absence of H_2O loss in both permethylated and underivatized species).

EVALUATION OF VARIABLE POST-TRANSLATIONAL MODIFICATION OF HISTONES BY ELECTROSPRAY IONIZATION MASS SPECTROMETRY AND TANDEM MASS SPECTROMETRY. *C.G. Edmonds, M.S. Weir, B.D. Thrall, J.D. Morris and D.L. Springer, Pacific Northwest Laboratory, P.O. Box 999, Richland WA 99352.

The basic subunit of chromatin structure, the nucleosome, consists of 146 base pairs of DNA reversibly wrapped around a central lysine and arginine rich histone protein octamer with an additional histone binding the linker regions. The nature and function of covalent modifications of proteins occurring after translation and simple proteolytic processing is a recurring theme in structural biology. In the case of histone proteins, such post-translational modifications include acetylation, methylation, phosphorylation, mono- and poly(ADP)ribosylation and ubiquitination. These modifications are known to be associated with the alteration in chromatin structure which occurs through the cell cycle and in response to chemical or radiation induced damage and repair to the cell nucleus.

Electrospray ionization mass spectrometry (ESI-MS) permits the direct analysis of the intact modified protein with precise mass measurement allowing the direct and unambiguous evaluation of the nature and extent of post-translational modification. Preliminary experiments on HPLC-purified histones revealed an array of materials, which, when compared to the masses predicted from the gene sequences, had mass values that precisely matched combinations of methylation and acetylation. We have sought to confirm the notion that these measured mass increments are genuine reflections of natural post-translational processes. We have isolated histones from human K562 cells grown in normal cell culture and in the presence of 20 mM sodium butyrate, a deacetylase inhibitor which results in the hyperacetylation of proteins. HPLC isolation and SDS-PAGE separations of these histones show that the proteins are intact but reveal no detectable difference between the proteins from control and butyrate-treated cells. ESI-MS of these materials demonstrate significant increases in heterogeneity of the butyrate treated proteins, consistent with increased levels of acetylation. Differences in predicted masses and the measured values are precisely accounted for by methylation and acetylation. These strongly basic proteins show persistent contamination by noncovalently associated species incrementing the measured mass values by 98 daltons (putatively, sulfate or phosphate). Rigorous exclusion of these contaminants has not so far been possible. Dialysis, ultrafiltration and precipitation according to the method of Chait and co-workers (S.K. Chowadhury, V. Katta, R.C. Beavis and B.T. Chait, *J. Am. Soc. Mass Spectrom. 1*, **1990**, 382-388) have not been completely effective. Reduction of this artifact contribution to the mass spectra may be accomplished by an increase in the collisional activation occurring in the atmosphere/vacuum interface by increasing the voltage bias between the nozzle and skimmer elements. Figure 1 shows an example of the multiple acetylation observable in histone H4 from butyrate-treated cells. Further confirmation of these assignments was possible by employing the triton-acid-urea PAGE method. This method permits the separation of proteins by virtue of the effect of acetylation of a lysyl amino group, reducing the electrophoretic mobility of the protein by decreasing the net charge. The mobility of isolated histone H4 from control and butyrate-treated K562 cells are compared in Figure 2. In both the control and the butyrate-treated sample a series of five proteins are observed. The two principle H4 species present in the control culture are of the highest mobility. Three species migrating at successively slower rates are abundant in the butyrate-treated

sample and present in only trace levels in the control. Correlation with mass measurements identify the two common components (Figure 2, bands 1 and 2) as dimethylacetyl and dimethyldiacetyl H4 proteins and the three additional species (Figure 2: bands 3, 4 and 5) arise from successive acetylations. Further increases in the voltage bias between the nozzle and skimmer elements of the interface causes dissociation of the histone proteins. The success of our interpretive efforts suggest this method has realistic prospects for more direct evaluation of the nature and extent of modification and new information on site of specific modified residues. In future studies we will seek to extend this approach for the evaluation of normal variations in the levels of acetylation and other modification chemistries through the cell cycle in flow cytometry sorted populations. This will be followed by studies which seek to demonstrate the perturbation of these normal variations by physical or chemical insult.

The results of these experiments demonstrate the feasibility of analyzing both natural and altered modifications of histone proteins by ESI-MS. Alterations in chromatin structure which accompany transcription and replication are governed in part by the modulation of DNA-protein interactions through histone post-translational modifications. We hypothesize that the normal temporal profile of these modifications will be measurably and predictably perturbed by physical or chemical insult. These changes are cell cycle dependent and damage induced perturbations in these modifications may be in part responsible for aberrant cell functions. Our technique will permit the full evaluation of the profile of normal modifications by specific detection of perturbations which indicate the response to DNA damage and its repair.

PRODUCT ION SCANS OF THE BH_2^+ ION: A TOOL FOR INVESTIGATING THE STRUCTURE OF DEOXYNUCLEOSIDES MODIFIED BY ARYLAMINE AND DIOL EPOXIDE CARCINOGENS, J.O. Lay, Jr., M.P. Chiarelli, and P.S. Branco, National Center for Toxicological Research, Jefferson, AR, 72079 and University of Arkansas at Little Rock, Little Rock, AR 72204.

ABSTRACT

We have reported nucleoside-base specific neutral losses, from low energy collision induced dissociation (CID) of mass selected BH_2^+ ions of C-8 substituted deoxyadenosine and deoxyguanosine (dG) adducts with arylamine carcinogens. Recently, using arylamine adducts substituted through different positions of the nucleoside base (i.e., N^2), other arylamines, and different classes of carcinogens, we continued our studies using low energy CID of the BH_2^+ ion. Differences were noted in the mass spectral behavior of the BH_2^+ ions of arylamine, arylamide, and polycyclic aromatic hydrocarbon (PAH) diol epoxide adducts. For instance, the formation of the BH_2^+ ion occurs to a lesser extent with PAH diol epoxide adducts than arylamine or arylamide-modified deoxynucleosides. Also, isomeric N^2- and C8-modified adducts are readily distinguished based on both the masses and intensities of product ions. Product ion data obtained in our laboratory was similar to data obtained elsewhere using high energy collisions.

Results and Discussion

Replicate product ion spectra, from the BH_2^+ ions of the model arylamine carcinogens dG-C8-AF and dG-C8-ABP were acquired over 2-3 years. Although variations in the sample loading, matrix, solvent, and collision energy were systematically studied, the variability in signal intensities appeared to increase primarily with the time between experiments. Nevertheless, the specific masses, especially when expressed as neutral losses, were used to provide evidence of structure, based on the large number of common neutral losses. The existence of these common neutral losses reflects cleavage within the base (dG) and the retention of charge on the carcinogen-containing portion of the molecule. Similar losses were also observed with adducts of related compounds, including the heterocyclic amine, dG-C8-PhIP (see table), but not from adducts of arylamide or PAH diol epoxides carcinogens.

Most of the neutral losses observed in our laboratory were also observed by Dietrich et. al. (Carcinogenesis 9, 2113 1988) using high energy CID and a similar arylamine adduct, dG-C8-NFA. Their spectrum showed all these fragments except loss of 42 daltons, although some appeared to be minor peaks. In another study using B/E scans, Annan et. al. (Anal. Biochem. 191, 86 1990), observed several of the same losses, but a few product ions differed in mass by one dalton from the values in our study and others were not observed at all.

Characteristic BH_2^+ Neutral Losses for dG-C8 Adducts

Mass Loss	dG-C8-ABP	dG-C8-AF	dG-C8-An	dG-C8-PhIP
17	302	314	226	357
42	277	289	201	X
44	X	287	(198)	(329)
70	249	261	173	304
72	247	259	171	302
99	X	232	144	275
111	208	220	132	X
124	195	207	119	250
139	180	192	104	235
151	168	180	92	X
166	153	165	77	208

Conclusions

Product ion masses (and neutral losses) taken as a group provided significant structure specificity. As expected, differences were observed when either the class of the carcinogen or the position of substitution were changed. When low energy CID spectra were compared with literature results obtained using high energy, the spectra were surprisingly similar. Previously acquired B/E scans showed more significant differences, whereas high energy product ions from the BH_2^+ of dG-C8-NFA showed 10 of the 11 expected neutral losses. Product ions from the BH_2^+ of arylamine, arylamide, and PAH diol epoxide modified bases showed significant structure specificity. The extent of fragmentation was greatest with arylamine-modified deoxynucleosides. As the structure of the carcinogen was varied, the typical "arylamine-adduct" fragmentation changed, so that only some of the expected fragments were observed using adducts of heterocyclic amines and fragmentation was entirely different using arylamide- and PAH diol epoxide modified deoxynucleosides. Loss of most of the base moiety to give common fragment ions, regardless of the specific base, was observed as a significant fragmentation pathway from the PAH diol epoxide adducts.

Studies on the Binding of Actinomycin D to Single-Stranded DNA by Negative Ion Spray Mass Spectrometry . Y.T. Li[1], Y.L. Hsieh[1], H.K. Lim[2], J. Henion[1], and B. Ganem[3]. Drug Testing[1] , Cornell University, 925 Warren Dr., Ithaca, NY 14850. Wyeth-Ayerst Research[2], Princeton, NJ 08543. Department of Chemistry[3], Cornell University, Ithaca, NY 14853.

Recently we reported the detection of the duplex form of an octanucleotide by ion spray mass spectrometry (MS)[a]. By using this promising technique, we have studied the binding of actinomycin D (AMD) to single-stranded DNA for which the binding of complexes has been reported by fluorescence[b]. It has been suggested the biological role of binding AMD to single-stranded DNA might inhibit RNA polymerase via blocking hybridization of RNA-DNA duplex formation, thus terminating DNA transcription. The noncovalent complexes are formed through hydrogen-bonded "outside-binding" model[c]. The intercalation binding of double-stranded DNA by AMD is not reported here.

Several nonself-complementary oligonucleotides and AMD,an inhibitor of RNA polymerase, which has been used as an antitumor drug were studied using negative ion spray MS (1:1 in 50/50 ACN/10 mM NH_4OAc, pH 7) under mild declustering energy (30 V) conditions. Rifampicin (RP), also an inhibitor of RNA polymerase, is used as a control drug for this study. Acetic acid (0.1 %) and ammonium hydroxide (0.1 %) were used to adjust pH.

The noncovalent complex of AMD and single-stranded 5'-CTCGACGG-3' was detectable by negative ion spray MS. When we replaced AMD (hydrophilic) by RP (hydrophobic), no complex was observed (Figure 1), suggesting that the formation of hydrogen bonds is required for the binding of the complex. Moreover, the complex disappeared at pH 3 and reappeared when the pH was adjusted back to pH 7 (Figure 2), indicating that the binding of complexes is pH dependent and reversible. By examining the effect of the DNA sequence on complex binding , G-C or C-G pairs are more favorable to the binding but AMD also could bind to non G-C or C-G sites (Figure 3), reflecting that the presence of deoxyguanine in a DNA is not necessary for complex formation. In fact, no complex formed between AMD and 5'-GGGGGGGG-3' (Figure 3). In summary, the binding of AMD to single-stranded DNA is dependent upon pH, the drug, and the DNA sequence.

Posttranslational Modifications and Mass Spectrometry: What the Well Dressed Protein is Wearing and How to Tell

Steven Carr, Roland Annan, Mark Bean, James Conboy, Mark Hemling, and Michael Huddleston, Physical and Structural Chemistry, SmithKline Beecham Pharmaceuticals, King of Prussia, PA 19406

Protein synthesis can be divided into three discrete stages: i) initiation of the translation process by synthesis and activation of the amino acids into the twenty unique amino(imino)acyl-tRNA adducts, ii) polymerization on the ribosome-mRNA complex of the amino acid moieties of the amino(imino)acyl-tRNA adducts into the sequence specified by the three-nucleotide codons of the mRNA, and iii) processing and release of the resulting polymer. Processing, or posttranslational modification, is almost always required to convert the polymeric end product of translation into a biologically active molecule and for transporting the protein to its proper compartment of action. In this context, posttranslational modifications include all changes to the molecule that are not coded for by the gene whether they have been introduced before, during or after the polymerization step.

Proteins having covalent modifications are the rule rather than the exception in nature. Nearly 200 structurally distinct covalent modifications have been identified thus far, ranging in size and complexity from conversion of amides to carboxylic acids, to the attachment of multiple complex oligosaccharides each with molecular masses up to several thousand daltons. Most posttranslational modifications are introduced by enzymes; the presence of the modification is often required for normal biological function or tissue disposition of the protein, although in many cases the role is as yet unknown. Proteolytic cleavage is perhaps the most common modification in that the amino-terminal Met residue that is the starting point for the synthesis of all proteins is, in most cases, removed through the action of aminopeptidases. Frequently the new amino-terminal residues, or the initiator Met residues if they have not been removed, are acylated through the action of acyltransferases. In addition to acetyl and formyl, longer chain acyl groups such as myristyl have been shown to be attached at the α-amino group. Covalent modifications of the side-chains of amino acids are also common, particularly glycosylation and phosphorylation.

Posttranslational modifications frequently complicate or even prevent the use of classical analysis tools such as automated Edman degradation, the most commonly used method for determining the sequence of peptides and proteins. The presence of lipid or carbohydrate on proteins can also dramatically decrease the accuracy of molecular weight estimates obtained by sedimentation velocity, gel permeation, or SDS-PAGE measurements. Mass spectrometry relies on entirely different principles than these other techniques, and it is uniquely suited for detection and structural characterization of posttranslational modifications in proteins. Many benefits are to be gained when MS-based methods are integrated with more conventional peptide, protein, and carbohydrate structure analysis techniques. For example, in the context of all structural information available for the protein, the molecular mass of the intact, modified protein determined by ESMS or MALDMS can be used to corroborate the overall sequence fidelity and to check for proteolytic processing of the protein, particularly at the C-terminus. Precise location and identification of modifications other than proteolytic processing usually requires a combination of LCMS, tandem MS, and Edman degradation. In our view, the potential for MS in the study of posttranslational modifications is virtually unlimited.

Glycosylation and phosphorylation are two of the most important modifications of proteins, and their characterization is a major emphasis in our laboratory. We have developed several approaches using LC-ESMS with CID for selective detection of glycosylated and phosphorylated peptides in complex mixtures. The most general of these approaches involves scanning or stepping of the collisional excitation potential prior to the mass analyzing quadrupole in order produce characteristic low-m/z marker ions. The orifice voltage, which controls the CID potential in the free-jet expansion region, needs to be adjusted so as to maximize within each spectrum the characteristic fragment-ion signals and to minimize parent-ion fragmentation. These contradictory requirements are met by scanning or stepping the orifice voltage during full-scan acquisition. In the positive-ion mode, collisionally-excited glycopeptides fragment to produce diagnostic sugar oxonium ions, particularly the $HexNAc^+$ and $Hex\text{-}HexNAc^+$ fragments at m/z 204 and 366, respectively. We have used this approach to locate glycopeptides and to characterize the molecular heterogeneity of the carbohydrates at specific attachment sites in numerous glycoproteins including fetuin, gp120 (the surface glycoprotein of the HIV-virus), sCD4 (the soluble receptor to which gp120 binds), sCR-1 (a soluble complement-binding molecule), and various monoclonal antibodies (1,2). A similar approach has now been developed for selective detection of phosphopeptides in complex mixtures (see Huddleston et al., this volume). Phosphopeptides containing the three principal types of phosphate-peptide linkages (i.e., phospho-Ser, -Thr, and -Tyr) yield phosphate-specific fragment ions at m/z 79 and 63 during negative-ion LC-ESMS analysis with stepped collision energy. Figure 1 illustrates the results for a complex mixture of 16 peptides, only three of which are phosphorylated (gray = TIC;

solid = m/z 79 + m/z 63). Once phosphopeptides have been identified, Edman degradation and tandem MS may be used to define the sequence and locate the specific phosphorylation site(s). An example of this is illustrated in Figure 2 for the phosphotyrosine-containing peptide identified by LC-ESMS in Figure 1 (peak 14). Collision energy scanning may find broader application in the identification of other common modifications such as isoprenyl-moieties on Cys and phospholipid membrane anchors on protein C-termini, and for unnatural modifications such as covalently-bound enzyme inhibitors and photoaffinity labels.

"Mass Spectrometric Based Strategies for the Structural Characterization of Recombinant Human IL-12"

S.A. Martin, W. Yu, J.E. Vath, B.S. Tangarone, A.S. Harris, E.B. Nickbarg and H.A. Scoble,
Genetics Institute Inc., One Burtt Road, Andover, MA 01810, USA

Interleukin-12 is a pleiotropic cytokine that was originally identified on the basis of its ability to stimulate natural killer cells to kill tumors *in vitro*. Recently, the genes for both the light and heavy subunits of human IL-12 have been cloned and sequenced. When expressed in Chinese hamster ovary cells, heterodimeric rhIL-12 has an apparent molecular mass of 75-80 kD based on SDS-PAGE. Upon reduction, the protein yields light and heavy subunits with apparent molecular masses of 35 and 40 kD, respectively. Recombinant IL-12 has a unique structure among cytokines in that the heavy subunit shows significant sequence homology with the extracellular domain of the IL-6 receptor while the light chain may display a distant relationship with IL-6. Based upon the cDNA sequence of the light and heavy subunits, the heterodimeric protein contains seventeen cysteines, seven consensus sites for N-linked glycosylation and numerous potential sites of O-linked glycosylation.

In this presentation we focused on contributions of mass spectrometric based strategies to the overall solution of the primary structure of this glycoprotein. This strategy utilizes MALD-TOF (a Bruker REFLEX consisting of both linear and reflector modes), FAB MS and MS/MS in addition to protease and glycosidase treatment and various modes of chromatography. The first step in this approach is the determination of the molecular mass by MALD-TOF MS of the intact dimer and the mixture of reduced light and heavy monomers prior to and after treating the molecule with a variety of specific proteases and glycosidases.

MALD-TOF MS is playing an increasing role in the identification and site-specific structural characterization of glycopeptides obtained from proteolytic digestion of recombinant proteins. One feature of this technique, which had not been previously reported, is illustrated with a comparison of the linear and reflected mass spectra of an O-linked glycopeptide from the light chain of rhIL-12 (Figure 1). In the linear mode, abundant ion signals are observed at *m/z* 4299.7 and 4950.1 which correspond in mass to the peptide sequence shown containing a HexNAcHex moiety and one and two neuraminic acid (NeuAc) residues, respectively. In the reflected mass spectrum of the same sample acquired immediately after the linear spectrum, no ion signal is observed corresponding to the bisialylated O-linked species at *m/z* 4590.1 and a weak multiplet of peaks is observed in the mass region corresponding to the monosialylated species (*m/z* 4299.7). The base peak in the reflected mode corresponds to the peptide sequence shown in Figure 1 with one unit each of HexNAc and Hex. The loss of the majority of the neuraminic acid residues in the reflected mode is characteristic of sialylated glycopeptides (both N- and O-linked) and suggest that the species observed in the linear mode are composed of primarily metastable ions. These observations, i.e., the shift down in mass in increments of 291 daltons in the reflected mode as compared to the masses observed in the linear mode, permit the identification of sialylated glycopeptides by a comparison of the linear and reflected mass spectra.

A feature of this reflector instrument is the ability to vary the reflector potential (from its full value to zero in a number of steps) in an effort to identify low energy fragment ions resulting from the metastable decomposition of the desorbed molecule. This is illustrated in Figure 2 which shows a reconstructed metastable reflected mass spectrum of a peptide from the heavy chain of rhIL-12 obtained by stepping the reflector potential from 500 volts to 30 kV. A complete series of b ions are observed as well as a number of a and y ions. In addition to these fragment ion series a number of internal peptide ions and immonium ions are also observed. This technique shows promise for sequencing bioploymers with much less material and under less stringent conditions than are currently possible.

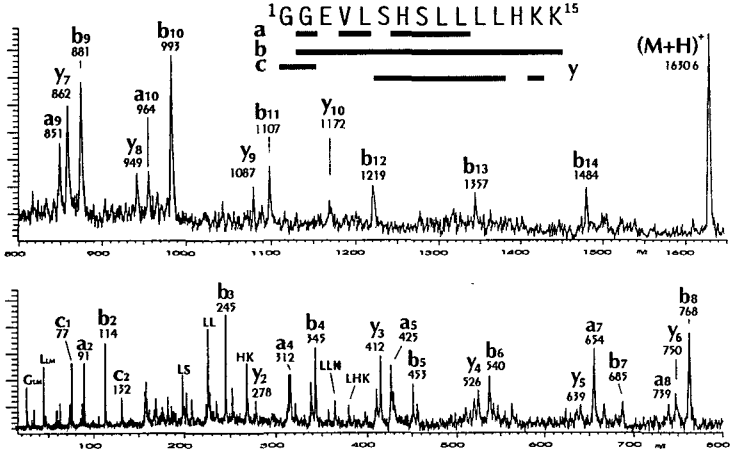
Peptide Sequencing by maLD-TOF Mass Spectrometry



COMBINATION OF MASS SPECTROMETRIC METHODOLOGIES FOR THE DETERMINATION OF PEPTIDE AND PROTEIN STRUCTURE

I.A. Papayannopoulos and K. Biemann, Department of Chemistry, Massachusetts Institute of Technology, Cambridge, MA 02139-4307

The availability of a variety of methods in generating and detecting ions from biological samples suggests a complimentarity of methodologies which can be applied to the determination of peptide and protein structure. Molecular weight data obtained from intact proteins, either by electrospray (ESI) or matrix-assisted laser desorption ionization (MALDI), offer an assessment of the homogeneity and purity of a protein sample. ESI in particular, carried out on a magnetic deflection mass spectrometer, can take advantage of the higher resolution available in sector instruments. The molecular weights of proteolytic peptides often suffice to identify post-translational or other modifications to proteins of known amino acid sequence. For proteins of unknown structure, tandem mass spectrometry of proteolytic peptides provides the sequence.

This is demonstrated first with the structure determination of the thioredoxin from *chloroflexus*. MALDI MS of the protein (Figure 1) attested to the success of its purification, but its ESI mass spectrum (Figure 2) indicated structure inhomogeneities.

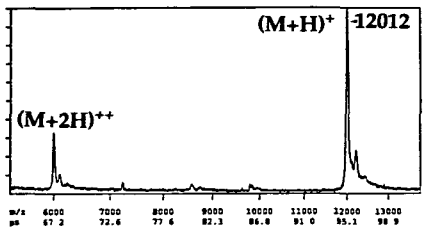


Figure 1. MALDI mass spectrum of *chloroflexus* thioredoxin.

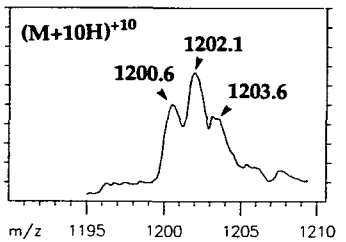

Figure 2. The +10 ion from the ESI spectrum of *chloroflexus* thioredoxin.

Proteolytic peptides, partially fractionated by reversed-phase high performance liquid chromatography, were analyzed by fast atom bombardment (FAB) mass spectrometry (MS). Thus the sequence inhomogeneities, inferred from the ESI mass spectra of the intact molecule, were assigned to positions in the amino acid sequence:

AKPIEVHDSDFNTVLLKSKTPVVVDFWAPWCGPCRVIAPI$^{L}_{N}$DKLTVGYAGRLTIAKV$^{NT}_{DV}$ 60

DDNVQYASQLGIKGLPTLVIFKDGREVGRLVGARPEAMYREIFDA$^{G}_{A}$VLAAM 110

In addition to the inhomogeneities indicated above, which are, presumably, a result of the presence of several gene products, the methionine residues in the protein were found to be partially oxidized; however, this may have been effected unwittingly during isolation and purification of the thioredoxin.

The inhomogeneity at position 41, involving substitution of leucine by asparagine,

was established by collision-induced dissociation (CID) of two protonated peptides (from a tryptic digest) differing by 1 u. One of the two CID mass spectra obtained appears in Figure 3, and the expanded regions of both spectra with sequence-significant ions in Figure 4. The interpretation of the spectra is somewhat complicated by the fact the ion of the ^{12}C isotope of the heavier peptide ($[M+H]^+$ m/z 869.5) also contains the ^{13}C isotope of the lighter one ($[M+H]^+$ m/z 868.5). Nevertheless, the unit mass resolution available on both MS-1 and MS-2 of the four sector tandem mass spectrometer, allows for unambiguous assignment of the fragment ions.

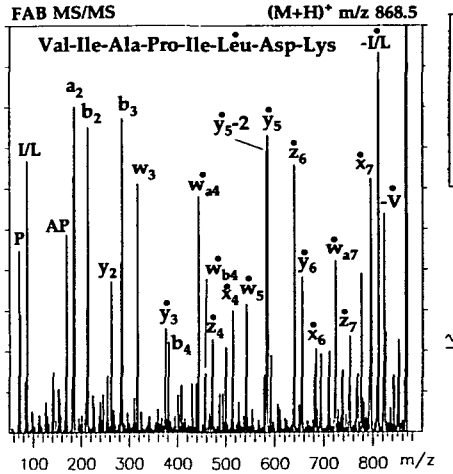

Figure 3. CID mass spectrum of $[M+H]^+$ m/z 868.5; fragment ions marked with a bullet (•) shift by 1 u higher in the CID mass spectrum of m/z 869.5.

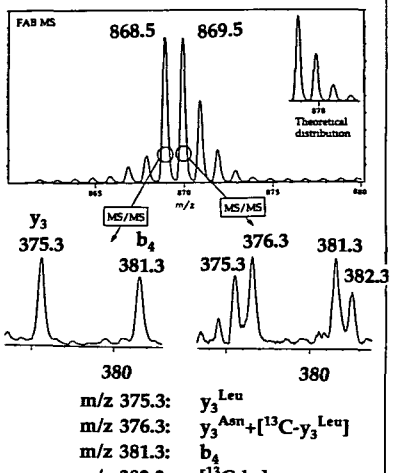

Figure 4. Expanded regions of CID mass spectra of m/z 868.5 and m/z 869.5.

Another modification to protein structure, investigated by MALDI MS, has been the insulin-sensitive phosphorylation of calmodulin in intact cells. Calmodulin was isolated from rat testes cells, half of which had been treated with insulin, and digested with endoproteinase Lys-C. Two peptides were found to have added one and two phosphates in the presence of insulin; calmodulin from insulin-free cells showed no evidence of phosphorylation. These peptides were assigned to the sequence with the aid of the computer program COMPOST, enabling the identification of the amino acids phosphorylated in the presence of insulin as Thr-79 and Ser-81.

Acknowledgements: The support of the MIT Mass Spectrometry Facility by the National Institutes of Health (Grant No. RR00317) is gratefully noted. The thioredoxin sample was provided by Dr. Bob Buchanan and Dr. Hyman Hartman (U.C. Berkeley); samples of calmodulin were provided by Dr. David Sacks (Brigham & Women's Hospital, Boston).

A Strategy for Mass Spectrometric Characterization of Nucleotide-Protein Complexes after UV-induced Crosslinking†

Ole N. Jensen, Department of Biochemistry & Biophysics, Oregon State University, Corvallis, OR 97331; ***Mark C. Young and Peter H. von Hippel***, Institute of Molecular Biology, University of Oregon, Eugene, OR 97403; ***Stephen Swenson and Steven E. Seifried***, Department of Biochemistry & Biophysics, University of Hawaii, Honolulu, HI 96822; ***Douglas F. Barofsky***, Department of Agricultural Chemistry, Oregon State University, Corvallis, OR 97331.

Protein-nucleic acid interactions are involved in important cellular processes such as DNA replication, recombination and repair, RNA transcription and processing, protein synthesis, and regulation of enzyme activities. We present here a novel approach for characterizing the structural details of protein-nucleic acid interactions or, more specifically, for identifying protein domains and amino acid residues in close contact with nucleic acids. The strategy is based on using UV-crosslinking and photoaffinity-labeling techniques to 'trap' a given protein-nucleic acid complex by introduction of a covalent bond between the two molecules and on subsequent mass spectrometric analysis of the newly formed, covalently modified protein.

To demonstrate that this approach is feasible, we have analyzed two systems of UV-crosslinked protein-nucleic acid complexes by MALDI TOF MS.

Experimental: UV-laser crosslinking of gp32 to $(dT)_{20}$ was performed as described previously [Hockensmith *et al.*, *Meth. Enzym.* **208**, 1991] using 10 μL samples containing gp32 (22 μM) and $(dT)_{20}$ (10 μM). Crosslinking yields (4-7% of total protein) were determined by SDS-PAGE and radiodetection of [^{32}P]-labeled $(dT)_{20}$ crosslinked to gp32 Photoaffinity-labeling of rho was accomplished by incubating rho (5 μM) with the ATP-analogue 4sUDP (50 μM) [Favre, in *Bioorganic Photochemistry* (Ed. Morrison), 1989] under 335 nm UV light for 60 min. An ATPase inactivation assay was used to determine the crosslinking yield ($\sim$100%).

MALDI MS experiments (355 nm) were performed using a custom built TOF instrument (60 cm flight tube) equipped with a Nd:YAG laser (Spectra-Physics GCR 11). An ion guide wire potential of -300 V was used to improve ion transmission.

Results: Protein/nucleic acid mixtures exposed to UV-light were analyzed by MALDI TOF MS without prior purification. We have obtained molecular weight information for i) the phage T4 single stranded DNA-binding protein (gp32) crosslinked to the oligonucleotide $(dT)_{20}$ by a single 266 nm laser pulse (figure 1, table 1), and ii) the *E. coli* transcription termination factor rho photoaffinity-labeled with 4-thio-uridine-diphosphate (4sUDP) by exposure to 335 nm light (table 1). The analyses were performed using 1-5 picomoles of protein. The crosslinked gp32:$(dT)_{20}$ complex, consisting of only 5-7% of total protein present in the sample, was detected by MALDI MS after optimizing the matrix-solvent combination used in sample preparation.

Conclusion: Molecular weight determination of intact, covalent protein-nucleic acid complexes by MALDI MS can identify low levels (0.5-2 μM) of crosslinked species present in protein/nucleic acid mixtures as demonstrated with the gp32:$(dT)_{20}$ complex. The choice of solvent system appears to be as important as the choice of matrix compound for MALDI MS analysis of the covalent protein-nucleic acid complexes.

Given our results, it seems feasible to apply strategies used for mass spectrometric characterization of post-translationally modified proteins (MALDI MS peptide mapping, LC-electrospray MS and MS/MS for peptide identification) to the detailed characterization of UV-crosslinked protein-nucleic acid complexes and peptide-nucleic acid complexes in order to identify nucleic acid binding domains of proteins. Structural data obtained this way should be an aid to elucidating the molecular mechanisms involved in protein-nucleic acid interactions.

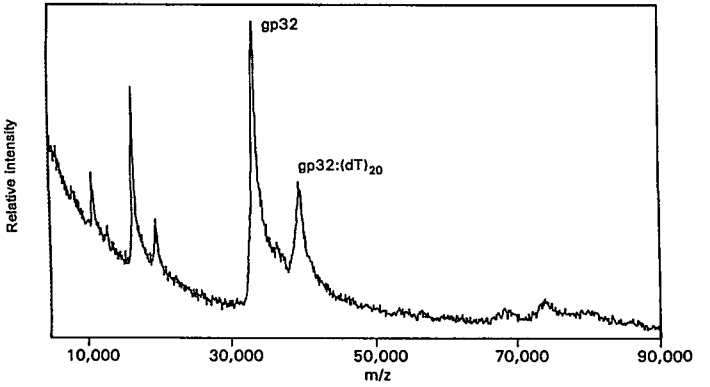

Figure 1. MALDI TOF mass spectrum of a gp32/$(dT)_{20}$ sample exposed to a single 266 nm laser pulse. Matrix: sinapinic acid (10 g/L) in formic acid/acetonitrile/glycerol (66:33:1). The sample was deposited on the probe, allowed to crystallize, and then washed in cold (4°C) water. The crosslinked gp32:$(dT)_{20}$ complex is detected along with non-crosslinked gp32.

Table 1. Molecular weight determinations of nucleic acid binding proteins and UV-crosslinked protein-nucleic acid complexes by MALDI TOF mass spectrometry.

Analyte	MW Measured (Average ± std. error)	MW Calculated
gp32	33,508 ± 3	33,502
gp32:$(dT)_{20}$	39,637 ± 69	39,603[a]
rho	47,004 ± 4	47,003
rho:4sUDP	47,560 ± 37	47,422[b]

[a]Assuming a zero-length photochemical bond. The molecular weight of $(dT)_{20}$ is 6,102.
[b]Assuming a zero-length photochemical bond. The molecular weight of 4sUDP is 420.

The newly developed technique of electrospray (ESI) MS represents an important advancement in MS technology which significantly extends the range of MS applications to the field of biomedical research.The unique feature which sets ESI apart from the rest of the available MS techniques is that ESI utilizes highly charged liquid droplets as the ion evaporation medium allowing the sample being analyzed to remain in its solution form prior to MS analysis [1]. We have been studying the noncovalent interaction of human *ras* protein with its guest ligands GDP and GTP, and the successful ESI MS detection of the *ras*-GDP noncovalent complex has recently been reported [2]. An extention of this research is the feasibility study of using ESI MS for probing the noncovalent interaction between protein molecules. We used Interferon (IFN-γ) as the protein-protein interaction model for this purpose. Mature IFN-γ is a protein of 143 amino acids with an excess of basic amino acid residues. The active form of this protein is a homodimer and is also known to be both heat and acid labile [3]. Here, we describe the use of ESI for the detection of the biologically active IFN-γ dimer. The effect of the orifice potential on the detection of this protein dimer and its charge state distribution is also discussed. This effect is further extended to study the *ras*-GDP complex.

Results and Discussion

Our earlier attempts to analyze the IFN-γ dimer under the typical ESI condition (i.e., 50% MeOH, 0.1% TFA, pH ~2.5) resulted in the detection of mass spectrum with a well-defined "bell-shape" multiply-charged ion distribution (+8 charges to +22 charges, data not shown) whose molecular weight corresponded to the monomeric IFN-γ. However, we have recently discovered that the IFN-γ noncovalent dimer can be detected by ESI MS with the use of an alkaline solution.

Since the protein has a pI of higher than 9, the protein was, therefore, prepared in aqueous solution of pH ~9 (adjusted with 30% NH_4OH). Under this condition, the dimeric form of IFN-γ (observed MW 33,819 Da) was preserved and successfully detected (**Figure 1**). The key to determining the presence of a protein homo-dimer is that one should look for the signals corresponding to their multiply protonated *odd* charge states [4]. For easy comparison, the *odd* charged ions are denoted by an asterisk.

It has been shown, with horse heart cytochrome *c*, that random protein aggregation can occur due to high protein concentration [5]. In order to rule out the potential of forming a protein dimer via the *concentration effect*, the MS detection of the protein dimer was further investigated. First, horse heart cytochrome *c* was analyzed at high concentration (40 mM) by ESI MS. The observed signals (**Figure 2A**) at m/z 2061, 1766, 1546, and 1374 correspond to the +6 to +9 charge states, respectively, of the monomeric cytochrome *c*. Signals corresponding to the *odd* charges (+11 and +13) of cytochrome *c* dimer were also observed at m/z 2248 and 1902, respectively. When the protein concentration was diluted to 70 μM, no signals corresponding to the *odd* charges of cytochrome *c* dimer were detected (**Figure 2B**). Next, an equal molar mixture of IFN-γ dimer and cytochrome *c* (each at a final concentration of 35 μM) was prepared, and the mass spectrum was recorded (**Figure 2C**). In addition to IFN-γ dimer, signals corresponding to the +6 to +9 charge states of cytochrome *c* were detected. No signals of the cytochrome *c* dimer were observed. Signals corresponding to the random attachment between IFN-γ and cytochrome *c* were also absent. This result confirmed that the IFN-γ dimer detected by MS under these experimental conditions was the specific noncovalent IFN-γ dimer, and was not the result of the random dimerization due to the *concentration effect*.

Mass spectra of the IFN-γ dimer (pH ~9) were also recorded at **OR** settings from 40 to 200 volts. The percentage of the dimeric form was calculated from the change in intensity of signal corresponding to the *odd* charge states of the dimer. This ratio of ion intensity was then normalized against the value obtained at **OR**=50 volts. The percentage of IFN-γ in the dimer form thus obtained is not an ***absolute*** value; rather, it should be treated as a *relative* measurement of preservation of the protein dimer upon change in the **OR** setting. **Figure 3** shows the percentage of IFN-γ dimer observed against experimental **OR** setting. Dissociation of the IFN–γ noncovalent dimer was triggered by an **OR** setting as low as 60 volts. These results imply that dissociation of the gas phase IFN-γ dimer requires very little energy. A similar experiment was conducted for *ras*-GDP complex at different **OR** setting. The energy required to dissociate *ras*-GDP complex is relatively higher (~ 120 volts) than that applied for IFN–γ dimer.

Conclusion

The noncovalent complexes of IFN–γ dimer and *ras*-GDP have been successfully detected by ESI MS. Dissociation of the gas phase noncovalent complexes can be induced by increasing the **OR** voltage. In the two noncovalent complexes studied, the gas phase *ras*-GDP complex required a substantial amount of energy to initiate the dissociation process while the IFN–γ dimer started to dissociate immediately following the **OR** increase. It has been suggested that covalent and noncovalent complexes observed under electrospray ionization can be easily differentiated by raising the **OR**. Our study of the noncovalent complexes of *ras*-GDP and IFN–γ dimer, however, underscores the importance of careful use of this approach. The ESI MS technique could be extended further to study the complexes between proteins and other compounds of pharmaceutical interest. The extension of this research in probing the various kinetics of enzyme-substrate interactions is the subject of current research in our laboratory.

Identification of Proteins in One- and Two-Dimensional Gels by Mass spectrometric Peptide Mapping

*E. Mørtz, H. H. Rasmussen+, O. Vorm, M. Mann++, P. Højrup and P. Roepstorff.
Department if Molecular Biology, Odense University, 5230 Odense M, Denmark. +Institute of Medical Biochemistry, Ole Worms Allé 170, 8000 Aarhus C, Denmark. ++EMBL, Meyerhofstr.1, 6900 Heidelberg, Germany.

One- and two-dimensional polyacrylamide gel electrophoresis (PAGE) is well established for analytical separation and characterization of complex protein mixtures and is due to its high resolution and reproducibility frequently used for protein identification. Proteins in gels can be identified from their position in the gel, frequently supplemented by partial sequencing. However, in spite of the high resolution a given protein spot may contain several proteins or the proteins are positioned so close in the gel that identification may be ambiguous. To get a fast and reliable identification we have investigated the combination of protein separation by PAGE and identification based on mass spectrometry.

Proteins were separated by 1- or 2-D SDS PAGE. Stained proteins from 2-D gels were cut from several gels and recovered by elution-concentration gel electrophoresis. Proteins were then electroblotted onto polyvinylidene difluoride (PVDF) membranes and visualized by staining. The proteins were either extracted from the membrane with 40% acetonitrile, 10mM octylglucoside and analyzed by MALDI MS, or digested on the membrane with specific endoproteases and the peptides extracted with 5-50% TFA. Mass spectrometric peptide maps were established either by direct analysis of the peptide mixture by MALDI or after peptide separation by reverse phase HPLC followed by PDMS of the fractions. The proteins were identified from their peptide maps using a previously described program[1] that allows identification of proteins by comparing the experimental peptide maps with those generated from protein and DNA sequence databases.

To investigate the applicability of the method we used 6 for us unknown human proteins separated by 2-D SDS PAGE. Proteins No. 1-5 (table 1) were digested with trypsin on PVDF membranes, the peptides separated by HPLC and analyzed by PDMS. The MS peptide maps were used for searches in the transformed database (Protein Identification Resource, PIR) and the proteins identified (table 1 and 2). For protein No. 6, 0.2% of the extracted peptide mixture was analyzed by MALDI, but the peptide map did not resonably match that of any protein in the database and was recorded as unknown. At this point the identification of the first 5 proteins was confirmed by correlation with The Human Keratinocyte 2-D Gel Protein Database and the 6th protein found not to be recorded in the PIR database. A simulated search based on its sequence showed that if the protein had been present in the database it would have been identified. To further investigate direct mapping by MALDI two known proteins (No. 7 and 8) were blotted from gels, digested, mapped (figure 1) and identified.

Table 1. Proteins identified by mass spectrometric peptide mapping.

Sample	Peptide map	Protein identified	MW Da.
1	HPLC + PD	Heterogeneous ribonuclear particle	60176
2	HPLC + PD	Ubiquitin	8450
3	HPLC + PD	Heat shock 27kD protein	22325
4	HPLC + PD	variant	22325
5	HPLC + PD	variant	22325
6	MALDI	Unknown	(27772)
7	MALDI	β-lactoglobulin A	18362
8	MALDI	Carbonic Anhydrase	28980

The specificity of a search by MS peptide maps can be considerably improved if the search is performed within a narrow mass range defined by the approximate molecular weight of the protein. We therefore investigated the possibility to determine the molecular weight of the proteins from gels. 9 proteins were separated by 1-D SDS PAGE, blotted to PVDF membranes, extracted and their molecular weight determined by MALDI MS (figure 2). The mass precision and resolution obtained by MALDI of proteins extracted from gel is not as good as for pure proteins, but by far sufficient for the desired task.

Table 2. Search based on 18 peptides from protein No 1.

Rank	Peptide match	PIR number	MW Da.	Protein
1	11	21725	60176.98	Heterogeneous particle protein L - Human
2	9	13202	89988.17	Topoisomerase 1 - Yeast
3	9	14263	46456.62	Troponin T, skeletal muscle - Fruit fly

Surface Induced Dissociation of Peptides in a Four Sector Mass Spectrometer

Kevin L. Schey and Kelly R. Thornburg
Department of Pharmacology, 171 Ashley Ave
Medical University of South Carolina, Charleston, SC 29425

A novel in-line surface induced dissociation (SID) device has been constructed for a JEOL HX110/HX110 tandem mass spectrometer in efforts to dissociate larger peptides with greater efficiency than can be accomplished with conventional high energy CAD. The device geometry is shown in Figure 1 and includes an isolated tail electrode to assist in the extraction of product ions from the target surface. The electrodes were made from brass and inserted into a grooved Kel-F plate which mounts on a Kel-F base machined to the dimensions of the commercial collision cell base.

Initial characterization of the in-line SID device involved the measurement of internal energy distributions with the thermometer molecules tetraethylsilane and tungsten hexacarbonyl. Internal energy distributions similar to those measured using previously reported SID geometries were observed. Average internal energies of over 15 eV were deposited in 400 eV collisions. The resolution of MS-2 allowed the observation of both the sputtered $C_2H_5^+$ ion and the product ion SiH^+ in 500 eV collisions of tetraethylsilane. In addition, proton abstraction by $W(CO)_6^{+\cdot}$ molecular ions was observed as evidenced by the protonated product ions WH^+, $WCOH^+$, and $W(CO)_2H^+$.

Peptide molecular ions were generated by LSIMS of typically 1-3 nmoles of material placed in glycerol or glycerol/NBA matrices. The entire sequence of petaalanine and leucine enkephalin were obtained as a_n, b_n, and y_n ions at collision energies of 80 eV. In addition, in 100 eV collisions of pentaalanine, the high energy a_2-16 ion at m/z 99 was generated. The ratio of b_3 to y_2 ions from leucine enkephalin, an indicator of internal energy deposition, increases to 2:1 at 60 eV collisions.

The 130 eV SID spectrum of renin substrate, m/z 1758.9, is shown in Figure 2 where nearly the entire sequence is observed as a_n ions. Furthermore, high energy d_3 and d_{11} ions are also observed. A high energy d_3 ion is observed in 80 eV SID spectrum of substance P. The largest peptide dissociated with this device was melittin, m/z 2846, as shown in Figure 3 for 200 eV collisions. Prominent b_n ions are generated as well as a series of immonium ions in the low mass range for this large peptide.

The dissociation efficiency measured for leucine enkephalin in 80 eV ion/surface collisions was 7.2% with a brass target. Detection limits for peptide dissociation approach 100 pmol. for renin substrate in 200 eV collisions although limited sequence information is available at this high collision energy.

In conclusion, this in-line device has produced promising results on a variety of standard peptides. Peptide sequence information is typically in the form of a_n, b_n, and y_n ions with several high energy d_n ions also being generated. Future studies on the device geometry and, in particular, using modified surfaces should provide higher dissociation efficiencies as well as the ability to dissociate larger peptides.

Determination of Posttranscriptional Modification in Ribosomal RNA by Mass Spectrometry

Jeffrey A. Kowalak and James A. McCloskey
Departments of Biochemistry and Medicinal Chemistry
University of Utah, Salt Lake City, Utah 84112

Posttranscriptional modification of nucleosides plays an important, yet incompletely defined role in the structure and function of large ribosomal RNAs. The most compelling evidence for the functional importance of modified nucleosides is the clustering of these residues at the functional center of the ribosome as defined by chemical footprinting and photoreactive cross-linking studies (1).

Experimental approaches have been developed for the structural characterization and the determination of sequence location of modified nucleosides in ribosomal RNAs, based principally on electrospray mass spectrometry (2). Oligonucleotide fragments produced by site specific ribonuclease digestion of RNA are analyzed by ES-MS with sufficient accuracy such that the base composition can be ascertained solely from the measurement of molecular mass (3).

The method has been applied to *E. coli* 16S rRNA (1542 nucleotides, M_r 499,759) in which six different modified nucleosides are located at 10 sequence positions. The chemical identity of these modified residues was confirmed by directly combined HPLC-mass spectrometry (LC-MS) of an enzymatic hydrolysate of the intact rRNA molecule. The rRNA was then digested using RNase T_1, an endoribonuclease which cleaves at Gp↓N sites, and the resultant oligonucleotide mixture fractionated by DEAE anion exchange chromatography. An aliquot of each DEAE pool was then analyzed by LC-MS to determine in which pools the modification-containing oligonucleotides reside Electrospray mass spectrometry (ES-MS) was used to determine the molecular weight of the oligonucleotides in modification-containing DEAE pools. Experimentally determined oligonucleotide mass values, used in conjunction with LC-MS and gene sequence data, were used for characterization and sequence placement of modified residues.

This approach was successfully employed to characterize modification-containing oligonucleotides, of chain length ≥ 4 residues, in *E. coli* 16S rRNA (Table 1).

Table 1. Compositions of Modification-containing Oligonucleotides from RNase T_1 Digestion of *E. coli* 16S rRNA Determined by Electrospray MS.

Modified Nucleoside	M_r Meas.	Oligonucleotide Composition	M_r Calc.	Sequence Position
m^4Cm	1306.35	$C_3Gp+2CH_2$	1306.83	$m^4Cm_{1402}CCG$
m^5C	1646.10	$C_2A_2Gp+CH_2$	1646.04	$m^5C_{967}AACG$
m^6_2A	1994.28	$C_2UA_2Gp+4CH_2$	1994.29	$m^6_2A_{1518}m^6_2A_{1519}CCUG$
m^3U	2305.80	CUA_4Gp+CH_2	2305.44	$m^3U_{1498}AACAAG$
m^5C	3198.30	$C_4U_2A_3Gp+CH_2$	3197.95	$Um^5C_{1407}ACACCAUG$

In the first application of this methodology, the chemical identity and sequence location of the modified nucleoside N^4-acetyl-2′-*O*-methylcytidine (ac^4Cm) were determined in 5S rRNA from a hyperthermophilic archaeon, *Pyrodictium occultum* (4). While ribosomal RNAs have been used for the development and initial applications of the method, the basic principles are generally applicable to characterize covalent structural modifications in any RNA. For example, the chemical identification and sequence position of 2-thiothymine riboside (s^2T) has been determined in unfractionated tRNA from *Pyrococcus furiosus*.

Transfer RNA was isolated from *P. furiosus* cells which were grown at 100°C. LC-MS analysis of an enzymatic hydrolysate of unfractionated tRNA revealed the presence of s^2T, which represents the first occurrence of this modified ribonucleoside in the Archaea. The related nucleoside, thymine riboside, is ubiquitous in bacterial tRNA and is known to occur only at position 54, the first position of the TΨC loop .

Unfractionated tRNA (>50 species) from *P. furiosus* 100°C culture was digested with RNase T_1 and the resultant oligonucleotide mixture was fractionated by DEAE anion exchange chromatography. The molecular weight of one oligonucleotide was determined to be 1324.7 by ES-MS, for which no allowable composition exists. Only after replacement of a sulfur atom for and oxygen atom (Δm 16.02), was a single allowable composition found; $CU_2Gp + 2\ CH_2 - O + S$ (M_r 1324.9 calc.). The oligonucleotide was then completely hydrolyzed and analyzed by LC/MS. The chromatogram presented in Figure 1 indicates that the nucleoside components of the oligonucleotide are Ψ, Cm, G and s^2T. 2′-*O*-methylcytidine is universally conserved at position 56 in Archaeal tRNA, therefore, we conclude that the sequence of the oligonucleotide is 54-s^2TΨCmG-57.

The Hows and Whys of Multiply-charged Oligonucleotide Decompositions

Sohrab Habibi-Goudarzi and Scott A. McLuckey
Analytical Chemistry Division, Oak Ridge National Laboratory
Oak Ridge, TN 37831-6365

Multiply-charged gaseous biopolymers, which can be formed by electrospray ionization, constitute new and unusual species. They are unusual in that the unimolecular and bimolecular chemistry of these ions can be highly influenced by the coulombic repulsion arising from the presence of multiple charge sites. This paper emphasizes the unimolecular behavior of multiply-charged single-stranded deoxy oligonucleotides. The objective of this research is to develop an understanding of the influence of charge and sequence on the fragmentation of an oligonucleotide.

Previous work in our laboratory demonstrated that multiply-charged adenosine-containing oligomers tend to lose charged adenine as the lowest energy decomposition followed by cleavage at the 3' C-O bond of the sugar from which the adenine had been lost [1]. Subsequent studies have shown that in general base loss occurs first followed by cleavage at the sugar. Such a sequence can be rationalized by two successive 1,2-elimination reactions to yield a furan attached to the rest of the chain at the 3'-carbon (see Scheme). Two scenarios are depicted in the scheme. In one scenario, proton transfer from a base to a charged phosphodiester linkage precedes base loss. In the other, no proton transfer occurs prior to base loss. Which scenario prevails determines whether or not the base is lost as a neutral or as an ion. Singly-charged mononucleotides tend to lose the base as a neutral under quadrupole ion trap collisional activation conditions. Adenosine monophosphate shows a small signal due to lose of charged adenine. We propose that the coulombic field associated with a multiply charged oligonucleotide can promote intramolecular proton transfer to one or more of the nucleobases depending upon the strength of the electric field. The relief of coulombic repulsion must be sufficient overcome the intrinsic difference in the gas-phase acidities of the nucleobase and the phosphodiester group. Apparently, adenine is the strongest acid of the base substituents followed by thymine. The loss of charged adenine is therefore preferred, followed by loss of charged thymine, because charge is most likely to be transferred to those bases to relieve coulombic strain. The relief in coulombic repulsion provided by loss of a charged base relative to the loss of a neutral base presumably facilitates the loss of charged bases.

As the coulombic field decreases, the likelihood for charge to reside on one of the nucleobases also decreases. For this reason, the appearance of MS/MS spectra can change dramatically with charge state. Figure 1 compares the MS/MS spectra of the triply- and doubly-charged forms of 5'-d(AAAA)-3'. Virtually 100% of the fragmentation of the triply-charged ion proceeds via loss of charged adenine whereas roughly 75% of the fragmentation of the doubly-charged ion fragments through loss of neutral adenine. Similar structural information is present in both spectra despite their remarkably different appearance. This is a common observation in comparing MS/MS spectra of various charge states of the same parent oligonucleotide. This behavior can be understood, at least qualitatively, by the occurrence or non-occurrence of intramolecular proton transfer followed by the reactions depicted in Scheme 1. Further support for these conclusions have been summarized [2].

ELECTROSPRAY IONIZATION OF PLASMID DNA AND DETECTION BY MASS SPECTROMETRY. *Charles G. Edmonds[a,b], David L. Springer[b], Brent J. Morris[c], Brian D. Thrall[b] and David G. Camp II[c], (a) Chemical Sciences Departments, (b) Biology and Chemistry, Pacific Northwest Laboratory, Richland WA 99352, and (c) Eastern Oregon State College, Badgley Hall, La Grande OR 97850

We are interested in exploring the limits of electrospray ionization (ESI) for biopolymers. Fenn and co-workers have published examples of the electrospray ionization-mass spectrometry (ESI-MS) of synthetic polymers up to 5 megadaltons in average molecular weight (T. Nohmi and J.B. Fenn, *J. Am. Chem. Soc. 114* **1992** 3242-3246). Ou objective has been to investigate the potential utility of ESI as the basis of a mass spectrometric approach to high speed DNA sequencing. We have successfully employed negative ion ESI-MS to ionize and detect pGem-5S, a 3126 base pair supercoiled closed circular double-stranded plasmid which includes the 5S ribosomal RNA gene from *Xenopus borealis* (Mr 1,945,664 for the free acid). We chose a plasmid for these studies because of the unique topomeric characteristics of these materials which facilitate the purification and provide highly specific characterization of the material on the basis of sedimentation velocity and electrophoretic mobility. DNA samples were purified to eliminate contamination by lower mass DNA, ribonucleic acid and salts. The plasmid was cultured in transformed *E. coli* JM109 and following alkaline lysis the supercoiled DNA was separated by CsCl density gradient centrifugation. Successive 100% ethanol precipitation from ammonium acetate solution was followed by ultrafiltration with Centricon-100 (Amicon, Danvers MA) (100,000 MWCO). Preparations consisted principally of the supercoiled species with small contributions by nicked circular and linearized plasmid. Following final lyophilization plasmid samples were dissolved in deionized water and subjected to ESI-MS using a TAGA 6000E tandem quadruple instrument with a differentially pumped atmosphere/vacuum interface with mild interface conditions. Electrospray ionization of the plasmid DNA sample as illustrated in Figure 1 afforded a single broad envelope of ionized species extending between *m/z* 500 and *m/z* 1400. Maximum relative abundance was found at approximately *m/z* 700. This observation was consistent with the production of gas phase multiply charged molecular anions of more than a megadalton in mass given the low resolving power of the quadrupole mass spectrometer. We further characterized the behavior of the plasmid under ESI conditions by electrospraying the nucleic acid onto targets of stainless steel foil or TRIS-EDTA-Borate buffer droplets stabilized by 1% agarose gel. After electrospray onto these targets, the plasmid was extracted with TEB buffer and examined by 1% agarose gel electrophoresis. The results of this experiment is illustrated in Figure 2. When electrosprayed onto a dry stainless steel target the plasmid was substantially altered with the production of a wide range materials of both higher and lower electrophoretic mobility. However, when the plasmid was prepared onto a liquid buffer surface the plasmid remained substantially intact with the closed circular form of the nucleic acid was opened to the nicked circular. No degradation to material of lower mass was observed. This result substantiates our interpretation of the mass spectrum of pGEM-5S as that of intact nucleic acid of more than 1 megadalton in mass.

L. Omar Henderson, Larry L. Needham, Gerald R. Cooper
Centers for Disease Control, Atlanta, GA 30333

Atherosclerosis is the leading cause of morbidity and mortality in the U.S. Major risk factors for atherosclerosis include increased serum cholesterol levels and abnormal distributions of lipoproteins carrying serum lipids. These lipoproteins are composed of both lipid and protein components. As opposed to the variable amounts of lipid material in lipoproteins, the protein structural components remain constant. Recently there has been great interest in measurement of the protein components, called apolipoproteins (apos), as a measure of atherosclerosis risk. One factor which helps to reduce the risk of atherosclerosis is the "good" cholesterol containing lipoprotein HDL. The major protein component of HDL is Apo A-1. Measurement of Apo A-1 has been exclusively done by immunoassay. There is great variation in the clinical measurement of Apo A-1 because of standardization aspects of the assays, primarily the lack of primary reference standard Apo A-I with assigned protein mass values.

We have recently employed isotope dilution high resolution mass spectrometry to assign mass values on an Apo A-1 primary reference standard. The approach utilized enzymatic digestion of Apo A-1 and quantification of three of the resulting peptides with isotopically labeled peptides with the same sequences (Figure 1). The initial portion of this study was to verify the expected molecular weight of Apo A-1 in the reference standard by electrospray ionization MS (Figure 2) and to confirm the sequence via peptide mapping (98% coverage). Enzymatic digestion conditions which yielded reproducible quantitative cleavage at several sites were then determined and three peptides that were found to be reliably formed were chosen for quantification standards. Native and labeled (which range from six to nine mass units higher than native standards) were then synthesized, purified and quantified. The peptide quantification was performed by a combination of amino acid analysis and nitrogen analysis. Peptide purity was determined by a combination of HPLC and CE. The quantification of the standard reference material was then performed by the addition of a known amount of two of the labeled peptides to the Apo A-1 standard, dividing each standard vial into four equal portions, followed by enzymatic digestion of each aliquot. The resulting mixtures were then purified by HPLC and fractions which contain the newly formed native and the labeled peptides were subjected to four replicate FAB MS runs. The third labeled peptide was then utilized as a recovery standard. These results were then quantified against standard curves prepared from synthetic native and labeled peptides. Using this approach, the mean from each standard vial was found to be 1.050 mg Apo A-1. The analytical CV was 3.96% (see Figure 3 for variance component percent of total) and the 99% confidence limits was found to be 1.050 ± 0.010 mg or 1.050 mg ± 1%.

Detailed Structural Characterization of Carbohydrate and Glycoconjugate Oligomers Using Selective Chemical Modification, HPLC-ES-MS-CID-MS.

Vernon N. Reinhold, Bruce B. Reinhold, Stephen Chan
Departments of Nutrition and Biological Chemistry, Harvard University
Schools of Public Health and Medicine. 665 Huntington Avenue, Boston, MA 02115

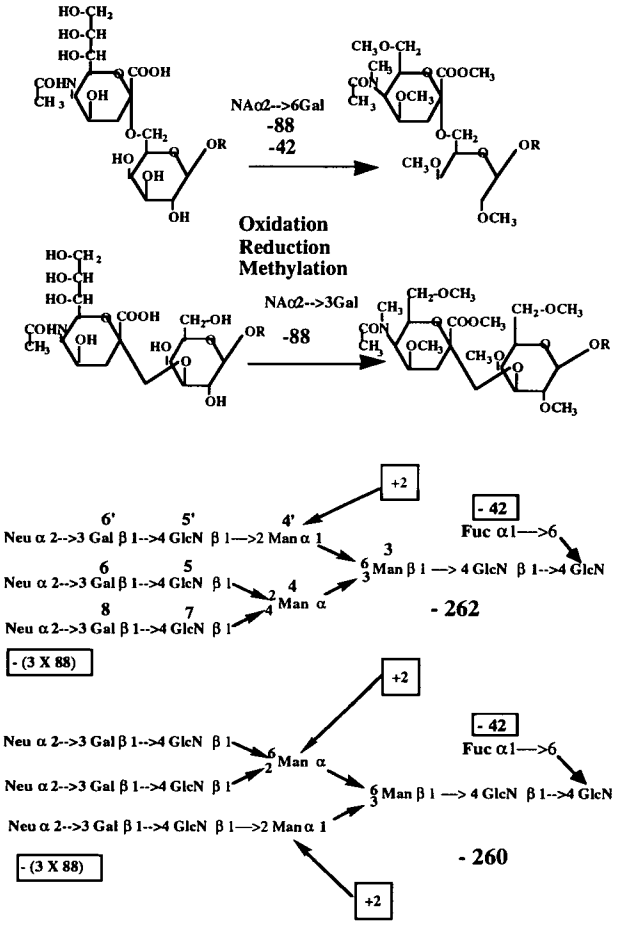
The functional roles being unraveled in the study of cell-cell interactions point frequently to carbohydrate residues on their surfaces. In part, N-, and O-linked glycans have been shown to influence protein folding during biosynthesis, have a directing control during intra-, intercellular trafficking, stabilize a proteins conformation to the extremes of pH and temperature, protect against proteolysis, provide an effective foil against immune surveillance, and serve as components in signal transduction. As numerous and compelling as these problems are, the analytical effort required to fully understand carbohydrate structural detail can be overwhelming.

The structural characterization of glycoprotein glycans can be considered to fall into three categories: a determination of glycotype, glycoform, and glycomer. A comparative profile of glycoprotein heterogeneity (glycoform distribution) is one of the most critical pieces of analytical information, although appropriate techniques for its measurement have eluded carbohydrate analysts for years. The glycoform distribution mirrors four fundamental characteristics; (i) the complement of glycosyl transferases expressed during glycoprotein biosynthesis; (ii) the *in vivo* physiological milieu of the Golgi; and, (iii) the time frame of elaboration, and (iv) the tissue origin (organelle, intra- or extracellular). Although direct structural differences are noted, the physiological significance is little understood. Production and marketing of recombinant glycoprotein pharmaceuticals have reinforced the need for reliable procedure(s) of product comparison. Chromatographic, chemical and enzymatic techniques all pose the possibility of enriching or excluding particular subforms, thus, given the choice of current analytical techniques, physical methods would be favored over biological measurements for determining a glycoform distribution. Mass measurement of a glycopeptide isolated by reverse phase HPLC may provide the most complete measure of glycan heterogenity since separations are dependent on peptide properties and not influenced by the glycan. Linkage and branching features are hidden as mass isobars and for these features further effort must be invested.

To approach isomeric glycans on N-linked glycoproteins, and glycosphingolipids, and induce molecular specificity we have combined pre-analysis chemistry and chromatography with ES-MS and CID. The altered molecular weights imparted to isobaric structures yield, in some cases, a precise fingerprint of the reacting glycoform without resorting to the classical sample consuming procedures of linkage analyses. As a complement to this improved specificity, the chemically modified glycans are very lipophilic following derivatization, and hence, easily cleaned up by extraction. Electrospray ionization provides multiple charging for lower effective mass measurement, improved signal-to-noise ratios for greater signal amplification and analyte detection, and with the permethylated glycans, a higher efficiency of ionization. The strategies we have found most informative define unique CID fragments from permethylated glycans when infused with alkali metal ions for electrospray ionization by adduction. For determining structural detail, samples prepared in this way are pertinent for several reasons: (i) enhanced ionization efficiency and singularity in adduction type; (ii) mass shifts associated with each glycosidic cleavage to provide a measure of cleavage multiplicity; (iii) adequate detection of cross-ring cleavages that relate to linkage; (iv) the ease of product clean-up by solvent extraction; and (v) consistent with periodate chemistry to enhance molecular specificity.

The location of polylactosamine and N-acetylneuraminic acid residues are positional isomers that are transparent to mass profiling and periodate oxidation, reduction and methylation offers a chemically selective strategy to differentiate linkage and branching patterns, especially when those details are lost among isomeric mixtures. As an example, the linkage isomers of N-acetylneuraminic acid frequently occur as either an a(2—>6) or a(2—>3) to a penultimate galactose, a linkage resolvable by oxidation, reduction and methylation chemistry. Also, the positional isomers of lactosylamine residue (at the 4 or 4' mannose) in triantennary structures yield unique products by oxidation, reduction and methylation chemistry. With these structural entities, each N-

acetylneuraminic acid residue will decrease the glycan mass by 88 amu, and the 4' mannosyl moiety will increment by 2 amu, (4 amu if a 4'-linked triantenna). Furthermore, a terminal fucosyl group will cause a decrease in mass by 42 amu (adjacent glycols), as will all terminal galactosyl residues. Not only does the new pattern of ions unravel difficult isomeric problems, it also provides a reexamination of all structures previously profiled following methylation.



MS/MS of Cobalt-coordinated Branched Pentasaccharide Isomers: Linkage Position Determination using Electrospray Ionization

Julie Leary* and Aberra Fura, University of California, Dept of Chemistry, Berkeley, CA 94720

Our previous research has demonstrated that MS/MS of lithium coordinated oligosaccharides can be used to determine the linkage position in linear glucose polymers (1,2). Extensions of this methodology have also shown that ESI tandem mass spectrometry can be used to distinguish linkages in calcium and magnesium coordinated branched trisaccharides(3). The work described herein is the next step in this characterization process which involves ESI tandem mass spectrometry of cobalt coordinated branched pentasaccharides. In this particular instance, four isomeric pentasaccharides (LNFP I, II, III, and V) were investigated by MS/MS and MS/MS/MS and distinct differences in the linkages were observed. Figures 1 and 2 below are the MS/MS spectra of LNFP-1 and LNFP-V coordinated to cobalt.

In addition to MS/MS, MS/MS/MS of some important intermediate ions was also carried out. By using consecutive mass spectrometric measurements one can sequence the oligosaccharide throughout beginning at the reducing ring. Figures 3 shows the MS/MS/MS spectra for LNFP-V which in addition to MS/MS/MS of m/z 441 (not shown) allows for linkage position determination throughout the molecule.

In all four cases the data suggest that Co^{+2} is partially coordinated to the N-acetyl function of the glucosamine ring. The charge site is clearly located near this ring as evidenced by the dissociation ions detected which also clearly indicate the presence of nitrogen in their composition. Additionally, formation of an aziridine ring always accompanies the facile loss of the substituent vicinal to the N-acetyl group. The nitrogen proton is easily transfered to the adjacent ring which is lost as a neutral.

Experimental: The instrument used for all experiments was a BIO-Q triple quadrupole mass spectrometer equipped with electrospray ion source (Fisons/VG Biotech, Manchester, England). The mobile phase used was a 50:50 mixture of acetonitrile and water. The ratio of metal to oligosaccharide was 1:1 using 1.0 nmole of oligosaccharide. Skimmer voltage was 70 ev except for MS/MS/MS for which it was 150 ev. Optimization studies were not performed on the pentasaccharides but were carried out for the branched trisaccharides which were analyzed at concentrations of 10 pmol/ul (submitted to Anal. Chem.)

From the Outer Membrane to the Gas Phase: Making Ions of Bacterial Surface Antigens

Bradford W. Gibson*, William Melaugh, Nancy J. Phillips, Jeffrey Engstrom
and Michael Tullius
Department of Pharmaceutical Chemistry
University of California, San Francisco, CA 94143-0446.

Bacterial pathogens interact with their host through a complex set of surface and secreted biomolecules that enable the organism to adhere, invade and multiply in the changing and hostile environment of the host. We are interested in elucidating the roles of bacterial lipooligosaccharides (or LOS), one of the major surface antigens from a group of human mucosal pathogens. These bacterial pathogens include *Neisseria* and *Haemophilus* species that are responsible for an array of serious and often life-threatening illnesses ranging from chancroid and gonorrhea to such respiratory and disseminated infections as pneumonia and meningitis.

LOS are complex biomolecules that contain a largely conserved lipid A moiety and a highly branched and variable carbohydrate domain [1]. The carbohydrate domain can consist of over a dozen different structures from a single bacterial strain. The major analytical challenge facing us is how to best sort out this heterogeneous LOS population and correlate their structures to important biological data. Initially we used liquid secondary ion mass spectrometry (LSIMS) to analyze these LOS as their water soluble O-deacylated derivatives. However, the spectra we obtained were often very weak (particularly at masses above m/z 2000), and usually gave a high level of sodium and potassium adducts (see Fig. 1). If the O-deacylated LOS were also dephosphorylated with aqueous HF, a better spectrum could be obtained, but some glycosidic bonds were hydrolyzed and all information regarding phosphorylation heterogeneity was lost

When electrospray ionization mass spectrometry (ESI-MS) is used, an excellent overall assessment of the LOS components can be obtained with a dynamic range far superior to LSIMS (see Fig. 2) [2]. If these O-deacylated LOS are treated with glycosidases, specific questions concerning structure/function relationships can be readily obtained as well. For example, the identification of LOS containing terminal sialic acid can be readily determined, even in very complex mixtures if these LOS samples are treated with neuraminidase and compared to the original spectra [3]. Unlike most electrospray data, our spectra generally contain a single peak for each LOS component and, therefore, the multiplicity of peaks observed in these spectra arise from heterogeneity of the LOS and not from multiple charge states of specific components.

Neutralization-Reionization Mass Spectrometry.

Fred W. McLafferty and Russell A. Chorush. Chemistry Department, Baker Laboratory, Cornell University, Ithaca, NY 14853-1301.

This review is dedicated to my longtime colleague Professor Richard F. Porter[1] who passed away on September 1, 1991. Dick pioneered the neutralization techniques used in our research and unselfishly helped us implement these.

The development of NMRS for molecular species in the last decade has been phenomenal,[2-4] with pioneering research in many other laboratories such as those of Holmes,[5,6] Schwarz,[7] Harrison,[8] Gellene,[1] Wesdemiotis,[9] Turecek,[10] and Terlouw.[5] An original effort was to characterize the neutral species produced in the dissociation of singly charged ions, such as the loss of HCN or HNC from aniline and pyridine. Other research efforts have been aimed at finding ways to characterize ions that isomerize readily, based on the fact that their neutral counterparts can often be dissociated with sufficient rearrangement minimization to provide isomeric charcterization. This was successful in many cases, such as four isomers of $C_4H_4^{+\cdot}$, five of $C_4H_8^{+\cdot}$, and seven of $C_2H_4O^{+\cdot}$.

However, by far the most interesting NRMS application outside of mass spectrometry has been the preparation of a wide variety of unusual neutral species whose reactivity has made them extremely difficult to study by other experimental methods. Detailed energy surfaces for the unimolecular chemistry of carbenes, ylides, diradicals, clusters, organometallics, and hypervalent, sterically strained, and anti-aromatic molecules have attracted broad interest across the chemistry community. A variety of instrumentation developments and refinements, plus computer acquisition and reduction of data, have greatly aided this progress. For example, surface induced neutralization can add more than 20 eV of internal energy to the neutral formed.

NEUTRALIZED ION BEAM STUDIES OF O_2: A NEW STATE FOR AN OLD MOLECULE

K.S. Griffith and G.I. Gellene, Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061

One of the more intriguing applications of neutralized ion beam techniques is its use to produce previously unknown novel molecules or new states of well known molecules. This use of neutralized ion beam techniques is illustrated by a recent study of the O_2 molecule which provides evidence for a new high energy metastable state of O_2. We investigated the charge exchange of O_2^+ with alkali metals using a technique which is sensitive to both dissociative and nondissociative products. Briefly, ions formed by electron ionization in a high pressure source are accelerated to 5 keV and magnetically mass resolved. The ions then enter a neutralization chamber containing a few mTorr of metal atoms (Na or K). Both neutral and ions exit the chamber, and the ions are removed from the beam by a pair of electrostatic plates. The neutral beam, which spreads as species dissociate, travels to a translatable detector, which samples intensity as a function of angle. Metastable products appear as a spike of intensity around $\theta = 0$. In a second experiment, an additional slit is placed after the neutralization chamber, which allows direct investigation of the dissociation of the metastable species by discriminating against signal from promptly dissociative species. A typical set of profiles is shown.

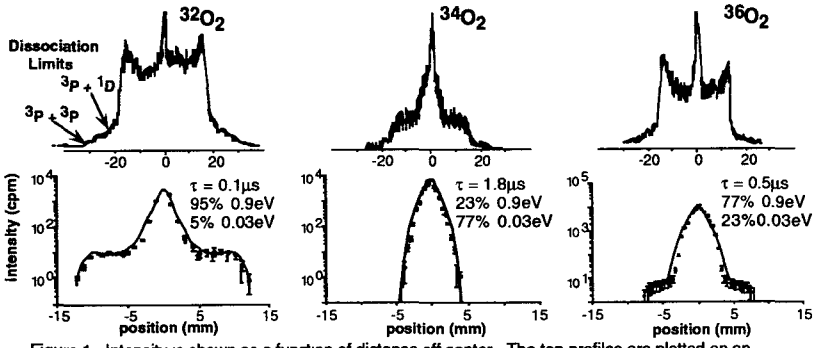

Figure 1. Intensity is shown as a function of distance off center. The top profiles are plotted on an arbitrary linear scale with center heights scaled to be equal. The bottom profiles are from the double slit experiment, and the curves are from the model (see text).

The results for the dissociative products are understandable in terms of previous studies of this charge exchange reaction. Surprisingly, however, undissociated O_2 in a long lived state was also observed. The experimental results of the double slit experiment were simulated using a model that included a geometric apparatus function, a probability of dissociation with time, and a probability of kinetic energy release (KER). The results of the model were not

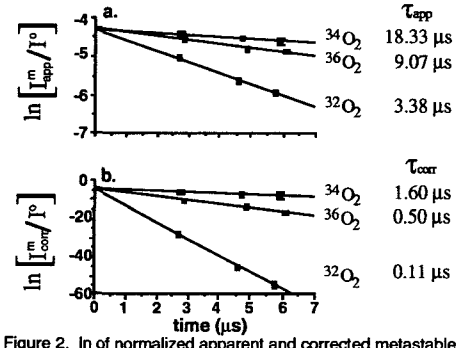

Figure 2. ln of normalized apparent and corrected metastable intensity as a function of time after neutralization. Lifetimes are obtained from the slopes Note the scale change

unique in that a finite range of lifetimes could be modelled. By measuring dependence of the normalized apparent metastable intensity (I^m_{app}/I^o) as a function of time after neutralization, apparent lifetimes were obtained (Figure 2a). These lifetimes were overestimated because of the inability to distinguish between signal from undissociated species and signal from near $\theta = 0$ dissociations. This was corrected for by using the model of the system which allows determination of the amount of dissociative signal, for a given lifetime and KER distribution, that is counted as undissociated. The results are shown in Figure 2b.

Because the metastable relaxes dissociatively, it cannot be identified with any of the known metastable states of O_2, all of which lie below the first dissociation limit. The results of the modelling of the double slit experiment indicate two relaxation pathways, one predissociative (KER = 0.9eV) and one radiative (KER ≈ 0.03eV). Inspection of the predicted bound states of O_2 reveals one candidate that can account for the predissociation, $1^1\Delta_u$. Calculation of the Franck-Condon overlaps of the first five vibrational states of $1^1\Delta_u$ with the state that predissociates it $2^3\Delta_u$, reveals that the v=2 level FCF's vary significantly with mass (Figure 3) and that this variation can account for the difference in the predissociative lifetimes of the isotopic variants. Further, a spin orbit coupling constant of 9(±1) cm^{-1} was determined for the $1^1\Delta_u \sim 2^3\Delta_u$ interaction. *Ab initio* calculations indicate that this small spin orbit coupling constant is reasonable for this interaction. Additional investigation indicates that the only dipole allowed transitions, $1^1\Delta_u \rightarrow 1^1\Pi_g$ and $1^1\Delta_u \rightarrow a^1\Delta_g$, are not efficient relaxation pathways. There are two states to which the $1^1\Delta_u$ state might radiate to which would be expected to give a very small KER, $2;3^3\Pi_g$.

We have identified the metastable species as the previously unobserved $O_2(1^1\Delta_u)$ state. Considering the near 8 eV of electronic energy in this state, the long lifetimes suggest that this metastable state may be capable of unprecedented new oxygen chemistry.

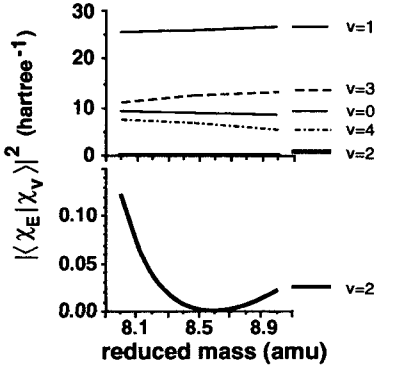

Figure 3. Variation of Franck-Condon factors with reduced mass for $1^1\Delta_u \sim 2^3\Delta_u$.

COLLISIONAL ELECTRON TRANSFER: WHERE DOES THE ELECTRON GO?

Frantisek Turecek, Scott A. Shaffer, Ming Gu, Thuy B. Tran and David W. Kuhns
Department of Chemistry, University of Washington, Seattle, WA 98195

Neutralization-reionization mass spectrometry relies upon fast electron transfer from a thermal neutral target to an ion of keV kinetic energy to produce an intermediate neutral species. The collisional electron transfer may involve the generation of excited electronic states in the neutral formed. The nature and reactivity of these excited states, for example, singlet or triplet biradicals, zwitterion biradicals, and Rydberg states, are discussed for several polyatomic molecules.

Neutralization with Hg of the $^{\bullet}CH_2CH_2CO^+$ distonic ion forms the $^{\bullet}CH_2CH_2CO^{\bullet}$ biradical whose singlet state dissociates exothermically to C_2H_4 and CO (ΔH_r = -358 kJ mol^{-1}). In a parallel reaction the less stable triplet $^{\bullet}CH_2CH_2CO^{\bullet}$ dissociates exothermically to CH_2 and CH_2CO (ΔH_r = -282 kJ mol^{-1}). The latter reaction forming the stable triplet CH_2 is spin allowed whereas the formation of singlet C_2H_4 and CO is not.

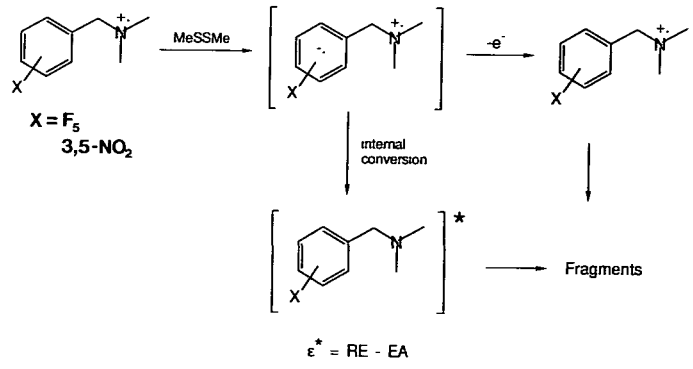
Neutralization with CH_3SSCH_3 of the stable $^{\bullet}CH_2NHCH_2^+$ distonic ion forms the $^{\bullet}CH_2NHCH_2^{\bullet}$ biradical which shows remarkable stability. Its reionization produces the survivor ion of a relative abundance exceeding those of the stable $CH_3N{=}CH_2$ and aziridine ions. Ab initio calculations show that the equilibrium C_{2v} structures of $^{\bullet}CH_2NHCH_2^+$ and singlet $^{\bullet}CH_2NHCH_2^{\bullet}$ are very similar, causing negligible Franck-Condon effects upon vertical electron transfer. Dissociation of singlet $^{\bullet}CH_2NHCH_2^{\bullet}$ to the 2-azaallyl radical and H$^{\bullet}$ is 106 kJ mol^{-1} endothermic in keeping with the biradical stability. Triplet $^{\bullet}CH_2NHCH_2^{\bullet}$ geometry shows twisted methylene groups and pyramidization at nitrogen. Vertical neutralization to the triplet state is accompanied with 57 kJ mol^{-1} vibrational excitation causing rapid dissociation by loss of H$^{\bullet}$. The surviving $^{\bullet}CH_2NHCH_2^+$ is therefore due to reionization of the stable singlet biradical.

Neutralization with CH_3SSCH_3, $(CH_3)_3N$, and Xe of aromatic amine cation-radicals induces dissociations which are unparalleled by CAD of the corresponding ions. N,N-dimethylbenzylamine exhibits extensive fragmentations of the aromatic ring to form C_6H_{0-5}, C_5H_{0-5}, C_4H_{0-2}, C_3H_{0-2}, and C_2H_{0-2}, whereas CAD of the cation-radical mostly cleaves the benzylic C-N and phenylic C-C bonds to form $C_7H_7^+$ and $CH_2{=}N^+(CH_3)_2$, respectively. In N-methylbenzylamine a clean transfer of the N-bound H-atom to form benzene is observed for the neutral but not for the ion. A mechanism is proposed considering electron capture by the aromatic ring to form a Rydberg resonance which undergoes dissociative electron detachment accompanied with ring fragmentation.

Hypervalent N-benzyl-N,N-dimethyl-N-hydrogenammonium and N-benzylmethylhydrogen ammonium radicals show extensive cleavages of the bonds in the vicinity of the nitrogen atom, in addition to aromatic-ring fragmentations. The C-N and H-N bond cleavages can result from both electron capture in a Rydberg orbital on nitrogen to form a hypervalent radical, and dissociative electron detachment from the aromatic ring.

Dissociations of *ar*-pentafluorobenzyl- and 3,5-dinitrobenzyl-N,N-dimethylamine following neutralization of their cation-radicals are consistent with this model. The neutral pentafluoro derivative undergoes >6 eV endothermic dissociations forming CF$^{\bullet}$ as the predominant product, while the nitro

derivative yields NO by aromatic fragmentations. The loss of HF and the formation of $CH_2{=}N^+(CH_3)_2$, which are characteristic for ion fragmentations, are absent or negligible in the neutralization-reionization spectra. The neutral fragmentation may be triggered by electron capture in a bound state of the substituted benzene ring (EA ≈ 1.6 eV for 3,5-NO_2, <0.5 eV for F_5). The latter represents a biradical-zwitterion excited state of the neutral which undergoes forbidden electron transition to the ground state accompanied by deposition of >7 eV internal energy.



Energy transfer upon neutralization has also been investigated with the newly developed kinetic method that provides phenomenological rate constants for unimolecular neutral and ion dissociations. The kinetic method is based on selective monitoring of ions that have undergone neutralization and reionization at different and variable time scales for neutral and ion dissociations. This is accomplished by applying variable positive and negative potentials on the segments of a long collision cell, so that only ions formed in the segment having the correct potential are detected. In this way the neutral and ion dissociations are distinguished and the rate constants for both the neutral and ion dissociations can be calculated from the time-dependent ion abundances. Neutralization of $CH_3I^{+\bullet}$ with several atomic and molecular targets followed by reionization with oxygen gave different and target-dependent rate constants for the dissociation of neutral CH_3I to $CH_3^{\bullet}$ and I$^{\bullet}$, and ionic $CH_3I^{+\bullet}$ to I^+ and $CH_3^{\bullet}$. In spite of its greater endothermicity the ion dissociation following reionization is faster that the dissociation of the neutral. This points to the dominant role of collisional activation in the reionization process. Neutralization of $CH_3I^{+\bullet}$ with targets of very similar vertical ionization energies (IE_v) results in different excitations of the neutral formed. Resonant neutralization of $CH_3I^{+\bullet}$ with CH_3I (IE_v = 9.54 eV) is less energetic than those with $(C_2H_5)O$ (IE_v = 9.61 eV) and NO (IE_v = 9.54 eV), which cause more rapid fragmentation of the neutral. Endothermic electron transfer from Xe (IE_v = 12.13 eV) results in substantially greater excitation increasing the rate constants of both neutral and ion dissociations.

INVESTIGATION OF ION STRUCTURES BY NEUTRALIZATION-REIONIZATION MASS SPECTROMETRY METHODS

Marcela M. Cordero, Jinnan Cai, Sarka Beranova, Michael J. Nold, Thomas L. Selby, and *Chrys Wesdemiotis

Department of Chemistry, The University of Akron, Akron OH 44325-3601.

Conventional tandem mass spectrometry analyzes ion structures based on the *ionic* products arising upon the unimolecular fragmentation of the studied ion. Neutralization-reionization mass spectrometry (NRMS) offers two alternative means for obtaining complementary structural information: it allows (1) to study the unimolecular reactions of neutralized ions and (2) to also identify *neutral* losses.

Neutralized Ions

The structure of an ion can be determined by examining the stability and reactions of its neutralized form. Since neutrals seldom undergo complex rearrangements, neutralization-reionization (NR) spectra may contain more specific structural information than collisionally activated dissociation (CAD) spectra. This is demonstrated for protonated glycine, $[H_2NCH_2COOH]H^+$. H^+ can attach to the amino or carboxyl functionality. The resulting ions, namely $^+H_3NCH_2COOH$ and $H_2NCH_2C(OH)_2^+$, can best be distinguished from the reactivities of the corresponding neutrals. Neutralization of $H_2NCH_2C(OH)_2^+$ yields a dihydroxy substituted, C-centered radical. Such radicals are stable, as shown by the NR spectrum of protonated acetic acid, $CH_3C(OH)_2^+$, which contains an abundant survival ion (Figure 1b). In sharp contrast, no recovery peak is observed in the NR spectrum of $[Gly]H^+$ (Figure 1a), in agreement with exclusive N-protonation. Based on the fragments observed in Figure 1a, the hypervalent radical generated upon neutralization of $^+H_3NCH_2COOH$ decays mainly to H + Gly, H_2N + CH_3COOH, H_3N + CH_2COOH, and CH_5N + COOH.

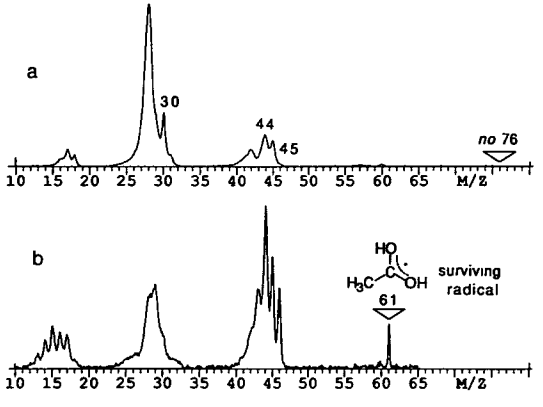


Figure 1. Neutralization-reionization (NR) spectra of (a) $[Gly]H^+$ and (b) $[CH_3COOH]H^+$. Xe is used for neutralization and O_2 for reionization.

Neutral Losses

The neutral products formed upon CAD of a mass-selected ion can be reionized and collected in the corresponding neutral fragment-reionization (N_fR) mass spectrum, which consists of the superimposed collision induced dissociative ionization (CIDI) spectra of the individual neutral fragments. Isomeric ions can be differentiated if they yield different neutral losses.

The interpretation of N_fR spectra and structural assignments are significantly facilitated by the availability of reference CIDI mass spectra of single, important neutral losses. The CIDI spectra of amino acids, which are eliminated as complete units from the *C-termini* of peptides, can readily be obtained by producing them independently from proton-bound dimers. Such CIDI spectra can be used to identify the C-terminal amino acid of isomeric dipeptides. This is illustrated for $[Ala\text{-}Gly]H^+$ and $[Gly\text{-}Ala]H^+$ in Figure 2: their N_fR spectra, combined with the reference CIDI spectra of Gly and Ala, clearly indicate Gly loss from the former but Ala loss from the latter dipeptide. Although protonated Ala-Gly and Gly-Ala can be distinguished from the their normal CAD spectra, the additional N_fR data is essential for confirming the correct sequence. Similar results are obtained for several other isomeric dipeptides, including Asp-Gly / Gly-Asp and Trp-Ala / Ala-Trp.

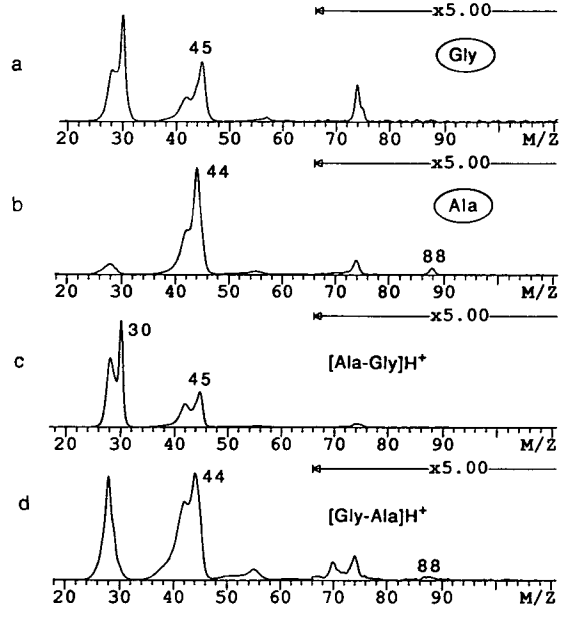

Figure 2. CIDI spectra of (a) Gly and (b) Ala, liberated from the corresponding proton-bound dimers. Neutral fragment-reionization (N_fR) spectra of (c)) $[Ala\text{-}Gly]H^+$ and (d) $[Gly\text{-}Ala]H^+$. He is used for precursor ion dissociation and O_2 for reionization.

NEUTRALIZATION-REIONIZATION MASS SPECTROMETRY; WHAT NEXT?

John L. Holmes, Chemistry Department, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5

Neutralization-Reionization Mass Spectrometry (NRMS) is a technique of great promise, which perhaps has yet to reach its full potential.

The experiment is basically simple, involving the collisional transfer of an electron from a target atom or molecule to a beam of mass selected ions $(M)^{+\bullet}$ and, having deflected remaining ions away, reionizing the (hoped for) neutral (M) by collision with a second target gas. In the resulting mass spectrum, (NRMS), the presence of $M^{+\bullet}$ provides the evidence for the successful production of M. However, the absence of such a "recovery peak" is not conclusive evidence that the neutral is not a bound state.

The NRMS technique has certainly provided some spectacular results, in terms of the generation of novel, stable neutral species, and some recent examples will be discussed in the oral presentation, including a discussion of the elusive stable small molecule OC_2O [1].

Apart from experimental difficulties related to ensuring the structural or even chemical purity of the mass selected ion $M^{+\bullet}$, there are significant difficulties to be encountered in the interpretation of observations.

The first problem relates to the nature of the electron transfer itself. This is a fast event ($<10^{-15}$s) and so is a vertical (Franck-Condon) process. Thus the neutralization step will only produce a significant yield of ground state molecules (or radicals) when the mass selected ion has a ground state geometry similar to that of its neutral counterpart and provided that the majority of the ions are also in their ground state. A good example of this is provided by acetone [2] whose autoneutralization is far from resonant. In general too, mass selected ions from a conventional mass spectrometer's electron impact ion source, will have a range of internal energies from the ground state up to the lowest energy threshold for dissociation. This can be a wide range indeed, as exemplified below. Surprisingly, a lack of resonance in the electron transfer process appears to be far from critical and differences between the ionization energy of the target atom (or molecule) and the vertical neutralization energy of the ion of up to 5eV, can still result in the production of significant neutral yields [3].

Although it appears to be generally assumed that the "recovery peak" in a NRMS is proof of the existence of a stable neutral counterpart of the ion there is very little available alternative physicochemical evidence which provides information as to the state of the "neutral". A good example is the hypervalent $CH_5^\bullet$ radical, believed to exist as a short-lived high Rydberg state [4]. Here, the ion core, of essentially undisturbed geometry,is stable and the acquired electron in its distant orbit gives the system its neutrality.

Good yields of the hypervalent radicals $CH_3O^\bullet(H)CH_3$ and $CH_3CH_2O^\bullet H_2$ have been reported in NRMS experiments [5,6]. There is no evidence from studies of the kinetics of H atom reactions with dimethyl ether and ethanol or methyl radicals with methanol to indicate that the potential hypervalent

intermediate is chemically bound. The energy diagrams below illustrate the internal energy ranges relevant to the NR experiment. Experiments in our laboratory have failed to provide evidence for high Rydberg species and so the nature of these neutrals remains unknown.

It has been found [5], that only $CH_3O^+(H)CH_3$ ions of high internal energy content yield a large "recovery peak". For such species neutralization with Xe to the lower energy radical pair is only about 3 eV endothermic and this energy deficit can readily be provided from the ions' translational energy. With Cd, this neutralization is almost resonant. But are the ground state radical species bound?

These results emphasize the need for an alternative physicochemical method (not another mass spectrum) for characterizing the neutrals.

Measuring their ionization energy is one approach, but the presence of a broad range of excited neutral species could make such experiments difficult to interpret. Spectroscopic measurements certainly hold promise, as exemplified by the experiments of Selgren and Gellene [7] and Helm [8] on the $H_3^\bullet$ radical, but their utility for polyatomic systems remains to be explored.

The Quest for the Elusive Iminols with *NRMS* and Multiple Collision Experiments (*MS/MS/MS*)

Graham A. McGibbon, Richard W. Smith, Peter C. Burgers and Johan K. Terlouw*

McMaster University, Department of Chemistry, Hamilton, Ontario L8S 4M1, Canada
Hercules European Research Center BV, Nijverheidsweg 60, 3771 ME Barneveld, The Netherlands

Ionized enols are readily accessible via the McLafferty rearrangement and often their neutral counterparts are easily generated and identified using Neutralization-Reionization Mass Spectrometry [NRMS] [1]. In contrast, iminols or imidic acids, RN=C(OH)R', have so far eluded observation as stable species in the gas phase although their role in the proton exchange of amides, peptides and proteins has been firmly established [2]. In addition, the prototype iminol formamidic acid, H-N=C(OH)H, is predicted by ab initio MO calculations to be separated by high barriers from both its keto isomer H_2N-C(=O)H [3a] and the carbene H_2N-$\ddot{C}$-OH [3b] and the same holds true for their ionized counterparts [3c]. Inspired by these findings, we have explored the use of NRMS for the generation and identification of H-N=C(OH)H and its homologues CH_3N=C(OH)H and HN=C(OH)CH_3.

One of the two methyl analogues, CH_3N=C(OH)H, was readily generated from its ionic counterpart and it has an NR spectrum that is distinctly different from those of its stable isomers, which include the species CH_3N(H)C(=O)H, CH_3N(H)-$\ddot{C}$-OH, H_2NC(=O)CH_3 and H_2NC(OH)=CH_2. We had anticipated that the ionic counterpart of the other methyl analogue, HN=C(OH)CH_3, could be generated by dissociative ionization of an appropriate precursor molecule. However, the m/z 59 ions from acetaldehyde acetylhydrazone produced a CA mass spectrum that was closely similar to that from ionized acetamide and intriguingly the m/z 59 ions from our alternative precursor diacetamide had a CA mass spectrum like that of H_2NC(OH)=CH_2 ions

The identification of formamidic acid was even less straightforward: double collision experiments on ionized formamide, the carbene isomer and the iminol show that formamidic acid **ions** are cleanly generated, but MS/MS/MS type experiments, i.e. CA mass spectra of the survivor ions in the NR spectra, see Fig. 1, do not permit an unambiguous structure assignment of the reionized **neutrals**.

However, from the combined information that (i) the CA spectra of source generated ions of the labelled isotopomers $D_2{}^{15}NC$(=O)D and $D_2{}^{15}N$-C-OD are virtually identical to their corresponding survivor ion CA mass spectra, see Fig. 2, and that (ii) the survivor ion CA mass spectrum of the iminol is characteristically different from those of its isomers it follows that formamidic acid is indeed a stable species in the gas phase.

In addition, Neutralization-Target mass spectra [NTMS] were obtained with the "perpendicular" Quadrupole mass analyser of our ZAB-R instrument of B(⊥Q)EE geometry using formamide, N-methyl formamide, trimethylamine and N,N-dimethylaniline as targets for the neutralization. These spectra confirm distinct structural identities for the three CH_3NO isomers.

Investigation of Ionized Cyclopropanol. Does it Exist?

*Michael J. Polce, Fred A. Wiedmann, and Chrys Wesdemiotis
Department of Chemistry, The University of Akron, Akron, OH 44325-3601

The molecular cation of cyclopropanol, the simplest cyclic alcohol, has not been characterized unequivocally yet. It is not known whether electron ionization (EI) produces the cyclic ion or a ring-opened $C_3H_6O^+$ isomer or a mixture. Neither has it been determined whether chemical ionization (CI) of cyclopropanol yields an O-protonated ion or a C-C-protonated species

The first question was addressed by investigating ionized cyclopropanol and several of its isomers with the C-C-C-O framework by using metastable ion (MI), collisionally activated dissociation (CAD), and neutralization-reionization mass spectrometry (NRMS) performed on our modified VG Autospec instrument.[1] The studied ions include the molecular cations of cyclopropanol [*cyclo*-C_3H_5-OH]$^{\cdot+}$ (**1**$^{\cdot+}$), allyl alcohol [CH_2=$CHCH_2OH$]$^{\cdot+}$ (**2**$^{\cdot+}$), and propanal [CH_3CH_2CH=O]$^{\cdot+}$ (**3**$^{\cdot+}$), as well as, ionized 1-propenol [CH_3CH=$CHOH$]$^{\cdot+}$ (**4**$^{\cdot+}$) (formed by CH_3CH=CH_2 loss from 2-methylpentanal) and the distonic radical cation CH_2CH_2CH=OH^+ (**5**$^{\cdot+}$) (formed by CH_2=O loss from 3-hydroxytetrahydrofuran).

All of our results show the spectra of **1**$^{\cdot+}$ and **2**$^{\cdot+}$ to be nearly indistinguishable, in agreement with earlier findings of Bombach et al.[2] that they isomerize to a common structure **1**$^{\cdot+}$/**2**$^{\cdot+}$. However, trying to determine what this structure is has proven to be challenging. The major peak in the MI spectra of the studied ions **1-5**$^{\cdot+}$ is at m/z 57 (H$^{\cdot}$ loss), and all exhibit similar peak shape and width. Minor peaks present in the spectra may provide a means to determine differences in ion structure, but more experiments are needed.

The CAD and NRMS spectra of **3**$^{\cdot+}$ are discernibly distinct from those of **1**$^{\cdot+}$/**2**$^{\cdot+}$, **4**$^{\cdot+}$, and **5**$^{\cdot+}$ which eliminates ionized propanal as the structure of **1**$^{\cdot+}$/**2**$^{\cdot+}$. However, the CAD spectra (Figure 1) of **1**$^{\cdot+}$/**2**$^{\cdot+}$, **4**$^{\cdot+}$, and **5**$^{\cdot+}$ are found to be nearly identical within experimental error which contradicts an earlier CAD study in which we found **1**$^{\cdot+}$, **4**$^{\cdot+}$, and **5**$^{\cdot+}$ to be distinguishable isomers.[3] These differences can now be attributed to the earlier use of poor precursors for **4**$^{+}$ and **5**$^{\cdot+}$. [CH_3CH=$CHOH$]$^{\cdot+}$ was formed by C_2H_4 loss from 2-methylbutanal and contained 12% contaminant from isobaric $C_4H_{10}^{\cdot+}$ thus producing a more abundant peak at m/z 42 (from CH_4 loss). **5**$^{\cdot+}$ was provided by CO_2 loss from an 18% aq. soln. of 4-oxobutanoic acid. This generated a very weak ion and therefore background contamination at m/z 43 and 44 The NRMS spectra (Figure 2) for **1**$^{\cdot+}$/**2**$^{\cdot+}$, **4**$^{\cdot+}$, and **5**$^{\cdot+}$ again are very similar, with the major difference being the relative and absolute abundances of the recovery peak (m/z 58). Since no unique fragments are formed it is difficult to deduce the structures of the neutral parents.

All of these results indicate that the incipient $C_3H_6O^{\cdot+}$ cations from EI of cyclopropanol and allyl alcohol initially isomerize to the distonic structure **5**$^{\cdot+}$ via C-C ring opening and 1,2-H shift, respectively. Some further rearrangement to the more stable enolic structure **4**$^{\cdot+}$ seems likely Thus, it appears the structure of **1**$^{\cdot+}$/**2**$^{\cdot+}$ may be a mixture of **4**$^{\cdot+}$ and **5**$^{\cdot+}$.

Our preliminary studies on protonated cyclopropanol indicate that both O- and C-C-protonation occur. The latter is by far the predominant channel and ultimately yields protonated propanal.

Detection and Characterization of Novel $[C_2,H_3,N,O]^{+\cdot}$ Isomers and their Neutral Counterparts

Cornelis E.C.A. Hop* and D.F. Snyder
Department of Chemistry, University of Wisconsin-Madison
1101 University Avenue, Madison, Wisconsin 53706.

Mass spectrometry has distinguished itself as an extremely powerful technique for characterization of the structure of ions. Two complementary approaches are available to determine the structure of ions: (i) ion/molecule reactions and (ii) metastable and collision-induced dissociation. The latter technique will be used here to characterize a variety of $[C_2,H_3,N,O]^+$ ions. Neutralization-reionization (NR) can be to probe the stability of the neutral counterparts of these ions.

Methyl isocyanate, H_3CNCO, is of significant commercial interest because of its role in the large-scale production of insecticides and herbicides. However, its toxicity is of great concern. The isomers H_3COCN, H_3CCNO and H_3CONC have been detected as well, but all three of them are extremely reactive. Glycolonitrile, $HOCH_2CN$, is the second isomer which is commercially available. Via NR mass spectrometry it has been shown that $H_2NC{\equiv}COH$ is a stable species in the gas phase.[1] $H_2C{=}C(H)NO$ has been generated by low pressure pyrolitic deoxygenation of nitro ethene [2] and $H_2C{=}N{-}C(H)O$ has been obtained via flash vacuum pyrolysis of N-formyl-2-azabicyclo[2.2.1]hept-5-ene.[3] Other isomers, e g $CH_2{-}NH{-}CO$ and $O(H)C{-}C(H){=}NH$ have been considered in theoretical studies, but not yet identified.

In Table 1 the metastable ion (MI) mass spectra of nine different $[C_2,H_3,N,O]^+$ isomers are presented as well as their precursors All spectra are distinctly different The isomers can also be distinguished based on their collision-induced dissociation (CID) mass spectra and these CID spectra allow structural characterization. The structures of the $[C_2,H_3,N,O]^+$ ions generated by $\overline{CH_2{-}NH{-}C(O){-}O{-}C(O)}^+$ and $\overline{HN{-}CH{=}CH{-}O{-}C{=}O}^+$ require more attention.

The MI mass spectrum of ionized 2(3H)-oxazolone, $\overline{HN{-}CH{=}CH{-}O{-}C{=}O}^+$, contains an intense signal at m/z 57, $[C_2,H_3,N,O]^+$ *Is CO loss from the molecular ions accompanied by ring closure?* Ring closure leads to $\overline{HN{-}CH{=}CH{-}O}^+$. If no ring closure occurs the m/z 57 ions have the $O(H)C{-}C(H){=}NH^+$ structure Based on the absence of HNO^+ in the CID mass spectrum of the $[C_2,H_3,N,O]^{+\cdot}$ ions we propose that $O(H)C{-}C(H){=}NH^+$ ions are generated The NR mass spectrum of these ions contains an intense signal at m/z 29, which is much more intense than in the CID mass spectrum, and the recovery signal at m/z 57 is extremely small Thus, $HN{=}C(H){-}C(H)O^+$ ions do not survive neutralization-reionization intact The abundant signal at m/z 29 is due to (i) generation of HCO by metastable $HN{=}C(H){-}C(H)O^+$ ions and (ii) fragmentation of neutralized $HN{=}C(H){-}C(H)O^+$ into HCO + HCNH and/or H_2CNH + CO.

The molecular ions of 2,5-oxazolidinedione, $\overline{CH_2{-}NH{-}C(O){-}O{-}C(O)}^{+\cdot}$, undergo only one fragmentation process on the metastable time scale· generation of $[C_2,H_3,N,O]^+$, i.e loss of CO_2 Remarkably, the m/z 57 signal is composite and it is comprised of two broad, dished components of approximately equal abundance ($T_h(A)$ = 128 meV; $T_h(B)$ = 513 meV) Thus there are two ways to lose CO_2 *Is CO_2 loss from the molecular ions accompanied by ring closure?* Ring closure leads to $\overline{CH_2{-}NH{-}CO}^+$ If ring closure does not occur two distonic isomers are generated. $CH_2{-}NH{-}CO^+$ and $NH{-}CH_2{-}CO^+$. The MI mass spectrum of 2,5-

oxazolidinedione-5-^{13}C displays loss of CO_2 and $^{13}CO_2$. The MI and CID mass spectra of the corresponding$[H_3,{}^{12}C,{}^{13}C,N,O]^+$ and $[H_3,{}^{12}C_2,N,O]^+$ ions are not identical! Thus, 2,5 oxazolidinedione yields the distonic ions $\overline{CH_2{-}NH{-}CO}^{+\cdot}$ and $NH{-}CH_2{-}CO^{+\cdot}$. (Note that the isoelectronic compound succinic anhydride, $\overline{CH_2{-}CH_2{-}C(O){-}O{-}C(O)}^{+\cdot}$ yields distonic $CH_2{-}CH_2{-}CO^{+\cdot}$ ions via a similar process.[4]) The NR mass spectrum of these $[C_2,H_3,N,O]^+$ ions is dominated by m/z 28 and the recovery signal is extremely small. Therefore, the distonic ions $CH_2{-}NH{-}CO^{+\cdot}$ and $NH{-}CH_2{-}CO^+$ do not survive neutralization-reionization intact and the m/z 28 signal is due to generation of CO by metastable $CH_2{-}NH{-}CO^+$ and $NH{-}CH_2{-}CO^{+\cdot}$ ions

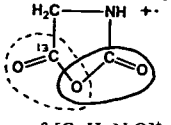

Table 1. Metastable ion mass spectra of $[C_2,H_3,N,O]^+$ ions with the kinetic energy release values ($T_{0.5}$ in meV) in parentheses.

precursor	neutral lost	proposed structure	fragment ions, m/z				
			56	43	29	28	27
CH_3NCO	-	CH_3NCO^+	60 (70)		100 (221)		
$NC{-}C(O){-}OCH_3$	CO	CH_3ONC^+	100 (a)				
$H_3CC(O)N(H)OH$	H_2O	CH_3CNO^+	b (b)	100 (785)			52 (23)
$HOCH_2CN$	-	$HOCH_2CN^+$				100 (29)	
Threonine	C_2H_3OH + H_2O	$H_2N(H)C{=}C{=}O^+$	100 (168)		9 (7 0)		
$H_2C{=}C(H)NO_2$	O	$H_2C{=}C(H)NO^+$					100 (0.8)
$\underline{CH_2{-}NH{-}C(O){-}O{-}C(O)}$	CO_2	$CH_2{-}NH{-}CO^+$ + $NH{-}CH_2{-}CO^+$	76 (265)		100[c] (24/340)		
$\underline{HN{-}CH{=}CH{-}O{-}C{=}O}$	CO	$O(H)C{-}C(H){=}NH^+$				100 (0 5)	

a. Too weak to determine accurately b. The m/z 56 signal is base peak in the spectrum However, it is partially overlapped by an interfering signal of unknown origin. c The signal is composite; it contains a narrow component as well as a broad, dished component

All experiments were performed with VG Analytical ZAB-2F mass spectrometers (University of Wisconsin-Madison and University of Ottawa) The NR mass spectra were acquired with Xe as neutralizing gas and He or O_2 as reionizing gas.

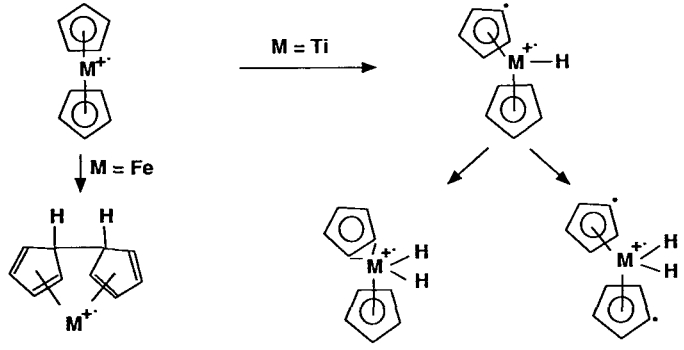
The Characterization of Labile Metallocenes and Their Neutral Counterparts by Tandem Mass Spectrometry.

Dmitri V.Zagorevskii and John L.Holmes
Department of Chemistry, University of Ottawa, Ottawa, Ontario, Canada K1N 6N5.

Tandem mass spectrometry has been used for the generation and characterization of elusive titanocenium and rhodocenium derivatives and their neutral counterparts. The behaviour of these species has been compared with that of stable analogues of the other transition metals.

Titanocenium has been generated by electron impact dissociation of Cp_2TiI_2. Decomposition of the metastable and collisionally activated Cp_2Ti^+ ions involves metal-ligand bond cleavage, hydrocarbon ligand destruction, and dehydrogenation with H and H_2 loss The mechanism of H_2 loss from Cp_2Ti^+ ion and other metallocenium ions, in particular ferrocenium, are different (Scheme). Cyclopentadienyl ligands coupling precedes H_2 loss in the case of Cp_2Fe^+, whereas decomposition of Cp_2Ti^+ proceeds via formation of the intermediate metalhydrides. The latter is clearly evidenced from the neutralization-reionization (NR) mass spectrum of Cp_2Ti^+ (Fig. 1a). It displays an abundant recovery signal and fragment ions indicative of hydrogen atom(s) migration from the cyclopentadienyl ring(s) to the central metal atom ($C_{10}H_8Ti^+$, $C_5H_4Ti^+$, TiH^+, TiH_2^+).



Decomposition characteristics of the rhodocenium cation and its substituted derivatives resemble those of the corresponding ferrocenium derivatives. For example, dissociation of the metastable carboxyl and hydroxymethylrhodocenium ions involves simple metal-ligand bond cleavage with formation of the $CpRh^+$ ion and hydroxy group migration to the metal atom giving rise to the $CpRhOH^+$ ion. The NR mass spectra of unsubstituted rhodocenium (Fig. 1b) and its carboxyl derivative display recovery signals indicating a stability of the corresponding neutral species in the gas phase.

Current status and new leads in the analysis of small molecules by LC-MS

J. van der Greef, W.M.A. Niessen and U.R. Tjaden, Leiden/Amsterdam Center for Drug Research, Division of Analytical Chemistry, P.O. Box 9502, 2300 RA Leiden, and TNO Centre for Structure Elucidation and Instrumental Analysis, P.O. Box 360, 3700 AJ Zeist, The Netherlands

Introduction

The field of liquid chromatography - mass spectrometry has become mature and impressive results have been obtained for a broad variety of compounds for qualitative as well as quantitative analysis. Various robust interfaces are nowadays commercially available enabling routine laboratories to apply this technology. In fact quantitative analysis of drugs at low levels have been one of the major driving forces in the development of LC-MS or LC-MS/MS. Important in setting up systems aiming at the analysis of large series of samples in an automated way is the optimization of the chromatographic part. Some traditional approaches in bioanalysis will be discussed followed by some possible new trends in the area of small molecules.

Discussion

In general depending on the concentration range to be measured simple chromatographic systems can be used as shown in Figure 1.

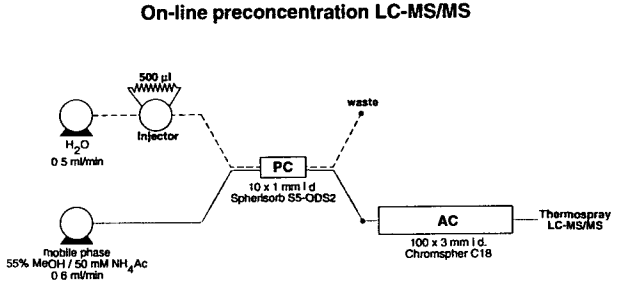

Figure 1. Schematic diagram often used for bioanalytical LC-MS/MS

A precolumn for preconcentration and cleanup purposes is followed by a short analytical column with sufficient separation efficiency to separate the matrix from the analyte and/or metabolites. If for instance direct injection of urine is performed such a system can be used to detect steroids at the ppb level in drug monitoring programmes as shown in Figure 2.

Lower levels down to the fmol/ml level and accurate quantitation can be obtained by TSP for various drugs by more extensive sample pretreatment. However, these levels are more easily obtained using the atmospheric pressure interfaces such as electrospray/ ionspray and the heated nebulizer/APCI. For instance in ESP at the 2-5 ul/min range a chromatographic system consisting of a packed-fused silica column (320 um I.D. x 100 mm) can provide fmol/ml LOQ's for steroids, when peak focusing is used enabling a loadibility of 10 - 20 ul. Such an example is given for two veterinary steroid drugs (20 pg each) in Figure 3.

Developments in this area are the availability of so-called restricted access stationary phases allowing direct plasma injection and on-line protein removal. Depending on the drug-protein binding characteristics such an approach can be attractive.
Another interesting strategy is based on biomimetic chromatography. In such an approach a biological recognition is used in the sample pretreatment of separation process. For instance in screening programs for monitoring illegal use of drugs, it is of interest to use receptor-based technology. We have recently shown this principle for the isolation of analytes such as 17-ß oestradiol and diethylstilbestrol using the oestrogen receptor.
Various approaches have been described to circumvent the incompatibility problem in ion-pair chromatography.
Pseudo-electrochromatography has been inroduced by us as an alternative in such cases. In this methodology a pressure driven system is combined with a electromigration component by applying a high voltage across a packed-fused silica column. This provides an additional selectivity tool for instance by acceleration or deceleration of charged molecules. Even combined effects using voltage programming have been shown to be very useful in the separation of dyes and aromatic glucoronides using ESP LC-MS.

Electrospray Ionization at LC Compatible Flow Rates on a Magnetic Sector Mass Spectrometer

Jeffrey W. Finch[1], Brian D. Musselman[1], J. Fred Banks[2], and Craig M. Whitehouse[2]

[1]JEOL USA Inc., 11 Dearborn Rd., Peabody MA 01960

[2]Analytica of Branford, 29 Business Park Dr., Branford, CT 06405

Introduction: Electrospray Ionization (ESI) for sector mass spectrometers has been limited to low flow rates of typical 2-5 μL/min due to the source design. While these low flow rates are compatible with packed capillary columns, LC/MS applications with larger diameter analytical columns require a split ratio where only a fraction of the effluent is directed into the source, reducing sensitivity. In addition, the use of gradients usually require the use of sheath flow to maintain a stable spray. To overcome these problems, an ultrasonic-assisted electrospray (*Ultraspray*) source has been developed for high-flow LC/MS applications on magnetic sector instrumentation.

Experimental: The ESI source, developed by Analytica of Branford, has been previously described (1) and is shown in Figure 1. The low flow needle has been replaced with an ultrasonic needle operated in "grounded needle" mode, where the needle is held at ground while the capillary entrance is floated at -4.5 kV with the capillary exit and skimmers floated at accelerating potentials. Power for the ultrasonic needle is delivered from a "frequency lock" controller which maintains resonant nebulization regardless of changes in source conditions such as temperature or solvent viscosity. The fine areosol produced at the needle is directed toward the capillary by a stream of N_2 flowing across the needle tip. LC/MS data were recorded on JEOL HX110 (EB), SX102 (BE), and LX2000 (EB) sector mass spectrometers operating at accelerating voltages of 5 kV, 5 kV, and 3 kV respectively. Scan speeds for LC/MS were on the order of 2-5 sec/scan. HPLC separations were carried out using either an Applied Biosystems Aquapore 300 ODS 7 μm 250x1 mm column (tricyclics and peptides) or a Keystone Scientific Hypersil BDS C18 5 μm 150x1 mm column (phenothiazines and triazines). Tricyclic antidepresants were analyzed at a flow rate of 40 μL/min using isocratic elution with an 80% isopropanol/20% H2O solvent with 0.04% NH_4OH. Mixtures of phenothiazines and triazine herbicides were analyzed at flow rates of 50 μL/min using gradient elution where Solvent A =10 or 50 mM NH_4OAc (pH 5.5 or 6.0) and Solvent B = acetonitrile. Peptide mixtures were analyzed using a gradient elution (Solvent A = 0.1% formic acid, Solvent B= acetonitrile with 0.084% formic acid) at a flow rate of 50 μL/min.

Results and Conclusions: Infusion studies of small molecules where ion intensities are measured versus flow rates for full scans indicate optimal flow rates of 100-200 μL/min. Flow injection and LC/MS data indicate good reproducibility for repeated injections. However, if power to the ultrasonic nebulizer is turned off, there is a significant decrease in sensitivity and reproducibility. LC/MS analysis of tricyclic (20 ng/component) and phenothiazine (100-150 ng/component) drug mixtures yield clear ion chromatograms and "clean" mass spectra consisting of the protonated molecular ions. Data for the LC/MS separation of a mixture of four triazine herbicides is shown in Figures 2 and 3.

For LC/MS of peptide mixtures, data can be acquired in real time at sufficient resolution (R=1500, 9 sec/scan, scan range m/z = 200-1400) to resolve the isotopic envelope of doubly and triply charged ions, aiding in the identification and molecular weight determination of the peptides.

LC/ESMS Characterization of Small Molecule Mixtures in Industry

Kevin L. Duffin, James P. Doom, Fred D. Hileman and David G. Corley, Monsanto Corporate Research, Monsanto Company, St. Louis, MO, 63198.

Liquid chromatography/electrospray mass spectrometry was used to characterize unknown natural product mixtures generated in fermentation broths, These natural products were biologically active in suppressing prostaglandin formation in an inflammation screening assay. LC/MS, LC/MS/MS and LC/CID/MS were used to help identify the structure of the active components. Active fractions were also characterized by ^{1}H and ^{13}C NMR to completely identify the unknown structures.

Two fermentation broths contained compounds that exhibited nanomolar or subnanomolar activity in suppressing prostaglandin formation. When separated by C-18 reversed-phase liquid chromatography, the first broth was shown to contain numerous components, but only one of these components exhibited substantial activity in the prostaglandin assay. The LC chromatogram obtained with in-line UV and electrospray mass spectrometric detection indicated the elution position of the active component, which yielded a $(M+NH_4)^+$ and $(M+H)^+$ at m/z 520 and 503, respectively, in the LC mass spectrum (not shown). A library search of compounds with a molecular weight of 502 amu that exhibited similar UV absorbance tentatively identified the compound as verrucarin A (Figure 1). The MS/MS spectrum of the compound then confirmed this tentative assignment. Verrucarin A is a known potent antagonist of protein synthesis and was active in the prostaglandin assay because it inhibited synthesis of cyclooxygenase, which is an enzyme involved in conversion of arachidonic acid to prostaglandins. A second fermentation broth that also antagonized prostaglandin production was found to contain actinomycin D using the same procedures outlined above. Actinomycin D also inhibits protein synthesis.

Other compounds present in the verrucarin A fermentation broth were found to be structurally related to verrucarin A by a LC/CID/MS experiment. In this experiment the separated compounds are collisionally-dissociated in the mass spectrometry source region. With good chromatographic separation, the CID mass spectrum obtained from this procedure using a single quadrupole mass analyzer closely mimics the MS/MS spectrum of the compound obtained on a triple quadrupole mass analyzer [1]. Figure 2 compares the selected ion LC/CID/MS and parent ion LC/MS/MS chromatograms that are monitoring formation of the m/z 231 product ion. This common product ion results from the conserved ring structure shown in Figure 1. The bioactivity differences between these structurally related compounds suggest that the macrocylic region of verrucarin A is important for its potent activity and that the conserved ring structure is not so important. Figure 3 compares the LC/CID/MS spectrum and MS/MS spectrum of another of the eluents in the verrucarin A fermentation broth. The mass spectra are nearly the same and both contain the product ion at m/z 231.

LC/MS and LC/CID/MS are extremely useful in helping to identify active components in natural product mixtures. Comparison of LC/CID mass spectra of eluents from the same natural product source often leads to identification of structurally similar compounds. Comparison of common structural features of these compounds to their activity profiles leads to structure/activity relationships that can quickly be exploited by medicinal chemists. The efficiency and additional information obtained by LC/MS characterization of unknown natural products makes its use more desirable than mass spectrometric characterization of active components fractionated from an LC column in an off-line fashion.

Liquid Chromatography (LC)/Particle Beam (PB) and Thermospray (TSP)/Mass Spectrometry (MS) in Environmental Analyses

U. S. Environmental Protection Agency
Office of Research and Development
Environmental Monitoring Systems Laboratory
Cincinnati, Ohio 45268

Most organic environmental analyses are multi-analyte determinations of small molecules (MW < 400) extracted from often complex matrices along with sometimes considerable background material. Users of environmental data are very sensitive to analytical costs but demanding of accurate identifications and accurate and precise concentration measurements at low µg/L or µg/kg concentrations. These "keep it good but cheap" requirements have led to the widespread use of high resolution gas chromatography/mass spectrometry (GC/MS) for the simultaneous qualitative and quantitative determinations of 60 or more analytes in a sample. Because of the typically large number of analytes, the emphasis on qualitative accuracy, and the concern for minimizing costs, selected ion monitoring data acquisition is uncommon and full spectra data acquisition dominates the business.

Although a tremendous amount of research has been devoted to developing LC/MS methods for multi-analyte determinations of non-volatile compounds, no present LC/MS method can match the broad capabilities of present GC/MS methods for amenable compounds. Furthermore, when compared to GC/MS, a significantly smaller number of environmentally significant compounds have been identified as candidates for LC/MS analyses. For example, although over 50 compounds and mixtures are currently regulated in drinking water and have established maximum contaminant levels (MCLs) under Safe Drinking Water Act regulations, only the following 10 are candidates for LC/MS analyses:

Compound	Maximum Contaminant Level (micrograms/L)
carbofuran	40
dalapon	200
dinoseb	7
2,4-dichlorophenoxyacetic acid	70
diquat	20
endothall	100
glyphosate	700
oxamyl	200
picloram	500
2(2,4,5-trichlorophenoxy) propionic acid	50

Currently several different methods must be used to monitor this short list of compounds. The acidic compounds are usually converted into methyl esters and analyzed by GC or GC/MS. The other compounds are determined using high performance liquid chromatography, post column derivatization for some compounds, and detection with conventional detectors such as fluorescence or ultraviolet absorption. In order to minimize monitoring costs and ensure maximum qualitative accuracy, a single LC/MS method for this group of compounds would be ideal. However, no LC/MS method has been developed that can be used to adequately monitor even a few of these compounds simultaneously.

A few additional non-volatile compounds may be regulated in drinking water over the next few years. These include the herbicide, aldicarb, two of its oxygenated metabolites, and a series of chloro-and bromoacetic acids that are formed by chlorine disinfection of drinking water. Although methylation and GC or GC/MS may be used for the acids, no satisfactory LC/MS method is available for the free acids, aldicarb, or its metabolites. A number of other non-volatile compounds appear on various hazardous substances lists, but regulation is unlikely until evidence of significant environmental occurrence is available.

Present LC/MS methods, based on thermospray and particle beam techniques, have been limited to research and a few specialized analyses. Thermospray is useful to distinguish the relatively innocuous diphenylamine from the relatively hazardous N-nitrosodiphenylamine[1]. Particle beam LC/MS has been applied to a quantitative study of the pesticide, rotenone, in river water.

Better and more comprehensive LC/MS technologies are needed for environmental research to aid in the discovery and solution of environmental health and ecological problems. Better and more comprehensive LC/MS technologies are also needed to provide routine monitoring tools and allow expansion of environmental monitoring to more compounds and classes of compounds.

INTRODUCTION

The marriage of LC with MS was initially one of compromises. Long analysis times imposed by solvent, buffer or flow rate restrictions and the trade off in MS sensitivity or specificity limited the usefulness of the technique. Developments in the areas of LC, LC/MS interfaces and in MS have overcome some of these problems permitting the monitoring of non volatile and unstable polar organics in complex matrices. This paper will highlight current techniques using (1) high speed LC and (2) electrospray MS (ES-MS) to determine nonvolatile components in biological or environmental matrices.

EXPERIMENTAL

Separations were performed on 2.1 x 150 mm, 0.32 x 150 mm C_{18} columns or 0.32 x 150 mm perfusion LC columns. The 2.1 mm i.d. column was coupled to the ES-MS using a 50:1 split resulting in a flowrate of 4-6 µL/min into the interface. The flow from the 0.32 mm columns (10 µL/min or 60 µL/min for the perfusion column) was directly coupled to the ES interface. The electrospray-MS system was an HP 5989 equipped with a HP electrospray interface and an ultrasound nebulizer (Analytica of Branford) or a Finnigan MAT Ion Trap Mass Spectrometer (ITMS) with an electrospray interface from Analytica of Branford.

RESULTS AND DISCUSSION

The advantages of LC are obvious for resolving nonvolatile components in complex matrices. Incompatibilities between LC and the LC/MS interface due to solvent choice or flow rate and disadvantages of long analysis times have been minimized through the use of high speed perfusion LC columns and ultrasonic nebulization in ES. Perfusion chromatography offers tremendous speed advantages while minimizing problem due to diffusional broadening. Chromatographic separation of six β-lactams in milk, neuropeptides in plasma or aromatic amines in water can be completed in less than 5 minutes. These rapid separations are a result of the high flowrate (60 µL/min) through the 0.32 mm i.d. perfusion column. Normally this flowrate is too high to achieve optimal ES sensitivity, but with ultrasonic nebulization perfusion columns can be directly coupled to the ES interface without a significant loss in signal intensity. Operation of the ultrasonic nebulizer resulted in less than 20% variance in ion current for flow rates from 5 to 60 µL/min flowrate. Furthermore, many solvent and buffer combinations used in the LC separation of the antibiotics, peptides or aromatic amines studied could be employed with minimal compromise of electrospray-MS operation. Ultrasound minimizes the variability in ES response from differences in nebulization of the liquid, due to surface tension or viscosity. Therefore, solvent systems incorporating 80-90% water, 0.1% TFA, or higher molarities of buffer (>10 mM) could be used in ES determinations with minimal losses in sensitivity. On the other hand, operation of the electrospray interface without the

ultrasonic nebulizer resulted in a decrease in ion current by a factor of 5 for 0.1% TFA or a factor of 2-3 for 25 mM heptafluorobutyric acid.

Electrospray ionization has the capability to ionize nonvolatile and thermally unstable compounds without loss of structural information associated with gentle ionization processes. Electrospray can generate molecular ions (e.g., $[M+H]^+$) from pg quantities of β-lactam antibiotics, neuropeptides or aromatic amines. Fragment ions for identification or confirmation can be generated in the electrospray transport region or by the use of ion trap mass spectrometry (ITMS). Collisional activation in the transport region of the electrospray interface resulted in higher product ion yields, a large range of collisional energies and is nearly universal. However, this method is often less specific since all ions present in the transport region undergo collision induced decomposition (CID). The use of the MS/MS capabilities of the ITMS reduces this problem due to the isolation and excitation of a chosen ion. This approach will produce specific CID product ions for the particular compound of interest, but limits the analysis to only a few chosen target compounds. Perfusion LC/electrospray MS using CID provided the specificity to detect target β-lactams (ampicillin, amoxicillin, cephapirin, cloxacillin, cetiofur and penicillin G) in milk, target neuropeptides (α-MSH, ACTH, β-endorphin, α-endorphin and dynorphin A) in plasma or target aromatic amines (chloro, nitro, hydroxy, and methyl anilines; chloro, nitro and amino naphthylamines and benzidine) in wastewater streams. The matrix did not interfere with the LC/MS determination or confirmation of these lower molecular weight molecules.

CONCLUSIONS

LC/Electrospray-MS provides the sensitivity and specificity to determine a variety of lower molecular weight molecules These determinations have been greatly aided using perfusion chromatography to reduce separation times to under five minutes. The ultrasound nebulizer enables near optimal electrospray MS response using flowrates, aqueous levels or buffers used in perfusion chromatography that have historically resulted in up to an order in magnitude decreases in signal intensity.

Summary

A LC/MS/MS assay for the quantitation of coeluting corticosteroids in a serum matrix was developed and implemented utilizing a Finnigan MAT APCI source. Pg detection and quantitation levels were easily acheived. The assay was determined to be linear over 3.0 orders of magnitude with precision of <10% RSD over the linear range of the standard curve. Total data system control of critical source, instrument and peripheral parameters provided total automation of the corticosteroid assay.

Introduction

Prednisone metabolizes to prednisolone in a biological system. Accurate quantitation of prednisolone in a serum matrix is a considerable challenge by non-specific HPLC detectors. This is due to the presence of endogenous hydrocortisone in serum which coelutes with prednisolone using a conventional HPLC separation. An LC/MS/MS assay was developed to simultaneously quantitate prednisolone, hydrocortisone and prednisone in a serum matrix.

Experimental

The assay was performed utilizing a Finnigan MAT TSQ® 700 mass spectrometer and APCI source in the positive ion SRM mode. The APCI vaporizer temperature used was 575° C and a capillary temperature of 150°C was utilized for this assay. The SRM conditions specific to each compound are given in Figure 1. HPLC separations were performed on a 50 x 4.6 mm, 3 µm , 20% carbon loaded C_{18} Phenomenex column, utilizing an LDC 4100 MS pump, 4100 UV detector at 240nm, and an Autometric 4100 Autosampler. An isocratic mobile phase of 60/40 MeOH/H_2O at 1.0 ml/min and 20 µl injection volume was employed.

Data

Figure 2. illustrates the MS/MS spectrum of prednisone which is representative of the SRM spectra for the corticosteroids for this assay. Figure 3. shows the chromatography of the methyl-prednisolone internal standard in the serum blank. The UV and SRM chromatograms of 500 pg of the corticosteroids on column are illustrated in Figure 4. Figure 5. is a standard curve for prednisolone which represents a linear range of 3.0 decades. Finally, figure 6. is a table of the statisitcs for the assay which demonstrates precision over the linear range of the standard curve of <10 %RSD.

Comparison of Thermospray and Ionspray for the Analysis of Drug Conjugates. Patrick J. Rudewicz,[1] Robert F. Stack and Charles D. Kennedy, Department of Drug Metabolism and Pharmacokinetics, Sterling Winthrop, Rensselaer, NY 12144; Thomas R. Covey and Takeo Sakuma, Perkin-Elmer Sciex, 55 Glen Cameron Road, Thornhill, Ontario L3T 1P2, Canada.

Since 1985 liquid chromatography-tandem mass spectrometry (LC-MS/MS) has played a significant role in the identification of drug metabolites. The majority of these studies have utilized thermospray ionization (TSP) for LC-MS analysis. Although TSP has proven useful for generating molecular ions for phase I metabolites, it has been unreliable for generating molecular ions for the more polar phase II drug conjugates. The application of heat to the TSP vaporizer often causes thermal degradation of the conjugate. For example, glucuronide conjugates of hydroxylated metabolites are often converted to the corresponding aglycone during the thermospray ionization process, resulting in the formation of an apparent molecular ion for the primary metabolite, not the conjugate. Similar thermal decomposition is observed with sulfate conjugates. Thermal decomposition of the conjugate to the primary metabolite often leads to conflicting results in metabolism profiling studies: the thermospray spectrum indicates a primary metabolite, but the LC retention time is indicative of a more polar compound. Additionally, with thermospray ionization, the weak molecular ion intensities for drug conjugates often preclude the use of MS/MS scans as a screen for these compounds in biological matrices.

The use of ionspray (pneumatically-assisted electrospray) offers an attractive alternative for the analysis of thermally-labile drug conjugates.[1] With ionspray, sample ionization is achieved at ambient temperature; hence thermal decomposition is minimal, facilitating the analysis of polar conjugates. In this study, both TSP and ionspray were used to identify the biotransformation products of zanoterone in man. Zanoterone is an androgen receptor antagonist currently in clinical trials for treatment of benign prostate hyperplasia.

EXPERIMENTAL SECTION

Dosing and Urine Collection. Six healthy male volunteers were administered a single 400 mg oral dose of ^{14}C-zanoterone (0.26 µCi/mg). Urine samples were collected from each subject over various time intervals for 240 hr.

Sample Preparation. 3 mL of combined (0-24 hr) urine containing ^{14}C-labelled metabolites were acidified with 40 µL of glacial acetic acid and applied to a conditioned Bakerbond C8 solid-phase extraction cartridge. The column was washed with 6 mL of water and the metabolites eluted with 3 mL of methanol. The samples were brought to a final volume of approximately 500 µL using a Savant Model AS290 Automatic SpeedVac concentrator. 100 µL of the urine extract was injected onto an LC column for the TSP experiments. 1 µL was used for the ionspray experiments.

The thermospray experiments were done using a Finnigan MAT TSQ 700 triple quadrupole mass spectrometer equipped with a TSP 2 ion source. The operating conditions were: vaporizer, 90 °C, ion source block, 200 °C, repeller, 40 volts. For the CID experiments, argon was used as a collision gas at a pressure of 1 millitorr. The collision energy (quadrupole 2 offset voltage) was 30 eV (E_{lab}).

The ionspray experiments were done on a Perkin-Elmer/Sciex API III triple quadrupole mass spectrometer with an ionspray interface. The ionspray voltage was -3350 V. For the CID experiments, the collision energy (E_{lab}) was 70 eV and the collision gas was argon at a pressure of 8.7 x 10^{14} atoms/cm^2.

DISCUSSION

After oral administration of ^{14}C-zanoterone, 20 % of the dose was excreted as four metabolites (A-D) in urine as determined by LC-flow scintillation experiments. Initially, TSP LC-MS/MS experiments indicated the presence of monohydroxylated metabolites; however, their LC retention times indicated more polar structures. These results and the poor sensitivity of TSP led us to analyze these samples by ionspray LC-MS/MS.

Upon CID, the protonated molecular ion of zanoterone (m/z 417) fragments to give a major ion of m/z 339 which corresponds to loss of the methyl sulfonyl group. This fragmentation corresponds to a neutral loss of 78 amu; hence it was hypothesized that a neutral loss scan of 78 amu could be used to identify any metabolites of zanoterone which contain the methyl sulfonyl moiety. Figure 1 is a contour plot of a negative ion neutral loss (78 amu) ionspray experiment. In this plot, the signal at each m/z is plotted as a function of retention time with increasing ion intensity represented in the Z direction. Although this neutral loss experiment was done using a crude extract of urine, the four metabolites (A-D) are immediately evident. Examination of their ionspray spectra indicated that all four metabolites are conjugates: A is a glucuronide of a hydroxylated metabolite (M-H)$^-$ m/z 607, B is a sulfate of a hydroxylated metabolite (M-H)$^-$ m/z 511, C is a glucuronide of zanoterone (M-H)$^-$ m/z 591and D is a sulfate of zanoterone (M-H)$^-$ m/z 495. One peak in this plot, with a retention time between metabolites A and B had not previously been seen using either TSP LC-MS or LC with scintillation detection. The spectrum of this metabolite, labelled A', is shown in Figure 2 and contains an ion of m/z 527 as the base peak which corresponds to the (M-H)$^-$ ion of a dihydroxylated sulfate conjugate. Examination of the peaks in the contour plot with m/z values less than the molecular weight of zanoterone indicated that they are not drug-related. From this one ionspray neutral loss scan, all of the major biotransformation pathways of zanoterone in man were determined.

CHARACTERIZATION OF LOW MOLECULAR WEIGHT, THERMALLY LABILE ANALYTES USING CAPILLARY SUPERCRITICAL FLUID CHROMATOGRAPHY/MASS SPECTROMETRY (SFC/MS)

*** J. David Pinkston, Donald J. Bowling, and Claudia A. Smith, The Procter & Gamble Company, Miami Valley Laboratories, P.O. Box 398707, Cincinnati, OH 45239-8707**

With respect to gas chromatography/mass spectrometry (GC/MS), SFC/MS using CO_2 as mobile phase offers a solvating mobile phase, lower analysis temperatures, and reduced volatility requirements. With respect to liquid chromatography/mass spectrometry (LC/MS), packed-column SFC/MS offers greater speed of analysis (thanks to higher diffusion coefficients) and the possibility of using longer columns and achieving higher plate counts (thanks to lower mobile-phase viscosities). Open-tubular-column SFC offers greater column inertness and a simpler interface to the traditional electron/chemical ionization (EI/CI) source, with its flexibility and good sensitivity. This combination of features offers advantages for the characterization of thermally labile or "active" analytes. ("Active" compounds refers here to compounds that interact strongly with active sites in chromatographic systems.) In fact, early workers in the field predicted that SFC/MS might provide a route to the separation and mass spectral characterization of thermally labile compounds [1,2]. The mobile phase most commonly used in open-tubular-column SFC, CO_2, is nonpolar. This limits practical applications of SFC/MS using this mobile phase to relatively nonpolar analytes. But within this realm there exists a multitude of thermally labile or active analytes of significant industrial importance which are not amenable to gas chromatography, but which can be chromatographed and characterized by SFC/MS. SFC/MS thus provides an alternative to LC/MS for the characterization of these types of analytes.

We've used open-tubular-column SFC/MS for the characterization of thermally labile or active compounds such as organic peroxides, derivatized organo-phosphates, amines, and selenium sulfides. The instrumentation consists of a custom-built SFC system, a modified commercial interface, and a TSQ-700 triple quadrupole mass spectrometer [3]. Studies involving peroxides have been especially useful in mapping out the parameters critical for success with thermally labile materials. In fact, SFC with CO_2 mobile phase offers a unique advantage in the characterization of acyl peroxides. Certain degradation pathways of these compounds, such as the unimolecular and the higher order pathways shown below, generate CO_2.

Unimolecular Decomposition:

R-COO-OOC-R ↔ 2 R-COO· (1)

2 R-COO· ↔ **CO_2** + R-COO-R (2)

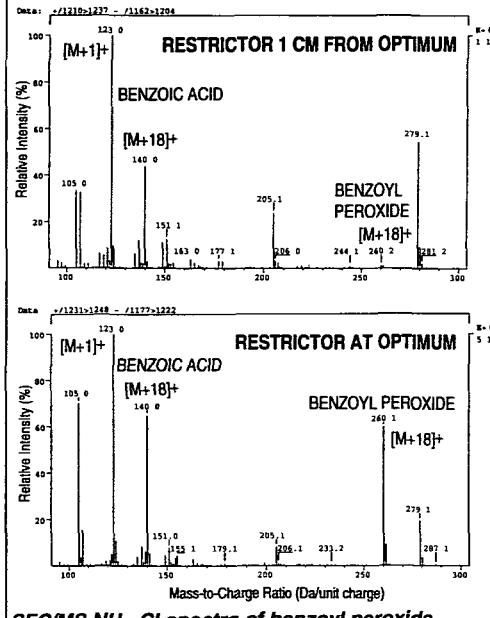
Chain Reaction:

R-COO· + R-COO-OOC-R ↔ **CO_2** + R-COO-R + R-COO· (3)

We expect that the high pressure of CO_2 in the SFC system will inhibit these degradation pathways. (Evidence that these reactions are reversible exists [pers. comm., D. Bjorquist, P&G].)

In the course of our investigations we have established guidelines for the characterization of peroxides by open-tubular SFC/MS. As would be expected, low column, interface tip, and ion

source temperatures give the best results (maximums of 70 °C, 140 °C, and 140 °C, respectively, for benzoyl peroxide). We use short (2-5 m), thick film (0.5 µm) columns. High linear velocity (10-20 cm/s at 100 atm and 100 °C for a 50-µm i.d. column) *restrictors provide less degradation than* restrictors with linear velocities more typical of open-tubular SFC (1-2 cm/s). The importance of the position of the restrictor aperture with respect to the ion source is illustrated in the figure at left, showing two NH_3 chemical ionization spectra of benzoyl peroxide. In the upper spectrum, the tip of the restrictor is positioned 1 cm from the optimum position in the direction of the oven (away from the ion source). The protonated molecule, 123 Da/unit charge (*m/z*), *and the ammonium adduct ion*, m/z 140, of benzoic acid (the primary decomposition product under these conditions) dwarfs the ammonium adduct ion of the intact benzoyl peroxide, at m/z 260. (The ions at m/z 205 and m/z 279 are in the background.) The lower spectrum shows a dramatic increase in the relative abundance of the ammonium adduct ion of benzoyl peroxide when the restrictor tip is placed at the optimum position. The optimum position for the tip of the restrictor corresponds to the ion-source end of the interface probe, approximately 1 cm from the ion source ion volume. The chromatographic data indicate that the decomposition occurs in the restrictor and ion source region, not on the column. Other influences we have investigated include the co-injection of a free-radical-chain-reaction inhibitor, and the use of an alternate mobile phase, N_2O.



SFC/MS NH_3 CI spectra of benzoyl peroxide showing influence of restrictor position

The straightforward interface of open-tubular SFC to the traditional EI/CI ion source has been useful in experiments involving thermally labile species. For example, negative CI provided the most intense signal in SFC/MS separations of heat- and light-sensitive selenium sulfides [4]. Unfortunately, the negative CI spectra were dominated by low molecular weight fragment ions and provided little structural information. Electron ionization with electron energies of 150 eV, 70 eV, and 20 eV was used to obtain copious structural information [4].

PROFILING OF BACTERIAL METABOLITES BY ON-LINE CAPILLARY LIQUID CHROMATOGRAPHY - ELECTROSPRAY MASS SPECTROMETRY.

G.J. Feistner

Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010.

For about fifteen years now, I have been involved in the characterization of bacterial metabolites, with an emphasis on their importance as virulence factors and cell-cell communication. Mass spectrometry has always been an integral part of the structure elucidations, but mostly after extensive isolation and purification protocols. More often than not, I found that the metabolites of interest had been previously described, although at the time, they were not known to be produced by the particular organisms. Thus, the introduction of electrospray was most welcome, because with its assistance it seemed possible to expedite such analyses by on-line LC-ES-MS and LC-ES-MS/MS. I have since used these methods extensively for metabolic profiling of wildtypes, mutants, cosmid bank clones, and the study of environmental influences. These applications are now routine.

For example, I am interested in the evaluation of siderophores as virulence factors in fire blight, a bacterial disease of apples and pears caused by *Erwinia amylovora*. The first step in this investigation was the identification of the siderophores. LC-ES-MS/MS quickly identified them as proferrioxamines based on their characteristic fragmentation at their peptide and/or hydroxamate bonds [1]. A total of 20 proferrioxamines were identified on grounds of, for example, their ability to loose a succinylamino hydroxyaminopentane subunit. Of these, five, namely X_8, X_9, T_{4-6}, remain to be fully characterized. Fifteen have been identified as proferrioxamines D_2, E, G_1, G_{1t}, G_{2a-c}, T_1, T_2, T_3, T_7, T_8, X_1, X_2, X_7, with T_{1-8} being novel tetrameric hydroxamates and T_3 and X_7 being novel diaminopropane containing proferrioxamines. The latter were readily recognized based on their loss of a succinylamino hydroxyaminopropane unit, while the novel tetrameric proferrioxamines were readily identified based on the superimposability of their product ion spectra onto the ones for the trimeric hydroxamates. The fragmentation pattern of the proferrioxamines, which is believed to involve transfer of α-hydrogen atoms from the succinyl subunits, is still under investigation because the latter cannot explain why in the cyclic proferrioxamines every other peptide/hydroxamate bond is especially susceptible to fragmentation. Instead, hydrogen transfer may occur between two nitrogen atoms involving the sterically and energetically favorable formation of succinylimide rings. We plan on corroborating this hypothesis by deuteration studies.

LC-ES-MS was found to be a valuable tool to rapidly confirm the incorporation of deuterium-labeled and other precursors and to study environmental influences on the metabolic profiles. For *Streptomyces* it has been reported that external diamines but not succinic acid analogues are incorporated into proferrioxamines, Thus, it was not a priori clear whether external (deuterated) succinic acid would be incorporated by *E. amylovora*, but this has now been confirmed. On the contrary, malic acid, which is a hydroxylated succinic acid and a prominent constituent of apple and pear, does not get incorporated into proferrioxamines but appears to prevent their cyclization. In the presence of malic acid, proferrioxamine G_1 is the major proferrioxamine, whereas in its absence the cyclic proferrioxamines D_2 and/or E are the most abundant. Siderophore profiles are being used as taxonomic markers. The finding that these profiles are heavily dependent on environmental factors makes it necessary to obtain these profiles under standardized conditions. With regard to our understanding of the virulence mechanisms of fire

blight, it will be necessary to perform corresponding studies in planta. For these, we will be able to take advantage of the excellent sensitivity of our on-line capillary LC system.

Proof that the proferrioxamines are necessary for *E. amylovora* to establish itself in planta has to come from mutants that are unable to produce these siderophores and that can be shown to be avirulent but to regain virulence upon reconstitution of the defective gene. LC-ES-MS has proved to be a good method to verify the phenotype of transposon mutants and recombinants and I have been able to correct several wrong assignments based on less sensitive and less specific assays. It remains a non-trivial problem to distinguish between true biosynthetic and regulatory mutants. Virulence studies with regulatory mutants would not allow us to arrive at a definitive conclusion as to whether proferrioxamines are indeed virulence factors because we would not know how they would behave in planta. The best proof for biosynthetic mutants is the demonstration of accumulated proferrioxamine intermediates. Thus far we have not been able to do so, in part because our present capillary chromatography is not suited for very hydrophilic components such as the expected biosynthetic intermediates. It will be necessary to develop appropriate derivatization schemes or to employ different chromatographic systems. Such modified LC-ES-MS methodology will also be needed for verifying success in generating the desired biosynthetic mutants by homologous recombination. It is important to note that the latter approach has only become feasible with the structural identification. Another lesson learned from the structure determination is that, because of likely multiple biosynthetic routes for the proferrioxamines, several mutations may be necessary to achieve the desired mutants. Previous mutation attempts have all been aimed at generating single site mutants.

Interest in *E. herbicola* arises from the potential use of this epiphyte in the biological control of fire blight. Not all strains of *E. herbicola* are inhibitory. LC-ES-MS showed a clear difference between the metabolic profiles of one inhibitory and two non-inhibitory strains. The non-inhibitory strain produced the same proferrioxamines as *E. amylovora*, whereas the inhibitory strain produced different, as yet uncharacterized siderophores. This lead to the hypothesis that siderophores that cannot be utilized by*E. amylovora* may perhaps prevent it from multiplying due to iron starvation. Because recent taxonomic studies have reclassified the numerous strains in the *E. herbicola/Enterobacter agglomerans* group into *Pantoea dispersa* and *Pantoea agglomerans,* it was of interest to investigate whether there was a correlation between virulence, siderophore production, and *Pantoea* species. It was found that *P. agglomerans* is a proferrioxamine producer whereas *P. dispersa* is not. However, analysis of an additional inhibitory strain revealed that proferrioxamine producing strains of *E. herbicola* may also be inhibitory, consistent with the general consensus in the field that the various *E. herbicola* strains have developed multiple inhibitory mechanisms.

E. persicinus is a newly discovered species and its potential for causing disease is not yet known. LC-ES-MS readily proved that *E. persicinus* produces proferrorosamine A, which has been implicated as a virulence factor in plant diseases caused by *Erwinia rhapontici*. This finding suggests that *E. persicinus* may also be a plant pathogen.

In conclusion, it has been shown that LC-ES-MS can play an important role in the metabolic profiling of bacterial metabolites, in the monitoring of mutageneses and directed fermentations, and, via differential profiling of virulent and avirulent strains, in the elucidation of microbial virulence mechanisms.

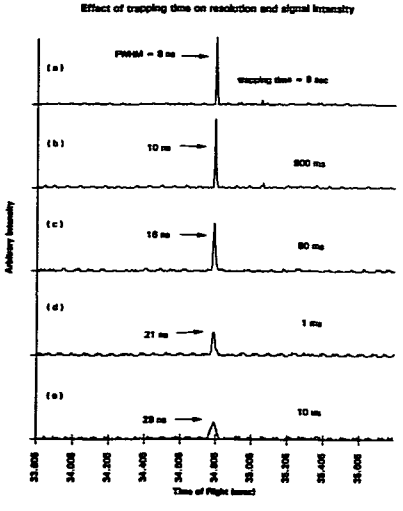
Electrospray and Plasma Source Ionization Using an Ion Trap Storage/Reflectron Time-of-Flight Mass Spectrometer

*Benjamin M. Chien, Steven M. Michael, and David M. Lubman
Department of Chemistry, University of Michigan, Ann Arbor, MI 48109

The main goal of this work is to interface various API sources including electrospray and plasma source ionizations to time-of-flight devices by using a quadrupole ion trap as a front end source [1]TOF is known for its speed and high mass measurement capability with high transmission. TOF is intrinsically a pulsed ionization technique while ions produced from most API sources are continuous The conventional method in converting a continuous ion beam into a pulse ion beam called beam deflection[2] provides very low duty cycle. Recently, another method called orthogonal extraction[3] was developed to improve the duty cycle. However, the duty cycle is only ~ 0.005% when operated at a pulse repetition frequency of 10 Hz. Higher duty cycle can be achieved by using higher rate such as 5 KHz but this rate is not practical for real time application because the data storage is still limited by the speed of the computer. In contrast, by using a quadrupole ion trap as the front end source for TOF, a nearly 100% duty cycle can be achieved independent of pulse repetition frequency. This is because all the ions that are sampled into the vacuum are stored in the ion trap device and upon applying a dc voltage to the exit endcap all the ions are ejected into the time of flight tube for mass analysis This results in a significant improvement in enhancing the sensitivity over the orthogonal



extraction method, especially when operated at a low pulse repetition frequency In addition, high resolution is also achieved in using this method. This can be attributed to a tight ion packet formation owing to the collisional cooling of the ions with background gases inside the trap. It is shown in the Figure 1 that the storage capabilities of the device provide enhanced resolution and sensitivity as the storage time is increased.[4] A resolution of nearly 2100 at m/z 79 is demonstrated using external injection from the atmospheric pressure DC plasma source when a storage time of 9 sec is used before ejection. Further, as shown in Figure 2, a resolution of ~ 3300 at m/z 1060 is demonstrated using external injection from an electrospray ionization source into the trap with a storage time of 931 ms. Figure 3 shows the bovine heart cytochrome C (MW 12,327) spectrum. The multiple charged peaks from +5 to +12 were observed. The charged state of +5 corresponds to a trapped ion of m/z 2,466.[5] The detection limit of this device is also demonstrated with liquid injection techniques for a typical sample and found to be less than a single femtomole.

STRUCTURE ELUCIDATION STRATEGIES APPLIED TO TAXOL AND TAXANES

Edward H. Kerns, Kevin J. Volk, Susan E. Hill and Mike S. Lee
Bristol-Myers Squibb Pharmaceutical Research Institute, Wallingford, CT 06492

Analytical strategies involving tandem mass spectrometry have been developed for the rapid structure elucidation of trace components of mixtures commonly encountered in pharmaceutical discovery and development research. These strategies provide rapid structural results compared to common lab-scale methods involving scale-up, fractionation and indivividual spectroscopic analysis of each component. However, they are more rapid and require only small samples. The strategies of LC/MS and LC/MS/MS Profiling and MS/MS Screening, developed for screening drug metabolites directly from physiological fluids (1,2) and natural products in crude extracts (3), were applied for the rapid structure elucidation of trace taxol analogs in crude plant extract mixtures, bulk drug substance, and degraded samples. These strategies combine HPLC separation, UV spectroscopy, full scan MS and MS/MS analysis in one instrumental configuration, thus paralleling common lab-scale trace mixture analysis strategies.

LC/MS and LC/MS/MS Profiling was applied to the direct structure elucidation of taxanes in mixtures, such as impurities and degradation products in bulk drug. Photodiode array UV analysis of HPLC separations were obtained for chromatographic comparisons and to obtain class and substructure specific data from UV spectra. Ionspray LC/MS chromatograms are consistent with LC/UV chromatograms Full scan LC/MS, obtained in the same analysis, provided molecular weight and purity analysis. Ammonium acetate in the mobile phase produced abundant $(M+NH_4)^+$ ions for taxanes using ionspray ionization Application of a consistent HPLC separation involving an E.S Scientific pentafluorophenyl HPLC column and gradient elution with acetonitrile and 2mM ammonium acetate buffer provided a consistent database of taxane chromatographic and MS characteristics useful for the rapid identification of taxanes in subsequent samples MS/MS substructural analysis was performed on each unknown component during HPLC elution, eliminating the need to scale-up and isolate individual compounds. Interpretation of the structures of unknown taxanes was based on the CID fragmentation of taxol. Prominent substructural ions of taxol include· m/z 286^+ characteristic of the sidechain, m/z 569^+ characteristic of the taxol core ring structure, and m/z 509^+ characteristic of the deactyl core ring structure Examples of taxanes elucidated include 10-deacetyl taxol and taxol n-pentyl analog (taxol C)

MS/MS Screening was applied to the screening of crude biomass extracts. Using parent MS/MS screens based on CID fragment ions characteristic of taxol substructures the molecular ions of taxanes containing taxol substructures were observed. For example a parent screen of m/z 509^+ indicated compounds containing the taxol core ring substructure Subsequent daughter MS/MS analysis of the molecular ions observed by these screens rapidly provided information used to interpret the structure of the unknonw taxane. An example of a taxane elucidated in this manner is 7-xylosyl deacetyl taxol.

These structure elucidation strategies are applicable to a wide range of pharmaceutical research and development projects, including: natural products, metabolites, impurities, degradation products, biomolecule sequencing, biochemical reaction products, and in-vivo and in-vitro on-line monitoring via direct microdialysis sampling into the mass spectrometer.

PETROLEUM POLARS CHARACTERIZED BY COMPOUND CLASS SEPARATION AND ON-LINE LC/MS

C. S. Hsu, K. Qian and W. K. Robbins
Exxon Research and Engineering Co.
Route 22 East, Clinton Township, Annandale, NJ 08801

Petroleum polars contain a variety of compounds, particularly hetero-atom containing, which are often difficult to characterize by mass spectrometry because of the complexity, polarity and/or thermal instability of the molecules. The abundance of polars is generally increased with increasing boiling range of the crude oil. Separation into compound classes can eliminate some of the uncertainties of compound identification by MS. Using on-line liquid chromatography-mass spectrometry (LC/MS) the selectivity of separation can also be evaluated. We recently have examined the polars of a 650-1050°F distillate of a Californian crude of high heteroatom content.

A combination of traditional clay and silicic acid chromatographies have been used to isolate three fractions designated "neutral nitrogen", "basic nitrogen" and "complex polars" on the basis of model compounds (see Figure 1).[1] By subjecting the "neutral nitrogen" and "basic nitrogen" fractions to on-line LC/high resolution MS analysis, we have been able to understand some of the overlaps encountered in chromatographic studies. In this instance, we used the normal phase chromatographic system previously described for the resolution of heavy oils into saturates, 1-4 ring aromatics, and polars on a dinitroanilinopropyl (DNAP) silica.[2, 3] Figure 2 shows the compound distribution in these elution regions for the "neutral nitrogen" and "basic nitrogen" fractions. Some diaromatic and triaromatic hydrocarbons are noticeably present in the "neutral nitrogen" fraction due to imperfect Biosil separation. High resolution MS reveals that the nitrogen compounds present are mainly $C_nH_{2n-15}N$ (carbazoles) and $C_nH_{2n-21}N$ (benzocarbazoles) appearing in the tetraaromatic and polars regions, respectively, as shown in Figure 3. Deuterated ammonia chemical ionization (ND_3/CI) demonstrated that all of the carbazoles (pyrrole benzologs) contain one exchangeable hydrogen (see Figure 4) and therefore none has N-R functionality where R is an alkyl substituent attached to the nitrogen atom.

Another interesting result of these combined chromatographies was the finding that the "basic nitrogen" fraction was dominated by NO_x (x = 1 and 2) species rather than pyridine benzologs (Figure 5). Chromatographically, while the open column isolated these components in the "basic nitrogen" fraction the LC technique lumped them in polars. A combination of ancillary techniques, ND_3/CI, x-ray photoelectron spectroscopy (XPS), and infrared (IR), have been used to characterize the NO species as cyclic imides (lactams). In addition, some non-aromatics with NO_2 composition were found; because these compounds show three exchangeable hydrogens in ND_3/CI experiment consistent with molecules containing both amino and acidic functionalities.

At the present time, we are continuing to use the LC/MS approach in evaluating alternative chromatographic techniques in order to obtain better resolution of the petroleum polars. In addition, the existing techniques are being extended to other crudes for comparison with the Californian crude studied here.

BOND ENERGIES AND ELECTRONIC STATES OF UNSATURATED ORGANOMETALLIC COMPLEXES

F. A. Khan, C. Haynes, N. F. Dalleska, R. H. Schultz, and P. B. Armentrout

Chemistry Department, University of Utah, Salt Lake City, UT 84112

The sequential bond dissociation energies (BDEs) of a series of cationic organometallic complexes in the gas-phase have been measured by collision-induced dissociation (CID) studies in a guided ion beam tandem mass spectrometer [1,2,3,4]. We are interested in two interrelated facets of the resulting information: 1) how do the BDEs vary as the metal approaches saturation (either electronically, in terms of reaching a stable 18-electron valence configuration, or sterically, in terms of reaching a complete solvent shell), and 2) can these BDEs help elucidate how the valence electrons on the metal reorganize to accommodate the ligand shell. The latter consideration may be thought of in terms of ligand field theory and may allow an understanding of how to use ligands to manipulate the electronic configuration at the metal center.

Table 1 lists results for a few representative systems. In addition, complete experimental data has now been obtained for the following systems: $Co(CH_4)_n^+$, n = 1-4; $Ni(N_2)_n^+$, n = 1-4; $Ni(NO)_n^+$, n = 1-3; and $M(H_2O)_n^+$, n = 1-4 where M = Ti, V, Cr, Fe, Co, Ni, and Cu. For the carbonyl results shown in Table 1, the sums of the BDEs agree with literature thermochemistry in all three cases. In general, our results are in good agreement with other CID [5,6] and theoretical [7] work on $M(H_2O)^+$ and $M(H_2O)_2^+$; with equilibrium [8] and CID [9] measurements on $Cu(H_2O)_3^+$ and $Cu(H_2O)_4^+$; and with equilibrium [10] and theoretical [11] work on $Co(CH_4)_n^+$, n = 1-3.

It might be anticipated that if the bonding is largely due to simple electrostatic interactions (as seems likely for all ligands considered here but NO), the BDEs would gradually decrease as the ligand sphere is increased due to ligand-ligand repulsions. Table 1 shows that this is true for the nickel carbonyl cations, but for the chromium and iron carbonyl cations, the sequential BDEs exhibit nonmonotonic changes. $Cr(CO)_6^+$, $Fe(CO)_5^+$ and $Ni(CO)_4^+$ are all expected to have doublet ground states because they are formed by removing a single electron from an 18-electron complex. In contrast, the atomic ions have ground states of $Cr^+(^6S)$, $Fe^+(^6D)$, and $Ni^+(^2D)$, such that only in the nickel system are there no spin changes as CO ligands are added to the atomic metal ion. Therefore, we attribute the nonmonotonic changes observed in the BDEs of $Cr(CO)_6^+$, $Fe(CO)_5^+$, and several other systems to the electronic reorganization that must occur at the metal center as the strength of the ligand field increases with increasing ligation. This explanation is supported by studies that vary the ligand field strength by changing the type of ligand and also by studies of ligand exchange reactions. The comparison of the $Fe(CO)_n^+$ and $Fe(CH_4)_n^+$ systems illustrates the former effect. Note that $D[Fe(CH_4)_2^+\text{-}CH_4]$ *exceeds* $D[Fe(CO)_2^+\text{-}CO]$, a fairly nonintuitive result that can be rationalized in terms of spin changes.

Substituent Effects and Solvation Energetics from Electron-Transfer Equilibrium Studies of Gas-Phase Metal Complexes

David E. Richardson, Matthew F. Ryan, Paul Sharpe,
Md. Nazrul I. Khan, and John R. Eyler
Department of Chemistry, University of Florida, Gainesville, Florida 32611-2046

We have focused in this research on the use of gas-phase ion techniques to study the reactivity and thermodynamic properties of gas-phase metal complexes that have direct solution analogs. The opportunity then arises to address several fundamental questions regarding the intrinsic chemistry of such systems as well as to gain insight into the effect of solvation on reactivity and thermochemistry. The principal instrumental technique used in this research is Fourier transform ion cyclotron resonance mass spectrometry (FTICR-MS).

Several electron-transfer equilibrium (*ETE*) studies of organometallic and coordination complexes have been completed.[1-7] This method allows the accurate determination of the free energies of ionization and/or electron attachment of a molecule under thermal conditions in the gas phase (eqs 1 and 2).

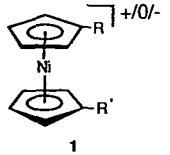
$$ML_n \rightleftharpoons ML_n^+ + e^- \qquad \Delta G_i^\circ \text{ (ionization)} \qquad (1)$$

$$ML_n + e^- \rightleftharpoons ML_n^- \qquad \Delta G_a^\circ \text{ (electron attachment)} \qquad (2)$$

The values of $\Delta G_a^\circ$and ΔG_i° can be derived from the equilibrium constant of equilibria of the general type shown in eq 3, where A is a reference compound with known ΔG_a° or ΔG_i° value (for anions or cations, respectively).

$$ML_n + A^\pm \rightleftharpoons ML_n^\pm + A \qquad \Delta G_{et}^\circ = RT \ln K_{eq} \qquad (3)$$

In general, we have used the data to interpret the thermochemistry and bonding of metal complexes, to give quantitative insight into solvation energetics by comparison to solution redox thermochemistry, and to provide a basis for the prediction of electronic substituent effects on the reactivity of transition metal catalysts.

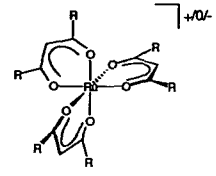


1

Two recent studies[1,6] have addressed the nature of alkyl substituent effects in transition metal complex oxidation-reduction energetics. ETE methods have been used to establish the gas-phase ionization and electron attachment energetics for nickelocene and several alkylated derivatives, (RCp)(R'Cp)Ni (1, R, R'= H, Me, Et, t-Bu).[1] Alkyl substituents larger than methyl decrease the ionization energy and increase the electron affinity relative to the parent (R = H) compound and are thus not uniformly "electron donating" in character. This result was not unexpected, since analogous alkyl effects are well known in the proton affinities and acidities of organic bases and acids in the gas phase. However, the poor solution electrochemical reversibility of the reduction couple for nickelocenes makes direct comparison to solution trends difficult.

Alkyl substituent effects in gas-phase *and* solution redox thermochemistry have *recently been studied for a series of ruthenium coordination complexes.*[6] The gas-phase ΔG_i° and ΔG_a° values (Figure 1) were compared to electrochemical oxidation and reduction half-wave potentials ($E_{1/2}$) for six ruthenium tris(β-diketonate) complexes (2, R = methyl, ethyl, *n*-propyl, *n*-butyl, *i*-propyl, and *t*-butyl). Gas-phase cations and anions are stabilized relative to the neutral by larger alkyl substituents, rendering ΔG_i° less endoergic and ΔG_a° more

exoergic as the alkyl group size increases. Analysis of the gas-phase data by a model of substituent effects based on polarizability and inductive contributions of a group shows that alkyl inductive effects are small in these complexes and that relative stabilities of gas-phase ions are primarily due to differences in polarizability of the alkyl substituents at the β positions.



2

Substitution of R = methyl in 2 with larger alkyl groups results in cathodic shifts in both oxidation and reduction $E_{1/2}$ values (in N,N-dimethylformamide), so the trends for solution and gas-phase reduction of the neutral ruthenium(III) complex are therefore reversed. Values of $\Delta\Delta G_{solv}^\circ$(0/-) range from -48 ± 5 kcal mol^{-1} (R = methyl) to -36 ± 5 kcal mol^{-1} (R = *t*-butyl), and these changes in $\Delta\Delta G_{solv}^\circ$(0/-) are identified as the cause of the reversal in the trends for *gas-phase and solution reduction free energies. In contrast,* $\Delta\Delta G_{solv}^\circ$ *(0/+) values all fall in* the range -19 to -16 kcal mol^{-1} and show no correlation with the size of the alkyl substituents.

This work was supported by a grant from the National Science Foundation.

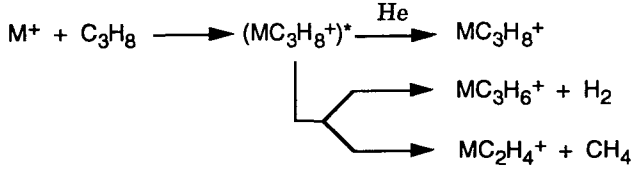
Mechanistic Details of First Row Transition Metal Ions, Sc^+ through Zn^+, Reacting with Propane

*Petra A.M. van Koppen, Paul R. Kemper and Michael T. Bowers
Department of Chemistry, University of California, Santa Barbara, California 93106
Chris Haynes and Peter Armentrout
Department of Chemistry, University of Utah, Salt Lake City, Utah 84112

Introduction

Studies of atomic transition metal ions reacting with simple alkanes in the gas phase have given detailed insight into the mechanism and energetics of these reactions. Metal ions react with propane to form a collision complex, which can be stabilized by collisions with helium or it can dissociate to eliminate molecular hydrogen or methane.



Propane is the smallest alkane to undergo elimination reactions with first row transition metal ions. The electrostatic attraction is sufficient to overcome intrinsic barriers that may be associated with insertion into a C–H or C–C bond. Because these reactions are inefficient, small changes in the potential energy surface greatly effect the reactivity. In a recent study of Co^+ reacting with propane, tremendous progress was made towards the understanding of C–H and C–C bond activation.[1] We have extended this study to include the reactivity of all first row transition metal ions, Sc^+ through Zn^+, with propane.

Observed branching ratios for adduct formation, CH_4 and H_2 elimination were found to vary widely for first row transition metal ions.[2] At 300K and 0.75 Torr of He, adduct formation dominates for V^+ through Zn^+. CH_4 and H_2 elimination are observed for Fe^+, Co^+ and Ni^+ whereas only dehydrogenation and no demethanation is observed for V^+. For Sc^+ and Ti^+, H_2 elimination dominates over CH_4 elimination and over adduct formation. Exclusive adduct formation is observed for Cr^+, Mn^+, Cu^+ and Zn^+.

There are several factors which influence the reactivity of metal ions with propane. The ground state valence electron configuration ($3d^n$ or $4s3d^{n-1}$) of the metal ion, the reaction thermochemistry, crossing to low lying excited state surfaces and sd hybridization are all important factors in determining the reactivity. Several experimental techniques as well as theoretical calculations are necessary to understand the details of these reactions.

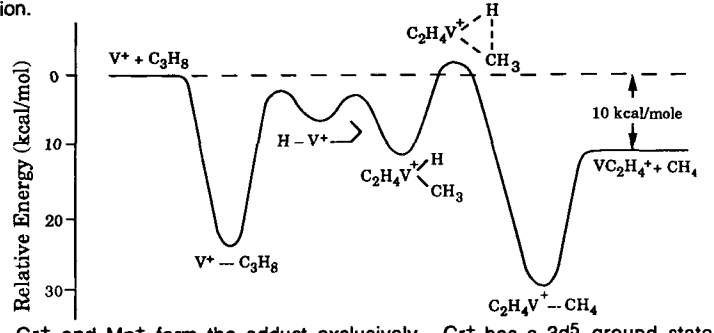
Results and Discussion

For Fe^+, Co^+ and Ni^+ reacting with propane, the total cross sections for H_2 and CH_4 elimination are observed to be inefficient, less than 15% of the collision limit, and decrease with the extent of deuteration. The inefficiency of the reaction indicates a rate limiting transition state exists along the reaction coordinate. The decrease in cross section with extent of deuteration indicates this rate limiting transition state is associated with C–H bond activation. Kinetic energy release distributions for H_2 and CH_4 loss from nascent $M(C_3H_8)^+$ complexes for Fe, Co and Ni were measured. For H_2 loss the distribution is bimodal. Studies with propane-2,2-d_2 and propane-1,1,1,3,3,3-d_6 indicate that both initial primary and initial secondary C–H bond activation are involved. The kinetic energy release distribution for demethanation is statistical. Modeling the reaction cross sections, the H, D isotope effect

and the kinetic energy release distribution for demethanation using statistical phase space theory allows for accurate determination of the energy of the C–H bond activation transition state.

The ground state valence electron configurations for Fe^+, Co^+ and Ni^+ are $4s3d^6$, $3d^8$ and $3d^9$ respectively. Adduct formation is the dominant product for all three systems despite the repulsive 4s electron for ground state Fe^+. State selected studies[3] indicate that this is due to a crossing from the $Fe^+(^6D\ 4s3d^6)C_3H_8$ ground-state surface to the $Fe^+(^4F\ 3d^7)C_3H_8$ first excited-state surface where the propane is more strongly bound.

Adduct formation is the most abundant channel for V^+ reacting with propane but only H_2 elimination is observed at thermal energy. A threshold for CH_4 elimination is observed in the ion beam studies. The transition state for C–H reductive coupling was calculated to be 10 kcal/mol higher than the H–H transition state due to the directionality of the sp^3 hybrid orbital on carbon versus the spherically symmetric s orbital on hydrogen.[4] Consequently, it appears the transition state for C–H reductive coupling is very near or above the threshold for reaction.



Cr^+ and Mn^+ form the adduct exclusively. Cr^+ has a $3d^5$ ground state electron configuration which is very stable. The elimination reactions are essentially thermoneutral and are therefore not observed. For Mn^+, however, the elimination reactions are more exothermic than for V^+. In this case, the elimination channels are not observed because of the relatively weak electrostatic interaction of the $4s3d^5$ ground electronic state of Mn^+ with propane resulting in the C–H insertion transition state energy being above the energy of the reactants.

$Sc^+(4s3d)$ and $Ti^+(4s3d^2)$ are the only transition metal ions in the first row where the *elimination reactions dominate over adduct formation. The key difference is that for early* transition metal ions, the s and d orbitals are close enough in energy to efficiently hybridize. Ab initio calculations indicate Sc^+ and Ti^+ form two equivalent sd hybrid orbitals with maximum charge density at 90° angles, ideal for forming two covalent bonds.[5] As a result, the C–H bond activation transition state energy is significantly lowered and elimination is favored over adduct formation.

Accurate Bond Dissociation Energies for $M^+\bullet(H_2)_n$ Clusters

Paul R. Kemper,* J. Bushnell, G. von Helden, and M.T. Bowers
Dept. of Chemistry, University of California, Santa Barbara, CA 93106 U.S.A.

Using temperature dependent equilibrium studies, clustering enthalpies (ΔH°_T) and entropies (ΔS°_T) have been determined for $Na^+\bullet(H_2)_{1,2}$, $K^+\bullet(H_2)_{1,2}$, $Sc^+\bullet(H_2)_{1\text{-}4}$, $V^+\bullet(H_2)_{1\text{-}6}$ and $Co^+\bullet(H_2)_{1\text{-}7}$. In these experiments, the mass selected metal ions (M^+) are injected into a drift reaction cell containing 2-5 torr of pure H_2. The ions are moved through the cell with a small $\vec{E}$ field. At these pressures, sequential clustering readily occurs and

$$M^+\bullet(H_2)_{n-1} + 2H_2 \rightleftharpoons M^+\bullet(H_2)_n + H_2 \qquad (1)$$

equilibrium is quickly established. The ions exiting the cell are quadrupole mass analysed and the resulting equilibrium constants calculated:

$$K_{eq} = M^+\bullet(H_2)_n \cdot 760 \,/\, M^+\bullet(H_2)_{n-1} \cdot P_{H_2} \qquad (2)$$

A plot of ΔG° (= $-RT \ln K_{eq}$) vs temperature has slope = ΔS°_T and intercept = ΔH°_T. The enthalpies are converted to bond dissociation energies (BDE = $-\Delta H^\circ_0$) using a statistical mechanical fit to the ΔG° vs T data.

The Na^+ and K^+ clusters are the most weakly bound (BDE $Na^+\bullet H_2$ = 2.52 kcal/mol, BDE $K^+\bullet H_2$ = 1.88 kcal/mol). The corresponding D_e for $Na^+\bullet H_2$ is in good agreement with theoretical calculations by Siska and coworkers[1] who find the binding to be electrostatic (charge induced dipole and charge-quadrupole) with negligible electron exchange. The H_2 ligands are essentially unperturbed, and are oriented perpendicular to the M^+–H_2 bond axis.

The Co^+ clusters are far more strongly bound[2] (BDEs for $Co^+\bullet(H_2)_{1\text{-}7}$ are 18.2, 17.2, 9.6, 9.6, 4.3, 4.0 and 0.8 kcal/mol, respectively). Theoretical calculations by Partridge and Bauschlicher[3] show that the H_2 ligands are only slightly perturbed. The increase in BDE is largely due to three factors: $H_2\ \sigma \rightarrow Co^+4s$ donation (stabilizes ion); $Co^+\ d\pi \rightarrow H_2\ \sigma^*$ (increases Co^+ d–d exchange); $3d\sigma \rightarrow 4s$ hybridization (reduces repulsion on bond axis). Again, experiment and theory agree well. The pair-wise behavior of the BDEs reflects the symmetry of the clusters. That is, the first and second hydrogens approach the Co^+ 180° apart and experience very similar interactions. The same is true of the third and fourth hydrogens. The reduction in BDEs for this pair is due largely to steric interference. The fifth and sixth hydrogens complete a quasai-

octahedron and are again more weakly bound due to increased ligand–ligand interference.

The $V^+\bullet(H_2)_n$ clusters have BDEs of 10.1, 10.7, 8.8, 8.8, 4.5 and 9.4 kcal/mol for n = 1 to 6, respectively. Preliminary calculations by Maitre and Bauschlicher indicate that the lower BDEs (relative to Co^+) are due to reduced $M^+\ d\pi \rightarrow H_2\ \sigma^*$ back donation. The increase in BDE in $V^+\bullet(H_2)_6$ is accompanied by a large increase in ΔS°, indicating that a large increase in the BDEs in the existing $V^+\bullet(H_2)_5$ occurs when the sixth H_2 is added. This indicated increase in bond strengths is probably due to a transition from a high spin metal center $V^+\ {}^5D$ g.s. ($3d^4$) to a low spin configuration $V^+\ {}^3F$ ($3d^4$). Calculations indicate the low spin cluster should be more strongly bound.

The $Sc^+\bullet(H_2)_n$ BDEs are 5.1, 6.5, 5.7 and 5.3 kcal/mol (for n = 1 - 4, respectively). Theory by Harrison[4] and Upton and Rapeé[5] shows the $Sc^+\bullet H_2$ to be an inserted covalent H–Sc^+–H, however, a large barrier is predicted for the insertion and necessary spin flip.[5] The present experiments indicated that a barrier is present (~10 kcal/mol, based on the forward reaction efficiency). The experimental BDE (5.1 kcal/mol) also agreed fairly well with the 2.0 kcal/mol calculated by Harrison.[4]

Work in progress on other $M^+ + H_2$ systems and on $M^+ + CH_4/C_2H_6$ systems.[6]

Gas-Phase Ion-Molecule Reactions of Atomic Transition Metal Ions with Polar Organic Molecules: Ground Versus Excited Electronic State Reactions

*Vincent J.B. Oriedo, Touradj Solouki and David H. Russell
Department of Chemistry
Texas A&M University
College Station, TX 77843

Studies of gas-phase ion-molecule reaction chemistry of atomic transition metal ions (M^+) with small organic molecules have shown that the ability of M^+ to activate C-C and/or C-H bonds is strongly influenced by the electronic state of the reactant M^+. We recently reported the use of charge-exchange ion-molecule reaction chemistry for measuring the metastable electronic states of M^+.[1] Using this method we estimate that excited states of Fe^+ ions with energies of *ca.* 3.5 eV are formed when Fe^+ is produced by electron impact of $Fe(CO)_5$. We are now using this method to probe the reaction dynamics of Fe^+ with polar organic compounds.

In this paper we report on the reaction chemistry of Cr^+ and Fe^+ with N-methylformamide, N,N-dimethylformamide and N,N-dimethylacetamide. The electronically excited metal ions are denoted $(M^+)^*$ and the ground state metal ions are denoted $(Fe^+)^o$. These studies were performed in a differentially pumped two-section FT-ICR cell. The reactant Cr^+ and Fe^+ were formed in region 1 of the two-section cell by electron impact of $Cr(CO)_6$ and $Fe(CO)_5$, respectively. The reactant M^+ is then isolated using ion-ejection methods and transferred to region 2 of the two-section ion cell where it is allowed to react with the respective neutral amide. The reaction time was varied between 0 and 500 milliseconds.

$(Cr^+)^*$ and $(Fe^+)^*$ ions reacts with N-methylformamide, N,N-methylformamide and N,N-dimethylacetamide to form dissociative and non-dissociative charge-transfer products. The charge-transfer product ion reacts further with a second amide molecule (denoted "A") by proton-transfer to form a protonated amide molecule $[(A+H)^+]$. The enthalpies of the charge-transfer reactions are presented in Table 1.

$(Fe^+)^*$ ions also react with N-methylformamide, N,N-methylformamide and N,N-dimethylacetamide to form C-N bond insertion products. On the basis of molecular orbital arguments[2] we suggest that the $(Fe^+)^*$ ions giving rise to C-N bond insertion products consist of the $3d^7$ electron configuration. That is, $(Fe^+)^*$ ions with the $3d^7$ configuration have an empty 4s-orbital that can accept a pair of electrons from the C-N bond of the amide molecule and spin-paired d-electrons to donate in the C-N antibonding orbital. It should be noted that the $(Fe^+)^o$ ion has a $4s^13d^6$ electron configuration but reacts to form C-N bond insertion products. The reactivity of the $(Fe^+)^o$ ion to form bond insertion products is attributed to the curve-crossing between the ground state $^6D(4s^13d^6)$ and the first excited state $^4F(3d^7)$.[3] The $(Fe^+)^o$ ion also reacts to form the $(Fe\text{-}A)^+$ adduct ion.

In contrast to $(Fe^+)^o$ and $(Fe^+)^*$ ions, the $(Cr^+)^o$ and $(Cr^+)^*$ ions do not react to form C-N bond insertion products. Cr^+ ions reacts to form the $(Cr\text{-}A)^+$ adduct ion. Figure 1 depicts the relative reaction rates of Cr^+ with N-methylformamide, N,N-dimethylformamide, N,N-diethylformamide and N,N-dimethylacetamide. $(Cr^+)^*$ ions also react by collisional relaxation.

In summary, reactions of Fe^+ with amides yield charge-transfer, Protonated, metal adduct, and C-N bond insertion product ions and these ions can provide structural information of the reactant neutral amide. In contrast, Cr^+ does not react with amides to from C-N bond insertion products. Based on the ion-molecule reaction chemistry of Cr^+ with amides, Cr^+ can be used as a chemical ionization reagent for polar organic molecules.

Charge - transfer Reaction Pathway

$Fe^+ + A \longrightarrow A^{+\cdot} + Fe$

$\Delta H = I.E(A) - R.E\{Fe^+[^6D(4s^13d^6)]\}$

(1) N-Methylformamide
$\Delta H = +43.12$ kcal / mol (1.89 eV)

(2) N,N-dimethylformamide
$\Delta H = +27.90$ kcal / mole (1.21 eV)

(3) N,N-dimethylacetamide
$\Delta H = +20.52$ kcal / mole (0.89 eV)

$Cr^+ + A \longrightarrow A^{+\cdot} + Cr$

$\Delta H = I.E(A) - R.E\{Cr^+[^6S(3d^5)]\}$

(1) N-methylformamide
$\Delta H = +69.63$ kcal / mol (3.02 eV)

(2) N,N-dimethylformamide
$\Delta H = +54.42$ kcal / mole (2.36 eV)

(3) N,N-dimethylacetamide
$\Delta H = +47.04$ kcal / mole (2.04 eV)

ISOTOPIC FRACTIONATION IN THE FORMATION OF He_2^+

K.S. Griffith and G.I. Gellene, Department of Chemistry and Biochemistry, Texas Tech University, Lubbock, TX 79409-1061

Recently, it was observed in this laboratory[1] that under some conditions the clustering reaction of O_2^+ and O_2 to produce O_4^+ would equivalently incorporate heavy isotopes of oxygen up to 100 times their natural abundance levels. The explanation of this extraordinarily large non-mass dependent kinetic isotope effect (KIE) required the development of a new symmetry correlation scheme[2] which connected symmetry distinct rovibronic states of the isolated reactants with distinct electronic symmetries of the system in the interaction region independent of the detailed geometry of the collision complex. This correlation scheme provided a framework for identifying systems where non-mass dependent KIE's might be observed. In particular, a potential system is required to have an asymptotic degeneracy arising from either (1) one or both reactants being in a degenerate electronic state or (2) identical reactants in different electronic states. One of the simplest chemical systems which fulfills these requirements is the association reaction:

$$He^+ + He \xrightarrow{M} He_2^+ \qquad (1)$$

which is considered to consist of the two bimolecular reactions:

$$He^+(^2S_{1/2}) + He(^1S) \rightleftarrows (He_2^+)^* \qquad (2a)$$

$$(He_2^+)^* + He \rightarrow He_2^+ + He \qquad (2b)$$

In this case an asymptotic degeneracy arises from the inability to specify which atom is the $He(^1S)$ neutral and which is the $He^+(^2S_{1/2})$ ion when the atoms are the same isotope of He. Decreasing the internuclear separation removes this degeneracy, giving rise to the $^2\Sigma_u^+$ ground and $^2\Sigma_g^+$ first excited Born-Oppenheimer electronic states. This degeneracy is removed at all internuclear distances when the He isotopes are nonidentical because the different ionization energies of ^3He and ^4He energetically distinguish the two possible asymptotes. These energetic considerations are shown in the figure at left.

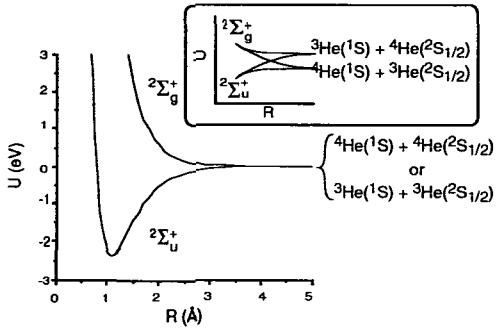

Figure 1. Potential energy curves relevant to collisions of $He^+(^2S_{1/2})$ and $He(^1S)$. The inset is qualitative.

Application of the symmetry correlation scheme to reaction (1) indicates that all of the He/He^+ collisions are capable of accessing the He_2^+ ground electronic state when the He isotopes are nonidentical, whereas only half the collisions of identical isotopes can do so. The direct kinetic consequence of this symmetry restriction is the prediction that the isotopically heteronuclear $^7He_2^+$ ions will be produced at approximately twice the rate of the isotopically homonuclear $^{6,8}He_2^+$ ions. This prediction was tested by a mass spectrometric study. He^+ ions were produced by electron ionization of room temperature $^3He/^4He$ mixtures at ion source inlet pressures of 10-1500 mTorr. Ions exiting the source were accelerated through 5 keV, magnetically mass resolved, and detected by a Channeltron electron multiplier. The results are shown in Figure 2. The near-equivalent enhanced formation of the nonsymmetric $^7He_2^+$ ion relative to that of either symmetric $^{6,8}He_2^+$ ion at low pressure clearly demonstrates the existence of a symmetry dependent (i.e., non-mass dependent) KIE in reaction (1). The apparent loss of the enhancement at increased pressure is best understood not as a loss of the KIE but rather as an increase in the importance of reactions like:

$$^7He_2^+ + {}^4He \rightarrow {}^8He_2^+ + {}^3He \qquad (3)$$

which have no symmetry restrictions and can serve to scramble the nascent isotopic distribution of He_2^+ ions.

Additionally, the results can be used to gain insight into the stabilization step since He is used as the third body. The independence of the zero-pressure KIE on $^3He/^4He$ ratio can be shown to indicate that stabilization occurs primarily without atom exchange, suggesting a role for large impact parameter *l*-changing collisions in the stabilization step. The zero-pressure KIE is approximately 50% larger than can be accounted for by the symmetry restriction alone, implying that an additional KIE is occurring in the stabilization step as well. A likely origin for this additional effect is that *l*-changing collisions for $(^7He_2^+)^*$ for which $\Delta l = \pm 1$ is allowed would be expected to be more efficient than for $(^{6,8}He_2^+)^*$ for which $\Delta l = \pm 2$ is the minimum *l* change.

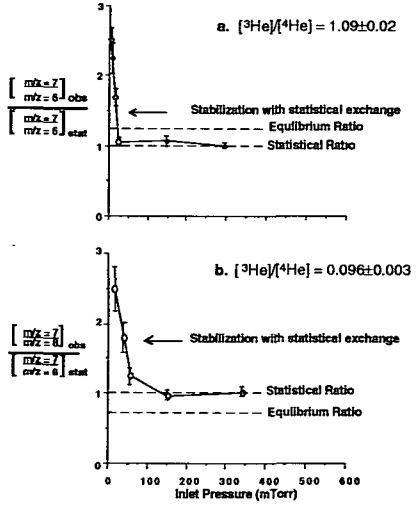

Figure 2. Statistically normalized ratios as a function of ion source inlet pressure.

FUNDAMENTALS OF TANDEM MASS SPECTROMETRY

Anil Shukla and *Jean Futrell
Department of Chemistry and Biochemistry, University of Delaware, Newark, DE 19716

Utilizing an unique crossed beam mass spectrometer apparatus (1), we have completed a suite of experiments providing accurate measurements of energy deposition, angular scattering, fragmentation patterns, and the translational energy dependance of these parameters for several model compounds These experiments have demonstrated dramatic changes in mechanism as a function of collision energy and have identified the "collision time" in which the activation step occurs as the singularly important variable in collisional activation. We have previously drawn attention to the importance of analyzing these experiments in the center-of-mass or collisional coordinates frame in order to separate out mass effects on the interpretation of data which necessarily must be taken in the laboratory frame These studies have shown, for individual molecules, interesting correlations with photoelectron spectroscopy (PIPECO), breakdown graphs, RRKM/QET theories and simple scattering theories. These correlations have been used by us, and others, to discuss such important issues as energy deposition, internal energy randomization, scattering dynamics and activation/dissociation lifetimes

In this paper we review briefly some of the general features of collisional activation mass spectrometry revealed in our experiments and discuss the extent to which simple models can be used to interpret general features of collisional activation of polyatomic ions. In particular, we demonstrate that the Massey Criterion for dependence of energy transfer efficiency on relative velocity provides quantitatively correct results for hydrocarbon ions, such as the propane molecular ion Our conclusion is that CID is accounted for quantitatively, both with regard to energy deposition and fragmentation processes, over a very broad range of collision energies (1 eV to 6 Kev) and a broad selection of scattering gases, by combining a modified Massey distribution with the breakdown graph of propane obtained using PIPECO measurements.

Figure 1 illustrates the remarkable accord between theory and experiment for the three primary dissociation products from collisional activation of propane cations carried out in collaboration with Prof. Gross at the University of Nebraska (2) In this figure the theoretical prediction is botained, as indicated above, by multiplying the breakdown graph for propane by the Massey function

$$P(E) \propto e^{-\frac{\pi \Delta E}{\hbar v}}$$

computer for the collision conditions of Fig 1 The experimental bar graph is in poor agreement as measured; however, when corrected for angular scattering effects measured using our scattering apparatus, the near-perfect agreement between theory and experiment illustrated in Fig 1 is obtained. Accordingly Fig. 1 demonstrates both strong support for the theoretical model and the severe impact of scattering on observed fragmentation patterns in CID.

One detailed test of the theoretical model is a comparison of calculated and experimental energy depositions as a function of collision energy. Essentially quantitative agreement is achieved Closer inspection of the details of the model reveals that the breakdown graph is the controlling factor for propyl ion and ethylene ion formation For ethyl ion the energy deposition function and breakdown graphs are equally important parameters. For more endothermic reactions the energy deposition function is the dominant factor.

The gratifying agreement of experiments with model predictions for the propane cation (and, by inference, other ions following RRKM/QET decay pathways) and the stark disagreement with data for acetone (3), nitromethane (4), SO_2 (5) and benzene (6) molecular ions supports the hypothesis that CID proceeds mainly from isolated electronic states for ions which have intramolecular energy exchange "bottlenecks" which impede energy relaxation. It will be shown that the ensemble of results support the hypothesis that decomposition from the ground state manifold is adequately described by the Massey function/QET model but electronically excited state decay is not.

In these cases coupling of upper and lower electronic state manifolds proceeds on crossing seams of the relevant hypersurfaces We suggest the role of impulsive collisions in inducing remarkably efficient ***T-E*** energy exchange is a very strong dependence of coupling coefficients on nuclear coordinates. According to this hypothesis the Franck-Condon factors for energy transfer in collisionally-perturbed molecular ions is dramatically different from that for isolated ions. Our results for these "pathological" molecules in which this effect is observed is rationalized by combining photoelectron spectroscopy information with molecular orbital descriptions of ground and excited states A predictive feature of this somewhat speculative scheme is that electronic state pathways are commonly found in pi-bonded heteroatomic molecules

These generalizations follow from the microscopic detail on reaction mechanisms deduced from simultaneous measurements of energy deposition and angular scattering in collisional activation mass spectrometry. A completely general feature is that back-scattering and large angle scattering are predominant dynamics features of CID reactions. This clearly implies that most collisional activation processes proceed via small impact parameter collisions, contrary to generally accepted mechanisms used for interpretation of tandem mass spectrometry experiments for the past 20 years. Extrapolation of these results and our conceptual understanding of CID dynamics to large molecule systems provides a partial explanation for the remarkable efficiency of collisional activation mass spectrometry.

Isotopomer Differentiation using Metal Ion Chemical Ionization Reagents

Yongqing Huang and Ben S. Freiser*
H. C. Brown Laboratory of Chemistry
Purdue University
West Lafayette, IN 47907

Catalytic hydrogenation of perdeuterated aromatic species generate selectively deuterated hydrocarbon species.[1] Detailed structural characterizations of these selectively deuterated end products hold the key to understanding the stereochemistry involved in the hydrogenation process. Proton NMR may be employed in limited cases where the sample consists predominantly of one component as a result of high regioselectivity and stereoselectivity during the hydrogenation. Even in these simple cases, however, the interpretation of the NMR spectra is not trivial and high resolution NMR instruments are needed to acquire spectra with enough useful structure information. The task becomes prohibitive for slightly more complicated mixtures of end products. Here we report a versatile technique to address such an analytical problem by using transition metal ions as chemical ionization reagents,[2] in conjunction with Fourier transform mass spectrometry.[3] This technique takes advantage of the intrinsic regioselectivity and stereoselectivity involved in the dehydrogenation of hydrocarbons by transition metal ions. In an elegant paper by Schwartz and coworkers, for example, they reported that in the gas-phase reaction of Fe^+ with octane-1,8-diol, chelation of the metal center by the terminal hydroxyl groups creates conformational configurations inducing regio- and stereo- selectivity during the dehydrogenation process.[4] However, in this work the presence of ring structures on the hydrogenation products creates regio- and stereo-specificity in their dehydrogenation by transition metal ions. Thus, the pattern by which dehydrogenation occurs permits differentiation of isotopomer structures.

All experiments were performed on an Nicolet FTMS-2000 equipped with a 3 Tesla Nicolet superconducting magnet and a dual cell[5] connected through a conductance limit, as well as an array of leak valves and pulsed valves permitting the introduction of various reagents.[6] Metal ions were generated by laser desorption of pure metal targets, mounted outside the magnetic field on the analyzer side, using a Nd:YAG laser operated at its fundamental frequency.[7] A static background pressure of 1-4 x 10^{-6} torr was maintained serving to cool the metal ions and for collision-induced dissociation experiments.[8-9]

The complete characterization of a hydrogenation end product requires the determination of isotopolog distribution and presence of isotopomers for each of isotopolog in the distribution. The former provides information on regioselectivity involved in the hydrogenation process and the latter provides information on stereoselectivity. A tetralin sample obtained from the niobium catalyzed homogenous hydrogenation of perdeuterated naphthalene has been shown by ^1H NMR to be the all cis isotopomer of $C_{10}H_4D_8$. This relatively simple sample was subsequently used to establish and validate the method developed in this study. Its isotopolog distribution was easily determined from its condensation reaction with Ag^+, confirming that tetralin-d_8 is by far the most predominant component, along with only minor amounts of other isotope impurities being present.

The following experiments indicate the presence of the all cis isotopomer of $C_{10}H_4D_8$. The reaction of Co^+ with tetralin gives mostly the double dehydrogenation product ion, Co^+-naphthalene, and a small amount of the condensation product ion, Co^+-tetralin. With the

knowledge that tetralin-d_8 is the main isotopolog, the deuterated tetralin sample gives mostly $2H_2$ and $2D_2$ loss, along with minor amounts of other dehydrogenation products. CID on carefully isolated Co(tetralin-d_8)$^+$ from the condensation reaction gives loss of $2H_2$, $2D_2$, as well as the appearance of Co^+ at higher energies. This indicated that the smaller amounts of dehydrogenation other than $2H_2$ and $2D_2$ are due to the presence of a minor amount of other isotopologs, provided conclusive evidence of regiospecificity and stereospecificity in the dehydrogenation process, and allowed the assignment of the single all cis isotopomer structure.

Subsequently, this methodology was applied to a sample of tetralin obtained by the niobium catalyzed heterogeneous hydrogenation of naphthalene-d_8.[10] While an isotopolog distribution pattern similar to that from the first tetralin sample was observed, the isolation of Co(tetralin-d_8)$^+$ and subsequent CID indicated that two isotopomers were present. Although the isotopomer with four hydrogen atoms on the same side of the ring was still the predominant structure, molecules with two deuterium atoms distributed on each side of the ring were also present, as indicated by a fragment corresponding to $CoC_{10}H_2D_6^+$ (loss of H_2 and D_2, or 2HD). This result is consistent with 1,2-dihydronaphthalene being formed and released during the heterogeneous hydrogenation reaction.[10]

In conclusion, this study indicates the feasibility of using transition metal ions as a class of unique CI reagents, coupled with MS/MS experiments involving isotope selection, to probe isotope distribution and stereo configuration. We are currently applying this method to a variety of other selectively deuterated species.

Transition Metal Cluster Anions: Periodic Trends in Oxidation and Chemisorption Reactions

Paul. A. Hintz, Elizabeth G. Kapiloff, Taeck-Hong Lee, Joseph Mwakapumba, and Kent M. Ervin,
Department of Chemistry and Chemical Physics Program,
University of Nevada, Reno, NV 89557

Gas phase transition metal clusters often exhibit strongly size-selective chemical reactivity. Relating the reactivity of clusters to their geometric or electronic structures is important, but problematic because there is limited experimental or theoretical information about the structures. Chemical reactions can probe structural features of the clusters. Chemisorption reactions are particularly useful in this regard, since it may be possible to determine the number and types of adsorption sites on a cluster. Several groups have studied chemisorption on neutral or cationic metal clusters;[1] examining anionic clusters allows us to differentiate reactivity effects due to cluster geometry or size from effects due to electronic configuration. Investigations of selected transition metal elements across and down the periodic table also help elucidate electronic and geometric effects in reactivity/structure relationships.

In this work, we employ Flow Tube Reactor (flowing afterglow) techniques to study the oxidation and chemisorption reactions of transition metal cluster anions. The metal cluster anions are produced by a metal cathode discharge source and are thermalized by 10^5 collisions with the helium buffer gas before interaction with the neutral reagent. The absolute thermal rates of cluster ion reactions are measured, along with product ion spectra.

For most of the metal clusters studied, oxidation by O_2 occurs rapidly via an etching-like process yielding small metal oxide anions containing 1-3 metal atoms. In contrast, the copper-group metals react slowly by addition of O_2. A strong even-odd reaction dependence is found for Ag_n^- clusters—the open-shell even n clusters add O_2 but the closed-shell odd n species are unreactive.

Chemisorption reactions with CO have been studied for titanium-, vanadium-, manganese-, nickel-, and copper-group metal cluster anions. The copper-group clusters are relatively unreactive, yielding only addition of one or two carbonyl groups, but the other metals tend to react rapidly by sequential addition of CO. For the nickel-group clusters, the rate of adsorption of the initial CO molecule on the cluster for all clusters sizes larger than three atoms is efficient, 50% or more of the ion-dipole collision rate.

When the CO concentration is increased, sequential CO additions to the metal cluster anions occur until a limit is reached where no further CO addition is observed. This behavior is shown in Fig. 1, which plots the $Pt_3(CO)_m^-$ product ion intensities as a function of the flow rate of CO in the flow tube reactor. For this case, the saturation limit is reached with the addition of six CO units. The triangular $M_3(CO)_6$ moiety with three terminal and three edge-bridging carbonyls is a common structural unit in condensed phase nickel and platinum complexes.

Fig. 2 plots the observed highest CO coordination numbers for various nickel-group clusters anions. The saturated products can be compared with known organometallic complexes and to the predictions of electron counting theories. In general, Ni_n^- clusters form saturated products that match expectations for a typical for an 18-electron transition metal, while platinum is less highly coordinated both for the gas phase cluster anions and known condensed phase platinum complexes. Palladium appears to be a bridging case, matching platinum for smaller cluster sizes while reaching

higher coordination numbers for clusters with $n > 5$. Cobalt and rhenium cluster anions have higher CO saturation limits, because they have more d-orbital based molecular orbital vacancies into which the CO ligands can donate electrons and form bonds. The skeletal structures consistent with our observed saturation limits for $M_6(CO)_m^-$ (Ni, $m=12$; Pd, $m=12$; Pt, $m=10$; Co, $m=15$) clusters, as predicted by Polyhedral Skeletal Electron Pair Theory, are shown in Fig. 3. For these clusters, compact skeletal structures with near maximum metal-metal bonding are indicated, and more open structures (chains, rings, or planar arrays) can be excluded.

THE NEGATIVE CHEMICAL IONIZATION REACTIONS OF THE ATOMIC OXYGEN RADICAL ANION WITH SELECTED ALKENES.

Joseph J. Grabowski,† Jeehiun Lee§ and Phillip K. Chou†
Departments of Chemistry,
†University of Pittsburgh, Pittsburgh, PA 15260
§Harvard University, Cambridge, MA 02138.

The atomic oxygen radical anion ($O^{\bullet-}$) is an extremely reactive species that is readily produced by electron ionization of nitrous oxide. Because of its importance in ionospheric chemistry and in the chemistry of flames and plasmas of various types, a great number of studies have been carried out on its chemistry with typical constituents of these environments. More recently, $O^{\bullet-}$ has been received attention as a practical reagent in negative ion chemical ionization (CI) mass spectrometry; among its special attributes are the ease of its production from readily available, easily handled, non-toxic precursors and the rapidity with which it reacts with essentially all molecules.[1] A special and unique feature of this *radical anion* is its ability to generate didehydro anions from many organic molecules. A didehydro anion results when a parent neutral, M, which possesses at least two hydrogen atoms, loses the equivalent of $H_2^{\bullet+}$ to generate a ion denoted as $(M\text{-}2H)^{\bullet-}$. For example, $O^{\bullet-}$ CI has been used to generate the radical anions of *o*-benzyne, vinylidene and a variety of carbenes; the radical anions thus generated have been investigated by a variety of techniques including ion-molecule reactivity studies, thermochemical measurements and negative ion photoelectron spectroscopy.

We have been interested in the detailed CI reactions of $O^{\bullet-}$ with organic molecules[2,3] and in the chemistry of the products thus formed.[4,5] As part of this ongoing characterization of the mechanisms and competitions inherent when the atomic oxygen radical anion reacts with organic compounds, we have examined the processes by which it reacts with propene, isobutylene, isoprene and 2,3-dimethyl-1,3-butadiene (DMB) in the flowing afterglow, under thermally equilibrated (298 K) conditions.

Of particular interest is the yield of the $(M\text{-}2H)^{\bullet-}$ from each alkene - these results are summarized in the table on the next page. Hydrogen atom dominates all of the alkenes except DMB, for which the didehydro anion is the major product (see Scheme on next page; similar reactions are observed for the other three alkenes as well). Since all four alkenes are less acidic than $HO^{\bullet}$, no proton transfer is observed *except* as a secondary reaction (the initial HO^- product ion reacting with a second equivalent of the alkene). Deuterium labeling studies have confirmed the structure of the distonic radical anion from DMB shown in the Scheme.

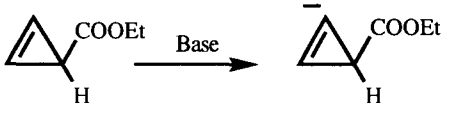
Antiaromatic Ions: The Formation, Reactivity, and Thermodynamic Properties of a Cyclopropenyl Anion

Roseann Kroeker and Steven Kass
Department of Chemistry
University of Minnesota, Minneapolis, MN 55455

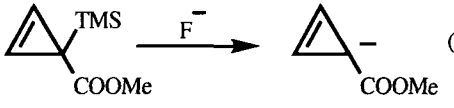
The generation of cyclopropenyl anions has been a long standing and elusive goal. The difficulty in forming these species has been attributed to antiaromaticity.[1] Our recent preparation of the diazirinyl anion (c-CHN_2^-) in a flowing afterglow[2] has led us to believe that substituted cyclopropenyl anions should also be accessible.

The reaction of 3-carboxymethylcyclopropene with a base produces the 3-carboxymethyl-1-cyclopropenyl anion (eq. 1). The vinyl position is the most acidic one in this molecule and ΔH_{acid} = 364 ± 3 kcal/mol.



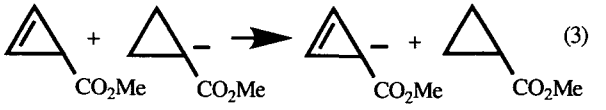
(1)

In order to generate the ion of interest we have made use of a procedure first developed by DePuy and coworkers i.e. fluorodesilylation.[3] In particular, methyl 1-(trimethylsilyl)-2-cyclopropene-1-carboxylate reacts with fluoride to afford 3-carboxymethyl-3-cyclopropenyl anion (eq. 2). This anion has been fully characterized



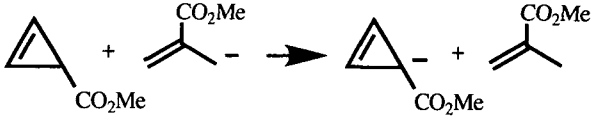
(2)

by reactivity, basicity, collision-induced dissociation, and computational studies. Its proton affinity is 391 ± 4 kcal/mol, it's 13 kcal/mol less stable than its saturated analog (eq. 3) and 14 kcal/mol less stable than it's corresponding acyclic (allylic) isomer (eq. 4). Consequently, this ion is antiaromatic.



(3)

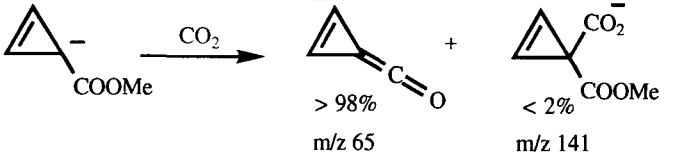
ΔH = +13 kcal/mol



(4)

ΔH = +14 kcal/mol

Not surprisingly, the 3-carboxymethyl-1-cyclopropenyl anion is very reactive. For example, it reacts with carbon dioxide to form >98% of the anion of triafulvenone (eq. 5). The structure of this ion was verified using labeled compounds, examining its



(5)

H/D exchange behavior, and by measuring its proton affinity (345 ± 3 kcal/mol) and comparing the result with theory (346.7 kcal/mol (MP2/6-31+G(d)//6-31+G(d)).

Our results suggest that methylcyclopropene carboxylate has a pK_A of approximately 44, and that cyclopropenyl anions are viable (and attractive) synthetic targets. Efforts along these lines are currently in progress.

Ion-Molecule Reactions of Dicoordinated Boron Cations

Hilkka I. Kenttämaa, Thilini D. Ranatunga, James M. Kennady and Varjira Nanayakkara
Department of Chemistry Purdue University, West Lafayette, IN 47907-1393

Boron cations with low coordination numbers are of interest as intermediates in solution reactions of substituted boranes.[1] However, solution studies are limited to ions with bulky substituents and at least one nitrogen-substitient that stabilizes the charge through π-back bonding. This is not true for the gas phase. We have used a dual-cell FT/ICR (Extrel FTMS Model 2001) to study dicoordinated boron cations with no strongly stabilizing substituents. The ions were found to be exceedingly reactive toward oxygen lone pairs in organic substrates, e.g., they rapidly dehydrate organic ethers by elimination of two neutral alkenes.[2] Quite unexpectedly, elimination of an alkene also occurs for carbonyl compounds. The mechanism of this reaction is discussed here.

Electron impact on boron compounds yields abundant dicoordinated boron cations.These ions react to yield two types of primary products with carbonyl compounds (R'C(O)R"; R'= alkyl; R"= H, alkyl): an allyl cation from abstraction of OH from the carbonyl compound by the boron cation, and an adduct of the boron cation and an aldehyde (R"C(O)H) through elimination of an alkene (see Figure 1). The structures of the product ions were verified by CAD through the use of reference ions with known structures.

The reaction of the borocations with carbonyl compounds is facile (efficiencies typically 0.6). The proposed mechanism for the generation of the two product ions are shown in Scheme 1. CH_3-B^+-CH_3 and CH_3O-B^+-OCH_3 yield a similar product distribution; hence, the oxygen atoms in the latter ion do not play an important role in these reactions. Examination of the reactions of CD_3O-B^+-OCD_3 show that the hydrogen atoms in the boron cation do not participate in H/D scrambling with the carbonyl compound.

Both the reactions are estimated to be highly exothermic. Formation of the boron cation as the final product is the faster but less exothermic of the two reactions. The

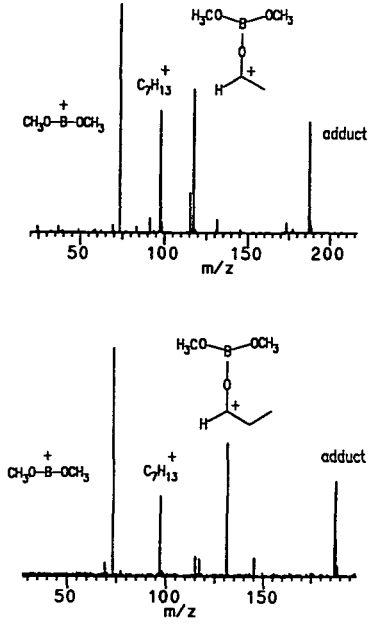

Figure 1. Reaction of (a) 2-heptanone and heptanone and (b) 3-heptanone with CH_3O-B^+-OCH_3.

overall enthalpy change associated with this reaction is fairly unaffected by the size of the carbonyl compound. However, the exothermicity of the reaction leading to abstraction of OH increases dramatically with increasing chain length, being ~19 kcal/mol more exothermic for hexanal than for pentanal. Hence, a strong size dependence is expected and observed: generation of the allyl cation dominates over formation of the boron cation for long-chain aldehydes and ketones (seven carbons or more).

The reactions discussed above are driven by the formation of the very strong B-O bond: generation of the initial addition product (Scheme 1) is estimated to be exothermic by as much as 80 kcal/mol. Much of the chemistry discussed above can be understood on the basis of acid-catalyzed dissociation reactions of carbonyl compounds.

The Structure Elucidation of Taxol Analogs and Impurities Using LC/MS and LC/MS/MS Profiling Protocols

Susan E. Hill, Edward H. Kerns, Kevin J. Volk and Mike S. Lee
Bristol-Myers Squibb Company, 5 Research Parkway, Wallingford, CT 06492

Structure elucidation strategies applied to samples from taxol research studies have resulted in a database of taxol analogs and impurities. This analytical strategy utilizes a systematic approach for the rapid identification of unknown impurities and taxanes which retain the key substructures of taxol. The first step of this methodology utilizes HPLC/UV/MS analysis to obtain chromatographic relative retention times, UV spectra, and full scan mass spectra of each component. Comparison of unknowns to known analogs provides information about polarity and difference in molecular weight relative to taxol. Product ion spectra of each unknown component are obtained on-line (LC/MS/MS) and compared to the product ion spectrum of taxol which is used as a template for subsequent structure elucidation (Figures 1 and 2).

This methodology utilized a Sciex API III triple quadrupole mass spectrometer equipped with an Ionspray interface. Chromatographic conditions included an ES Industries PFP column (25 cm x 4.0 mm) and an ammonium acetate : acetonitrile gradient run at a flow rate of 2.0 mL/min.. The separation was monitored on-line at 230 nm with a Perkin Elmer LC-235 diode array detector. CID was performed on the ammoniated molecular ion of each unknown component.

The database includes knowledge of more than 50 taxanes, including structures, molecular weight from full scan mass spectra, substructural characteristics from MS/MS analyses, HPLC chromatographic behavior, and UV spectra from on-line diode array detection. Taxanes having proposed structures based on LC/MS/MS profiling are often later isolated or synthesized and their proposed structures confirmed by analysis using the same LC/MS/MS protocols. Samples analyzed for the database include taxol degradation studies, taxol bulk drug substance, semi-synthetic taxol, taxol from plant cell culture, taxol from various yew species, and taxol metabolism samples.

The information included in this structural database has been utilized for many aspects of drug discovery and pharmaceutical development on taxol. This methodology allows for the rapid and systematic elucidation of taxol impurities and analogs on-line without the need to scale up or isolate individual components. The added dimension of mass separation allows for the identification of chromatographically co-eluting components which are often found in mixtures containing taxanes.

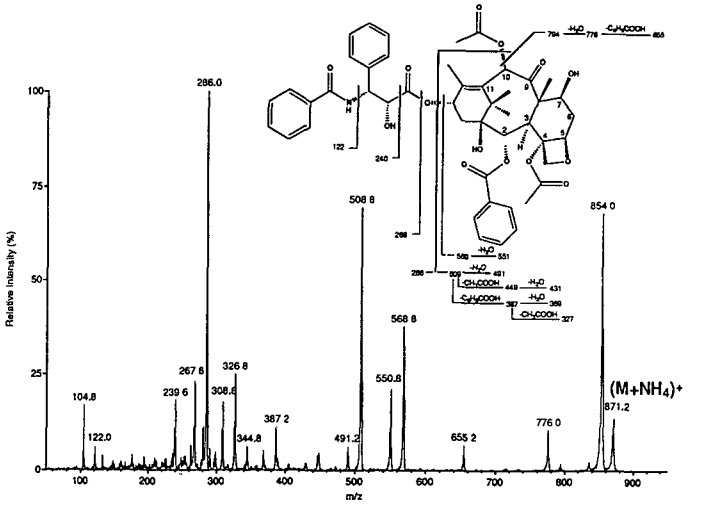

Figure 1. MS/MS substructural template of taxol.

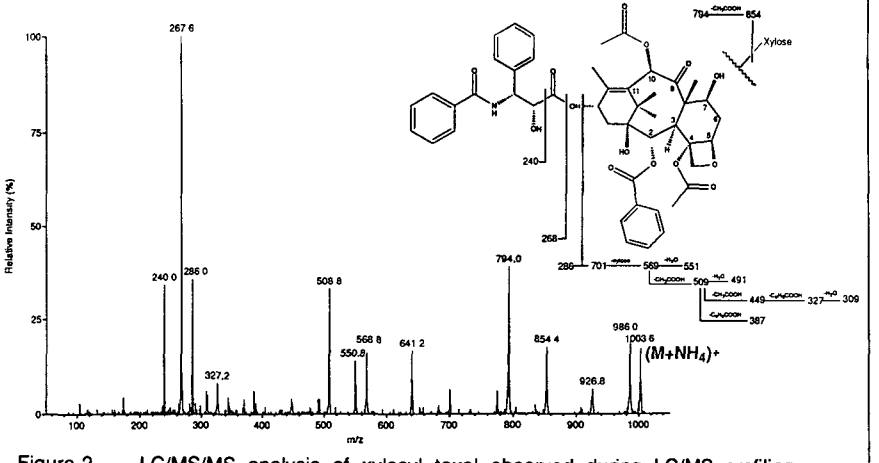

Figure 2. LC/MS/MS analysis of xylosyl taxol observed during LC/MS profiling. Proposed structure is based on comparison to the MS/MS substructural template of taxol.

Detection of Alkaloids by Positive Ion Thermospray LC/MS Using a Nonconventional Ion-Pairing Agent.

Mantai Z. Mesmer, Lorrie A. Lin, Rick A. Flurer and R. Duane Satzger, National Forensic Chemistry Center, United States Food and Drug Administration, 1141 Central Parkway, Cincinnati, OH 45202.

The Forensic Center is frequently called upon to analyze samples of material from incidents of consumer product tampering and counterfeiting. In such cases it is absolutely essential that the identity of adulterants or counterfeit products be unambiguously established when present. In addition adulteration or counterfeiting must be ruled out with certainty when a suspected tampering or counterfeiting has in fact not occurred. Because a false negative or a false positive could have costly consequences, there is no room for error. Therefore, mass spectrometric confirmation of identity is generally required.

Alkaloids are a group of nitrogenous bases that are derived from plants which have application as therapeutics and as rodenticides. Because many alkaloids are Class 6 or Class 5 poisons and are readily accessible to the public, they are potential candidates for misuse. The NFCC is frequently called upon to screen for alkaloids in foods and beverages in cases of suspected product tampering. At the Forensic Center we have been developing RP-HPLC screening methods for classes of compounds using UV-VIS and/or electrochemical detectors. The nature of our work requires that results obtained by these screening methods be confirmed by at least two techniques. The lack of volatility and thermal lability of some analytes preclude the use of GC/MS. Therefore liquid chromatography with mass spectrometry is generally the technique of choice for confirmation. Most of the liquid chromatographic conditions reported in the literature including the ones developed in this laboratory require the use of ion-pairing agents (typically sodium octanylsulfonate) and/or a phosphate buffer. Neither of these substances is suited for thermospray LC/MS. A number of reports in the literature suggest using fluorinated alkanoic acids instead of sodium alkylsulfonates as the ion-pairing agents (1,2) for LC/MS. We have used pentadecafluoro-octanoic acid as an ion-pairing agent for the separation of alkaloids and have obtained good chromatographic separation.

Mass spectra were acquired on a Hewlett-Packard 5989A mass spectrometer using a Hewlett-Packard thermospray probe and ion source. Mass spectrometric conditions: source temperature, 250^0 C; quadrupole temperature, 100^0 C; probe stem temperature, 105^0 C; mass range scanned, 140-360amu; discharge on.

The liquid chromatographic solvent delivery system consisted of a Hewlett-Packard 1090 liquid chromatograph. Separations were carried out on a Supelco Suplex PKB-100, 5 m, 250 mm x 4.6mm ID column. The mobile phase consisted of: (A) Aqueous: 0.1M ammonium acetate with 0.0003M pentadecafluorooctanoic acid and 2% acetic acid. The pH of the resulting solution is 4. (B) Methanolic: 0.1M ammonium acetate with 0.0003M pentadecafluorooctanoic acid and 0.05% formic acid.

The total ion chromatogram for a six alkaloid mixture (codeine, cocaine, yohimbine, strychnine, meperidine and pentazocine) separated using pentadecafluorooctanoic acid as the ion-pairing agent and acetate buffer is shown in Figure 1 (a); (eluent 90:10 A:B to 60:40 A:B at 20 minutes and 50:50 A:B at 30 minutes, flow rate 0.8ml/min). The mass spectrum obtained by averaging across the entire chromatogram is shown in Figure 1 (b).

The predominant ion in all cases is the $[M+H]^+$ ion, except for codeine where the $[M+NH_4]^+$ ion is also significant. Positive ion thermospray LC/MS is an effective technique for the determination of alkaloids and other basic substances. The use of fluorinated ion-pairing agents makes reverse phase HPLC easily adaptable to this class of compounds. Pentadecafluorooctanoic acid ion-pairing agent shows good selectivity for this class of compounds without any apparent adverse effects on the performance of the LC/MS interface.

Coupling of Capillary HPLC with Continuous-Flow LSIMS for the Identification of Flavonoid Conjugates in Plant Extracts

L. W Sumner[1], N L Paiva[2], R A. Dixon[2] and P W Geno[3]

1 Oklahoma State University, Stillwater, OK 74078
2. Plant Biology Division, The Noble Foundation, Ardmore, OK 73402
3. Southwest Research, San Antonio, TX 74078-0047

Flavonoids encompass a wide range of polyphenolic secondary plant metabolites that are found in most plant systems These compounds serve a multitude of functions, and it is now known that the subclasses of flavonoids known as the isoflavonoids, chalcones, and pterocarpins demonstrate phytoalexic or antimicrobial properties These compounds are typically stored in plant cells as O or C-glycoside conjugates Upon infection of the cell, the conjugates are hydrolyzed to yield the free aglycones The newly released aglycones may be biologically active in their hydrolyzed form, or they may be immediately consumed in further syntheses that generate biologically active species Thus, identification of these conjugates will further enhance our understanding of these processes Furthermore, current research is now being conducted to identity these conjugates and to examine there location in the plant tissues, such as surface or subsurface to infected tissue This has resulted in the generation of smaller samples quantities that require new and more sensitive analysis methods

To provide a solution to the mass spectral analysis of flavonoid conjugates, we have developed an on-line capillary HPLC continuous-flow liquid secondary ion mass spectrometry (LC-CF-LSIMS) method The on-line capillary HPLC was interfaced with CF-LSIMS to accommodate the small quantities generated and to avoid the decomposition of flavonoid conjugates associated with HPLC fraction collection followed by mass spectral analysis

Capillary LC-CF-LSIMS was performed on cotyledon acetone extracts from

1 Chickpea (*Cicer arietinum*)
2 Soybean (*Glycine max*)
3 Peanut (*Arachis hypogaea*)
4 Clover (*Trifolium pratense*)
5. Alfalfa (*Medicago sativa*)

and the results from the chickpea experiment are presented A UV chromatogram of the chickpea extract is given below The extract was separated into ten components which were then successfully identified The identification of the components is summarized in the table of Identification of Peaks

Mass spectra of the ten components were obtained Spectrum III, IV, and VII are provided The resulting spectra identify the majority of the components as malonated glucoside conjugates of previously described aglycones found in chickpea The spectra of peaks V and VI have been tentatively identified as IGM and MeBGM respectively and will be further investigated

MASS SPECTROMETRY OF THREE NEW TOXINS PRODUCED BY *Alternaria alternata* f.sp. *lycopersici*

***Eloisa D. Caldas[1], A. Daniel Jones[2], Barney Ward[3], Carl K. Winter[1] and David G Gilchrist[3].**
1. Department of Food Science and Technology; 2. Facility for Advanced Instrumentation; 3. Department of Plant Pathology. University of California, Davis-CA, 95616.

The fungus *Alternaria alternata* f.sp. *lycopersici* causes the stem canker disease in tomato, and is a producer of phytotoxins (AAL toxins)[1]. Two toxins, referred to as TA and TB, were isolated in 1981 and shown to be tricarballylic acid esters of amino polyols[2]. The structural similarities of these toxins to the fumonisins, which are mycotoxins associated with animal and human disease[3], have stimulated concerns about their implications to human health.

Liquid culture of *A. alternata* (AS27-3) was grown for 25 days at room temperature. The toxins were extracted using XAD-2 and fractionated on a silica gel column. Final purification was achieved on a SAX (strong anion exchange) column.

Electrospray spectra were obtained in a VG Quattro-BQ (Fisons Instruments), in positive mode. 1% formic acid in 50:50 MeOH/H_2O was used as solvent. Positive FAB mass spectra were obtained using a VG ZAB-HS-2F mass spectrometer (VG Analytical) from a matrix of 3-nitrobenzyl alcohol. Daughter spectra were obtained using helium for collisional activation. For GC/MS method, hydrolyzed toxins were derivatized with BSTFA + 1%TMCS. Electron impact spectra were obtained in a Trio-2 quadrupole mass spectrometer (VG Masslab). The chromatographic conditions were: 15m DB-5, 0.25 mmI.D., 0.25µm film column; splitless injection at 280°C; temperature program - 100 to 220°C at 20°C/min, 220-300°C at 10°C/min.

Mass spectra of isolates obtained from culture filtrates of *A. alternata* revealed the presence of three new AAL toxins (TC, TD and TE). Positive ion Electrospray (Fig. 2) and FAB mass spectra showed $[M+H]^+$ ions at m/z 490, 548 and 532, respectively. Daugther spectra (Fig. 3) obtained for the protonated molecules each yielded abundant daughters at $[M+H-176]^+$, corresponding to a loss of the tricarballylic acid group. The presence of a succession of fragments at $[M+H-176-nH_2O]^+$ is an evidence of the number (n) of hydroxyl groups in the molecule. TD and TE showed in the daughter spectra peaks at m/z 294 and 296 $[M+176-nH_2O-42]^+$, respectively, indicating the presence of N-acetyl group. The final structures were confirmed by 2D ^{1}HNMR and ^{13}CNMR. As is the case of TA and TB, TC, TD an TE are mixtures of two structural isomers of tricarballylic acid esters at either C_{13} or C_{14} of the amino polyol backbone.

Electron ionization spectra of trimethylsilyl derivatives of AAL toxins showed a common peak at m/z 159 and a peak at $[M-159]^+$, which is characteristic of each toxin (Fig. 4 and 5). The use of the 159 peak can be used for trace detection of all of these toxins in foodstuffs using selected ion monitoring (SIM). Electrospray ionization mass spectrometry is a sensitive method that could be used for rapid screening of the presence of AAL toxins in liquid cultures and foodstuffs without the necessity of any derivatization.

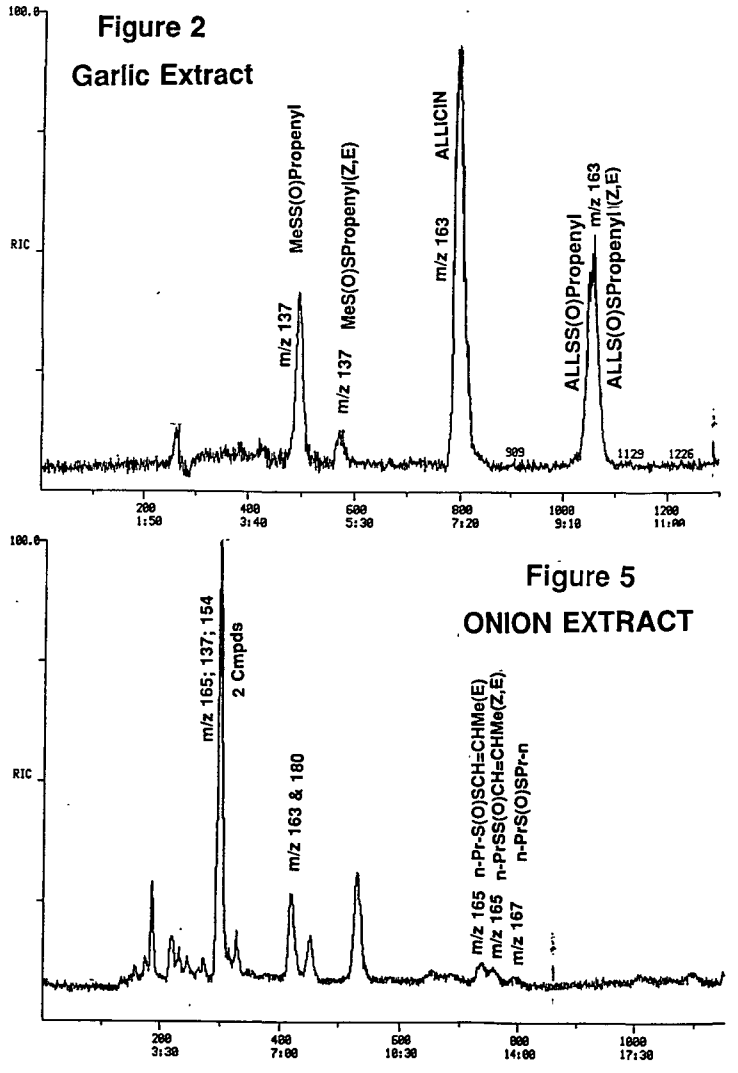
Supercritical Fluid Extraction and LC/MS of Thiosulfinates Found in *Allium* Species, *Jean E. Matusik, E.M. Calvey, E. Block & J. Sphon, Food & Drug Admin., Washington, DC 20204.

Characteristic flavors of fresh garlic (*Allium satinum*), onion (*Allium cepa*) and other allium spp. are associated with thiosulfinates, RS(O)SR, and related compounds, formed enzymatically from odorless amino acid precursors when the plants are cut or crushed. Allicin (2-propene-1-sulfinothioic acid-S-propenyl ester), derived from the non-volatile alliim ((+)-S-allyl-L-cysteine-S-oxide), is the major thiosulfinate metabolite found in crushed garlic. Thiosulfinates are further decomposed by heat to form sulfides.

Supercritical fluid extraction(SFE) was used to obtain garlic or onion thiosulfinate containing extracts. A method for the extraction, separation and characterization using SFE, HPLC, TSP\MS and MS\MS techniques is reported here. Various thiosulfinate components in garlic or onion were studied.

The HPLC\TSP\MS of the garlic extract is shown in figure 2. The components at RT 7.2 and 9.3 mins. give essentially the same TSP\MS spectra, i.e., m/z 163. To characterize these compounds HPLC\TSP\MS\MS was performed. The product ion analysis of the ions at m/z 163 from the garlic extract was compared to synthesized standards. Product ion analysis for m/z 137 was also performed. Allicin, ALLSS(O)Propenyl(E) and ALLS(O)SPropenyl(Z,E) were identified and characterized based on the MS\MS mass spectra and chromatographic RT and their comparison to standards.

The HPLC\TSP\MS of the onion SFE is shown in figure 5. The peak at the RT of 7.0 mins. shows a spectra with ions at m/z 163 and m/z 180. The product ion analysis of the m/z 163 reveals that this component is not allicin. Onion is not known to contain allicin. The peaks at RT of 12.5 mins and 13.3 mins are geometric isomers and their spectra exhibit ions at m/z 165. The first compound to elute is the n-Pr-S(O)SCH=CHMe(E) and the second is n-PrSS(O)CH=CHMe(Z,E). The MS/MS spectra of each of these isomers in the onion extract were compared to the spectra from authentic standards for confirmation.



LC/MS Identification and Characterization of Components Isolated from Chaparral, ***Jean E. Matusik, Steven M. Musser, William R. Obermeyer, Jr. and James A. Sphon, FDA, CFSAN, Washington, DC 20204.**

Chaparral is an herbal preparation obtained from the leaves and twigs of the creosote bush (*Larrea tridentata*). This bush is an evergreen desert shrub. The leaves and twigs are ground and used in teas and formed into dietary supplement tablets and/or capsules. This herbal nutritional product has been recommended in non-scientific publications as an antioxidant, a free radical scavenger, as a blood purifier, to retard aging and to treat skin conditions (acne). Also, American Indians use chaparral tea as a medicine.

The U.S.F.D.A. became interested in chaparral products and their respective components because of two patients reported toxic effects. Both patients had taken chaparral tablets and developed hepatotoxic symptoms. After each ceased taking the tablets, their liver enzyme levels returned to normal. The diagnosis of toxin induced hepatitis is supported by the relation between hepatic disease and the patients use of chaparral and by the rapid improvements when they stopped ingesting the formulation.

Our interest has focused on the natural product identification of components in chaparral and toxicity studies to identify the causative agent or agents. A method was developed to separate and identify some of the natural products present. The method and our findings are reported herein.

The HPLC method uses a Ultrasphere C18 column and a gradient run. The gradient was 25% B hold 1 min, then program to 60% B in 50 mins and hold 5 mins. A was 90/10 H_2O/ACN; B was 10/90 H_2O/ACN. For the TSP/MS ammonium acetate was added post UV & prior to MS. MS was done on a Vestec 201 & MS/MS was done on Finnigan TSQ46. Methanolic extracts of chaparral were analyzed by UV & MS after HPLC separation. Our investigations centered on 2 areas, Nordihydroguaiaretic acid (NDGA) and flavonoids. Figure 1 shows the structure of NDGA. NDGA is a potent antioxidant. The retention time for NDGA is app. 28 mins. with its corresponding ion at m/z 303 and an ammonium adduct ion at m/z 320. Figure 2 is a compilation of the UV and MS analysis of a typical chaparral extract. NDGA was confirmed based on its comparison with authentic standard and MS/MS analysis. The TSP/MS of the peak directly after NDGA gives an ion at m/z 331 and was tentatively identified as dihydroguaiaretic acid (DHGA). Additionally the peak at 18 mins. gave an ion at m/z 299, representative of guaiaretic acid diquinone (GADQ). The peak at 21 mins. shows an ion at m/z 301 and is suggestive of guaiaretic monoquinone (GAMQ). The peak at 40 mins. with an ion at m/z 331 is consistent with

desmethyldihydroguaiaretic acid (DMGA) .

Ten authentic flavonoids standards were obtained and analyzed by the HPLC/UV & MS. The extract peak at the RT of 31 mins with an ion at m/z 285 corresponds to RT and MH+ ion for 4',5-dihydroxy-7-methoxyflavone standard.

Toxicity studies of various peak isolates are currently in progress. As this data becomes available we will focus on the respective peak identification and characterization using the various HPLC liquid interface techniques available in our laboratory.

Separation and Identification of Didemnins and Ecteinascidins by On-line Microbore Liquid Chromatography / Continuous Flow Fast Atom Bombardment Mass Spectrometry

K. Janota and K.L. Rinehart,
School of Chemical Sciences, University of Illinois, Urbana, IL 61801.

Didemnins and ecteinascidins are marine natural products which exhibit potent anticancer and antiviral activities. Didemnins are cyclic depsipeptides which were isolated from the extract of the Caribbean tunicate *Trididemnum solidum*. The didemnins have a common ring structure and differ in the amino acid sequence of the side chain. The ring structure consists of commonly encountered amino acids with the exception of two novel subunits: hydroxyisovalerylpropionate (Hip) and isostatine (Sta) (1). Didemnin B, the most potent didemnin, shows strong activity against both L1210 leukemia cells and Herpes simplex virus types 1 and 2 (2). Didemnin B is the first marine natural product introduced as an antitumor agent into Phase II clinical trials.

Ecteinascidins are a group of nitrogen-containing heterocycles which were isolated from an extract of the Caribbean tunicate *Ecteinascidia turbinata*. These alkaloids contain di- and trimeric tetrahydroisoquinoline units and are related to the group of saframycin and safracin antitumor antibiotics. Recently, ecteinascidin 729, which exhibited antitumor activity higher than didemnins and other ecteinascidins against P388 murine leukemia and B16 melanoma (3), has entered pre-clinical evaluation.

Both didemnin B and ecteinascidin 729 are present in mixtures of compounds related to them. Therefore, the development of chromatographic conditions needed for their separation and a method for assessment of their identity and purity on the nanogram scale are necessary. Analysis on such a scale may also be helpful in determining whether or not these compounds are present in the early stages of purification. To achieve these goals, we employed on-line microbore liquid chromatography/coaxial continuous flow fast atom bombardment mass spectrometry.

The analysis of an unknown mixture of didemnins on a 50-ng scale resulted in compounds eluting at 3.2, 4.8 and 8.0 min (Figure 1). The last two components were identified from their molecular ions $(M+H)^+$ at *m/z* 943 and *m/z* 1112 as didemnins A and B, respectively (Figure 2). It is thought that didemnin B was retained longer on the column due to the more hydrophobic character of the additional lactylproline side chain. The third component of the mixture produced a molecular ion at *m/z* 805 (Figure 2).

High resolution measurement of the ion at *m/z* 805 indicated a molecular composition $(M+H)^+$ of $C_{41}H_{69}N_6O_{10}$, which corresponds to hydrolyzed didemnin A lacking a Hip unit. The fragmentation pattern of the ion at *m/z* 805 was obtained by MS/MS. This analysis partially confirmed the amino acid sequence based on the presence of Y" fragments due to the loss of leucine at *m/z* 692, proline at *m/z* 595, and dimethyltyrosine at *m/z* 402. The bioassay against L1210 leukemia cells showed that the linear peptide, acyclo-desHip-didemnin A, is inactive. The bioactivity reported in the short abstract for this meeting was due to contamination with didemnin A, not detected by LC/UV or regular probe FABMS but subsequently identified using LC/CFFABMS. The discovery of the linear peptide, acyclo-desHip-didemin A, related to didemnins yet lacking biological activities characteristic for didemnins, confirms that the Hip unit is necessary for the biological activity.

In the analysis of ecteinascidins, the presence of the ammonium acetate required to obtain partial separation between ecteinascidins 701 and 729 (Figure 3) resulted in formation of a series of adduct ions $(glycerol+NH_4OAc+MeOH+H)^+$ and $(glycerol+NH_4OAc+H_2O+H)^+$. Despite this background interference, most of the components of the ecteinascidin mixtures were identified on a 100-ng scale as ecteinascidins 701, 729, 743, 745 and 736. In comparison to LC/MS using a moving belt interface previously employed by this group (4), LC/CFFABMS yielded mass spectra with a similar fragmentation pattern such as the presence of the base peak at *m/z* 204, and other low molecular weight fragment ions at *m/z* 218 and 234. The fragment ions, including the base peak,

were observed only after the glycerol peaks were subtracted. The bioassay results were consistent with our study that the most active fraction was the one containing ecteinascidin 729.

On-line microbore LC/CFFABMS provided valuable data which were not available by other methods. Separation and identification of closely related components of didemnin and ecteinascidin mixtures, assessment of purity of individual fractions and structural information were obtained using nanogram quantities.

Identification of *S*-linked Conjugates of 2-Chloroethyl Isocyanate as Metabolites of *N,N'-bis*(2-Chloroethyl)-*N*-nitrosourea (BCNU) in the Rat by Ionspray LC-MS/MS.

M.R. Davis, K. Kassahun, C.M. Jochheim, K.M. Brandt and T.A. Baillie.
Department of Medicinal Chemistry, University of Washington, Seattle, WA 98195

The antitumor agent BCNU is known to be unstable in aqueous solution, and to degrade spontaneously to reactive alkylating and carbamoylating intermediates.[1] Whereas the alkylating component is believed to be responsible for the antitumor effects of this drug, it has been speculated that the carbamoylating species 2-chloroethyl isocyanate (CEIC) may mediate some of the serious adverse effects of BCNU therapy.[2] BCNU is known to cause isocyanate-mediated depletion of cellular stores of GSH through mechanism-based inhibition of glutathione reductase.[3] Since GSH plays a key role in the cell's defense against locally-generated reactive oxygen species, it is possible that CEIC-mediated inhibition of glutathione reductase may cause acute lung injury and, ultimately, lead to the development of the pulmonary fibrosis that has been observed in some patients undergoing BCNU therapy.[4]

In a recent study, we found that rats dosed ip with methyl isocyanate excreted the corresponding GSH adduct in bile[5] and the corresponding *N*-acetylcysteine (NAC) conjugate in urine.[6] Interestingly, these *S*-linked conjugates were shown to be formed in a reaction which is chemically reversible at physiological pH. This may explain why the adducts themselves are cytotoxic and act as carbamoylating agents *in vitro*.[7] In light of their reversible formation, it has been speculated that *S*-linked conjugates of isocyanates formed biologically may act as "carriers" of their respective isocyanates.[8]

In order to determine whether CEIC is released from BCNU *in vivo*, rats were administered an i.p. injection of the drug and a targeted search was made by ionspray LC-MS/MS techniques for the GSH conjugate of CEIC in bile and the corresponding *N*-acetylcysteine (NAC) adduct in urine. Following the successful detection of the predicted *S*-linked conjugates in bile and urine, studies were performed to quantify these conjugates in the excreta of BCNU-treated rats. To test the hypothesis that *S*-linked conjugates of CEIC are formed reversibly and may act as "carriers" of CEIC, these conjugates and the parent drug were tested for their ability to inhibit glutathione reductase *in vitro*.

Experimental:

Bile from rats given an i.p. dose of BCNU was collected over ascorbic acid for 4 h after dosing while urine was collected for 24 h after dosing. Samples of bile and urine were analyzed by ionspray tandem mass spectrometry utilizing on-line HPLC (qualitative analysis) or flow-injection (quantitative analysis) for sample introduction. Mass spectrometry and combined liquid chromatography-tandem mass spectrometry (LC-MS/MS) were carried out using a Perkin Elmer-Sciex API III triple quadrupole instrument equipped with an atmospheric pressure ionization source and an Ionspray™ interface. Tandem mass spectrometry was based on collision-induced dissociation of ions entering the rf-only quadrupole region, where argon was used as the target gas.

Product ion spectra of parent ions of synthetic compounds were obtained by directly infusing 10 μg ml^{-1} solutions of the analytes (in methanol / 1% formic acid [1:1, v/v]) into the instrument at a flow rate of 5 μl min^{-1}. Qualitative analysis of biological specimens was performed by LC-MS/MS. 50 μl samples of bile or urine were injected onto a narrow-bore C_{18} HPLC column (150 mm X 2.0 mm i.d.), the effluent from which was split such that 75% of the flow entered a UV detector and 25% was diverted to the mass spectrometer. The mobile phase, delivered at a constant flow rate of 200 μl min^{-1}, consisted of 100% solvent A (0.06% aqueous TFA) for 5 min after injection, followed by a linear increase to 40% solvent B (0.06% TFA in acetonitrile) in 40 min. MS/MS analyses were carried out utilizing constant neutral loss scanning of 129 daltons (derived from the glutamyl moiety of GSH) for the detection of GSH conjugates in bile and parent ion scanning of *m/z* 164 (protonated NAC) for the detection of NAC conjugates in urine. Calibration curves for the quantitative determination of conjugates in bile and urine were generated by selected reaction monitoring analysis of samples of bile or urine from untreated rats to which was added the corresponding synthetic material and the conjugate of benzylisocyanate as internal standard.

Inhibition of glutathione reductase by the *S*-linked conjugates of CEIC *in vitro* was measured in isolated rat hepatocytes. Test compounds (0.1 mM) were incubated with cell extracts and GSSG (50 mM). The reductase reaction was initiated by the addition of NADPH (0.2 mM) and the rate of consumption of this cofactor was measured spectrophotometrically at 340 nm.

Results:

Ionspray LC-MS/MS provided a rapid method for the detection of the GSH and NAC conjugates of BCNU *in vivo*. By the use of ionspray MS/MS, it was found that 3.90 ± 0.64% of the dose of BCNU was excreted as the GSH conjugate of CEIC in bile (4 h post-dose) and 18.1 ± 3.3% was excreted as the NAC conjugate of CEIC in urine (24 h post-dose).

The GSH and NAC conjugates of CEIC were found to be equipotent to BCNU in their ability to inhibit glutathione reductase *in vitro*.

Supported by NIH grants ES05500 and RR05543.

THE UTILISATION OF MODERN LC/MS METHODS TO STUDY THE PHASE I AND PHASE II METABOLISM OF TRIMETAZIDINE IN HUMAN SUBJECTS

R.Brownsill[1], P.Jackson [1], A.Taylor [1] & B.Walther [1] J.Rontree [2], B.Bollen [2] & M.McDowall [2]
1. Servier Research & Development, Fulmer, England
2. Fisons Instruments ,VG Biotech, Manchester, England

INTRODUCTION The use of LC/MS as a method for studying the metabolism of drug compounds has increased rapidly in recent years due to the advent of electrospray ionisation(ESI). Electrosprays' ability to handle gradient solvent systems containing aqueous mobile phases and its wider dynamic range of compound response, is essential when investigating drug biotransformation products, particularly where very polar products are involved eg. conjugated metabolites Trimetazidine(TMZ) is a drug which is extensively used throughout the world for the treatment of ischaemic heart desease. Previous studies have used GC/MS to identify some of the major metabolites, however this technique was not suitable for conjugates unless samples were first hydrolysed and derivatised.
In this study we have investigated the potential of ESI LC/MS and LC/MS/MS to study the metabolism of Trimetazidine in human subjects to:- (i) evaluate the potential of Electrospray ionization with on-line LC/MS and LC/MS/MS for drug metabolism studies, (ii) quantitate TMZ and its metabolites in urine and (iii) study the effects of the biological matrix on metabolite identification and quantitation procedures.

EXPERIMENTAL Urine samples were obtained from subjects participating in a repeat dose pharmacokinetic study of a sustained release formulation of Trimetazidine (80mg). The urine samples were analysed directly, and following BondElut extraction and concentration, using gradient elution LC/MS and LC/MS/MS in the parent-ion scan mode then using the mutiple reaction monitoring (MRM) mode to both identify and quantitate TMZ and its metabolites.All MS analyses were performed using a VG QUATTRO system (Fisons Instruments, VG Biotech, Manchester, England). Quantitation was achieved by reference to a calibration curve produced by the addition of known amounts of Trimetazidine (1ng.ml $^{-1}$ to 20ug.ml $^{-1}$) and an internal standard (S3498) to urine. Quantitation of metabolites was based on their MS response factors relative to TMZ. The levels of TMZ were also quantitated using a validated method based on HPLC with fluorescence detection for comparison with the MRM analyses. Putative metabolites were synthesised and their MS and chromatograhic characteristics were compared with in-vivo metabolites.

RESULTS All the synthesised TMZ reference compounds showed good ESI responses generally within an order of magnitude of the parent drug (see Table 1).LC/MS permitted the detection of five expected metabolites of TMZ from the extracted biological matrix, but LC/MS/MS (parent-ion scan mode) enabled the identification of four new metabolites, including a sulphate and glucuronide conjugate which were detected without initial hydrolysis. The use of LC/MS/MS in the Multiple Reaction Monitoring mode resulted in the confident quantitation of seven of these relatively minor metabolic products (see Table 1,Figure 1),as well as the parent drug which gave results very comparable to those from a validated analytical method (see Table 2). Comparable qualitative and quantitative results were obtained using both extracted and unprocessed biological samples indicating minimal effects of the biological matrix on the ESI LC/MS response.

CONCLUSIONS The Electrospray LC/MS responses for Trimetazidine and its metabolites were generally very comparable. Furthermore, influence of the biological matrix was minimal making it a most usefull ionisation procedure for metabolism studies where compounds of varying polarity and concentration are present in complex biological matrices.

Although quantitative analysis of the metabolites by LC/MS was less conclusive due to the very low levels present within the biological matrix, using gradient elution LC/MS/MS in the MRM mode, definitive data was obtained for most of the metabolites, including two Phase II metabolites not previously identified.

The results clearly show that gradient elution Electrospray LC/MS and LC/MS/MS MRM has a great potential as a robust routine technique for the analysis of drug biotransformation products.

Development of a LC/MS/MS assay for FIAU

*Alan P. Breau[1], Patricia M. Dhahir[2] and Thomas Covey[3], [1]Allergan, 2525 Dupont Drive, Irvine, CA, 92715, [2]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis IN, 46285 and [3]PE/Sciex, Thornhill, Ontario, Canada.

1-(2-Deoxy-fluoro-1-beta-D-arabinofuranosyl)-5-iodouracil (FIAU) (Figure 1), is a potent antiviral agent against herpesviruses and hepadnarviruses that is currently in clinical trials. An assay for plasma levels of FIAU and its metabolite FAU (Figure 2) using the heated nebulizer option and negative ion detection on a Sciex API III mass spectrometer was developed. One hundred microliters of reconstituted extracts were injected onto a 50 mm X 4.6 mm, 5 u particle, 120 A pore size Keystone Hypersil Phenyl-2 reverse phase HPLC column. The column was equipped with a 0.5 micron pre-column filter and a 5 u particle size, 10 mm X 4.0 mm Keystone Deltabond C8 guard column.

The isocratic separation, for the fast-high sensitivity FIAU method utilized a mobile phase of acetonitrile:0.1 % acetic acid (15:85) at a flow rate of 1 mL/min (Figure 3). The slower less sensitive method that separated FAU from serum interferences (Figure 4) was achieved by changing the mobile phase to acetonitrile:0.1 % acetic acid (5:95). The LC eluent was introduced into the Sciex API III APCI source with a quartz transfer line temperature of 500°C and a nebulizer nitrogen gas pressure of 90 psi. The negative charge de-protonated molecular ion at 371 daltons was mass filtered into the collision cell with a collision gas thickness of 671.1 x 200 x 10^{12} atoms/cm^2 of argon gas (Figure 5). Fragment ions at 42 daltons ($N{=}C{=}O^-$) and 127 daltons (I^-) were monitored for quantitation and verification of FIAU (Figure 5). The major metabolite, FAU, produced a negatively charged de-protonated molecular ion at 245 daltons which yielded a robust daughter ion at 42 amu ($N{=}C{=}O^-$) for quantitative purposes (Figure 6). Similarly, the internal standard reference produced a negatively charged de-protonated molecular ion at 277 daltons which yielded a robust daughter ion at 42 amu ($N{=}C{=}O^-$) for quantitative purposes.

A detection limit of 100 pg/mL serum and a quantitation limit of 250 pg/mL serum for FIAU was obtained using the slow non-optimal sensitivity assay option. This assay option was chosen in order to be able to quantitate the metabolite, FAU, simultaneously. The detection limit for FAU was approximately 250 pg/mL serum and the quantitation limit was 500 pg/mL serum using the combined FIAU/FAU procedure. If only FIAU quantitation is desired, a 40 pg/mL detection limit would be feasible.

The calibration of FIAU resulted in a standard curve that was linear from 250 pg to 10 ng/mL serum with a correlation coefficient of 0.999561. The calibration for FAU resulted in a standard curve that was linear from 500 pg to 10 ng/mL serum with a correlation coefficient of 0.999609.

LC/PARTICLE BEAM/NCI MS ASSAY OF KYNURENIC ACID IN THE MEDIA OF CULTURED CELLS

D.B.Naritsin, R.L.Boni, K. Saito, and S.P. Markey,
Section on Analytical Biochemistry, NIMH, Bethesda, MD 20892.

Kynurenic acid (KYNA) is a metabolite of L-tryptophan (L-TRP) that in the central nervous system can act as a non-selective antagonist of excitatory amino acid receptors. In contrast, another L-TRP metabolite, quinolinic acid (QUIN) is an agonist of N-methyl-D-aspartate (NMDA) receptor. Our laboratory is studying the regulation of L-TRP metabolism in order to define the roles of QUIN and KYNA in pathogenesis or neuroprotection in a wide spectrum of immunologically mediated processes which activate the kynurenine pathway. We have previously reported the assay of L-TRP and L-kynurenine (L-KYN) using LC/particle beam/ NCI/MS, and have modified that assay to measure KYNA, which is several orders of magnitude less concentrated than its metabolic precursors. This assay has been applied to the quantification of KYNA isotopomers in the media of cultured cells fed [$^{13}C_6$]-L-TRP, to determine the metabolic activity of various types of human cells in response to cytokines, and the effects of two inhibitors of QUIN synthesis, 6-chloro-DL-tryptophan (6-Cl-TRP) and 4-chloro-3-hydroxyanthranilate (4-Cl-3HAA). In the course of these studies, we compared the relative merits of LC/particle beam/MS with GC/MS for KYNA quantification.

EXPERIMENTAL

Cells were grown with 50μM [$^{13}C_6$]-TRP, either with or without interferon-γ for 48 h [1]. [$^{18}O_2$]-KYNA (exchange labeled) was used as an internal standard, and added to each sample prior to analysis. Culture medium (150μL) was deproteinized, filtered and freeze dried. Pentafluoro-benzylation was effected with phase transfer catalysis as previously reported [2]. A Hewlett-Packard model HP1050 LC coupled to an HP5989 MS system through an HP59980B particle beam interface was used in these studies. GC/MS analyses were performed on the same mass spectrometer using the HP5890 gas chromatograph. The $(M\text{-}PFB)^-$ ions at m/z 368 (KYNA), 372 ([$^{18}O_2$]-KYNA), 374 ([$^{13}C_6$]-KYNA) and 402 (7-Cl-KYNA) were measured by NCI (methane) for quantification. The contribution of different KYNA isotopomers made necessary algebraic deconvolution of overlapped mass spectra, the most significant of which was the contribution at m/z 374 from [$^{18}O_3$]-KYNA. L-KYN was quantified as reported in [2], and QUIN as reported in [3].

RESULTS

The sensitivity of the LC/MS assay was 10pg of KYNA standard (injected) with a signal to noise ratio 10. Reverse phase chromatography using 0.4M ammonium acetate/ methanol/ acetonitrile (28/32/40) produces good separation of L-KYN and KYNA and retains desirable particle beam performance characteristics. The use of ammonium acetate improves significantly transfer through the particle beam interface and eliminates a mass transfer effect (nonlinear dependence between amount injected and absolute response). The absolute response was linear in the range 2pg-10ng KYNA injected (R>0.999).

An important advantage of particle beam LC/MS with respect to GC/MS is for the analysis of polar, thermally labile compounds that are not suitable for gas phase analysis. We had reported that the PFB derivative of L-KYN, which was difficult to analyze by GC, was readily analyzed by LC/MS [2]. The PFB derivative of KYNA is well suited for GC/MS, and we observed excellent chromatographic characteristics and a signal/noise ratio of 55 for the analysis of 4.3pg of diluted standard. Efforts to quantify KYNA in culture media did not give satisfactory results because of interfering unknown chemical background. The large quantity of extractive alkylation reagents limited the portion of the concentrated extract which could be injected into GC. One or more purification steps would be required for GC/MS analysis of KYNA after extractive alkylation. Thus, while GC/MS may exhibit lower limits of detection for pure analytical standards, LC/particle beam/MS analyses are advantageous for the measurement of chemically complex samples because the LC has a high capacity tolerance relative to GC. We have enhanced the capacity advantage of LC by installing a programmed valve that can divert the LC effluent to waste during periods when large quantities of reagents or chemical contaminants are eluting. The LC injection volume can be varied from 0.1 to 100 μL, so that a large proportion of the sample can be injected routinely. In GC/MS analytical procedures, we have generally limited the injection volume to 1-2μL, usually less than 1/5th of a biologically derived sample.

We studied the metabolism of [$^{13}C_6$]-TRP by a variety of human cultured cells lines derived either from central nervous system or peripheral organs. Although interferon-γ increases L-KYN formation in all cell types, only monocytes (THP-1) and liver cells (SKHep1) can convert L-KYN to QUIN [1]. None of the cells derived from central nervous system tissues or lung exhibited metabolic capacity to convert L-KYN to QUIN. In this study, we have quantified the QUIN antagonist, KYNA. All cells studied demonstrated increased synthesis of [$^{13}C_6$]-KYNA from [$^{13}C_6$]-TRP after immune activation.

We also investigated the action of two inhibitors, 6-Cl-TRP (0.5 mM) and 4-Cl-3HAA (1μM), on THP-1 cells. Our data indicate that 4-Cl-3HAA (a known metabolite of 6-Cl-TRP) is a more potent inhibitor of QUIN formation.

Our LC/NICI MS method was suitable for quantification of 6-Cl-TRP and its metabolites, 4-Cl-KYN and 7-Cl-KYNA, without significant modifications. Commercially available 7-Cl-KYNA was used to confirm metabolite identity and prepare standard dilutions. 4-Cl-KYN was identified as one of the major metabolites of 6-Cl-TRP.

Identification of rat liver microsomal metabolites of Atevirdine Mesylate by Particle Beam LC/MS. ***Phillip E. Sanders, Stephen M. Maio, Richard L. Voorman, Zhiyang Zhao, and J. James Vrbanac. Drug Metabolism Research, The Upjohn Company, Kalamazoo, MI 49001.**
Id

Atevirdine mesylate, (1-[3-ethylamino)-2-pyridinyl]-4-[(5-methoxy-1H-indol-2yl)carbonyl] piperazine, monomethane sulfonate is a bis heteroarylpiperazine inhibitor of HIV-1 reverse transcriptase, and is currently under clinical investigation as an anti-AIDS therapeutic agent. As a part of the pre clinical evaluation of atevirdine, metabolites were generated in incubations of rat liver microsomes and subjected to direct analyses by particle beam liquid chromatography mass spectrometry (PB/LC/MS). Ateverdine (50 uM) was incubated with rat liver microsomes (1 mg protein/ml) in 50 mM tris, pH 7.4, containing 0.1 mM EDTA in a final volume of 1 ml. Following 3 min pre-incubation at 37°C, the reaction was started by addition of an NADPH generating system and was stopped after 30 min by addition of 1mL acetonitrile. The mixture was vortexed, centrifuged, lyophilized, and reconstituted with 0.1 mL of mobile phase. PB/LC/MS was performed on a Finnigan 4500 equipped with a particle beam interface built at the Upjohn Company after the design of Extrel Corporation's (Pittsburgh, PA) Thermabeam© interface (design used by permission). Scan control and data acquisition was accomplished with a Teknivent Vector 2 data system (Teknivent, Maryland Heights, MO). Data was acquired in both electron ionization and chemical ionization (ammonia) modes.

The base peak in the electron ionization mass spectra of atevirdine and its metabolites was the result of cleavage of the piperazine moiety. Atevirdine and its desmethyl metabolite displayed this prominent ion at m/z 150. The desethyl metabolite displayed the analogous fragment at m/z 122. Molecular species were present for the parent drug and both metabolites. The chemical ionization (ammonia) spectra were comprized of the pseudo-molecular ion as the base peak and prominent fragment ions (m/z 207, 235) resulting from cleavage and charge retention from either side of the carbonyl group. The combination of electron ionization and chemical ionization spectra of the metabolites of atevirdine were sufficient to determine their structures.

Electrospray (ESI)/MS, and ESI/MS/MS were also performed on atevirdine to determine its potential usefulness as an analytical tool with this particular class of compounds. Data was acquired on a Finnigan TSQ-70 equipped with an ESI interface developed at the Upjohn Company. Results from the ESI experiments determined that no structural information was present in the simple ESI experiment. However either source induced daughter ions generated by having a DC offset voltage of approximately 150 V (drift tube to sampling orifice offset) or ESI/MS/MS produced the same qualitative spectra obtained from particle beam CI. The difference between PB/CI and ESI/MS is to be found in the relative ease with which informative spectra are generated, and the instrumentation necessary to generate the data. Generally, PB/MS (CI) spectra have been shown to be identical to ESI/MS (source daughters) and ESI/MS/MS (quad daughters). It has been our experience that the necessary offset required to produce ESI source induced daughters is very compound dependent, making screening of unknown samples difficult. Also, in order to obtain ESI/MS/MS data, proper parent ion selection and quad offsets must be determined for each compound in a given LC/MS analysis. PB/MS (CI or EI) will produce the same qualitative results with far less user intervention and without the need for MS/MS instrumentation. However, the relative sensitivity of particle beam is less than ESI and is useful only when nanogram quantities of analyte are anticipated.

Quantitation of Hydroxybenzoates in Biological Fluids as Indices of Hydroxyl Radical Production.

*Jane A. Montgomery, Line Ste-Marie and Julie Brunet, Nutrition Department, Université de Montréal, Notre-Dame Hospital Research Center, Montréal, Canada, H2L 4M1.

Free radical production is increasingly associated with human pathologies, especially those involving reperfusion injury following ischemia as is seen in heart attack, organ transplant or stroke. *In vivo*, hydroxyl radicals are produced from hydrogen peroxide in the presence of metal ions. To estimate hydroxyl radical production, we have developed a method using gas chromatography-ion trap mass spectrometry to quantitate hydroxylation products of benzoic and hydroxybenzoic acids. Analyses were performed on a Varian Saturn II under EI conditions. A DB-5 (30 m x 0.25 mm) column was temperature programmed at 110° for 2 min, 6°/min to 280° which was maintained for 6 min. Helium flow rate was 1 ml/min. The TBDMS derivatives of hydroxybenzoates were quantitated using deuterium labeled internal standards. Retention times and fragment ions are presented in Table 1. Standard curves prepared from extracts of aqueous solutions are linear in the range 0.1-10 μM, R = 0.98-0.999. The detection limit is < 1 pmol injected on-column which is an improvement on HPLC methods with reported limits of 10 pmol (1) and 125 pmol (2). We can simultaneously analyze 13 different hydroxylation products derived from benzoic acid, making the method suitable for screening hydroxyl radical formation. A Fe^{3+}/ascorbate hydroxyl radical generating system was used to evaluate and quantitate hydroxylation of benzoate and 4-hydroxybenzoate *in vitro*. Hydroxybenzoates (Table 2) in urine samples from volunteers were determined to establish normal values prior to assaying these compounds in urine from patients suffering from ischemic disease where hydroxyl radical production is expected to be elevated.

Table 1: Characteristic Ions and Retention Times for the TBDMS Derivatives of Hydroxylate Benzoic Acids.

Compound		MW	RT (min)	Ion (%Intensity)
Benzoate	I	236	9.4	**179**(100),**105**(18)

Quantitiative Determination of All-*trans* -Retinoic Acid in Rat Serum and Rabbit Plasma by GC/NCI-MS

* C. D'Arienzo, M. Jemal, D. Hawthorne, P. J. Gale and A. I. Cohen, Department of Metabolism and Pharmacokinetics, Bristol-Myers Squibb Pharmaceutical Research Institute, New Brunswick, N. J. 08903

Retinoic acid, a multiply substituted 9-carbon tetra-*ene* carboxylic acid, is known to be chemically unstable with respect to heat, air and full spectrum light. Its quantitative analysis requires conditions suited to the fragile nature of this compound. LC and LC/MS have been employed for such assays to minimize the possibility of isomerization and to provide resolution of the 13-*cis* and all -*trans* isomers of retinoic acid [1].

In this GC/NCI-MS method which utilized the HFIP ester of all-*trans* -retinoic acid (*tr*-RA), no chemical transformation resulting from the use of the GC was evident. The cis and trans isomers are chromatographically resolved, and *tr*-RA can be measured quantifiably at levels corresponding to injection of 1 pg with a S/N of ~ 40:1. With only 2% of the sample injected, this suggests a limit of quanitification (LLQ) of 25 pg/mL with 1 mL extracted.

However, the achievable LLQ in any assay will in part be determined by the volume available for extraction. If only 50 µL of each sample is available, as was the case for the rat study shown here, the LLQ will be raised by a minimum of a factor of 20 - suggesting an LLQ of 500 pg/mL.

For this assay, the LLQ is further limited by the existence of endogenous *tr* -RA. Because the size of the peak representing the endogenous material increases with the volume of matrix extracted, larger sample sizes afford no improvement in the concentration corresponding to LLQ. For the rat and rabbit studies discussed above, 1 ng/mL was the smallest concentration of *tr*-RA that could be distinguished from endogenous *tr*-RA, regardless of extracted volume.

The stable compound β-ionylidene acetic acid (β-IAA) was chosen to enhance accuracy and precision and troubleshoot the extraction and analysis.

All work was done in yellow light because of the light sensitive nature of *tr* -RA

Quantitative Determination of Lanosterol and Dihydrolanosterol in Plasma, Serum and Tissues by GC-MS for Evaluation of Cholesterol Lowering Agents. **S. Murakami, K. Johansen, P. Haroldsen, and I. Massey. Syntex Discovery Research, Palo Alto, CA. 94304**

RS-21607-197 is a specific inhibitor of 14α-lanosterol demethylase, an enzyme in the biosynthetic pathway of cholesterol. Syntex is currently investigating the therapeutic utility of the compound to lower cholesterol. Lanosterol (LAN, structure 1) and dihydrolanosterol (DHL, structure 3) were selected as biological markers to monitor the effect of RS-21607-197 on the 14α-lanosterol demethylase activity. To support these studies, specific GC-MS methods have been developed for the quantitation of LAN and DHL in dog plasma, human serum, and hamster liver.

A brief description of the methods for the determination of LAN and DHL in dog plasma, human serum and hamster liver homogenate is as follows. LAN, DHL, and an added internal standard (D_3-DHL) are extracted from plasma, serum, or liver homogenate into chloroform / methanol. The organic extracts are evaporated to dryness and the residue is reconstituted with chloroform. Following adjustment of the polarity of the organic extract by the addition of hexane, the analytes are further purified using a silica gel mini-cartridge. The analytes are eluted with ethyl ether / hexane, the eluate is evaporated to dryness and the residue is treated with BSTFA-1% TMCS in toluene. A portion of the reaction mixture is injected into a Hewlett Packard 5971 MSD GC-MS operating in the electron ionization mode. Under the ionization conditions employed the trimethylsilyl derivatives of the analytes (structures 2 and 4) produces abundant molecular ions at m/z 498^+ (LAN, Figure 2), m/z 500^+ (DHL), and m/z 503^+ (D_3-DHL). Selected ion monitoring of the molecular ions provides specificity for the quantitation of LAN and DHL with a sensitivity of 0.050 mcg of LAN and DHL per ml of plasma, serum, or amount of tissue. Since there are endogenous levels of lanosterol in the biological media from untreated animals or subjects, calibration curves produced from the biological media would result in a positive offset at the zero level. By producing a calibration curve from buffer the problem of an offset can be eliminated. Since calibration curves produced from buffer have been determined to be parallel with those produced from biological media, calibration curves produced from buffer were used to quantitate LAN and DHL in samples. Linear calibration curves are obtained in the range of 0.050 - 2.00 mcg of LAN and DHL per ml of buffer. The linear range of the method is from 0.050 to 20.0 mcg of LAN and DHL per aliquot of plasma, serum, or liver homogenate using 0.1 to 1 ml of plasma or liver homogenate for analysis.

Quality control (QC) samples (two at each of three concentrations) were analyzed with each set of unknowns to monitor method performance. The inter-assay varibility (%CV) for the plasma and serum QC samples ranged from 4.2 - 7.8 for LAN and 2.3 - 5.9 for DHL. The % recovery of LAN and DHL (found / added) ranged from 93.2 - 104.7 for LAN and 98.6 - 101.9 for DHL. The inter-assay variability (%CV) for the tissue QC samples ranged from 2.0 - 30.6 for LAN and 1.1 - 26.8 for DHL. The % recovery of LAN and DHL (found / added) ranged from 90.8 - 103.7 for LAN and 86.5 -99.6 for DHL.

These methods have been applied to the analysis of samples obtained from dogs, humans, and hamsters following administration of RS-21607-197. Administration of RS-21607-197 to dogs and hamsters increases the concentration of LAN and DHL in plasma and liver up to two orders

of magnitude. The concentrations of LAN and DHL in the plasma of dogs after daily administration of RS-21607-197 for 1 month are proportional to the dose (Figure 3). Liver from hamsters treated with a single dose of ^{14}C-RS-21607-197, shows a postive correlation between the total tissue radioactivity and elevation of LAN and DHL.

In conclusion, specific methods to determine LAN and DHL in dog plasma, human serum and hamster liver homogenate have been developed to monitor the effect of RS-21607-197 on the 14α-lansterol demethylation step in the biosynthesis of cholesterol. These methods fulfill the analytical requirements necessary to support preclinical and clinical studies.

Quantitative Determination of Butorphanol in Human Plasma by GC/ECCI/MS

Daniel E. Mulvana
Bristol Myers Squibb, Pharmaceutical Research Institute
Syracuse, NY 13221

Butorphanol (Figure 1) is a synthetic opioid[1] indicated for the relief of moderate to severe pain. Due to the low transnasal doses administered (1 mg), a very sensitive assay was needed for the determination of complete plasma pharmacokinetic profiles. An assay method was developed which fulfilled this requirement by incorporating solid phase extraction, derivatization, and separation and detection by capillary gas chromatography-electron capture chemical ionization-mass spectrometry (GC/ECCI/MS).

Plasma samples (0.5 ml) containing butorphanol were diluted with 0.5 ml 10 mM ammonium acetate, pH 6.0. The internal standard (Figure 1) was added and the samples were transferred to Bond Elut® CN-N extraction columns. Following two washes with buffer and one wash with 70% acetonitrile in water, the compounds were eluted with 1% triethylamine in acetonitrile with an extraction recovery of 90%. After removal of the elution solvent under nitrogen, the compounds were derivatized by adding 0.1% pentafluorobenzoyl chloride in methylene chloride in the presence of pyridine, capping the tubes and heating the sample in a dry block at 40°C. The solvent was removed under nitrogen and the sample was reconstituted in 30 µl of toluene.

Separation and detection were accomplished using a Hewlett-Packard 5988A mass spectrometer interfaced to an HP 5890 Series II gas chromatograph. The processed samples (3 µl) were injected in the splitless mode onto a 15m DB-1 (0.25 mm ID, 0.25 µm film thickness) GC column at an injection port temperature of 285 °C. The initial oven temperature was 200 °C and was ramped at 25 °C/min to a final temperature of 310 °C for 2.1 min. The molecular ion was the base peak for both compounds (Figure 2). The compounds were detected by selected ion monitoring of ions 521.0 for derivatized butorphanol and 507.0 for the internal standard. The ion source temperature was 200°C and methane was used as the buffer gas at a pressure of 0.75-0.85 Torr.

The assay was linear over the desired concentration range of 20 -2000 pg/ml and all standard curves from the validation (n=7) had r^2 values of ≥ 0.994. The processed samples were stable at ambient temperature for at least 42 hours and butorphanol was stable in plasma when stored at -20 °C for at least 123 days. Analysis of replicates (n=5) of plasma quality control (QC) samples at concentrations of 170, 1100, and 1680 pg/ml over three separate days showed the assay to be precise and accurate. Intra- and inter-assay precisions (%RSD) were within 12% and the grand mean predicted concentrations for all QC samples deviated from the nominal by less then 3%. Intra-assay QC deviations were all within 10%.

The results show that the assay is sensitive, specific, precise, accurate, and reproducible and is expected to be suitable for accurate determination of butorphanol in human plasma.

Quantitative determination of the antipsychotic agent CP-88,059 in human serum by HPLC/MS/MS.

Hassan G. Fouda, Kimberly Navetta, Elbridge Luther and Richard. P. Schneider
Central Research Division, Pfizer INC, Groton, CT 06340

CP-88,059 is a promising antipsychotic agent currently undergoing clinical evaluation. A specific analytical method for its quantitative determination in human serum was required to support human pharmacokinetic and pharmacodynamic studies. This presentation describes the assay which utilizes on-line HPLC and atmospheric pressure chemical ionization (HPLC-APCI) tandem mass spectrometry (MS / MS). A structural analog served as the internal standard for the assay. The drug and the internal standard are extracted from serum and following a simple clean-up, aliquots are injected onto a standard reverse phase HPLC column. The effluent from the HPLC column at 1ml/min is introduced into the atmospheric pressure source of a SCIEX API III mass spectrometer. The protonated molecular ion undergoes collision induced dissociation to a specific product ion. CP-88,059 concentrations in serum are determined by the selected monitoring of the product ion from the drug and the internal standard.

The assay concentration range extends from 0.5 ng/ml to 50 ng/ml, and its precision and accuracy over that range are 9% or better. It has thus far been utilized for the analysis of several thousand clinical samples.

Analysis of serum samples containing known amounts of CP-88,059: *intra*-assay parameters; 6 samples at each concentration.

A NCI GC/MS Method for Olanzapine in Human Plasma

R.M. Goodwin, R.D. Barton , T.A. Gillespie
Lilly Laboratory for Clinical Research
Indianapolis, IN 46285

Introduction

Olanzapine is a new drug candidate targeted for the treatment of psychotic illnesses such as schizophrenia and schizophreniform disorder. This antipsychotic compound is an antagonist of dopamine action at D1 and D2 receptors. It also has serotonin antagonist activity at the 5HT2 receptor and thus has anticholinergic properties. This profile suggests that it may provide antipsychotic efficacy without extrapyramidal side effects. Olanzapine is presently being evaluated in Phase II clinical trials in the U.S., Europe, and Asia. A NCI capillary GC/MS method for quantitating Olanzapine in human plasma is described here. The structure of Olanzapine is shown in **Figure 1**.

Extraction & Derivitization

Careful sample preparation is critical for the success of the assay. After addition of 5 ng of an internal standard (I.S.), LY170222, Olanzapine and the I.S. are extracted from 1 ml aliquots of human plasma. To achieve a sufficiently "clean" preparation, the extraction requires several steps. The plasma is first acidified (<= pH 2.0) with 1 N HCL and washed with a 1:1 mixture of ethyl acetate and hexane containing 0.3% butanol. This removes a significant amount of lipids and other chromatographically interferring substances. The wash is discarded and the aqueous phase is alkalinized (>= pH 9.0) with 1 N NaOH. Olanzapine is partitioned into ethyl acetate and removed to a clean tube. The ethyl acetate is acidified with 2 ml of 0.1 N HCl. The ethyl acetate is discarded and the acidified aqueous fraction is alkalinized (pH >= 10) with 1N NaOH. This fraction is then extracted with methylene chloride and reduced to dryness using a Speed Vac. The resulting extracts are treated with heptafluorobutric acid anhydride (HFAA) to form the heptafluorobutyl (HFBA) derivatives of Olanzapine and LY170222 (I.S.). The derivatized materials are dissolved in 200 µl of methanol and separated via GC on a 15 meter DB-5 fused silica capillary column. Injection volume is 1 to 5 µl.

Experimental

Peaks eluting from the GC column are detected mass spectrometrically with a Finnigan 710 or a Finnigan 4500 single quadrupole MS operated in the methane chemical ionization mode (CI) with multiple ion detection of appropriately selected negative ions (MID). The ratio of an ion at m/z=470 (Olanzapine) to an ion at m/z= 484 (LY170222) is is used for quantitation. On the 4500, ions at m/z 370 (Olanzapine) and m/z=384 (I.S.) are used because they are more intense. Plasma concentrations of unknowns are calculated relative to a standard curve constructed from drug-free plasma samples spiked with Olanzapine (0 to 64 ng/ml in 9 steps). Response across the specified range is linear. The limit of detection is 0.1 ng/ml.

Analysis of Bile Acids and Sterols in Cecum and Colon Contents from the Sprague-Dawley Rat by GC/FID-MS

*M.P. Purdon, R. Takigiku, R.E. Schneider, L.O. Whiteley
Procter & Gamble Co., Miami Valley Laboratory
P.O. 398707, Cincinnati, OH 45239

INTRODUCTION

Bile acids have been implicated as potential indicators of colon cancer risk. They originate from cholesterol metabolism in the liver. There they are conjugated with taurine or glycine before they are secreted into the bile. Once in the intestine the bile acids can be deconjugated into the free acid form and then transformed into secondary bile acid structures by the gut microflora. A significant portion of the bile acids are reabsorbed but some are excreted in the feces. Most studies have been based on bile acid analysis of the excreted feces and not on the actual colon contents. Our study targeted transformation of primary bile acids to their secondary analogs in the cecum and colon of the rat.

Here we present the methodology used to extract, identify and quantify bile acids directly from colon contents.

EXPERIMENTAL

Lyophilized samples were extracted in methanol:chloroform. The extract was hydrolyzed and then saponified to convert all bile acid sulfates and conjugates to the free acid form. The bile acids and sterols were then separated by liquid-liquid extraction and the bile acid fraction cleaned up using reverse-phase, solid phase extraction.

The bile acid methyl esters were formed using diazomethane followed by silylation of the hydoxyl groups with HMDS/TMCS. The sterols were silylated before injection.

Both fractions were gas chromatographed on the same DB-1701 phase. Using a "X" press-tight connector (Restek), the column effluent was split between a flame ionization detector and HP 5971A mass spectrometer. The separation was performed isothermally to insure a consistent spit to both detectors throughout the entire run. Components were quantified on the FID while obtaining structural confirmation with the MSD.

RESULTS AND DISCUSSION

Current methods for bile acid & sterol analyses are complex and time consuming. They cover the range from exhaustive separation of all classes (free, sulfated, conjugated) to total bile acid content only. Our goal was to develop a simplified procedure to quantify total bile acids. Our approach was to chemically convert all species to their free acid analogs before isolation. The finished extracts are extremely clean and chromatography can be performed with minimal interference.

We were not able to obtain all standards that we needed for quantification by SIM. In particular the ω-muricholic is not available and the other muricholic epimers are often of questionable purity. FID can be used to accurately quantify these isomers because all give the same response as other trihydroxy-substituted acids. Nevertheless the complex matrix prompted us to use EI-MS to identify the components we were quantifying by FID.

To meet the above criteria we implemented a post-column splitter to go to both detectors. The splitter is made from a simple press-tight "X" (Restek) and deactivated fused silica tubing. In general the connecting line to the FID needs to be half the length and twice the diameter as the line inserted into the MSD. A flow regulator supplies He make-up gas to the splitter to force sample to the FID. Since the splitter is pressure dependent, the separation must be performed isothermally. Even using constant flow during a temperature programmed run does not provide a consistent split.

Chromatography of the Me/TMS derivatives has been done on non-polar columns simply because the columns are more stable. Typically Carbowax or QF-1 phases give slightly better separation but deteriorate quickly. We needed good separation of our components since we were not using SIM, and in addition, needed a column on which the separation could be done isothermally. A cyanopropyl-phenyl substituted phase (DB-1701) gives baseline resolution of all components of interest even under isothermal conditions. Shown at left is a FID trace of bile acids using the equipment described.

Quantitative Determination of α-Cyclodextrin in human urine by Electrospray LC/MS.

*K. Michaelis, Z.B. Salama, L.A.B. Inc. Ridgefield, N.J. 07657, U.S.A., J. Rontree, Fisons Instruments, Altrincham, U.K. and H. Bökens, Schwarz Pharma AG, Monheim, Germany

The unique features of cyclodextrins in various pharmaceutical areas have been widely acknowledged in recent years. An improvement in the stability or solubility of drugs using cyclodextrins, reported in the literature, is due to inclusion complexation properties of cyclodextrins. For example, cyclodextrins form inclusion complexes with barbiturates or prostaglandin-E1 is stabilized with α-cyclodextrin (α-CD). Only a few papers have been published on the bioanalysis of cyclodextrins. Therefore, we have developed and validated a highly selective and sensitive Electrospray LC-MS method capable to quantitate α-cyclodextrin (fig. 1) in human urine. MS analysis was performed an a VG Quattro triple stage quadrupole system using the electrospray ion source. An Applied Biosystems HPLC system operated at 200μl/min was coupled to the mass spectrometer via a splitter (20 : 1 split). The urine extracts of the cyclodextrins were separated on a C_{18} 1 x 150 mm column using a acetonitrile/water solvent system containing 1% formic acid. The isolation of α-cyclodextrin and the internal standard ß-cyclodextrin from the biological matrix was carried out by solid phase extraction with C_{18} cartridges. The extracts were derivatized with acetic anhydride. The ES mass spectra (positive ions) of the peracetylated cyclodextrins showed a couple of intense peaks (fig. 2a/b). For the quantitation of α-CD m/z 1748 was used and for the quantitation of ß-CD m/z 1027. Using α-CD standard solutions, separate series of blank urine (1ml) were spiked at concentrations ranging from 0.2 - 20μg/ml (fig. 3). These calibration samples were extracted as described by determining the peak area ratios of α-CD/ß-CD and comparing these ratios with the standard curve obtained from analysis of the calibration samples. The selected chromatograms of a subject sample and a control sample spiked with 1μg α-

CD per ml urine are shown in fig. 4. The analytical method described here provides the appropriate sensitivity and selectivity for the determination of α-cyclodextrin (CD) in human urine, in clinical trials evaluating the fate and pharmacokinetic profile of α-cyclodextrin.

Quantitative Analysis of GR38032 by Isotope Dilution Particle Beam-LC/MS Using Normal Phase and Reverse Phase HPLC

* Brian P. Downey and Daniel L. Norwood, Glaxo Research Institute, Five Moore Drive, Research Triangle Park, NC 27709

Particle Beam-Liquid Chromatography/Mass Spectrometry is a well known technique for obtaining electron ionization (EI) mass spectra from samples separated by high performance liquid chromatography (HPLC). The utility of PB-LC/MS for qualitative analysis is well known, however, quantitative analysis is hampered by the existence of a "carrier effect" in which a coeluting substance enhances the sensitivity of a target compound and may produce non-linear responses. Previous work by this laboratory[1] indicates that reliable quantitation by isotope dilution PB-LC/MS is possible. This report describes the utility of PB-LC/MS for the quantitation of pharmaceuticals by both reverse phase and normal phase HPLC. HPLC assays were developed and characterized for the quantitation of GR38032F (a new $5HT_3$ antagonist) by isotope dilution PB-LC/MS using d_3-GR38032 as the internal standard. This isotope labeled analog coelutes with GR38032 using each of the HPLC systems developed. A linearity comparison with thermospray-LC/MS is also included.

Enhancements in ion abundance for coeluting substances during PB-LC/MS analyses have been observed by several laboratories[2,3,4]. These enhancements are generally recognized as the result of a particle beam "carrier effect" in which increased transport efficiency through the momentum separator is observed for coeluting substances. Formation of molecular clusters in the liquid phase exist as particles in the nebulizer spray and act as particle beam carriers by increasing the effective mass and reducing the vapor pressure of the analytes[2]. The carrier effect potentially results in non-linear response and may limit the applicability of PB-LC/MS for quantitative analysis. This laboratory is currently investigating the quantitative analysis of GR38032F by isotope dilution PB-LC/MS using d_3-GR38032 as the internal standard.

The particle beam carrier effect has negative implications for qualitative analysis as well as quantitative analysis. Selected ion chromatograms (m/z 293, 279, 167, 149) generated from the analysis of GR38032F by PB-LC/MS show a peak that elutes at approximately 9 5 minutes. The molecular ion for GR38032 is m/z 293, while ions 279, 167, and 149 are associated with a phthalate impurity in the mobile phase, and are not part of the GR38032 EI+ spectrum. Therefore, difficulties may exist in obtaining appropriate background subtracted spectra for GR38032, as well as spectra for low level GR38032 impurities.

The utility of PB-LC/MS for the quantitative analysis of pharmaceutical compounds was assessed by examining the linearity and detection limits for both normal and reverse phase chromatography systems. The linearity of response for GR38032F was investigated by injecting five standard solutions of GR38032F containing 13, 52, 258, 512, and 1312 ng of GR38032F (each containing a constant 381 ng of d_3-GR38032) on a normal phase HPLC system. A linear regression was performed on the relative responses obtained for the standard solutions and the response was linear with a correlation coefficient of 0.995. The same experiment was repeated using a reversed phase chromatographic system, however,

the detection limit obtained was higher than that obtained for the normal phase system and thus precluded using standards in the same concentration range. The linearity of response for GR38032F using the reverse phase chromatography system was investigated by injecting five standard solutions containing 0.6, 1.2, 2.4, 4.8, and 9.6 μg of GR38032F (each containing a constant 19 μg of d_3-GR38032). Linearity of response was demonstrated by the correlation coefficient of 0.998 obtained for the reverse phase system. For comparison purposes, the linearity of response for GR38032F was investigated by injecting five standard solutions containing 13 - 1300 ng GR38032F and a constant 381 ng of d_3-GR38032 on the TSP-LC/MS system. Linearity of response was demonstrated and a correlation coefficient of 0.997 was obtained for the TSP-LC/MS analysis.

The effect of different mobile phase buffers on the relative response of GR38032F to d_3-GR38032 was assessed by injecting standard solutions containing 13 ng and 52 ng, respectively, of GR38032F on several chromatographic systems utilizing different buffers. Each standard solution contained a constant 381 ng of d_3-GR38032. The buffers examined included 0.1% trifluoroacetic acid, 0.025 M ammonium acetate, 0.024 M ammonium citrate, and 0.1% ammonium formate. Each HPLC system used a mobile phase of 50% acetonitrile and 50% of the appropriate buffer solution. The relative response for each standard solution was calculated and the results indicate that no significant difference was observed for the relative responses obtained for the 52 ng standard in each of the mobile phases tested. The average relative response was 0.1846 ± 0.0101 (5.5% RSD). However, the average relative response obtained for the 13 ng standard was 0.1199 ± 0.0361 (30% RSD). The higher % RSD obtained for the 13 ng standard is probably due to the irreproducibility of results for consecutive injections in the same mobile phase buffer at this concentration level.

The notion that body constituents are continually formed and utilized was one of the most far reaching ideas of biology in this century.[1,2] The rate at which a cell, organ, or whole organism synthesizes and degrades biopolymers ultimately controls structure and function, and it is likely that most diseases will reduce to disorders of production or removal of specific molecules such as biological polymers.* Nevertheless, there is currently no comprehensive solution to the measurement of their synthesis rates.

Most previous approaches to the measurement of synthesis rates of biopolymers have used tracers labelled with radioactive isotopes. A major limitation of using radiolabelled monomers, however, is that the ratio of tracer to unlabeled monomer in the pool of monomers used to synthesize the biopolymer is difficult to determine and is usually not known with confidence. Although plasma levels are readily accessible, the tracer is not necessarily distributed uniformly throughout the organism.

MIDA is a new method for measuring the synthesis rates of biopolymers. Monomers labelled with stable isotopes are used, and the perturbed isotope pattern of the biopolymer resulting from incorporation of the labelled monomer is compared to the isotope pattern from the native polymer.[3] The synthesis rate is calculated by determining the fraction of the polymers that are new. By comparing the observed pattern to ones predicted from probability theory, the ratio of labelled to unlabeled monomer that existed *at the site of synthesis* can be determined rigorously, without regard to cell and tissue compartmentalization. MIDA has been applied successfully to the determination of the synthesis rates of cholesterol, lipids, glucose, and fructose in humans and rats.

We have begun to apply MIDA to the determination of protein turnover. Initial studies have focused on the use of an automated peptide synthesizer to model *in vivo* protein synthesis occurring on ribosomes using tRNA amino acids. The peptide SVVLLLR was synthesized from FMOC-leucine containing increasing amounts of the d_3-leucine derivative. SVVLLLR was chosen because it is a proteolytic fragment of human serum albumin, the protein for the human studies.

To apply MIDA to the determinaiton of protein turnover it is necessary to meausue isotope ratios with high precision and, ideally, high accuracy. FAB-MS and electrospray MS were used to measure the isotope ratios of the unlabeled oligopeptide, and electrospray ionization was superior. Accuracy and precision were improved considerably by fitting Gaussian curves to the observed peaks.

*Here, polymer refers to molecules synthesized from repeating units and includes cholesterol from acetate monomers, proteins from amino acid monomers, and glucose from three-carbon monomers.

DETERMINATION OF ^{15}N ENRICHMENT OF TAURINE IN CAT URINE BY GC/MS

Andreas A. Stämpfli, Olivier Ballèvre and Laurent B. Fay,
Friskies Research, P.O. Box 44, CH-1000 Lausanne 26, Switzerland

A study of taurine kinetics in the cat was undertaken to understand the physiological basis of taurine requirements. A method was therefore developed for the accurate determination of ^{15}N-taurine enrichment in cat urine by gas chromatography/mass spectrometry.

^{15}N-taurine was given to six animals as an oral bolus dose of 20 mg/kg body weight and the urine was collected over 6 days and pooled on a daily basis. The hydrolysed or non-hydrolysed urine samples (for total and free taurine respectively) were directly derivatised without further purification. The N-pentafluorobenzoyl di-*n*-butyl amide derivative obtained was analysed by GC/MS and the fragment [M-(di-*n*-butyl amide)]+, carrier of the labelled nitrogen atom, selectively recorded at m/z 302 (^{14}N-taurine) and m/z 303 (^{15}N-taurine).

Calibration curves prepared in hydrolysed and non-hydrolysed urine samples spiked with ^{15}N-taurine gave similar slopes to the calibration curve prepared in water. The average coefficient of variation observed for the mole percent excess (MPE) in the non-hydrolysed samples was 1.22 % (n=92) and for the hydrolysed urine 1.00 % (n=98). There was no significant difference between free and total taurine enrichment.

Since the enrichments of free and bound taurine were similar, the half-life and kinetics data were also similar using both non-hydrolysed and hydrolysed samples of urine.

The half-life of taurine in cat body was found to be 29.3 ± 2.9h and 35.0 ± 1.4 h for free and total taurine respectively (non significant). The taurine body pool, calculated by extrapolation of the curve to zero time, had a value of 137 ± 22mg/kg and 157 ± 11 mg/kg for free and total taurine, respectively.

These results illustrate that the bound taurine pool is in equilibrium with the free taurine pool. In these urine samples, 85% of urinary taurine was in the free form. This is related to the fact that taurine intake was in excess of the requirements for cats which is not always

achieved on a diet of unsupplemented commercial petfood. The comparison between free and bound taurine kinetics using both sample enrichment determinations (free and total) should help in the understanding of taurine metabolism in cats and optimise taurine content in different cat foods.

The analysis of urine samples is suitable for taurine kinetics since taurine half-life is longer than a day in the cat. Therefore, any imprecision in the determination of time-related evolution of enrichment in daily pooled urine samples is minimised. Thus the different pathways of taurine metabolism can be determined accurately from taurine pool size and rate constant using a stochastic analysis of the open one-pool model. The presented method allows a fast determination of enrichment in urine samples and can easily be applied to other biological samples, i.e. plasma, whole-blood, since a complete analysis required only 50 nmol of taurine.

Enantioselective Glucuronidation of the Antipsychotic Agent 4-Fluorophenyl-hydroxybutyl-5-fluoro-pyrimidinylpiperazine (5F-FHPP) and Selected Analogs by Rat Liver UDP-glucuronosyltransferases (UDPGTs)

*Frank J. Belas[1], Amin Kamel[1], Lewis J. Klunk[3], Robert Mayol[3], and Ian A. Blair[1,2]. Departments of Pharmacology[1] and Chemistry[2], Vanderbilt University, Nashville, TN, 37232; [3]Bristol-Myers Squibb Co., Pharmaceutical Research Inst., Wallingford, CT, 06492.

The availability of psychoactive drugs has had a profound effect on the treatment of mental illness. However, many of them have significant side-effects when used chronically. The recent development of drugs related to buspirone containing either an azaspirodecanedione or a 1-(2-pyrimidinyl)piperazine (1-PP) moiety has provided a class of drugs with markedly reduced side-effects. The metabolism of the antipsychotic agent 4-Fluorophenyl-hydroxybutyl-5-fluoro-pyrimidinylpiperazine (BMY-14802, 5F-FHPP) has been investigated, and the major urinary metabolites were identified as glucuronide diastereomers. The present study investigated enantioselective glucuronidation in control and phenobarbital induced rat liver microsomes using racemic mixtures and individual enantiomers of 5F-FHPP. Racemic mixtures of 5F-FHPP analogs (5Cl-FHPP, and 5Br-FHPP) were also incubated with phenobarbital induced rat liver microsomes. Structures of the metabolites were confirmed by LSI MS/MS using a Kratos Concept tandem four sector mass spectrometer.

Glucuronidation incubations were carried out in 400 µL of 1M Tris (pH 7), 1.2 mL of 0.1M $MgCl_2$, 0.1M 2-mercaptoethanol, 100 µL Brij 58 solution, 400 µL UDPGA, and 129 µL of rat liver microsomes (1 mg/mL protein) in 0.01M Tris, 0.001M EDTA, 20% glycerin buffer. Enantiomers of BMY-14802 were added to give concentrations of 25 µM to 250 µM. Mixtures were incubated for 20 min. at 37 °C, and the reaction was stopped by the addition of ethyl acetate. Samples were then evaporated to dryness, and the resulting pellet was dissolved in 1.5 mL of methanol/0.01M ammonium acetate (pH 5; 1:1 v/v). After sample clean-up using a C18 SPE column, the eluate was evaporated to dryness, and the residue was re-dissolved in 100 µL of methanol/1N formic acid (2:1, v/v). An additional 100 µL of 1N formic acid was added to this solution. The sample was then spun for 4 min. in an Eppendorf centrifuge. The supernatant was separated and analyzed by reverse-phase HPLC.

Previous studies have demonstrated that BMY-14802 undergoes virtually no oxidative metabolism *in vitro* with human and rat liver microsomes. The major route of BMY-14802 metabolism involves glucuronidation. Glucuronidation was enantioselective *in vivo* with the (-) enantiomer being a better substrate than the (+) enantiomer. Previous studies have also demonstrated that (-) BMY-14802 was a better substrate for UDPGTs from human, bovine, and rabbit microsomes when compared with the (+) enantiomer. Results presented in Figure 1 indicate that in control studies using rat liver microsomes, the (-) enantiomer is preferentially glucuronidated over the (+) enantiomer, but this selectivity was lost upon phenobarbital (PB) induction. Additionally, results suggests that there was

no competitive inhibition between the two enantiomers. Racemic mixtures of 5F-FHPP analogs (5Cl-FHPP, and 5Br-FHPP) were also incubated with PB induced rat liver microsomes. Different substituents at the 5 position of the 1-PP moiety caused differential effects on glucuronidation with Vmax/Km for 5Cl-FHPP>>5Br-FHPP>>5F-FHPP. Structures of the metabolites were confirmed by positive LSI MS/MS using a Kratos Concept tandem four sector mass spectrometer. The positive LSI MS/MS of the BMY-14802-glucuronide is shown as Figure 2.

Derivatizations for Enhanced Detection of N- linked and O- linked Glucuronide Conjugates by LSIMS

P. Haroldsen and I. Massey: Syntex Discovery Research, Palo Alto, CA 94304

Ionization by LSIMS of analytes of biologic origin is often hampered by the presence of interfering substances and by the polarity of the analyte. The greater the polarity, the lower the surface activity of the analyte on the sputtering matrix (1). Modification of analytes by derivatization to improve surface activity for LSIMS has been successsfully employed for both peptides (2) and non-peptide drugs (3). This approach has been extended and applied to the analysis of polar glucuronide drug metabolites and is described herein.

The findings indicate that: a) ester derivatives improve LSIMS sputtering yields of M^+ by greater than 60 fold to allow immediate and unambiguous identification of previously undetectable glucuronide conjugates in extracts of biologic origin; b) the greater the chain length of the alkyl ester derivative of the conjugate, the greater the improvement in sputtering yield (signal to noise ratio) of the M^+ or MH^+ compared to background matrix ions, c) CID and product ion analysis of the M^+ of three quaternary N-linked conjugate esters indicates an unusual type of fragmentation which has been elucidated by stable isotope labeling studies and ester alkyl chain length alteration; d) a key substructural fragment ion elucidates the site of a unique conjugation to be quaternary quinuclidine N-linked.

3. Kidwell, D. et. al. (1985) Biomed. Mass Spectrom. 12: 254.

EXPERIMENTAL: GLUCURONIDES: Quinuclidine N-linked quaternary glucuronides M8, M9 and M12 were isolated from cynomologus monkey urine by C18 Bond Elute cartridges followed by C18 RP-HPLC in tandem with an SCX cation exchange column. HPLC buffer salts were removed with C18 Bond elute cartridges prior to LSIMS. Commercially available glucuronides were obtained from Sigma (Phenothalein, morphine and estradiol).

DERIVATIZATIONS: Dried glucuronide samples, 3 - 20 µg, were treated with 0.1 ml methanol, n-propanol, $^2H_7$-n-propanol (CIL) or n-hexanol acidified with acetylchloride (20 µl / ml alcohol) for 45 minutes at 45°C. The samples were then evaporated to dryness and redissolved in methanol / water (1/1) for analysis by LSIMS.

LSIMS: LSIMS was performed on a Finnigan TSQ-70 mass spectrometer employing an Antek Cesium ion gun operated at 8 keV. Samples were applied to 1µl of glycerol or a glycerol/thioglycerol mixture (1/1).

CID TANDEM MS: Collision induced dissociation was performed in the second quadrupole region employing argon at 0.8 - 1.2 mtorr as collision gas and collision energies of -15 to -25 eV.

RESULTS: Initial attempts to characterize three unknown radiolabeled major components (M8, M9 & M12) of an experimental drug, RS-42358, isolated from monkey urine, by thermospray met with failure. Analysis of the three HPLC purified components by LSIMS did not produce sufficiently intense molecular ions for ready detection of metabolites M8 (Fig 1A) and M9 but did so for M12 . The ion at m/z = 471 for M12 indicated it to be a glucuronide conjugate of the unaltered parent drug RS-42358 (mw = 294). Based on the known structure of RS-42358 the conjugate appeared to be a quaternary N-linked quinuclidine glucuronide.

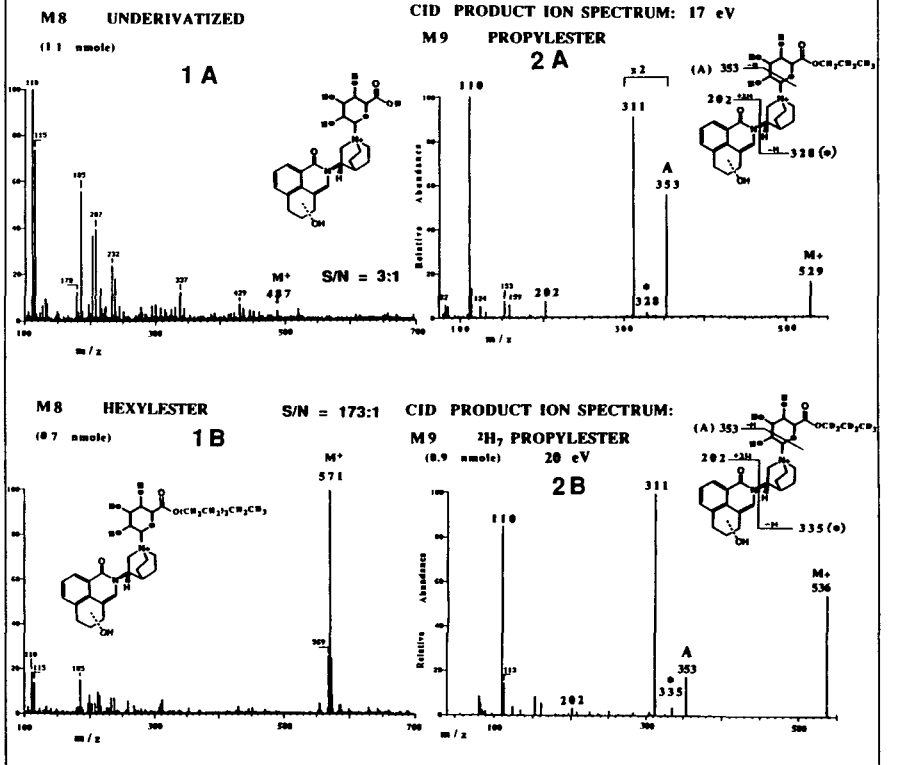
IMPROVED M^+ and MH^+ INTENSITY BY DERIVATIZATION: Derivatization of M8, M9 and M12 to produce propyl esters and reanalysis by LSIMS resulted in sufficiently intense M^+ for detection of M8 and M9 and a significant improvement in the intensity of the M^+ ion for M12. The M^+ ions for M8 and M9 at m/z = 529 indicated them to be the propyl esters of mono-hydroxylated RS-42358 glucuronides. Calculations of the improvements in signal to noise (S/N) responses for the conjugate free acids vs propylesters indicate a 5 (M8), 22 (M9) and 17 fold (M12) increase. Analysis of M8 (Fig 1B) and M12 as hexylesters indicated an even greater improvement in S/N with ratios of S/N for M^+ of esters vs. M^+ free acids at 54 (M12) and 67 fold(M8). Improvements in S/N responses of MH^+ for commercial glucuronides, phenothalein and morphine, as methyl, propyl and hexylesters vs. free acids have been evaluated. The greatest improvement in all cases is observed with hexylesters, resulting in increased S/N ratios of 29 - 60 fold compared to those for free acids.

ELUCIDATION OF SITE OF CONJUGATION: M8, M9 and M12 were structurally characterized by CID and product ion analysis of the M^+ ions. As propyl and hexylester derivatives, M8, M9 (Fig 2A) and M12 were able to be conclusively characterized as unusual quaternary quinuclidine N-linked glucuronides based on the presence of a weak but diagnostically important fragment ion containing the quinuclidine and glucuronic acid moieties (indicated by *). This ion was observed at m/z = 328 for the propylesters at m/z = 335, for the $^2H_7$-propylesters, and at m/z = 370 for hexylesters of the metabolites. The observed shift in this diagnostic fragment ion with derivative type is consistent with the assignment of these metabolites as quaternary quinuclidine N-linked glucuronides.

CHARACTERIZATION OF A UNIQUE FRAGMENT ION: The CID product ion spectra for the propylesters of M8, M9 (Fig 2A) and M12 indicated a unique fragment ion which was observed at 42 amu above the aglycone

fragment ion (indicated as fragment 'A'). For M8 and M9 this ion was observed at m/z = 353 and at m/z = 337 for M12. The propylester adds 42 amu to the nominal weight of the metabolites and the possibility of this fragment arising from a unique propyl group rearrangement was investigated. Following esterification with $^2H_7$ -propanol, CID and product ion analysis of M9 (Fig 2B) and M12 as $^2H_7$ -propylesters indicated that the aglycone +42 amu fragment ion 'A' did not shift. It is likely that this fragment arises from cleavage through the glucuronic acid ring with retention of the elements C_2H_2O(42 amu) on the aglycone. CID and product ion analysis of the M^+ ions of the hexylesters of M8 and M12 indicated that the aglycone +42amu fragment ion 'A' still formed, demonstrating that this fragment is not unique to propylesters. It is not known if the aglycone +42 amu fragment ion is intrinsic to all quaternary N-linked glucuronides following low energy CID. The presence of the CID aglycone +42 amu fragment ion has been observed in one O-linked glucuronide but has not been observed in the spectra of esters of several other O-linked glucuronides, including those presented here for morphine, phenothalein or estradiol, and warrants further investigation.

Acknowledgement: The technical expertise of Adva Yani in the department of Drug Metabolism is gratefully acknowledged for guidance in the isolation of M8, M9 and M12.



ANALYSIS OF INSULIN - ACYL GLUCURONIDE ADDUCTS BY ELECTROSPRAY IONIZATION / MASS SPECTROMETRY.

INTRODUCTION

The elimination of acidic drugs, such as the nonsteroidal anti-inflammatory drugs (NSAIDs), from the body often occurs through conjugation with glucuronic acid to form acyl glucuronides. These conjugates are potentially reactive intermediates which may undergo hydrolysis, acyl migration or irreversible binding to plasma proteins[1,2]. Covalent binding of reactive metabolites to cellular constituents is of interest, as it may result in toxicity, hypersensitivity reactions, mutagenesis or carcinogenesis. The objectives of this study are to evaluate model proteins to study reactions of acyl glucuronides, to determine whether ESI/MS can be used to identify the covalent adducts formed between a model protein (insulin) and acyl glucuronides, and finally to determine if a variety of acyl glucuronides react with insulin by nucleophilic displacement or by imine formation.

EXPERIMENTAL

Acyl glucuronide conjugates of suprofen (SG) , zomepirac (ZG), salicylic acid (SAG), etodolac (EG) and tolmetin (TG) were extracted from human or rabbit urine after oral dosing. *Drug acyl glucuronides were purified by HPLC and characterized by FAB/MS. The formation of* acyl glucuronide adducts was examined with a number of model proteins. Insulin, aprotinin, lysozyme, RNAse, bovine lens protein, and human serum albumin were separately incubated with suprofen glucuronide. Insulin was chosen as the model protein since it was successfully resolved from its acyl glucuronide adduct by HPLC. Recombinant human or bovine insulin and drug acyl glucuronide were incubated with and without reducing agent, $NaCNBH_3$, to examine its influence on the extent of adduct formation.

HPLC Fractionation: Insulin and each drug were measured using a Vydac C18 column (4.6mm X 150mm) coupled to two HP-1050 UV detectors connected in series to HP-3396A integrators; fractions were collected via a Gilson FC 204 fraction collector. Separation of insulin and insulin adducts was accomplished using linear gradients consisting of 100% CH_3CN and 0.1% TFA. One UV detector monitored insulin at 214 nm while the other monitored either 295 (SG), 313 (SA), 313 (ZG), 280 (EtG), or 315 nm (TG).

ESI/MS Identification: Insulin and acyl glucuronide adducts were characterized using electrospray ionization/mass spectrometry (ESI/MS). Samples (5 to 10 pmol/µl) were dissolved in methanol containing 0.5% acetic acid and introduced into the ESI interface at a rate of 1 µl/min. Mass spectra were acquired on a Finnigan-MAT model SSQ700 using an electrospray energy of - 3.5 kV. The ESI spectra were obtained after signal averaging for approximately 1 min.

RESULTS

Insulin reacted with a variety of NSAID acyl glucuronides to form adducts. The mechanism of adduct formation between acyl glucuronides and proteins is not well understood. Binding has been proposed to occur through either a nucleophilic displacement mechanism[3-4] or via a process involving intramolecular acyl migration followed by imine formation between the glucuronic acid moiety of the isomeric conjugate and an amino group of the protein[5]. Reducing

agents increased the formation of imine adducts such that when $NaCNBH_3$ was incubated with insulin and drug acyl glucuronide, an increase of approximately 10 to 20 fold was observed for SG, ZG, and EG.

Insulin, insulin-drug acyl glucuronide adduct, and the respective drug were separated and detected using the gradient HPLC system with dual UV monitors. Insulin acyl glucuronide adducts formed multiple peaks which may suggest that acyl glucuronides reacted at more than one site on insulin. The HPLC fraction that contained the multiple peaks was examined by ESI/MS. The results showed that only one molecular species was present. Acyl glucuronides may react with insulin at either the ε-amino group of Lys or the N-terminus of the A and B chains of insulin. If the multiple peaks were due to the attachment of acyl glucuronides to more than one site on insulin, ESI/MS would not be expected to discern such isomeric adducts since all would have the same molecular weight. Representative mass spectra are shown for human insulin (Fig. 1) and ZG-insulin adduct (Fig. 2). The calculated and observed molecular weights of drug acyl glucuronide-human insulin adducts are presented in Table 1.

HPLC and ESI/MS gave no evidence of adducts that might be formed by a nucleophilic displacement mechanism. The reaction appears to be general for reactive acyl glucuronides since five structurally diverse acyl glucuronides react similarly with the model protein, insulin. These results demonstrate that ESI/MS is an excellent means to identify covalent adducts between small proteins such as insulin and reactive metabolites.

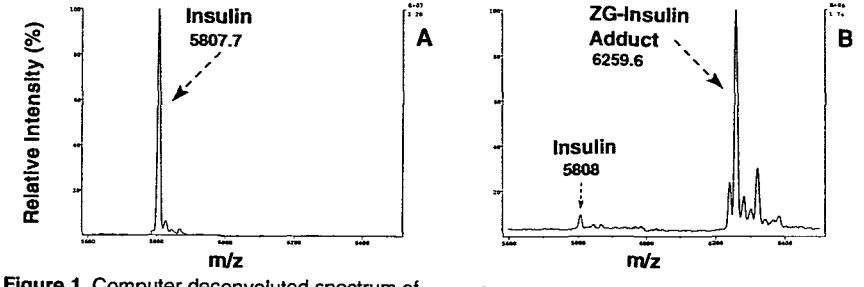

Figure 1. Computer deconvoluted spectrum of (A) human insulin, (B) ZG-insulin adduct by ESI/MS.

Table 1. Calculated and observed mass of drug acyl glucuronide - insulin adducts by ESI/MS.

Acyl Glucuronide Conjugates	Calculated Mass of Insulin Adduct	Observed Mass of Insulin Adduct
Suprofen	6228.1	6227.9
Salicylic Acid	6105.7	6105.4
Zomepirac	6259.5	6259.5
Etodolac	6255.1	6254.8
Tolmetin	6225.1	6225.1

ASSAY OF THE [^{13}C]ENRICHMENT AND CONCENTRATION OF ACETATE IN BIOLOGICAL FLUIDS

France David, Michel Beylot, Mitchell W. Reider,
Vernon E. Anderson and Henri Brunengraber
Depts of Nutrition and Biochemistry,
Case Western Reserve University, Cleveland OH 44106.

[^{13}C]Acetate is extensively used for investigating intermediary metabolism, particularly for tracing gluconeogenesis. In general, the incorporation of label into products is not correlated to the molar percent enrichment (MPE) of acetate in biological fluids. Its measurement is difficult because of (i) low concentration of acetate in plasma (20 to 60 μM), (ii) poor extractibility of acetate from water into organic solvents, (iii) difficulty to find suitable derivatives for HPLC or GC-MS, and (iv) ubiquitous presence of acetate in the environment and in many reagents.

We tried techniques, involving organic extraction (1,2). These yielded high blanks and low recoveries. We then developed an assay that converts acetate to acetyl-CoA, then to acetyl-glycine (3) which is assayed by GC-MS as methyl or pentafluorobenzyl ester.

METHODS

A clean laboratory is dedicated to the assay. Plasma samples are spiked with 237nmol of [1-^{13}C,^{2}H$_3$]acetate internal standard. Neutralized perchloric acid extracts are incubated for 2 hr with 1.8 mM ATP, 3.0 mM $MgCl_2$, 0.8 mM CoA, 60 mM TRIS/30 mM KCl pH 8.0 and 1.3 U of acetyl-CoA synthetase (final vol: 1.7 ml). Then, 1.7 ml of 1 M glycine pH 9.8 is added to convert acetyl-CoA to acetyl-glycine. After 4h at 60°, the solution is run on a AG-50-X8 Cl^- column. Acetyl-glycine, eluted with water, is dried and reacted with CH_2N_2 or PFBBr + pyridine. The methyl and PFB derivatives are assayed by PCI and NCI-MS, respectively. For acetyl-CoA assay, the latter is reacted with glycine, then with PFBBr.

RESULTS

The PCI spectrum of acetyl-glycine methyl ester has a useful ion at m/z 132 ([M+H$^+$]). The NCI spectrum of acetyl-glycine-PFB has a useful ion at 116 (loss of PFB group). Figs 1-3 show linear standard curves of [2-^{13}C]acetyl-CoA enrichment, acetate concentration in dog plasma (blank 17nmol) and [2-^{13}C]acetate enrichment in dog plasma. Similar sensitivity is achieved with the methyl and PFB esters.

A dog was infused with [2-^{13}C]acetate at 3 sequential rates of 3, 6 and 9 μmol/kg x min. Fig 4 shows the concentration and MPE of plasma acetate. Rates of acetate appearance (corrected for tracer infusion) were 7.5, 5.5 and 4.7 μmol/kg x min, respectively.

APPLICATION OF GC-CRIMS IN THE INVESTIGATION OF METABOLIC DISEASE

Donald H. Chace, Diane S. Roe, and David S. Millington, Department of Pediatrics, Division of Genetics and Metabolism, Duke University Medical Center, Durham, N.C. 27710

Capillary Gas Chromatography - Chemical Reaction Interface Mass Spectrometry was utilized in the investigation of biochemical pathways of patients with inherited metabolic disease. A chemical reaction interface (CRI) is primarily a helium plasma generated inside a ceramic tube that is present in a tunable cavity connected to a microwave power supply. The input to the reaction interface consists of a capillary GC and a reactant gas supply and the output is a transfer line connected to the mass spectrometer. Compounds that enter the CRI following gas chromatography are completely decomposed to elemental species. With addition of an oxidizing or reducing reactant gas, low molecular weight polyatomic molecules containing the elements present in the original compound are produced. These small molecules are detected using a mass spectrometer. Isotopic enrichment with the stable isotopes ^{13}C, ^{15}N, and D is detected by monitoring the mass of the low molecular weight molecule produced in the CRI that is representative of the isotope present in the original compound. For example, the isotopes of carbon and nitrogen are monitored at unit mass resolution as $^{12}CO_2$, $^{13}CO_2$, ^{14}NO, ^{15}NO when SO_2 is used as a reactant gas. Isotopic enrichment with deuterium is detected by monitoring HD when hydrogen is used as the reactant gas. A resolution of ca. 1500-2000 is needed to separate HD from H_3^+. Since this resolution was not attainable on the benchtop GC/MS system, a magnetic sector MS was employed. The detection of deuterium-enriched metabolites in the urine of patients with metabolic diseases after the infusion of deuterium-labelled precursors is described.

The metabolic pathways of patients with known metabolic disorders in amino acid catabolism were studied following administration of deuterium labelled (>98%) substrates. Methyl-D_3-leucine was administered to a patient with HMG-CoA lyase deficiency. Methyl-D_3-isoleucine (50:50 isoleucine and alloisoleucine) was administered to patients with β-Ketothiolase deficiency. Control (baseline) urines were collected before the start of these infusion studies. HMG-CoA lyase deficiency is a disorder in the catabolism of L-leucine resulting in the increased excretion of 3-OH-3-methyl glutaric acid (HMG), 3-methylglutaric acid, 3-methylglutaconic acid and 3-OH isovaleric acid. β-Ketothiolase (2-methylacetoacetyl-CoA thiolase) deficiency is a disorder in the catabolism of L-isoleucine. Characteristic urinary organic acid profiles of patients with this disorder usually reveal elevated levels of 3-OH-2-methylbutyric acid and often 2-methylacetoacetic acid with or without tiglylglycine.

1 mL of urine was treated with ethoxyamine-HCl to convert oxoacids to their corresponding oximes, acidified to pH 1, and extracted 3 times with 1 mL of ether and 1 mL of ethyl acetate. The extracts were dried under N_2 and derivatized with 100 μL of BSTFA (bis-trimethylsilyl-trifluoroacetamide) and 5μL of pyridine. One μL of each derivatized sample was analyzed. Various amounts of d_4-glutaric acid, (0.1, 1, 5, 10, and 20 μg) were added to separate vials containing 5 μg of d_3-palmitic acid (external standard) and derivatized with 100μL of BSTFA (85°C for 30 minutes). One μL of sample was analyzed by splitless injection onto a DB-1 column. To test detection limits, 1 μL of serial dilutions of 1 μg/μL of d_{10}- fluorene in CCl_4 was analyzed by splitless injection onto a DB-1 column. A VG 70S mass spectrometer was used at a resolution of 2000 in order to separate HD (3.0219) from H_3^+ (3.0234) and ^3He (3.0160). The amount of H_3^+ produced in the source relative to HD is affected by the amount of hydrogen introduced into the CRI and the repeller voltage. The maximum signal for HD relative to H_3^+ was produced using a high positive repeller voltage. The amount of reactant gas needed in the CRI is determined by the red color of the plasma, ratio of H_3^+ to HD (≈5:1), and the performance of deuterium labelled standards in a test analysis. The raw signal for HD was monitored directly (peak top) using a Shimadzu C-R5a chromatographic data processor.

The metabolic profiles of a patient with HMG-CoA lyase deficiency before and after D_3-leucine administration and metabolic profiles of a patient with β-Ketothiolase deficiency before and after administration of D_3enriched Isoleucine was examined. In each metabolic profile in which D_3-labeled substrate was administered, several deuterium enriched peaks were detected *Figures 1 & 2*. These are catabolites of the D_3-labeled precursors which retain at least 1 deuterium atom. A control chromatograms for each disease profile was determined. These are metabolic profiles of the same patients before administration of the D_3-labeled precursor. The absence of any significant peak in the chromatogram demonstrates selectivity. For a patient with HMG-CoA Lyase Deficiency several deuterium enriched peaks corresponded to the catabolites known to be excreted by a patient with this disease as shown in *Figure 1*. The retention times for each peak were recorded and the peaks at each specified retention time were structurally identified using conventional EI/MS under the same chromatographic conditions. Although a separate instrument was used in this laboratory to obtained EI spectra, it has been previously demonstrated that conventional EI/MS can be obtained using the same instrument

containing the CRI apparatus but with the microwave power turned off. As expected several deuterium peaks were identified as 3-OH-isovaleric acid, 3-methylglutaric acid, and 3-methylglutaconic (2 isomers), and 3-OH-3-methylglutaric acids. Spectra for three peaks (a,b,c) containing enriched deuterium have been obtained but no structure assignment has yet been made. For a patient with β-Ketothiolase Deficiency the peaks detected in the CRIMS chromatogram correspond to 3-OH-2-methylbutyric acid (2 isomers) and 2-ethyl-3-hydroxypropionic acid as shown in *Figure 2*. Identification of each peak was performed by conventional EI/MS in a similar manner as described for HMG-CoA Lyase Deficiency. The linearity of deuterium analysis using GC-CRIMS was examined using $d_3$palmitate (external standard) and serial dilutions of $d_4$glutaric acid. The correlation coefficient of the analysis was 0.93 for a range of 10 ng to 200 ng (on column injection). The detection limit for d_{10}-fluorene was 100 pg was detected with a signal to noise ratio of 5:1.

The ability of GC-CRIMS to selectively detect deuterium enriched substrates has been demonstrated. CRIMS detects deuterium in a structure independent manner which simplifies the search for metabolites of a deuterium labeled precursor. In the metabolic studies described above, several deuterium enriched metabolites were detected. Conventional EI/MS for the major metabolites confirmed the presence of 1 to 3 deuterium atoms. Several additional peaks which contained excess deuterium and gave uninformative EI/MS spectra were also detected.

and *Laboratory of Chemical Physics, NIDDK, NIH, Bethesda, MD 20892

Introduction

Cyclic boronate derivatives of diols (or other bifunctional compounds), which could capture electrons and stabilize significant structure specific fragment ions are being investigated. The use of these derivatives has been of interest since we observed the potential utility of pentafluorophenylboronic acid (FPBA)[1]. While FPBA exhibited facile boronate formation and excellent chromatographic properties, it did not enhance negative chemical ionization (NCI) detectability for our analytes of interest. Several substituted phenylboronic acids were investigated which could exhibit greater electron affinity and anion stabilization relative to phenylboronic acid (PBA). They were 3-nitrophenylboronic acid (NPBA), 4-bromophenylboronic acid (BrPBA), 2,4-dichlorophenylboronic acid, 3,5-dichlorophenylboronic acid (ClPBA) and FPBA. The four model compounds used for derivatization were methyl 2-methylglycerate, *cis* -1,2-cyclohexanediol, 1,2-dihydroxybenzene (catechol), and 3,4-dihydroxyphenylethylene glycol (DHPG). The derivatives were analyzed by GC/ or particle beam (PB)/ MS in electron impact and negative chemical ionization modes.

Experimental

All the boronic acids used, with the exception of FPBA, are commercially available and were used as supplied without further purification. PBA, NPBA and BrPBA were obtained from Aldrich and the chloroboronic acids were obtained from Lancaster Synthesis. FPBA was synthesized as previously described[2].

A 200 µL aliquot of a boronic acid in dimethoxypropane (DMP) or methylene chloride was added to 200 µL of a dissolved diol in a 7:2 mole ratio. The mixture was vortexed briefly and allowed to stand at room temperature for 15 minutes. An aliquot was then taken for analysis. NPBA was found to have limited solubility in methylene chloride. DMP was preferred in comparison with THF because it scavenges water as the reaction proceeds[3]

Analytical Conditions

Mass spectral analyses were performed on either a Finnigan TSQ-70 (scanning Q1) interfaced with a Varian 3400 GC, or on a Hewlett-Packard 5989 with a particle beam interface. The mass spectrometers were scanned from m/z 50 to 550 for GC/EI and NCI/MS, and m/z 100 to 650 for PB/MS. The ion source temperature was 150°C (250°C for PB/MS). Methane was used as the reagent gas for all chemical ionization experiments.

Typical GC conditions were ramping from 70°C to 280°C at 30°/min, with the injection port and transfer line at 280°C. A DB-5 column (15 m x 0.25 mm x 0.25 µm film thickness) was used for the analyses. The DHPG-boronates did not elute under these conditions and were analyzed by direct flow injection through the particle beam interface on the HP-5989. Hexane was used as the solvent at 0.4mL/min. The desolvation chamber was held at 55°C and helium nebulization pressure was 60 psi.

Results and Discussion

The boronate derivatives formed quantitatively at room temperature and exhibited excellent chromatographic properties. The NPB derivatives gave the best NCI response with methyl 2-methylglycerate/NPB yielding the largest increase in signal enhancement, 26 times that of EI. The remaining NPB derivatives also exhibited NCI signal enhancement of approximately a factor of 10 over EI. NPB derivatives of standards were stable for over one month; the derivatives were also stable to evaporation under N_2 and re-dilution as long as anhydrous conditions were maintained. The NCI mass spectra of the NPB derivatives were dominated by the molecular anion. The EI mass spectra yielded high mass, structure specific ions for all derivatives tested. The chloro- and phenylboronates exhibited the poorest response in NCI. The bromophenylboronate exhibited excellent chromatographic properties, however all of the ion current was the result of facile loss of bromide resulting in an NCI spectrum dominated by the ions m/z 79 and 81. The sensitivity of the boronates follows the order:

NCI: nitrophenyl > bromo-, fluorophenyl > chlorophenyl > phenyl
EI: phenyl > bromo-, chloro-, fluorophenyl > nitrophenyl

The total ion chromatogram (TIC) for the methyl 2-methylglycerate/NPB is shown in Figure 1A, and its NCI mass spectrum is shown in Figure 1B.

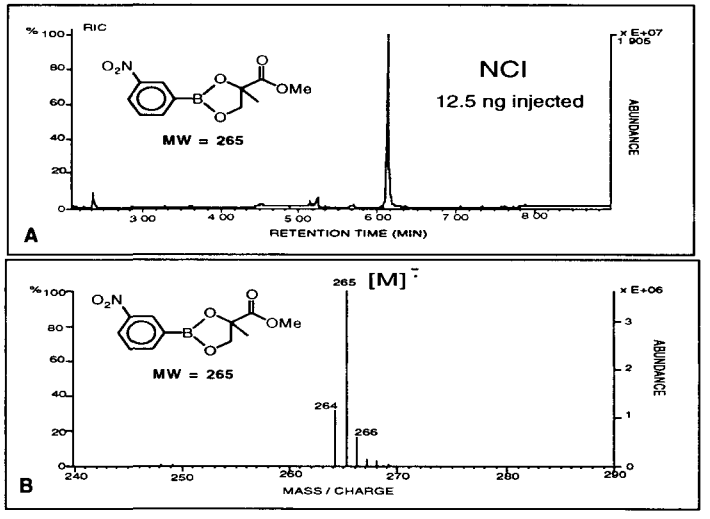

FIG 1: A) TIC of methyl 2-methylglycerate/NPB and B) its NCI mass spectrum.

INTRODUCTION: The peptido-leukotrienes (LTC4, LTD4 and LTE4) have profound effects on bronchial and vascular smooth muscle contractility and also promote extensive plasma extravasation by increasing the permeability of the postcapillary venules. These compounds have been implicated in pulmonary and allergic diseases, inflammation, psoriasis and other disorders. In order to screen the effects of new drugs on peptido-leukotriene synthesis, a simple, selective and sensitive method to measure leukotrienes in various body fluids is required. This report describes a new method for determination of LTC4, LTD4 and LTE4 in human nasal secretions collected on filter paper disks. The method involves separation of the peptido-leukotrienes by HPLC, collection of individual fractions containing each of the compounds, reduction of the compounds to 5-hydroxyeicosanoic acid (5-HEA), derivatization, gas chromatography and detection of the pentafluorobenzyl (PFB), trimethylsilyl (TMS) derivative by negative chemical ionization gas chromatography/mass spectrometry.

EXPERIMENTAL: The method is described briefly as follows. Deuterated analogs (20,20,20-d_3; Cascade Biochem Ltd., Reading, Great Britain) of the leukotrienes were added to 7 mm diameter filter disks containing nasal secretions. Leukotrienes were eluted from the disks with ethanol, separated by HPLC on an Econosphere C-18 column (150 x 4.6 mm x 5 μm) using 65% methanol in 0.1% ammonium acetate buffer (pH 5.4) and collected individually. The leukotrienes were reduced to 5-HEA by bubbling a solution of PtO_2 in methanol (1 mg/ml) with hydrogen. The PFB ester of 5-HEA was prepared and extracted with hexane and water. TMS derivatives were prepared and separated by two-dimensional capillary gas chromatography employing RTx-1701 (30 m x 0.53 mm x 0.25 μm) and Stabilwax (30 m x 0.32 mm x 0.5 μm) fused silica columns. Ions at m/z 399 and m/z 402 were monitored.

RESULT AND DISCUSSION: This method differs from previously published methods in three major ways. First, commercially available deuterated analogs (20,20,20-d_3) were employed instead of unique [^{13}C] or [^{18}O] labeled internal standards. Although concern about the possibility of the exchange of deuterium with hydrogen during the reduction step has been expressed [1], deuterium at the C_{20} position is not exchanged under our conditions and linear calibration curves very clearly demonstrate this (Fig. 1). Second, platinum oxide was used as a catalyst instead of rhodium oxide. Platinum oxide gives a homogeneous solution in methanol and may be pipetted precisely in small amounts,

thereby decreasing irreversible adsorption. Third, two-dimensional gas chromatography combined with mass spectrometry was applied to analyze the final product. Two dimensional gas chromatography eliminated the need for a time-consuming HPLC cleanup step between the two derivatizations. It also significantly increased the sensitivity by reducing background noise. The limit of detection was 100 pg/sample with a coefficient of variation less than 20%. Linearity was indicated by an average correlation coefficient of 0.992 for LTC4 and 0.996 for LTD4 and LTE4.

This method was used to measure leukotrienes in nasal secretions from two seasonal allergic rhinitis patients treated with ragweed antigen. Nasal secretions were collected using filter paper disks, placed in both nostrils 5 minutes before and 2 minutes after vehicle challenge and 2, 4 and 6 minutes after challenge with a disk containing 333 PNU of ragweed antigen in one nostril. Compared to vehicle, antigen administration increased LTC4 release by 17- to 22-fold, LTD4 by 16- to 31-fold and LTE4 by 28- to 38-fold. The time of peak concentration of the peptido-leukotrienes was in the order: LTC4 < LTD4 < LTE4, which is consistent with the synthetic pathway LTC -> LTD4 -> LTE4. Antigen administration also produced higher concentrations of peptido-leukotrienes on the ipsilateral (challenged) side than on the contralateral side, and increases in peptidoleukotriene levels generally occured sooner on the ipsilateral side compared to the contralateral side.

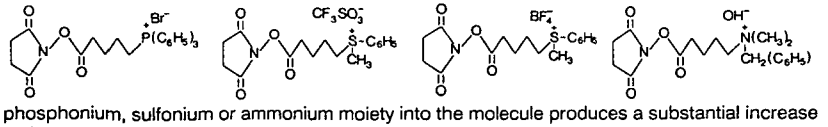
On the Problem of Sensitivity for Detecting LTC_4, LTD_4 and LTE_4 in CF-LSIMS.

O.A. Mamer, McGill University Biomedical Mass Spectrometry Unit,
1130 Pine Ave West, Montreal Que., Canada H3A 1A3 and
C.S. Li, R. Young and J.A. Yergey, Merck Frosst Centre for Therapeutic Research,
PO Box 1005 Pointe Claire - Dorval Que., Canada H9H 3L1.

Leukotrienes LTC_4, LTD_4 and LTE_4 are present in mammalian tissues and fluids in fmol/g concentrations and because they are unstable and highly polar and they respond poorly in FAB, their detection and determination is difficult especially in situations where sample size is severely limited, as in human studies. Studies with methyl S-benzylcysteine as an LT model have shown that when the free amine function is alkylated with the reagents illustrated below, introduction of a



phosphonium, sulfonium or ammonium moiety into the molecule produces a substantial increase in the strength of the signal in FAB (Fig 1). Fig 2 shows the relative signal strengths for an equimolar mixture of the LT model and its triphenylphosphonium valerylamide (TPPV) derivative. We selected for further study the TPPV derivatives of authentic LTs.

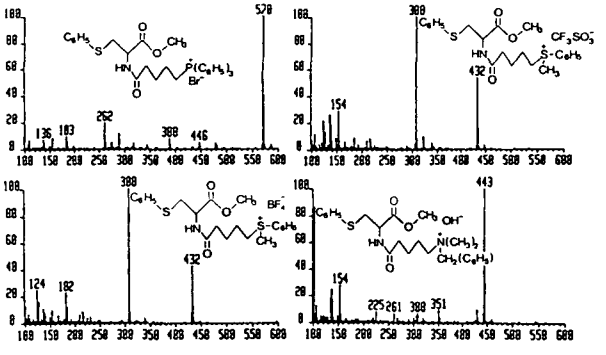


Fig 1

Fig 3 shows the TPPV derivatives of LTE_4, LTD_4 and LTC_4 both as the free acids and the methyl esters. Very prominent ions are noted for the cations produced. When an equimolar mixture is made of the TPPV derivatives of each LT in its acid and ester forms, Fig 4A shows the relative NBA FAB responses obtained immediately after mixing. Fig 4B shows the same mixture run under the same conditions after 21 h at 50° in methanol solution in air. Very little signal degradation has occured for the esters, and only relatively slight loss of intensity is noted for the free acids. The TPPV derivatives therefore are much more stable to oxidation and heat than the underivatized LTs

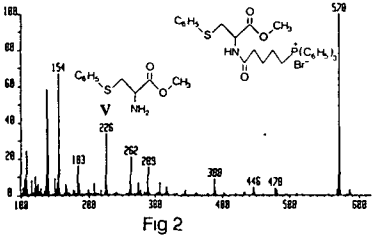

Fig 2

Analysis of a mixture of 5 pmol of free acid LTD_4 and LTD_4-TPPV in CF-LSIMS by HPLC inlet shows (Fig 5a) the TIC for 0-1000 Da, (5b) the RIC for 497 Da and the background subtracted spectrum for the peak, and (5c) the RIC for 841 Da and the subtracted spectrum for the peak. The LTD_4-TPPV peak is obviously much larger than the underivatized LTD_4 peak as seen in the TIC panel. When successive dilutions are made of a solution containing LTD_4-TPPV, 5 pg is easily detected, which corresponds to 3 pg of underivatized LTD_4. Fig 6 illustrates the SIM traces (841.4 Da) for 20 pg, blank, and 5 pg injections of LTD_4-TPPV.

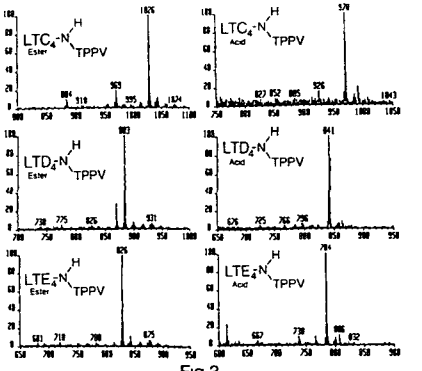

Fig 3

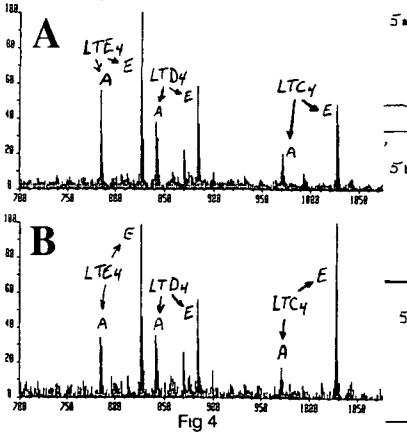

Fig 4

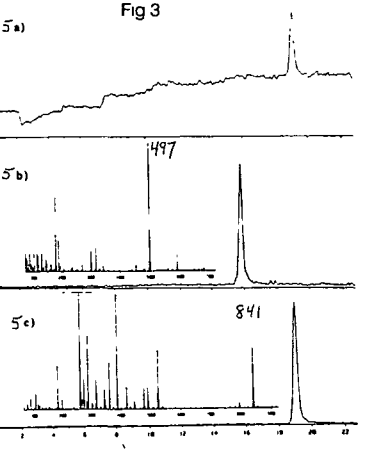

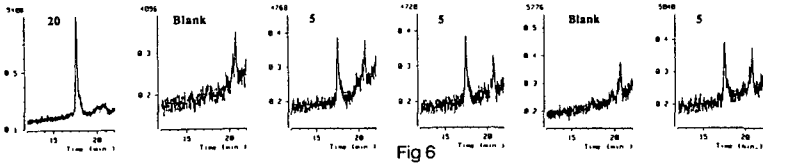

Fig 6

The TPPV derivatives of the LTs provide not only greater molar responses than do the native LTs, but they are also substantially more stable to oxidation and heating. For an example of the use of these derivatives in determining concentrations of the LTs in physiological fluids, please see the poster by Yergey *et al* (TP 43).

Continuous-Flow/Liquid Secondary Ion Mass Spectrometric Characterizationof *in vivo* and *in vitro* Metabolism of the 5-Lipoxygenase Inhibitor L-702,618

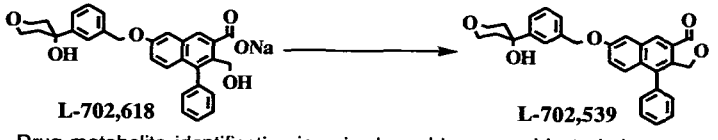
*Leukotrienes derive from the metabolism of arachidonic acid via the action of 5-*lipoxygenase[1]. The peptido-leukotrienes (LTC4,LTD4,LTE4) are strongly implicated as principal factors in the elicidation of the symptoms of asthma and other pulmonary conditions[2]. LTB4 is a potent chemotatic agent and is believed to be involved in diverse inflammatory conditions[3]. One major class of agents that modulate the effects of the leukotriene portion of the arachidonic acid cascade is the enzyme inhibitors which exercise their action by preventing or reducing the formation of lipoxygenase products. Because of the biological prominence of the 5-lipoxygenase products, great efforts of finding inhibitors of the 5-lipoxygenase enzyme have been undertaken in several pharmaceutical companies. Our search for potent, specific inhibitors of 5-LO led us to *discover a new series of naphthalenic lignan lactones*, exemplified by L-702,539 and its prodrug L-702,618.[4] The open form lactone of L-702,618 was found to close to give L-702,539 both *in vivo* and *in vitro* (the rate of closure is species dependent).



Drug metabolite identification in animals and human subjects is important from both a scientific and product development perspective. Both *in vitro* and *in vivo* metabolism studies[5] of L-702,539 were carried out in order to understand the metabolic stability of the different moieties of this compound. Continuous flow/liquid secondary ion mass spectrometry[6-7] has found its important applications in identification of small amount of polar metabolite. This technique offers great sensitivity compared with thermospray LC/MS. Full scan mass spectra of minor metabolites can usually be obtained rapidly, without sample purification or concentration. In cases where the full scan mass spectra did not give enough information to determine the structures of the metabolites, preparative isolation by HPLC and further characterizations were performed.

JEOL HX110A double focusing mass spectrometer (EB configuration) operated in the continuous flow/liquid secondary ion mass spectrometry mode was used in this study. Waters 600MS HPLC was operated at a flow of 0.9 mL/min, with the flow split just prior to a Rheodyne injector (with a 0.5 µl loop) by the aid of a 60 µm i.d fused silica open tubular column to produce a flow of 3 µl/min through a Spherisorb 0.32x100mm capillary column (Keystone Scientific, Bellefonte, PA) and then to the frit probe of JEOL mass spectrometer. A linear gradient from 55%A : 45%B to 90%A : 10%B in 25 minutes was used for separation (A: 1.5% Glycerol in CH_3OH; B: 1.5% Glycerol in 20 mM NH_4OAc, pH 5). Ions were produced by bombardment with a beam of Cs^+ ions (10 keV), the accelerating voltage was 10 kV and the resolution was set at 1,000.

L-702,539 was found to be metabolized extensively both *in vitro* and *in vivo*, especially on the pyran portion of the molecule. Three major oxidative metabolites were observed and identified to be: hydroxypyran (L-705,212), hydroxylactone (L-705,261) and hydroxyacid (L-745,244).

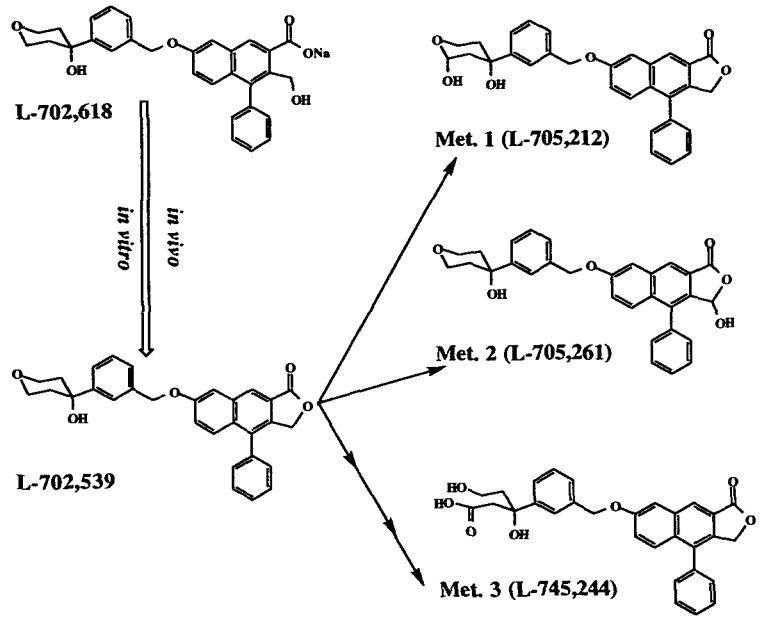
Metabolism Profile of L-702,618 (L-702,539)



Characterization of Pineal Metabolites by Thermospray LC/MS/MS and GC/MS.

Hee-Yong Kim* and Lisa Edsall, Section of Mass Spectrometry, LMBB, NIAAA, NIH, Building 10, Room 3C-102, 9000 Rockville Pike, Bethesda, MD 20892

Lipoxygenation of polyunsaturated fatty acids leads to the production of many biologically active compounds such as monohydroxy fatty acids and leukotrienes. Since we have previously observed that lipoxygenation in the rat brain occurs only in the pineal, we have investigated the lipoxygenation of major polyunsaturates present in the pineal body.

Pineals obtained after the rat brain was perfused were homogenized in PBS buffer and incubated with 20:4n6, 22:6n3, 18:2n6 or 18:3n3 at 37°C for 30 min. Rat leukocytes were also incubated in parallel. The incubation mixture was extracted with dichloromethane after acidification to pH 3.0. The pineal and leukocyte metabolites were isolated by HPLC and derivatized to pentafluorobenzyl (PFB) derivatives for thermospray LC/MS/MS analysis as reported earlier (1). Subsequently, trimethylsilyl (TMS) derivatives were prepared for GC/MS analysis. In some cases, hydrogenation proceeded trimethylsilylation.

Thermospray LC/MS/MS analysis of PFB derivatives of pineal metabolites in the negative ion mode provided information concerning the position of oxygenation. Likewise, hydrogenated PFB-TMS-derivatives of metabolites analyzed by GC/EIMS in the positive ion mode also provided structural information. Unlike methylester-TMS-derivatives, positional isomers of the metabolites were well separated as hydrogenated PFB-TMS-derivatives. This allowed sensitive quantification of each isomer in the NCI mode based on the $(M\text{-}PFB)^-$. Using these techniques, it was found that rat pineal metabolizes arachidonic (20:4n6) and docosahexaenoic (22:6n3) acid through both 12- and 15-lipoxygenase pathways, primarily through the 12-lipoxygenase pathway.

Linoleic (18:2n6) and linolenic acid (18:3n3) were also well metabolized by rat pineal to primarily 13-hydroxy-derivatives as is shown in the radiochromatogram for 18:2n6 (Figure 1). The thermospray LC/MS/MS spectra obtained from PFB derivatives of 18:2n6 and 18:3n3 metabolites contained peaks resulting from the characteristic a-cleavage of the hydroxylated C-C bond. The cleavage occurred on the conjugated diene side, accompanying the hydrogen transfer toward that side. Characteristic fragments observed in the thermospray LC/MS/MS spectra of various positional isomers of 18 carbon metabolites are shown in Table 1. Production of 9-hydroxy derivatives were also observed in the thermospray spectra, although they occured at a level less than 3 % of 13-hydroxy derivatives, as determined by the NCI analysis. On the contrary to these results, rat leukocytes produced various isomers including 13-, 12-, 16- and 9-hydroxy derivatives from 18:3n3 and 9- and 13-hydroxy derivatives from 18:2n6, using the same incubation condition. Platelets also metabolized 18:2n6 and 18:3n3 to 9- and 13-hydroxy derivatives. These results indicated that the metabolites observed from pineal homogenate were not derived from blood cell components, and the property of 15-lipoxygenase present in the pineal body differs from that in leukocytes or platelets.

Table 1. Peaks observed in thermospray LC/MS/MS spectra of pineal 18 carbon metabolites as PFB derivatives.

		Parent ion $(M\text{-}PFB)^-$	$(M\text{-}PFB)^-\text{-}H_2O$	Fragment
18:2n6	9-OH	295	277	171
	13-OH	295	277	195
18:3n3	9-OH	293	275	171
	12-OH	293	275	211
	13-OH	293	275	195
	16-OH	293	275	235

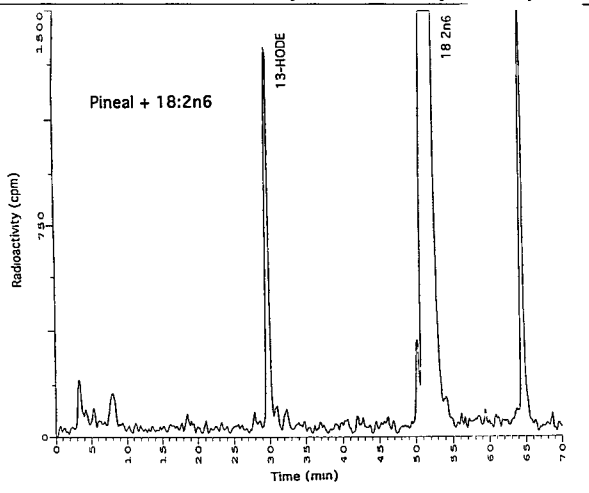

Figure 1. Radiochromatogram obtained after incubation of ^{14}C-18:2n6 with rat pineal homogenate.

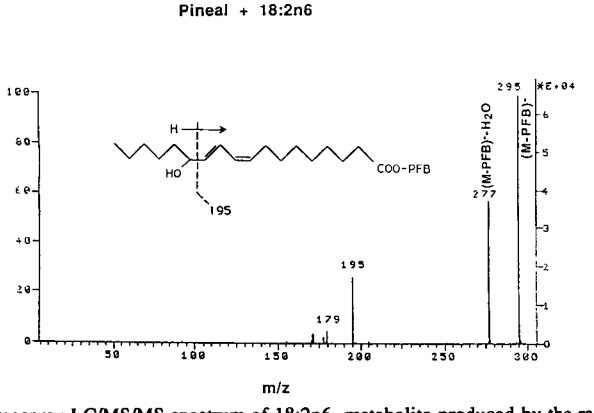

Figure 2. Thermospray LC/MS/MS spectrum of 18:2n6 metabolite produced by the rat pineal. A Finnigan TSQ-70 mass spectrometer was used. The thermospray vaporizer control and source temperatures were 75 and 250°C, respectively. The PFB-derivative was injected into an ODS column with methanol as the mobile phase at the flow rate of 1 mL/min.

CHARACTERIZATION OF SYNTHETIC IMMUNOSTIMULATORY LIPOIDAL PEPTIDES BY FAB-, ESI- AND MALDI-MS

Yoon Seok Chang[1], Patrick Kanda[2] and Douglas A. Gage[3]
[1]Korea Basic Science Center, Seoul, Korea; [2]Southwest Foundation for Biomedical Research, San Antonio, TX; [3]MSU-NIH Mass Spectrometry Facility, Department of Biochemistry, Michigan State University, East Lansing , MI

The introduction of a modified lipoidal residue, N-palmitoyl-S-[2,3-bis(palmitoyloxy)-propyl-cysteine (Pam3-Cys, Figure 1), at the amino terminus of a peptide [1] provides a potent immunoadjuvant which enhances the IgM and IgG antibody response to the rest of the molecule [2]. These synthetic peptides have significant advantages as potential vaccines, since the addition of other adjuvants is not required, and most importantly, because the epitope can be specifically defined. It is critical, however, that these peptides be structurally characterized prior to their use in immunological studies, particularly because the synthesis involves several steps where the peptide is exposed to conditions that promote amino acid side chain modification and/or deacylation. Moreover, the lipoidal nature of these peptides makes them extremely difficult to purify and analyze. On reversed phase HPLC columns, peak broadening caused by their tendency for self-aggregation can obscure contaminating peaks. Thus, amino acid analysis may not be adequate for structural confirmation. Further, because the amino terminal is blocked, traditional Edman degradation cannot be employed. We are currently using several MS techniques to characterize synthetic Pam_3-Cys peptides based on amino acid sequences found in the envelop glycoproteins of HIV-1 and Simian Immunodeficiency Virus (SIV). FAB-MS is useful in some cases for analysis, but the tendency for aggregation, which is somewhat dependent on the particular amino acid residues present, can often preclude detection of ions representative of the Pam_3-Cys peptides present. We have found that the use of nonpolar matrices, such as 3-nitrobenzyl alcohol, together with N-methyl-2-pyrrolidone as the solvent for the peptides, will produce interpretable spectra. Nevertheless, under these conditions some Pam3-Cys peptides yield only weak signals, while others are still refractory. Two alternative techniques, ESI-MS and MALDI-MS, provide much more reliable results with much better sensitivity (picomole level *vs* nanomole level for FAB-MS). The appearance of the ESI and MALDI spectra of Pam_3-Cys peptides can differ significantly, however (see Figures 2 and 3). Salt adducts are more prominent in MALDI spectra, while both techniques seem to have differential sensitivity for various components in a sample. Whether these effects are solvent or matrix dependent is not known. The influence of these factors is currently under investigation.

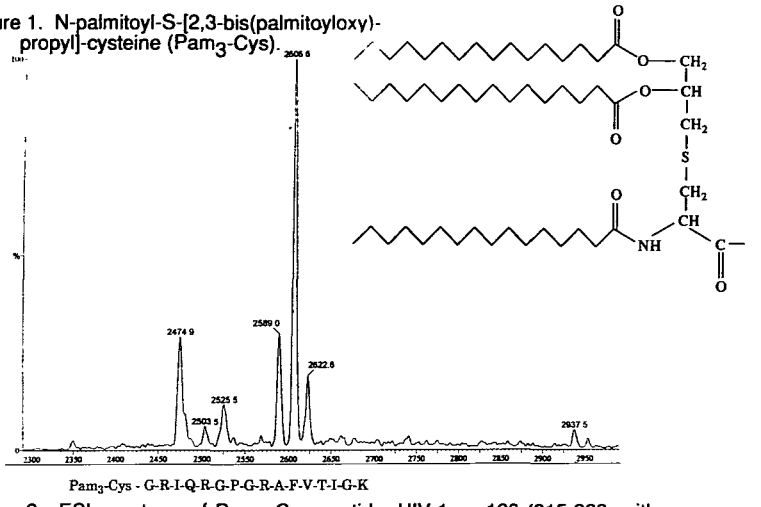

Figure 2. ESI spectrum of Pam_3-Cys peptide, HIV-1 gp 120 (315-329, with an additional G at the N-terminus). The expected MH^+ ion was the largest analyte peak in the spectrum, although other side-products from the synthesis were also detected. FAB-MS analysis of this sample produced no detectable signals.

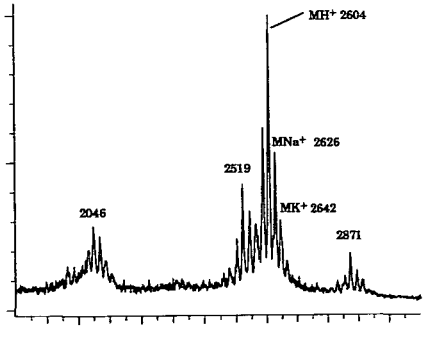

Figure 3. MALDI spectrum of the Pam_3-Cys peptide shown in Figure 2. The expected synthetic product was the largest peak in the spectrum, but the presence of salt adducts was more prominent than in the ESI spectrum. Further, the response of other components in the sample differs significantly from that found in the ESI spectrum.

ENZYMATIC CONVERSION OF NAAG TO NAA *IN VIVO* USING MICRODIALYSIS/MASS SPECTROMETRY

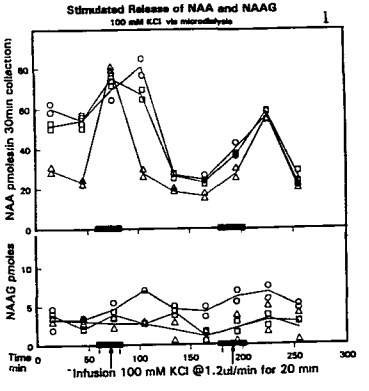
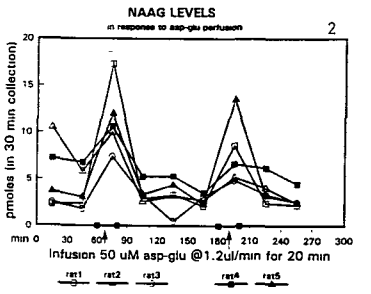
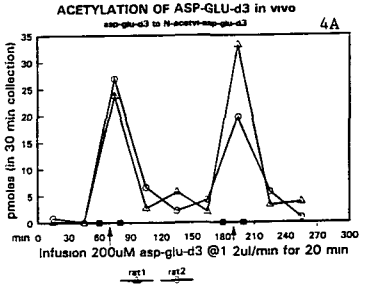
In vivo microdialysis with GC/MS analysis is capable of accurately determining stimulated release of extracellular NAA and NAAG from rat hypothalamus. Previous *in vivo* studies have shown stimulated release of NAAG but not NAA from other regions of rat brain, using immunohistochemical methods. Our results demonstrate release of NAA in high concentration but no increase in NAAG concentrations in the hypothalamus. To substantiate these findings, we have addressed the following questions. 1. How reproducible is the methodology? 2. Does rapid catabolism of NAAG occur rendering it difficult to observe in dialysate? 3. Does NAA meet at least one criterion for a neurotransmitter in the hypothalamus?

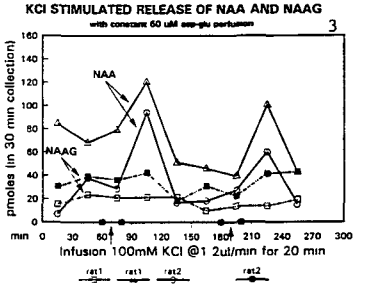
Male Sprague-Dawley rats were used with pentobarbital anesthesia. A 3 mm microdialysis probe was inserted into the hypothalamus stereotaxically. Artificial CSF dialysis buffer containing 5 mM KCl was delivered at 1.2 μl/min. Microdialysate samples were collected at 30 min intervals. Neuronal depolarization was stimulated in some experiments by infusion of 100 mM KCl for 20 min intervals. Hydrolytic enzyme inhibitor, asp-glu, was administered also by the infusion method. The dialysate samples were derivatized with 3N HCl in N-butanol, separated on an DB-5 fused silica capillary column and analyzed by a Finnigan Incos 50 mass spectrometer with chemical ionization source using ammonia as reactant gas. MH^+ ions of all neuro-compounds were selected for quantitative measurements.

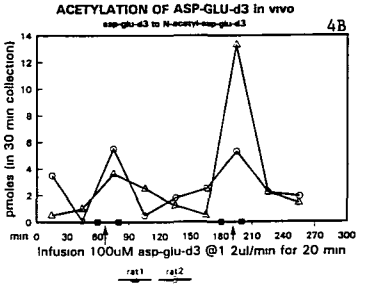
In Fig. 1, microdialysis samples collected in 30 min fraction were divided into two parts, NAA and NAAG concentrations were measured to show the reproducibility of the measurements. The result also shows that NAA is released by the 100 mM KCl perfusion in the hypothalamus but not NAAG. Hydrolytic enzyme activity for degradation of NAAG to NAA *in vivo* was demonstrated by perfusion of NAAG-d3 (977 pmoles) via the dialysis probe and amounts of NAA-d3 break down product in the dialysate was measured. We found substantial amounts (90 ± 15 pmoles) of NAA-d3 in 6 dialysate samples collected from three animals, each rat receiving two NAAG-d3 perfusions. Asp-glu, an inhibitor of NAALADase which is a proposed specific catabolic enzyme system to cleave NAAG to NAA plus GLU, was perfused via the microdialysis probe. Fig. 2 shows that elevated NAAG levels were consistently observed in the fraction collected











following inhibitor perfusion. When we repeated the catabolic experiments, we did not find differences in the amounts of NAA-d3 produced in the presence (90 ± 15, n=6) or absence (98 ± 20, n=4) of asp-glu. Finally, asp-glu and 100 mM KCl was perfused during the final experiment to stimulate release of NAAG. In Fig. 3, persistently elevated NAAG levels shown appear to be due to constant perfusion of asp-glu. No stimulated release can be observed. The results are in marked contrast to the observation of stimulated release of NAA measured in the same samples. These data suggest the elevated extracellular NAAG levels are not due to KCl stimulated release of NAAG, but instead are directly related to the presence of asp-glu in the perfusate. Our hypothesis is that acetylation of exogenous asp-glu is one of the metabolic events that takes place in the hypothalamus leading to NAAG elevation. Asp-glu-d3 (100 and 200 μM) in artificial CSF was perfused via the microdialysis probe and the acetylated product NAAG-d3 was measured. Figs. 4A and B shows significant amounts of NAAG-d3 proportional to the Asp-glu-d3 concentrations are in the dialysate. In contrast to previous results (Fig. 2), we did not find elevated endogenous NAAG levels resulting from asp-gly-d3 infusion.

In conclusion, we have demonstrated *in vivo* enzymatic conversion of NAAG to NAA. Our observation of KCl stimulated release of NAA support an independent role of NAA as a neurotransmitter in hypothalamus. We have also demonstrated *in vivo* acetylation of infused exogenous asp-glu to NAAG, suggesting the presence of an endogenous N-acetylation enzyme system in hypothalamus.

HYDROLYSIS OF PEPTIDE AND PROTEIN DRUGS BY IMMOBILIZED HEPATIC PROTEASES MEASURED USING CONTINUOUS-FLOW FAB LC-MS AND MS-MS.

Richard B. van Breemen and R. Kevin Blackburn
Department of Chemistry, Box 8204
North Carolina State University, Raleigh, NC 27695

Because biotechnology methods such as recombinant DNA technology facilitate the large scale preparation of pharmacologically active peptides and proteins, the therapeutic importance of peptide and protein drugs is rapidly increasing. Although most protein drugs must be administered parenterally, peptide drugs can often be administered by non-invasive routes, including oral, nasal, or transdermal administration. However, the bioavailability of drugs administered by these methods can be limited by poor absorption or degradation at the site of administration. In order to assess the significance of degradation in the gut prior to absorption of orally administered peptide drugs, we have developed a method using an immobilized digestive enzyme assay and continuous-flow FAB LC-MS to identify proteolytic peptides formed in the gut (1) and the rates of peptide drug degradation (2).

Following absorption from the digestive tract, orally administered peptide drugs must pass through the liver and resist proteolysis before reaching the general circulation. Peptide and protein drugs already in the bloodstream are degraded primarily by proteases in the liver. Therefore, we are developing an *in vitro* immobilized hepatic digestive enzyme assay to study degradation of peptide and protein drugs.

MASS SPECTROMETRY. Positive ion CF-FAB mass spectra were obtained using a JEOL HX110HF double focusing mass spectrometer equipped with a DA5000 data system and frit-FAB version of a continuous-flow FAB interface. Xenon fast atoms at 6 kV were used for FAB ionization. The resolution was 1200 and the ion source temperature was 47°C. B/E Linked Scanning MS/MS was carried out using static FAB and CAD in the first field-free region (helium collision gas). For MS/MS measurements, the range m/z 1-1,500 was scanned in 15 sec. using an equivolume mixture of glycerol/thioglycerol (v/v) as the matrix. Approximately 1 µg of unpurified peptide digest was analyzed per MS/MS measurement.

For CF-FAB measurements, the range m/z 100-1,500 was scanned in 8 sec. An Applied Biosystems Model 140A Microgradient HPLC Pump was used with a Vydac C18 HPLC narrowbore column (25 cm x 2.1 mm) at a flow rate was 100 µL/min. For compatibility with the CF-FAB ion source, the flow was split post-column so that flow rate to the mass spectrometer was 5 µl/min. A 30 min linear gradient from water to acetonitrile was used for reversed phase peptide separations. The mobile phase contained 0.5% glycerol, which functioned as the FAB matrix, and 0.1% trifluoroacetic acid. For each analysis, 10 µL of the incubation mixture was injected.

Enzyme Immobilization and Incubation with Peptide and Protein Substrates. Hepatic microsomes and cytosolic proteases were prepared from homogenized Sprague Dawley rat liver using ultracentrifugation. Microsomal proteases were solubilized in detergent using ultrasound at either pH 7.5 or pH 4.0. Microsomal proteases (pH 4.0 and pH 7.5) and cytosolic proteases (pH 7.5) were immobilized using previously published procedures (1). Each peptide or protein substrate (100 mL; 1 mg/mL) was incubated 8 or 24 hr with 10 mg glass beads containing immobilized proteases prior to analysis using LC-MS. Substrates investigated included recombinant human insulin, substance P, a cyclohexapeptide, and angiotensin II.

The specific activities of each immobilized enzyme preparation were determined by measuring the disappearance of human insulin as a function of time in an HPLC UV absorbance assay (see ref. 2). All fractions showed activity towards insulin. Next, the initial sites of hepatic proteolysis of each peptide substrate were identified using continuous-flow FAB LC-MS and MS/MS. For example, Figure 1 shows the CF-FAB LC-MS analysis of angiotensin II incubated for 24 hr with immobilized rat hepatic proteases, pH 7.5. The peptide eluting at 19.8 min formed a protonated molecule at m/z 775 (see Figure 2), which was shown by MS/MS to correspond to the peptide Val-Tyr-Ile-His-Pro-Phe.

For a given peptide substrate, each of the three enzyme groups displayed similar sites of initial cleavage. This observation suggests that these sites are the most susceptible to proteolysis. Because CF-FAB LC-MS is limited to the analysis of peptides weighing up to approximately m/z 3,000, the proteolytic fragments of human insulin must be identified using another ionization method.

AN ASSAY FOR URINARY PEPTIDAL LEUKOTRIENES USING IMMUNOAFFINITY EXTRACTION AND CAPILLARY HPLC / CF-LSIMS DETECTION.

***J. A. Yergey, R. Young, C.S. Li, Merck Frosst Centre for Therapeutic Research, P.O. 1005, Pointe Claire-Dorval, Quebec, Canada H9R 4P8, O. Mamer, McGill University Biomedical Mass Spectrometry Unit, 1130 Pine Avenue West, Montreal, Quebec, Canada H3A 1A3**

OVERVIEW: Measurment of urinary excretion of peptidal leukotrienes (LT) is of vital importance in assessing the effectiveness of leukotriene synthesis inhibitors in human clinical studies, and for understanding the role of these potent endougenous inflammatory mediators. Radioimmunoassay of the peptidal leukotrienes requires HPLC separation of the three peptidal leukotrienes (LTC_4, LTD_4, LTE_4) prior to quantification, in order to eliminate cross reactivity[1]. Existing mass spectrometric methods also require HPLC isolation, followed by removal of the peptide part of the molecule, catalytic reduction, derivatization, and GC/MS[2]. The use of continuous-flow FAB for the detection of LT has been demonstrated, but detection limits were not sufficient for the picogram quantities found in many biological fluids[3]. Our goal has been to demonstrate a sensitive and specific capillary HPLC, continuous-flow liquid secondary-ion mass spectrometry (CF-LSIMS) methodology for the detection of urinary LT. We believed that immunoaffinity extraction for initial sample clean-up would provide efficient and clean extracts of the LT in a single step, as has been demonstrated in previous work with extraction of prostaglandins[4]. We also sought to utilize our recently described derivatization of the LT to a precharged triphenylphosphonium amide (Poster TP-36) to provide lower detection limits by CF-LSIMS.

EXPERIMENTAL: Immunoaffinity columns: The gel from Cascade Biochem Limited LTE_4 immunoffinity columns was removed and repacked into 1.5 mL syringe columns fitted with polyethylene frits. The flow rate of PBS through the columns was adjusted with slight pressure to frit / gel to yield about 30-50 µL/min. Columns were stored at 4°C in PBS. **Extraction Procedure:** Urine was adjusted to pH 11 using NaOH and frozen. Thawed urine was adjusted to pH 7.4 using HOAc. Appropriate standards were added (^3H or $^2H_3$ labelled LTD_4 or LTE_4), and some samples were spiked with LTD_4 or LTE_4 for determination of immunoaffinity binding capacity. Urine was centrifuged at 14,000 rpm for 10 min, and the supernatant filtered (0.45 µm). Standards of 1000, 300, 100, 30 and 10 pg LTD_4 plus 200 pg $^2H_3$-LTD_4 were prepared in PBS. Immunoaffinity extraction was automated using a Gilson ASPEC. Previously conditioned columns were allowed to drain and come to R T. Samples were applied in 750 µL aliquots and rinsed with 2 x 750 µL PBS and 2 x 750 µL H_2O. The leukotrienes were eluted with 750 µL H_2O:CH_3CN:NH_4OH (120:40:1) followed by 750 µL $(CH_3)_2CO$:H_2O (90:10). Columns were reconditioned with 2 x 750 µL $(CH_3)_2CO$:H_2O followed by 4 x 750 µL PBS. All flow through columns was by gravity feed. **Microscale Derivatization:** Sample extracts were dried in a Speed-Evap, and redissolved in 15 µL $NaPO_4$ buffer (0.5 M, pH 7.9). Buffer strength and pH were critical; no reaction occurred at pH ≤ 7.4, and the activated ester hydrolyzed too quickly at pH ≥ 8.1. The reaction was initiated by adding 20 µL of the triphenylphosphonium activated ester (TPPAE, 10.0 mg/mL H_2O). After 45 min, the reaction was quenched with 8 µL CH_3OH:NH_4OH (200:1). **Capillary HPLC / CF-LSIMS:** A standard HPLC pump (Waters 600 MS), supplied 1 mL/min of mobile phase consisting of CH_3OH:20 mM NH_4OAc, pH 5 (1.5 % glycerol in each). The gradient was 50:50 linear to 70:30, 5min, linear to 90:10, 15 min, and hold for 10 min. The main flow was split prior to the injection valve using ~ 5 cm of 50 µm fused silica on the open end of a Valco ZDV tee. Flow passed through a 20 µL injection loop on 6-port electrically actuated Valco valve, a 0.25 x 40 mm pre-column, a 0.3 x 100 mm analytical capillary column and into the JEOL HX-110A CF-LSIMS mass spectrometer ion source. Both columns were packed with KAPPA Spherisorb ODS2 (Keystone Scientific). Flow was diverted from the ZDV tee connecting pre-column and analytical column to waste for the first 5 min of each run, with a flow rate of 20 µL/min when passing through the pre-column to waste, and 3 µL/min when flow was reestablished through the analytical capillary column. The leukotrienes were detected by CF-LSIMS using electric-field SIM (m/z 784.38, 787.40, 841.40 and 844.42 for LTE_4-TPPV, $^2H_3$-LTE_4-TPPV, LTD_4-TPPV and $^2H_3$-LTD_4-TPPV, respectively).

RESULTS AND DISCUSSION: Immunoaffinity extraction of the peptidal leukotrienes, using 1.5 mL syringe cartridges, gave reproducible recovery of LT; between cartridge SD ≤ 7% in all experiments. It was important to compress the gel slightly during packing, in order to regulate the flow of aqueous solvents to 30-50 µL/min. Extraction efficiency of ^3H-labelled leukotrienes from PBS was greater than 85% using new columns, but degraded to about 60% after 4-5 uses. Extraction efficiency from spiked human urine was greater than 70% using new columns, but degraded to less than 40% after 4-5 uses. After several uses, columns retained their original capacity to bind 50-100 ng of either LTD_4 or LTE_4. The extraction procedure was automated using a Gilson ASPEC, allowing 108 samples to be processed in parallel. Aqueous reaction of the extracted leukotrienes, to produce the triphenylphosphoniumvalerylamide (TPPV) derivatives, required using high buffer strength $NaPO_4$ at pH 7.9 and high concentrations (10 mg/mL) of the triphenyphosphonium activated ester. Under these conditions, the reaction proceeded to greater than 85% completion in under 45 minutes at both nanomole and picomole levels of leukotriene. The reaction was quenched in order to eliminate any unreacted TPPAE. Mass spectra of the derivatized leukotrienes contained strong molecular cations, with sensitivity about three times greater than for the analogous protonated molecule of the underivatized leukotrienes. Utilization of pre-column splitting of the reaction mixture permitted elimination of the large quantities of buffer and reagent present, while concentrating the leukotrienes at the head of the pre-column. Subsequently, the derivatized leukotrienes could be efficiently eluted through the analytical capillary and into the CF-LSIMS ion source. Use of injection volumes of 10-50 µL provided the opportunity to inject a substantial portion of the extracted / derivatized sample. Immunoaffinity extracted standards of LTD_4 could be quantified at the level of 10 pg / sample, and a standard curve was constructed from 10-1000 pg (LLS fit: y = 1.010 x + 10.43 pg, RSD = 17.2 %). Peaks other than the expected derivatives were observed in reagent blanks as well as in standards, but did not interfere with quantification (See Figure 1). Examination of extracted standards without derivatization, monitoring masses corresponding to the underivatized leukotrienes, revealed significantly higher background contamination, obviating the possibilty of detection of the underivatized species. SIM chromatograms of extracted urine samples, both unspiked and spiked with LTD_4, contained significant background peaks, obscuring low-level leukotriene peaks. LTD_4 could be observed in extracted urine only at spiked levels in excess of 300 pg (see Figure 2). The additional contamination observed in urine samples is likely due to non-specific binding in the immunoaffinity extraction, however this possibilty is not yet proven. The polyethylene frits used in the immunoaffinity columns have been reported to be a potential source of non-specific binding. The means to minimize the contamination are being investigated, such that urine samples might be extracted, derivatized and detected with the same efficiency as standard mixtures.

CONCLUSION: This work is the first demonstration of immunoaffinity extraction and mass spectrometric detection of peptidal leukotrienes at sub-picomolar levels. The use of immunoaffinity extraction, aqueous derivatization to cationic amides, and detection using capillary HPLC / CF-LSIMS should provide a useful alternative to GC/MS methods for the quantification of the leukotrienes.

The Upjohn Company, Kalamazoo MI 49001

The recent communication on the detection of noncovalent receptor-ligand complexes by mass spectrometry[1] has generated a great deal of interest. Since then several communications on noncovalent binding of enzyme-substrates have been published and others have been reported at mass spectrometry meetings. All these examples refer to highly specific molecular recognition phenomena which result in the formation of very tight complexes with K_d values in the subnanomolar range. The majority of the studies reported so far has been accomplished using ion-spray (pneumatically assisted electrospray) ion sources where most of the solvent is removed with the help of a curtain gas. Also these investigations were limited to smaller proteins. We were interested in extending these experiments to larger proteins (e.g. albumins) as well as testing other types of electrospray ion sources, where the solvent is removed with the help of heat (thermally assisted electrospray).

Serum albumins are important proteins that circulate in the blood stream and are thought to be responsible for the transport of various substances such as steroids, fatty acids, and hormones. There are some indications that bovine growth hormone releasing factor (bGRF) binds to BSA in vitro[2,3]. BSA has previously been used as a standard for testing mass spectrometers fitted with an electrospray ion source (ESI). It was therefore of interest to use ESI MS for the possible detection of noncovalent complexes formed between BSA and [Leu^{27}]-bGRF(1-29)NH_2 or its more helical, Ala^{15}-substituted counterpart used as model peptides.

All experiments were run on a Vestec 201A instrument outfitted with a Vestec ESI source[4]. The BSA and the peptides, at the 1:10 molar ratio, were dissolved in 10mM ammonium acetate pH 7.4 and incubated at room temperature for 1-3 hours. The solution was then infused at a rate of 2 µL/min. The high mass end of the resulting ESI mass spectrum of the BSA - [Leu^{27}]-bGRF(1-29)NH_2 mixture is shown in Fig. 1. The deconvolution program developed in-house for the determination of mixtures of clusters was applied to this ESI mass spectrum. The association of one, two and three molecules of bGRF with one molecule of BSA was detected as shown in Fig. 1. When the GRF-BSA mixture was treated with acetic acid, the clusters corresponding to the mono-, di- and tri-adducts disappeared and the clusters corresponding to BSA were left which points to the non-covalent nature of these complexes. The Ala^{15}-bGRF analog also formed 1:1, 2:1 and 3:1 molar complexes with BSA.

Under the same conditions as used for the bGRF analogs, insulin and bradykinin (Fig. 2) formed a 1:1 molar complex with BSA. On the other hand, glucagon was more similar to the bGRF analogs in its binding pattern to BSA and formed 1:1, 2:1, and 3:1 complexes with BSA (data not shown). This data shows that BSA does bind various biologically active peptides and such non-specific and non-covalent complexes can be detected by ESI-MS. Our results also indicate that electrospray ion sources of different design are amenable for binding studies.

Study of Molecular Association by Electrospray Mass Spectrometry.

Lubomyr Baczynskyj, George E. Bronson, Teresa Kubiak, and Yuanda Zhang.
Upjohn Research Laboratories, The Upjohn Company, Kalamazoo MI 49001.

The recent disclosure of the detection by ion spray mass spectrometry of the formation of molecular complexes between a protein such as FKBP and the macrolide FK506[1)] has attracted a great deal of attention. In the ion spray (pneumatically assisted electrospray) the bulk of the solvent is removed with the assistance of a drying gas. In other source designs, the bulk of the solvent is removed thermally. The Vestec electrospray ion source[2)] belongs to this latter category. In this source the block is heated to 250° C and it was interesting to determine if the complexes formed in the ion source region could survive the thermal treatment. For this reason we repeated the experiments described in the communication referenced above[1)] using calf thymus FKBP (see Fig.1). Here a 1:1 molar ratio of FK506 to FKBP was used. In addition to a cluster at m/z 1799 of 7^+ charges corresponding to the monoadduct, a second cluster corresponding to the association of 2 molecules of FK506 with one molecule of FKBP was apparent at m/z 1914. When the molar ratio of FK506 to FKBP was increased to 3:1, the monoadduct ion cluster became the most abundant cluster in the ESI spectrum and the abundance of the ion cluster at m/z 1914 was 65%. Does this indicate that FKBP has a second binding site for FK506?

Similarly, when a 1:1 molar solution of rapamycin was infused at 2 μL/min at pH 7.4 in 10 mM ammonium acetate, the cluster at m/z 1814 was by far the most intense in the ESI spectrum. This corresponds to the 7^+ charged monoadduct of rapamycin to FKBP. A small cluster corresponding to the bis adduct of rapamycin to FKBP was present at m/z 1945.

The competitive binding experiments of FK506 and rapamycin with FKBP were also repeated (see Fig.2). The abundances of the monoadducts of $(FKBP+FK506)^{7+}$ at m/z 1799 and $(FKBP+rapamycin)^{7+}$ at m/z 1814 were in a ratio of 1·5. In addition to the clusters corresponding to the bis adducts of each macrolide with FKBP, which were present at m/z 1914 and 1945, very strong clusters appeared at m/z 1929 and 1688. The first corresponds to $(FKBP+1FK506+1rapamycin)^{7+}$ and the second to the same adduct but with 8+ charges. The abundance of the first cluster at m/z 1929 was 70% of the most abundant cluster which corresponds to the $(FKBP+rapamycin)^{7+}$ at m/z 1814. We studied the binding of calmodulin with Ca^{++} ions under the same conditions. Competitive binding between the NH_4^+ and the Ca^{++} ions was observed. These unexpected binding of calmodulin with ammonium ions contribute to peak broadening and less accurate MW determinations. However when acetic acid was added to the solution the peak broadening disappeared and a good MW determination of calmodulin was obtained.

α-, β-, and γ-cyclodextrins are known complexation agents of various organic compounds. Here we studied the association of each of them with pyridine, D- and L-Phe, D- and L-Trp and with bradykinin. In all cases strong association between the cyclodextrins and the organic compound could be demonstrated. If the three cyclodextrins were allowed to compete for L-Phe or L-Trp, the β-cylodextrin seem to form the most abundant clusters. The presence of sodium and potassium ions which are present in HPLC water and other solvents yielded sodium and potassium adduct ions with the cyclodextrins and the complexes.

Pulmonary surfactant, composed of ca 95% phospholipids and ca 5% proteins, reduces the alveolar surface tension and is essential for normal lung function and the prevention of alveolar collapse at end expiration. Insufficient surfactant levels or metabolism have been associated with respiratory distress syndrome, a frequent cause of death in premature infants. Among the lung surfactant proteins, the two hydrophobic proteins SP-B (ca 18 kD, unreduced) and SP-C (ca 4 kD) have been identified as essential components for in vivo surfactant activity [1].

Natural SP-B proteins from several mammalian species (tab. 1) have been isolated from lung tissue as well from lung lavage. Extraction from lung lavage was carried out by a modified procedure of Flügge et al. [2]. Initial characterization was obtained by SDS-PAGE for SP-B from several species. Exact molecular weight determinations and structural studies of natural SP-B proteins were perfomed by desorption-ionization mass spectrometric methods (PDMS, ESMS). ESMS enabled the first direct identification of the SP-B monomeric form after reductive cleavage of a covalent disulfide-dimer with dithiothreitol (DTT). The SP-B polypeptide chain consists of 79 amino acid residue (best studied for human-SP-B) and contains a large number of hydrophobic residues over the entire molecule. Furthermore, all SP-B proteins contain an odd number of cystein residues forming one inter- and several intramolecular disulfide bridges (three for human-SP-B).[3] The dimeric and monomeric forms can be distinguished by ESMS by their specific molecular ion series (fig. 1). All natural SP-B proteins investigated so far were identified as disulfide-dimers which can be cleaved by DTT (tab 1).

Use of Electrospray Mass Spectrometry to Characterize Covalently Modified Proteins

*K. Straub†, L. Antonino†, and M. Levy‡
Syntex Discovery Research† and Syva Corp.‡, Palo Alto, CA 94304

There are numerous examples in protein chemistry where it is desirable to covalently modify amino acid residues to give specifically derivatized macromolecules. For example, immunoconjugates such as haptens linked to carrier proteins are useful for eliciting the production of specific antibodies for use in immunoassays, and hapten-modified enzymes form the basis of many types of enzyme immunoassays. Conjugation of proteins with low molecular weight haptens gives a mixture of macromolecules which differ in the number and site of modified residues. The modification number n describes the average number of covalently modified residues per protein, and is a key parameter that must be carefully optimized when preparing enzyme tracers for use in immunoassays. Methods such as absorption spectroscopy, the use of radiolabeled hapten, and matrix-assisted laser desorption mass spectrometry[1] allow the calculation of an average modification number, but information on the actual distribution of modified proteins is more difficult to obtain

In principle, electrospray MS is an ideal technique for this type of problem, since it can directly give both the average modification number and the relative amounts of each species present. The latter result is useful for optimizing reaction conditions to yield a more precisely defined product for use in immunoassays. We have employed ESI-MS on a quadrupole analyzer to characterize the stoichiometry of covalent binding of small molecules to proteins in the molecular weight range of 50-60 kDa. The results obtained to date show that this methodology can be successfully applied to mixtures of derivatized proteins in this molecular weight range where the modifying hapten has a molecular weight of as little as 150 Da

ESI mass spectra were obtained using a Finnigan TSQ700 equipped with a standard electrospray source. Samples were prepared at concentrations of 1-5 pmol/µl in 10mM NH_4OAc and infused directly into the source at 1 µl/min A sheathing flow of 2-methoxyethanol and a nebulizing flow of nitrogen were used to assist the electrospray process Results obtained with the enzyme glucose-6-phosphate dehydrogenase (G6PDH; mw 54.5kDa) are shown in figure 1A. This protein gives a typical ESI mass spectrum with a distribution of multiply charged species of between +30 and +60, with well-resolved multiply charged ions Modification of the protein by reaction with a carboxylic acid-containing hapten (primarily by reaction with ε-amino groups of lysine residues) yields a mixture of modified proteins, each of which contributes to the overall spectrum The complexity of the resulting spectrum is dependent upon both the modification number and the relative mass of the hapten As the mass of the hapten species decreases, the multiply charged species begin to overlap, eventually reaching a point where individual components can no longer be resolved. An example is shown in figure 1B, obtained on G6PDH modified with a carbamazepine hapten with a residue mass of 290 Da Despite the significant overlap between the series of multiply charged ions, complete deconvolution of the electrospray data to yield a molecular weight distribution is still possible. Figure 1C shows the transformed spectrum obtained from the data in figure 1B. With a quadrupole analyzer, a practical limit to analyzing these types of mixtures appears to occur for a 60kDa protein at a modification number of *ca.* 8 and a hapten mass of approximately 150 Da.

Increasing the resolution of the analyzer does not yield substantial improvements in the deconvoluted data, since the resulting decrease in sensitivity offsets any real gain in signal. It is sometimes possible to improve the quality of the data by employing conditions to shift the entire envelope of multiply charged ions to higher m/z (lower charge number), where the m/z difference between successive charged species is larger This is limited by the decreased sensitivity and resolution of quadrupole systems above m/z 2000, however. In many instances the major factor limiting resolution is not the analyzer, but the presence of non-covalently bound adducts that contribute to broadening and attendant overlap of the multiply charged sample peaks. Removal of these interfering substances using techniques such as ultrafiltration is sometimes successful, but severe loss of sample limits this approach.

Another problem we have encountered is that of proteins that are not soluble under the usual conditions that are employed for ESI An example of this is inosine monophosphate dehydrogenase (IMPDH) This enzyme has a molecular weight of 56 kDa, contains 8 free sulfhydryls, and has very low solubility below pH 7. Treatment with 2-vinylpyridine converted the protein to a derivative with enhanced solubility and which gave a good response with ESI-MS using standard conditions (10 mM NH_4OAC, pH 5, 20% MeOH), as shown in figures 2A and 2B.

Structural and Functional Characterization of the Lung Surfactant Protein SP-C: Electrospray Mass Spectrometric Identification of "Leucine zipper-Analogue" Dimeric Complexes

C. Maier[a], K. Müller[a], K. Baumeister[a], E. Bauer[b], E. Hannappel[b], R. Nave[c], K. Melchers[c], E. Sturm[c], W. Gernandt[c], U. Krüger[c], K.P. Schäfer[c] & M. Przybylski[a]

Introduction

Lung surfactant is a complex mixture of phosholipids and proteins (approx. 5 %) that coats the alveoli to effect reduction of surface tension. Lack of surfactant causes respiratory distress syndrom (RDS). Among the LSF proteins, the extremely hydrophobic surfactant-associated protein C (SP-C, approx. 4 kD) plays the crucial role for the development of surfactant preparations, e.g. for the therapy of infant RDS. Therefore, detailed knowledge of the structure and functional characteristics of natural SP-C is necessary to develop corresponding recombinant human SP-C proteins. Based on recent structural data, a molecular comparison of natural SP-C proteins and human identical recombinant SP-C (rh-SP-C, Tab.1) has been carried out by chemical, chromatographic and mass spectrometric methods.

Materials and Methods

Rh-SP-C was obtained by chemical palmitoylation of recombinant SP-C, expressed in E. coli. The molecular homogeneity was established by PDMS and ESMS.
A Vestec A201 single quadrupole mass spectrometer was used for ESMS-analyses. Sample solutions (0.1 µg/µl) were sprayed at a needle voltage of 1 8 kV, a needle temperature of 40 °C and a flow rate of 2-4 µl/min. Mixtures of varying amounts of isopropanol and diluted acetic acid or 0.1 N HCl were used as solvent systems.

Results and Discussion

Natural SP-C was isolated by lung lavage from several species using Sephadex LH60-chromatography [1]. Rh-SP-C and crude natural SP-C proteins were chromatographed by HPLC on a RP-C4 column and yielded comparable retention times. Their primary structures in particular the identification of the thioester-palmitate moiety were established by ^{252}Cf-PDMS-analysis combined with chemical methods, e.g. deacylation by DTT-treatment followed by S-alkylation and N-terminal Edman/PDMS-sequence analysis [2].
New solvent systems for ESMS-analysis were developed and yielded molecular weight data with high accuracy and resolution, enabling the identification of methione oxidation in some of the SP-C proteins. The discovery by ESMS of dimeric supramolecular structures of SP-C ("Leucine zipper-analogue" dimers) via their multiply protonated odd charge states has been an interesting feature for the evaluation of the biological function of SP-C. The formation of the dimeric complexes was shown to be pH- and solvent-dependent. Furthermore, the successful formation of heterodimeric complexes between different recombinant SP-C mutants suggests a structure model of the SP-C dimer, based on the dimerization principle of the "leucine zipper"-proteins [3].

Reversibility of Heat Induced Conformational Changes of Proteins studied by Electrospray Ionization Mass Spectrometry

*Urooj A. Mirza and Brian T. Chait
The Rockefeller University, 1230 York Ave, New York, NY.10021

Introduction In their native states, globular proteins are tightly folded, compact structures that can be denatured and caused to unfold by subjecting them to extremes of pH, denaturants such as guanidinium hydrochloride, organic solvents, detergents, and high temperatures. A variety of techniques have been applied to the measurement of conformational changes of proteins in solution, including acid-base titrations, calorimetry, spectrophotometry, viscometry, circular dichroism, fluorescence, and nuclear magnetic resonance. Recently, we and others have demonstrated that conformational changes of proteins can also be detected by electrospray ionization mass spectrometry.[1,2] In the present study we demonstrate a new mass spectrometric method for probing the **reversibility** of heat induced conformational changes in globular proteins and the effects of different solutions on the reversibility of these conformational changes.

Experimental The method that we developed for probing the reversibility of heat-induced conformational changes[2] involves comparison of the electrospray ionization mass spectra of a protein acquired under three different conditions. Spectra are obtained from:

1) A solution sprayed at room temperature (25°C), where the protein is expected to be in its native conformation.
2) A solution sprayed at an elevated temperature Td, in excess of that required to bring about the conformational change(s).
3) A solution that has previously been heated in a vial to a temperature Td, maintained at Td for 4-5 minutes, and then cooled to room temperature prior to electrospray MS analysis.

When the spectrum acquired under condition 3 is found to be identical with that acquired under condition 1, we infer that the conformational change is reversible. Conversely, when the spectrum acquired under condition 3 is observed to be closer to that acquired under condition 2, we infer that the change is irreversible.

Results Cytochrome c (MW. 12,229) in an aqueous acetic acid solution at pH 3.6 was found to undergo two separate heat-induced denaturation transitions at temperatures T_1 and T_2 (fig 1). The probe of reversibility outlined above showed that the conformational changes occuring at the lower temperature (T_1) are reversible (fig 2abc), while those occuring at the higher temperature (T_2) are irreversible (fig 3abc) on the time-scale of the experiment (minutes to hours). The presence of (50%) methanol was found to render the high temperature conformational changes reversible on the same time-scale. Analogous reversibility experiments with bovine ubiquitin (MW 8565) indicate that the protein undergoes reversible heat induced conformational changes in all the solutions that were tested. Chicken egg lysozyme (MW 14,306) was found to undergo reversible heat induced conformational changes in an aqueous acidic solution or an aqueous acidic solution to which methanol have been added. By contrast, denaturation of lysozyme in water and 50% methanol was determined to be irreversible on a time scale of hours but reversible over longer time scales (days).

Determination of primary structure and biological activity of different recombinant human epidermal growth factor proteins

*M.Svoboda[a], A.Bauhofer[b], E G.Bade[b] and M.Przybylski[a]
Faculties of Chemistry[a] and Biology[b], University of Konstanz, P.O.Box 5560, D-7750 Konstanz, FRG

Natural epidermal growth factor (EGF) is a 53-aa polypeptide (1) with three intramolecular disulfide bonds. EGF modulates the proliferation and a variety of other functions of almost every cell type studied (2) Recombinant human EGF (rhEGF) is expressed in E. *coli* with an additonal N-terminal Met residue (3). The primary structures and molecular homogeneities of rhEGF's from different manufacturers were characterized using ^{252}Cf plasma desorption (PDMS) and electrospray mass spectrometry (ESMS). Only one protein, rhEGF-A, showed the correct MW of 6346 D, while a second protein, rhEGF-B, had a significantly higher MW of 7020 D both in ESMS and PDMS. Furthermore, the series of multiply protonated ions in ESMS shifted to higher protonation states for rhEGF-B, indicating the presence of additional basic aa in this protein (see figure 1).

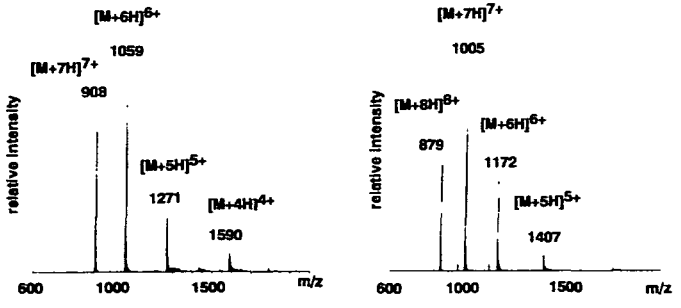

Figure 1: Electrospray mass spectrum of rhEGF-A (left) and rhEGF-B (right) showing the series of multiply protonated molecular ions

Reduction and carboxymethylation of cystines using dithiothreitol and iodacetamide followed by PDMS analysis confirmed the presence of three intramolecular disulfide bridges both in rhEGF-A and in rhEGF-B. Cleavage of C-terminal Arg using Carboxypeptidas B showed a correct C-terminus in both proteins (figure 2). Edman degradation of rhEGF-B combined with PDMS analysis revealed, that this protein had additional Lys residues, because three instead of the expected two phenylisothiocyanates (PITC) coupled to ε-amino groups of Lys residues in the first Edman step. Edman gas phase analysis revealed, that rhEGF-B had 59 aa and an elongated, strongly hydrohilic N-terminus, containing the pentapeptide -**KKYPR**- following the N-terminal Met residue(figure 2)

(3) Kishimoto, F et al.(1986) Gene 45,311-316

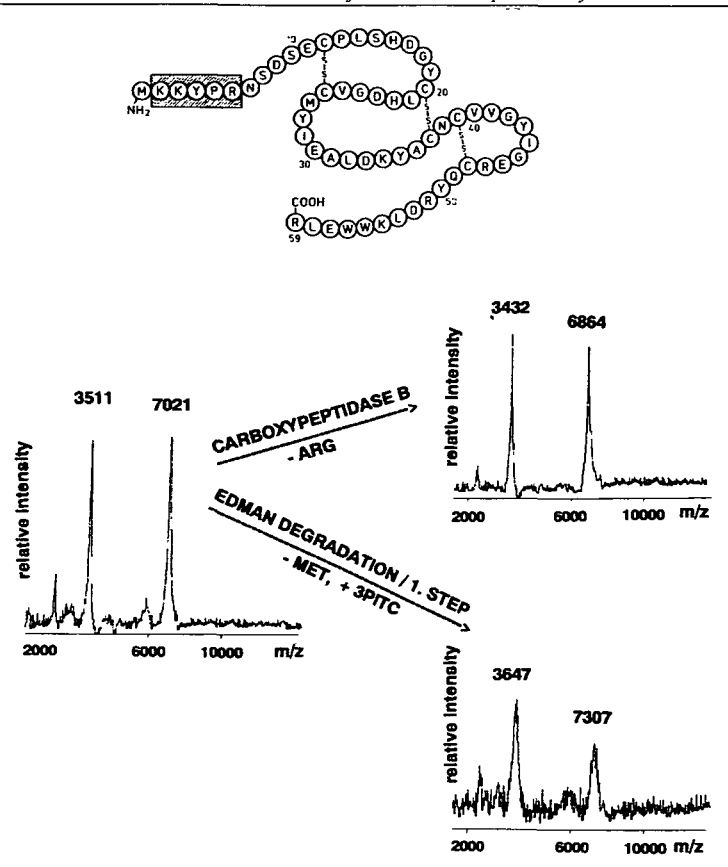

Figure 2 Enzymatic cleavage of C-terminal Arg of rhEGF-B by Carboxypeptidase B and Edman-degradation of intact rhEGF-B showing loss of N-terminal Met but additional coupling of three phenylisothiocyanates (PITC) to intramolecular Lys (K) residues.

This sequence insert leads both to a significant decrease in the proliferation activity as well as to a reduced cell migration activity of this recombinant protein, which can be explained by a change in receptor binding affinity. These results underline the importance of desorption ionization mass spectrometry as fast and accurate molecular analytical method for the structural control of recombinant proteins.

Structural Characterization of Cyclic RGD-Containing Peptides by Ionspray Tandem Mass Spectrometry

Yiping Sun, David J. Eickhoff, Stephen G. Wood, Mark D. Bauer,
Thomas W. Keough and Charles R. Degenhardt
The Procter and Gamble Co., Miami Valley Laboratories,
PO Box 398707, Cincinnati, OH 45239-8707

Introduction

Cyclic RGD-containing peptides and their analogs are important inhibitors of cell adhesion associated with angiogenesis and platelet aggregation. They can be either thioether or disulfide forms. It is very important to establish a method for rapidly identifying these peptides, and for confirming the structure of the final products. The cyclization and blocked N-termini of these RGD-containing peptides make them difficult to analyze by Edman sequencing. Although ionspray ionization mass spectrometry has proven very useful for the structural characterization of peptides and proteins, the mass spectra of the cyclic RGD-containing peptides obtained by ionspray MS/MS analysis showed very little fragmentation. In this study, we report an approach by which cyclic peptides were first converted to their linear counterparts by tryptic digestion or performic acid oxidation (Figure 1), and then sequenced by ionspray MS/MS.

Experimental

Performic Acid Oxidation - Cyclic peptides were dissolved in H_2O and oxidized with performic acid (35% H_2O_2:88% HCOOH, 1:19, v/v) at room temperature for 10 minutes.

Tryptic Digestion - Cyclic peptides were digested with trypsin in 0.1 M NH_4Ac (pH=7.7) at 37 °C for one hour.

Ionspray MS and Ionspray MS/MS - All experiments were carried out on a Sciex API-III LC/MS/MS triple quadrupole instrument. The delivery solvent was CH_3OH:H_2O (1:1) with 0.1% HCOOH using a flow of 5 µl/min. For MS/MS analysis, ultrapure argon was used as the collision gas at a target gas thickness of 3.3×10^{14} atoms/cm^2.

Results and Discussion

Cyclic RGD-containing peptides and their analogs analyzed by ionspray mass spectrometry are listed in Table 1. The molecular masses of these peptides are in the range of 500-1500 Da. Figure 2 is a fragment ion spectrum obtained from an RGD-containing peptide (disulfide form, MH^+=551.0). Unfortunately, this spectrum showed a strong parent ion with little fragmentation. Figure 3 is a fragment ion spectrum of an RGD-containing peptide analog (thioether form, MH^+=649.0), which also showed little fragmentation. Changing MS/MS parameters like the collision gas thickness had little effect on the fragmentation. In order to get sequence information and to confirm the structure of these cyclic peptides, they were first converted to their linear counterparts by tryptic digestion or performic acid oxidation, and then sequenced by ionspray MS/MS. MS/MS data obtained from the disulfide peptide (MH^+=551.0), after performic acid oxidation, is shown in Figure 4. Significantly increased fragmentation is seen in the spectrum compared to that seen in Figure 2. These data confirm the peptide sequence. MS/MS analysis of the RGD-containing peptide analog (thioether form, MH^+=649.0), after tryptic digestion, also showed many fragment ions which provided the sequence of the peptide (Figure 5). This same approach has been used successfully for the characterization of many other cyclic RGD-containing peptides and their analogs.

Conclusions

An approach which combines tryptic digestion or performic acid oxidation with ionspray MS/MS sequencing has been used for analyzing cyclic RGD-containing peptides. The method is simple and rapid. It provides sequence information which is difficult to obtain by classical Edman sequencing.

Application of Electrospray Mass Spectrometry to Structure Studies of Bovine Adenosine Deaminase

**Michele A. Kelly, Suming Hua[a] and Catherine C. Fenselau.*
Department of Chemistry and Biochemistry, University of MD, Baltimore County, Baltimore, MD 21228; [a]Department of Biological Chemistry, University of MD at Baltimore, Baltimore, MD 21201

Adenosine deaminase (ADA) is an enzyme required in mammals for the deamination of adenosine to inosine. The genetic deficiency of this enzyme results in severe combined immunodeficiency disease (SCID). Enzyme replacement therapy has been effective in treating victims of SCID as a nontoxic alternative to bone marrow transplantation and red-cell transfusion[1,2]. The primary sequence of bovine ADA is presently unknown although it is used clinically, as an orphan drug. Polyethylene glycol (PEG) is covalently attached to the therapeutic enzyme to increase its lifetime when administered to patients[1,2]. Using the known human ADA gene sequence as a reference[3], the amino acid sequence of bovine ADA is being investigated. Ultimately, the PEG attachment sites on bovine ADA will be determined using experimental methods developed previously in our laboratory[4].

The molecular weight of reduced and carboxymethylated bovine adenosine deaminase was determined to be 40549 ± 16 daltons by electrospray mass spectrometry (ES-MS) (**Figure 1**). This value is close to the calculated molecular weight of human ADA containing 362 amino acids (40933 Da, allowing for 5 carboxymethylated cysteine residues and excluding the initiator, Met). Subsequently, bovine ADA was digested using several proteolytic enzymes and mapped by ES-MS.

Clostripain, which cleaves specifically after arginine residues, was used to digest bovine ADA to produce several proteolytic fragments ranging in molecular weight between 2000-8000 daltons. Few fragments could be mapped perfectly to the human ADA reference; thus, several amino acid substitutions had to be ascertained. Incomplete digestion aided the placement and order of clostripain pieces. For example, two peptides in an ES-MS spectrum of a clostripain fraction have a mass difference corresponding to residues [81-100]. Concluding that the larger peptide (7657 Da) is an incomplete cut from residues [81-141], the smaller peptide (5333 Da) must map onto residues [100-141]. This is 101 Da higher than the value predicted from the human sequence.

Unassigned clostripain fragments were further digested with *S. aureus* V8 protease to produce smaller sized fragments ending in aspartic or glutamic acid residues. This approach provides certainty in mapping resultant peptides within the larger clostripain proteolytic fragment as shown in **Figure 2** and further localizes any mass discrepancies. Tandem mass spectrometry was then used to confirm proposed amino acid changes where mass differences were apparent. Using this approach, residue 351 was assigned as arginine. In the human sequence, the corresponding residue is a glycine so this peptide was not predicted for a clostripain digestion.

CNBr is a useful chemical for obtaining specific cleavage of a protein after methionine residues, resulting in homoserine and/or homoserine lactone termini. Since methionine is not a relatively abundant amino acid in most proteins, fewer fragments are formed. In this case, even if mass variations exist, fragments of distinct sizes can be mapped with confidence against the human gene sequence. Corrected for known mass changes obtained from clostripain experiments, all but five residues from [52-352] can be mapped by CNBr cleavage.

In order to locate the C-terminus of bovine ADA, BNPS-skatole was used to cleave specifically after tryptophan residues. Like CNBr, the infrequent occurrence of tryptophan in protein sequences results a limited number of fragments. The ES-MS spectrum of the C-terminus suggests that this peptide exists as a mixture. Further investigation of this fragment will seek to confirm this result.

Electrospray MS has been used to quickly and conveniently map various proteolytic digests of bovine ADA against a reference sequence. This approach is useful in pinpointing regions with mass discrepancies. Twenty amino acid substitutions have been confirmed by tandem mass spectrometry in the present work. This implies that the sequence of bovine ADA is over 90% homologous to the human sequence. The reproducibility and accuracy of these methods will be crucial when locating the sites of modification on the therapeutic drug, PEG-ADA.

Electrospray Mass Spectrometry Characterization of Cathepsin B *C*-Terminal Processing

Rong Feng[1], Andrew D. Rowan[2], Yasuo Konishi[1] and John S. Mort[2]

(2) Shriners Hospital for Crippled Children, Joint Disease Laboratory, 1529 Cedar Avenue, Montreal, Quebec, Canada

Cathepsin B, an abundant lysosomal cysteine proteinase, has been implicated in the progression of malignant tumor, arthritis, and muscular dystrophy. The DNA coding sequence shows that the enzyme precursor is synthesized as a single-chain polypeptide of 30 kDa. However, as the enzyme matures, the polypeptide chain is shortened and glycosylated. Of particular interest is the finding that, in addition to the usual *N*-terminal extension found in the majority of proteins, the *C*-terminus of the DNA coding sequence of cathepsin B also possesses a 6-residue extension that is not found in the corresponding amino acid sequence of the mature enzyme. It has been *speculated* that the six *C*-terminal residues are removed during the intracellular processing of cathepsin B. In this study we utilized electrospray mass spectrometry (ESMS) in conjunction with site-directed mutagenesis to establish the mechanism of the cathepsin B *C*-terminal processing.

Rat liver cathepsin B was used in the study. It was suspected that the peptidyldipeptidase activity of cathepsin B itself was responsible for the intracellular removal of the *C*-terminal extension. To test this self-processing possibility, a nonactive mutant was expressed in yeast using the recombinant technique. In this nonactive mutant, the active-site amino acid residue, Cys-29, was replaced with a 'dummy' Ser residue to incapacitate the enzyme to determine whether the *C*-terminal extension would survive. However, the mass measurement from ESMS did not produce conclusive evidence, due to the spectral complexity resulted from the heterogeneous glycosylations. To overcome this problem, the glycosylated *N*-terminal pro-region was removed by pepsin cleavage, and a second mutation was introduced to substitute an additional residue, Ser-115, with an Ala residue to alter the *N*-glycosylation consensus sequence (Asn-Gly-Ser) to remove the second oligosaccharide attachment in the middle of the polypeptide chain (see Fig. 1 for a diagrammatic representation). Elimination of the carbohydrate heterogeneity resulted in a greatly simplified electrospray mass spectrum, which in turn clearly showed that the nonactive *double* mutant (with two mutations at residues no. 29 and no. 115) contained the 6-residue *C*-terminal extension (Gln-Tyr-Trp-Gly-Arg-Phe). This evidence suggests that the active cathepsin B is required to remove the *C*-terminal extension.

To further prove that cathepsin B itself is responsible for the removal of the *C*-terminal extension, a trace of the active cathepsin B was added to the nonactive mutant and the mass changes of the mutant were monitored by ESMS (see Fig. 2; only the 21+

charge-state region is shown). The fact that the addition of the active cathepsin B quickly led to the mass reductions of the nonactive mutant established unequivocally that the active cathepsin B served as a processing enzyme for the nonactive mutant. The electrospray mass monitoring data also revealed that the *C*-terminal extension was cleaved two residues at a time and the processing stopped once all six *C*-terminal residues were removed. The reaction kinetics indicated that the dipeptidyl removal became more and more difficult as the *C*-terminal processing progressed, pointing to a possible conformational restriction in fitting the *C*-terminal extension to the cathepsin B active site.

In conclusion, we have demonstrated, using ESMS in conjunction with site-directed mutagenesis, that cathepsin B itself is responsible for removing the 6-residue *C*-terminal extension. It is also shown that the *C*-terminal processing of cathepsin B is stepwise with two residues being cleaved at a time, consistent with the known peptidyldipeptidase activity of cathepsin B.

Studies of the *Ras*-GDP and *Ras*-GTP Noncovalent Complexes by Electrospray Mass Spectrometry

E.C. Huang*, B N. Pramanik, A. Tsarbopoulos, V.M. Girijavallabhan, and S. Liberles[ψ]
Schering-Plough Research Institute, 2015 Galloping Hill Road, Kenilworth, NJ 07033

The *ras* protein can exist in two interconvertible states: GDP-bound and GTP-bound representing the inactive and active forms, respectively. In oncogenic *ras*, the rate of hydrolysis of the GTP to GDP is dramatically reduced, which "locks" the *ras* in the active state resulting in unregulated cell growth. Therefore, the detection and differentiation of the *ras*-GDP and *ras*-GTP complexes is important to the study of abnormal cell growth, as well as to the discovery of organic molecules as anticancer drugs.

To successfully perform direct MS analysis of the pre-formed noncovalent complexes, the MS technique utilized must satisfy the following criteria: (1) the ionization method must be capable of generating intact gas phase protein ions from a solution containing biological buffer; (2) the internal energy transfer to the macromolecule during the ionization process must be minimal to prevent complex dissociation; (3) the MS must have sufficient mass range to observe the ionized complex. Ganem et al.[1] reported the first applications of using electrospray (ESI) MS for the detection of noncovalent interactions. We have been studying the noncovalent complex of *ras*-GDP and *ras*-GTP using ESI, and a preliminary report of the successful ESI MS detection of *ras*-GDP has been published.[2] Here we provide the details of using ESI MS for the detection of *ras*-GDP and *ras*-GTP complexes. The effect of the pH and organic solvent to the stability of complexes is also discussed.

Preparation of ras-GDP Complex

C-terminally truncated normal human *ras* (1-166) was expressed in *E. coli* from a synthetic *ras* gene under the control of both the *lpp* and tac promoters.[3] The noncovalent complex of *ras*-GDP was subsequently purified from fermentor-grown, IPTG-induced cells. The activity of the *ras* in GDP binding assays and GTPase assays was comparable to published data. The final apo-*ras* protein was stored in 750 mM ammonium sulfate, 50 mM Hepes buffer pH 6, and 10 mM 2-mercaptoethanol at a concentration of 6.15 mg/mL. The FPLC isolated *ras*-GDP sample was kept in the solution containing 64 mM Tris HCl pH 7.6, 10 mM $MgCl_2$, 1 mM NaN_3, 0.5 mM DTE, and 250 mM NaCl. All sample solutions were stored at 4°C prior to MS analysis.

Preparation of ras-GTP Complex

An aliquot (100 µL) of apo-*ras* solution was diluted in Hepes buffer (50 mM, pH 7.5, 1 mM DTT) to two mL. To this, 10.2 µL of GTP were added (i.e., 2 - 3 molar excess) from solution of GTP in Hepes buffer. The concentration of the GTP solution was 3.34 mg/mL. This solution was refrigerated overnight and then concentrated to roughly 200 - 250 µL using a centrifuge concentrator. All samples were further treated with 1 mM EDTA and 1 mM $MgCl_2$ prior to MS analysis.

Mass Spectrometry

A SCIEX API III triple quadrupole mass spectrometer equipped with a ESI source (Sciex, Canada) was used. Sample was introduced either through direct infusion of the protein solution or via Rheodyne injector with a preselected solvent. In the latter case, an Applied Biosystems (Foster City, CA) Model 140A micro LC pump was used to deliver a constant liquid flow of 5-100 µL/min.

Results and Discussion

Figure 1 is the ESI spectrum of *ras*-GDP complex obtained at pH 5.8 (no MeOH). The signals at m/z 2396, 2145, and 1931 yielded an average molecular weight (MW) of 19,295 Da which corresponds to the *ras*-GDP complex. Computer deconvolution of this spectrum revealed the presence of a second species with an average MW of 19,344 Da, a component that could have resulted from the addition of two Mg^{2+} to the complex. Nevertheless, this assignment has not yet been confirmed experimentally. When the pH was lowered to ~4.0, the *ras*-GDP complex was still obesrved (**Figure 2**) with the charge distribution apexed at +11 charge state. Further lowering the pH to 3.3 resulted in partial release of GDP, leading to the observation of both the *ras*-GDP and the apo-*ras* signals. When the pH was adjusted to 2.8, the complex was almost completely dissociated.

ψ Undergraduate research participant, Department of Chemistry, Harvard University.

The effect of pH on ESI detection of *ras*-GDP complex is summarized in **Table 1**. It is known that the addition of organic solvent disrupts the well-ordered water molecules, allowing solvent molecules to penetrate into protein's hydrophobic interior and subsequently denature the prtotein. **Table 2** summarizes the effect of the organic solvent (MeOH) content on the ESI detection of the *ras*-GDP complex. This methodology was further extended to monitor the formation of the *ras*-GTP complex. The spectrum obtained from the solution of *ras*-GTP complex at pH 4.0 showed a series of ions at m/z 2154, 1938, 1762, 1616, and 1491, yielding an average MW of 19,374 Da. This indicat es the formation of an 1:1 *ras*-GTP complex. The multiply-charged ion distribution profiles are identical for both *ras*GDP and *ras*-GTP complex. The effect of pH on detection of *ras*-GTP complex was also studied and the results indicated that the *ras*-GDP and the *ras*-GTP complexes possessed the same behavior upon ESI MS analysis. Everything being the same for MS analysis of *ras*-GDP and *ras*-GTP complexes, the data suggest that even though there is a significant difference in biological activity, the change in solution conformation during the transition between the "*on*" and the "*off*" state is not significant enough to allow the differentiation to be made by ESI MS.

Conclusion

The *ras*-GDP and *ras*-GTP noncovalent complexes were successfully detected by ESI MS. This observation indicates that the protein-ligand noncovalent complex (with high association constant) can be desorbed, at its native or very close to its native solution conformation, as multiply-charged ions. From the MW determined by ESI MS, one can readily obtain information regarding the stoichiometry of protein-ligand interactions. The method can be further extended to study the protein unfolding processes associated with the acid-induced, as well as organic solvent-induced, denaturation. Correlation of these changes with specific events in the unfolding is not possible. The ability to observe such noncovalent interactions in solution highlights the potential of using electrospray MS for protein-protein interaction studies, kinetic studies of protein-ligand interactions, and for screening enzymes and receptors for inhibitors and substrates of pharmaceutical interest.

Comparison of Charged Peptide Derivatives for High Energy CID MS/MS

*J. Zaia and K. Biemann, Dept. of Chemistry, M.I.T., Cambridge, MA 02139

A comparison of charged derivatives for high energy CID spectra is the purpose of this work. The experiments have been limited to the N-terminal derivatives because it is difficult to prepare C-terminal derivatives without simultaneous alkylation at carboxyl side chains. Specific N-terminal derivatization can be accomplished in the presence of lysine with proper pH control[1].

The structures of the derivatives tested are shown in Figure 1. TPPE[2], TMAA, and DMOAA[1,3,4,5] have been previously described. Trimethylpyridiniumbutyrl (TMPB) is an N-terminal derivative which is a modification of a lysine specific derivative used in earlier work in this laboratory[6,7]. Peptides modified with the derivatives in Figure 1 produce primarily a_n and d_n ions although the abundance of ions produced from the derivative moiety varies widely among them. The abundance of ions containing solely the derivative moiety must be low for a useful charged derivative so that ion current is not diverted from the peptide sequence product ions.

A systematic comparison showed that the TMAA derivative produced the lowest abundance fragment ions containing only the derivative moiety (data not shown). In contrast, these fragment ions were observed to be quite abundant for the TPPE, 4-NMPA, and 3-NMPA derivatives. It was also determined that the effect of TMAA derivatization on ionization efficiency was approximately neutral compared to the underivatized peptide (data not shown). The usefulness of the TMAA derivative is shown in the following example. Consider the CID spectrum of α-endorphin (YGGFMTSEKSQTPLVT), Figure 2a. This spectrum shows lengthy gaps in its product ion pattern which is probably due to the basic lysine in the center of the sequence. The TMAA- derivative (Figure 2b) vastly improves the spectrum. The a_n series is complete for all three with the exception of the glycine residues at positions 2 and 3. Similar results are obtained for ACTH 1-14 (SYSMEHFRWGKPVG) and somatostatin (AGC[*4vp*]KNFFWKTFTSC[*4vp*]), peptides whose underivatized spectra are quite poor (data not shown).

Method. TPPE- derivatives were prepared according to the published method[2]. Trimethylpyridiniumbutyric acid was synthesized according to a literature method[8], and coupled to the peptide N-terminus using 1-Ethyl-3-(dimethylaminopropyl)carbodiimide hydrochloride (EDC) at pH 4.5. 4-NMPA- derivatives were prepared by coupling N-methyl-4-pyridiniumacetic acid to the N-terminus of the peptide using EDC. The same method was used for the 3-NMPA derivatives using N-methyl-3-pyridiniumacetic acid. The TMAA-, DMOAA-, and PyrA- derivatives were prepared by reacting the appropriate amine with an N-terminal iodoacetylated peptide. Peptides were iodoacetylated according to a published method[1].

High Resolution and MS/MS Matrix-assisted Laser Desorption on a Fourier Transform Mass Spectrometer

Robert J. Cotter* and Amina S. Woods
Johns Hopkins School of Medicine
Baltimore, MD 21205

J.A. Castoro and C.L. Wilkins
University of California at Riverside
Riverside, CA 92521

Recently, Wilkins and coworkers (1) described a method for trapping *MALDI* ions in a Fourier transform mass spectrometer (*FTMS*) that is used here for the analysis of two synthetic peptides containing amino acid sequences for antigens associated with the Major Histocompatibility Complex (MHC) and displayed on tumor cells genetically engineered to produce specific lymphokines for activating inadequately functioning helper T cells.

Approximately 1-2 nmoles of peptide in a 50 mM 2,5-dihydroxybenzoic acid solution in 0.1% trifluoroacetic acid/methanol was sprayed as an aerosol onto a rotating stainless steel probe tip for homogeneous deposition. Spectra were obtained with 355 nm radiation from a Lambda Physik (Gottingen Germany) FL-2001 dye laser pumped by a Lambda Physik EMG 201-MSC excimer laser (308 nm, 180 mJ/28 nsec pulse) and a Millipore Extrel (Madison WI) FTMS-2000 equipped with a 7 Tesla superconducting magnet. Spectra were obtained using a 9 volt gated trap decelerating potential prior to source side 1-1.5 volt trapping and detection, except for the high resolution spectrum where analyzer side, 0.4 volt trap, heterodyne detection was employed. *SID* spectra were the result of 100 laser shots with a 3 volt trap. No apodization was used. Poly(ethylene glycol) 1000 was used as an external calibrant.

Positive and negative ion mass spectra were obtained for each peptide. For *ASNENMETN* $[M+Na]^+$ and $[M-H]^-$ were detected with a resolution of ~8,000 and a mass error of 8 ppm for the monoisotopic peaks (Figure 1). For *TYQRTRALV* $[M+H]^+$ and $[M-H]^-$ were detected with resolutions of 13,500 and 17,900 and mass errors of 13 ppm and 81 ppm, respectively. A high resolution heterodyne mode mass spectrum of *TYQRTRALV* $[M+H]^+$ was also obtained with an average resolution of 300,000. Surface induced dissociation was carried out on the $[M+H]^+$ ion of *TYQRTRALV* and the $[M+Na]^+$ of *ASNENMETM*. All fragments and impurities below 1000 daltons were ejected prior to an on-resonance excitation of the parent ion. Each ion was excited to a calculated radius of 0.85 cm, resulting in translational energies of 133 eV for $[M+H]^+$ and 141 ev for $[M+Na]^+$, prior to a 25 volt *SID* pulse for around 90 us. For the peptide *ASNENMETM*, ions of m/z 1048 (corresponding to the $M+Na^+$ ion) were selectively excited, producing the product ion mass spectrum shown in Figure 2, containing the sequence ions: A_3+Na (267.1), B_3+Na (295.1), A_4+Na (396.2), B_4+Na (424.1), A_5+Na (510.2), B_5 (516.9), B_5+Na (538.2), A_6+Na (641.2), B_6 (648.2), Z_4+Na (630.2), Z_5 (493.2), X_6 (406.1), Y_6 (380.1), Z_6 (363.1) and X_7 (277.1).

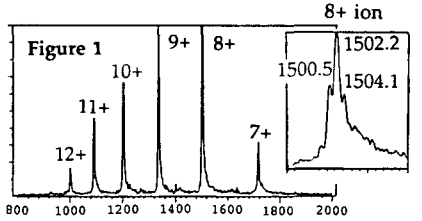
The Analysis of Biomolecules by Electrospray Ionization on a Magnetic Sector Tandem Mass Spectrometer

K.M. Downard, I.A. Papayannopoulos, C.E. Costello and K. Biemann
Dept. of Chemistry, Massachusetts Institute of Technology, Cambridge, MA, 02139

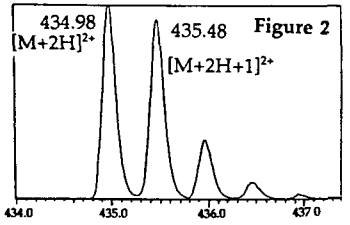
In 1988, Fenn and co-workers showed that the electrospray ionization (ESI) technique developed in their laboratory could be successfully applied to the analysis of large biomolecules to 40 kDa.[1] This mass limit was soon exceeded and to date molecules to 5 million daltons have been ionized by this approach.[2] The success of this technique is due in large part to the phenomenon of multiple charging, where large biomolecules are detected at integral fractions of their mass allowing their detection on spectrometers of limited *m/z* range.

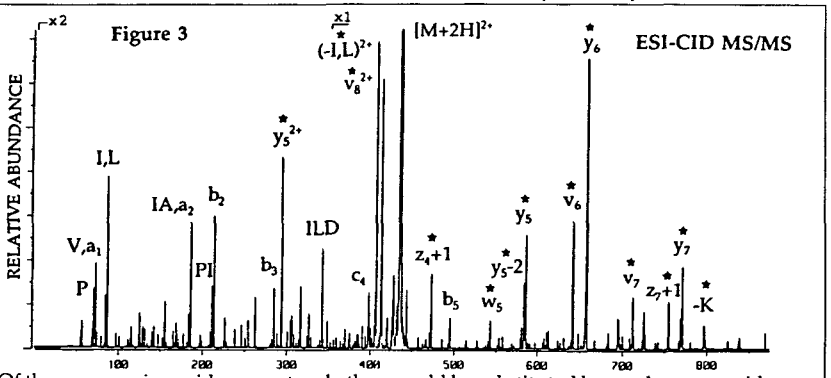
To date most electrospray studies have been performed on quadrupole instruments but recent interest has focused on integrating the technique to other mass analyzers. In this regard sector instruments offer several advantages over quadrupoles; namely higher resolution and the ensuing improvement in mass accuracy, and extended *m/z* range and the potential for high energy CID of multiply charged ions. We have been exploiting the electrospray approach in our studies of proteins, glycoproteins and other glycoconjugates.

The ESI mass spectrum of *Chloroflexus* Thioredoxin is shown in Figure 1. This spectrum indicates that the protein is a heterogeneous mixture containing proteins 14 Da. lower (A to G) and 16 Da. higher (M to M=O) than that of the major protein at M_{av} 12009.



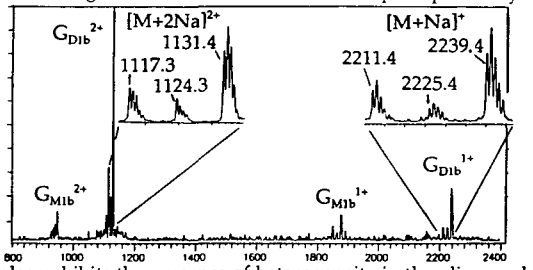
A further site of heterogeneity has been realized upon screening the tryptic digestion products by ESI-MS. The isotopic distribution of a tryptic peptide of M.Wt. 868 is shown in Figure 2. This spectrum indicates that an additional component is present having a molecular weight of one dalton higher. CID spectra of the doubly charged ions $[M+2H]^{2+}$ and $[M+2H+1]^{2+}$ produced by ESI were recorded. The CID spectrum of the $[M+2H]^{2+}$ ion is shown in Figure 3. Examination of this spectrum reveals the smaller tryptic peptide has the structure VIAPILDK. Peaks which shift to higher *m/z* values in the spectrum of $[M+2H+1]^{2+}$ are indicated with a ★.





Of the seven amino acids present, only three could be substituted by an alternate residue one mass unit higher. These are I, L and K. Since the peptides were isolated from a tryptic digest, substitution of K for E is unlikely. Note that b_2 and b_5 fragment ions do not shift to higher *m/z* values in the CID spectrum of the $[M+2H+1]^{2+}$ ion, thus heterogeneity exists at position 6 where L is substituted for N.

The ESI mass spectrum of a permethylated ganglioside G_{D1b} is shown in Figure 4. The base peak of the spectrum corresponds to the doubly charged ion $[M+2Na]^{2+}$ of the di-sialylated ganglioside. This peak shows some multiplicity, a consequence of the heterogeneity in the long chain base (-28 Da) and incomplete permethylation (-14 Da)



The spectrum also exhibits the presence of heterogeneity in the oligosaccharide portion, where G_{M1b}^{2+} and G_{M1b}^{1+} denote the doubly and singly charged ions of the mono-sialylated gangliosides respectively.

Growth and certain disease conditions are related to high turnover rates of collagens. Tissue metabolism results in the release of fragments into blood and urine, some of which contain the collagen-specific, 3-hdroxypyridinium crosslinks. Preliminary studies, using these components to monitor collagen degradation rates, have indicated that a large proportion are present as small peptides. As the crosslinks are found out in a variety of tissues containing different genetic types of collagen, identification and sequencing of these crosslinked peptides would facilitate the development of tissue-specific markers of collagen degradation. By monitoring their natural fluorescence, peptides containing these crosslinks will be isolated from biological materials, such as urine and serum using a variety of chromatographic and electrophoretic techniques. Mass spectrometry analysis of pyridinoline and its derivatives described here.

EXPERIMENTAL

All mass spectra were obtained on a CONCEPT II HH four-sector tandem mass spectrometer (Kratos Analytical Ltd, Manchester, UK) operated at 8 kV ion-acceleration and equipped with a cesium ion gun with 15 keV impact energy, standard LSI mass spectrometry probe and a final scanning-array detector. All experiments were completely controlled by a MACH 3 data system and the data was collected and processed in an identical manner to that obtained from a point detector. Tandem mass spectrometric experiments were carried out by using all four sectors (EBEB) on the instrument. CID of the precursor ions occurred in the flexcicell where a potential of 4 kV related to earth was floated. Argon was used as the collision gas at a pressure sufficent to attenuate the precursor ion beam by 60%.

RESULTS

Structures of the trifunctional crosslink molecules (fig.1), pyridinoline (Pyd), deoxypyridinoline (Dpd) and glycosylated pyridinoline (Glc-Gal-Pyd), have been characterized by positive-ion LSIMS and four-sector tandem mass spectrometry. The naturally-occurring cations are desorbed by LSIMS readily in the positive-ion mode, using G/TG(1:1) or PEG 400 as matrixes, and intense stable M^+ ions dominate the spectra, facilitating an accurate mass measurement of molecular mass (fig.2). Changing matrix to NBA leaves little evidence of the cation since facile decomposition, of Pyd yields $[M-O]^+$, of Glc-Gal-Pyd yields the equivalent $[M-Gal-Glc]^+$, while the $M^+$of the two molecules are drastically reduced in intensity. Electrochemical reaction between analytes and NBA has been evidenced. CID of major ions produced by positive-ion LSIMS (fig.3) gives a wealth of fragmentation for structural elucidation (scheme 1), and the concept of remote-site fragmentation with the charge located on the ring nitrogen (scheme 2) is considered with caution. (M-92) and (M-92-92) peaks in the CID spectra are due to glycerol matrix. It was evidenced by the absence of such ions in the CID MS/MS spectrum of Dpd when NBA was used as the matrix. However, it is unclear how these ions are formed. The study on structures of trifunctional crosslink molecules by MS provide valuable information to identify such markers.

HPLC-PB-CI-MS and HPLC-TSP-MS of Linear Peptides (Efrapeptins) and Cyclodepsipeptides (Destruxins) of Fungal Origin

Matt J. Sweeney and Dr. Sandeep Gupta, ISK-MVRC, 1195 W. Fremont Ave Sunnyvale, CA 94087

Introduction-

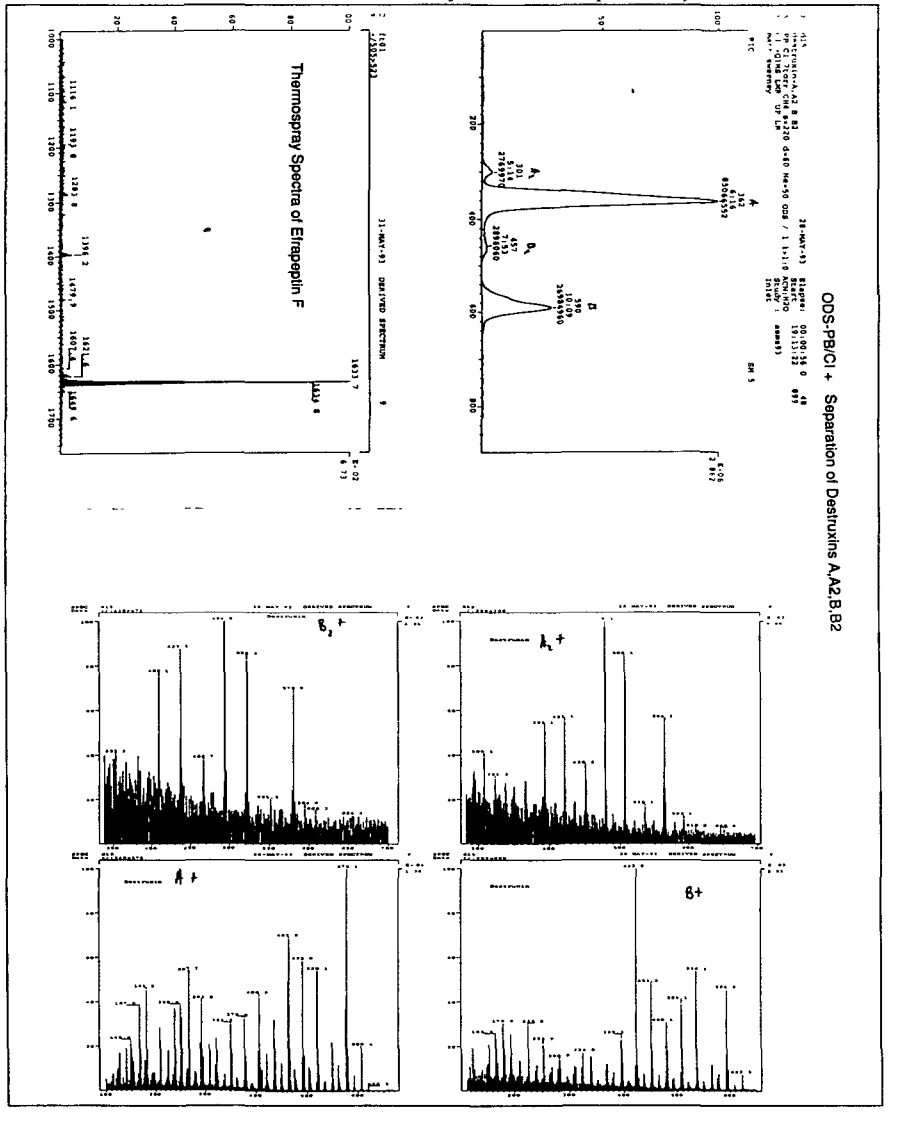
Efrapeptins and destruxins are fungal peptides which are typically isolated by RP-HPLC and identified by NMR, FD- or FAB-HR-MS and sequence analysis. Particle Beam-MS with an EI/CI source and Thermospray can be used for on-line detection of these metabolites. The fungal genus Tolypocladium includes species which are invertebrate pathogens. Because of this, the genus has attracted interest as a potential biological control agent. The efrapeptins are rich in alpha-aminoisobutyric acid and have an unusual carboxy-terminal blocking group which confers upon them potent mitochondrial ATP-ase inhibitory activity. The molecular weights of these compounds are (efrapeptins C,D,E,F,and G); 1606,1620, 1634, 1634, and 1648. The Destruxins are insecticidal Cyclodepsipeptides originally isolated from an entomogenous fungus.

Methods-

A Waters 600MS pump with a 712 Autosampler was used to inject all samples and for all PBI work. A Waters 6000 pump was used for 0.1 M NH4OAc make up flow with the TSP. Finnigan TSP2 and PBI inlets were used on an SSQ710. Destruxin A was used to optimize He flow, source and desolvation temperature with the PBI interface. Optimizations were done for ends of the gradient run and a suitable value chosen. Efrapeptin F and Destruxin A were used to optimize TSP conditions. Destruxins were dissolved in MeOH and Efrapeptins in ACN:H2O at about 0.5-0.05 ug/ul. Methane was used as the CI reagent gas.

Results

The Efrapeptins were not observable by PB-CI but gave molecular ions with TSP. The Destruxins gave molecular ions with both PB-CI and TSP interfaces. The Destruxins produced greater response in negative PB-CI rather than positive. Attempts with TSP to induce fragmentation of Destruxin A by increasing repeller voltage failed as did variation in the vaporizer temperature. The use of the fragmentation seen in the PB-CI spectra of the Destruxins is useful in confirmation of identities in unknowns and the reduced fragmentation observed in negative CI spectra is helpful in improving detection limits. Shown is an ODS separation of a 4 Destruxin mixture using PB-CI detection in positive and negative modes and a representative Efrapeptin F spectra.



Capillary HPLC/MS Analysis of Hydrophobic Peptides from the α_2-Adrenergic Receptor

*Jane J. Z. Huang[1], Lee E. Limbird[2] and Ian A. Blair[1,2]
Departments of Chemistry[1] and Pharmacology[2], Vanderbilt University
Nashville, TN 37232-6602

α_2-Adrenergic receptor are membrane proteins that bind endogenous epinephrine and norepinephrine and are involved in the regulation of a variety of physiological processes. through molecular cloning, the entire DNA sequence of the α_{2A}-subtype of receptor is known. However, the funtionally important amino acid residues for binding of adrenergic ligands to the α_2-receptor have not yet been identified although there is some evidence that the putative forth transmembrane region is involved. Preliminary experiments have been carried out on the analysis of model peptides that span the putative third and fourth transmembrane domain of the receptor. Six peptides were synthesized that could arise from a combination of tryptic and chymotryptic digestion of the receptor: FGKAW, LALDVLF, WSITQAIEY, TPRRIKAIIVTIW, VISAVISF, PPLISIEKK. The peptides were charaterized by a combination of MALDI TOF MS and LSI MS/MS. The LSI MS/MS spectra of the six synthetic peptides indicated a wealth of sequence ions were present. The peptide spanning reisdues 167-175 (PPLISIEKK) showed the entire series of b and y ions, together with selected a, x, and w ions. Capillary HPLC was then explored for separation of the peptides by using Applied Biosystems 140 B dual syringe pump system. The peptides had excellent chromatographic charateristics when analyzed using a reversed-phase C_{18} column (320 µm i.d. x 50 mm, 300 A, 3 µm; LC Packings). A split of approximately 1:30 was made using an Accurate™ (LC Packings) so that the flow through the capillary column was 3.5 µL/min. It was possible to use a 20 µL loop on the injector because the LC gradient system started with a high aqueous content and the peptides simply adsorbed to the front of the column. High sensitivity UV detection was achieved by the use of a Z flow cell and it was possible to routinely detect 40 pmol of each of the peptides. On line LC/MS analysis of these peptides was successfully achieved by interfacing the capillary LC system with a triple quadrupole mass spectrometer equipped with an electrospray ionization (ESI) source.

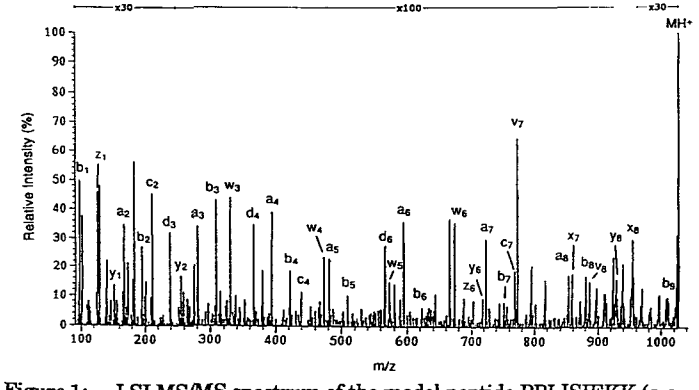


Figure 1: LSI MS/MS spectrum of the model peptide PPLISIEKK (a.a. residue 167-175).

In addition to the model peptides studies, nanomole quantities of α_{2A}-receptor protein were obtained by over-expressing the porcine brain α_2-receptor gene in *LLC.PK1* cells. Purification of the protein was carried out by yohimbine-agarose affinity chromatography. Receptor protein concentration was determined using a binding assay with the α_2-receptor antagonist [^{3}H]-yohimbine. A photoaffinity labelling probe ^{125}I-Rau-AzPEC(17α-hydroxy-20α-yohimbane-16β-[N-(4-azido-3-[^{125}I]-iodo)phenethyl]carboxamide) was bound specifically to the adrenergic binding pocket of the α_2-receptor. The labelled receptor moved as a single band at molecular weight around 66 kDa. on SDS polyacrylamide gel. The radiolabelled tryptic fragments were generated by enzyme proteolysis with immobilized trypsin resin, and separated by 10-21.5% SDS-tricine polyacylamide gel electrophoresis. The fragments were then transferred to nylon membranes and microsequencing was carried out. Unfortunately, the sequence was obscured by autolysis products derived from the trypsin.

Supported by NIH grant ES00267.

Electrospray Mass Spectrometry Analysis of Opioid Peptide Precursors

Lin Yan , Genevieve Fridland, Jih-Lie Tseng and Dominic M. Desiderio
Department of Neurology and Charles B. Stout Neuroscience Mass Spectrometry Laboratory, University of Tennessee, Memphis, 800 Madison Avenue, Memphis, TN 38163

Mass spectrometry (MS) methods are being developed to study the production of several important neuropeptides that derive from the metabolic cascade that occurs in a neuron: DNA → mRNA → various large and intermediate-sized precursors → neuropeptides → inactive metabolites. Those data are needed to clarify the metabolism of neuropeptides that occurs in control and pathophysiological tissues and fluids.

Recently, electrospray ionization (ESI) MS, in combination with gel permeation (GP) chromatography, RIA, HPLC , LSIMS and MS/MS, has been used in this laboratory to characterize intermediate-sized neuropeptide precursor molecules from their respective precursors, preproenkephalin A , which produces methionine enkephalin (ME) and proopiomelanocortin (POMC), which produces β-endorphin (BE)

METHODS

The bovine pituitaries were homogenized at neutral pH with enzyme inhibitors. The homogenate was separated by GP chromatography (G75), and 5% of each aliquot was analyzed for ME-like immunoreactivity (ME-li) following trypsin and CNBr treatments. Those GP peaks that contained immunoreactivity were fractionated further by reverse phase HPLC (RP-HPLC, linear gradient of 15-60% acetonitrile in TEAF buffer pH=3.15 over 90 min.). A portion (5%) of each fraction was used similarly to monitor ME-li after treatment with CNBr and trypsin. Commercial ME RIA kits were used in this study.

Aliquots of all immunoreactive fractions after RP-HPLC were studied by ESIMS on a VG Auto Spec Q (EBE-qQ) mass spectrometer to produce $(M+nH)^{n+}$ ions to determine the molecular weights. The ESI source was operated at 4 kV, and the samples were introduced into the source at a rate of 3 µl/min 1:1 CH_3OH:H_2O containing 1 % CH_3COOH

All remaining immunoreactive fractions were treated with trypsin and were analyzed by ESIMS and LSIMS for detection of $(M+H)^+$ of ME-K, ME-R and LE-K from preproenkephalin A, and BE_{20-24} and BE_{10-19} from POMC.

After separation with HPLC and/or CZE, all tryptic peptides will be sequenced by MS/MS to locate the intermediate-sized precursors within the preproenkephalin $A_{bovine,1-263}$ and the $POMC_{bovine,1-265}$ precursor molecules.

RESULTS AND DISCUSSION

ESIMS analysis of one immunoreactive fraction showed three major components, with M.W. of *ca.* 6550, 8440 and 9855, respectively (Figure 1) Trypsin treatment of this mixture, when analyzed by LSIMS, showed the presence of ions at m/z 558 and 1134 (among others) (Figure 2), which correspond to the tryptic peptides BE $_{20-24}$(=$POMC_{254-258}$) and BE_{10-19}(=$POMC_{244-253}$). The peaks at m/z 558 and 1134 were also present in the FAB spectra from trypsin treatment of endogenous BE (M.W. 3465) in our previous studies.[1] Therefore, that peak may well be an indication that this fraction contains intermediate-sized precursors deriving from POMC. "Intermediate size" means less than the 265 amino acids of POMC but more than the 31 amino acids in BE.

At this stage, we feel that the component with a M.W. of 9,855 is the intemediate-sized precursor of BE. Therefore, this HPLC fraction will be subjected to further HPLC and/or CZE separation, and the putative precursor ion at 9,855 will be studied by trypsin treatment, ESIMS, LSIMS, and MS/MS sequencing of each tryptic fragment. In that manner , we will locate the intemediate-sized precursor of 9,855 mass units within the larger POMC precursor molecule itself. These data will permit the elucidation of the processing of the precursor molecule.

We are also searching for the intemediate-sized precursors of ME by the same method. For example, ESIMS analysis of another active fraction showed the presence of a major peak with a M.W. of *ca.* 15,034 Da, as shown by the series of $(M+nH)^{n+}$ ions 12+-23+ at m/z 1254-655, and a smaller peak (*ca.* 5%) at M.W. *ca.* 14,879 Da. (see Figure 3) Trypsin treatment of this fraction yielded 12 tryptic fragments, which were analyzed by LSIMS and ESIMS and which showed very small peaks at m/z 701 and 729, corresponding to the $(M+H)^+$ ions of ME-K and ME-R.

Finally, this analytical system will be used to analyze human pituitaries (post-mortem controls and post-surgical tumors).

TANDEM MASS SPECTROMETRIC IDENTIFICATION OF A SPECIFIC CYSTEIC ACID RESIDUE IN OXIDIZED LOW DENSITY LIPOPROTEIN.

Odile Burlet, Chao-Yuh Yang and Simon J. Gaskell Department of Medicine, Baylor College of Medicine, Houston, TX 77030.

Low density lipoprotein (LDL), the major carrier of cholesterol in the blood, is composed of a cholesterol ester-rich core which is stabilized by a surface of more polar lipids and protein. The primary sequence of apoprotein B-100, the principal protein constituent of LDL, has been established from the complementary DNA sequence (Chen et al., 1986) and substantially confirmed by classical sequencing methods (Yang et al., 1986). When LDL is subjected to oxidation *in vitro*, significant changes in its biological properties are observed, each of which (if reproduced *in vivo*) may be relevant to the formation of atherosclerotic plaques. Modification of the apoprotein B-100 component, for example, is known to influence receptor uptake. As a first stage in the examination of the undoubtedly complex protein structural changes which accompany oxidation, we have undertaken the detection and location of cysteic acid residues resulting from oxidation of cysteine. LDL was isolated from human plasma, oxidized in the presence of 5 μM copper ions, and delipidated to obtain oxidized apo B-100. The protein was subjected to tryptic hydrolysis and the hydrolysate was fractionated by reverse-phase HPLC; UV-absorbance detection revealed the highly complex profile expected for the digest of a protein of this molecular mass. An aliquot of each of approximately 75 chromatographic fractions was examined by conventional amino acid analysis. Two fractions were identified in which cysteic acid was relatively prominent; these were studied further by FAB MS and tandem MS. Tandem MS with low energy (20-150 eV, laboratory frame of reference) collisional activation was performed using a hybrid instrument of BEqQ configuration. The portions of the hydrolysate used for tandem MS analysis corresponded to approximately 1.5 nmol of the original protein. Each of the tryptic fractions contained multiple components, as judged by FAB MS. Product ion spectra yielded full or partial sequence data; in the latter instances, the partial sequences were sufficient to identify the tryptic fragment of the known apo B-100 sequence. In some instances, data for the native peptide were supplemented by analyses of N-acetylated or esterified derivatives. Table 1 shows the peptides identified in a single HPLC fraction. There are some ambiguities of MS interpretation (such as the inability to distinguish between leucine and isoleucine residues) but for each component the data allow mapping onto the known apo B-100 sequence and the identification of oxidized residues. Figure 1 shows the product ion spectrum for a component yielding an $[M+H]^+$ ion of m/z 1205. The spectrum is readily attributed to the sequence corresponding to residues 4187-4195 in apo B-100 (EELCTMFIR) in which the cysteine and methionine residues are oxidized to cysteic acid and methionine sulfoxide, respectively. (The extraordinary clarity of this product ion spectrum, consisting solely of Y-series ions, is attributed to a gas phase interaction of the cysteic acid and arginine side-chains, promoting a precursor ion population heterogeneous with respect to the site of charge (Burlet et al., 1992)) Coleman et al. (1990) have used a fluorescent probe to identify the cysteine at residue 4190 as one of two cysteines exposed on the LDL surface and therefore potentially available for intermolecular coupling, for example to apolipoprotein (a) via a disulfide bond.

Structural Determination of a Modified Membrane Lipopeptide from *Mycobacterium avium* by Using Electrospray, FAB, and Precursor Ion Scanning.

*Denise K. MacMillan, *Robert C. Murphy, #Hee-Joo Park, and #Patrick J. Brennan
*National Jewish Center for Immunology and Respiratory Medicine, Denver, CO 80206.
#College of Veterinary Medicine and Biomedical Sciences, Fort Collins, CO 80523.

Diseases caused by *Mycobacterium avium*, a commonly occurring pathogen, are increasing in recent years, especially among patients already infected with the AIDs virus. Treatment with cycloserine effectively kills *M. avium* by modifying a cell membrane lipopeptide and interrupting peptidoglycan synthesis. However, side effects such as dizziness, headaches and confusion, as well as depression and psychosis, limit the usefulness of cycloserine in the treatment of *M. avium*-caused illnesses (1).

Our goal is to determine the structures of lipopeptides using a combination of chemical and instrumental techniques. Acid hydrolysis of the lipopeptide generated free fatty and amino acids. Trimethylsilyl derivatives of the amino acids were formed and then analyzed by GC\MS. Those experiments indicated that alanine, phenylalanine, N-methylvaline (NMV), leucine, isoleucine and valine are present. Analysis of the methyl ester derivatives of the fatty acids by using GC\MS suggested that four saturated fatty acids occur for both the untreated and modified lipopeptides: octadecanoic, eicosanoic, docosanoic, and tetracosanoic acids. A minor amount of hexacosanoic acid is also observed. As is true with many other biological materials, the lipopeptide is a complex mixture of related compounds.

Both electrospray ionization with single quadrupole mass analysis and FAB ionization with triple quadrupole mass spectrometry were used for molecular weight determination and gave a molecular ion cluster of seven major species, each differing by 14 mass units (M = 1193, 1207, 1221, 1235, 1249, 1263, 1277 amu). The component fatty acids differ by 28 mass units, however, suggesting that the complexity of the mixture extends beyond differences in the acylated acid to the peptide portion of the molecules.

Interestingly, the lipopeptide is not soluble in water but in chloroform. The hydrophobic nature of this molecule posed problems for sample handling, as the material did not behave as a typical peptide. Perhaps for this reason, product ion scans in the molecular ion region gave little characteristic sequence information.

One procedure found to be quite useful for the study of lipopeptide sequence was precursor ion scanning. Precursor ion experiments performed on the most abundant lipopeptide fragment ions provided significant information regarding the complexity of the mixture. Depicted in Fig. 1 is the precursor ion experiment performed on the ion of *m/z* 555.

The precursor mass spectrum suggests that the ion *m/z 555* is produced from three different pathways. One path involves decomposition of m/z 1236 and suggests the sequence 555-NMV-F-A-NMV-A-F. (NMV could also be one of the isobaric amino acids, I or L, as these cannot be differentiated by low energy MS.) Another path starts with *m/z* 1250 to give the sequence 555-NMV-F-A-NMV-A-F-OCH_3. A portion of the ion of *m/z* 1236 may also be a methyl ester. If the C-terminus were methylated, loss of F and methanol would give the ion of *m/z* 1057, a high mass ion along the second path. The sequence which would generate the ion of *m/z* 555 corresponds to 555-NMV-F-A-V-A-F-OCH_3. The contribution to the abundance of the ion of *m/z* 555 has not yet been determined.

Precursor Ion Scan of m/z 555 from the Cycloserine-Treated Lipopeptide

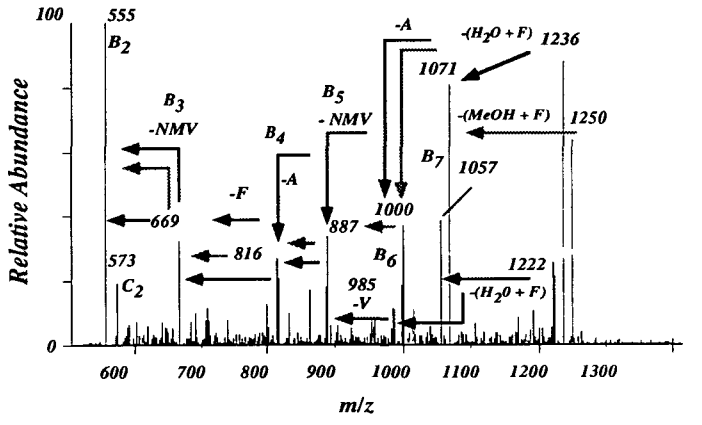

Figure 1: Precursor ion scan of m/z 555 obtained with a tandem quadrupole instrument from the isolated lipopeptide from cycloserine-treated mycobacterium. The ion at m/z 555 corresponds to a dipeptide fragment (F-NMV) acylated with eicosanoic acid.

The ion of *m/z* 1222 can fragment according to the third pathway to give the ion of *m/z* 555. The sequence which fits this route is 555-NMV-F-A-V-A-F. The ion of *m/z* 555 from the treated lipopeptide does not result from decomposition of the ion of *m/z* 1208.

The analysis of this lipopeptide from *Mycobacterium avium* presents unusual analytical challenges not normally faced in elucidating the structure of peptides by mass spectrometry. First of all, the normal methods employed to isolate, purify, and degrade the peptide are not amenable to this chloroform soluble product. Secondly, the mass spectrometry revealed that this product is a complex mixture of peptides differing in amino acid substitutions, methylation sites, as well as fatty acyl molecular species at the amino terminus. While the general motifs in the structure of this lipopeptide are beginning to fall into place, the precise extent of this complex mixture is currently under investigation.

Mass Spectral Analysis of Protein Adducts of the Lipid Peroxidation Product 4-Hydroxy-2-nonenal.

*Bernd A. Bruenner[1], A. Daniel Jones[1], J. Bruce German[2], and T. William Hutchens[3]

[1]Facility for Advanced Instrumentation, [2]Department of Food Science and Technology
University of California, Davis, CA 95616

[3]Department of Pediatrics, Baylor College of Medicine, Houston, TX 77030

Lipid peroxidation in biological systems as a consequence of oxidative stress can result in the formation of toxic and reactive aldehydes, such as 4-hydroxy-2-nonenal (HNE). The double bond of this α,β-unsaturated aldehyde reacts readily with nucleophilic sulphydryl groups by a Michael addition reaction, and the aldehydic moiety can form covalent Schiff base linkages (imines) to amino residues, resulting in loss of protein functionality. The reaction of HNE with macromolecular proteins can form stable, long lived adducts, and their detection may allow for their use as biomarkers of oxidative damage *in vivo*. In order to probe the chemistry of HNE-protein adduct formation, proteins exposed to HNE were characterized by electrospray (ES) mass spectrometry to determine the extent of reaction and to attempt to elucidate the specific sites of modification within the amino acid sequence.

Proteins reacted with HNE *in vitro* included β-Lactoglobulin B (β-LgB), a representative of the lipocalin superfamily of hydrophobic ligand binding proteins, and human hemoglobin A. Several milligrams of each protein were dissolved in 0.01 M HEPES buffer pH 7.4, and HNE was added to the proteins as an 8 mM solution in the same buffer. The final concentration of HNE resulted in a 40-fold molar excess of HNE to hemoglobin and a 60-fold molar excess to β-LgB. Corresponding controls were also prepared using buffer solution only. The mixtures were allowed to react at 37 °C for three hours, and then the samples were extensively dialyzed against 0.01 M ammonium bicarbonate buffer pH 7.4. Heme was removed from the hemoglobin solutions by precipitation in acidic acetone. The proteins were subsequently lyophilized, and taken up in 50/50 MeOH/water + 1% formic acid to give a final concentration of approximately 20 pMol/μl for analysis by ES. Intact proteins were analyzed on a VG/Fisons BioQ mass spectrometer using 50/50 MeOH/water + 1% formic acid as the mobile phase at a flow rate of 5 μl/min using direct flow injection. Capillary voltage was 3.6 keV and source temperature was 60 °C.

The multiple peaks in the mass spectrum of hemoglobin exposed to HNE indicate that a heterogeneous mixture of protein adducts was obtained (Fig.1). Some unmodified α chain was observed, as well as peaks corresponding to addition of from one to four HNE per α chain. Similar results were obtained for the HNE modified β-LgB. A greater number of adducts appear to form in the case of β-LgB, as from three to a maximum of nine HNE appear bound per protein molecule. To confirm that these adducts were not merely the result of hydrophobic binding to the protein, the HNE exposed β-LgB was reacted with dithiothreitol to reduce the two intramolecular disulfide bridges and promote a more "open" structure of the protein and then hexane extracted to remove any HNE which may have been noncovalently bound. No changes in the number of HNE adducts were observed after this treatment.

Sequential peaks in the computer deconvoluted spectra (Fig. 1b) all differ by 156 mass units (within experimental accuracy), the molecular weight of HNE. The

increase of 156 mass units indicates that reaction has occurred via a Michael addition, since the formation of a Schiff base involves loss of water and the corresponding mass shift would be 18 mass units less, or 138, which was not observed. As both proteins have too few free sulphydryl residues to account for the number of Michael adducts, HNE appears to react with amino acids other than cysteine. Lysine and histidine also possess nucleophilic side chains, and Michael addition of HNE to these amino acids may account for the high degree of modification.

These results illustrate the potential of electrospray mass spectrometry for identifying xenobiotic modifications of intact proteins and in relating structural determinants of proteins to their susceptibility towards modification. Future research will involve the analysis of proteolytic digests to determine the specific amino acids of the primary sequence which become modified on exposure to HNE, and to determine if these adducts form *in vivo* under conditions of oxidative stress and can serve as biomarkers of oxidative damage.

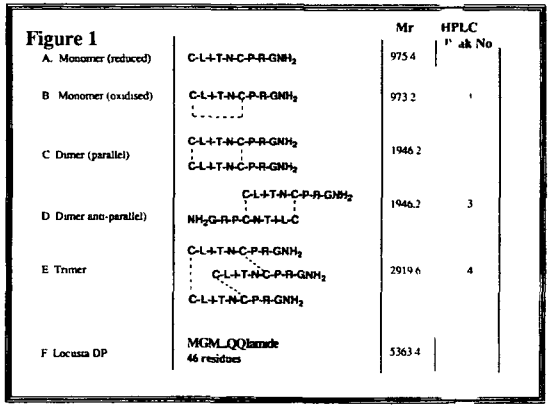
STRUCTURE DETERMINATION BY ESI-MS OF PUTATIVE LOCUST DIURETIC PEPTIDES.

A.I. Mallet, G.M. Coast, R.C. Rayne & J.P. Bacon, St John's Institute of Dermatology, UMDS and Birkbeck College, University of London, Lambeth Palace Road, London SE1 7EH and Sussex Centre for Neuroscience, University of Sussex, BN1 9QG, UK.

INTRODUCTION.

Proux *et al* in 1987 **(1)** extracted two arginine-vasopressin-like peptides from over 50,000 suboesophageal and thoracic ganglia of *Locusta migratoria* . These were sequenced and synthesised and reported to be an amidated nona-peptide and its anti-parallel dimer. These were named F1 and F2 **(Figure 1**, A & D). This peptide was reported to have diuretic activity in the insect. Recently a second active diuretic hormone has been identified in the Locust and this is related to corticotropin releasing factor **(Figure 1**, F). Difficulties in obtaining appropriate biological activity from arginine-vasopressin nona-peptide preparations prompted us to examine the activities of a number of defined polymeric peptide structures.



METHODS.

The reduced peptide CLITNCPRG-NH2 was synthesised using fMOC chemistry (Alta Bioscience, Birmingham, UK). The structure was confirmed by sequencing and M_r was determined by electrospray. The oxidised peptides were obtained by glutathione-based oxido-shuffling oxidation system **(2)**. The mixture of products was separated on HPLC (Aquapore C8 RP300 column with a propan-2-ol:0.1% aq. TFA gradient solvent system.

Dimer proteolysis was perfomed with Thermolysin (0.1 mg) in 10 ml of 100 mmol l-1 TES at pH 7.2, 30°C for 2h. Products were purified by HPLC as above.

Electrospray mass spectra were obtained from a VG Biotech source on a VG Masslab Trio-2 mass spectrometer (Fisons Instruments, UK). Peptides were dissolved and run in 50:50:1 water:acetonitrile:acetic acid solvent at 5ml min^{-1}. 1 to 10 pmole were injected.

RESULTS 1.

The electrospray of the reduced monomer peptide confirmed the successful synthesis of this starting product. The oxidation step should lead to the formation of at least three products, an internal bridged monomer, two dimers one parallel and the other anti-parallel **(Figure** 1 B, C and D.). The HPLC trace showed four products and an absence of starting reduced monomer. The electrospray spectra of material from HPLC peaks 1,2,3 and 4 gave Mr values corresponding

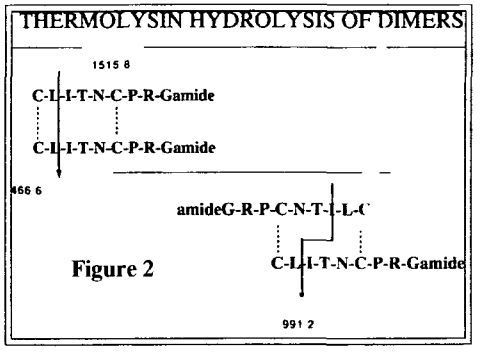


Figure 2

to the oxidised monomer from peak 1 and two identical values for the dimers in peaks 2 and 3. The distinction between the parallel and anti-parallel isomers required further analysis.

Thermolysin proteolysis takes place between the Leu and Ile residues. In the case of the parallel dimer this will lead to two products of M_r 466.6 and 1515.8; in contrast the anti-parallel dimer should only give a single product of M_r 991.2 **(Figure 2)**. The spectra of the products isolated from HPLC confirmed the anti-parallel nature of the material in the original HPLC peak 2.

It was possible to confirm this identification by careful examination of the electrospray spectra of material from peaks 2 and 3 taken at increased 'cone voltage'. The fragment ion patterns were clearly different ions at 701.9 and 758.5 from peak 3 could only have arisen from fragmentation of a parallel dimer. These spectra are shown in **Figure 3**. Peak 4 from the HPLC trace showed a M_r corresponding to the cyclic trimer **(Figure 1** E). All these products were found to be inactive in the relevant biological assay.

CONCLUSIONS.

We have produced unequivocal evidence for the structures of the oxidised products from the nine amino acid peptide. The combination of a number of biological and biochemical techniques together with electrospray mass spectrometry has been essential to the success of this work.

Further studies are now in progress to demonstrate the production of the Locusta -DP peptide from appropriate tissues under the correct biological regimes.

INTRODUCTION

The spider silk dragline (major ampullate) collected from *Nephilia clavipes* has been a subject of interest in materials research, due to its enormous strength and elasticity. However, little is definitively known about its primary structure and molecular weight. Since dragline is insoluble in almost all solvents, the commonly used enzymatic digest procedures are not applicable for fragmenting the protein. Therefore, we developed a chemical method to digest this protein using N-bromosuccinimide (NBS) in formic acid, which cleaves primarily on the C-terminal side of Tyr[1]. Following the digest, the peptide mixture was characterized by SDS-PAGE, amino acid analysis, HPLC and MS. Also, standard peptides were subjected to the same digest procedure and examined by CFFAB MS in order to identify the modification on Tyr by the NBS digest.

EXPERIMENTAL

Materials: Dragline silk was collected from the abdomens of the live spiders. NBS was purchased from Aldrich (Milwaukee, WI).

Digest procedure: The silk was first solubilized in a minimum volume of formic acid, followed by the addition of ~10x excess of NBS (by weight). The mixture was incubated on ice for 1.5 hours, then another 1.5 hours at room temperature. Next, equal volume of acetone was added to stop the reaction. The solution was then spun at 14000 rpm for 1 hour in a microcentrifuge, after which a white pellet was observed. The supernatant was disgarded and the pellet was washed twice with acetone. At the end, the pellet material was dried in a Speed-Vac and kept frozen until further use. The same procedure was also applied to the standard peptides examined in this work.

HPLC: A Waters 625 LC system equipped with a 991 photodiode array detector and a WISP 722 autoinjector was used in this work. A C_4 column (4mmx25mm) with 5 μm particles and 300Å pore size (YMC, Inc., Wilmington, NC) was used. The gradient was 0-35% B in 88 minutes followed by a 5-minute hold at 35% B (A=H_2O and B=ACN, both containing 0.05% TFA). Flow rate was 1.0mL/min. Sample injections were 200μL, each containing 1 to 2mg of the original protein material in solvent A. Fractions were collected manually.

CFFAB MS: All data were obtained on a VG Quattro triple quadrupole mass spectrometer (VG Biotech, UK) equipped with a CsI gun. Mass range scanned was m/z 100-2300 in 8 seconds.

RESULTS

1. SDS-PAGE on the digest mixture revealed that most of the peptides generated appeared to be in the high mass range (40kDa and above), and that they were generated by reaction with NBS, not hydrolysis by formic acid.
2. Two "silk-like" standard peptides (GLY and GAGAGSGAGAGY) were subjected to the NBS digest procedure and were examined by CFFAB MS and MS/MS. The MS and CID data of the peptide GLY taken before and after the digest are shown in Figures 1 and 2. A mass shift of +158 in the MH^+ ion can be seen in the MS spectra. CID spectra clearly show the modification

to be on the C-terminal side of Tyr, judging from a shift by +158 in only the y ions. The modification is thus similar to that described in the literature[2,3].

3. All HPLC fractions of the digest were screened by CF FAB, using a variety of matrix solutions (glycerol, NBA, thioglycerol, magic bullet, etc.). However, it appeared that none of the fractions contained any peptides in the mass range examined.

CONCLUSIONS

At this stage of our work, we have:

- developed a chemical digest procedure suitable for the dragline silk;
- established the chromatographic conditions for fractionating the digest mixture;
- studied the NBS reaction mechanism and product by MS and MS/MS, and identified the modified y ion series which will aid in future CID data interpretation.

Future work to be carried out includes:

- examination of the present digest fractions by electrospray ionization, and
- increase in incubation time and/or amount of NBS for the digest in order to generate smaller peptides more suitable for examination by FABMS.

CHARTING OF PITUITARY GLYCOPROTEINS BY CAPILLARY LIQUID CHROMATOGRAPHY - ELECTROSPRAY MASS SPECTROMETRY.

G. J. Feistner[1], Jens Andersen[2], Ole Vorm[2], Terry D. Lee[1], Peter Roepstorff[2]

[1]Division of Immunology, Beckman Research Institute of the City of Hope, Duarte, CA 91010
[2]Department of Molecular Biology, University of Odense, DK-5230 Odense M, Denmark

Previously, we have successfully charted bovine and rat pituitary hormones as large as the neurophysins (ca. 10 kDa) by plasma desorption and fast atom bombardment mass spectrometry and as large as rat prolactin (22,5 kDa) by electrospray mass spectrometry. We suggested that on-line capillary liquid chromatography - electrospray mass spectrometry may be the method of choice for the qualitative and quantitative determination of entire pituitary hormone profiles [1]. In pursuing this goal, we found that many observed peptides and small proteins could not be readily identified, possibly indicating hitherto unknown neuropeptides. On the other hand, we were not able to identify the physiologically important anterior pituitary glycoproteins, follicle-stimulating hormone (FSH), thyroid-stimulating hormone (TSH), and luteinizing hormone (LH). This did not necessarily mean that the glycoproteins were not amenable to electrospray mass spectrometry because their carbohydrate structures are not yet known and their molecular masses could not be calculated.

In order to address this issue, pituitary glycoprotein standards were obtained from the National Institutes of Health. Initial ES investigations on the α-chain of TSH indicated that the pituitary glycoproteins may be too heterogeneous to be amenable to ES-MS, at least at the low mass resolution typically employed in our charting studies. MALDI spectra revealed average molecular masses of 14.5 kDa (α-FSH), 14.4 kDa (α-LH), and 14.7 kDa (β-TSH), consistent with the reported corresponding DNA sequences plus allowances for glycosylation. As judged by the MALDI spectra as well as inferred from the existence of only one potential N-glycosylation site (versus 2 for the other glycoproteins), β-TSH was the least heterogeneous of the glycoproteins and was thus selected for further off-line ES investigations. These revealed eight major species with molecular masses of 14.5 to 14.8 kDa, which could be separated into two sets of four by RP-HPLC (14542, 14643, 14712, 14815, and 14557, 14660, 14727, 14830 u) (Fig. 1). The same species could be identified by on-line capillary LC-ES-MS. Under RP-HPLC conditions, β-TSH was less protonated than in the H_2O-MeOH-AcOH solvent used for the batch infusions, requiring that the extended mass range of 700-3,000 u had to be scanned for optimum sensitivity (Fig. 2).

Unfortunately, we were not able to confirm the above components as natural products by retroactive screening of our rat pituitary peptide charts. Again, this may be due to insufficient chromatographic resolution and molecular ion crowding that could not be resolved under our low resolution ES-MS conditions. On the other hand, the observed molecular masses of the standard are smaller than the ones expected for the natural product. The two major carbohydrate moieties of *human* β-TSH have reported masses of 1854 (24%) and 2024 u (18%), respectively, with the mass difference of 170 u corresponding to partial terminal sialylation versus sulfation. This diagnostic Δm is observed four times between the rat β-TSH components (14542/14712, 14643/14815, 14557/14727, 14660/14830), suggesting that the carbohydrate moieties in rat and man may be identical. However, addition of these carbohydrate masses to the protein molecular mass of rat β-TSH (13,454 Da) leads to expected molecular masses of 15,308 and 15,478, which are considerably larger than the

observed values. To investigate whether the difference was due to N-terminal truncation, Edman-type sequence analysis on the rat β-TSH standard was performed. Two sequences could be read, one representing the expected N-terminal sequence while the other corresponded to the internal sequence (K)YALSQD.... The latter suggested that some trypsin-like cleavage had occurred but could not explain the observed molecular masses. Reduction-pyridylethylation of the rat β-TSH standard followed by deglycosylation with N-glycosidase F, unexpectedly did not give rise a single protein of mass 14,728 u, but to two small proteins of molecular masses 8131 and 8230. Interestingly, the mass difference between these two products (99 u) is close to the second characteristic mass difference of 101/103 u (give or take a few reduction equivalents) that is observed between the components of the rat β-TSH standard (14542/14643, 14712/14815, 14557/14660, and 14727/14830 u). Further studies, including ES peptide mapping, will be needed to fully characterize the β-TSH standard.

With regard to the feasibility to extend our ES peptide charting to the pituitary glycoproteins, it is probably fair to say that the glycoproteins do not present special desorption/ionization problems but that their successful analysis depends heavily on sufficient chromatographic and mass spectrometric resolution.

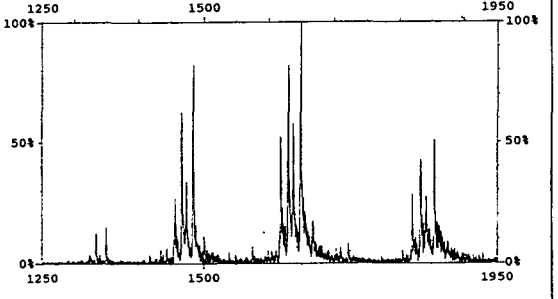

Fig. 1 ES-MS of subset 2 of rat β-TSH acquired on a Vestec instrument; batch infusion of an estimated 10-20 *pmol/μl* at a rate of 0.3 μL/min (1/5 of the corresponding RP-HPLC fraction obtained by chromatography of 600 pmol β-TSH standard, dissolved in 4 μl H_2O: MeOH:AcOH (50:50:1); data averaged over ca. 10 min.

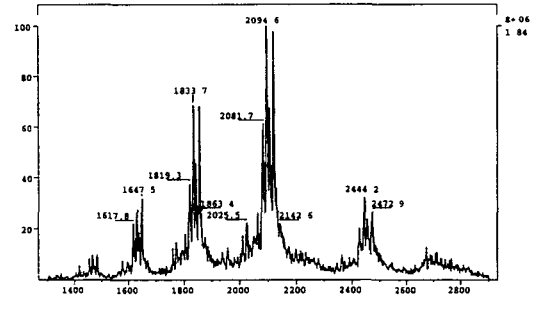

Fig. 2 ES-MS of subset 2 of rat β-TSH (NIH standard) acquired on-line on a capillary-C_{18}-RP-HPLC-Finnigan TSQ700 ES-MS system; 150 pmol rat β-TSH injected, 1-50% CH_3CN in 0.1% TFA/60 *min* at 2 *μl/min*; data averaged over the LC peak (20 scans, total of 1.5 minutes).

Analysis of Abnormal Glycoproteins of Patients with Carbohydrate Deficient Glycoprotein Syndrome

*Michiko Kanai[1], Katsuko Yamashita[2], Hiroko Ideo[2], Takashi Ohkura[2] and Keiko Fukushima[2]

1 Finnigan MAT Instruments, Inc., 2-5-8 Hatsudai, Shibuya-ku, Tokyo, Japan
2 Dept. of Biochemistry, Sasaki Institute, 2-2 Kanda-Surugadai, Chiyoda- ku, Tokyo, Japan

We applied ESI/MS for the structural characterization of abnormal serum transferrins in patients with carbohydrate deficient glycoprotein (CDG) syndrome.
Transferrin has two potential sites for asparagin-N-liked glycosylation. Transferrin from healthy control mainly has one isoform that has two N-linked disialylated biantennary sugar chains, thus it is tetrasialylated (S4). On the other hand, transferrin from CDG syndrome patients has 3 major isoforms. Yamashita et. al. determined that one of the isoforms has same structure as the major transferrin isoform from healthy control (S4) and abnormal species are missing either or both of two N-linked disialylated biantennary sugar chains using SDS-PAGE, chromatofocusing, lectin affinity chromatography and structural studies of sugar chains linked to these transferrin molecules (1). Thus the abnormal species are disialylated (S2) and desialylated (S0).
Our goals in this study are to determine the molecular weights of transferrin isoforms by ESI/MS providing the direct evidence of the above conclusion, and to determine if the non-glycosylation site in transferrin isoform S2 is <u>not</u> specific by HPLC-ESI/MS analyses of enzymatic digests of transferrin isoforms.

<u>Experimental</u> A TSQ 700 triple quadrupole mass spectrometer (Finnigan MAT, CA) equipped with an ESI source was used. For molecular weight determination, transferrins were dissolved in 0.1% TFA/water at a concentration of ca. 5 pmol/µl, introduced to the ESI source at a flow rate of 1µl/min. Transferrin isoforms S4 and S2 were reduced and pyridylethylated and then digested with trypsin. The tryptic peptides were subjected to the HPLC-ESI/MS analyses. A 4.0 mm x 25 cm, ODS column was used with the 1%/min gradient of 0.1% TFA/water/MeCN at a flow rate of 500 µl/min. Purification of serum transferrin and separation of transferrin isoforms were described in the reference (1).

<u>Results and discussion</u> The ESI mass spectrum of transferrin from a healthy control showed single distribution of multiply charged molecular ions (Fig. 1a). On the other hand, the ESI mass spectrum of transferrin from a CDG syndrome patient showed at least two molecular species (Fig. 1b), one was same as normal and the other was smaller than the normal transferrin. The difference between the molecular weights of two species was just the size of a disialylated biantennary sugar chain, 2206 Da. But the presence of transferrin isoform S0 was not clear in this spectrum. Then we analyzed each isoform separated by chromatofocusing. The molecular weights calculated from the ESI mass spectra of transferrin isoforms S4, S2 and S0 were 79 570 ± 5 Da, 77 364 ± 6 Da and 75 157 ± 6 Da (data not shown). These are very close to the theoretical molecular weights of transferrin polypeptide with 2, 1 and 0 disialylated biantennary sugar chains, respectively. These results consisted with the conclusion of the previous study (1). The proposed structures of transferrin isoforms are shown in Fig. 2.

There are two potential N-linked glycosylation sites in transferrin, so one of them is not glycosylated in transferrin isoform S2. Since desialylated transferrin isoform S0 was detected from the CDG syndrome patients, we supposed that the non-glycosylation occurs randomly at each potential glycosylation site in S2. Analyses of tryptic tansferrin isoforms S4 and S2 were performed by HPLC-ESI/MS. The tryptic fragments containing the potential N-linked glycosylation site are T41 and T67. In the peptide map of S2, we analyzed both T41 and T67 peptides with and without sugar chain (Fig. 3). The result demonstrated that non-glycosylation site in transferrin isoform S2 is not specific.
Accordingly, CDG syndrome can be concluded to be an asparagin-N-linked oligosaccharide transfer deficiency, although the primary deficient enzyme has not yet been determined.

<u>Acknowledgments</u> We would like to acknowledge to Dr. Seta and his colleagues at Tokyo Metropolitan University for valuable technical supports and discussions.

Structure of the Disialylated Transferrin Specifically Found in Carbohydrate-deficient Glycoprotein Syndrome

Y. Wada
Research Institute, Osaka Medical Center for Maternal and Child Health.
840 Murodo-cho, Izumi, Osaka 590-02, Japan

INTRODUCTION

Carbohydrate-deficient glycoprotein (CDG) syndrome[1)] is a newly recognized disease with nervous system involvement. The most specific diagnostic marker for this hereditary disease is the increase of an isoform of transferrin (TF) called "disialylated TF"[#] in serum; TF is mostly tetrasialylated in normal subjects. Since similar changes have been demonstrated in many other serum proteins, a structural defect in the N-linked sugar chains of secretory proteins containing sialic acid is suspected in the CDG syndrome.

I characterize here the structure of "disialylated TF" by mass spectrometry and give an important clue to the etiology of the CDG syndrome.

MATERIALS AND METHODS

Profile of Patients: Two unrelated patients were examined. Patient-1 was a severe case. She was 5-year old and have typical manifestations of the CDG syndrome including ataxia and developmental retardation. Patient-2, one of the affected brothers from consanguineous parents was a mild case.

Biochemical Analyses: Following analyses were carried out.

1. Isoelectric focusing followed by western blotting of TF.
2. Purification of TF by affinity chromatography.
3. Hydrazinolysis and reversed phase HPLC of pyridylaminated sugar chains.

Mass Spectrometry of Transferrin:

Electrospray Ionization (ESI) MS: The author reported the ESI mass spectra of human transferrin before[2)]. A magnetic sector mass spectrometer SX102A (JEOL, Japan) equipped with an electrospray ion source (Analytica of Branford, USA) was used. Samples were dissolved in a solution of 49/49/2 methanol/H_2O/acetic acid (v/v/v) at about 50 (20-100) pmol/µl, introduced into ion source at a flow rate of 0.7 µl/min and electrosprayed. Operating conditions were as follows: accelerating voltage was 5 kV, a range from m/z 3,300 to m/z 4,000 was scanned in two minutes and the mass data from ten scans were accumulated. Molecular weight is expressed by chemical mass.

Matrix-assisted Laser Desorption (MALDI) MS: MALDI-MS was carried out by JMS-LDI1700. Sample matrix was sinapinic acid.

RESULTS AND DISCUSSION

Isoelectric focusing of TF identified the increase of "disialylated TF" in both patients (data not shown). The content was larger in patient-1 than in patient-2. "Asialo-TF" was also detected in the patient-1. The HPLC profiles of sugar chains from TFs of patients were not different from those from normal subjects (data not shown).

[#]The term "disialylated" is a classificatory name of an isoform of TF separated by electrophoresis, not indicating true structure.

Molecular weights of the TFs in a complex mixture of normal and defective forms were then measured by ESI-MS. The mass spectrum of a normal healthy control showed multiply charged ions of a single molecular species. On the other hand, the mass spectra of the TFs from the patients revealed both the normal species and a smaller one. In both patients, the relative intensities of the small and the normal ion species correlated with the relative contents of disialo- and tetrasialoTF observed in IEF. The difference between the molecular weights of the normal and abnormal components was calculated to be 2,200 ± 60 Da for patient-1 and 2,200 ± 20 Da for patient-2, and was almost the same as the theoretical molecular weight, 2,206 Da, of disialylated biantennary sugar chain. We therefore conclude that the "disialylated TF" in CDG syndrome is missing a sugar chain at either of two glycosylation sites of the TF molecule[3)]. "Asialo-TF" was identified in patient-1 by MALDI-MS.

Our result signals a new direction for the etiological approach to this disease. The most probable metabolic defect of this disease would be in the early steps of protein glycosylation, from the synthesis of precursor sugar chain in the endoplasmic reticulum to the transfer of the synthesized chain to the nascent polypeptides. Further understanding of these mechanisms will uncover the biochemical cause and pathogenesis of this multisystemic syndrome.

HPLC/ESI/MS of Tryptic Digests on Modified Cytochromes

*Baiwei Lin[a], Joe Sears[b], Jan Sunner[b], Al Jesaitis[c], and Mark Quinn[c],
[a]Lederle Laboratories, American Cyanamid, Pearl River, NY 10965, [b]Department of Chemistry and
[c]Department of Microbiology, Montana State University, Bozeman, MT 59717

INTRODUCTION

A combination of HPLC with electrospray has been used to identify sites of covalent modification in important proteins of the human neutrophil. One such protein is the cytochrome b. This is the electron transferase that delivers energetic electrons to reduce molecular oxygen to superoxide anion. It was recently shown that cytochrome b contains at least 2 hemes. The placement of the hemes is unknown. However, such structural information can be obtained by labeling the protein with fluorescent probes and studying the fluorescent quenching as a function of probe position along the protein chain.

In this work, the experimental protocol for the determination of the labeling site using HPLC/ESI/MS was developed. Horse heart cytochrome c was used as a model protein to develop the experimental procedure for tryptic mapping. Subsequently, the sites of modification in a labeled cytochrome c was determined by the same procedure.

EXPERIMENTAL

The tryptic digestion of unmodified as well as modified cytochrome c was carried out at a pH of 8 and an enzyme-to-substrate ratio of 1:50 (w/w). The digest was performed at 37°C for 16 hours. The HPLC system used consisted of a Gilson liquid chromatograph and a Spectra-Physics UV-detector. Elution was accomplished using a C18 reverse-phase column at a flow rate of 1 ml/min. In a gradient elution, solvent A was 1% HCl in distilled water and the concentration of B (1% HCl in acetonitrile) was increased from 6 to 60% in 30 minutes. ESI/MS was performed in a transport capillary ion source interfaced to VG-TRIO2 quadruple mass spectrometer.

RESULTS AND DISCUSSIONS

(1) Intact Labeled Cytochrome c. The labeled cytochrome c had two series peaks in ESI/MS spectrum. The molecular weight obtained from one series was that of cytochrome c, 12,361 Da. Another series yielded the molecular weight of labeled cytochrome c, 12,860 Da. The mass difference was 499 Da. In this particular sample modification, a Cascade Blue derivative was covalently bonded to the protein. Its molecular weight was calculated to be ca 500 Da. This matches the mass difference between the labeled and the unlabeled cytochrome c.

(2) Tryptic Mappping of Cytochrome c. In the process of enzyme digestion, trypsin breaks the polypeptide chain after the lysine and arginine amino acids. The peptide fragments produced in this digest and their corresponding labels are listed in Table 1, together with their calculated masses. The HPLC of tryptic digests of unlabeled cytochrome c is shown in Figure 1. Fraction numbers are indicated in the same figure. Electrospray mass spectra of each fraction was then obtained and some of them are presented in Figure 2.

Inspection of the ESI spectra in Figure 2 showed that all the expected fragments (except one) were indeed observed, within 1-2 Da of the expected mass. The identification was facilitated by the fact that each peptide has a distinct mass. Results are summarized in Table 1. All those fragments that were observed have "yes" and those that were missing have "no".

(3) Labeling Site Identification. HPLC separation of the tryptic digest of labeled cytochrome c (Figure 3) and mass determination by ESI/MS (Figure 4) was performed using the same experimental

conditions as did in the unlabeled protein. In general, the ions obtained from labeled cytochrome c were very similar to those obtained from unlabeled protein. There was a difference, however, for the peptide fragment T6(His26-Lys27). As shown in Figure 2(E9), the unlabeled protein gave an intense peak at 284 amu due to fragment T6. However, this peak was not detected in any of the fractions from the labeled protein. Instead, a peak at $m/z=392$ amu was observed in fractions L10-L12. This is the expected mass of the doubly protonated ion of His26-Lys27 bounded to the label compound.

CONCLUSIONS

Inspection of the ESI spectra showed that all the expected peptides of unlabeled cytochrome (except one) were observed. The peak observed at 392 is likely due to the His26-Lys27 tryptic fragment, labeled with the Cascade Blue derivative, and doubly protonated. ESI/MS was successfully used to determine the site of covalent modification of a cytochrome by a fluorophore label.

Characterization of Cytochrome $P450_{lin}$ by Mass Spectrometry

Rong Huang, Dipak K. Ghosh, Furong Sun, Anthony G. Thompson, Irwin C. Gunsalus, and Kenneth L. Rinehart, School of Chemical Sciences, University of Illinois, Urbana, IL 61801

Cytochrome P450 enzymes play important roles in the oxidative metabolism of a variety of biologically significant substrates.[1-3] A newly isolated species, $P450_{lin}$(MW=ca. 45kDa), that utilizes the acylic terpene linalool has been sequenced recently by the cDNA technique[4] and mass spectrometry has been used to confirm, or modify if necessary, the primary sequence.

The protein was digested with trypsin or *S. aureus*(Strain V8) and partially separated by HPLC. The HPLC fractions were then analyzed by FABMS. High resolution(HR) and FABMS/CID/MS data were also collected whenever possible to help confirm or assign the sequences of the peptides. The tryptic digest revealed about 83% of amino acids predicted by cDNA study, mostly before position 375. In the meantime, three peptides, with protonated MWs of *m/z* 995, 893, 866 were observed which could not be fitted into the proposed sequence. FABMS/MS spectra and HR data showed the sequences for these peptides as NLNVVLVPK(*m/z* 995), SNFLDGL(I)K(*m/z* 893) and (pyroglutamyl)-RPELLK(*m/z* 866), respectively. The *m/z* 866 peak corresponded to positions 273-279 in the proposed sequence, with glutamine being cyclized to pyroglutamic acid. The corresponding uncyclized peptide ([M+H] = 883 m/z) could also be observed in the same tryptic digest. There were no corresponding positions for *m/z* 995 and 893 peptides. The *S. aureus*(Strain V8) digest revealed about 75% of the proposed amino acids and provided very good overlapping with the tryptic digest, helping the alignment of these peptides. Still no peptides beyond position 375 were observed to confirm the sequence. These results indicated possible mistakes in the sequence proposed by the cDNA study.

The doubt became certain when the MW of intact $P450_{lin}$ was determined by electrospray(ESI) mass spectrometry. As shown in Table 1, the measured MWs were quite consistent from three different sources. The average MW measured was about 1650 Da higher than the calculated average MW. Reexamination of the nucleotide sequencing gel found a guanine that was missed. The omission misidentified an early stop codon. Its insertion corrected the sequence starting at position 378 and extended the protein sequence from 395 residues to 406 residues. The *m/z* 995 peptide was found to be the C-terminus(398-406) in the corrected sequence. The peptide with *m/z* 893 corresponded to positions 390-397 with N^{394} being hydrolyzed to D. The unhydrolyzed peptide ([M+H] = 892 m/z) did not appear under the tryptic digest conditions, but it was observed accidentally in the *S. aureus*(Strain V8) digest because of trypsin contamination in the V8 enzyme. Other peptides in the corrected sequence were also found later and the peptide mapping was completed except for one R at position 387, a mono-peptide in the tryptic digest.

After correction, the calculated average MW was about 160 Da lower than the measured value(Table 1). Also, it was noticed that the ESI spectra generally gave two ion series. The deconvoluted spectra showed two components differing by about 80 Da(Fig.1 & Table 1). The difference coincides with the mass of HPO_3 and SO_3, suggesting possible phosphorylation or sulfation of the protein. Considering the 160 Da difference between the measured and calculated MWs, there are possibly two modifications involved. To the best of our knowledge this is the first evidence of phosphorylation or sulfation to any P450 enzyme. Similar spectra were also obtained on $P450_{cam}$ (Fig.2), indicating a possible common modification among P450 enzymes.

Intact $P450_{lin}$ was also analyzed by MALDI/TOF/MS(Fig. 3). Due to the relatively poor resolution of the TOF analyzer, MALDI failed to identify the two components 80 Da apart. Its mass accuracy with external standards was also not quite as good as ESI, but its sensitivity under normal operating conditions was a little higher(1-10 pmol for MALDI, 100-200 pmol for ESI) and showed capability for mixture analysis(Fig. 4). In Figure 3, an impurity peak was detected along with singly and doubly charged $P450_{lin}$ molecular ions.

Both ESI and MALDI have been used to analyze tryptic digest mixtures. Coupled with HPLC, ESI revealed some peptides that were not observed in normal FABMS, showing the advantage of higher sensitivity, but it did not determine some of the peptides that were detected by FAB due to the difficulties in interpreting some of the peaks. Figure 4 shows the MALDI spectrum of the tryptic digest mixture of $P450_{lin}$. Relatively large peptides were detected without any separation. With internal standards at both the low and high mass ends of the peptides, the accuracy in the spectrum was better

than 1 Da. The resolution in the spectrum was about 700. FABMS is generally less sensitive compared with the other two techniques, but because of its ability to yield HR data and MS/CID/MS spectra on magnetic sector machines, it is still an indispensable tool. For instance, the tryptic peptides with *m/z* 892.49 and *m/z* 893.47 would not have been differentiated by ESI data, which gave *m/z* 892.85±0.4 .

In conclusion, the cDNA-derived amino acid sequence of $P450_{lin}$ was corrected by this MS study. MS data showed evidence of phosphorylation or sulfation of $P450_{lin}$ and $P450_{cam}$, the first indication of this type of modification of any P450 enzyme and implying a possible common modification within the P450 superfamily. Finally, deamidation during hydrolysis may cause a potential problem of misidentification of Q and N. Thus, proper control of the reaction conditions is important.

Previously, we and others found a novel posttranslational modification in the α subunit of retinal heterotrimeric G-protein transducin (Tα) [1-3] and recoverin [2,4] with heterogeneous fatty acids. They were modified at the N-termini with four kinds of fatty acids consisting of laurate (C12:0), myristate (C14:0) and unsaturated C14:1 and C14:2. We further suggested that these lipid modifications might mediate formation of the Tα/T$\beta\gamma$ complex. In the present study, we verified the structures of these N-terminal fatty acids of Tα by negative-ion FAB tandem mass spectrometry and chemical synthesis.

Tα was treated with *Achromobacter lyticus* protease I (API) as described previously [1]. In order to get simple fragmentation pattern and to achieve efficient fragmentation on the lipid moieties in MS/MS analysis, the N-terminal API peptides (Gly-Ala-Gly-Ala-Ser-Ala-Glu-Glu-Lys, 0.1~0.5 nmol) isolated by reversed-phase HPLC were completely digested with carboxypeptidase Y to yield the acyl glycine with four kinds of fatty acids. Negative-ion FAB mass spectra of the digests showed the ion signals at m/z=256.2, 284.2, 282.2, and 280.2, which agreed well with the theoretical masses calculated for lauroyl, myristoyl, C14:1-, and C14:2-glycine, respectively. Their negative-ion FAB tandem mass spectra gave highly specific fragmentations [5]. Figure 1 shows the MS/MS spectra of C14:0 (myristoyl), C14:1- and C14:2-Gly. The patterns of the intense peaks marked by asterisks, which correspond to ions arising from cleavage of the carbon-carbon bond allylic to the double bond together with dramatically less intense intervening signals, made it possible to assign the locations of the double bonds, Δ^5 and Δ^5,Δ^8 in C14:1 and C14:2, respectively. Finally, we synthesized the N-terminal nonapeptides modified at the α-amino group with the four kinds of fatty acids (laurate, myristate, *cis*-Δ^5-C14:1, and *cis,cis*-Δ^5,Δ^8-C14:2) and compared them with the N-terminal API fragments of Tα by reversed-phase HPLC. These synthetic peptides were completely identical with the API fragments.

The above results demonstrated the structures of the heterogeneous fatty acids linked to the N-terminus of Tα to be laurate, myristate, *cis*-Δ^5-C14:1 and *cis,cis*-Δ^5,Δ^8-C14:2. It will be interesting to see the role of such heterogeneous lipid modification at the

N-terminus of Tα in a signal transduction process.

Characterization of Peptides Extracted from the Human Class I MHC Molecule, HLA-B7. *Wanda M. Bodnar, Jeffrey Shabanowitz, Donald F. Hunt, Eric L. Huczko, David Benjamin, and Victor H. Engelhard, Departments of Chemistry and Microbiology, Univ. of Virginia, Charlottesville, VA 22901.

Microcapillary HPLC electrospray ionization tandem mass spectrometry has been used to characterize the primary structures of peptides associated with the human class I molecule, HLA-B7 (1). Class I molecules of the major histocompatibility complex (MHC) are a set of glycoproteins which present self and foreign peptides to cytotoxic T lymphocytes (CTLs) of the immune system. It is believed that a small fraction of nascent proteins, both self and viral, are degraded in the cytosol by proteosomes, and that the short peptides which are produced are transported to the endoplasmic reticulum where they bind to newly synthesized class I MHC molecules. The MHC-peptide complex is subsequently transported to the cell surface for examination by CTLs (2). Should a CTL receptor recognize a peptide derived from a foreign protein, the CTL becomes activated, multiplies, and secretes a mixture of enzymes which lyse the infected cell. If only self peptides derived from normal cellular proteins are presented on the cell surface, the CTLs remain inactive and continue to screen other cells nearby.

Although over one hundred structurally distinct class I MHC molecules have been identified in humans, only as many as six different forms will be expressed by the cells of any one individual. Given the limited number of MHC variants per cell, and the fact that a cell synthesizes and degrades thousands of proteins, it follows that each MHC molecule must be capable of binding and presenting a wide variety of structurally distinct peptides. Sequence analysis of the complex mixtures of peptides presented to the immune system by different MHC molecules will lead to a better understanding of how the immune system responds to the presence of foreign proteins. And ultimately, more detailed information about the peptide binding specificities of MHC molecules will be useful in the design of vaccines and therapeutic agents against numerous disease states. This task is challenging however, since each peptide in the complex mixture will only be present at a level of 10 to 1,000 fmol per 10^8 cells.

The development of microcapillary HPLC electrospray ionization tandem mass spectrometry has made possible the sequence analysis of individual peptides present at very low levels within complex mixtures (3). Mass spectrometric analysis of extracts from 10^8 cells bearing the HLA-B7 molecule has revealed that at least 2,000 naturally processed peptides are bound by this MHC molecule. The complete sequences for 18 of these peptides have been determined by collision activated dissociation experiments and the results are presented in table 1. The majority of peptides are nine residues in length and share a consensus motif dominated by Pro in position 2 (P2) and Leu or a small hydrophobic residue at P9. Homology searches in a protein database revealed 7 matches within 6 different human proteins. Synthetic peptides with sequences corresponding to those of the 18 endogenous peptides were tested for association with HLA-B7 in a qualitative binding assay. All were found to increase the expression of a stable conformation of the HLA-B7 molecule on the surface of T2 cells. The sequences obtained by mass spectrometric analysis were used in conjunction with computer modeling to make testable predictions about the binding requirements of HLA-B7. A structure for this molecule with bound peptide was derived from the crystal coordinates of the HLA-B27

molecule by substitution of the appropriate amino acids (4). Modeling of the complex of HLA-B7 with the peptide 899 (APRTVALTA) has allowed us to explain the binding specificity observed for this MHC molecule. Although much of the immune response remains a mystery, mass spectrometry has opened new doors to immunologists by providing a means to a better understanding of the peptide binding interactions of MHC molecules.

Structural Analysis of Peptides Associated with the Class I MHC Molecule HLA-A24.1

David Arnott, Jeffrey Shabanowitz, and Donald F. Hunt, Department of Chemistry, University of Virginia, Charlottesville, VA 22901; Ralph Kubo, Allessandro Sette, and Howard M. Grey, Cytel Corporation, San Diego, CA 92121.

Class I molecules of the major histocompatability complex (MHC) bind peptides derived from intracellular proteins and transport them to the cell surface where they are displayed to cytotoxic T-lymphocytes (CTLs or killer T-cells). If a peptide is recognized as foreign the T-cell lyses the infected cell and proliferates in reaction to the discovery of infection. CTLs react against viral infection, cancerous cell transformations, and are implicated in autoimmune diseases Characterization of peptides which bind to class I molecules and the structural features required for efficient binding is therefore of intense interest. Such a characterization is also challenging; over 2,000 peptides may be presented at femtomole levels per 10^8 cells.

A complex mixture of peptides present at the low to subpicomole level was isolated from the class I molecule HLA-A24.1 Microcapillary HPLC/ electrospray ionization and tandem mass spectrometry was used to sequence 10 peptides. In combination with binding assays a binding motif is proposed which requires tyrosine at position 2 and a hydrophobic residue at position nine of nine residue peptides.

Several peptides were sequenced which did not bind to HLA-A24.1 and have a distinct motif of proline or alanine at residue 2 and a small hydrophobic residue at the c-terminus. These peptides, of eight or nine residues may be associated with HLA-B54.

The cell line chosen for study was LKT3, a homozygous cell line derived from the 10th Histocompatability workshop B cell reference panel. Its class I specificities are A24.1, B54, and C1.

Peptides bound to HLA-A24.1 were isolated by immunoaffinity chromatography. A KT3 cell lysate was passed over three columns of monoclonal antibody B1.23.2 to remove HLA -B,-C and then three columns of antibody W6/32 to bind HLA-A. Peptides were eluted under acidic conditions, collected by centrifugation through a 5 kDa filter and concentrated by vacuum centrifugation.

More than 1,000 peptides were recovered from ~600 micrograms of MHC. The complexity of the mixture was reduced by reversed phase HPLC separation:

2.1mm x3 cm Brownlee OD300 cartridge column
200 uL/min flow
0-60% MeCN/0.1% TFA gradient in 40 minutes
Fractions were collected every 60 seconds.

Each HPLC fraction was examined by microcapillary HPLC- Electrospray Ionization- Triple quadrupole mass spectrometry.

10-15cm C18 or POROS II/RH beads were packed in 50 micron i.d. fused silica capillaries behind a glass frit.

Samples were loaded hydrostatically and eluted with a 0-80% gradient of MeCN/0.1M HOAc.

A precolumn splitter resulted in a flow of 0.2 - 0.5 uL/min to the electrospray source where the eluant mixed with a sheath of 90% MeOH/0.1M HOAc flowing at 3 uL/min.

Quadruple 1 of a Finnigan TSQ700 was scanned to acquire spectra; 30 fmol limit of detection. The most dominant peptides in each fraction were subjected to collisionally activated dissociation in the TSQ700 instrument.

Sample was introduced by microcapillary HPLC/ESI as above.

The ion of interest was isolated in the first quadrupole, caused to dissociate in quadruple 2 by collisions with 3 mtorr argon at energies of 15-30v, and the fragments analysed in quadruple 3. Peptide sequences were reconstructed from the product ion spectra. Chemical modifications such as acetylation,esterification and manual Edman degradation facilitated interpretation. MS/MS is typically carried out on 100 - 300 fmol of peptide.

Synthetic peptides were provided by Dr. Ettore Appella or synthesized by F-moc chemistry on a Gilson model AMS 422 multiple peptide synthesizer according to standard procedure.

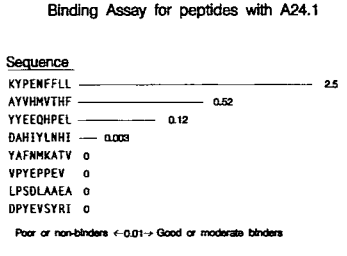
The binding of peptides to HLA-A24 1 was measured in a competative binding assay. 50% inhibatory concentrations of the test peptides to a 'consensus' sequence peptide which binds well to HLA-A24.1 were measured. The results are reported as a ratio of the 50% inhibatory concentration of the test peptide to that of two standard peptides.

(M+H)+	Sequence	Source Protein
1207	YYEEQHPEL	Unk. protein in natural killer cells
1170	KYPENFFLL	Phosphoprotein Phosphatase I
1103	AYVHMVTHF	
1055	VYXXHPVSX	
1141	DPYEVSYRI	Btg1 Protein
929	VPYEPPEV	Cellular Tumor Antigen P53
886	XPSDXAAEA	
1095	DAHIYLNHI	Thymidylate Synthase
1044	YAFNMKATV	Heat Shock Conjugate Protein
1053	DAEMTTRMV	

The complete sequences of 10 peptides were determined. The source proteins for six were identified by protein or DNA database searches. **Figure 1** lists the sequences The amino acids found at residue nine were in all cases hydrophobic, with Val, Leu, or Ile being most prevalent. Three amino acids were observed at residue 2, the other anchor position Tyr in 4 peptides, Pro in three peptides, and Ala in three. All but one peptide was nine residues long; one had only eight residues.

Seven peptides have been synthesized and assayed for binding to HLA-A24.1. The binding data are illustrated in **Figure 2.** The peptides containing Tyr at position 2 were found to bind well, but those with Pro or Ala at position 2 bound weakly or not at all. Because no monoclonal antibody with high specificity for A24.1 was available it is possible that HLA-B54 or HLA-C1 peptides are found in the preparation.HLA-C1 is expressed at only 10% of the level of HLA-A24.1 so it is unlikely to contaminate the sample, but the non-binding peptides could have been associated with HLA-B54. The sequences of these peptides resemble those of HLA-B7, in which Pro is the dominant amino acid at residue 2, and Ala is also tolerated; these peptides do not, however, bind well to HLA-B7. The differences in binding motifes of the class I molecules are due to polymorphism in the pockets of the binding cleft, but in the absence of crystallographic data it is difficult to draw conclusions about this data. It is, however, possible to assay these peptides for binding to HLA-B54, and these experiments will be carried out.

Microcapillary HPLC coupled with Electrospray Ionization/ triple quadrupole mass spectrometry was used to sequence ten peptides isolated from the class I molecule HLA-A24.1. In conjunction with binding assays this data suggests a binding motif of Tyr and a hydrophobic amino acid at positions 2 and 9 respectively of a nine residue peptide. Those peptides which did not bind to HLA-A24.1 may be associated with HLA-B54, in which case this molecule's binding motif would allow Pro or Ala at position 2 and a small hydrophobic residue at position 9. This hypothesis will be tested with HLA-B54 binding studies.



Application of Matrix-Assisted Laser Desorption Time-of-Flight Mass Spectrometry in the Structural Characterization of Proteins

Jimmy R. Calaycay, Tracey A. Dickinson, Richard A. Mumford, and Patrick R. Griffin, Merck Research Laboratories, Rahway, NJ
